I would like to dedicate this atlas to Children's Hospital, Louisiana State University School of Medicine in Shreveport and Shriners Hospitals for Children, Shreveport, Louisiana, USA

Preface to the Third Edition

It has been 5 years since the publication of the second edition of this atlas in 2012. Since then, significant progress has been made in the field of genetic diagnosis and counseling, especially in genomic medicine. The third edition covers 284 chapters with the addition of the following 30 new chapters: Congenital Infiltrating Lipomatosis of the Face, Congenital Radioulnar Synostosis, Cutaneous Vasculitis, Emanuel Syndrome, Feingold Syndrome, Fibular Hemimelia, Gilbert Syndrome, Hemangiomas of Infancy, Hereditary Sensory and Autonomic Neuropathies, Hereditary Spastic Paraplegia, Hydranencephaly, Hypertrophic Cardiomyopathy, Isolated Growth Hormone Deficiency in Children, Lymphangiomas and Lymphangiomatosis, Macrodactyly, Mitochondrial Myopathies, Mőbius Syndrome, Nager Acrofacial Dysostosis, Nasal Obstruction in Neonates and Children, Niemann-Pick Disease, Opitz Trigonocephaly Syndrome, Osteogenesis Imperfecta/Ehlers-Danlos Syndrome Overlap Syndrome, Patellar Instability, Peutz-Jeghers Syndrome, Primary Microcephaly, Schwartz-Jampel Syndrome, Symphalangism, Tibial Hemimelia, Tyrosinemias, and Winchester Syndrome.

As with the previous edition, a detailed outline of each chapter is provided, describing the genetics/basic defects, clinical features, diagnostic investigations, and genetic counseling including recurrence risk, prenatal diagnosis, and management. The illustrative cases are supplemented by case history and diagnostic confirmations through imaging, cytogenetic, biochemical, and/or molecular genetic studies. In this edition, it was a formidable task trying to cite the relevant references in the text, which was not done in the previous editions.

In addition to the individual contributions mentioned in the acknowledgments in previous editions, I thank the following individuals for their contribution and support to this edition: Richard A. Hruska, Springer Publishing Editor, for inviting me to write this third edition of the atlas and Neha Thapa, Springer Editor, and K. Arun Kumar, Springer Project Manager, for editing and production of this atlas. Individual contributors have been acknowledged in the case illustrations. I am especially thankful to the staff at the Shreveport Shriners Hospitals for Children (Kim Green, administrator; Dee Chambers, Medical Staff Coordinator; Kim Blankenship, Director of Outpatient Clinic; Dr. John Fox, Chief of Staff; Dr. Anne Hollister, hand surgeon; Dr. Don Holton, radiologist; Sheila Barritt, Director of Radiology) and staff at LSU School of Medicine (Dr. Susonne Ursin, clinical geneticist; Mary Moore, BBA, Administrative Assistant; Dr. Joseph Bocchini, Chairman of the

Department of Pediatrics; Dr. Jennifer Woerner, Program Director of Craniofacial Fellowship and Oralmaxillofacial Residency Program; Diane DunkiJacobsNolten, RN, Clinical Coordinator; and Dr. Ghali Ghali, Chancellor and Dean of School of Medicine and Chairman of the Department of Oral and Maxillofacial Surgery). Special thanks are due to Dr. Grace Guo, a pediatric radiologist at Nemours/Alfred I. duPont Hospital for Children, for her contributions to cases with excellent imagings provided throughout this atlas.

As previously, I would welcome comments, corrections, and criticism from readers.

Shreveport, LA, USA Harold Chen

Preface to the Second Edition

It has been 5 years since the publication of the first edition of this atlas in 2006. Since then, significant progress has been made in the field of genetic diagnosis and counseling. The first edition of the atlas covered 203 chapters which were revised with current literature and addition of many illustrations, mostly in color. Fifty-two new chapters have been added to this edition. Selected references have also been added to the text for the sources of the information.

As with the previous edition, a detailed outline of each disorder is provided, describing the genetics, basic defects, clinical features, diagnostic investigations, and genetic counseling, including recurrence risk, prenatal diagnosis, and management. Relevant references are added in the second edition. The cases are supplemented by case history and diagnostic confirmations by imaging, cytogenetic, biochemical, and/or molecular studies.

I am grateful to the following individuals for their contribution and support of this edition: Dr. Susonne Ursin, my genetic colleague and Chief of Perinatal Genetics, for case studies (Joubert syndrome, Mowatt-Wilson syndrome, otopalatodigital syndrome, rigid spine syndrome, Saethre-Chotzen syndrome, Silver-Russell syndrome); Dr. RMS Riel-Romero for megalencephalic leukoencephalopathy with subcortical cysts; Dr. Amal Anga for Duncan syndrome; Drs. Richard McCall, Phillip Gates, and Anne Hollister, Shreveport Shriners Hospital for Children; Dr. Ghali Ghali, Chairman of Oral and Maxillofacial Surgery; and Dr. Renata Pilatova, Pinecrest Development Center, for providing patients for studies and inclusion into this edition; Dr. Leonard Prouty, Ms. Rhonda Lee Young, and Mr. Jozo Ivancic, LSU Cytogenetics Laboratory for part of the karyotypes used in this edition; Mrs. Lynn Martin, Beverely Gildon, and Diane DunkiJacobsNolten for nursing care; and Ms. Ashli Daigle and Mrs. Barbara McHenry for their excellent clerical and secretarial help. My apologies in the event that I failed to mention others who have contributed to this edition. Without the patience and encouragement of my dear wife, Cheryl, this edition of the atlas would not have been possible. I would like to express my sincere appreciation to Dr. Joseph Bocchini, Chairman of the Department of Pediatrics, for his encouragement and support. I would like to dedicate this edition of the atlas to the Children's Hospital,

Louisiana State University Health Sciences Center in Shreveport, for its excellence in pediatric care and education.

As previously, I would welcome comments, corrections, and criticism from readers.

Shreveport, LA, USA Harold Chen
October 2011

Preface to the First Edition

This book, *Atlas of Genetic Diagnosis and Counseling*, reflects my experience in 38 years of clinical genetics practice. During this time, I have cared for many patients and their families and taught innumerable medical students, residents, and practicing physicians. As an academic physician, I have found that a picture is truly "worth a thousand words," especially in the field of dysmorphology. Over the years, I have compiled photographs of my patients, which are incorporated into this book to illustrate selected genetic disorders, malformations, and malformation syndromes. A detailed outline of each disorder is provided, describing the genetics, basic defects, clinical features, diagnostic investigations, and genetic counseling, including recurrence risk, prenatal diagnosis, and management. Color photographs are used to illustrate the clinical features of patients of different ages and ethnicities. Photographs of prenatal ultrasounds, imaging, cytogenetics, and postmortem findings are included to help illustrate diagnostic strategies. The cases are supplemented by case history and diagnostic confirmation by cytogenetic, biochemical, and molecular studies, if available. An extensive literature review was done to ensure up-to-date information and to provide a relevant bibliography for each disorder.

This book was written in the hope that it will help physicians improve their recognition and understanding of these conditions and their care of affected individuals and their families. It is also my intention to bring the basic science and clinical medicine together for the readers. *Atlas of Genetic Diagnosis and Counseling* is designed for physicians involved in the evaluation and counseling of patients with genetic diseases, malformations, and malformation syndromes, including medical geneticists, genetic counselors, pediatricians, neonatologists, developmental pediatricians, perinatologists, obstetricians, neurologists, pathologists, and any physicians and health care professionals caring for handicapped children such as craniofacial surgeons, plastic surgeons, otolaryngologists, and orthopedics.

I am grateful to many individuals for their invaluable help in reading and providing cases for illustration. The acknowledgments are provided on a separate page. Without the patience and encouragement of my dear wife, Cheryl, this atlas would not have been possible. I would like to dedicate this book to the Children's Hospital, Louisiana State University Health Sciences

Center in Shreveport, for its continued excellence in pediatric care and education.

I would welcome comments, corrections, and criticism from readers.

Biography

Harold Chen was born in I-Lan, Taiwan, and was a graduate from the National Taiwan University School of Medicine (M.D. degree) in Taipei, Taiwan. He received M.S. degree in Human Genetics from the University of Michigan Graduate School in Ann Arbor, Michigan. He finished pediatric residency and fellowship training from Wayne State University School of Medicine in Detroit, Michigan. He had been faculty at Wayne State University (Detroit), Wright State University (Dayton, Ohio), and University of South Alabama (Mobile, Alabama). Currently, he is Professor of Pediatrics, Obstetrics and Gynecology, Pathology, and Oral and Maxillofacial Surgery at the Louisiana State University Health Sciences Center. He is also Chief of Medical Genetics at the Shriners Hospitals for Children, Shreveport, LA. Dr. Chen is board-certified in American Board of Pediatrics and American Board of Medical Genetics in Clinical Genetics and Clinical Cytogenetics.

Acardia

Contents

Acardia is a bizarre fetal malformation occurring only in twins or triplets. It is also called acardius acephalus, acardiac twinning, or twin reversed arterial perfusion (TRAP) syndrome or sequence. This condition is very rare and occurs in 1 in 34,600 births or 1 in 100 monozygotic twins (Gillim and Hendricks 1953) and 1 in 30 monozygotic triplets (Van Allen et al. 1983; Napolitani and Schreiber 1960; Moore et al. 1990; Sanjaghsaz et al. 1998; Blenc et al. 1999) and even in quintuplets. Almost all cases reported are monozygotic twins. However, there are reports of dichorionic monozygotic twin gestations with TRAP sequence (French et al. 1998; Gewolb et al. 1983).

Acardia requires the presence of arterial-arterial anastomosis in the placenta, with retrograde perfusion of poorly oxygenated blood from the normal twin (also called donor or pump twin) to the acardiac twin, venous-venous anastomosis carrying blood back from the acardiac to the donor twin, and circulatory failure of the acardiac twin (Steffensen et al. 2008).

Synonyms and Related Disorders

Acardiac twinning; Acardius acephalus; Twin reversed arterial perfusion sequence

Genetics/Basic Defects

1. Etiology
    1. Rare complication of monochorionic twinning, presumably resulting from the fused placentation of monochorionic twins.
    2. Represents manifestation of abnormal embryonic and fetal blood flow rather than a primary defect of cardiac formation.
    3. Heterogeneous chromosomal abnormalities are present in nearly 50% of the cases, although chromosome errors are not underlying pathogenesis of the acardiac anomaly. Rather, the placental vascular anastomoses are the principal pathogenetic event (Benirschke and des Roches Harper 1977).

2. Pathogenesis: reversal of fetal arterial perfusion
    1. First hypothesis
        1. A primary defect in the development of the heart
        2. Survival of the acardiac twin as a result of the compensatory anastomoses that develop
    2. Second hypothesis
        1. The acardiac twin begins life as a normal fetus.
        2. The reversal of the arterial blood flow results in atrophy of the heart and the tributary organs.
3. Classification of TRAP sequence (syndrome)
    1. Classification according to the status of the heart of the acardiac twin
        1. Hemiacardius (with incompletely formed heart)
        2. Holoacardius (with completely absent heart)
    2. Morphologic classification of the acardiac twin (Gillim and Hendricks 1953; Napolitani and Schreiber 1960; Nicolaidis et al. 1990; Alderman 1973; Thelmo et al. 2007; Obladen 2010; Buyukkaya et al. 2015)
        1. Acardius amorphous
            1. The least differentiated form
            2. Little more than a lump of connective tissue, covered by edematous skin
            3. No identifiable organs
            4. No resemblance to classical human form
            5. Anatomical features: presence of only bones, cartilage, muscles, fat, blood vessels, and stroma
        2. Acardius myelacephalus
            1. Resembles the amorphous type except presence of rudimentary limb formation
            2. Presence of rudimentary nerve tissue in addition to anatomical features in acardius amorphous
        3. Acardius acephalus
            1. The most common type (60–75%)
            2. Missing head, part of the thorax, and upper extremities
            3. May have additional malformations in the remaining organs
        4. Acardius anceps (~20%)
            1. The least atrophied form
            2. Presence of a partially developed fetal head, a thorax, abdominal organs, and extremities
            3. Lacks even a rudimentary heart
        5. Acardius acormus
            1. The rarest type (10%).
            2. Presence of a rudimentary head only.
            3. Lacks thorax.
            4. The umbilical cord inserts in the head and connects directly to the placenta.
4. The acardia
    1. Characterized by the absence of a normally functioning heart.
    2. Acardia as a recipient of twin transfusion sequence.
        1. Reversal of blood flow in all various types of acardia, hence the term “twin reversed arterial perfusion (TRAP) sequence” has been proposed.
        2. Receiving the deoxygenated blood from an umbilical artery of its co-twin through the single umbilical artery of the acardiac twin and returns to its umbilical vein. Therefore, the circulation is entirely opposite to the normal direction.
    3. Usually, the severe reduction anomalies occur in the upper part of the body.
    4. May develop various structural malformations.
        1. Growth retardation
        2. Anencephaly
        3. Holoprosencephaly
        4. Facial defects
        5. Absent or malformed limbs
        6. Gastrointestinal atresias
        7. Other abnormalities of abdominal organs
5. The co-twin
    1. Also known as the “pump twin or donor twin.”
    2. The donor “pump” twin perfuses itself and its recipient acardiac twin through abnormal arterial anastomosis in the fused placenta.

3. Increased cardiac workload often leading to cardiac failure and causing further poor perfusion and oxygenation of the acardiac co-twin.
4. May develop various malformations (about 10%).

Clinical Features

1. Perinatal problems associated with acardiac twinning.
    1. Pump-twin congestive heart failure
    2. In utero fetal death of the pump fetus
    3. Maternal polyhydramnios
    4. Premature rupture of the membrane
    5. Preterm delivery
    6. Spontaneous abortions
    7. Soft tissue dystocia
    8. Uterine rupture
    9. Postpartum hemorrhage
    10. Increased rate of cesarean section, up to 50%
2. Majority of acardiac twins and their normal twin counterparts are females.
3. Nonviable.
4. Gross features.
    1. Severe reduction anomalies, particularly of the upper body
    2. Characteristic subcutaneous edema
    3. Internal organs: invariably missing
    4. Absent or rudimentary cardiac development: the key diagnostic feature
        1. Pseudoacardia (rudimentary heart tissue)
        2. Holoacardia (completely lacking a heart)
5. Growth abnormality.
6. Cranial vault.
    1. Absent
    2. Partial
    3. Intact
7. Brain.
    1. Absent
    2. Necrotic
    3. Open cranial vault
    4. Holoprosencephaly
8. Facial features.
    1. Absent facial features
    2. Rudimentary facial features
    3. Present with defects
    4. Anophthalmia/microphthalmia
    5. Cleft lip/palate
9. Upper limbs.
    1. Absent
    2. Rudimentary
    3. Radial aplasia
    4. Syndactyly/oligodactyly
10. Lower limbs.
    1. Absent
    2. Rudimentary/reduced
    3. Syndactyly/oligodactyly
    4. Talipes equinovarus
11. Thorax.
    1. Absent
    2. Reduced
    3. Diaphragmatic defect
12. Lungs.
    1. Absent
    2. Necrotic or rudimentary
    3. Single midline lobe
13. Cardiac.
    1. Absent heart tissue
    2. Unfolded heart tube
    3. Folded heart with common chamber
14. Gastrointestinal
    1. Esophageal atresia
    2. Short intestine
    3. Interrupted intestine
    4. Omphalocele
    5. Incomplete rotation of the gut
    6. Imperforated anus
    7. Ascites
15. Liver.
    1. Absent
    2. Reduced
16. Kidney.
    1. Absent (bilateral)
    2. Hypoplastic and/or lobulated
17. Other viscera.
    1. Absent gallbladder
    2. Absent spleen
    3. Absent to reduced pancreas

4. Absent adrenal
5. Absent to hypoplastic gonads
6. Exstrophy of the cloaca
7. Skin with myxedematous thickening

18. Umbilical cord vessels.
    1. Two vessels
    2. Three vessels
19. Severe obstetrical complications.
    1. Maternal polyhydramnios
    2. Preterm labor
    3. Cord accidents
    4. Dystocia
    5. Uterine rupture
20. Severe neonatal complications.
    1. Hydrops
    2. Intrauterine demise
    3. Prematurity
    4. Heart failure
    5. Anemia
    6. Twin-to-twin transfusion syndrome
21. Outcome for the normal sib in an acardiac twin pregnancy (Healey 1994).
    1. Unsatisfactory
        1. Adapting to the increasing circulatory load, resulting in the following situations:
            1. Intrauterine growth retardation
            2. Polyhydramnios
            3. Preterm delivery
            4. Hydrops
            5. Ascites
            6. Pleural effusion
            7. Hypertrophy of the right ventricle
            8. Hepatosplenomegaly
            9. Severe heart failure resulting in pericardial effusion and/or tricuspid insufficiency
        2. Stillbirth
        3. Prematurity
        4. Neonatal death
    2. Mortality for the normal twin reported as high as 50–70% without intervention (Aggarwal et al. 2002; Ibne et al. 2013)

Diagnostic Investigations

1. Radiography
    1. Absent or rudimentary skull
    2. Absent or rudimentary thorax
    3. Absent or rudimentary heart
    4. Vertebral anomalies
    5. Rib anomalies
    6. Limb defects, especially upper limbs
2. Pathology
    1. Microcephaly
    2. Severely rudimentary brain
    3. Developmental arrest of the brain at the prosencephalic stage (holoprosencephaly)
    4. Hypoxic damage to the holospheric brain mantle with cystic change (hydranencephaly)

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: overall recurrence risk of about 1 in 10,000. (The recurrence risk is for monoamniotic twinning (1% for couples who have had one set of monozygotic twins) times the frequency of the occurrence of TRAP sequence with near-term survival (about 1% of monozygotic twin sets).)
    2. Patient's offspring: not applicable (a lethal condition)
2. Prenatal ultrasonography (Sherer et al. 1989; Stiller et al. 1989; Langlotz et al. 1991; Donnenfeld et al. 1991; Shalev et al. 1992; Zucchini et al. 1993; Coulam 1996; Schwarzler et al. 1999; Bonilla-Musoles et al. 2001; Martins et al. 2014)
    1. Prenatal diagnosis is suspected on the first trimester ultrasound, when one fetus appears anatomically normal and the other lacks apparent cardiac structures.
    2. Definitive flow is seen in the umbilical artery going toward the acardius (Bornstein et al. 2008).
    3. Fetuses with signs of high-output cardiac failure have poor prognosis and are candidates for intervention such as target occlusion of the umbilical cord of the acardiac twin, including laser ablation, bipolar cord

coagulation, or radiofrequency ablation (Ville et al. 1994).
4. Monochorionic placenta with a single umbilical artery in two-thirds of cases.
5. Acardiac fetus.
    1. Unrecognizable head or upper trunk.
    2. Without a recognizable heart or a partially formed heart.
    3. A variety of other malformations.
    4. Reversal of blood flow in the umbilical artery with flow going from the placenta toward the acardiac fetus (reversed arterial perfusion). Such a reversal of the blood flow in the recipient twin can be demonstrated in utero by transvaginal Doppler ultrasound as early as 12 weeks of gestation.
    5. Early diagnosis by transvaginal sonography on the following signs:
        1. Monozygotic twin gestation (absence of the lambda sign)
        2. Biometric discordance between the twins
        3. Diffuse subcutaneous edema or morphologic anomalies of one of the twins or both
        4. Detection of reversed umbilical cord flow, cardiac activity likely to disappear as the pregnancy progresses
        5. Absence of cardiac activity, although hemicardia or pseudocardia may be present
6. The donor fetus.
    1. Hydrops
    2. Cardiac failure (cardiomegaly, pericardial effusion, tricuspid regurgitation)

3. Amniocentesis to diagnose associated chromosome abnormalities (about 10% of pump twins)
4. Management of pregnancies complicated by an acardiac fetus (Donnenfeld et al. 1991; Hanafy and Peterson 1997; Søgaard et al. 1999)
    1. Conservative treatment
        1. Monitor pregnancy by serial ultrasonography
        2. Conservative approach as long as there is no evidence of cardiac circulatory decompensation in the donor twin
    2. Termination of pregnancies
    3. Treatment and prevention of preterm labor by tocolytics
        1. Magnesium sulfate
        2. Beta sympathomimetics
        3. Indomethacin
    4. Treatment of pump fetus heart failure involving maternal digitalization
    5. Treatment of polyhydramnios by therapeutic repeated amniocentesis
    6. Selective termination of the acardiac twin
        1. To occlude the umbilical artery of the acardiac twin in order to stop umbilical flow through the anastomosis
            1. Intrafunicular injection and mechanical occlusion of the umbilical artery
            2. Embolization by steel or platinum coil, alcohol-soaked suture material, or ethanol
            3. Hysterotomy and delivery of acardiac twin
            4. Ligation of the umbilical cord
            5. Hysterotomy and umbilical cord ligation
        2. Fetal surgery: best available treatment for acardiac twinning (Arias et al. 1998)
        3. Invasive treatment of TRAP sequence
            1. Endoscopic laser coagulation of the umbilical vessels at or before 24 weeks of gestation
            2. Endoscopic- or sonographic-guided umbilical cord ligation at 24 weeks of gestation
            3. Radiofrequency ablation (Tsao et al. 2002; Bebbington et al. 2012)
            4. Fetoscopic laser coagulation of placental communicating vessels or the umbilical cord (Hecher et al. 2006; Nakata et al. 2008)
        4. Summary of acardiac twins treated with invasive procedures reported in the literature
            1. Mortality of the pump twin (13.6%).
            2. Preterm delivery (50.3%).

3. Delivery before 30 weeks gestation (27.2%).
4. Perinatal mortality if untreated is at least 50%.

5. Successful non-invasive blood flow occlusion of TRAP sequence in the acardiac fetus by high-intensity focused ultrasound (HIFU) exposure from outside the maternal abdomen (Okai et al. 2013)
   1. HIFU was applied to blood vessels of the acardiac fetus at the point at which the umbilical cord entered the body in a series of four procedures at 3-day intervals starting at 13 weeks of gestation and in a final procedure with higher power at 17 weeks.
   2. As color Doppler examination revealed absence of blood flow to the acardiac fetus after the second round of HIFU exposure, complete occlusion of target vessels had been achieved.
   3. After delivery by Cesarean section at 37 weeks of gestation, the baby was healthy and growing normally, with exception of congenital pseudarthrosis.

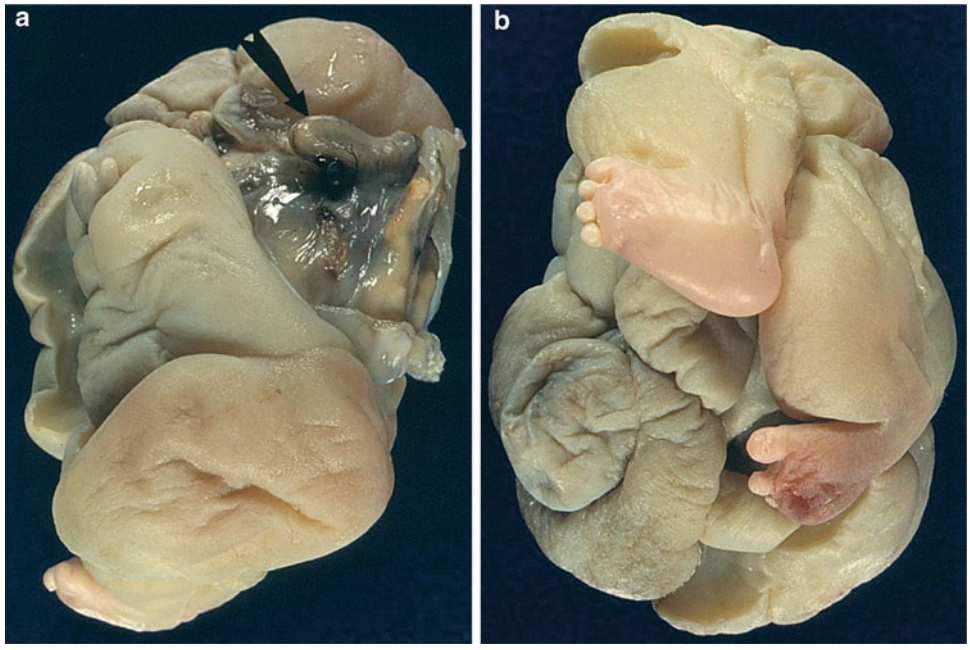

Fig. 1 (**a**, **b**) Ventral view of an acardiac acephalus fetus (**a**) showed a large abdominal defect, gastroschisis (*arrow*), through which small rudiments of gastrointestinal tract were seen. Dorsal view (**b**) shows a very underdeveloped cephalic end and relatively well-developed lower limbs. The co-twin had major malformations consisting of a large omphalocele, ectopia cordis, and absent pericardium, incompatible with life (Chen et al. 1983)

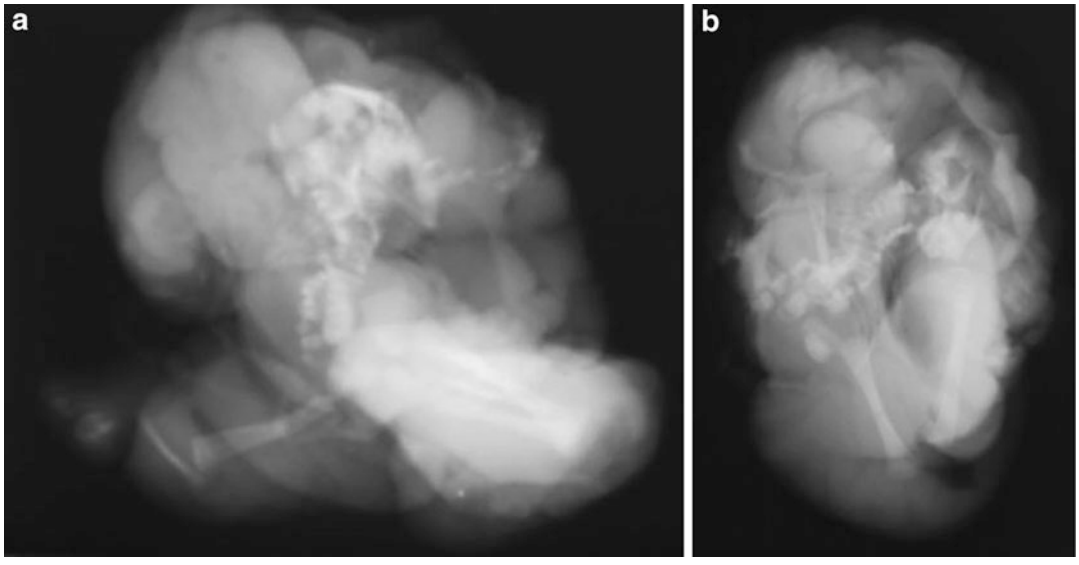

Fig. 2 (**a**, **b**) Radiographs of the above acardiac fetus showing a missing head, cervical vertebrae and part of upper thoracic vertebrae, rudimental lower ribs, malformed lower thoracic and lumbar vertebrae, and relatively well-formed lower limbs (**a**, **b**)

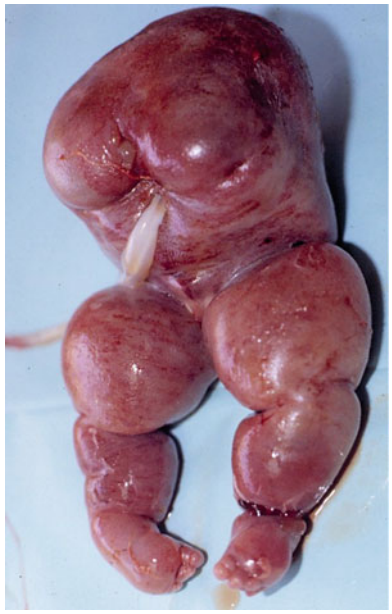

Fig. 3 The head and part of the thorax of this acardiac fetus were completely missing with relatively well-formed lower limbs

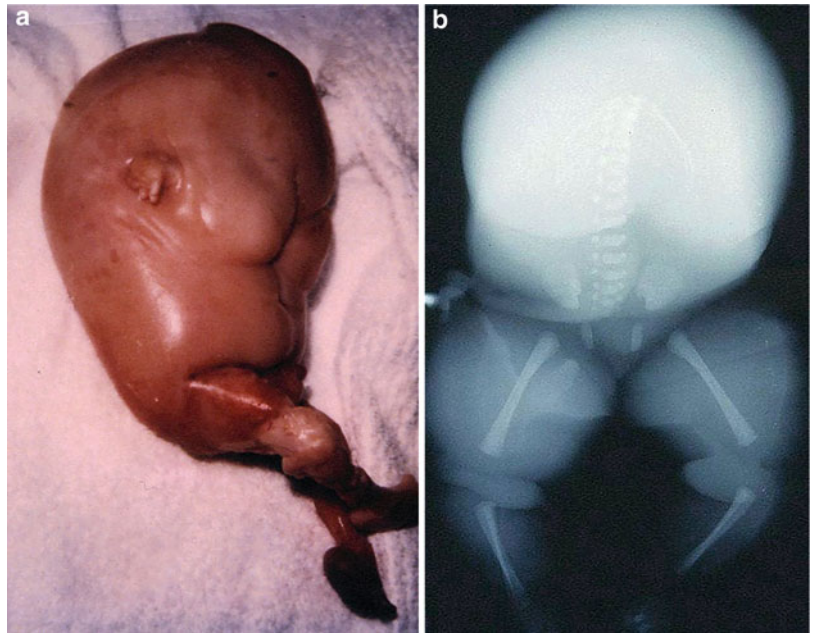

Fig. 4 (**a**, **b**) Another acardiac fetus with a missing head and part of the upper thorax (**a**). Radiograph (**b**) showed missing head, cervical and part of thoracic vertebrae, and ribs. Pelvis and lower limbs are well formed

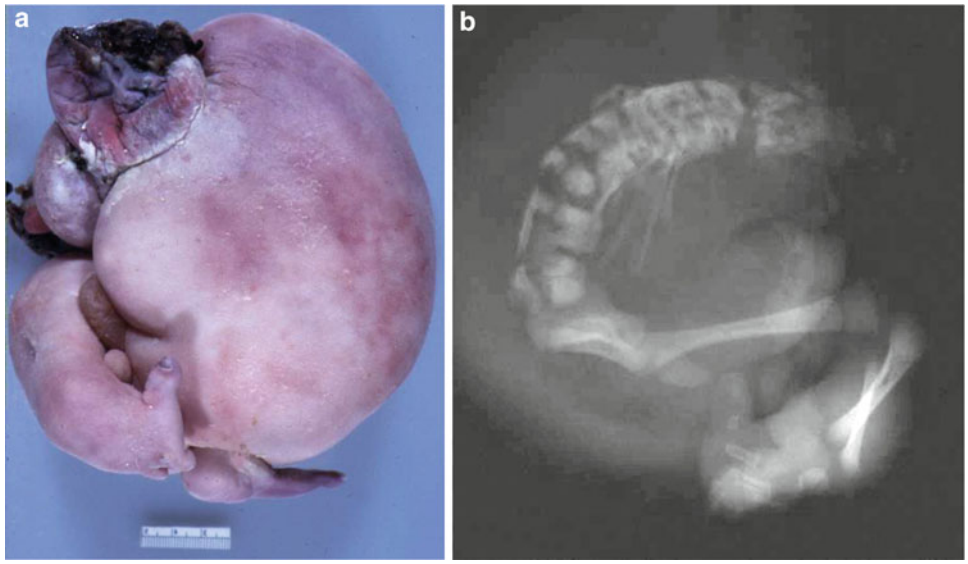

Fig. 5 (**a**, **b**) Acardius (second twin, 36 weeks gestation) showing spherical body with a small amorphous mass of leptomeningeal and glial tissue at the cephalic end (**a**). There were one deformed lower extremity and a small arm appendage. Small intestinal loops, nodules of adrenal glands, and testicles were present in the body. There was no heart or lungs. The placenta was monoamniotic monochorionic with velamentous insertion of the umbilical cord. The other identical twin was free of birth defects. Radiograph of acardius twin (**b**) showed a short segment of the spine, a femur, a tibia, and a fibula

Achondrogenesis

Contents

Marco Fraccaro first described achondrogenesis in 1952 (Fraccardo 1952). He used the term to describe a stillborn female with severe micromelia and marked histological cartilage changes. The term was later used to characterize the most severe forms of chondrodysplasia in humans, which were invariably lethal before or shortly after birth. By the 1970s, researchers concluded that achondrogenesis was a heterogeneous group of chondrodysplasias lethal to neonates; achondrogeneses type I (Fraccaro-Houston-Harris type) and type II (Langer-Saldino type) were distinguished on the basis of radiological and histological criteria.

Achondrogenesis type I was further subdivided, on the basis of convincing histological criteria, into type IA, which has apparently normal cartilage matrix but inclusions in chondrocytes, and type IB (Borochowitz et al. 1988), which has an abnormal cartilage matrix. Classification of type IB as a separate group has been confirmed recently by the discovery of its association with mutations in the diastrophic dysplasia sulfate transporter (*DTDST*) gene, making it allelic with diastrophic dysplasia.

Synonyms and Related Disorders

Achondrogenesis type IA (Houston-Harris type); Achondrogenesis type IB (Fraccaro type); Achondrogenesis type II (Langer-Saldino type); Type II achondrogenesis-hypochondrogenesis

Genetics/Basic Defects

1. Type IA: an autosomal recessive disorder, caused by mutation in the thyroid hormone receptor interactor 11 (TRIP 11) gene which is mapped on 14q32.12 (Smits et al. 2010)
2. Type IB
   1. An autosomal recessive disorder
   2. Resulting from mutations of the *DTDST* gene, which encodes the SLC26A2 sulfate transporter, which is located at 5q32–q33 (Superti-Furga et al. 1996a)
3. Type II
   1. Autosomal dominant type II collagenopathy.
   2. Resulting from mutations in the *COL2A1* gene, which is located at 12q13.1–q13.3.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_2

3. Report of a familial case of achondrogenesis type II caused by a dominant *COL2A1* mutation and "patchy" expression in the mosaic father (Forzano et al. 2007) suggests that somatic mosaicism can lead to a milder but generalized clinical phenotype.
4. Type II achondrogenesis-hypochondrogenesis (Borochowitz et al. 1986): identification of abnormal type II collagen (COL2A1 gene mutations) (Godfrey and Hollister 1988; Körkkö et al. 2000).

4. Mutations within the *COL2A1* gene also cause the following skeletal dysplasias (Forzano et al. 2007):
   1. Hypochondrogenesis
   2. Spondyloepiphyseal dysplasia (SED) congenita
   3. SED Namaqualand type
   4. Mild SED with precocious osteoarthritis
   5. Spondyloepimetaphyseal dysplasia, Strudwick type
   6. Kniest dysplasia
   7. Multiple epiphyseal dysplasia with myopia and conductive deafness
   8. Spondyloperipheral dysplasia
   9. Stickler dysplasia type I
5. Genetically related (allelic) disorders: three other phenotypes (all with an autosomal recessive inheritance) associated with SLC26A2 (DTDST) mutation (Bonafé et al. 2013)
   1. Atelosteogenesis type 2: a neonatal-lethal chondrodysplasia with clinical and histological characteristics that resemble those of diastrophic dysplasia (Hastbacka et al. 1996).
   2. Diastrophic dysplasia: a skeletal dysplasia characterized by short stature, joint contractures, cleft palate, and characteristic clinical signs such as the "hitchhiker" thumb and cystic swelling of external ears. The first mutations in *SLC26A2* were found in individuals with DTD (Hastbacka et al. 1994).
   3. Recessive multiple epiphyseal dysplasia (EDM4): characterized by joint pain (usually in the hips and knees); deformities of the hands, feet, and knees; and scoliosis. Approximately 50% of affected individuals have an abnormal finding at birth (e.g., clubfoot, cleft palate, or cystic ear swelling) (Superti-Furga et al. 1996b, 1999, 2001).

Clinical Features

1. Prenatal/perinatal history (Chen 2013, 2015)
   1. Polyhydramnios
   2. Hydrops
   3. Breech presentation
   4. Perinatal death
2. Achondrogenesis type I
   1. Growth
      1. Lethal neonatal dwarfism
      2. Mean birth weight of 1,200 g
   2. Craniofacial features
      1. Disproportionately large head
      2. Soft skull
      3. Sloping forehead
      4. Convex facial plane
      5. Flat nasal bridge, occasionally associated with a deep horizontal groove
      6. Small nose, often with anteverted nostrils
      7. Long philtrum
      8. Retrognathia
      9. Increased distance between lower lip and lower edge of chin
      10. Double chin appearance
   3. Extremely short neck
   4. Thorax
      1. Short and barrel-shaped thorax
      2. Lung hypoplasia
   5. Heart
      1. Patent ductus arteriosus
      2. Atrial septal defect
      3. Ventricular septal defect
   6. Protuberant abdomen
   7. Limbs
      1. Extremely short (micromelia), shorter than type II

2. Flipper-like appendages
3. Achondrogenesis type II (Langer-Saldino type) (Chen et al. 1981)
   1. Growth
      1. Lethal neonatal dwarfism
      2. Mean birth weight of 2,100 g
   2. Craniofacial features
      1. Disproportionately large head
      2. Large and prominent forehead
      3. Midfacial hypoplasia
         1. Flat facial plane
         2. Flat nasal bridge
         3. Small nose with severely anteverted nostrils
      4. Normal philtrum
      5. Micrognathia
      6. Cleft palate
   3. Extremely short neck
   4. Thorax
      1. Short and flared thorax
      2. Bell-shaped cage
      3. Lung hypoplasia
   5. Protuberant abdomen
   6. Extremely short limbs (micromelia)

Diagnostic Investigations

1. Radiological features (Chen 2013)
   1. Variable features
   2. No single obligatory feature
   3. Distinction between type IA and type IB on radiographs not always possible
   4. Degree of ossification: age dependent and caution is needed when comparing radiographs at different gestational ages
   5. Achondrogenesis type I
      1. Skull: varying degrees of deficient cranial ossification consisting of small islands of bone in membranous calvaria
      2. Thorax and ribs
         1. Short and barrel-shaped thorax
         2. Thin ribs with marked expansion at costochondral junction, frequently with multiple fractures
      3. Spine and pelvis
         1. Poorly ossified spine, ischium, and pubis
         2. Poorly ossified iliac bones with short medial margins
      4. Limbs and tubular bones
         1. Extreme micromelia, with limbs much shorter than in type II
         2. Prominent spikelike metaphyseal spurs
         3. Femur and tibia frequently presenting as short bone segments
      5. Subtype IA (Houston-Harris type)
         1. Poorly ossified skull
         2. Thin ribs with multiple fractures
         3. Unossified vertebral pedicles
         4. Arched ilium
         5. Hypoplastic but ossified ischium
         6. Wedged femur with metaphyseal spikes
         7. Short tibia and fibula with metaphyseal flare
      6. Subtype IB (Fraccaro type)
         1. Adequately ossified skull
         2. Absence of rib fractures
         3. Total lack of ossification or only rudimentary calcification of the center of the vertebral bodies
         4. Ossified vertebral pedicles
         5. Iliac bones with ossification only in their upper part, giving a crescent-shaped, “paraglider-like” appearance on X-ray
         6. Unossified ischium
         7. Shortened tubular bones without recognized axis
         8. Metaphyseal spurring giving the appearance of a “thorn apple” or “acanthocyte” (a descriptive term in hematology)
         9. Trapezoid femur
         10. Stellate tibia
         11. Unossified fibula
         12. Poorly ossified phalanges
   6. Achondrogenesis type II
      1. Skull

1. Normal cranial ossification
2. Relatively large calvaria

2. Thorax and ribs
1. Short and flared thorax
2. Bell-shaped cage
3. Shorter ribs without fractures

3. Spine and pelvis: relatively well-ossified iliac bones with long, crescent-shaped medial and inferior margins
4. Limbs and tubular bones
1. Short, broad bones, usually with some diaphyseal constriction and flared, cupped metaphyseal ends
2. Metaphyseal spurs, usually smaller than type I

2. Histological features (Yang and Bernstein 1975, 1977; Yang et al. 1974, 1976a, b; Molz and Spycher 1980; Horton et al. 1987; Yang and Gilbert-Barnes 1997)
1. Achondrogenesis type IA
1. Normal cartilage matrix
2. Absent collagen rings around the chondrocytes
3. Vacuolated chondrocytes
4. Presence of intrachondrocytic inclusion bodies (periodic acid-Schiff [PAS] stain positive, diastase resistant)
5. Extraskeletal cartilage involvement
6. Enlarged lacunas
7. Woven bone

2. Achondrogenesis type IB
1. Abnormal cartilage matrix: presence of "demasked" coarsened collagen fibers, particularly dense around the chondrocytes, forming collagen rings
2. Abnormal staining properties of cartilage
1. Reduced staining with cationic dyes, such as toluidine blue or Alcian Blue, probably because of a deficiency in sulfated proteoglycans.
2. This distinguishes type IB from type IA, in which the matrix is close to normal and inclusions can be seen in chondrocytes, and from achondrogenesis type II, in which cationic dyes give a normal staining pattern.

3. Achondrogenesis type II
1. Cartilage
1. Slightly larger than normal
2. Grossly distorted (lobulated and mushroomed)

2. Markedly deficient cartilaginous matrix
3. Severe disturbance in endochondral ossification
4. Hypercellular and hypervascular reserve cartilage with large, primitive mesenchymal (ballooned) chondrocytes with abundant clear cytoplasm (vacuoles) ("Swiss cheese-like")
5. Overgrowth of membranous bones resulting in cupping of the epiphyseal cartilages
6. Decreased amount and altered structure of proteoglycans
7. Relatively lower content of chondroitin 4-sulfate
8. Lower molecular weight and decreased total chondroitin sulfation
9. Absence of type II collagen
10. Increased amounts of type I and type III collagen

3. Scanning and transmission electron microscopy (Ornoy et al. 1976)
1. Metaphysis: deficient intercartilaginous septa with abnormally large calcifying globules
2. Diaphysis: disturbed orientation of bone trabeculae and collagen fibers within trabeculae
3. Osteocytic lacunae: numerous, wide, and irregular arrangement and shape

4. Biochemical testing
1. Lack of sulfate incorporation: cumbersome and not used for diagnostic purposes
2. Sulfate incorporation assay in cultured skin fibroblasts or chondrocytes: recommended in the rare instances in which the diagnosis of achondrogenesis type IB is strongly suspected but

molecular genetic testing fails to detect *SLC26A2* (*DTDST*) mutations

5. Molecular genetic studies
    1. Mutation analysis of the *DTDST* gene, reported in:
        1. Achondrogenesis type IB (the most severe form)
        2. Atelosteogenesis type II (an intermediate form)
        3. Diastophic dysplasia (the mildest form)
        4. Recessive multiple epiphyseal dysplasia
    2. Achondrogenesis type IB
        1. Mutation analysis: testing of the following four most common *SLC26A2* (*DTDST*) gene mutations (mutation detection rate about 60%)
            1. R279W
            2. IVS1 + 2 > C ("Finnish" mutation)
            3. delV340
            4. R178X
        2. Sequence analysis of the *SLC26A2* (*DTDST*) coding region (mutation detection rate over 90%)
            1. Private mutations
            2. Common mutations
    3. Achondrogenesis type II: mutation analysis of the *COL2A1* gene

Genetic Counseling

1. Recurrence risk (Superti-Furga 1996; Bonafé et al. 2013)
    1. Patient's sib
        1. Achondrogenesis type IA and type IB (autosomal recessive disorders)
            1. Recurrence risk: 25%
            2. Unaffected sibs of a proband: two-third chance of being heterozygotes
        2. Achondrogenesis type II
            1. Usually caused by a new dominant mutation, in which case recurrence risk is not significantly increased.
            2. Asymptomatic carrier parent (germline mutation for a dominant mutation) (Faivre et al. 2004) may be present in the families of affected patients, in which case recurrence risk can be up to 50%.
    2. Patient's offspring: lethal entities not surviving to reproduction
2. Prenatal diagnosis (Soothill et al. 1993; Maizner and Barnhard 1995; Tongsong et al. 1995; Taner et al. 2008)
    1. Ultrasonography
        1. Polyhydramnios
        2. Fetal hydrops
        3. Disproportionally big head
        4. Nuchal edema
        5. Cystic hygroma
        6. A narrow thorax
        7. Short limbs
        8. Poor ossification of vertebral bodies and limb tubular bones (leading to difficulties in determining their length)
        9. Suspect achondrogenesis type I
            1. An extremely echo-poor appearance of the skeleton
            2. A poorly mineralized skull
            3. Short limbs
            4. Rib fractures
    2. Molecular genetic studies: require prior identification of the disease-causing mutations in the family
        1. Prenatal diagnosis of achondrogenesis type IB and type II by mutation analysis of chorionic villus DNA or amniocyte DNA in the first or second trimester
        2. Achondrogenesis type IB
            1. Characterize both alleles of *SLC26A2* (*DTDST*) beforehand.
            2. Identify the source parent of each allele.
            3. Theoretically, analysis of sulfate incorporation in chorionic villi might be used for prenatal diagnosis, but experience is lacking.

3. Achondrogenesis type II
    1. The affected fetus usually with a new dominant mutation of the *COL2A1* gene
    2. Possible presence of asymptomatic carriers in families of an affected patient
    3. Prenatal diagnosis possible if the mutation has been characterized in the affected family
3. Preimplantation genetic diagnosis (PGD) for at-risk pregnancies requires prior identification of the disease-causing mutations in the family.
4. Management
    1. Supportive care
    2. No treatment available for the underlying lethal disorder

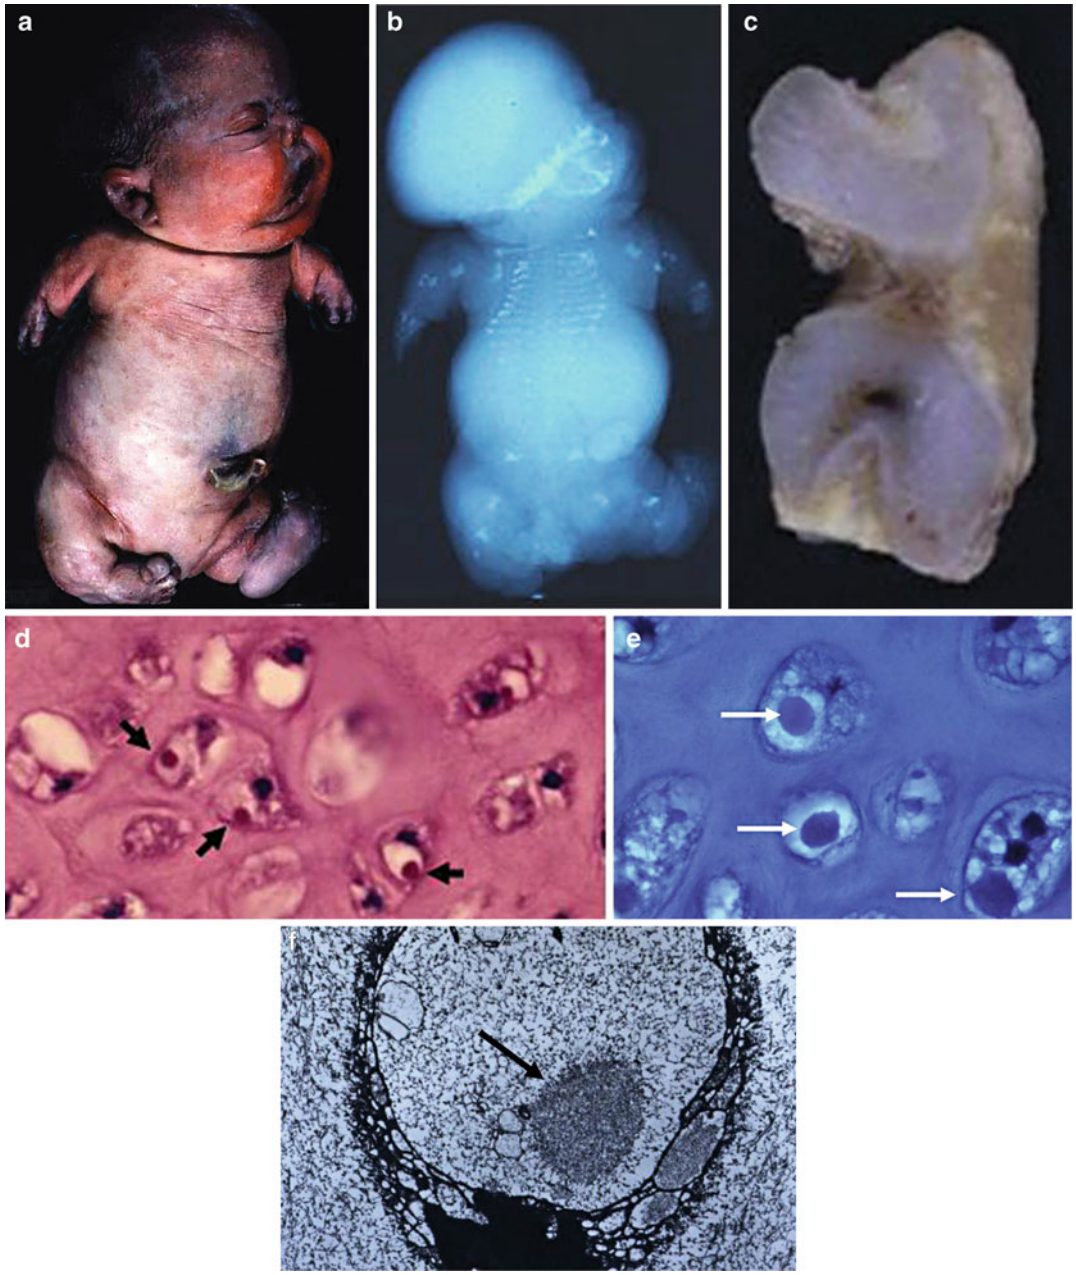

Fig. 1 A neonate with achondrogenesis type I showing large head, short trunk, and extreme micromelia (**a**). Radiographs (**b**) show unossified calvarium, vertebral bodies, and some pelvic bones. The remaining bones are extremely small. There are multiple rib fractures. The sagittal section of the femora and the humeri is similar. An extremely small ossified shaft is capped by a relatively large epiphyseal cartilage at both ends (**c**). Photomicrographs of resting cartilage with high magnification (**d**, **e**) show many chondrocytes that contain large cytoplasmic inclusions which are within clear vacuoles (*arrows*) (diastase PAS stain). Electron micrograph (**f**) shows inclusion as a globular mass of electron-dense material (*arrow*). It is within a distended cistern of rough endoplasmic reticulum (Yang and Bernstein 1977; Yang et al. 1976a) (Courtesy of Dr. Samuel Yang)

Fig. 2 (**a**–**e**) Achondrogenesis type II. As in type I, this neonate shows large head, short trunk, and micromelia (Yang and Gilbert-Barnes 1997). Sagittal section of the femur shows much better ossification of the shaft than type I. The cartilage lacks glistering appearance due to cartilage matrix deficiency. Photomicrograph of the entire cartilage shows severe deficiency of cartilage matrix. The cartilage canals are large, fibrotic, and stellate in shape. Physeal growth zone is severely retarded (Courtesy of Dr. Samuel Yang)

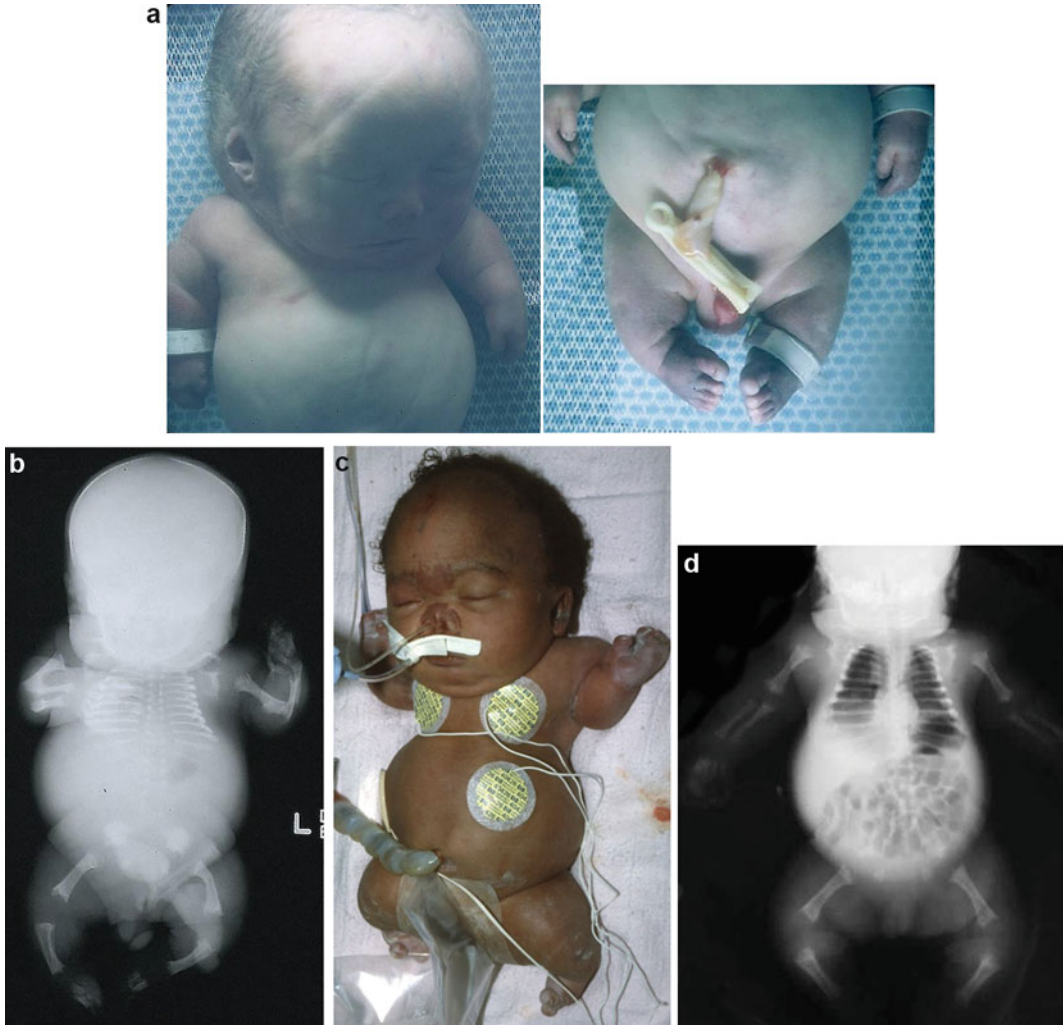

Fig. 3 Two infants (**a**, **c**) with achondrogenesis type II showing milder spectrum of manifestations, bordering the type II and spondyloepiphyseal dysplasia congenita (**b**, **d**)

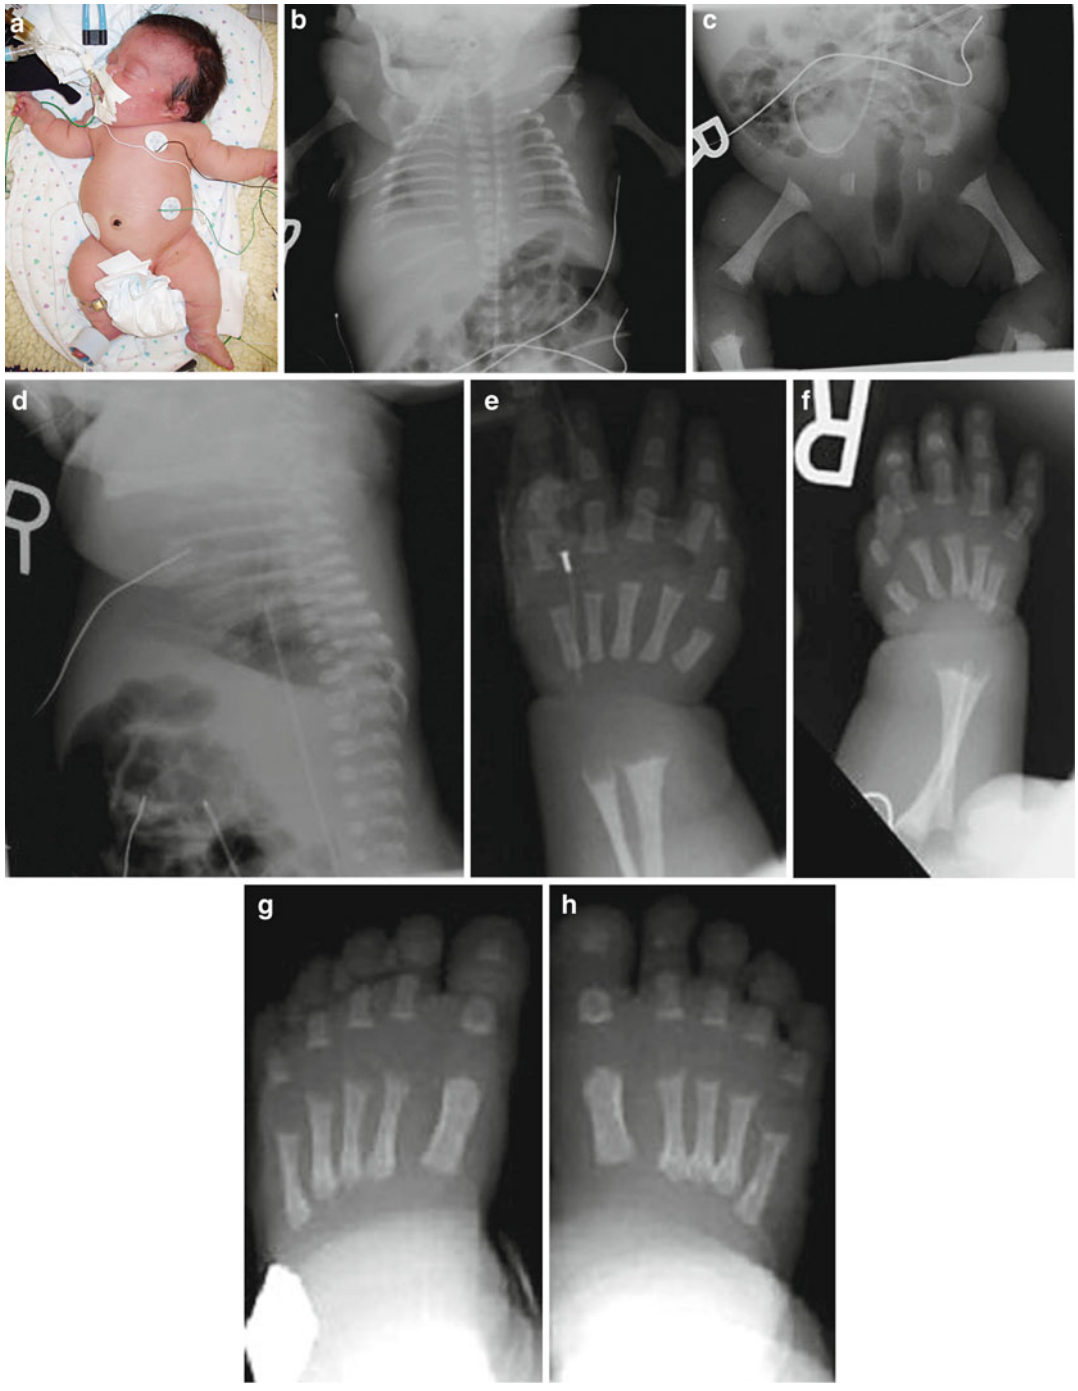

Fig. 4 A newborn girl with achondrogenesis type II showing large head, midfacial hypoplasia, short neck, small chest, and short limbs (**a**). The radiographs show generalized shortening of the long bones of the upper and lower extremities with marked cupping (metaphyseal spurs) at the metaphyseal ends of the bones. This is most evident at the distal ends of the tibia, fibular, radius, and ulna and distal ends of the digits (**c**, **e**–**h**). Radiographs also show short ribs without fractures and hemivertebrae involving thoracic vertebrae as well as the sacrum (**b**, **d**). Conformation-sensitive gel electrophoresis analysis indicated a sequence variation in the fragment containing exon 19 and the flanking sequences of the *COL2A1* gene (Gly244Asp). Similar mutations in this area have been seen in patients diagnosed with hypochondroplasia and achondrogenesis type II

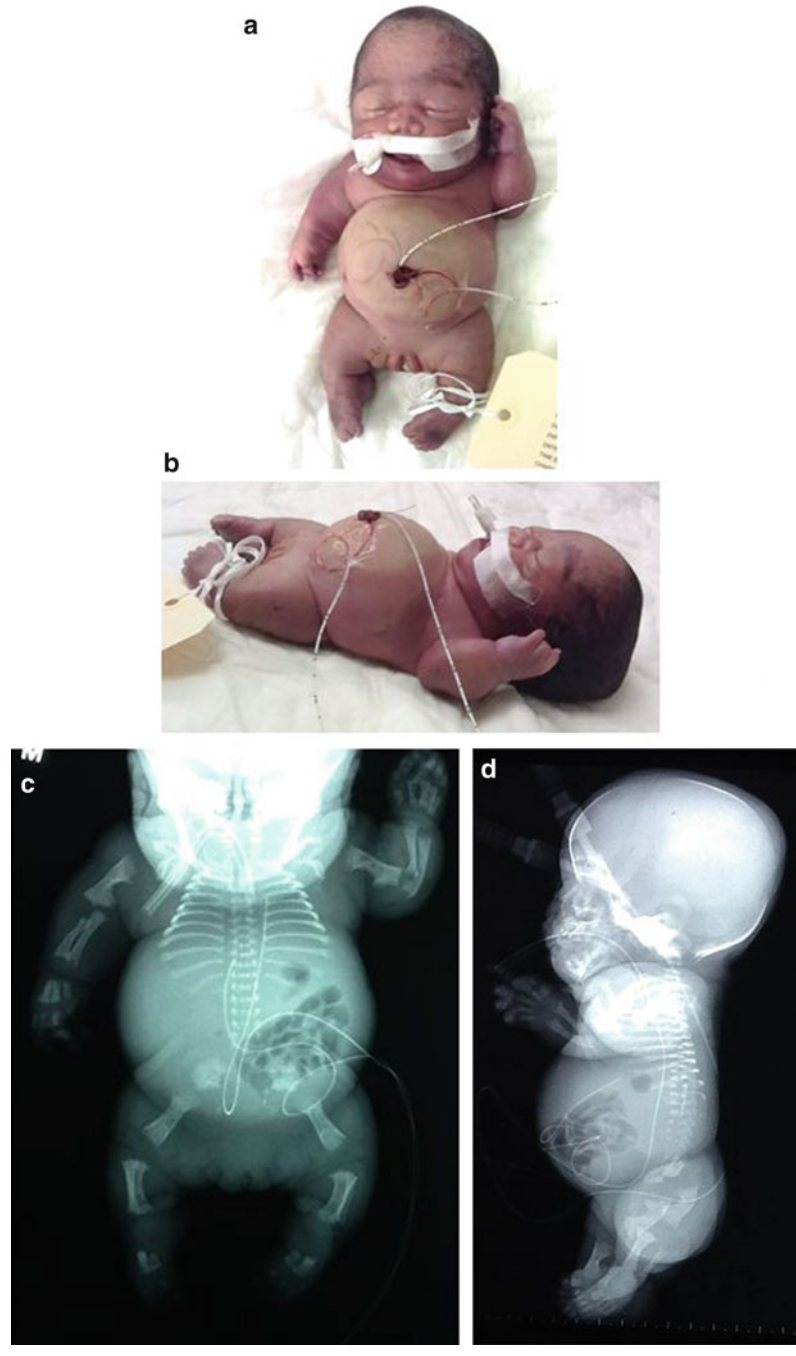

Fig. 5 A neonate (twin A) (**a**, **b**) with achondrogenesis II showing large head, midfacial hypoplasia, short neck, small chest, protuberant abdomen, and short limbs. The radiographs (**b**, **c**) showed generalized shortening of the long bones of the upper and lower extremities with marked cupping (metaphyseal spurs) at the metaphyseal ends of the bones, most evident at the distal ends of the tibia, fibular, radius, and ulna and distal ends of the digits. The infant was delivered at 29 weeks via cesarean section secondary to breech presentation of twin A. Twin B weighed 780 g and had APGARS of 1, 2, and 2 at 1, 5, and 10 min, respectively. The fetus expired shortly after birth due to respiratory failure despite ventilator support. *COL2A1* gene analysis from cultured fibroblasts showed a variation in the fragment containing exon 22 and the flanking sequences of the *COL2A1* gene. Sequencing revealed a nucleotide G to A substitution that converted a codon for glycine-316 (GGT) to a codon for aspartic acid (GAT) at cDNA position c.1340 (position from +1Met gly516asp c.1547). This exact mutation has been previously reported in patients diagnosed with achondrogenesis type II. The fetus is heterozygous for the mutation (c.1340G>A)

Achondroplasia

Contents

Genetics/Basic Defects

1. Inheritance.
    1. Autosomal dominant disorder with complete penetrance
    2. Sporadic in about 80% of the cases, the result of a de novo mutation
    3. Presence of paternal age effect (advanced paternal age in sporadic cases)
    4. Gonadal (germinal) mosaicism (two or more children with classic achondroplasia born to normal parents) (Fryns et al. 1983)
2. Caused by mutations in the gene of the fibroblast growth factor receptor 3 (*FGFR3*) on chromosome 4p16.3 (Velinov et al. 1994; Shiang et al. 1994).
    1. About 98% of achondroplasia with G-to-A transition and about 1% G-to-C transversion at nucleotide 1138. Both mutations resulted in the substitution of an arginine residue for a glycine at position 380 (G380A) of the mature protein in the transmembrane domain of *FGFR3*.
    2. A rare mutation causing substitution of a nearby glycine 375 with a cysteine (G375C).
    3. Another rare mutation causing substitution of glycine346 with glutamic acid (G346E).
    4. The specific mechanisms by which *FGFR3* mutations disrupt skeletal development in achondroplasia remain elusive.
3. Different mutations in *FGFR3* can cause the following spectrum of disorders (Spranger 1988; Spranger et al. 1994; Lemyre et al. 1999; Vajo et al. 2000; Superti-Furga and Unger 2007):
    1. Hypochondroplasia
    2. Severe achondroplasia with developmental delay and acanthosis nigricans (SADDN) (Bellus et al. 1999)
    3. Thanatophoric dysplasia
    4. Muenke coronal craniosynostosis
    5. Crouzon syndrome with acanthosis nigricans
4. *FGFR3* mutations affect the cartilaginous growth plate in the growing skeleton, therefore disturbing cartilage function during linear bone growth (Richette et al. 2008).
5. Basic defect: zone of chondroblast proliferation in the physeal growth plates.
    1. Abnormally retarded endochondral ossification with resultant shortening of tubular bones and flat vertebral bodies, while membranous ossification (skull, facial bones) is not affected.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_3

2. Physeal growth zones show normal columnization, hypertrophy, degeneration, calcification, and ossification. However, the growth is quantitatively reduced significantly.
3. Achondroplasia as the result of a quantitative loss of endochondral ossification rather than the formation of abnormal tissue.
4. Normal diameter of the bones secondary to normal subperiosteal membranous ossification of tubular bones, the results being production of short, thick tubular bones, leading to short stature with disproportionately shortened limbs.

Clinical Features

1. Major clinical symptoms (Spranger et al. 1974; Horton et al. 2007; Baujat et al. 2008; Shirley and Ain 2009)
    1. Delayed motor milestones during infancy and early childhood
    2. Sleep disturbances secondary to both neurological and respiratory complications
    3. Breathing disorders
        1. A high prevalence (75%) of breathing disorders during sleep.
        2. Snoring is the commonest observed abnormality, but the reported incidence of obstructive sleep apnea shows wide variation (10–75%) (Afsharpaiman et al. 2013).
        3. Obstructive apnea caused by upper airway obstruction.
        4. The majority of respiratory complaints due to restrictive lung disease secondary to diminished chest size or upper airway obstruction and rarely due to spinal cord compression.
    4. Symptomatic spinal stenosis in more than 50% of patients as a consequence of a congenitally small spinal canal
        1. Back pain
        2. Lower extremity sensory changes
        3. Incontinence
        4. Paraplegia
        5. Onset of symptoms: usually after 20 s or 30 s
    5. Neurologic symptoms classified based on neurologic severity and presentation of spinal stenosis (Lutter and Langer 1977)
        1. Type I (back pain with sensory and motor change of an insidious nature)
        2. Type II (intermittent claudication limiting ambulation)
        3. Type III (nerve root compression)
        4. Type IV (acute onset paraplegia)
    6. Symptoms secondary to foramen magnum stenosis
        1. Respiratory difficulty
        2. Feeding problems
        3. Cyanosis, quadriparesis
        4. Poor head control
    7. Symptoms secondary to cervicomedullary compression
        1. Pain
        2. Ataxia
        3. Incontinence
        4. Apnea
        5. Progressive quadriparesis
        6. Respiratory arrest
2. Major clinical signs
    1. Disproportionate short stature (dwarfism)
    2. Hypotonia during infancy and early childhood
    3. Relative stenosis of the foramen magnum in all patients, documented by CT
    4. Foramen magnum stenosis considered as the cause of increased incidence of:
        1. Hypotonia
        2. Sleep apnea
        3. Sudden infant death syndrome
    5. Symptomatic hydrocephalus in infancy and early childhood rarely due to narrowing of the foramen magnum
    6. Characteristic craniofacial appearance
        1. Disproportionately large head
        2. Frontal bossing
        3. Depressed nasal bridge
        4. Midfacial hypoplasia
        5. Narrow nasal passages

6. Prognathism
7. Dental malocclusion

7. A normal trunk length
8. A thoracolumbar kyphosis or gibbus usually present at birth or early infancy
9. Exaggerated lumbar lordosis when the child begins to ambulate
10. Prominent buttocks and protuberant abdomen secondary to increased pelvic tilt in children and adults
11. Generalized joint hypermobility, especially the knees
12. Rhizomelic micromelia (relatively shorter proximal segment of the limbs compared to the middle and the distal segments)
13. Limited elbow and hip extension
14. Trident hands (inability to approximate the third and fourth fingers in extension produces a "trident" configuration of the hand)
15. Short fingers (brachydactyly)
16. Bowing of the legs (genu varum) due to lax knee ligaments
17. Excess skin folds about thighs

3. Complications/risks (Hunter et al. 1998)
    1. Recurrent otitis media during infancy and childhood
        1. Conductive hearing loss
        2. Delayed language development
    2. Thoracolumbar gibbus
    3. Osteoarthropathy of the knee joints
    4. Neurological complications (Hecht et al. 1987; Hecht and Butler 1990; King et al. 2009)
        1. Small foramen magnum
        2. Cervicomedullary junction compression causing sudden unexpected death in infants with achondroplasia
        3. Apnea
        4. Communicating hydrocephalus
        5. Spinal stenosis
        6. Paraparesis
        7. Quadriparesis
        8. Infantile hypotonia
    5. Obesity
        1. Aggravating the morbidity associated with lumbar stenosis
        2. Contributing to the nonspecific joint problems and to the possible early cardiovascular mortality in this condition
    6. Obstetric complications
        1. Large head of the affected infant
        2. An increased risk of intracranial bleeding during delivery
        3. Marked obstetrical difficulties secondary to very narrow pelvis of achondroplastic women
4. Prognosis
    1. Normal intelligence and healthy, independent, and productive lives in vast majority of patients. Rarely, intelligence may be affected because of hydrocephalus or other CNS complications.
    2. Mean adult height.
        1. Approximately 131 cm $\pm$ 5.6 for males
        2. Approximately 124 cm $\pm$ 5.9 for females
    3. Weight for age charts: available for children with achondroplasia (Hoover-Fong et al. 2007).
    4. Standard growth curves: available for achondroplasia (Horton et al. 1978).
    5. Standard weight for height curves: available for achondroplasia (Hunter et al. 1996).
    6. Psychosocial problems related to body image because of severe disproportionate short stature.
    7. Life span for heterozygous achondroplasia.
        1. Usually normal unless there are serious complications
        2. Mean life expectancy approximately 10 years less than the general population (Wynn et al. 2007)
    8. Homozygous achondroplasia (Hall et al. 1969).
        1. A lethal condition with severe respiratory distress caused by rib cage deformity and upper cervical cord damage caused by small foramen magnum. The patients die soon after birth.
        2. Radiographic changes much more severe than the heterozygous achondroplasia.
    9. Normal fertility in achondroplasia.
        1. Pregnancy at high risk for achondroplastic women

2. Respiratory compromise common during the third trimester
3. Advise baseline pulmonary function studies before pregnancy to aid in evaluation and management
4. A small pelvic outlet usually requiring cesarean section under general anesthesia since the spinal or epidural approach is contraindicated because of spinal stenosis

10. Anticipatory guidance: Patients and their families can benefit greatly from anticipatory guidance published by the American Academy of Pediatrics Committee on Genetics (1995) and Clinical Report (2005).
11. Adaptations of patients to the environment to foster independence.
    1. Lowering faucets and light switches
    2. Using a step stool to keep feet from dangling when sitting
    3. An extended wand for toileting
    4. Adaptations of toys for short limbs
12. Support groups: Many families find it beneficial to interact with other families and children with achondroplasia through local and national support groups.

Diagnostic Investigations

1. Diagnosis of achondroplasia made by clinical findings, radiographic features, and/or *FGFR3* mutation analysis
2. Radiologic features (Langer et al. 1967; Horton et al. 2007)
    1. The skull
        1. Relatively large calvarium
        2. Prominent forehead
        3. Depressed nasal bridge
        4. Small skull base
        5. Small foramen magnum
        6. Dental malocclusion
    2. The spine
        1. Caudal narrowing of interpedicular distances in the lower lumbar spine
        2. Short vertebral pedicles
        3. Wide disk spaces
        4. Dorsal scalloping of the vertebral bodies in the newborn
        5. Concave posterior aspect of the vertebral bodies in childhood and adulthood
        6. Different degrees of anterior wedging of the vertebral bodies causing gibbus
    3. Th pelvis
        1. Lack of iliac flaring
        2. Narrow sacroiliac notch
        3. Horizontal acetabular portions of the iliac bones
    4. The limbs
        1. Rhizomelic micromelia
        2. Square or oval radiolucent areas in the proximal humerus and femur during infancy
        3. Tubular bones with widened diaphyses and flared metaphyses during childhood and adulthood
        4. Markedly shortened humeri
        5. Short femoral neck
        6. Disproportionately long fibulae in relation to tibiae
3. Craniocervical MRI
    1. Narrowing of the foramen magnum
    2. Effacement of the subarachnoid spaces at the cervicomedullary junction
    3. Abnormal intrinsic cord signal intensity
    4. Mild to moderate ventriculomegaly
4. Histology
    1. Normal histologic appearance of epiphyseal and growth plate cartilages.
    2. Shorter than normal growth plate: the shortening is greater in homozygous than in heterozygous achondroplasia, suggesting a gene dosage effect.
5. Mutation analysis (Bellus et al. 1995)
    1. G1138A substitution in *FGFR3* (about 98% of cases)
    2. G1138C substitution in *FGFR3* (about 1% of cases)

Genetic Counseling

1. Recurrence risk (Carter et al. 2007; Pauli 2012)

1. Patient's sib
    1. Recurrence risk after the conception of an affected child has always been considered very low, and less than 30 cases of recurrences among sibs have been reported so far (Natacci et al. 2008). It was possible to demonstrate somatic and germinal mosaicism in the mother (Henderson et al. 2000) and germinal mosaicism in the father (Natacci et al. 2008).
    2. Recurrence risk of achondroplasia in the sibs of achondroplastic children with unaffected parents: presumably higher than twice the mutation rate because of gonadal mosaicism. Currently, the risk is estimated as 1 in 443 (0.02%) (Mettler and Fraser 2000).
    3. Fifty percent affected if one of the parents is affected.
    4. Twenty-five percent affected with homozygous achondroplasia (resulting in a much more severe phenotype that is usually lethal early in infancy) and 50% affected with heterozygous achondroplasia if both parents are affected with achondroplasia.
2. Patient's offspring
    1. Fifty percent affected (with heterozygous achondroplasia) if the spouse is normal.
    2. Twenty-five percent affected with homozygous achondroplasia and 50% affected with heterozygous achondroplasia if the spouse is also affected with achondroplasia. There is still a 25% chance that the offspring will be normal.

2. Prenatal diagnosis
    1. Prenatal ultrasonography.
        1. Suspect achondroplasia on routine ultrasound findings of a falloff in limb growth (<3rd percentile), increased biparietal diameter (>95th percentile), and low nasal bridge (Cordone et al. 1993; Mesoraca et al. 1996), usually during the third trimester of pregnancy, in case of parents with normal heights. About one third of cases are suspected this way. However, one must be cautious because disproportionately short limbs are observed in a variety of conditions.
        2. Inability to make specific diagnosis of achondroplasia with certainty by ultrasonography unless by radiography late in gestation or after birth.
        3. Request of prenatal ultrasonography by an affected parent, having 50% risk of having a similarly affected child, to optimize obstetric management.
        4. Follow pregnancy by a femoral growth curve in the second trimester by serial ultrasound scans to enable prenatal distinction between homozygous, heterozygous, and unaffected fetuses, in case of both affected parents (Patel and Filly 1995).
    2. Prenatal radiography.
        1. Shortened long bones with wide metaphyses
        2. Slim and radiolucent area in the proximal femur
        3. Horizontal acetabular roof
        4. The above features not always detected
    3. Three-dimensional computed tomography scan (3D CT scan) may be used after 30 weeks of gestation (Krakow et al. 2003; Ruano et al. 2004).
        1. Slightly flat vertebral bodies with medial spurs
        2. Pointed femora with proximal extremity
        3. Round and square ilia with an oval radiolucent area in the proximal femur
    4. On computed tomography and postnatal X-ray, proximal femoral metaphysis appeared rounded, with poor, uneven

ossification. Connection to diaphysis was abnormal, with relative overgrowth of the periosteum, creating a new diagnostic sign, called the "collar hoop" sign (Boulet et al. 2009).

5. Prenatal molecular testing.
    1. Molecular technology applied to prenatal diagnosis of a fetus suspected of or at risk for having achondroplasia
    2. Simple methodology requiring only one PCR and one restriction digest to detect a very limited number of mutations causing achondroplasia
    3. Preimplantation genetic diagnosis
        1. Available at present (Moutou et al. 2003)
        2. The initial practice raising questions on the feasibility of such a test, especially with affected female patients

3. Management
    1. Adaptive environmental modifications
        1. Appropriately placed stools
        2. Seating modification
        3. Other adaptive devices
    2. Obesity control
    3. Obstructive apnea
        1. Adenoidectomy and tonsillectomy (Mogayzel et al. 1998)
        2. Continuous positive airway pressure (CPAP) and bi-level positive airway pressure (BiPAP) for clinically significant persistent obstruction
        3. Surgical improvement of the airway, including mid-face advancement (Afsharpairman et al. 2013)
        4. Extremely rare for requiring temporary tracheostomy
    4. Experimental growth hormone therapy (Horton et al. 1992; Shohat et al. 1996; Seino et al. 2000)
        1. Resulting in transient increases in growth velocity
        2. Long-term result not conclusive
    5. Hydrocephalus (Pierre-Kahn et al. 1980)
        1. Observation for benign ventriculomegaly
        2. May need surgical intervention for clinically significant hydrocephalus
    6. Kyphosis
        1. Adequate support for sitting in early infancy
        2. Bracing using a thoracolumbosacral orthosis for severe kyphosis in young children
        3. Surgical intervention for medically unresponsive cases
    7. Surgical decompression for unequivocal evidence for cervical cord compression
    8. Decompression laminectomy for severe and progressive lumbosacral spinal stenosis
    9. Limb lengthening through osteotomy and stretching of the long bones (Aldegheri et al. 1988; Lavini et al. 1990; Ganel et al. 1979; Rimoin 1991; Ganel and Horoszowski 1996; Yasui et al. 1997)
        1. Controversial
        2. Difficult to achieve the benefits of surgery
            1. Need strong commitment on the part of the patients and their families for the time in the hospital and the number of operations
            2. A high risk of infection
            3. Occurrence of possible severe permanent sequelae (damage to joint and soft tissue)
            4. May result in poorer quality of life
    10. Potential anesthetic risks related to:
        1. Obstructive apnea
        2. Cervical compression
    11. Risks associated with pregnancy in women with achondroplasia (Lattanzi and Harger 1982)
        1. Cephalopelvic disproportion secondary to marked pelvic contracture the most consistent features
        2. Worsening neurologic symptoms related to increasing hyperlordosis and maternal respiratory failure
        3. Anticipate a scheduled cesarean delivery due to cephalopelvic disproportion

4. Preeclampsia
5. Polyhydramnios
6. Increased fetal wastage and neonatal death

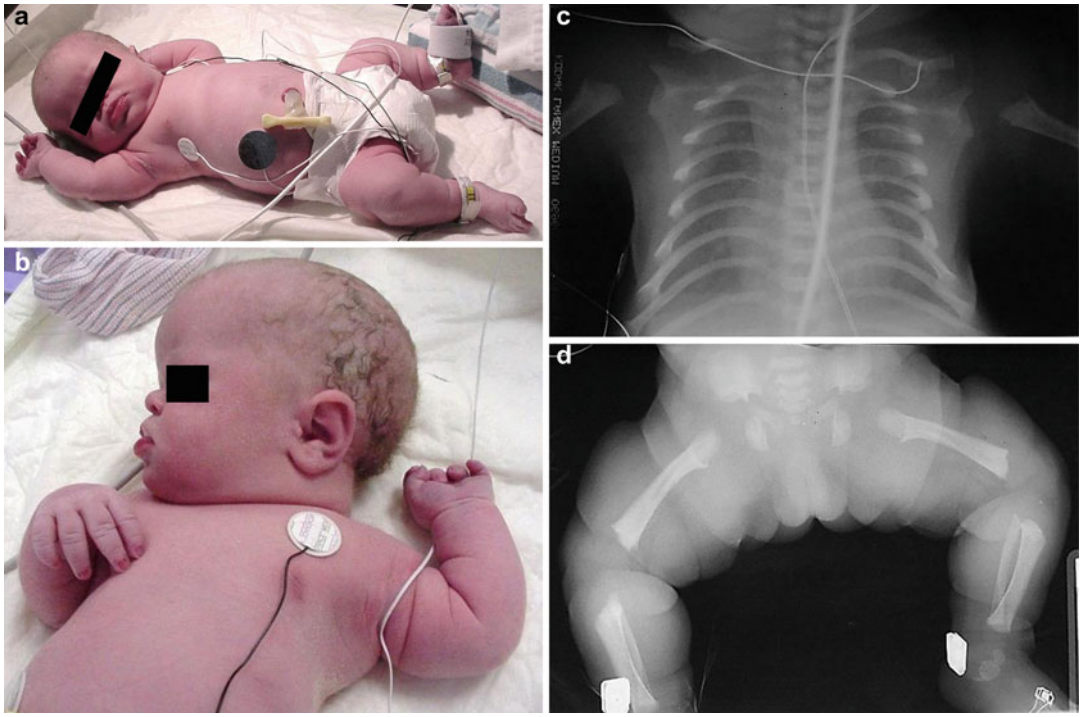

Fig. 1 A newborn with achondroplasia showing large head, depressed nasal bridge, short neck, normal length of the trunk, narrow chest, rhizomelic micromelia, and trident hands (**a**, **b**). The radiographs showed narrow chest, characteristic pelvis, micromelia, and oval radiolucent proximal portion of the femurs (**c**, **d**). Molecular analysis showed 1138 G → C transversion mutation which has been observed in approximately 1.9 % of achondroplasia chromosomes

Fig. 2 A 4-month-old boy with achondroplasia showing typical craniofacial features and rhizomelic shortening of limbs (confirmed by radiograms). Molecular study revealed 1138 G-to-A transition mutation which has been observed in approximately 98% of achondroplasia chromosomes

Fig. 3 Another achondroplastic neonate with typical clinical features (**a**) and radiographic findings (**b**, **c**). Note the abnormal vertebral column with wide intervertebral spaces and abnormal vertebral bodies

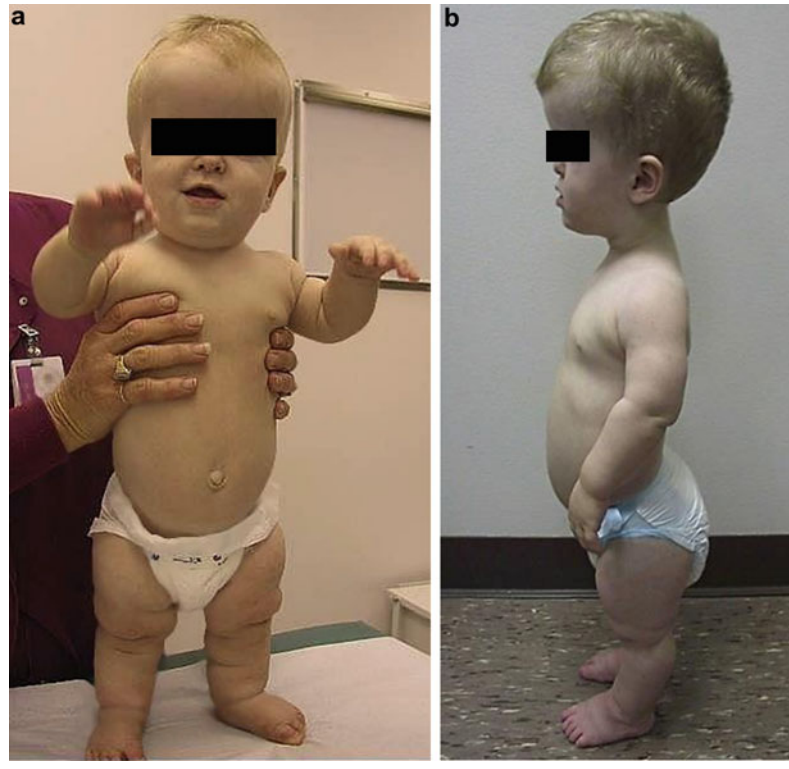

Fig. 4 A boy (7-month (**a**) and 2-year and 7-month old (**b**)) with achondroplasia showing a large head, small chest, normal size of the trunk, rhizomelic micromelia, and exaggerated lumbar lordosis

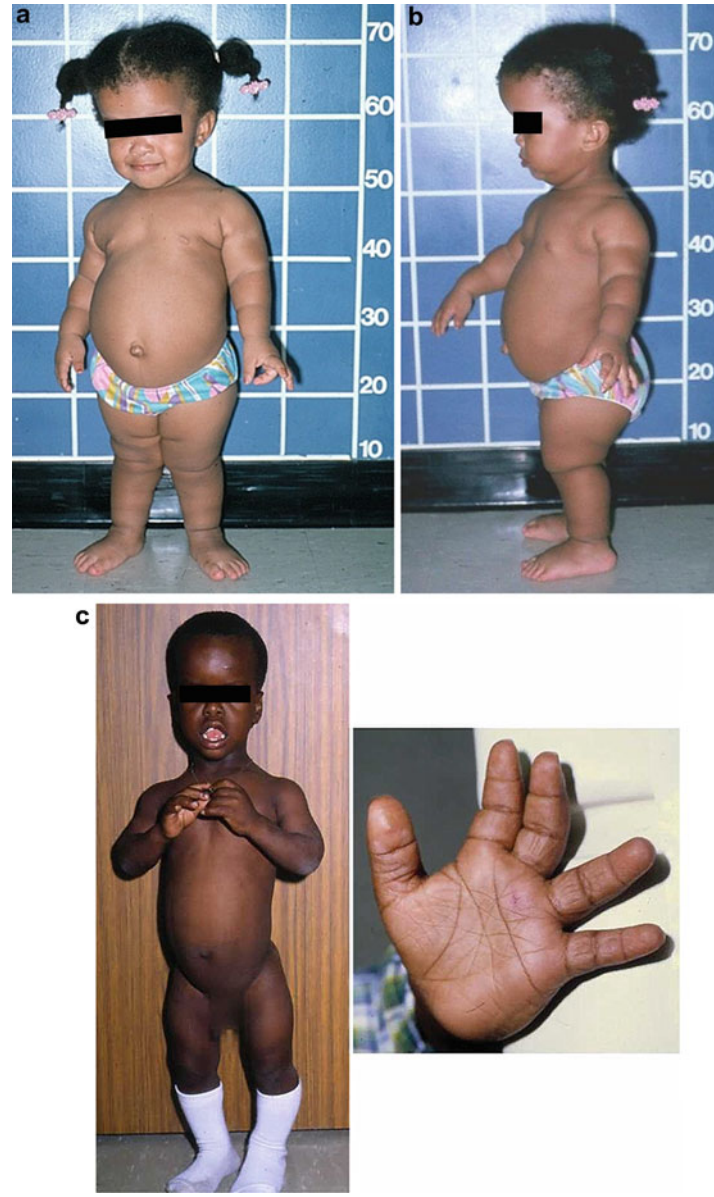

Fig. 5 Two older children with achondroplasia showing rhizomelic micromelia, typical craniofacial features, exaggerated lumbar lordosis (**a**–**c**), and trident hands (**d**)

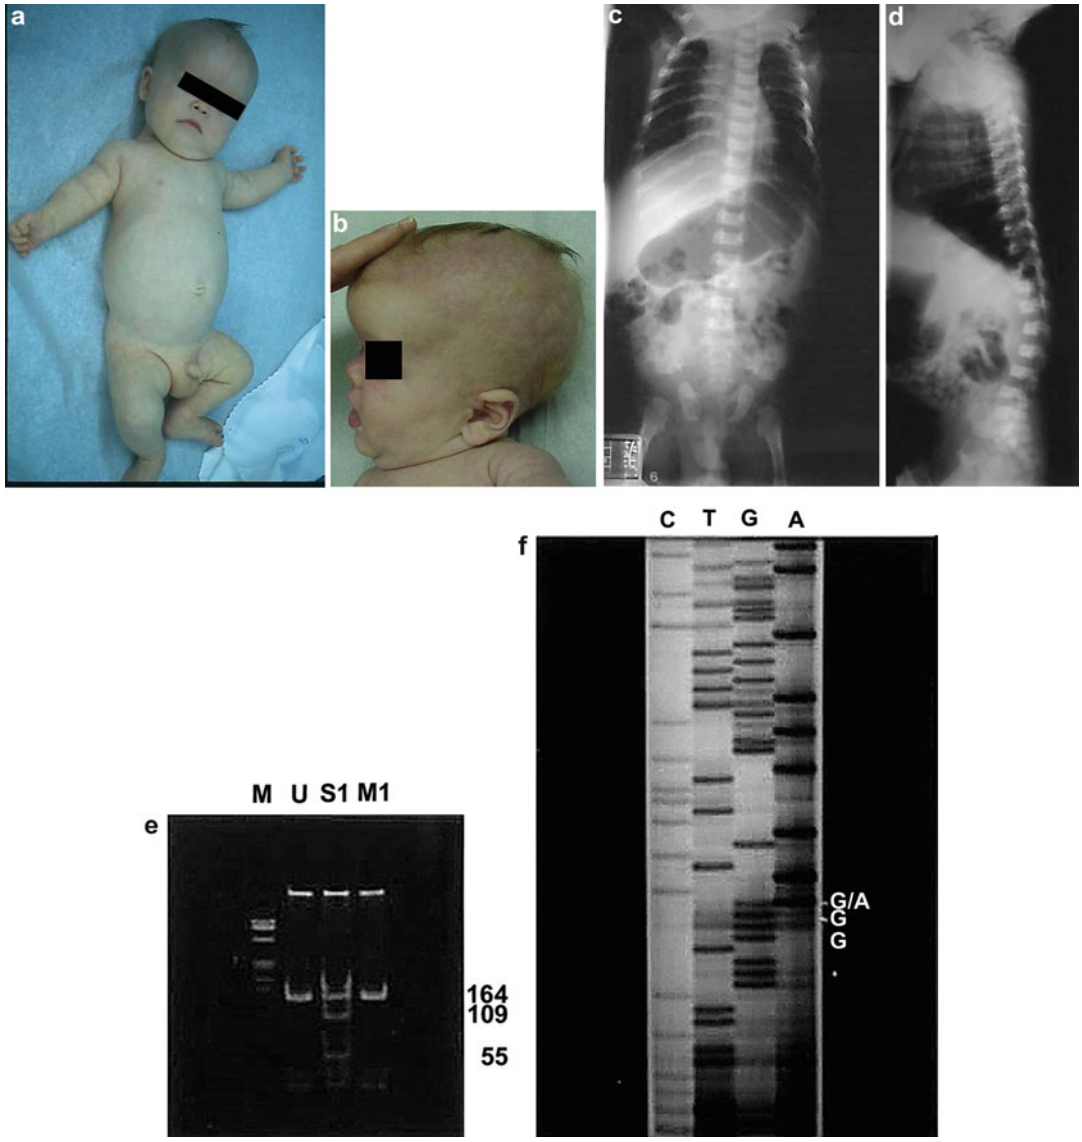

Fig. 6 A boy with achondroplasia and i(21q) Down syndrome presented with diagnostic dilemma. Besides craniofacial features typical for Down syndrome, the skeletal findings of achondroplasia dominate the clinical picture (**a**, **b**). The diagnosis of Down syndrome was based on the clinical features and the cytogenetic finding of i(21q) trisomy 21. The diagnosis of achondroplasia was based on the presence of clinical and radiographic findings (**c**, **d**) and confirmed by the presence of a common *FGFR3* gene mutation (Gly380Arg) detected by restriction enzyme analysis and sequencing of the PCR products (**e**, **f**) (Chen et al. 2000)

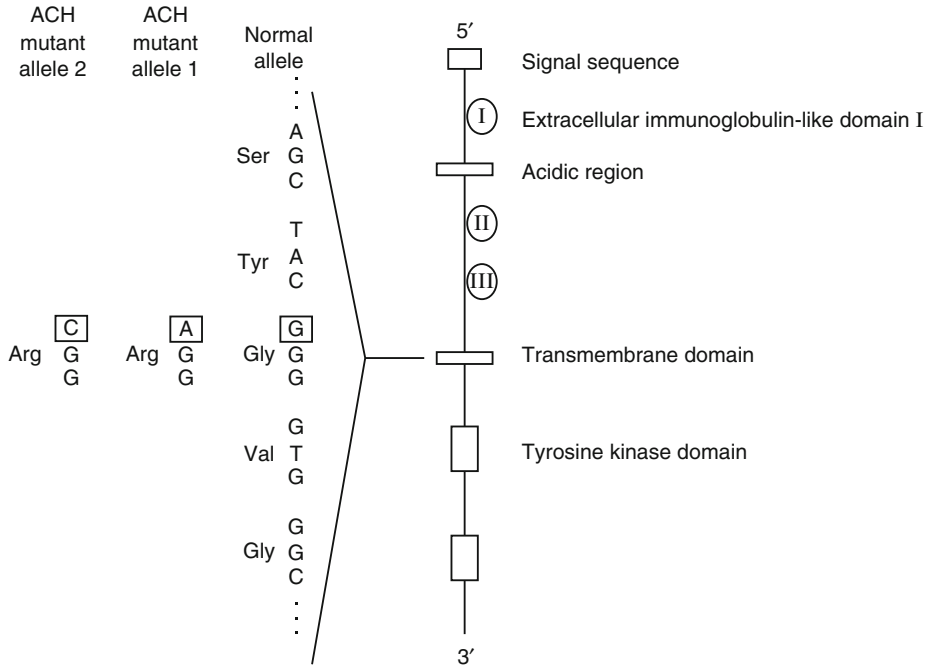

Fig. 7 Schematic of the *FGFR3* gene and DNA sequence of normal allele and mutant FGFR3 achondroplasia allele (Modified from Shiang et al. 1994)

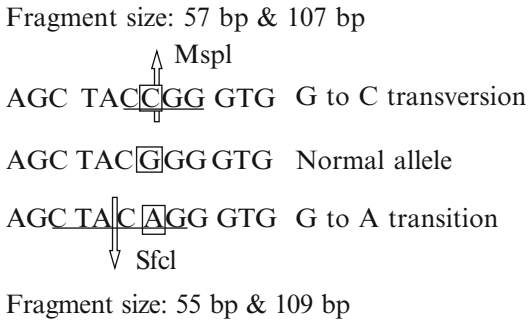

Fig. 8 Nucleotide change in the 1138 C allele creates a Msp1 site and nucleotide change in the 1138A allele creates a Sfc1. The base in the coding sequence that differs in the three alleles is *boxed* (Modified from Shiang et al. 1994)

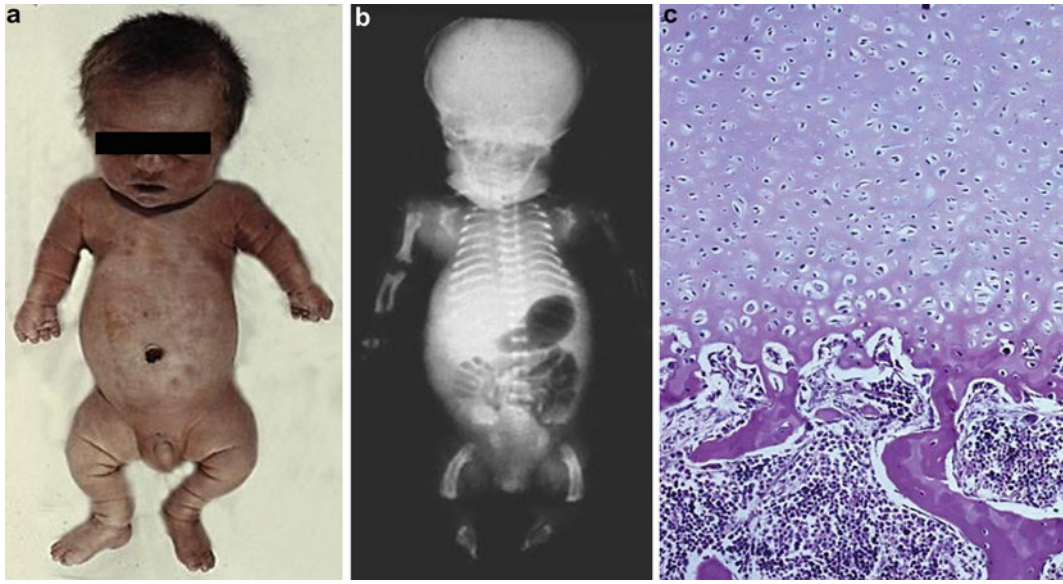

Fig. 9 Homozygous achondroplasia. Both parents are achondroplastic. The large head, narrow chest, and severe rhizomelic shortening of the limbs are similar to those of thanatophoric dysplasia (**a**). Radiograph (**b**) shows severe platyspondyly, small ilia, and short limb bones. Photomicrograph of the physeal growth zone (**c**) shows severe retardation and disorganization, similar to that of thanatophoric dysplasia (Yang and Gilbert-Barnes 1997) (Courtesy of Dr. Samuel Yang)

Fig. 10 This 4-month-old boy had typical clinical (**a**) and radiographic (**b**) features of achondroplasia. Molecular testings indicated the presence of a G>A transition at nucleotide 1138 (c.1138G>A) of the fibroblast growth factor receptor 3 (FGFR3) gene. The presence of this mutation is consistent with clinical diagnosis of achondroplasia

Adams-Oliver Syndrome

Contents

In 1945, Adams and Oliver described congenital transverse limb defects associated with aplasia cutis congenita in a three-generation kindred with typical autosomal dominant inheritance and intrafamilial variable expressivity.

Synonyms and Related Disorders

Aplasia cutis congenita with terminal transverse limb defects

Genetics/Basic Defects

1. Genetic heterogeneity
    1. Autosomal dominant in most cases (Burton et al. 1976; Bonafede and Beighton 1979; Küster et al. 1988):
        1. The family described by Adams and Oliver, and revisited by Whitley and Gorlin in 1991, illustrates vertical transmission, with multiple affected members spanning four generations, and includes male-to-male transmission, consistent with autosomal dominant inheritance.
        2. Reports from over 20 further kindreds provide support for the role of a heterozygous autosomal gene mutation (Snape et al. 2009).
    2. Autosomal recessive in some cases (Koiffmann et al. 1988; Klinger and Merlob 1998; Sybert 1989; Tekin et al. 1999; Temtamy et al. 2007):
        1. The combination of aplasia cutis congenita and terminal transverse limb defects within sibships provides evidence for an autosomal recessive mode of inheritance.
        2. Further supported by the occurrence of affected siblings within inbred families.
    3. Recent report of an autosomal recessive Adams-Oliver syndrome caused by homozygous mutation in *EOGT*, encoding an EGF domain-specific O-GlcNAc transferase (Cohen et al. 2014). This study, together with a parallel independent study by Shaheen et al. (2013) which identified three *EOGT* mutations in different Arab families, defines *EOGT* as a novel Adams-Oliver syndrome gene.
    4. Hassed et al. (2012) have identified two mutations in *RBPJ*, the key transcriptional regulator for Notch, in two independent

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_4

kindreds affected by Adams-Oliver syndrome.
5. Mutations in *ARHGAP31* (Southgate et al. 2011) and *DOCK6* (Shaheen et al. 2011) have been reported in AOS-affected kindreds with both autosomal dominant and autosomal recessive inheritance.
6. A large pedigree was reported to exhibit the vast clinical variability of Adams-Oliver syndrome resulting from *ARHGAP31* mutations, ranging from severe and milder phenotypes to complete absence of a recognizable limb defect (Islie et al. 2014).
7. Mutations in *NOTCH1* are the most common cause of Adams-Oliver syndrome and add to a growing list of human diseases that have a vascular and/or bony component and are caused by alterations in the Notch signaling pathway (Stittrich et al. 2014).

2. Pathogenesis (Baskar et al. 2009)
    1. Trauma
    2. Uterine compression
    3. Amniotic band sequelae
    4. Vascular disruption sequence
        1. Concomitant occurrence of Poland sequence
        2. Both Poland sequence and Adams-Oliver syndrome: secondary to vascular disruption due to thrombosis of subclavian and vertebral arteries
    5. Massive thrombus from the placenta occluding the brachial artery
    6. Abnormalities in small vessel structures manifesting during embryogenesis
    7. A developmental disorder of morphogenesis

Clinical Features

1. Marked intrafamilial (Bamforth et al. 1994) and interfamilial variability.
2. Terminal transverse limb defects:
    1. Most common manifestation (84%)
    2. Usually asymmetrical
    3. Tendency toward bilateral lower limb, rather than upper limb involvement
    4. Mild spectrum of defects
        1. Nail hypoplasia
        2. Cutaneous syndactyly
        3. Bony syndactyly
        4. Ectrodactyly
        5. Brachydactyly
    5. Severe spectrum of transverse defects
        1. Absence of the hand
        2. Absence of the foot
        3. Absence of the limb
3. Aplasia cutis congenita:
    1. Second most common defect (almost 75%).
    2. Associated with skull defect (64%): The most common site is the vertex, often with scalp defect extending to the periosteum, skull, and dura:
        1. Small lesion: 0.5 cm in diameter
        2. Intermediate lesion: 8–10 cm involving the vertex
        3. Severe lesion: involves most of the scalp with acrania
    3. Skull defect without scalp defect, often mistaken for an enlarged fontanel.
    4. May involve other areas of the body (Pereira-da-Silva et al. 2000).
    5. Severe end of the spectrum of scalp defects:
        1. Encephalocele
        2. Acrania
    6. Most severe manifestations can be associated with a mortality rate of 20–55% (Bajpai and Pal 2003):
        1. Associated with dilated and tortuous scalp veins with significant morbidity
        2. Associated with hemorrhage (from the sagittal sinus) or infection (Arand et al. 1991)
4. Congenital cardiovascular malformations (13.4–20%) (Zapata et al. 1995; Lin et al. 1998):
    1. Mechanisms proposed to explain the pathogenesis of congenital cardiovascular malformations:
        1. Alteration of mesenchymal cell migration resulting in conotruncal malformations, e.g., tetralogy of Fallot, double outlet right ventricle, and truncus arteriosus

2. Alteration of fetal cardiac hemodynamics resulting in different malformations such as coarctation of the aorta, aortic stenosis, perimembranous VSD, and hypoplastic left heart
3. Persistence of normal fetal vascular channels resulting in postnatal vascular abnormalities

2. Diverse vascular and valvular abnormalities
   1. Bicuspid aortic valve
   2. Pulmonary atresia
   3. Parachute mitral valve
   4. Pulmonary hypertension

5. Other associated anomalies:
   1. Cutis marmorata telangiectatica congenita (25%) (Bork and Pfeifle 1992)
   2. Dilated and tortuous scalp veins (11%)
   3. Poland anomaly (Hoyme et al. 1992)
   4. Encephalocele
   5. Facial features
      1. Hemihypoplasia
      2. Hypertelorism
      3. Epicanthal folds
      4. Microphthalmia
      5. Esotropia
      6. High-arched palate
      7. Cleft palate
   6. Cryptorchidism
   7. Lymphatic abnormalities
      1. Lymphedema of the leg
      2. Chylothorax
      3. Dilated pulmonary lymphatics
      4. Intestinal lymphangiectasia
      5. Marmorata telangiectatica congenita (a cutaneous vascular abnormality)
   8. CNS abnormalities: unusual manifestation
      1. Mental retardation
      2. Learning disability
      3. Epilepsy
   9. Short stature
   10. Renal malformations
   11. Spina bifida occulta
   12. Accessory nipples
6. Major and minor features of Adams-Oliver syndrome (Snape et al. 2009): The presence of two major features is considered sufficient for a diagnosis. The combination of one major and one minor feature should place Adams-Oliver syndrome high in the differential diagnosis of such individuals:
   1. Major features
      1. Terminal transverse limb defects
      2. Aplasia cutis congenita
      3. Family history of Adams-Oliver syndrome
   2. Minor features
      1. Cutis marmorata telangiectatica congenita
      2. Congenital cardiac defect
      3. Vascular anomaly
7. Differential diagnosis (Snape et al. 2009):
   1. Amniotic band sequence
   2. Moebius and Poland syndromes (McGuirk et al. 2001)
   3. Teratogenic agents such as phenytoin, misoprostol, and ergotamine
      1. Asymmetrical bilateral transverse terminal limb defects
      2. Tend to affect the upper limb more severely than the lower limb (Spranger et al. 1980; Holmes 2002)
   4. Limb anomalies
      1. Caused by thalidomide: tends to be symmetrical and longitudinal (Smithells and Newman 1992)
      2. Caused by chorionic villus sampling during pregnancy (Holmes 2002)
   5. Isolated aplasia cutis congenita: substantial heterogeneity based on association with known abnormalities or exposure to teratogens such as methimazole (Frieden 1986)
   6. Cutis marmorata telangiectatica congenita
      1. Common in kindreds with Adams-Oliver syndrome
      2. Can be seen in combination with both terminal transverse limb defects (Maniscalco et al. 2005) and aplasia cutis congenita (Verdyck et al. 2003)
      3. Can be an isolated finding in otherwise unaffected family members (Scribanu and Temtamy 1975; Toriello et al. 1988)
      4. Can be associated with skin atrophy and ulcerations, capillary malformations, capillary and cavernous vascular malformations, under- or overgrowth of the affected extremity, macrocephaly, and glaucoma and in association with

vascular syndromes including Sturge-Weber and Klippel-Trenaunay (Amitai et al. 2000)

Diagnostic Investigations

1. Radiography
   1. Transverse limb defects (Fryns 1987)
   2. Ectrodactyly
   3. Brachydactyly
   4. Syndactyly
   5. Nail hypoplasia
   6. Skull defect
2. CT scan or MRI of the brain (Fryns et al. 1996; Mempel et al. 1999)
   1. Polymicrogyria/pachygyria
   2. Ventriculomegaly
   3. Irregular cortical thickening
   4. Cerebral cortex dysplasia
   5. Microcephaly
   6. Arhinencephaly
   7. Periventricular and parenchymal calcium deposits
3. Gene sequencing to detect various causative gene mutations (*ARHGAP31* and *RBPJ* mutations for certain dominant forms; *DOCK6* and *EOGT* mutations for autosomal recessive forms)

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Autosomal dominant: not increased unless a parent is affected in which case the risk is 50%
      2. Autosomal recessive: 25%
   2. Patient's offspring
      1. Autosomal dominant: 50%
      2. Autosomal recessive: not increased unless the spouse carries the gene or is affected
2. Prenatal diagnosis by ultrasonography (Becker et al. 2002)
   1. Transverse limb defects
   2. Concomitant skull defect
3. Management
   1. Treat minor scalp lesions with daily cleansing of the involved areas with applications of antibiotic ointment.
   2. Surgically close larger lesions and exposed dura with minor or major skin grafting procedure (split thickness or full thickness).
   3. Prevent sepsis and/or meningitis from an open scalp lesion which is highly vascular and rarely involves the sagittal sinus predisposing to episodes of spontaneous hemorrhage.
   4. Urgent surgical intervention may be required with operative measures that include primary closure, skin grafting, local scalp flaps with or without tissue expansion, and cranial vault reconstruction using split rib grafts and free latissimus dorsi muscle flap (Bajpai and Pal 2003).
   5. Orthopedic care for various degrees of limb defects.

Fig. 1 A 9-month-old boy with Adams-Oliver syndrome showing alopecia, absent eyebrows and eyelashes (**a**), scalp defect (**b**), tortuous scalp veins (**c**), and limb defects (brachydactyly, syndactyly, broad great toes, and nail hypoplasia) (**d**). Radiographs (**e**, **f**) showed absent middle and distal phalanges of second to fifth toes and absent distal phalanges of the great toes

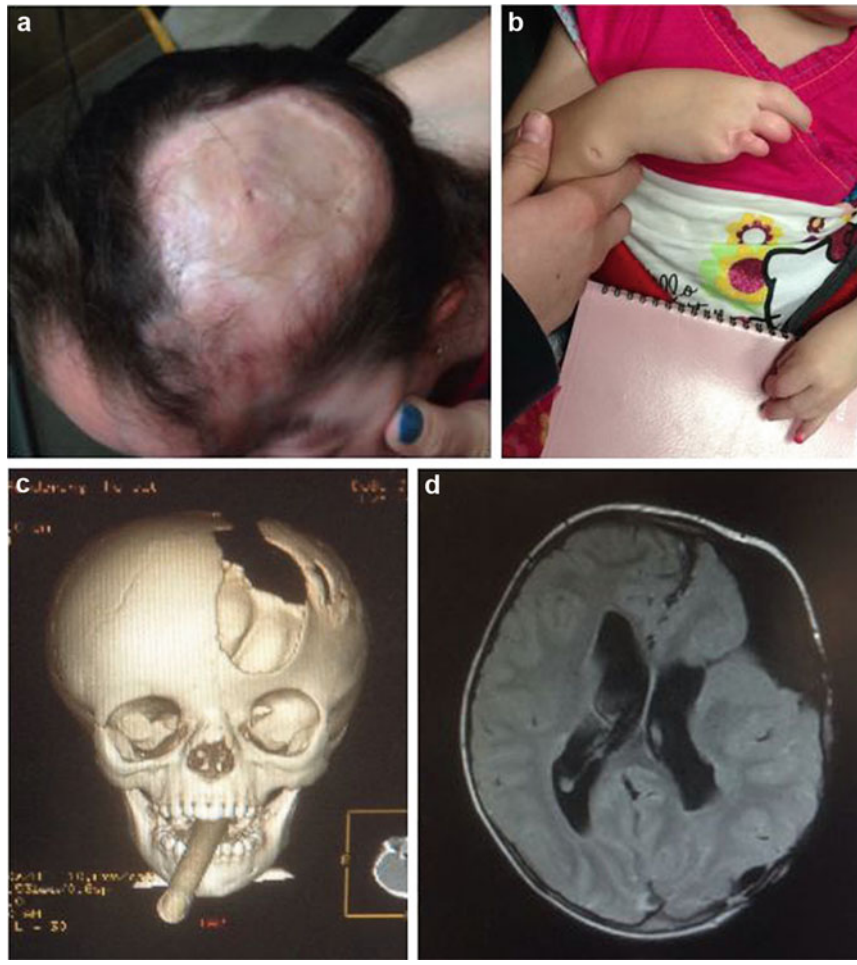

Fig. 2 This 3-year-and-7-month-old girl was evaluated for scalp defect (**a**) and terminal transverse limb defect (**b**). CT of the craniofacial bones (**c**) showed a large calvarial defect overlying the left frontal and parietal bones. MRI of the brain without contrast (**d**) showed a prominent axial cystic collection overlying the left frontal lobe directly overlying the schizencephaly, most comparable with arachnoid cyst. Mass effect from the extra-axial cystic focus results in approximately 5 mm of rightward midline shift. Continued abnormal configuration of the craniocervical junction with approximately 2.7 cm inferior extension of the cerebellar tonsils below the foramen magnum, concerning for underlying Chiari malformation (Courtesy of Dr. Ghali Ghali)

Agnathia

Contents

Agnathia is an extremely rare lethal neurocristopathy. The disorder has also been termed agnathia-holoprosencephaly spectrum, agnathia-otocephaly complex, agnathia-astomia-synotia, or cyclopia-otocephaly association. The incidence is estimated to be 1 in 70,000 infants (Schiffer et al. 2002).

The spectrum of agnathia ranges from isolated agnathia, or virtual absence of the mandible, to otocephaly, which refers to a broader malformation of mandibular hypoplasia or agnathia, downward displacement of the ears, and/or synotia (approximation of the ears in the midline), with or without aglossia (no tongue), and microstomia (small mouth) (Petrikovsky 1999). Agnathia-otocephaly is a lethal malformation complex characterized by absence of the mandible, microstomia, aglossia, and positioning of the ears toward the midline (Pauli et al. 1981; Bixler et al. 1985). Although ear positioning is variable and the use of the term "otocephaly" does not seem always justified, otocephaly is commonly used to assemble all ear abnormalities with displacement toward the midline (Schiffer et al. 2002; Faye-Petersen et al. 2006). Agnathia-otocephaly can occur alone or in combination with a variety of associated malformations, holoprosencephaly being the most commonly reported association.

Synonyms and Related Disorders

Agnathia-holoprosencephaly spectrum; Agnathia-otocephaly complex

Genetics/Basic Defects

1. Typically sporadic and often suspected during second-trimester ultrasound scans (Gekas et al. 2010).
2. Genetically heterogeneous (Sergouniotis et al. 2015).
    1. Rare autosomal recessive inheritance: two siblings with isolated dysgnathia complex who survived infancy (Baker et al. 2004); two stillborn sisters, both with agnathia and holoprosencephaly (Pauli et al. 1983).
    2. Possible autosomal dominant inheritance.
        1. Supported by an observation of dysgnathia in mother and daughter (Erlich et al. 2000).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_5

   2. Possibility of a defect in the *OTX2* gene as the basis of the disorder (Matsuo et al. 1995).
   3. Mutations in two genes, *PRRX1* (recessive or dominant) and *OTX2* (dominant), explain only a small subset of cases (Gekas et al. 2010; Chassaing et al. 2012; Donnelly et al. 2012; Patat et al. 2013).
3. Teratogenic factors have been described in humans (Cohen 1989).
   1. Salicylate (Benawra et al. 1980)
   2. Amidopyrine (Mollica et al. 1979)
   3. Theophylline (Ibba et al. 2000)
4. A prechordal mesoderm inductive defect affecting neural crest cells (Carles et al. 1987)
   1. A developmental field defect
   2. Different etiologic agents (etiological heterogeneity) acting on the same developmental field producing a highly similar complex of malformations
5. Possible existence of a mild form of agnathia without brain malformation (holoprosencephaly)
   1. Situs inversus-congenital hypoglossia
   2. Severe micrognathia, aglossia, and choanal atresia
6. Agnathia-holoprocephaly: a midline malformation association (Hanekam 1990)
7. Otocephaly-holoprosencephaly malformation association (Hersh et al. 1989)
8. A well-recognized malformation complex in the mouse (Juriloff et al. 1985), guinea pig (Wright 1934), rabbit, sheep, and pig

Clinical Features

1. Polyhydramnios due to persistence of oropharyngeal membrane or blind-ending mouth
2. Agnathia (absence of the mandible)
3. Microstomia or astomia (absence of the mouth)
4. Aglossia (absence of the tongue)
5. Blind mouth
6. Ear anomalies
   1. Otocephaly (variable ear positions)
   2. Synotia (external ears approaching one another in the midline)
   3. Dysplastic inner ear
   4. Atretic ear canal
7. Down-slanting palpebral fissures
8. Variable degree of holoprosencephaly: nearly 100 patients reported as having holoprosencephaly and features consistent with the spectrum of agnathia (Kauvar et al. 2010).
   1. Cyclopia
   2. Synophthalmia
   3. Arrhinencephaly
9. Other brain malformations
   1. Cerebellar hypoplasia
   2. Septum pellucidum cavum
   3. Absence of cranial nerves (I-IV)
   4. Absence of the corpus callosum
   5. Meningocele
10. Intrauterine growth retardation
11. Cleft lip/palate
12. Occular malformations
   1. Microphthalmos/anophthalmia
   2. Proptosis (protruding eyes)
   3. Absence of the eyelids
   4. Epibulbar dermoid
   5. Aphakia
   6. Retinal dysplasia
   7. Microcornea
   8. Anterior segment dysgenesis
   9. Uveal colobomas
13. Nasal anomalies
   1. Absence of the nasal cavity
   2. Cleft nose
   3. Blind nasal pharynx
14. Various visceral malformations
   1. Choanal atresia
   2. Tracheoesophageal fistula
   3. Absence of the thyroid gland
   4. Absence of the submandibular and parotid salivary glands
   5. Abnormal glottis and epiglottis
   6. Thyroglossal duct cyst
   7. Carotid artery anomalies
   8. Situs inversus (Leech et al. 1988; Meinecke et al. 1990; Ozden et al. 2000)
   9. Cardiac anomalies
   10. Unlobulated lungs
   11. Renogenital anomalies
      1. Unilateral renal agenesis
      2. Renal Ectopia

3. Cystic kidneys
4. Horseshoe kidneys
5. Solitary kidney
6. Mullerian duct agenesis
7. Cryptorchidism

15. Skeletal anomalies
    1. Vertebral anomalies
    2. Rib anomalies
    3. Tetramelia
16. Anatomical variations
    1. Ears
        1. Absence of the tragus
        2. Synotia
    2. Mandible
        1. Rudimentary
        2. Absent
        3. Two small separate masses
    3. Mouth: microstomia with vertical orientation
    4. Buccopharyngeal membrane: absent to present
    5. Tongue
        1. Small to absent body
        2. Present in (hypo)pharynx
    6. Absent submandibular glands
    7. Other skull bones: approximated maxillae, palatine, zygomatic, and temporal

Diagnostic Investigations

1. Radiography
    1. Reduced maxilla
    2. Absence of the zygomatic process
    3. Absence of the hyoid bone
    4. Vertebral anomalies
    5. Absence of the ribs
    6. Sprengel deformity
2. Cranial ultrasonography to define holoprosencephaly
3. Postnatal reconstructed CT for detailed 3D structure of the cranium in agnathia-otocephaly (Hinojosa et al. 1996)
4. Chromosome analysis (Krassikoff & Sekhon 1989)
    1. Normal in majority of cases
    2. Unbalanced der(18),t(6;18)(pter → p24.1; p11.21 → qter) in two female sibs with agnathia-holoprosencephaly
5. Utilization of exome sequencing as a means of elucidating the molecular pathology in fetuses with agnathia-otocephaly complex (Sergouniotis et al. 2015)
6. Autopsy to define postmortem findings

Genetic Counseling

1. Recurrence risks
    1. Risk to patient's sib: not increased unless in a rare autosomal recessive inheritance
    2. Risk to patient's offspring
        1. Not applicable to lethal cases since the patients do not survive to reproductive age
        2. Autosomal dominant (some cases may survive to reproductive age): 50%
2. Prenatal diagnosis by ultrasonography (Rolland et al. 1991; Ducarme et al. 2007; Tantbirojn et al. 2008). 3-D imaging by helical computed tomography (CT) (Ebina et al. 2001), and/or MRI imaging (Chen et al. 2003, 2007)
    1. Polyhydramnios: secondary to an atretic, constricted, or obstructed oropharynx that prevents the fetus from swallowing amniotic fluid efficiently or at all
    2. Intrauterine growth retardation
    3. Mandibular absence (agnathia) or major hypoplasia
    4. Holoprosencephaly: associated with agnathia-otocephaly (10%) (Blaas et al. 2002)
    5. Cyclopia, marked hypotelorism, or frontal proboscis
3. Management
    1. Although a lethal entity, several survivals beyond infancy have been reported (Brecht and Johnson 1985; Kamiji et al. 1991; Walker et al. 1995; Shermak and Dufresne 1996; Baker et al. 2004). Our third case with agnathia is still surviving with normal neurological development at 20 years of age.

2. All survivors required tracheotomy immediately soon after delivery since no laryngeal opening is most likely present for endotracheal tube insertion.
3. EXIT (*ex utero* intrapartum treatment) procedure, a technique for safely managing airway obstruction at birth, in which placental support is maintained until the airway can be evaluated and secured (Umekawa et al. 2007).

Wright, S. (1934). On the genetics of subnormal development of the head (otocephaly) in the guinea pig. *Genetics, 19*, 471–504.

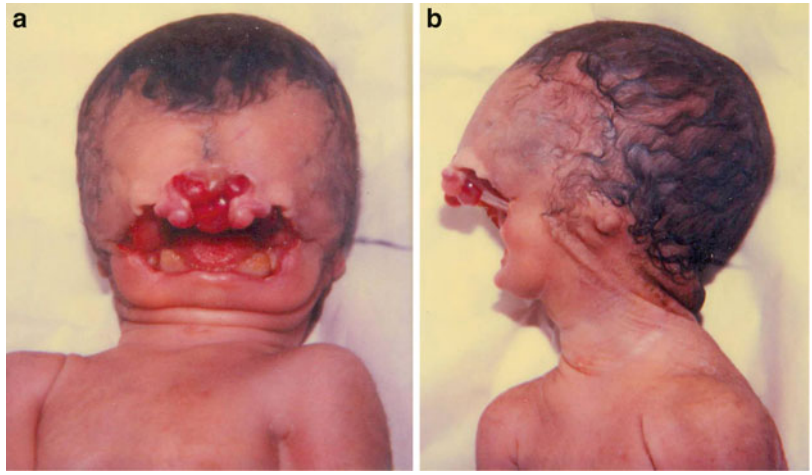

Fig. 1 (**a**, **b**) A neonate (28 week gestation) with agnathia-holoprosencephaly complex showing a large defect involving entire midface area with almost total absence of jaw, absence of eyes and nose, and severe microtia. Absence of olfactory bulbs and grooves (arrhinencephaly) was demonstrated by necropsy. Additional anomalies included 13 pairs of ribs, atresia of left ureter with resultant hydronephrosis, and left renal cortical cysts. Maternal hydramnios was present

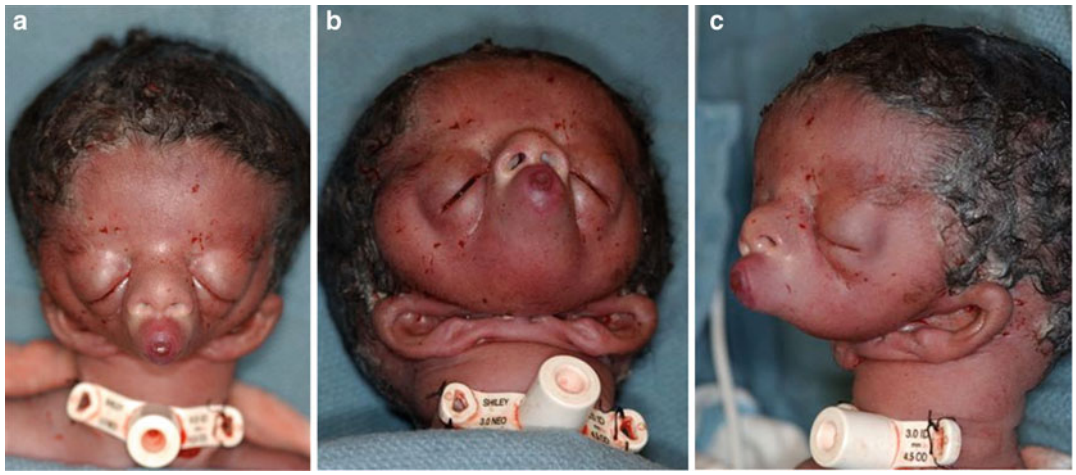

Fig. 2 (**a**–**c**) The female infant was born via elective cesarean section with Apgar scores of 1, 1, and 1 at 1, 5, and 10 min respectively. After a failed attempt at nasotracheal intubation, an emergent tracheostomy was performed. However, the infant expired shortly after placement. Postmortem examination of the baby revealed congenital absence of the mandible (agnathia), microstomia with a slit-like oral opening, posterior choanal atresia, proptosis, and external ears placed ventrally with posterior rotation approaching each other in the midline. Amniocentesis revealed normal chromosomes

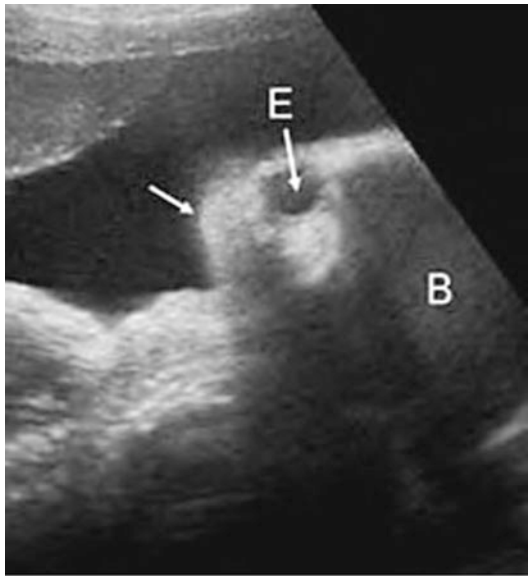

Fig. 3 Prenatal ultrasound showed absence of fetal jaw (*arrow*) (*E* fetal eye, *B* fetal brain)

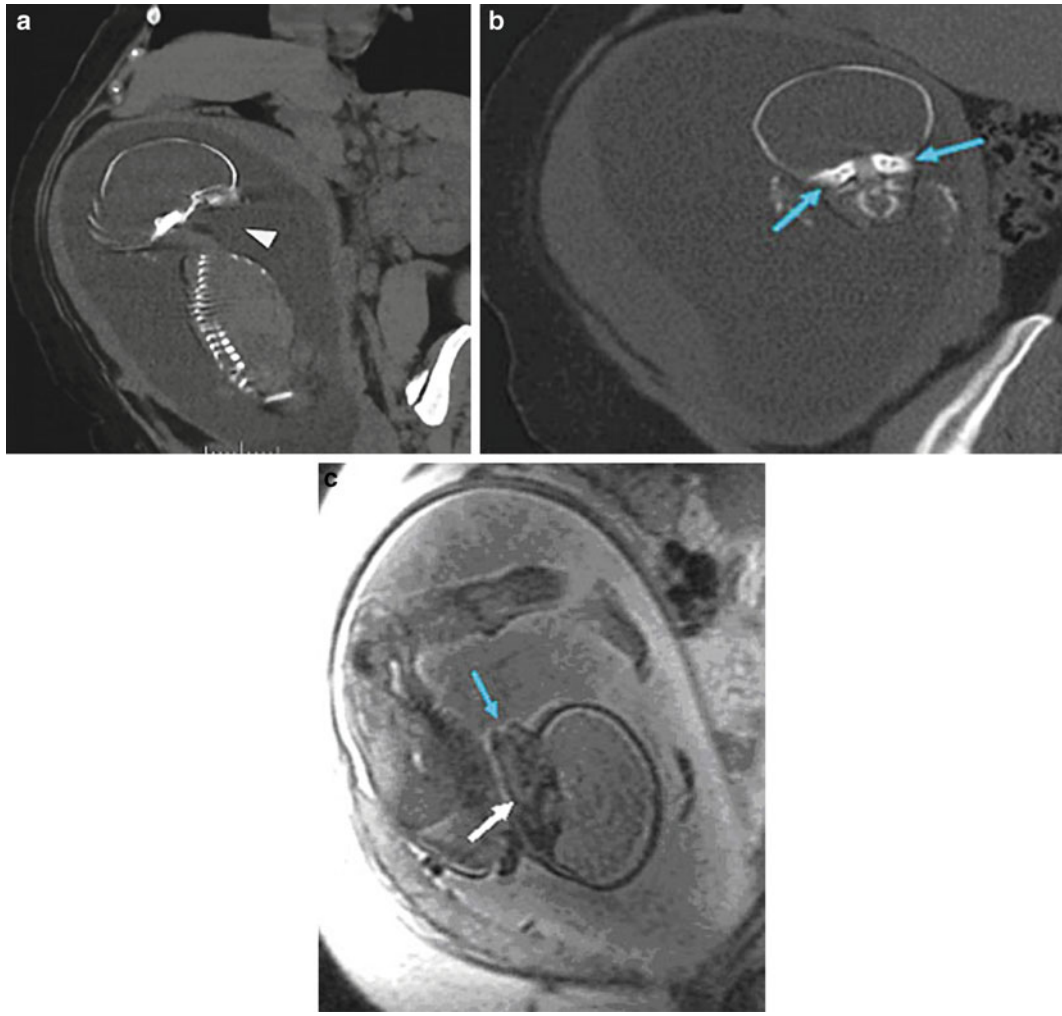

Fig. 4 (**a**–**c**) Maternal abdominal T2 MRI showed agnathia (*blue arrow*) and the lower end of the large horizontal ear meeting at the jaw area (*white arrow*)

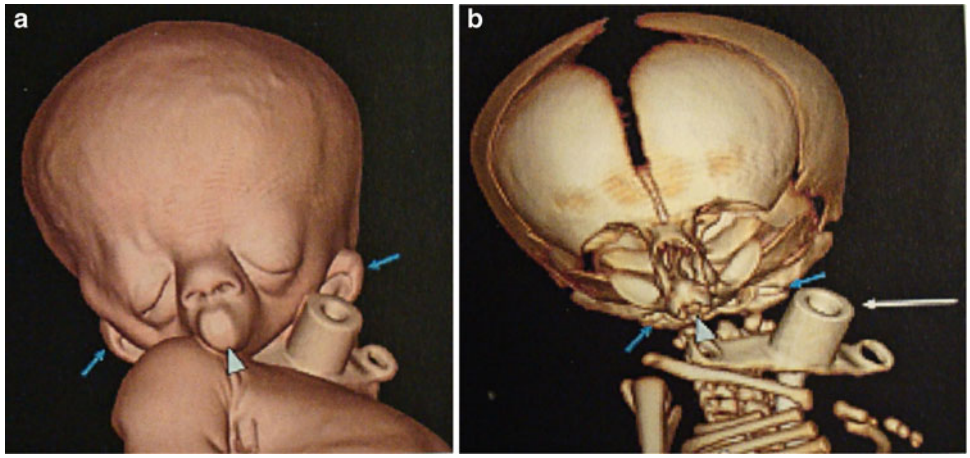

Fig. 5 (**a**, **b**) Postmortem CT scan demonstrated mandibular agnathia with synotia (posterior rotation with ventromedial displacement of the external ear structures approaching fusion near the midline), hypoplasia of the superior maxillary bone, and persistence of the inner ears in their initial fetal position

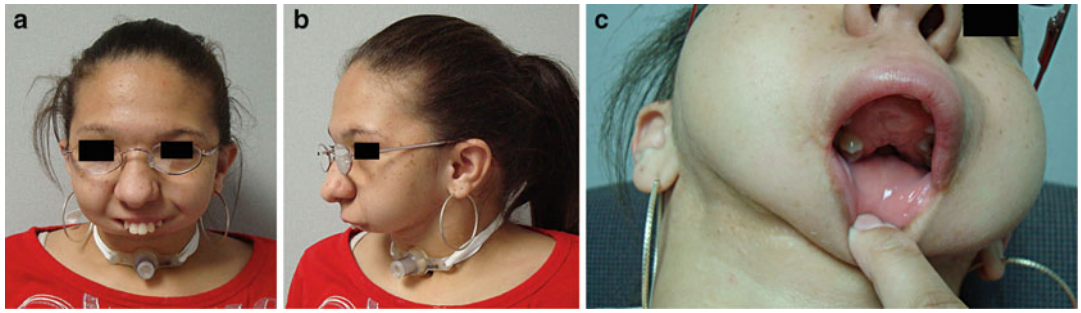

Fig. 6 (**a**–**c**) A 20-year-old female with agnathia with tracheotomy. She has severe microretrognathia due to absence of mandible, cleft palate, Arnold-Chiari malformation, severe bilateral hearing loss, Klippel-Feil syndrome, and scoliosis (Courtesy of Dr. Ghali Ghali)

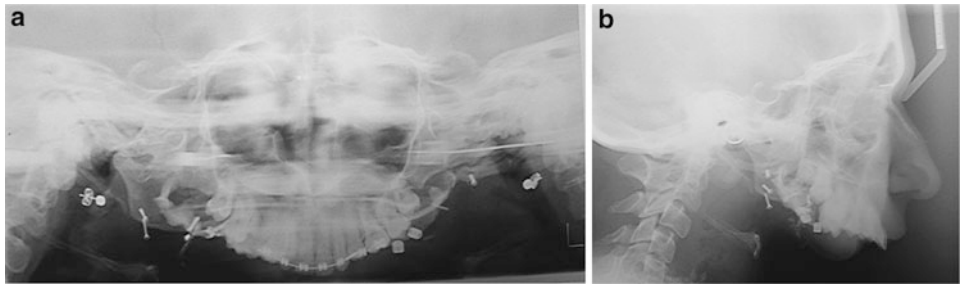

Fig. 7 (**a**, **b**) Radiographs of orofacial structures showed absence of mandible

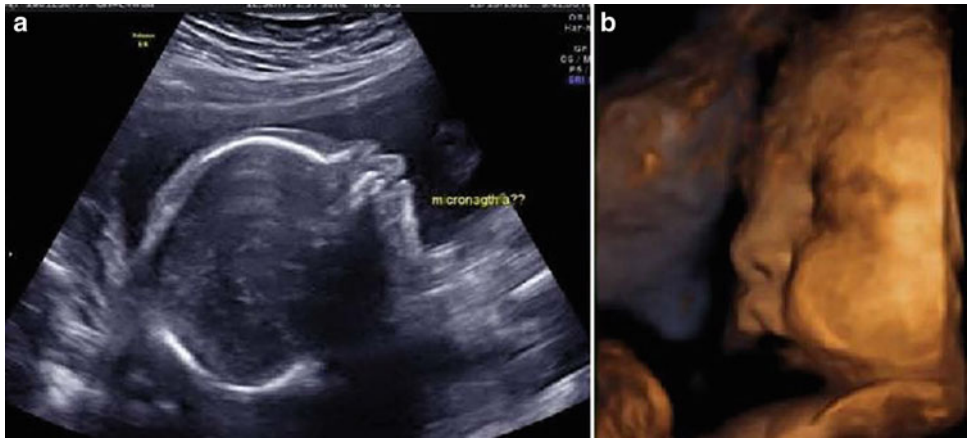

Fig. 8 (**a**, **b**) The newborn baby was born to an 18-year-old G2P1 mother at 39 weeks of gestation. Because of prenatal ultrasound findings at 24 weeks of gestation (courtesy of Dr. Rose Brouiellette) of severe retro/micrognathia by 2D ultrasound (**a**) and 4D real-time ultrasound (**b**), the baby had EXIT (ex utero intrapartum treatment) procedure, a technique for safely managing airway obstruction at birth, in which placental support is maintained until the airway can be evaluated and secured (Umekawa et al. (2007)). The EXIT procedure along with tracheostomy was performed successfully (Dr. ghali Ghali)

Fig. 9 (**a**, **b**) The baby at birth was ventilated with tracheostomy tube in place. There was virtual absence of mandible (agnathia) with severe retromicrognathia, microstomia, a small tongue without cleft palate, and slightly low-set and posteriorly rotated ears. No otocephaly was present

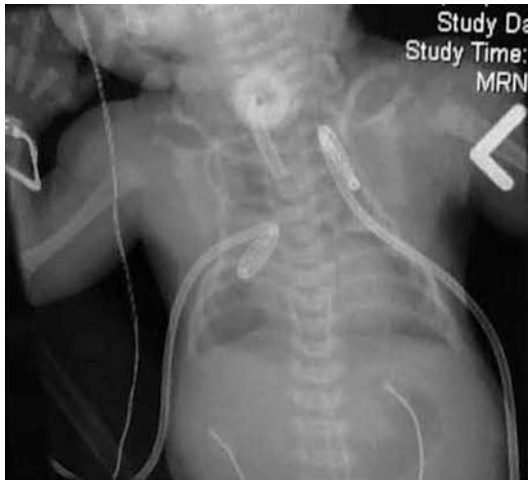

Fig. 10 Chest radiograph showing a narrow chest, especially upper chest associated with poorly defined and shortened ribs and tracheostomy in place

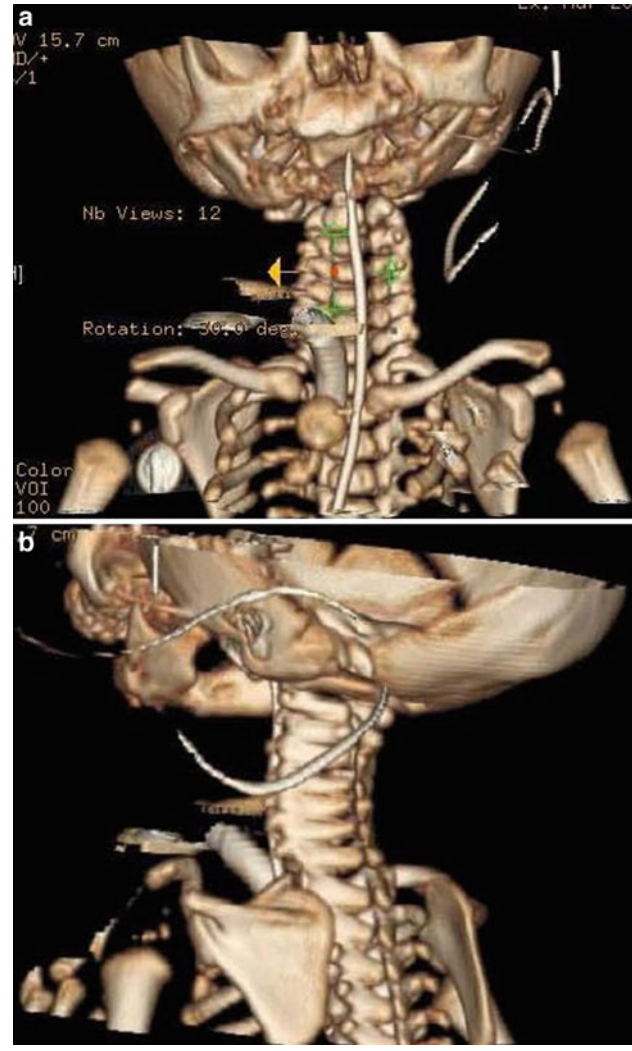

Fig. 11 (**a**, **b**) CT without contrast of the face showed micrognathia and gap in the anterior aspect of the mandible. There is no obvious airway in the area corresponding to the hypopharynx, larynx, and upper trachea (Courtesy of Dr. Ghali Ghali)

Aicardi Syndrome

Contents

In 1965, Aicardi et al. reported a new syndrome consisting of spasms in flexion, callosal agenesis, and ocular abnormalities. Actual frequency of the condition is not known, but about 1–4% of cases of infantile spasms from tertiary referral centers may be due to Aicardi syndrome.

Synonyms and Related Disorders

Agenesis of corpus callosum with chrioretinal abnormality

Genetics/Basic Defects

1. Inheritance (Aicardi 2005)
    1. An X-linked dominant, lethal in males (Donnenfeld et al. 1989; Aicardi 1999)
    2. Almost exclusively affects females with two X chromosomes (heterozygous for a particular mutant X-chromosome gene to manifest)
3. Exceptions
    1. Boys with XXY chromosome constitution (Hopkins et al. 1979; Aicardi 2005; Glasmacher et al. 2007; Chen et al. 2009) allowing heterozygous expression of the gene as in the female
    2. Two phenotypic boys with 46,XY males (Curatolo et al. 1980; Aggarwal et al. 2000): Aicardi has disputed the observations that are too atypical for classification as Aicardi syndrome due to the presence of lissencephaly or chorioretinal lesions not reminiscent of lacunae (Aicardi 1980)
    3. A 5-year-old male was reported to have clinical triad of Aicardi syndrome (Chappelow et al. 2008): Routine cytogenetic analysis showed 46, XY. A chromosome microarray analysis failed to detect any known microdeletion or microduplication. The possibility of low mosaic for 47, XXY Klinefelter cannot be ruled out
4. Not known to be a familial condition, except an isolated familial instance involving two sisters (Molina et al. 1989)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_6

5. The mutation
    1. Seems to arise de novo, accounting for the almost complete absence of familial cases
    2. Could occur as a postzygotic event in early embryonic development as suggested by the observation of a monozygotic twin in a pair in which only one twin had Aicardi syndrome, the other being unaffected (Costa et al. 1997)
2. A gene responsible for Aicardi syndrome has not been identified
3. Gene map postulated on chromosome Xp22.3 from an observation in an affected girl with t(X;3)(p22;q12) (Ropers et al. 1982)
4. Nonrandom X-inactivation in lymphocytes and possible other tissues in patients with Aicardi syndrome may reflect heterogeneity of thier molecular basis (Neidich et al. 1990)

Clinical Features

1. Classic triad
    1. Pathognomonic chorioretinal lacunae
        1. Multiple, rounded, unpigmented, and yellow-white lesions
        2. Occasionally unilateral
        3. May be absent in rare cases
    2. Infantile spasms: the most characteristic type of seizure
        1. Frequently asymmetric or even unilateral (Bour et al. 1986)
        2. Often preceded or precipitated by a focal clonic or tonic seizure limited to the side in which the spasms predominate
    3. Agenesis of the corpus callosum
2. Other CNS abnormalities
    1. Ependymal cysts
    2. Choroid plexus papillomas (Robinow et al. 1984; Trifiletti et al. 1995)
    3. Cortical migration abnormalities
    4. Optic disc coloboma
    5. Hydrocephaly
    6. Porencephaly
    7. Cerebellar agenesis
    8. Heterotopias
3. Variable neurologic abnormalities
    1. Hemiparesis or hemiplegia
        1. The most frequent abnormality
        2. Often on the side where the spasms predominate
    2. Quadriplegia
    3. Hypotonia
    4. Hypertonia
    5. Development of microcephaly, though head circumference is normal at birth
4. Microphthalmia
5. Extra-CNS tumors
    1. Soft palatal benign teratoma
    2. Hepatoblastoma
    3. Parapharyngeal embryonal cell carcinoma
    4. Limb angiosarcoma
    5. Scalp lipoma
    6. Multiple gastrointestinal polyps (Trifiletti et al. 1995)
6. Scoliosis or costovertebral anomalies
7. Severe cognitive and physical handicaps
    1. Global developmental delay
    2. Moderate to severe mental retardation in most patients
    3. Unable to ambulate in most children
    4. Limited visual ability
8. New diagnostic criteria (Aicardi 1999, 2005)
    1. Classic triad
        1. Infantile spasms
        2. Chorioretinal lacunae
        3. Agenesis/dysgenesis of the corpus callosum
    2. New major features (present in most patients studied by MRI)
        1. Cortical malformations, mostly microgyria (probably constant but may not be possible to evidence)
        2. Periventricular and subcortical heterotopia
        3. Cysts around the third ventricle and/or choroid plexuses
        4. Papillomas of choroid plexuses
        5. Optic disc/nerve coloboma
    3. Supporting features (present in some cases)
        1. Vertebral and costal abnormalities

2. Microphthalmia and/or other eye abnormalities
3. "Split-brain" EEG (associated suppression-burst tracing)
4. Gross hemispheric asymmetry

9. Estimated survival rate (Menezes et al. 1994)
   1. 76% at 6 years of age
   2. 40% at 15 years of age

Diagnostic Investigations

1. Ophthalmological examination
   1. Choroid retinal lacunae
   2. Optic disc coloboma
2. Electroencephalograms
   1. "Split-brain" EEG (Dennis and Bower 1972)
   2. Asymmetry or asynchrony
   3. Quasiperiodicity
   4. Hypsarrhythmia
3. CT or MRI of the brain (Hopkins et al. 2008)
   1. Agenesis or partial agenesis of the corpus callosum
   2. Choroid plexus papillomas
   3. Cerebellar dysgenesis
   4. Cortical heterotopias
   5. Porencephaly
   6. Agenesis or hypoplasias of the cerebellar vermis
4. Radiography for skeletal malformations
5. Chromosome analysis in case of Klinefelter syndrome
6. Not caused by copy number variants detectable with currently used high-resolution array platform (Wang et al. 2009)
7. Histopathology (Sunderkrishnan 2014)
   1. Multiple brain malformations
      1. Complete or partial agenesis of the corpus callosum
      2. Cortical heterotopias
      3. Gyral malformation
      4. Cysts of posterior fossa (de Jong et al. 1976)
      5. Microscopic evaluation of the parenchyma
         1. Disordered cellular organization
         2. Disruption of the normal layered appearance of the cortex
   2. Chorioretinal lacunae
      1. Well-circumscribed, punched-out lesions in the retinal pigment epithelium and choroid
      2. Severely disrupted retinal architecture
         1. All layers are thinned.
         2. Decreased choroidal vessel number and caliber are decreased
         3. Presence of pigmentary ectopia and pigmentary epithelial hyperplasia

Genetic Counseling

1. Recurrence risk
   1. Patient's sibs: recurrence not likely (exception with one report of two affected sibs, likely due to gonadal mosaicism in one of the parent).
   2. Patient's offspring: 50% of offspring of affected females are expected to carry the abnormal X chromosome but affected individuals are not expected to survive to reproduce.
2. Prenatal diagnosis (Bromley et al. 2000): The prenatal ultrasonographic findings include:
   1. Arachnoid cysts
   2. Agenesis of the corpus callosum (development of the corpus callosum may not be complete until 22 weeks of gestation)
   3. Ventriculomegaly
3. Management
   1. Anticonvulsants for control of seizures
   2. Specific therapy for infantile spasm
      1. Adrenocorticotropic hormone (ACTH): effective for some patients
      2. Vigabatrin, a more recently introduced therapy for infantile spasm
         1. An enzyme that breaks down GABA, the major inhibitory neurotransmitter in the brain
         2. Effective for infantile spasm without the serious life-threatening adverse effects of ACTH

3. Possible ophthalmologic sequelae of constriction of the visual fields
4. Not currently approved for use in the USA

3. A multidisciplinary team approach to developmental handicaps
4. Orthopedic surveillance and treatment of scoliosis
5. Vigorous treatment of any infection as pulmonary problems are the commonest cause of death (Figs. 1 and 2)

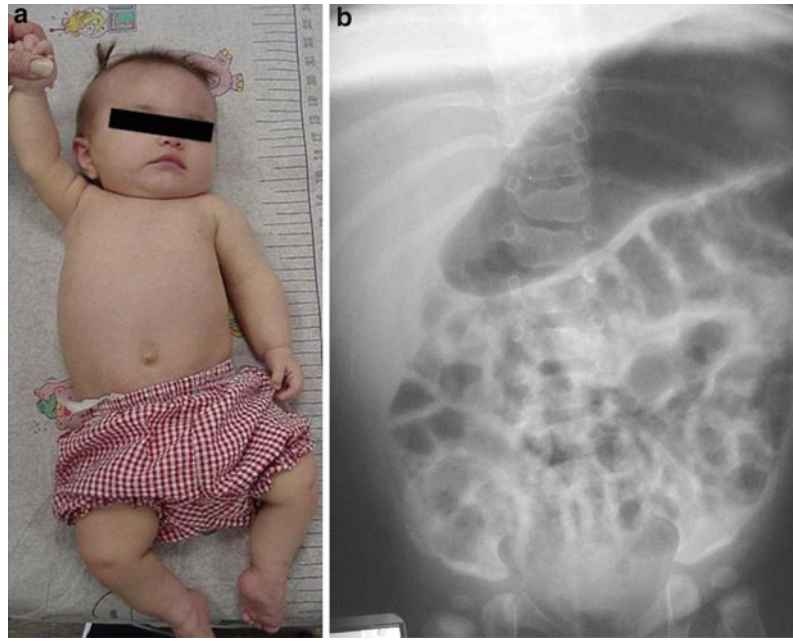

Fig. 1 (**a**, **b**) An 8-month-old girl with Aicardi syndrome characterized by infantile spasms, chorioretinopathy, brain malformation, and costovertebral anomalies

Fig. 2 This 10-year-old Caucasian female was evaluated for seizures, scoliosis, cerebral palsy, and global developmental delay. Evaluation of the intraorbital contents demonstrated bilateral colobomas at the optic nerve head insertion. On the left, subretinal effusion with detachment was present with abnormality extending into the coloboma. The MRI of the brain showed absence of the corpus callosum associated with an interhemispheric cyst. The cerebral hemispheres are also markedly abnormal with multiple foci of gray matter heterotopia identified along both ependyma. There was cortical dysplasia identified involving much of the left frontal lobe in a pattern most compatible with polymicrogyria. The underlying white matter appeared dysplastic. Areas of polymicrogyria also appeared to be present within the superior right frontal lobe. There was cerebellar volume loss. No definite olfactory bulbs were appreciated. An olfactory sulcus may be present on the right. The hippocampal formations appear within normal limits, other than atrophic. There are no areas of diffusion restriction. There are no areas demonstrating abnormal enhancement following contrast administration. Small choroid plexus cysts appeared present bilaterally at the level of the glomus. The constellation of findings of frontal cortical dysplasia, callosal agenesis with small interhemispheric cyst, and bilateral colobomas with retinal detachment is compatible with Aicardi syndrome

Alagille Syndrome

Contents

In 1969, (Alagille et al. 1969) described a syndrome characterized by chronic cholestasis resulting from paucity of interlobular bile ducts, peripheral pulmonary stenosis, butterfly-like vertebral arch defect, posterior embryotoxon, and peculiar facies. The syndrome is also known as arteriohepatic dysplasia.

Alagille syndrome occurs in approximately 1 in 60,000 live births based on the presence of neonatal cholestasis (Danks et al. 1977). This may be an underestimate as molecular testing has demonstrated that many individuals with a disease-causing mutation do not have neonatal liver disease (Kamath and Poccoli 2003).

Synonyms and Related Disorders

Arteriohepatic dysplasia; *JAG1*-related Alagille syndrome; *NOTCH2*-related Alagille syndrome

Genetics/Basic Defects

1. Inheritance
   1. Sporadic in 45–50% of cases
   2. Autosomal dominant
      1. Reduced penetrance
      2. Variable expressivity
   3. Alagille syndrome gene mapped to 20p12 (Anad et al. 1990; Li et al. 1996)
2. Molecular defect
   1. Caused by mutations or deletions of Jagged-1 gene (*JAG1*), encoding a ligand for the NOTCH transmembrane receptor, implicated in cell differentiation (Li et al. 1997)
   2. More than 120 described intragenic mutations of the *JAG1* gene
   3. Chromosome microdeletions: rare (Desmaze et al. 1992; Deleuze and Hadchouel 1996)
   4. Alagille syndrome type 1 (*JAG1*-associated) (Tumpenny and Ellard 2012)
      1. Detected in about 90% of cases due to mutations in JAG1 (20p12).
      2. JAG1 mutations include total gene deletions, protein truncating, splicing, and missense mutations (Krantz et al. 1999).
   5. Parental mosaicism in *JAG1* mutations in a phenotypically normal parent (Giannakudis et al. 2001)
   6. No clear genotype-phenotype correlation in Alagille syndrome (Colliton et al. 2001)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_7

7. *NOTCH2* mutations that were identified in 2/11 individuals with classic Alagille syndrome who do not have an identifiable *JAG1* mutation (McDaniell et al. 2006)
8. Alagille syndrome type 2 (*NOTCH2*-associated): detected in about 1% of cases due to mutations in NOTCH2 (1p13) (Tumpenny and Ellard 2012)

Clinical Features

1. High variability of phenotypic findings (Shulman et al. 1984; Krantz et al. 1997a; Crosnier et al. 2000a)
2. Major features
    1. Neonatal chronic cholestasis
        1. Episodes of jaundice separated by periods of remission
        2. Pruritus
        3. Hepatomegaly
        4. Splenomegaly: may be associated with portal hypertension
        5. Xanthoma, progressive and observed in:
            1. Extensor surface of the fingers
            2. Palmar creases
            3. Nape of the neck
            4. Anal folds
            5. Popliteal fossa
            6. Inguinal areas
    2. Facial features (Kamath et al. 2002)
        1. Broad prominent forehead
        2. Deep-set, widely spaced eyes
        3. Long, straight nose
        4. Bullous tip of the nose
        5. Underdeveloped mandible
        6. Sharply pointed chin
    3. Complex congenital cardiovascular anomalies
        1. Pulmonary artery stenosis (67%)
        2. Ventricular septal defects
        3. Patent ductus arteriosus
        4. Pulmonary valve atresia
        5. Tetralogy of Fallot (7–16%)
        6. Tricuspid regurgitation
        7. Right ventricular hypertrophy
    4. Vertebral arch anomalies (butterfly-like vertebrae)
    5. Posterior embryotoxon (prominent Schwalbe's ring)
3. Less frequently associated features
    1. Growth retardation
    2. Neurological complications from vitamin E deficiency
    3. Mental retardation (2–30%)
    4. Systemic vascular malformations
        1. Coarctation of the aorta
        2. Middle aortic syndrome
        3. Arterial hypoplasia/dysplasia (hepatic, renal, carotid, celiac) (Crosnier et al. 2000b)
        4. Artery stenosis (renal, subclavian)
        5. Moyamoya disease (Connor et al. 2002; Baird et al. 2015)
        6. Carotid artery aneurysm
        7. Intracranial hemorrhage
        8. Hypoplastic portal vein branch
    5. Renal involvement: occurs in 40% of *JAG1*-mutation-positive individuals (Kamath et al. 2013)
        1. Interstitial nephritis
        2. Glomerular intramembranous and mesangial lipidosis
        3. Tubular dysfunction
        4. Renal hypoplasia
        5. Renal agenesis
        6. Horseshoe kidney
        7. Cystic disease
    6. Small bowel atresia or stenosis
    7. Pancreas
        1. Diabetes
        2. Exocrine pancreatic insufficiency
    8. Lung: tracheal and bronchial stenosis
    9. Larynx: high-pitched voice
    10. Eye abnormalities (Brodsky and Cunniff 1993; Hingorani et al. 1999; Kim and Fulton 2007)
        1. Posterior embryotoxon (prominence of Schwalbe's ring at the junction of the iris and cornea)
        2. Optic disk drusen
        3. Angulated retinal vessels
        4. Pigmentary retinopathy

5. Nanophthalmia
6. Iris strands/hypoplasia
7. Cataract
8. Myopia
9. Strabismus
10. Glaucoma
11. Microcornea
12. Corneal pannus
13. Corectopia
14. Band keratopathy
15. Axenfeld anomaly
16. Fundus hypopigmentation
17. Congenital macular dystrophy

11. Skeletal abnormalities
    1. Lack of normal progression of interpedicular distance in the lumbar spine
    2. Spina bifida
    3. Shortening of distal phalanges and metacarpal bones
    4. Clinodactyly
12. Hepatocellular carcinoma: a rare complication of Alagille syndrome (Bhadri et al. 2005)
13. Immune dysregulation: a new feature of the evolving phenotype (Tilib Shamoun et al. 2015)

4. Prognosis
    1. Characterized by recurrent episodes of cholestasis
    2. Often associated with common respiratory tract infections, especially during the first year of life
    3. Pregnancy
        1. Possible but rare as in other chronic liver diseases because of decreased fertility, voluntary abortion, and miscarriages
        2. Few cases of successful pregnancy in mothers with Alagille syndrome reported (Ferrarese et al. 2015)
    4. Good long survival but mortality rate may be up to 25%
5. Other hereditary causes of cholestasis (Hartley et al. 2013)
    1. Progressive familial intrahepatic cholestasis
    2. Bile acid synthesis defects
        1. 3-Beta-hydroxy-delta-5-C27-steroid oxidoreductase deficiency (MIM #607765)
        2. Delta(4)-3-oxosteroid 5-beta-reductase deficiency (MIM #235555)
    3. Niemann-Pick type C disease
    4. Citrullinemia type II
    5. Arthrogryposis-renal dysfunction-cholestasis syndrome
    6. Aagenaes syndrome
    7. Alpha-1 antitrypsin deficiency
    8. North American Indian childhood cirrhosis
    9. Zellweger syndrome
    10. Ciliopathies
    11. Smith-Lemli-Opitz syndrome

Diagnostic Investigations

1. Biochemical studies (Alagille et al. 1987; Scheimann 2013)
    1. Hypercholesterolemia: cholesterol levels ranging from 220 to 1,600 mg% in all children with xanthomas (Garcia et al. 2005).
    2. Hyperphospholipidemia.
    3. Hypertriglyceridemia (500–2,000 mg/dL).
    4. Prominent increase in the pre–βlipoprotein and apolipoprotein B levels.
    5. Very high total bile acid, gamma-glutamyl transferase, and alkaline phosphatase blood levels.
    6. Fat-soluble vitamin deficiencies: frequently observed.
    7. Prolongation of prothrombin time (PT) or activated partial thromboplastin time (aPTT): often observed.
    8. Conjugated hyperbilirubinemia.
    9. Total bilirubin level: generally 4–14 mg/dL with a direct fraction generally 30% of total bilirubin. In most children, conjugated hyperbilirubinemia improves with time.
2. Ophthalmologic assessment for posterior embryotoxon and other ocular anomalies

3. Ultrasonography: allows hepatobiliary disease assessment and helps to establish indications for hepatic transplantation (Berrocal et al. 1997)
    1. Portal hypertension
    2. Cirrhosis
    3. Renal hypoplasia
4. Radiography: not specific (Berrocal et al. 1997)
    1. Abnormal "butterfly" vertebrae
    2. Ulnar or phalangeal shortening
5. MRI or MRA: identifies intracranial vascular anomalies
6. Other imagings
    1. Dimethyl iminodiacetic acid scanning
    2. Magnetic resonance cholangiopancreatography
    3. Endoscopic retrograde cholangiopancreatography
    4. Cholangiography: demonstrates the patency of the extrahepatic biliary tree (Hartley et al. 2013)
7. Echocardiography for cardiovascular malformations, especially pulmonary stenosis
8. Histology (liver biopsy) (Emerick et al. 1999)
    1. Paucity of interlobular bile ducts (85%)
    2. Cholestasis in hepatocytes and canaliculi (96%)
9. Cytogenetic analysis
    1. Cytologically balanced t(2;20) in a two-generation family with Alagille syndrome (Spinner et al. 1994)
    2. Detects cytogenetic abnormalities of 20p12 in 3.6% of patients with Alagille syndrome (Krantz et al. 1997b)
10. Molecular genetic analysis
    1. Sequence analysis of the *JAG1* gene detects mutations in approximately 70% of individuals who meet clinical diagnostic criteria.
    2. The ability to provide molecular confirmation for Alagille syndrome will be of great benefit to families with an affected child. The expression of Alagille syndrome is extremely variable both between and within families. A molecular assay will permit identification of family members with microforms of this disorder, greatly improving ability to appropriately counsel affected families (Krantz et al. 1998).
    3. FISH detects a microdeletion of 20p12, including the entire *JAG1* gene, in approximately 5–7% of cases (Spinner et al. 2001).
    4. Mutations in NOTCH2 gene have been observed in fewer than 1% of individuals with Alagille syndrome (McDaniell et al. 2006).
    5. Exome sequencing determines genetic etiology in patients lacking mutations in those genes commonly associated with their clinically diagnosed disorders, such as Alagille syndrome (Grochowski et al. 2015).

Genetic Counseling

1. Recurrence risk (Spinner et al. 2013)
    1. Patient's sib
        1. A low but slightly increased risk due to parental germ line mosaicism in clinically normal-appearing parents (Giannakudis et al. 2001; Laufer-Cahana et al. 2002)
        2. A 50% risk if a parent is affected
    2. Patient's offspring: a 50% risk of having an offspring with Alagille syndrome
2. Prenatal diagnosis
    1. Several issues to be considered before attempting pregnancy (Ferrarese et al. 2015):
        1. Severity of liver disease and the degree of portal hypertension: could worsen during pregnancy
        2. Degree of cardiac dysfunction, in particular the severity of pulmonary hypertension
        3. High probability of Alagille mutation in the fetus, although with variable phenotypic manifestations
    2. Prenatal ultrasonography (Albayram et al. 2002):

1. Severe pulmonary artery stenosis
2. Progressive severe intrauterine growth retardation
3. 2D and 3D ultrasound in the second trimester: identification of hemivertebrae and butterfly vertebrae (Wax et al. 2014)

3. Prenatal molecular diagnosis on fetal DNA obtained from amniocentesis or CVS (Witt et al. 2004) is available if a disease-causing mutation (demonstrated by molecular genetic testing) or a deletion (detected by FISH) is identified in an affected family member (Witt et al. 2004):
   1. *JAG1*: sequence analysis/mutation scanning, sequence analysis of select exons, and deletion/duplication analysis (including DISH)
   2. *NOTCH2*: sequence analysis and deletion/duplication analysis
4. Preimplantation genetic diagnosis (Renbaum et al. 2007):
   1. A polar body (PB)-based multiplex fluorescent PCR reaction for a female affected with Alagille syndrome.
   2. The protocol included analysis of the Jagged-1 (*JAG1*) familial mutation and four closely linked highly polymorphic markers (D20S162, D20S901, D20S894, and D20S186).
   3. A reliable diagnosis was possible in all developing embryos.

3. Management
   1. Medical care (Alagille et al. 1987)
      1. Low-fat diets with medium-chain triglyceride supplementation
      2. Hypercaloric diets to severely malnourished patients
      3. Vitamin supplements
      4. Cholestasis: ursodeoxycholic acid which may improve the biochemical cholestasis (Balistreri 1997)
      5. Pruritus
         1. Antihistamine agents
         2. Cholestyramine or rifampin in management of bile acid-induced pruritus
      6. Monitoring of oral hygiene and caries control: mandatory (Berniczei-Royko et al. 2014)
   2. Surgical care for patients with refractory disease
      1. Possible to perform orthodontic treatment combined with aesthetic restorative procedures or surgery in patients with less severe general manifestations (Berniczei-Royko et al. 2014)
      2. Biliary diversion
      3. Surgical revascularization in patients with Alagille syndrome with moyamoya (Baird et al. 2015)
      4. Eventual orthotopic liver transplantation (Cardona et al. 1995; Emerick et al. 1999; Kasahara et al. 2003; Englert et al. 2006; Arnon et al. 2010)
         1. Indications: progressive hepatic dysfunction, severe portal hypertension, failure to thrive, intractable pruritus, and osteodystrophy.
         2. Associated with good long-term graft survival, although it is lower than that in biliary atresia.
         3. Death from graft failure and neurological and cardiac complications was significantly higher than in patients with biliary atresia.
         4. The higher rate of mortality and graft failure may be related to the multisystem involvement of Alagille syndrome.
      5. Cardiac surgery for complex congenital heart defects

Fig. 1 An infant with Alagille syndrome showing neonatal jaundice, broad forehead, and underdeveloped mandible. This infant had peripheral pulmonary artery stenosis and paucity of interlobular bile ducts

Fig. 2 A 2-month-old boy with Alagille syndrome showing neonatal jaundice (conjugated hyperbilirubinemia). Liver biopsy showed paucity of the bile ducts. He was put on Mephyton 2.5 mg qd

Albinism

Contents

Albinism, derived from the Latin *albus*, is a group of inherited disorders in which melanin biosynthesis is reduced or absent. It involves the skin, hair, and eyes (oculocutaneous albinism) or may be limited primarily to the eyes (ocular albinism). Current classification of albinism is determined by the affected gene, making the previously used terms "partial or complete" and "tyrosinase positive or tyrosinase negative" obsolete (King and Oetting 2007; Summers et al. 1996). The prevalence of all forms of albinism varies considerably worldwide, estimated at approximately 1/17,000 and about 1 in 70 people carry a gene for oculocutaneous albinism (OCA) (Grønskov et al. 2007).

Synonyms and Related Disorders

Chediak-Higashi syndrome; Griscelli syndrome; Hermansky-Pudlak syndrome; OCA, X-linked; OCA type 2 (tyrosinase-positive OCA); OCA type 3 (brown albinism); Oculocutaneous albinism (OCA) type 1 (tyrosinase-negative OCA, tyrosinase-related OCA)

Genetics/Basic Defects

1. Classification of albinism (genetic heterogeneity) (King and Summers 1988; Carden et al. 1998; Biswas and Lloyd 1999):
    1. Oculocutaneous albinism (OCA): a common phenotype for a group of recessive genetic disorders of melanin synthesis. Reduction in melanin synthesis can involve the skin, hair follicle, and eye. Mutations in at least 12 genes are responsible for this phenotype. Mutations in OCA-related genes result in reduction of melanin synthesis by the melanocytes:
        1. Common types of OCA with cutaneous and ocular hypopigmentation without significant involvement of other tissue:
            1. Oculocutaneous albinism 1 (OCA1): subdivided into OCA1A, OCA1B, OCA1ts
            2. Oculocutaneous albinism 2 (OCA2)
            3. Oculocutaneous albinism 3 (OCA3)
        2. Less common types of OCA with more complex manifestations:
            1. Hermansky-Pudlak syndrome
            2. Chediak-Higashi syndrome
    2. Ocular albinism: reduction in melanin synthesis localized primarily to the eye:

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_8

1. Ocular albinism 1 (OA1): X-linked recessive (Lang et al. 1990)
2. Autosomal recessive ocular albinism (AROA)

2. Molecular defects causing four known types of OCA (Oetting and King 1999; Grønskov et al. 2007)
   1. OCA1 (tyrosinase-related albinism) (Oetting 2002; Oetting et al. 2003):
      1. Inherited in an autosomal recessive manner.
      2. Caused by mutations of tyrosinase (*TYR*) gene located at 11q14.3.
      3. Several different types of mutations to the tyrosinase gene (missense, nonsense, and frameshift) are responsible for producing OCA1A and OCA1B.
      4. OCA1A ("tyrosinase-negative" albinism with inactive enzyme) produced by null mutations of the *Tyr* gene:
         1. 0% tyrosinase enzyme activity
         2. Over 100 mutations spanning all parts of the gene reported
         3. Compound heterozygotes with different maternal and paternal alleles in majority of patients
      5. OCA1B (tyrosinase-related albinism with partially active enzyme) produced by leaky mutations of the *Tyr* gene:
         1. "Yellow" mutant of albinism with 5–10% activity of tyrosinase.
         2. A base substitution within the gene may result in reduced rather than completely abolished enzyme activity.
      6. OCA1ts (tyrosinase-related albinism with thermolabile enzyme):
         1. A temperature-sensitive tyrosinase is only partly functional.
         2. The first reported cases had a missense substitution within the tyrosinase gene.
   2. OCA2 ("tyrosinase-positive" albinism) (Oetting et al. 1998), brown OCA in Africans:
      1. *OCA2* gene: the pink-eyed dilution gene (*p*) located at 15q11.2-q12.
      2. Caused by mutations of the P gene on the chromosome 15, homologous to the mouse pink-eyed dilution, or p gene.
      3. Inherited in an autosomal recessive manner.
      4. The mutated region is also deleted in Prader-Willi syndrome (PWS) and Angelman syndrome (AS), accounting for close linkage of OCA2 to PWS and AS.
   3. OCA3 (brown albinism):
      1. *OCA3* gene: tyrosinase-related protein-1 gene (*TRP1*) (Sarangarajan and Boissy 2001) located at 9p23
      2. The gene homologous to the mouse "brown" gene
      3. Mutation of the gene possibly synergistic with a polymorphism or partially active mutation in OCA1 or OCA2
      4. 1 in 8,500 in Africans
      5. Rare in white Europeans and Asians
   4. OCA4:
      1. Resulting from mutation in the *SLC45A2* gene, formerly called membrane-associated transporter protein gene (*MATP*), located at 5p13.3
      2. 1 in 85,000 in Japanese
      3. Rare in white Europeans
3. Molecular defects causing other types of albinism
   1. XLOA (X-linked ocular albinism, OA1):
      1. *GPR143*, located at Xp22.3-22.2, is the only gene known to be associated with XLOA.
      2. Intragenic deletions, frameshift mutations, and point mutations identified (Rosenberg and Schwartz 1998).
      3. Affects males because of X-linked recessive inheritance.
      4. Eighty-five to 90% of obligate carriers show pigmentary mosaicism in the fundi, representing the lionization effect (X-inactivation), although there are no functional sequelae.
   2. OAR (autosomal recessive ocular albinism):
      1. Gene mapping: 6q13–q15

2. May not be a clinical entity
3. Tyrosinase in some cases
4. P protein in some cases

3. Hermansky-Pudlak syndrome (HPS): a bleeding disorder due to absence of dense bodies in platelets:
   1. Hermansky-Pudlak syndrome 1 is caused by mutations of the *HPS1* gene which is localized to 10q23.
   2. *HPS2* gene was localized to 5q13. Hermansky-Pudlak syndrome 2 is caused by mutation of the *APB1* gene, which is localized to 5q13, resulting in a defect in adapter complex 3 AP-3, β3A subunit.
4. Chediak-Higashi syndrome (Nagle et al. 1996):
   1. Immunodeficiency associated with neurologic problems
   2. Defect in *CHS1* gene (lysosomal trafficking regulator gene) located at 1q42–44
5. Griscelli syndrome: resulting from mutations in the *RAB27A* gene or *MYO5A* gene, both located at 15q21.

4. Pathophysiology
   1. Melanin in the skin:
      1. Melanin, a photoprotective pigment in the skin, absorbs UV light from the sun, thus preventing skin damage.
      2. Normal skin tans upon sun exposure due to increased melanin pigment in the skin.
      3. Patient with albinism develops sunburn because of the lack of melanin.
   2. Consequence of the absence of melanin during the development of the eye:
      1. Hypoplasia of fovea
      2. Alteration of neural connections between the retina and the brain
   3. Melanin pathway:
      1. Consisting of a series of reactions that converts tyrosine into two types of melanin, black-brown eumelanin and red-blond pheomelanin.
      2. Tyrosinase: a major enzyme in a series of conversions to melanin from tyrosine and it is also responsible for converting tyrosine to DOPA and then to dopaquinone, which subsequently converts to either eumelanin or pheomelanin.
      3. Two other enzymes involved in the formation of eumelanin: tyrosinase-related protein 1 (TRP1, DHICA oxidase) and tyrosinase-related protein 2 (TRP2, dopachrome tautomerase). Mutation of the TRP1 results in OCA3; mutation of the TRP2 does not cause albinism.
      4. P protein, a melanosomal membrane protein, believed to be involved in the transport of tyrosine prior to melanin synthesis. Mutation of this *P* gene causes OCA2.

5. Pathogenesis of the ocular features:
   1. Development of the optic system highly dependent on the presence of melanin
   2. Ocular features appear if melanin is reduced or absent
   3. Mechanisms
      1. Misrouting of the retinogeniculate projections resulting in abnormal decussation of optic nerve fibers
      2. Sensation of photophobia and decreased visual acuity caused by light scattering within the eye
      3. Light-induced retinal damage postulated as a contributing mechanism to decreased visual acuity
      4. Foveal hypoplasia: the most significant factor causing decreased visual acuity.

Clinical Features

1. General clinical features of albinism (Abadi and Pascal 1989; Oetting 1999; King et al. 2001; Bashour et al. 2014; Boissy and Nordlund 2014; Peracha et al. 2015):
   1. Skin, hair, and eye discoloration caused by abnormalities of melanin metabolism (might not be obvious in ocular albinism)
   2. Reduced visual acuity due to foveal hypoplasia (common to all types of albinism, even though a rudimentary annular reflex

has been described in a few patients with better visual acuity) (Creel et al. 1990; Summers 2009)
3. Translucent iris due to reduction in iris pigment
4. Visible choroid vessels due to reduction in retinal pigment
5. Photophobia due to iris pigmentary abnormalities
6. Anomalous visual pathway projections due to misrouting of the optic nerves at the chiasm
7. Nystagmus (Summers 2009)
    1. Due to abnormal decussation of optic nerve fibers.
    2. Typically pendular in nature.
    3. More noticeable with fatigue and illness.
    4. Amplitude of nystagmus diminishes as child matures.
8. Alternating strabismus.
9. Hyperopia, myopia, and astigmatism.

2. Oculocutaneous albinism 1 (OCA1) (Lewis 2013):
    1. Incidence: approximately 1 in 40,000 individuals
    2. Oculocutaneous albinism 1A (OCA1A)
        1. Classic "tyrosinase-negative" OCA: complete lack of melanin production throughout life
        2. Most severe form of OCA
        3. White hair and white skin that does not tan
        4. Blue and translucent irides that do not darken with age
        5. Foveal hypoplasia
        6. No tanning potential
        7. At risk for sun burning and skin cancer
        8. Diminished visual acuity as low as 20/400
        9. Photophobia and nystagmus worst in this subtype
    3. Oculocutaneous albinism 1B (OCA1B):
        1. Yellow mutant type OCA, referred to as Amish albinism, or xanthous albinism.
        2. Variable pigmentation ranging from very little cutaneous pigmentation to nearly normal skin pigmentation.
        3. Increased skin, hair, and eye pigment with age and tan with sun exposure.
        4. Yellow hair pigment develops in the first few years of life and continuously accumulates pigment, principally yellow-red pheomelanin, in the hair, eyes, and skin in the later life.
        5. Decreased visual acuity improving with age.
    4. Temperature-sensitive albinism (OCA1ts):
        1. A subtype of OCA1B.
        2. Mutation of the tyrosinase gene that produces a temperature-sensitive tyrosinase enzyme.
        3. The heat-sensitive tyrosinase enzyme activity is approximately 25% of the normal tyrosinase activity at 37 °C. The activity improves at lower temperatures.
        4. Dark hair pigment in the arms and legs (cooler areas of the body), while axillary and scalp hair remains white.
        5. Pigment is absent in the fetus because of high fetal temperature.
3. Oculocutaneous albinism 2 (OCA2):
    1. "Tyrosinase-positive" OCA
    2. Incidence: approximately 1 in 15,000 individuals
    3. Most prevalent type of albinism in all races and especially frequent among African-American population (1 in 10,000)
    4. Phenotypic variability:
        1. Ranging from absence of pigmentation to almost normal pigmentation
        2. Absence of black pigment (eumelanin) in the skin, hair, or eyes at birth
        3. Gradual development of pigmentation with age
        4. Increased pigmentation resulting in improved vision
4. Oculocutaneous albinism 3 (OCA3):
    1. Previously known as red/rufous OCA
    2. Incidence of the disease unknown

3. Phenotype in African patients:
   1. Light brown skin and hair
   2. Blue-brown irides
   3. Ocular features not fully consistent with diagnosis of OCA (no iris translucency, nystagmus, strabismus, or foveal hypoplasia)
4. Phenotype in Caucasians and Asians: not known.

5. Oculocutaneous albinism 4 (OCA4):
   1. Cannot be distinguished from OCA2 on clinical findings
   2. Hypopigmentation of the skin and hair
   3. Characteristic ocular changes found in all other types of albinism:
      1. Nystagmus
      2. Reduced iris pigment with iris translucency
      3. Reduced retinal pigment with visualization of the choroidal blood vessels on ophthalmoscopic examination
      4. Foveal hypoplasia associated with reduction in visual acuity
      5. Misrouting of the optic nerves at the chiasm associated with alternating strabismus
      6. Reduced stereoscopic vision
      7. An altered visual-evoked potential (VEP)

6. Ocular albinism 1 (OA1) (Shen et al. 2001; Lewis 2015):
   1. X-linked recessive OA (XLOA)
   2. Incidence of the disease approximately 1 in 50,000 individuals
   3. Extreme variability in clinical expression
   4. Involving eyes only:
      1. Decreased visual acuity
      2. Refractive errors: typical findings:
         1. Hypermetropia
         2. Astigmatism
      3. Hypopigmentation of the fundus and the iris
      4. Absent foveal reflex (foveal hypoplasia)
      5. Congenital nystagmus
      6. Photophobia
      7. Strabismus
      8. Iris translucency
      9. Posterior embryotoxon
      10. Loss of stereoscopic vision due to misrouting of the optic tracts
   5. Normal skin.
   6. Male manifesting complete phenotype.
   7. Carrier females:
      1. Normal vision
      2. Hypopigmented streaks (characteristic patchy hypopigmentation as a result of mosaic inactivation of the affected X chromosomes) in the periphery
      3. Marked iris translucency
   8. Severity depending on ethnic background: less severe in races exhibiting very dark constitutive skin pigmentation than those more lightly pigmented.

7. Autosomal recessive ocular albinism (OAR):
   1. Children with ocular features of albinism and normal cutaneous pigmentation born to normally pigmented parents
   2. Classified as autosomal recessive because both males and females are affected
   3. Not considered a clinical entity

8. Hermansky-Pudlak syndrome:
   1. A group of related disorders:
      1. Common oculocutaneous albinism
      2. A platelet storage disorder
      3. Ceroid-lipofuscin lysosomal storage disease
   2. An autosomal recessive disorder with very variable expression.
   3. Incidence of the disease: rare, except in Puerto Rico where its frequency is 1 in 1,800 individuals (Witkop et al. 1990).
   4. Bleeding diathesis resulting from a platelet storage pool deficiency.
   5. Patients exhibit severe immunologic deficiency with neutropenia and lack of killer cells (DePinho and Kaplan 1985).
   6. Ceroid storage disease:
      1. Accumulation of a ceroid-lipofuscin material in various organ systems
      2. Interstitial pulmonary fibrosis
      3. Granulomatous colitis and gingivitis
      4. Kidney failure
      5. Cardiomyopathy

9. Chediak-Higashi syndrome (Russell-Eggitt 2001):

1. An autosomal recessive disorder with variable expression
2. Consisting of a very rare group of conditions
3. Severe immune disorder:
    1. Abnormal intracellular granules in most cells, especially white cells
    2. Susceptible to bacterial infections
    3. Defective neutrophils function
    4. Episodes of macrophage activation known as accelerated phases:
        1. Fever
        2. Anemia
        3. Neutropenia
        4. Occasionally thrombocytopenia
        5. Hepatosplenomegaly
        6. Lymphadenopathy
        7. Jaundice
4. Hypopigmentation of the skin, hair, irides, and ocular fundi.
5. Bleeding diathesis:
    1. Easy bruising
    2. Mucosal bleeding
    3. Epistaxis
    4. Petechiae
6. Eye symptoms:
    1. Photophobia
    2. Nystagmus
    3. Reduced stereoacuity
    4. Strabismus
7. Often succumb during childhood to severe viral and bacterial infections, bleeding, or development of the accelerated phase.
8. May develop a peripheral and cranial neuropathy in survivors:
    1. Autonomic dysfunction
    2. Weakness and sensory deficits
    3. Loss of deep tendon reflexes
    4. Clumsiness with a wide-based gait
    5. Seizures
    6. Abnormal EEG
    7. Abnormal EMG with decreased motor nerve conduction velocities
10. Griscelli syndrome (Mancini et al. 1998):
    1. A rare disorder.
    2. Immune impairment.
    3. Neurological deficit.
    4. Hypopigmentation of skin and hair.
    5. Presence of large clumps of pigment in hair shafts.
11. Waardenburg syndrome: a syndrome of sensory deafness and partial albinism, referred to as the albinism-deafness syndrome (Waardenburg 1951).

Diagnostic Investigations

1. Ophthalmologic examination for detection of reduced retinal pigment with visualization of the choroidal blood vessels (OCA1) and foveal hypoplasia.
2. Ophthalmic images in oculocutaneous albinism (Goldberg et al. 2015):
    1. One-piece acrylic intraocular lens in the capsular bag, visualized through an undilated pupil by transillumination of the iris.
    2. Slit-lamp photograph: demonstrates miotic pupil, poliosis, and hypopigmented iris.
3. Visual acuity reduction.
4. Hair bulb incubation assay for tyrosinase activity:
    1. OCA1A: no tyrosinase activity.
    2. OCA1B: greatly reduced activity of tyrosinase but still present.
5. Visual-evoked potential (VEP): an accurate diagnostic test for albinism by demonstrating an asymmetry of VEP between the two eyes secondary to misrouting of optic pathways.
6. Electron microscopy of skin and hair bulb: not routinely performed but probably the best diagnostic method for albinism.
7. Ultrastructural examination of skin: The presence of macromelanosomes in the skin is considered specific for OA1.
8. Molecular genetic analysis: clinically available:
    1. OCA1 (Lewis 2013):
        1. Sequence analysis to detect sequence variants for OCA1A or OCA1B
        2. Deletion/duplication analysis to detect *TYR* exonic or whole-gene deletions for both forms

2. OCA2:
    1. Targeted mutation analysis to detect 2.7-kb deletion (most individuals of sub-Saharan African heritage)
    2. Sequence analysis/mutation scanning of OCA2 sequence variations other than 2.7-kb deletion
3. OCA3: sequence analysis of the entire coding region of *OCA3* gene
4. OCA4: sequence analysis to detect *MATP* mutations
5. XLOA: analysis of the *GPR143* gene

9. Hermansky-Pudlak syndrome:
    1. Simple blood clotting tests
    2. Electron microscopic examination of platelets for identification of the absence of dense bodies (delta granules)
10. Chediak-Higashi syndrome:
    1. Blood smear: identification of neutrophils containing giant cytoplasmic granules
    2. Defective neutrophils chemotaxis or killing
    3. Prolonged bleeding time caused by impaired platelet function
11. Griscelli syndrome:
    1. Immunological function evaluation
    2. CT and MRI for neurological abnormalities

Genetic Counseling

1. Recurrence risk:
    1. Patient's sib:
        1. Autosomal recessive oculocutaneous albinism: 25% recurrence risk of being affected (Lewis 2013)
        2. X-linked recessive ocular albinism:
            1. If the mother is a carrier: 50% of brothers affected and 50% of sisters carriers.
            2. If the mother is not a carrier: The recurrence risk is low but still exists since the risk of germ line mosaicism in mothers is not known but is likely rare.
    2. Patient's offspring:
        1. Autosomal recessive oculocutaneous albinism: recurrence risk not increased unless the spouse is also a carrier in which case, there is a 50% recurrence risk (as in the pseudodominance).
        2. X-linked recessive ocular albinism: None of the sons will be affected; all daughters will be carriers.
2. Prenatal diagnosis:
    1. Important to perform segregation analysis of mutation on both parents to exclude two mutations located at the same allele (Hsieh et al. 2001).
    2. Genetic sequence diagnosis possible on fetal DNA obtained from amniocentesis or CVS for pregnancies at 25% risk when the disease-causing mutations of the *TYR* gene in an affected family member is known:
        1. OCA1: available clinically in families with an identified *OCA1* mutation
        2. OCA2: possible in families with an identified *OCA2* mutation
        3. XLOA: available clinically in families with an identified *OA1* mutation (Lewis 2015)
    3. Fetoscopy (a high-risk procedure) to obtain fetal skin biopsy to demonstrate the lack of melanin in skin melanocytes: an invasive procedure not recommended clinically.
3. Management:
    1. Albinism (Okulicz et al. 2003):
        1. Skin care: avoid prolonged sun exposure to protect skin from sunburned, ultraviolet radiation and minimize the risk of malignancy:
            1. Protective clothing
            2. Sunscreens with at least a sun protection factor of 1.5
        2. Ophthalmologic care:
            1. Use of sunglasses for photophobia
            2. Correction of refractory errors secondary to hyperopia, myopia, or astigmatism to improve visual acuity
            3. Considering strabismus surgery for better ocular alignment
        3. Ensure full benefits of a good education:
            1. Provide large-print and high-contrast written textbooks

   2. Seating at the front of classroom
2. Hermansky-Pudlak syndrome:
   1. Treat extreme bleeding diathesis with platelet and blood transfusions
   2. High dose of steroids for granulomatous colitis or pulmonary fibrosis
3. Chediak-Higashi syndrome:
   1. Treat infections.
   2. Bone marrow transplantation: improves immunological status but no effect on ocular and cutaneous albinism.

Fig. 1 (**a**–**e**) Oculocutaneous albinism in different age groups including one set of identical twins

Fig. 2 A 7-month-old infant boy with light skin color, silverish white scalp hair, eyebrows, and eyelashes and absence of nystagmus or strabismus. The infant possesses one detectable mutation in the *OCA2* gene encoding the P protein, namely, V433I: c.1327G > A. This mutation has been reported in the literature and is a known cause of OCA2. The second variation, IVS12-44C > T, was noted. A homozygous sequence change (IVS7-17insA) was observed in the *OCA3* gene. The intronic sequence changes in the *OCA2* and *OCA3* genes have not been reported in the literature and therefore clinical significance is unknown. No mutations were observed in the *OCA1* gene, the *OCA4* gene, or the *OA1* gene

Alpha-Thalassemia X-Linked Mental Retardation Syndrome

Contents

Alpha-thalassemia X-linked mental retardation (ATRX) syndrome, one form of X-linked mental retardation, is characterized by severe mental retardation, typical dysmorphic facies, genital abnormalities, and an unusually mild form of hemoglobin H disease (Gibbons et al. 1995a).

Synonyms and Related Disorders

Alpha-thalassemia X-linked intellectual disability syndrome; ATRX syndrome; X-linked mental retardation-hypotonic face syndrome

Genetics/Basic Defects

1. An X-linked recessive disorder (Donnai et al. 1991).
2. The gene involved in the disease, *ATRX*, is mapped to Xq13.3 (Gibbons et al. 1995b; Carpenter et al. 1999).
3. X-chromosome inactivation.
    1. Skewed X inactivation: common feature of ATRX syndrome (Lossi et al. 1999; Plenge et al. 2002).
    2. Non-skewed X inactivation may cause mental retardation in female carriers of ATRX syndrome (Wada et al. 2005).
4. The ATRX protein belongs to the family of SWI/SNF DNA helicases involved in chromatin remodeling (Ratnakumar and Bernstein 2013; Lacoste et al. 2014).
5. Genetically related (allelic) disorders.
    1. Several X-linked mental retardation (XLMR) syndromes: These disorders should be considered to be in the phenotypic spectrum of ATRX syndromes, and there are no compelling reasons to maintain the syndromic names.
        1. Carpenter-Waziri syndrome (Abidi et al. 1999)
        2. Holmes-Gang syndrome (Stevenson et al. 2000)
        3. Chudley-Lowry syndrome
        4. XLMR with spastic paraplegia
        5. XLMR with epilepsy
        6. Nonsyndromic XLMR
    2. ATRX mutations are identified in the following two syndromes but not in the original reported families; therefore, the relationship between ATRX syndrome and these two syndromes is unclear.
        1. Juberg-Marsidi syndrome (Saugier-Veber et al. 1995; Villard et al. 1996)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_9

2. Smith-Fineman-Myers syndrome (Villard et al. 2000)

Clinical Features

1. Central nervous system features
   1. Global developmental delay
      1. Limited expressive language
      2. Delayed walking until late childhood or unable to ambulate
   2. Generalized hypotonia, a hallmark of the condition, in early childhood, contributing to facial manifestations, drooling, and developmental retardation
   3. Seizures (30%)
2. Characteristic craniofacial features (Gibbons 2006)
   1. Microcephaly (75%)
   2. Characteristic and recognizable facial gestalt during infancy (>90%)
      1. Upsweep of the frontal hair
      2. Hypotonic facies
      3. Telecanthus or ocular hypertelorism
      4. Small triangular nose with retracted columella
      5. Tented upper lip
      6. Prominent or everted lower lip
      7. Open mouth
   3. Other features
      1. Irregular anatomy of the pinnae
      2. Wide spacing of the teeth
      3. Tongue protrusion
      4. Coarse facial appearance particularly after the first few years of life
3. Abnormal external genitalia (80%): broad spectrum of possible genital anomalies but the type of genital anomaly appears to be consistent within a family
   1. Often minor anomalies
      1. First-degree hypospadias
      2. Undescended testes
      3. Underdevelopment of the scrotum
   2. More severe defects
      1. Second- and third-degree hypospadias
      2. Micropenis
      3. Ambiguous genitalia
   3. Occasional gonadal dysgenesis (Jezela-Stanek et al. 2009) resulting in inadequate testosterone production and ambiguous genitalia or normally appearing female external genitalia
4. Skeletal anomalies
   1. Short stature (65%)
   2. Digital anomalies
      1. Brachydactyly
      2. Clinodactyly
      3. Tapered digits
   3. Joint contractures
   4. Spine anomalies
      1. Pectus carinatum
      2. Kyphosis
      3. Scoliosis
      4. Dimples over the lower spine
   5. Foot anomalies
      1. Varus and valgus foot deformation
      2. Pes planus
5. Gastrointestinal features (Martussiello et al. 2006)
   1. Gastroesophageal reflux (two-thirds of cases) may cause aspiration with a fatal complication.
   2. Abdominal pain/distention.
   3. Chronic constipation (one-third of cases).
   4. Report of pseudo-obstruction (gastric pseudovolvulus) resulting from abnormal suspension of the stomach and constipation from colon hypoganglionosis.
6. Major malformations: uncommon
   1. Ocular coloboma
   2. Cleft palate
   3. Cardiac defects (20%)
   4. Inguinal hernia
   5. Heterotaxy
   6. Asplenia

Diagnostic Investigations

1. Diagnosis is suspected on the basis of characteristic craniofacial, genital, skeletal, other somatic features, and hematological findings and should be confirmed by molecular genetic testing.

2. Hematologic studies: demonstration of evidence of alpha thalassemia (Stevenson 2014).
    1. Light microscopy: demonstration of HbH inclusions in red blood cells after incubation with brilliant cresyl blue confirms the diagnosis (Gibbons et al. 1995a; Gibbons and Higgs 2000).
    2. HbH inclusions (β-globin tetramers) ranging from 0.01% to 30% in erythrocytes demonstrated in most individuals with *ATRX* mutations.
    3. Hemoglobin electrophoresis: demonstration of Hb H (not highly sensitive).
    4. Red blood cell indices: microcytic hypochromic anemia.
    5. Considerable variation in the hematologic manifestations associated with ATRX mutations.
3. Brain CT/MRI (Wada et al. 2013).
    1. Nonspecific brain atrophy (63%)
    2. White matter abnormalities, especially around the trigones (41%)
    3. Widespread and scattered white matter abnormalities (4%)
    4. Delayed myelination (15%)
    5. Severe and rapidly progressive cortical brain atrophy (4%)
    6. Multiple symmetric deep and subcortical lesions with high signal intensities on T2 and fluid-attenuated inversion recovery images (Lee et al. 2015)
4. Molecular genetic testing (Stevenson 2014).
    1. Sequence analysis and mutation scanning of select exons.
    2. Sequence analysis and mutation scanning of all exons and splice junctions.
    3. Deletion/duplication analysis.
    4. X-chromosome inactivation studies: the finding of nonrandom X-chromosome inactivation is not unique to ATRX syndrome and is therefore not diagnostic.
5. Whole-exome sequencing (Lee et al. 2015).
    1. Male patients with developmental delay and widespread white matter changes, even without distinctive facial dysmorphism and hematologic abnormalities, should be suspected having ATRX syndrome.
    2. Clinical utility of whole-exome sequencing: particularly in ultrarare neurological diseases and nonspecific developmental disabilities and atypical presentation.
6. Carrier testing in at-risk females possible when the disease-causing mutation in the family is known.

Genetic Counseling

1. Recurrence risk (Stevenson 2014)
    1. Patient's sib.
        1. Carrier mother
            1. A 50% chance of transmitting the *ATRX* mutation.
            2. Offspring with a 46,XY karyotype who inherit the *ATRX* mutation will be affected.
            3. Offspring with a 46,XX karyotype who inherit the mutation are unaffected female carriers.
        2. Sibs of proband with de novo gene mutation: at increased risk of inheriting the disease-causing mutation because of possible germline mosaicism in the mother (Bachoo and Gibbons 1999)
    2. Patient's offspring: affected individual does not reproduce.
2. Prenatal diagnosis and preimplantation genetic diagnosis: possible for pregnancies at increased risk for ATRX syndrome when the disease-causing mutation in the family is known (Fichera et al. 2001; Stevenson 2014)
3. Management
    1. Multidisciplinary interventions
        1. Infant stimulation
        2. Early intervention
        3. Special education
    2. Management of feeding and gastrointestinal problems
        1. Gavage feeding for difficulty in sucking.
        2. Fundoplication and feeding gastrostomy may be required for gastroesophageal reflux.
        3. Surgical correction of pseudovolvulus.
        4. Prevention of constipation.

5. Consider biopsy to rule out Hirschsprung's disease and colonic hypoganglionosis.
6. Control of severe drooling.
    1. Anticholinergics
    2. Botulinum toxin type A injection of the salivary glands
    3. Surgical redirecting of the submandibular ducts
3. Seizure control
4. Genitourinary problems
    1. Orchiopexy for cryptorchidism
    2. Treat recurrent urinary tract infections
5. Orthopedic management for musculoskeletal anomalies
6. Hearing loss management
7. Alpha thalassemia
    1. No treatment required for the mild anemia
    2. Iron not required unless iron stores are shown to be low

Fig. 1 (**a**, **b**) A 7-year-old boy with global developmental delay and the characteristic facial appearance of ATRX syndrome: upswept frontal hairline, ocular hypertelorism, epicanthal folds, a small triangular upturned nose, open mouth, tented upper lip, prominent everted lower lip, and hypotonic appearing face. He has mild microcytic, hypochromic anemia (mean cell volume 74.8 FL (76–90), MCH 23.6 pg (27–31), MCHC 31.5 g/dl (32–36)). Sequence analysis showed a C > T change at nucleotide 736 in the *XNP* gene (c.736C > T). This change results in the substitution of a cysteine for an arginine at amino acid 246 (R246C). This change is consistent with the diagnosis of ATRX syndrome. His mother has the same *XNP* gene mutation

Fig. 2 A maternal uncle was similarly affected (similar characteristic facial features) with recurrent pneumonias, anemia, and mental retardation

Ambiguous Genitalia

Contents

Most cases of ambiguous genitalia are discovered at birth, occurring approximately once in every 1,000 live births. Genital ambiguity usually is due to virilization of genetic females or undervirilization of genetic males who have normal gonads. Less common are disorders of sexual differentiation that involve gonadal dysgenesis (Chi et al. 2008). In females, congenital adrenal hyperplasia (CAH), specifically 21-hydroxylase deficiency, is the most common condition leading to inappropriate virilization. In males, defects in testosterone production, metabolism, or peripheral action can lead to ambiguous genitalia. Later presentations of ambiguous genitalia often include previously unrecognized genital ambiguity, inguinal hernia in a girl (e.g., complete androgen insensitivity), delayed or incomplete puberty, primary amenorrhea or virilization in a girl, breast development in a boy, and gross or cyclic hematuria in a boy (unrecognized virilized 46,XX with CAH) (Lee et al. 2006).

Synonyms and Related Disorders

Disorder of sex development (DSD); Female pseudohermaphroditism; Genetic disorders of sexual differentiation (gonadal dysgenesis, true hermaphroditism, sex reversal); Male pseudohermaphroditism; Testicular feminization syndrome; Undervirilization of male infant; Virilization of female infant

Genetics/Basic Defects

1. Normal development of the human reproductive system (Chi et al. 2008):
    1. Sexual differentiation of the fetus begins at 6–7 weeks of gestation.
    2. During embryogenesis, the fetus contains both female (Müllerian) and male (Wolffian) genital ducts:
        1. Müllerian ducts develop into fallopian tubes, uterus, and the upper one third of the vagina.
        2. Wolffian ducts develop into the vas deferens, epididymis, and seminal vesicles.
    3. "Default" pathway of the bipotential gonad and internal structures: female.
    4. The presence of the sex-determining region Y gene (SRY) in males activates a cascade of events that culminates in differentiation of the gonad as a testis which produces the following two key hormones:

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_10

1. Testosterone:
    1. Function: stimulates Wolffian duct differentiation.
    2. Production: initially driven by placental human chorionic gonadotropin (hCG) which subsequently replaced by fetal pituitary gonadotropins after the first trimester, both acting through the luteinizing hormone (LH) receptor.
    3. Local conversion of testosterone to dihydrotestosterone (DHT) by the enzyme 5α-reductase leads to fusion of the labioscrotal folds and formation of the scrotum and penis, both critical events occurring in the first trimester.
2. Müllerian-inhibiting substance (MIS) or anti-Müllerian hormone (AMH): stimulates Müllerian duct regression
5. The absence of testosterone and MIS in females leads to:
    1. Involution of the Wolffian ducts.
    2. Differentiation of the Müllerian ducts into female internal genitalia
    3. Needs both X chromosomes to develop normally differentiated and functional ovaries; females with X chromosome deletion (Turner syndrome) have abnormal gonadal differentiation and oocytes loss, leading to streak gonads.

2. Broad categories of ambiguous genitalia
    1. XX baby with virilization:
        1. In the virilized XX baby, the gonads are ovaries and the internal genitalia are female.
        2. The external genitalia are masculinized by circulating androgens to a variable degree, ranging from subtle clitoromegaly to complete labial fusion with urethral tubularization to the tip of the enlarged phallus.
        3. If exposure occurred late, clitoromegaly without labial fusion is seen. The gonads are not palpable.
        4. The commonest cause of virilization in the XX "female" is congenital adrenal hyperplasia. This autosomal recessive condition results from an enzymatic defect in adrenal steroidogenesis, leading to accumulation of steroids proximal to the block, which are converted to androgens. The commonest of these is 21-hydroxylase deficiency, followed by 11β-hydroxylase and 3β-hydroxysteroid dehydrogenase deficiency. The serum and urinary steroid profile will help to confirm the diagnosis. Other possible causes include exposure to exogenous androgens, such as from maternal androgens or progestin ingestion or, rarely, maternal androgen-producing tumors.
        5. The majority of true hermaphrodites also have a 46,XX chromosomal makeup, but these form a distinct group.
    2. The XY baby with undervirilization:
        1. The undervirilized XY baby presents with a small phallus with severe chordee, posterior hypospadias, and poorly formed bifid scrotum with or without testicular maldescent. Inadequate testosterone production, either as a result of testicular dysgenesis or autosomal recessive enzymatic defects, is rare.
        2. The commonest cause is a group of disorders known as androgen insensitivity syndrome (AIS), previously also known as testicular feminization syndrome. This is an X-linked disorder resulting from peripheral resistance to androgen action, either from mutations in the androgen receptor gene or elsewhere in the molecular pathway.
        3. Whether AIS may, in fact, be due to a defect in the conversion of dihydrotestosterone to 5α-androstanediol remains to be seen.
        4. 5α-reductase deficiency, an autosomal recessive defect resulting in deficient dihydrotestosterone necessary in the virilization of the external genitalia in early embryogenesis, is another cause of undervirilization.
    3. True hermaphroditism:
        1. In the true hermaphrodite, both testicular and ovarian tissues coexist.
        2. The gonads are usually ovary-testis or ovary-ovotestis.

3. The genotype is usually 46,XX (Damiani et al. 1997), although 46,XY or mosaicism can occur (Hadjiathanasiou et al. 1994).
4. Asymmetry of the gonads, internal and external genitalia, is a feature in true hermaphroditism. The right side is more commonly the "masculine" side, while the left side is often more "feminine."

4. Mixed gonadal dysgenesis:
   1. In mixed gonadal dysgenesis, there is a testis on one side (more commonly the right side) and a streak gonad on the other.
   2. The testis may be dysgenetic or initially normal, and the streak gonad histologically is composed of whorls of ovarian stroma without oocytes.
   3. The karyotype is most commonly 45,X/46,XY, but other mosaic patterns have been described.
   4. As with true hermaphrodites, asymmetry is a feature in mixed gonadal dysgenesis.

3. XX true hermaphroditism:
   1. Mechanisms:
      1. Hidden mosaicism with a Y-bearing cell line.
      2. Translocation of Y-material including SRY from paternal Y to X chromosome.
      3. An autosomal (Berkovitz et al. 1992) or X-linked mutation permits testis differentiation in the absence of SRY.
   2. An unusual cause of ambiguous genitalia:
      1. Both ovarian and testicular tissues present either in the same or in a contralateral gonad
      2. Predominantly 46,XX karyotype
   3. Several familial forms reported although the great majority of cases are sporadic:
      1. Occurring with a higher frequency in South African blacks suggesting a genetic origin
      2. Several families in which 46,XX males coexist with 46,XX true hermaphrodites strongly suggest that both disorders are alternative manifestations of the same genetic defect.
      4. SRY-negative true hermaphroditism could be the result of genetic defects at an unknown X-linked or autosomal sex-determining locus.
      5. Mutations in SRY originated ovotestes development described in 46,XY patients.
      6. The absence of SRY in gonadal tissue reported in cases of 46,XX true hermaphroditism.
      7. Possible underestimate of gonadal hidden mosaicism for SRY in XX true hermaphrodites suggesting that true hermaphroditism is a genetically heterogeneous condition.

4. Causes of ambiguous genitalia (Chi et al. 2008):
   1. Virilization of female infant:
      1. Excessive androgen production – congenital adrenal hyperplasia:
         1. 21α-hydroxylase deficiency
         2. 11β-hydroxylase deficiency
         3. 3β-hydroxysteroid dehydrogenase deficiency
      2. Defects in androgen metabolism: placental aromatase deficiency
      3. Maternal hyperandrogenism:
         1. Maternal androgen production (luteoma of pregnancy, adrenal tumor, untreated CAH)
         2. Progestational agents
   2. Undervirilization of male infant:
      1. Defects in testosterone production:
         1. Leydig cell hypoplasia/agenesis
         2. Defects in testicular and adrenal steroidogenesis (steroid acute regulatory (StAR) protein deficiency, 3β-hydroxysteroid dehydrogenase deficiency, 17α-hydroxylase/17,20 lyase deficiency, 17α-hydroxysteroid dehydrogenase (ketosteroid reductase) deficiency)
      2. Defects in testosterone metabolism: 5α-reductase deficiency
      3. Defects in testosterone action: androgen insensitivity syndrome
      4. Exogenous estrogen/progestin exposure
   3. Genetic disorders of sexual differentiation:
      1. Gonadal dysgenesis:
         1. 45,X (streak ovaries)
         2. 46,XX gonadal dysgenesis

3. 46,XY complete and partial gonadal dysgenesis
4. 45,X/46,XY mixed gonadal dysgenesis
5. 47,XXY (seminiferous tubular dysgenesis)

2. True hermaphroditism
3. Sex reversal:
   1. XX males (SRY±)
   2. XY female (SRY±)
   3. Smith-Lemli-Opitz syndrome (SLOS)
   4. *DAX1* mutations
   5. *WT1* mutations

5. 46,XY DSD, testicular development disorders: causative genes and phenotypes (Ono and Harley 2013):
   1. *ARX* (Xp22.13, testicular factor (TF)): dysgenetic testis, no Müllerian structures, ambiguous external genitalia, lissencephaly, epilepsy, and temperature instability
   2. *ATRX* (Xq13.3, chromatin-remodeling protein): dysgenetic testis, no Müllerian structures, female-like or ambiguous or male-like external genitalia, α-thalassemia, mental retardation, and dysmorphic face
   3. *CBX2* (17q25, polycomb protein): normal ovaries, Müllerian structures present, and female-like external genitalia
   4. *DHH* (12q13.1, signaling molecule): dysgenetic testis, Müllerian structures present, female-like external genitalia, and minifascicular neuropathy
   5. *DMRT1* (9p24.3, TF): dysgenetic testis or ovotestis +/− Müllerian structures, female-like or ambiguous or male-like external genitalia, facial abnormality, mental retardation, and microcephaly
   6. GATA4 (8p23.1-p22, TF): dysgenetic testis, Müllerian structures absent, ambiguous or male-like external genitalia, and congenital heart disease
   7. *MAMLD1* (Xq28, transcriptional co-activator): normal function of sex organs, no Müllerian structures, and hypospadias
   8. *MAP3K1* (5q11.2, kinase): dysgenetic testis, Müllerian structures may be present, and female-like or ambiguous or male-like external genitalia
   9. *NROB1* (Xp21.3, nuclear receptor (NR)/TF): dysgenetic testis or ovary +/− Müllerian structures, female-like or ambiguous or male-like external genitalia, cleft palate, and mental retardation
   10. *NR5A1* (9q33, NR/TF): dysgenetic testis +/− Müllerian structures, female-like or ambiguous or male-like external genitalia, and +/− adrenal insufficiency
   11. SOX9 (17q24-q25, TF): dysgenetic testis or ovotestis, +/− Müllerian structures, female-like or ambiguous external genitalia, and campomelic dysplasia
   12. *SRY* (Yp11.3, TF): dysgenetic testis or ovotestis, +/− Müllerian structures, and female-like or ambiguous external genitalia
   13. *WNT4* (1p35, signaling molecule): dysgenetic testis, Müllerian structures present, ambiguous external genitalia, cleft lips and palate, tetralogy of Fallot, intrauterine growth retardation, microcephaly, and mental retardation
   14. *WT1* (11p13, TF): dysgenetic testis +/− Müllerian structures, female-like or ambiguous external genitalia, Wilms tumor, renal abnormalities, and gonadal tumors (WAGR, Denys-Drash, and Frasier syndromes)
   15. *WWOX* (16q23.3-q24.1, oxidoreductase): dysgenetic testis, no Müllerian structures, and female-like external genitalia
6. 46,XX DSD, ovarian development disorders – causative genes (locus, protein) and phenotypes (Ono and Harley 2013):
   1. *MAMLD1* (Xq28, transcriptional co-activator?): streak or dysgenetic gonads, Müllerian structures present, and ambiguous external genitalia
   2. *NR5A1* (9q33, NR/TF): dysgenetic gonads (primary ovarian failure), Müllerian structures present, and female-like external genitalia
   3. *RSPO1* (1p34.3, signaling molecule): testis or ovotestis, no Müllerian structures, male-like or ambiguous external genitalia, palmoplantar hyperkeratosis, and squamous cell carcinoma of the skin

4. *SOX3* (Xq27.1, TF): gonadal histological phenotype (atrophic change in testis with loss of normal spermatogenesis), Müllerian structures not determined, male-like or ambiguous external genitalia, microcephaly, developmental delay, and growth retardation
5. *SOX9* (17q24-q25, TF): gonadal histological phenotype not determined, no Müllerian structures, and male-like or ambiguous external genitalia
6. *SRY* (Yp11.3, TF): testis or ovotestis, no Müllerian structures, and male-like or ambiguous external genitalia
7. *WNT4* (1q35, signaling molecule): ovary or testis or ovotestis, no Müllerian structures, female-like or ambiguous or male-like external genitalia, Mayer-Rokitansky-Küster-Hauser syndrome (autosomal dominant), and SERKAL syndrome (autosomal recessive)

Clinical Features

1. Physical features suggestive of ambiguous genitalia (Lee et al. 2006):
    1. Overt genital ambiguity (e.g., cloacal exstrophy)
    2. Apparent female genitalia with enlarged clitoris and posterior labial fusion (e.g., CAH)
    3. Apparent male genitalia with undescended testes, hypospadias, or micropenis
2. Rules of thumb and clinical significance of internal genitalia (the gonads and the genital ducts) (Low et al. 2003):
    1. Testes descend, while ovaries do not: the presence of a palpable gonad implies the presence of testicular tissue on the same side, which implies the presence of the *SRY* gene somewhere in the genome.
    2. Testicular descent – directly linked to Müllerian duct regression:
        1. The presence of two palpable gonads means there is no uterus.
        2. With asymmetrical gonadal descent, similar ductal asymmetry internally can be predicted.
        3. On the side of the descended gonad, there will be Wolffian duct derivatives but no Müllerian structures. Correspondingly, the contralateral hemi-uterus is likely to be present.
        4. When there are no palpable gonads, the gonadal and ductal status is unknown.
    3. The presence of a uterus (digitally palpated or ultrasonically detected) means no Müllerian-inhibiting substance/anti-Müllerian hormone (MIS/AMH) action during the "sensitive" period in early gestation. This implies either no testes, dysgenetic nonfunctional testes, or defects in production or action of MIS/AMH as occurs in the rare syndrome of persistent Müllerian duct syndrome (PMDS).
    4. Testosterone, as well as MIS/AMH, functions as a locally acting exocrine hormone in the development of the internal genital ducts:
        1. Gonadal asymmetry as occurs in true hermaphrodites, and mixed gonadal dysgenesis results in corresponding duct asymmetry.
        2. Circulating androgens in over-androgenized XX babies are insufficient to allow development of male internal genitalia.
3. Rules of thumb and clinical significance of external genitalia (Low et al. 2003):
    1. External virilization, of any degree, is due to the effect of androgens:
        1. "Clitoromegaly" in an otherwise phenotypic female is always abnormal, indicating abnormal exposure to androgens.
        2. The genotype may be "XX" with virilization or "XY" with undervirilization.
    2. The degree of external virilization proportionally predicts the degree of lower vaginal development:
        1. A baby who is incompletely virilized externally, an incomplete vaginal remnant, is likely to be retained.
        2. In a 46,XX "female" baby, the greater the external virilization, the smaller the vaginal remnant and the higher its opening into the posterior urethra.

3. With the exception of the phallus, circulating androgens masculinize the external genitalia only during a critical period (8th–12th weeks):
    1. Scrotal fusion indicates the presence of early circulating androgens, while an unfused scrotum means deficient early androgen effect.
    2. An enlarged phallus without urethral/scrotal fusion means there has been a delayed androgen effect (beyond 12 weeks).
    3. Enlargement of the phallus to normal penile size means continued presence of an androgen effect throughout later gestation (12 weeks to term).
4. Female pseudohermaphroditism (Anhalt et al. 1996):
    1. Congenital adrenal hyperplasia (please see the chapter):
        1. 21-hydroxylase deficiency
        2. 11α-hydroxylase deficiency
        3. 3β-hydroxysteroid dehydrogenase deficiency
    2. Maternal androgens
5. Male pseudohermaphroditism (Anhalt et al. 1996):
    1. Dysmorphic syndromes
    2. Defects in testosterone biosynthesis:
        1. Cholesterol desmolase deficiency (20,22-desmolase)
        2. 17α-hydroxylase deficiency
        3. 3β-hydroxysteroid dehydrogenase deficiency
        4. 17,20 lyase (desmolase) deficiency
        5. 17β-hydroxysteroid oxidoreductase (ketoreductase) deficiency
        6. Leydig cell hypoplasia or hCG resistance
    3. Defects in androgen target tissues:
        1. 5α-reductase deficiency
        2. Androgen insensitivity (testicular feminization)
        3. Incomplete resistance
    4. Persistent Müllerian duct syndrome
    5. Gonadal dysgenesis
    6. Vanishing testes
6. True hermaphroditism contains both ovarian and testicular gonadal tissue separately or, more commonly, together as ovotestis:
    1. During intrauterine life: the presence of ovarian and testicular tissue with variability in hormonal production results in abnormal differentiation of internal and external genitalia.
    2. At birth:
        1. Variable degrees of genital ambiguity present in nearly all patients.
        2. The presence of labioscrotal folds, normally developed labia majora in most affected individuals.
        3. A hemiscrotum or even a normal scrotum in a minority of cases.
        4. A phallus of variable length with chordee and urethra generally opens as a urogenital sinus in majority of cases while less severe hypospadias in some cases.
        5. Ovaries generally locate in ovarian position, while testes locate in the scrotum generally, inguinal canal, or even intra-abdominally.
        6. Location of ovotestis depends on the amount of testicular or ovarian tissue present.
        7. Development of internal genitalia – variable depending on the neighboring gonad:
            1. The presence of Müllerian derivatives: an ovary is present and ovotestes in most cases.
            2. Wolffian structures: observed in association with testes.
        8. A unicornuate uterus is usually found.
    3. At puberty:
        1. Relative production rate of sex hormones varies depending on the composition of the gonads.
        2. Secondary sex characteristics depend on the type of predominant steroid hormone production.
        3. Breast development frequent after puberty.
        4. Menstruation occurring in approximately 50% of patients.
        5. Ovulation common.
        6. Pregnancy reported in a few cases.

4. Pregnancy in true hermaphrodites:
    1. Complications with preterm labor, neonatal death, or the delivery process itself.
    2. Recommendation to remove the remaining gonad(s) due to an increased risk of germ cell malignancies after thorough discussion of the risks, benefits, alternatives, and implications of future sterility and hormone deprivation.
    3. Pregnancy can occur in true hermaphrodites spontaneously. To date all offspring are males (Schultz et al. 2009).
7. Recently proposed revised nomenclature (Lee et al. 2006; Hughes 2008):
    1. Disorders of sex development (DSD) replacing "intersex"
    2. 46,XY DSD replacing "male pseudohermaphrodite, undervirilization of an XY male, and undermasculization of an XY male"
    3. 46,XX DSD replacing "female pseudohermaphrodite, overvirilization of an XX female, and masculinization of an XX female"
    4. Ovotesticular DSD replacing "true hermaphrodite"
    5. 46,XX testicular DSD replacing "XX male or XX sex reversal"
    6. 46,XY complete gonadal dysgenesis replacing "XY sex reversal"
8. Recently proposed classification of causes of disorders of sex development (DSDs) (Hughes et al. 2006; Hughes 2008):
    1. Sex chromosome DSD:
        1. 47,XXY (Klinefelter syndrome and variants)
        2. 45,X (Turner syndrome and variants)
        3. 45,X/46,XY (mixed gonadal dysgenesis)
        4. 46,XX/46,XY (chimerism)
    2. 46,XY DSD (Mendonca et al. 2009):
        1. Disorders of gonadal (testicular) development: complete or partial gonadal dysgenesis (e.g., SRY, SOX9, SFI, WTI, DHH), ovotesticular DSD, and testis regression
        2. Disorders in androgen synthesis or action: disorders of androgen synthesis (e.g., LH receptor mutations, Smith-Lemli-Opitz syndrome) and disorders of androgen action (androgen insensitivity syndrome, drugs, and environmental modulators)
        3. Others: syndromic associations of male genital development (e.g., cloacal anomalies, Robinow, Aarskog, hand-foot-genital, popliteal pterygium), persistent Müllerian duct syndrome, vanishing testis syndrome, isolated hypospadias, congenital hypogonadotropic hypogonadism, cryptorchidism, and environmental influences
    3. 46,XX DSD:
        1. Disorders of gonadal (ovarian) development: gonadal dysgenesis, ovotesticular DSD, and testicular DSD (e.g., SRY+, dup SOX9, RSP01)
        2. Androgen excess: fetal (21 hydroxylase, 11β-hydroxylase), fetoplacental (aromatase deficiency, oxidoreductase deficiency), and maternal (maternal virilizing tumors such as luteomas, androgenic drugs)
        3. Others: syndromic associations (e.g., cloacal anomalies), Müllerian agenesis/hypoplasia (e.g., MURCS), uterine abnormalities (e.g., MODYS), vaginal atresia (e.g., McKusick-Kaufman), and labial adhesions

Diagnostic Investigations

1. Approach to the baby with ambiguous genitalia (Chen 1986; Low et al. 2003):
    1. History:
        1. Careful history taking indispensable to an accurate diagnosis:
            1. Maternal steroid ingestion.
            2. Antenatal diagnosis of an androgen-producing tumor.

3. A positive family history of a known intersex disorder will give important clues to the underlying disorder.
4. Majority of cases, however, will not yield a positive history.

2. Steps in the evaluation of a baby with ambiguous genitalia:
   1. Document the degree of external virilization: The greater the degree of virilization, the greater the amount of early androgen exposure (between 8 and 12 weeks) and the greater the extent of vaginal regression.
   2. Examine the urogenital sinus carefully by pulling it open. If skin tags with a slight bluish hue are seen, then the hymen and therefore the vagina is confirmed present.
   3. Determine the presence and location of gonads:
      1. Palpable gonads predict the presence of SRY, testicular development, and Müllerian regression on the ipsilateral side.
      2. The degree of testicular descent correlates with the degree of androgen exposure in the second half of pregnancy.
   4. Three possible clinical scenarios:
      1. Both gonads palpable and symmetrical: Palpable gonads are almost always testes, and the implication, in general, is that the baby is an inadequately virilized male and Müllerian duct structures are absent. The differential diagnoses include inadequate testosterone production, receptor deficiency, 5α-reductase deficiency, and minor testicular dysplasia (an exception is the occurrence of bilateral symmetrical ovotestes in a true hermaphrodite).
      2. Gonadal asymmetry with only one gonad palpable: This implies that at least one testis is present. The other may be an ovary, an ovotestis, or a streak gonad.
      3. When gonadal asymmetry is encountered, always consider true hermaphroditism or mixed gonadal dysgenesis.
   5. Impalpable gonads:
      1. Gonadal and duct status: unknown.
      2. Additional clues may be obtained by careful examination to determine if the external inguinal rings are open, which are felt as inverted V-shaped defects superior and medial to the pubic tubercle. Open external rings indicate a high likelihood of an undescended canalicular testis, while a closed external ring is consistent with the presence of ovaries or extremely dysplastic testes with minimal testosterone production. Per rectal examination is also useful in this circumstance. A gentle examination with the little finger will easily palpate the cervix and confirm the presence of the uterus.
      3. Look for other clues in the general physical examination, such as facial dysmorphism or developmental abnormalities that may be part of a sex chromosome abnormality. Hyperpigmentation may occur in congenital adrenal hyperplasia.
2. Clinical assessment strategy in the newborn with ambiguous genitalia (Wunsch 2007):
   1. Ultrasound of the inguinal region and the lower abdomen: used to detect the presence of a uterus, as well as the presence and position of intra-abdominal gonads. However, visualization may be difficult in the small neonate.
   2. Laparoscopy if gonads are not localized.
   3. MRI: suitable for older cooperative children, but imaging of small and developmentally disrupted gonads is frequently unsuccessful.
3. Urogenital sinogram to confirm the presence of and delineate the anatomy of the lower vagina

4. MRI (Choi et al. 1998):
    1. Female pseudohermaphroditism: shows normal internal female genitalia with masculinized external genitalia
    2. Male pseudohermaphroditism: shows normal or mildly defective testes with incompletely masculinized external genitalia
    3. Gonadal dysgenesis: shows combinations of normal, dysgenetic, and streak gonads; no gonads are evident in gonadal agenesis
    4. True hermaphroditism: shows both testicular and ovarian tissue
5. Hormonal investigations:
    1. Serum analysis of 17-hydroxyprogesterone.
    2. Serum profile of adrenal steroids, gonadal androgens, and its precursors.
    3. Human chorionic gonadotropin stimulation tests may be needed to confirm the normal rise of gonadal hormones with stimulation, while testosterone/dihydrotestosterone ratios reflect 5α-reductase activity.
6. Chromosomal analysis to identify the genotype of the affected baby, either as XX, XY, or a mosaic pattern
7. FISH analysis with SRY probes to identify the presence of Y sequences on the X chromosome in cases of 46,XX hermaphroditism and ambiguous genitalia
8. Biopsy of the genital skin for androgen receptor assay
9. Panendoscopy and/or laparoscopy to delineate the internal genitalia
10. Gonadal biopsies on occasion
11. Diagnostic evaluation and potential diagnoses based upon symmetry of genitalia (Mieszczak et al. 2009):
    1. Symmetrical external genitalia:
        1. Palpable gonad: gene testing of *SF1*
        2. Nonpalpable gonad – ultrasound:
            1. Uterus (lack of MIH): hormonal assessment (17-α-hydroxyprogesterone, androstenedione, testosterone, plasma renin activity) for congenital adrenal hyperplasia and in utero androgen exposure
            2. No uterus (presence of MIH): hormonal assessment (MIH, LH, testosterone, FSH (follicle-stimulating hormone), inhibin B, androstenedione) for Leydig cell hypoplasia, 3β-HSD, 17β-HSD (hydroxysteroid dehydrogenase), androgen insensitivity, 5α-reductase deficiency, and testicular regression
    2. Asymmetric external genitalia (virilization of labia different on each side) – assessment includes:
        1. Fluorescence in situ hybridization for SRY (sex-determining region Y)
        2. Hormonal assessment:
            1. MIH
            2. LH
            3. Testosterone
            4. FSH
        3. Inhibin B: androstenedione
        4. Gene testing:
            1. *SOX9* (17q24) – male gonadal dysgenesis, campomelic dysplasia, or XY sex reversal
            2. *WT1* (11p13) – XX male (SRY+), Frasier syndrome, or Denys-Drash syndrome with Wilms's tumor
            3. *DAX1* (Xp21.3) – mixed gonadal dysgenesis, XY female (SRY-), or congenital adrenal hypoplasia
            4. *WNT4* – XO/XY
            5. *DHH* – ovotesticular DSD
            6. *ATRX* – α-thalassemia X-linked mental retardation syndrome
            7. *SLOS* – Smith-Lemli-Opitz syndrome
        5. Imaging: ultrasound
12. Genetic testing (Wherrett 2015):
    1. Molecular analysis: available in many forms of DSD, particularly CAH and complete androgen insensitivity
    2. Microarray analysis for infants with syndromic forms of DSD: to detect chromosomal deletions
    3. Whole genome and exome sequencing: promising (Baxter and Vilain 2013; Tobias and McElreavey 2014)

4. Molecular techniques used to identify genetic causes of DSDs (Achermann et al. 2015):
    1. Array-CGH. SNP array-CGH:
        1. CNVs (copy number variants)
        2. Mosaicism
        3. Uniparental disomy
        4. LOH
    2. Sanger sequencing:
        1. SNVs
        2. Small insertions and deletions
        3. Microsatellite analysis
    3. qPCR:
        1. CNVs
        2. SNPs
        3. Gene expression
    4. MLPA:
        1. CNVs
        2. SNPs methylation defects
    5. Targeted capture array:
        1. SNVs
        2. CNVs
13. Online information on DSD: available for patients, parents and professionals (Ahmed and Rodie 2010)

Genetic Counseling

1. Recurrence risk depends on the inheritance pattern of the disorder (e.g., autosomal recessive disorders (congenital adrenal hyperplasia, testosterone biosynthetic defects, Leydig cell hypoplasia); autosomal dominant disorders (campomelic dysplasia, Denys-Drash syndrome, Frasier syndrome); X-linked recessive disorders (androgen insensitivity syndrome, male pseudohermaphroditism due to testicular 17,20-desmolase deficiency)):
    1. Patient's sib:
        1. Autosomal recessive: 25%
        2. Autosomal dominant: not increased unless a parent is affected or having gonadal mosaicism
        3. X-linked recessive: 50% of male sibs affected if the mother is a carrier
    2. Patient's offspring:
        1. Autosomal recessive: not increased unless the spouse is also a carrier.
        2. Autosomal dominant: 50%.
        3. X-linked recessive: All daughters of affected males will be carriers. All sons of an affected male will be normal.
2. Prenatal diagnosis:
    1. Prenatal ultrasonography. Pitfalls in sonographic fetal sex determination (Odeh et al. 2009) include:
        1. Fetuses with malformations of the external genitalia represent a diagnostic challenge.
        2. Clues to the presence of congenital malformations of the external genitalia include:
            1. Nonvisualization of the fetal bladder (Wilcox and Chitty 2001).
            2. Diagnosis of female genitalia at early gestation based on caudal orientation of the genital tubercle, followed at a later time by observation of male genitalia (Borneshtien et al. 1995).
            3. Marked phallic size discrepancy for gestational age, curvature of the phallus, and scrotal-phallus malpositions.
            4. Nondescended testis in the third trimester.
            5. The absence of phallic, labial, or scrotal structures (Mandell et al. 1995).
            6. Abnormalities of the genitalia should also be suspected whenever a mismatch is found between the sonographic fetal sex and the karyotypic fetal sex (Stephens 1984; Cheikhelard et al. 2000).
    2. Prenatal diagnosis of DSDs (Achermann et al. 2015):
        1. Fetal karyotyping from cells cultured from chorionic villi (at 11–14 weeks of gestation) or amniotic fluid (at about 16 weeks of gestation).
        2. Prenatal detection of ambiguous genitalia by ultrasonography or genotype-phenotype discordance.
        3. Identification of circulating cell-free fetal DNA (cfDNA) in maternal blood: provides an important alternative

approach for noninvasive prenatal diagnosis. Currently, PCR amplification of cfDNA is the gold standard method to define fetal sex early in pregnancy without any risk of spontaneous abortion.

3. Prenatal diagnosis is possible for pregnancies at increased risk for various genetic syndromes when the disease-causing mutation in the family is known.

3. Management:
   1. Ambiguous genitalia: likely the most devastating condition to face any parent of a newborn.
   2. Gender identity: dealing with emotional, psychosocial, cultural, diagnostic, and treatment issues (Byne 2006).
   3. Factors to consider when discussing sex assignment with families (Lee et al. 2006):
      1. Diagnosis
      2. Genital appearance
      3. Potential for fertility
      4. Surgical options
      5. Long-term hormone replacement therapy
      6. Family views
      7. Cultural practices
   4. Challenge facing clinicians – come to an accurate and expeditious diagnosis and then to a rational sex assignment:
      1. The condition is rare.
      2. Clinical diagnosis frequently difficult.
      3. Understanding of normal sexual differentiation is crucial to understanding these disorders.
   5. Hormone replacement therapy is often required to induce and sustain puberty and optimize bone mineral accrual and psychosexual development in individuals with ambiguous genitalia (Warne et al. 2005; Drobac et al. 2006; Nabhan and Lee 2007):
      1. Intramuscular injections of either testosterone cypionate or ethanate are used for pubertal induction for hypogonadal boys. Other testosterone preparations such as gels and patches are available, but there is limited experience of their use for the induction of puberty (Rogol 2005).
      2. Estrogen replacement orally or injection to induce secondary sexual characteristic development and menses for girls with hypogonadism. A progestin is usually added after breakthrough bleeding or after 1–2 years of continuous estrogen. In women without a uterus, there is no evidence that the addition of cyclic progesterone is beneficial.
   6. Surgical care:
      1. Feminizing genitoplasty, including vaginoplasty and clitoroplasty, in a virilized female.
      2. Surgical reconstruction in undervirilized males who typically have hypospadias: gender reassignment may be considered in patients with male pseudohermaphroditism and genital inadequacy.
      3. Testes in individuals with 46,XY gonadal dysgenesis or fragments of Y-chromosome material raised female should be removed to prevent testicular malignancy.

Fig. 8 A 17-year-old male was followed for 46,XX true hermaphroditism. He was born with low shaft hypospadias and *left* inguinal hernia. He underwent *left* groin exploration and *left* inguinal hernia repair. At operation, the patient was noted to have an odd testicle which looked like a typical ovotestis. Two biopsied specimens were obtained: one revealed immature ovary containing numerous follicles and other a fragment of immature testicle containing seminiferous tubules. He was followed at age of 11. He had Tanner III gynecomastia, Tanner III–IV pubic hair, and Prader 5–8 cm^3 volume testes that were somewhat irregular in size and firm. The LH and FSH were 3.2 and 21 μ/ml (both were normal pubertal levels), respectively. A beta HCG was <3 mIU/ml, and testosterone level 351 ng/dl (normal pubertal levels), estrone 1.3 ng/dl, and estradiol 0.8 ng/dl (normal male levels). His bone age was between 12 and 12.5 years of age

Amniotic Deformity, Adhesions, Mutilations (ADAM) Complex

Contents

ADAM complex occurs in 1 of every 5,000–15,000 births and had been demonstrated in 1–2% of malformed infants (Heifetz 1984). The birth prevalence rate was estimated at 1.16 per 10,000 live births (Garza et al. 1988).

Synonyms and Related Disorders

Amniotic band disruption complex; Amniotic band syndrome; Amniotic constriction band; Congenital ring constrictions; Constriction ring syndrome; The Early Amnion Rupture Spectrum (TEARS)

Genetics/Basic Defects

1. Streeter intrinsic theory (Streeter 1930; Wiedrich 1998)
    1. An intrinsic defect of the subcutaneous germplasm causes soft tissue to slough. The resulting external healing leads to the constriction ring.
    2. Significant rate of associated anomalies as indirect proof of existence of some genetic force at work to cause the syndrome.
2. Torpin extrinsic theory (Torpin 1965; Torpin and Fauklner 1966) (currently most popular theory)
    1. Early amniotic rupture leading to the formation of mesodermal fibrous strands that entangle limbs and appendages
    2. Amnion rupture without injury to the chorion resulting in amniotic bands
    3. Oligohydramnios playing a major role in the development of the constricting bands
    4. Higher incidence of clubfeet possibly resulting from continuous pressure on the feet from the undersized uterus
    5. Amniotic bands essentially encircling the affected part resulting in constricting rings
    6. Supporting evidence
        1. Constriction rings often occurring in a straight line across multiple digits as if one external band affects multiple adjacent digits
        2. Frequent involvement of the central digits
        3. Occasional attachment of amnion in the constricting ring
        4. Facial clefting which does not follow developmental planes

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_11

3. Other theory: simultaneous occurrence of both extrinsic and intrinsic factors in the development of constriction band syndrome
4. Other factors/mechanisms implicated in the etiology of amniotic band syndrome: the cause of amniotic band syndrome remains elusive and controversial (Bagatin et al. 1997; Ossipoff and Hall 1977).
    1. Simple oligohydramnios
    2. Fetal hypertension
    3. Venous stasis
    4. Localized fetal ischemia caused by uterine contractions
    5. Intrauterine hemorrhage as the precipitating event
    6. Vascular compromise (lack of distal blood flow demonstrated in association with forearm amputation defects)
    7. Cocaine drug abuse: cocaine acting as a teratogen by inducing fetal hypoxemia through impaired uteroplacental fetal blood flow and directly through its vasoconstrictive properties on the fetal vasculature
    8. Incompetent cervix
    9. Amniocentesis implicated. An increased incidence of anomalies related to amniotic band syndrome in association with prenatal amniocentesis in animal models (Kino 1975; Cignini et al. 2012)
    10. Familial occurrences reported despite no evidence for a genetic predisposition to amniotic band syndrome (Lubinsky et al. 1983)

Clinical Features

1. The nature and severity of deformities: related to the timing and initiating event of amniotic rupture (Heifetz 1984)
2. Triad of amniotic band syndrome
    1. Amnion-denuded placenta
    2. Fetal attachment or entanglement by amniotic remnants
    3. Fetal deformation, malformation, and/or disruption (Goldfarb et al. 2009)
        1. Fetal deformation
            1. Fetal compression secondary to oligohydramnios (talipes equinovarus, scoliosis, and various joint contractures)
            2. Fetal entanglement by amniotic bands
        2. Fetal malformation resulting from amniotic band interfering with the normal sequence of embryologic development. Classic malformations include:
            1. Body wall defects, internal organ abnormalities
            2. Craniofacial abnormalities
        3. Fetal disruption secondary to cleavage of structures that have already developed normally. Classic disruptive findings are:
            1. Constriction bands
            2. Amputations
            3. Acrosyndactyly
3. Craniofacial disruptions (up to one-third of cases) (Bagatin et al. 1997; Eppley et al. 1998)
    1. Facial clefting
        1. Most likely associated with swallowing of band at about 5 months of gestation
        2. Unusual extensions with asymmetric locations, such as oblique facial clefting (Mishima et al. 1996)
    2. Orbital defects
        1. Anophthalmos
        2. Microphthalmos
        3. Enophthalmos
        4. Hypertelorism
    3. Corneal abnormalities
        1. Anomalous eyelid configuration
        2. Ineffective eye closure
    4. Other ocular abnormalities
        1. Strabismus due to defects in extraocular muscles
        2. Epiphora related to either lachrymal system involvement or eyelid abnormalities
        3. Orbital clefts, lid anomalies (colobomas, ptosis, ectropia), lacrimal outflow obstruction, and globe involvement (Hollsten and Katowitz 1990)

5. CNS involvement: usually associated with amniotic band rupture before 45 days of gestation
    1. Neural tube defects (cranioschisis, atypical or asymmetrical meningocele, myelomeningocele, encephalocele, or anencephaly)
    2. Ventriculomegaly
    3. Pressure defects of the parenchyma
6. Calvarial defects
7. Cleft lip/palate

4. Limb abnormalities (Keller et al. 1978; Bourne and Klassen 1987; Askins and Ger 1988; de Pablo et al. 1995; Walter et al. 1998)
    1. Limb reduction defects/limb length discrepancies
    2. Intrauterine amputations (Baker and Rudolph 1971; Light and Ogden 1993; Al-Qattan 2000)
    3. Ring constrictions with or without distal lymphedema, clubbing, or syndactyly
        1. Deeper rings
        2. Circumferential rings
    4. Club feet
    5. Digital anomalies: frequently involved
        1. Syndactyly
        2. Acrosyndactyly
        3. Digital hypoplasia
        4. Symphalangism
        5. Symbrachydactyly
        6. Camptodactyly
    6. Significant neurovascular impairment distal to the constricting band
5. Umbilical cord strangulation by amniotic bands
    1. Common occurrence (10%)
    2. Cord strangulation
    3. Severe strangulation of the umbilical cord at times resulting in fetal death
    4. Stillbirths observed in about 97% of umbilical cord strangulation by amniotic bands
6. Associated anomalies
    1. Hemangiomas
    2. Cardiac defect
    3. Limb/body wall defects (Moerman et al. 1992)
    4. Thoracoabdominal wall defects
        1. Thoracoschisis
        2. Extrathoracic heart
        3. Omphalocele
        4. Gastroschisis
    5. Aplasia cutis
    6. Short umbilical cord
    7. Oligohydramnios sequence
7. Patterson's classification system of congenital ring constriction based on the severity of the syndrome (Patterson 1961)
    1. Simple constriction rings
    2. Constriction rings associated with deformity of the distal part, with or without lymphedema
    3. Constriction rings associated with soft tissue fusions of distal parts (acrosyndactyly)
    4. Intrauterine amputation
8. Hall's classification system for amniotic band syndrome
    1. Mild constriction without lymphedema
    2. Moderate constriction with lymphedema
    3. Severe constriction with amputation
9. Weinzweig's classification system for amniotic band syndrome (Weinzweig 1995)
    1. Mild constriction without lymphedema
    2. Moderate constriction with distal deformity, syndactyly, or discontinuous neurovascular or musculotendinous structures without vascular compromise
        1. Without lymphedema
        2. With lymphedema
    3. Severe constriction with progressive lymphaticovenous or arterial compromise
        1. Without soft tissue loss
        2. With soft tissue loss
    4. Intrauterine amputation
10. Lockwood's classification of fetal anomalies in amniotic band syndrome according to their presumed mechanism (Lockwood et al. 1989)
    1. Anomalies caused by interruption of embryonic morphogenesis
        1. Cleft lip and palate
        2. Omphalocele
        3. Cardiac anomalies
        4. Renal agenesis or dysplasia
        5. Bladder exstrophy
        6. Imperforate anus

2. Anomalies caused by fetal vascular compromise
    1. Gastroschisis
    2. Gallbladder agenesis
    3. Single umbilical artery
3. Anomalies caused by intrauterine constraint
    1. Club foot
    2. Clubbed hands
    3. Abnormal facies
    4. Valgus-varus deformities
    5. Kyphoscoliosis
4. Anomalies caused by disruption of normally developed structures
    1. Severe central nervous system or calvarial defect
    2. Acrosyndactyly
    3. Amputations
    4. Constriction bands
    5. Facial clefts (anatomically inappropriate)
    6. Aplasia cutis

11. Proposed prenatal classification in stages of amniotic band syndrome involving extremities (modified postnatal classification by Weinzweig 1995; Hüsler et al. 2009)
    1. Amniotic bands without signs of constriction
    2. Constriction without vascular compromise (normal vascular Doppler studies, when compared to opposite side) may have distal deformity
        1. Without or only mild lymphedema
        2. With severe lymphedema
    3. Severe constriction with progressive arterial compromise. The flow has to be measured proximally, at and distally to the constriction band.
        1. Abnormal distal Doppler studies when compared to contralateral extremity
        2. No vascular flow to extremity
    4. Bowing or fracture of long bones at constriction site
    5. Intrauterine amputation
12. Prognosis
    1. Early amniotic rupture results in spontaneous abortion or stillbirth, whereas late rupture results primarily in limb involvement (Higginbottom et al. 1979).
    2. Prenatally diagnosed amniotic adhesion with a grim prognosis.
    3. Most cases of cranial and body wall defects incompatible with extrauterine life.
    4. Infants born with limited limb abnormalities: better prognosis with good results after surgical repair of the constrictions or syndactyly.

Diagnostic Investigations

1. Radiography
    1. Syndactyly with amputation of distal parts
    2. Intrauterine amputation of limbs and digits
2. MRI (Laor et al. 1996)
    1. Delineate the depth of the constriction band.
    2. Delineate the extent of the resultant lymphedema.
    3. Delineate the integrity of the musculature.
    4. Define the vascular anatomy, which may be anomalous; may help to prevent injury to the vessels during surgery.
3. Histology (Day-Salvatore et al. 1995)
    1. Absence of amniotic membrane on the fetal surface of the chorionic sac, including the placental sac.
    2. Presence of amnion remnant as a cuff of thick membrane at the base of the umbilical cord at its insertion site.
    3. Amniotic squames and cellular debris are frequently embedded in the superficial soft tissue of the chorion indicating chronic amniotic rupture.
    4. Constricting bands encircling digits.
4. Placentas with early amnion rupture (Yang 1990)
    1. Absence of amniotic epithelium on the fetal surface.
    2. Presence of a slightly fibrotic small amniotic band (remnant) attaching to the umbilical cord at the placental end.

3. Presence of degenerated vernix squamous cells in the fibrous stroma of chorion and amnion.
4. The findings support Torpin's hypothesis that ADAM sequence is a complication of early amnion rupture.

Genetic Counseling

1. Recurrence risk (Levy 1998)
    1. Patient's sib: minimal risk
    2. Patient's offspring: minimal risk
2. Prenatal diagnosis (Mahony et al. 1985; Chen and Gonzalez 1987; Yamaguchi et al. 1988; Burton and Filly 1991; Laberge et al. 1995; Hüsler et al. 2009)
    1. Possible by ultrasonography during the second and third trimesters.
    2. Possible as early as the first trimester in certain cases (Nishi and Nakano 1994).
    3. Degree of deformity depends on the severity and location of the band formation and the gestational age at amniotic rupture.
    4. Visualization of amniotic sheets or bands attached to the fetus. The diagnosis of amniotic band syndrome should not be made solely on the basis of a membrane observed in the uterine cavity.
    5. Restricted fetal movement.
    6. Characteristic asymmetric fetal anomalies.
    7. Constriction bands around the limbs.
    8. Prenatal natural history of amniotic band sequence without body wall defect.
        1. Prematurity
        2. Preterm rupture of membranes
        3. Low birth weight (<2,500 g)
        4. May lead to compromised blood supply to the constricted body parts
        5. Constriction bands may spontaneously resolve (Pedersen and Thomsen 2001)
        6. Fetal death associated with amniotic band strangulation of the umbilical cord reported (Heifetz 1984; Lurie et al. 2008)
    9. Prenatal surgical intervention (Quintero et al. 1997): amniotic band was surgically interrupted to avoid spontaneous amputation of the extremity. Adequate blood flow distal to the obstruction was preserved with significant functional improvement of the extremity.
3. Management (Hall et al. 1982; Walter et al. 1998)
    1. Surgery not needed for shallow constriction bands that are not circumferential and without distal swelling.
    2. Distal edema or impairment of neurovascular function requiring staged constriction band excision, Z-plasty, or W-plasty.
    3. Digital amputation may be required for a ring so constrictive that distal edema is massive.
    4. Multiple plastic surgical procedures required for corrections of the complex craniofacial abnormalities.
    5. Procedures for the upper extremity deformities (Foulkes and Reinker 1994).
        1. Band release, Z- or W-plasty
        2. Syndactyly/web space release
        3. Skin graft
        4. Stump revision
        5. Osteotomy/osteoclasis
        6. Hardware removal
        7. Ray resection/transposition
        8. Distraction osteogenesis
        9. Pollicization/osteocutaneous transfer
        10. Tendon transfer
        11. Excision supernumerary digit
        12. Amputation
    6. Procedures for the lower extremity deformities (Foulkes and Reinker 1994).
        1. Band release, Z- or W-plasty
        2. Syndactyly release
        3. Simple revision
        4. Amputation/excision toe
        5. Clubfoot procedure
        6. Hip procedure
        7. Tibial derotation
        8. Removal of skin tag
    7. Surgical management of abdominopelvic constriction rings in amniotic band syndrome (Capone et al. 2015).
        1. Anterior sheath Y-V plasty.

2. Pteruges release of the Scarpa fascia.
3. Limited Z-plasty closure may minimize the need for serrated scar patterns.

8. Intrauterine release of extremity amniotic band should be indicated in severe cases with risk of intrauterine amputations or irreversible deformities when no other severe disorders are associated (Soldado et al. 2009). The most relevant risks that have to be assumed are premature rupture of membranes and complications related to prematurity.
9. In utero surgical intervention proposed to avoid amputation or permanent damage to the extremity of the fetus, provided the maternal and fetal risks of surgery are small.
10. Fetoscopic amniotic band release (Javadian et al. 2013; Derderian et al. 2014).
    1. A safe procedure.
    2. When umbilical cord involvement is present, it should be treated to reduce the risk of fetal demise.
    3. May allow preservation of life and/or limb function.

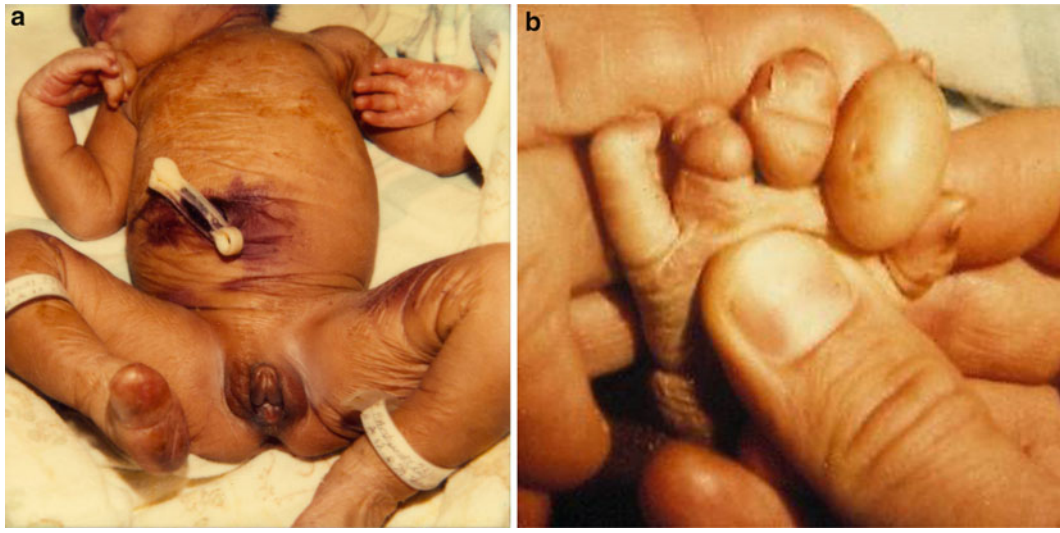

Fig. 1 (**a**, **b**) An infant with club left hand with a missing finger, constricting rings with marked distal lymphedema of the right index finger, and pseudosyndactyly of the right foot

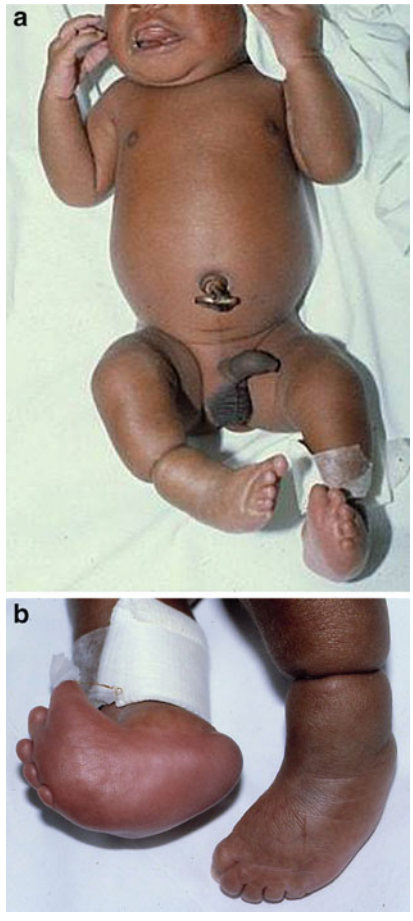

Fig. 2 (**a**, **b**) An infant with deep constricting groove around the lower one-third of both legs. The patient also had terminal amputation and constriction rings of fingers with a small amniotic band still attached to the constricting ring of the second finger (not shown)

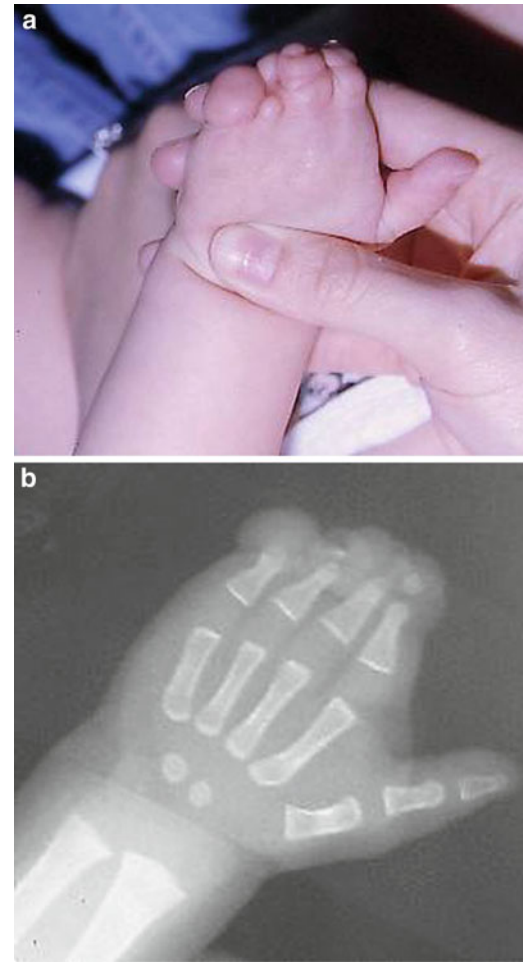

Fig. 3 (**a**, **b**) A hand of an infant with constriction bands of the fingers with amputations, shown by the radiograph

Fig. 4 A small stillborn fetus (110 g) showing amniotic constriction band at left ankle. Amputation and pseudosyndactyly of fingers and toes are present (Courtesy of Dr. Samuel Yang)

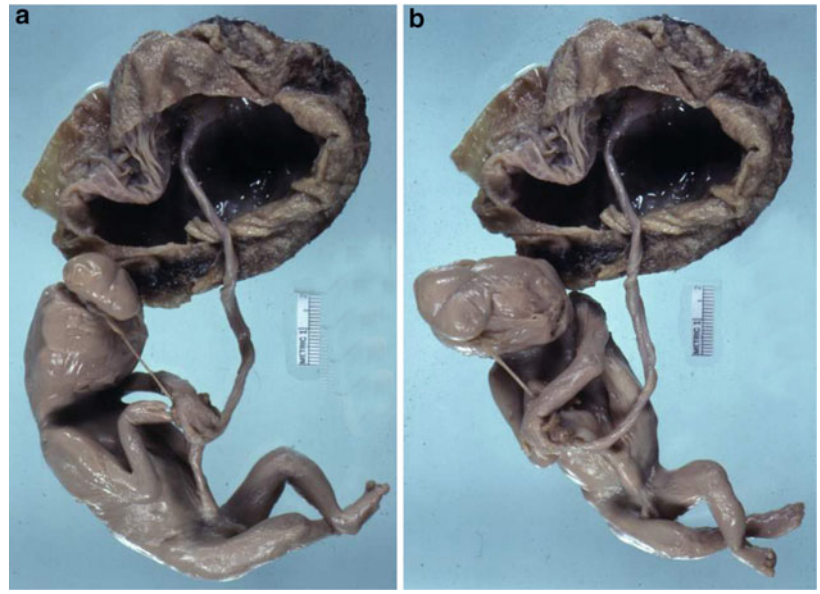

Fig. 5 (**a**, **b**) A small stillborn fetus (60 g) with a fibrous amniotic band constricting a portion of the head and facial cleft (Courtesy of Dr. Samuel Yang)

Fig. 6 (**a**, **b**) A small fetus with a large amniotic band which caused anencephaly (Courtesy of Dr. Samuel Yang)

Fig. 7 The left hand of a 1,100 g fetus showing in utero amputation of the third and fourth fingers

Fig. 8 A placenta with a long strand of amniotic band which was pulled out of the mouth of the premature neonate at birth. The baby did not have amniotic band syndrome (Courtesy of Dr. Samuel Yang)

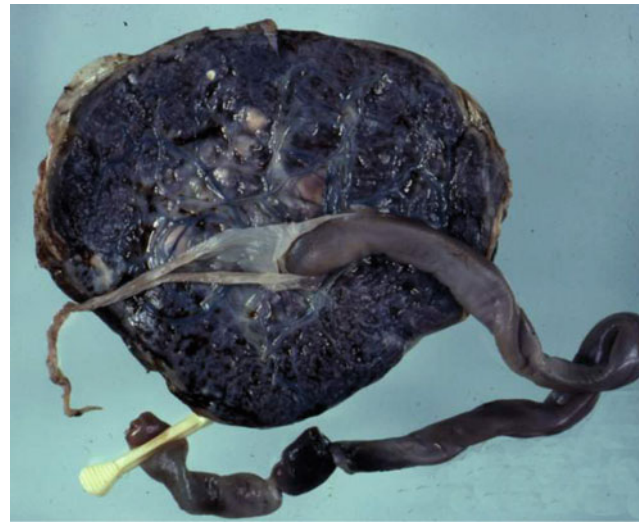

Fig. 9 Cord strangulation by amniotic band (Courtesy of Dr. Samuel Yang)

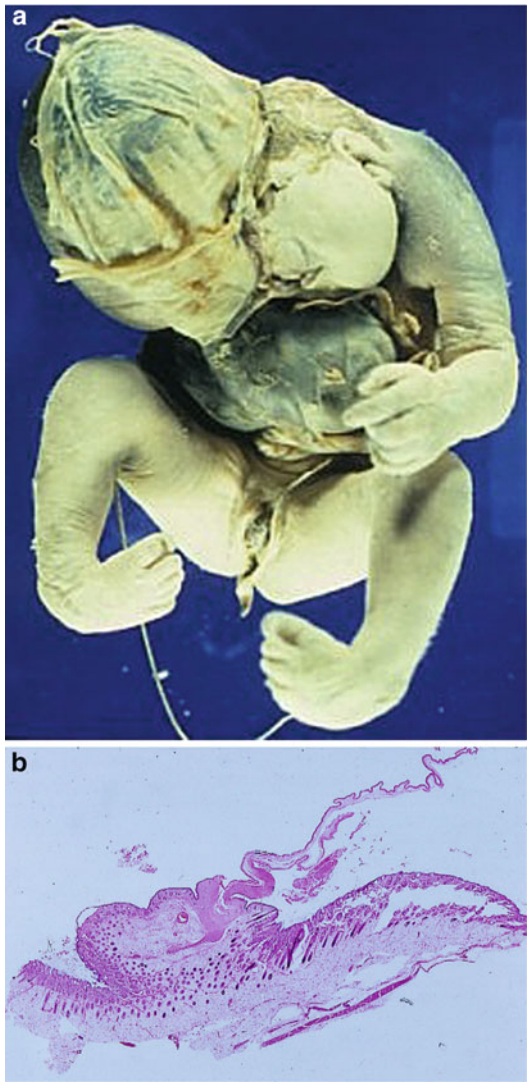

Fig. 10 (**a**, **b**) A fetus with a large meningoencephalocele and an amniotic band attaching to its base. Facial defects, a large gastroschisis, and talipes equinovarus were also present. Histology of the scalp shows an amniotic band fused with the soft tissue of the upper dermis. The amniotic epithelium of the band is visible as a darker line on the surface. The epidermis of the scalp is denuded at the site of band attachment (Chen and Gonzalez 1987)

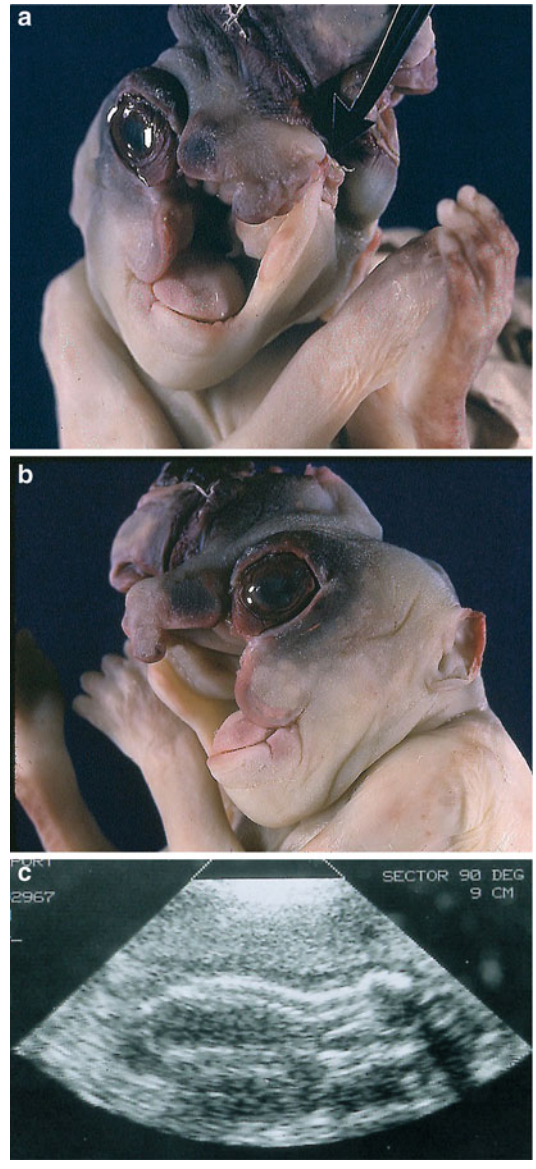

Fig. 11 (**a**–**c**) A fetus with marked craniofacial defects and the site of amniotic band attachment at the base of the skull. The fetus also had amputation of the distal left great toe (not shown). Prenatal ultrasonography showed a complex structure arising from the top and front of the craniofacial region

Fig. 12 An infant with marked craniofacial anomalies, a constricting ring of a finger with distal lymphedema, and an amputation of the fifth finger

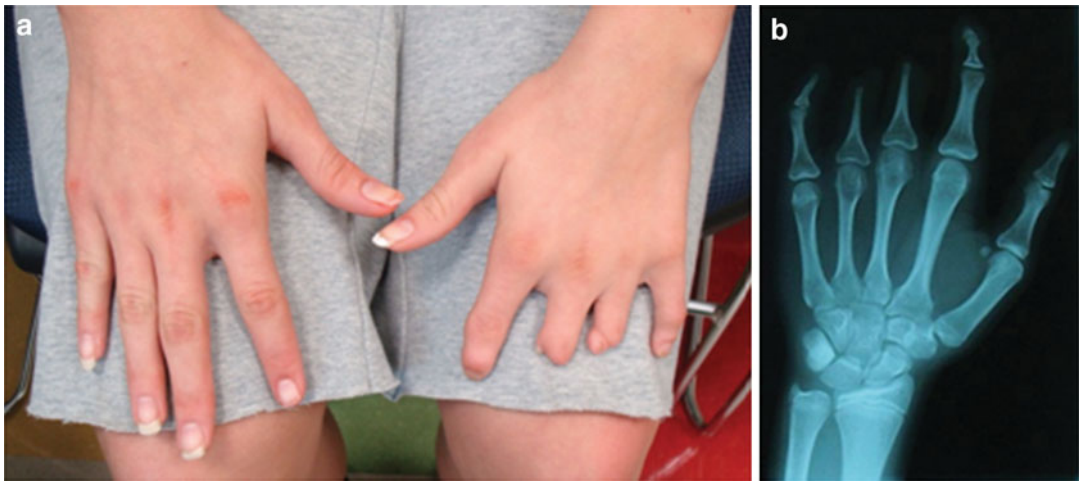

Fig. 13 (**a, b**) This 14-year-old Caucasian female was evaluated for amniotic band syndrome. The left hand was small and characterized by brachydactyly with characteristic preservation of nails (**a**). The radiograph of the left hand (**b**) showed poorly developed proximal phalanges, especially distal ends of 3rd–5th fingers, poorly developed middle phalanx of the 2nd and 5th fingers, missing middle phalanx of the 3rd and 4th fingers, and absence of distal phalanx of the 2nd-5th fingers. The right hand and fingers were normal

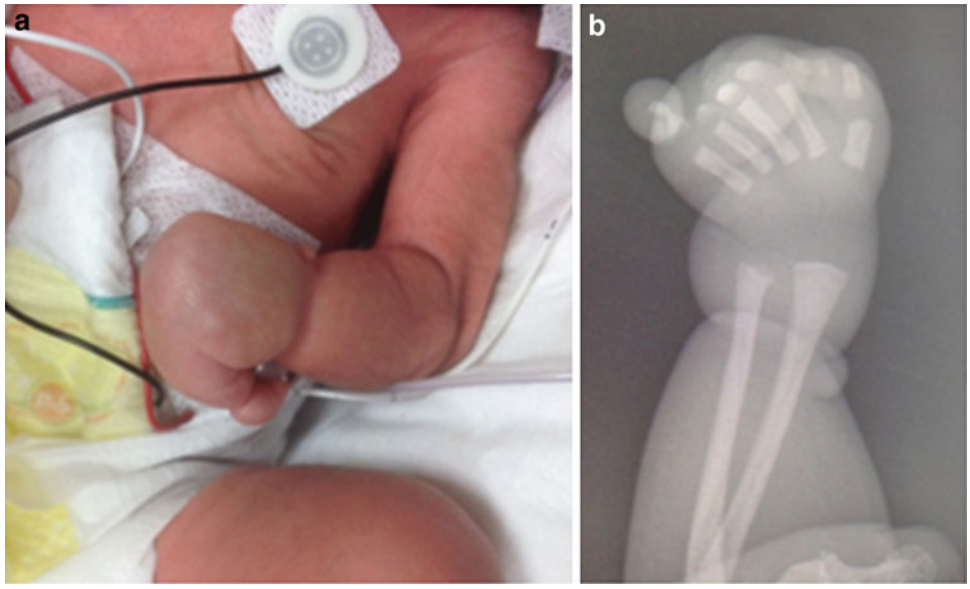

Fig. 14 (**a, b**) This newborn girl (**a**) was evaluated for amniotic band syndrome. The left hand was held in flexed position at the wrist with a constriction ring above. There was a fibrous strand extending from constriction ring area to the fingers. The 2nd and 4th fingers were partially amputated. There were constriction rings on the 3rd and 5th fingers with distal lymphedema, especially worst on the 5th. Radiograph of the left hand (**b**) showed the wrist in flexion position with absence of the mid- and distal phalanx of the 4th and 2nd fingers (Courtesy of Dr. Bharti Manchandia)

Androgen Insensitivity Syndrome

Contents

In 1953, Morris (Morris 1953) described the clinical phenotype of "testicular feminization" after reviewing 82 cases. Morris's phenotype included a female body habitus with normal breast development, minimal pubic and axillary hair, and typically absent or rudimentary vagina or absent uterus. The term "testicular feminization syndrome" was based on the observation of the complete absence of signs of virilization in phenotypic females with testes and a 46,XY karyotype. The change in nomenclature from testicular feminization to androgen insensitivity syndrome (AIS) was prompted by the finding of normal urinary 17-ketosteroid levels, an androgen metabolite, as well as by the absence of treatment effect when 46,XY women were treated with methyl testosterone, suggesting androgen resistance rather than a deficiency (Wilkins 1950; Speroff and Fritz 2005; Oakes et al. 2008).

AIS probably represents the most common cause of male pseudohermaphroditism (Holterhus et al. 1997). It is an X-linked recessive disorder in 46,XY individuals with normal androgen production and metabolism. The prevalence of AIS is estimated to be 1 in 20,000–1 in 99,000 genetic males (Bangsboll et al. 1992; Boehmer et al. 2001). The prevalence of phenotypic females with inguinal hernias is estimated to be 0.8–2.4% (Gans and Rubin 1962; Nielsen and Bulow 1976).

Synonyms and Related Disorders

Androgen receptor deficiency; Dihydrotestosterone receptor deficiency; Testicular feminization syndrome

Genetics/Basic Defects

1. Inheritance:
   1. X-linked recessive inheritance:
      1. Affected XY individuals
      2. Carrier XX females
   2. Manifesting carrier females (about 10% of carrier females)
2. Caused by mutations of androgen receptor (*AR*) gene (mapped to chromosomal locus Xq11–q12) (Lubahn et al. 1988):
   1. Mutations of androgen receptor: responsible for a variable degree of impaired androgen action
   2. De novo mutations:

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_12

1. De novo mutation rate close to 30%
2. Somatic or germ-line mosaicism observed for "de novo" mutations in which the mutation is present in some of the cells in one of the clinically unaffected parents (Boehmer et al. 1997)

3. Type of mutations (Gottlieb et al. 1999a, b)
   1. Point mutations
   2. Complete and partial gene deletions
   3. Small insertion deletions
4. Variable expressivity of a particular point mutation attributable to somatic mosaicism for the mutation (Holterhus et al. 1997)

3. Pathogenesis:
   1. Androgen insensitivity syndrome:
      1. Target tissue resistance to the androgen testosterone and its 5α-reduced product dihydrotestosterone leads to androgen insensitivity syndrome (Hughes and Deeb 2006).
      2. Normal production of testosterone and normal conversion to dihydrotestosterone (DHT) by the normal testes in affected individuals, differentiating this condition from 5α-reductase deficiency.
      3. Absence of fallopian tubes, uterus, or proximal (upper) vagina in affected individuals because testes produce normal amounts of müllerian-inhibiting factor (MIF).
   2. Complete androgen insensitivity syndrome (CAIS):
      1. Most severe form
      2. Complete resistance to all actions of testosterone and dihydrotestosterone
   3. Incomplete androgen insensitivity syndrome (IAIS) (Reifenstein syndrome):
      1. Partial resistance to the action of testosterone and dihydrotestosterone.
      2. Phenotypic variation in two siblings with partial androgen insensitivity syndrome with a point mutation of the androgen receptor gene (Evans et al. 1997): One sibling had clitoromegaly and labial fusion and was raised as a girl, whereas the other sibling had micropenis and penoscrotal hypospadias and was raised as a boy. The phenotypic variation in this family is thus dependent on factors other than abnormalities of the androgen receptor gene alone.
      4. Mild androgen insensitivity syndrome (MAIS): resistance to the action of androgen varies in different tissues
   4. Causes of a partial androgen insensitivity syndrome (Hughes et al. 2012):
      1. Defects in androgen production:
         1. Partial gonadal dysgenesis: mutations in *SRY*, *NR5A1*, and *WT1*
         2. Mutations of the luteinizing hormone receptor
         3. Biosynthetic enzyme deficiencies: 17,20-lyase deficiency, P450 oxidoreductase deficiency, 17β-hydroxysteroid dehydrogenase deficiency type 3, and 5α-reductase deficiency type 2
      2. Genetic:
         1. Klinefelter syndrome
         2. Smith-Lemli-Opitz syndrome
         3. Denys-Drash syndrome
         4. Frasier syndrome
      3. Partial androgen insensitivity syndrome:
         1. Mutations of the androgen receptor gene
         2. Normal androgen receptor gene with fetal growth restriction

Clinical Features

1. Variable phenotypic expression allowing the classification of AIS into complete and partial forms and a rare group of phenotypically normal men with azoospermia
2. Complete androgen insensitivity syndrome:
   1. Presumptive diagnosis of CAIS (Gottlieb et al. 2014):
      1. Absence of extragenital abnormalities
      2. Two nondysplastic testes
      3. Absent or rudimentary müllerian structures (absence of fallopian tubes, uterus, or cervix)
      4. A short vagina
      5. Under-masculinization of the external genitalia at birth

6. Impaired spermatogenesis (sterility) and/or somatic virilization at puberty
2. External phenotype:
   1. Invariably presenting as a normal female external appearance (female habitus)
   2. Female external genitalia ("testicular feminization," Tfm)
   3. Underdeveloped, short blind-ending vagina
   4. Normal breast and female adiposity development
   5. Unaffected sexual identity and orientation
   6. Scant or absent pubic and/or axillary hair
3. Urogenital tract:
   1. Absent or rudimentary Wolffian duct derivatives (epididymitis and/or vas deferens)
   2. Inguinal or labial masses subsequently identified as testes in a phenotypic female infant or child
   3. Inguinal hernia: the commonest presentation of CAIS in childhood (Deeb and Hughes 2005)
   4. 1.1% incidence rate of CAIS in a child with a premenarcheal inguinal hernia while 80–90% of girls with CAIS eventually develop an inguinal hernia (Gans and Rubin 1962; Viner et al. 1997; Sarpel 2005)
4. Other features:
   1. Primary amenorrhea in a phenotypic female adolescent: most typical presentation.
   2. Complete androgen insensitivity syndrome almost always runs true in families (i.e., affected XY relatives usually have normal female external genitalia and seldom have any sign of external genital masculinization, such as clitoromegaly or posterior labial fusion).

3. Partial androgen insensitivity syndrome (PAIS):
   1. Predominantly female external genitalia (incomplete androgen insensitivity syndrome):
      1. Signs of external genital masculinization:
         1. Clitoromegaly
         2. Partial fusion of the labioscrotal folds
      2. Female habitus and breast development
      3. Normal axillary and pubic hair
      4. Inguinal or labial testes as in CAIS
      5. Wolffian duct derivatives emptying into the vagina
      6. Distinct urethral and vaginal openings or a urogenital sinus
      7. No müllerian duct derivatives
   2. Ambiguous external genitalia (Reifenstein syndrome):
      1. Microphallus (<1 cm) with clitoris-like underdeveloped glans
      2. Labia majora-like bifid scrotum
      3. Descended or undescended testes
      4. Perineoscrotal hypospadias or urogenital sinus
      5. Gynecomastia in puberty
   3. Predominantly male external genitalia (Reifenstein syndrome):
      1. Simple (glandular or penile) or severe (perineal) "isolated" hypospadias with a normal-sized penis and descended testes or severe hypospadias with micropenis
      2. Bifid scrotum
      3. Either descended or undescended testes
      4. Gynecomastia in puberty
4. Mild androgen insensitivity syndrome:
   1. Two phenotypic forms at puberty:
      1. Impaired spermatogenesis and fertility
      2. Normal or sufficient spermatogenesis to preserve fertility
   2. Clinical features common to both forms:
      1. Male external genitalia ("undervirilized male syndrome")
      2. Gynecomastia in puberty
      3. High-pitched voice
      4. Sparse sex hair
      5. Impotence
5. Manifesting carrier females:
   1. Asymmetric distribution and sparse or delayed growth of pubic or axillary hair
   2. A history of late (15 years) or delayed (16 years or older) menarche
6. Classification of causes of disorders of sex development (please see the chapter of "► Ambiguous Genitalia")

7. Differential diagnosis (Oakes et al. 2008; Mendoza and Motos 2013):
    1. 5α-reductase deficiency:
        1. Internal male genitalia (testosterone dependent)
        2. No external genitalia (DHT dependent)
        3. Ambiguous or female genitalia at birth
    2. Mayer-Rokitansky-Kuster-Hauser (MRKH) syndrome (müllerian agenesis):
        1. A more common cause of primary amenorrhea: an incidence rate of 1 in 5,000 (Aittomaki et al. 2001)
        2. Lack a uterus and a vagina due to the absence of müllerian duct development
        3. Normal breast development
        4. Normal axillary and pubic hair (Speroff and Fritz 2005)
        5. A 46,XX karyotype
    3. Swyer syndrome (XY gonadal dysgenesis) (Nunes et al. 2014):
        1. There is complete gonadal dysgenesis and the lack of secretion of antimüllerian hormone leads to normal development of müllerian structures.
        2. Lack of breast development.
        3. Short stature.
        4. Localize testes and to rule out testicular tumors by ultrasound and MRI.

Diagnostic Investigations

1. Diagnostic workup:
    1. Diagnosis of CAIS usually based on:
        1. Clinical findings.
        2. Laboratory evaluation: hormone resistance is diagnosed when serum hormone concentrations are normal or high but the clinical effect is subnormal (Jääskeläinen 2012).
        3. Imaging studies including transabdominal pelvic ultrasound and MRI: to document internal anatomy.
    2. Diagnosis of PAIS and MAIS based on:
        1. Clinical findings
        2. Laboratory evaluation
        3. Family history consistent with X-linked recessive inheritance
2. Laboratory investigations:
    1. AIS:
        1. Chromosome analysis: 46,XY karyotype
        2. Evidence of normal or increased synthesis of testosterone by the testes
        3. Evidence of normal conversion of testosterone to 5α-dihydrotestosterone
        4. Evidence of normal or increased luteinizing hormone production by the pituitary gland
        5. Evidence of deficient or defective androgen-binding activity of genital skin fibroblasts
    2. CAIS, IAIS, Reifenstein syndrome, and MAIS:
        1. Chromosome analysis: 46,XY karyotype
        2. Testosterone: normal or high male plasma levels and production rates
        3. Estrogen: plasma levels and production rates higher than in normal men
        4. Gonadotropin: elevated plasma LH levels (may be normal in MAIS)
    3. Additional findings of sporadic cases of predominantly male phenotype of PAIS:
        1. Impaired development of the prostate and of the Wolffian duct derivatives demonstrated by ultrasonography or genitourography
        2. Less than normal decline of sex hormone-binding globulin in response to a standard dose of the anabolic androgen, stanozolol
        3. Higher than normal levels of antimüllerian hormone during the first year of life or at the beginning of puberty
3. Histologic investigations:
    1. CAIS:
        1. Testes: apparently normal in early life but begin to lose their germ cell population in late childhood
        2. Development of testicular hamartomas (composed of Sertoli and Leydig cells (Rutgers and Scully 1991), spindle cells, stroma, and germ cells in varying proportion) and benign and malignant tumors beginning in the postpubertal period

3. Germinal cell tumors, usually seminomas, in approximately 8% of CAIS cases
2. IAIS:
   1. Histologic appearance of the gonads similar to that of CAIS
   2. Cryptorchidic testes, usually containing spermatocytes and rare observation of spermatozoa in a minority of patients
3. MAIS with oligospermia or azoospermia in phenotypically normal males with testicular biopsy showing:
   1. Presence of Sertoli cell only
   2. Arrest of spermatogenesis at the spermatid stage

4. Detection of known mutations of the androgen receptor gene clinically available by sequence analysis and (multi)exonic or whole-gene deletion/duplication Gottlieb et al. 2014):
   1. CAIS: detected in 65–95% of patients
   2. PAIS: detected in <50% of patients
   3. MAIS: proportion of patients with detected mutations unknown

Genetic Counseling

1. Recurrence risk: genetic counseling according to X-linked recessive inheritance (Gottlieb et al. 2014):
   1. Patient's sib:
      1. Recurrence risk: low but greater than that of the general population because the possibility of germ-line mosaicism (Boehmer et al. 1997) exists provided the mother is not a carrier
      2. Fifty percent of sibs inheriting the mutation from the carrier mother:
         1. Sibs with a 46,XY karyotype who inherit the mutation will be affected.
         2. Sibs with a 46,XX karyotype who inherit the mutation will be carriers.
      3. Risk for another child with AIS is low if somatic mosaicism is present in the index patient (Holterhus et al. 1997).
   2. Patient's offspring:
      1. 46,XY individuals with AIS (i.e., CAIS, PAIS, MAIS): almost always infertile
      2. Manifesting carrier females: 50% risk of transmitting the AR gene mutation in each pregnancy
   3. Offspring of a known *AR* mutation carrier female:
      1. Twenty-five percent of 46,XY children: affected
      2. Twenty-five percent of 46,XY children: unaffected
      3. Twenty-five percent of 46,XX children: carrier
      4. Twenty-five percent of 46,XX children: not a carrier
      5. A wide range of phenotypes observed for the same mutation in different families making genetic counseling more difficult
2. Carrier detection:
   1. Family pedigree
   2. Clinical features:
      1. Asymmetric distribution and sparse or delayed growth of pubic or axillary hair in manifesting carriers (10% of carriers), resulting from skew X chromosome inactivation.
      2. Normal pubic and axillary hair do not rule out the 46,XX carrier state.
   3. Deficient or defective androgen-binding activity of single-cell clones from a genital skin fibroblast line, provided an affected 46, XY family member is known to have deficient or defective androgen-binding activity in a genital skin fibroblast cell line
   4. Molecular genetic testing (Davies et al. 1995; Hiort et al. 1998):
      1. A complete screening strategy of the entire androgen receptor gene needed to find the mutation in a new case of androgen insensitivity syndrome. Once the mutation is identified in the proband, carrier detection of other family members is possible.
      2. Intragenic polyglutamine and polyglycine trinucleotide repeats in the

N-terminal region of the androgen receptor may be used as polymorphisms to follow the affected X chromosome through the family and used for carrier status determination.

3. Prenatal diagnosis:
    1. Request for prenatal diagnosis uncommon.
    2. Finding of discordance between chromosomal and phenotypic sex by ultrasonographic and cytogenetic analysis (Bianca et al. 2009).
    3. 3D and 4D ultrasonography and surface rendering of external genitalia demonstrate the power in the detection of external and internal genital malformations (Mazza et al. 2013).
    4. Cell-free fetal DNA (cfDNA) testing (Zilberman et al. 2015).
    5. Molecular prenatal diagnosis of partial androgen insensitivity syndrome bases on the Hind III polymorphism of the androgen receptor gene (Hughes and Patterson 1994).
    6. Prenatal diagnosis by mutation analysis: clinically available in families in which the disease-causing allele has been identified in an affected family member.
    7. Fetal sex determination by amniocentesis or CVS:
        1. XX fetus: additional testing not warranted
        2. XY fetus: extract DNA for mutation analysis
    8. Sequencing of the androgen receptor, SRY, and 5α-reductase when the fetal genotype is male and fetal phenotype is female sonographically (Zilberman et al. 2015).
    9. Preimplantation and prenatal genetic diagnosis made using androgen receptor mutational analysis (deletion/insertion mutation) (Yu et al. 2012).
4. Management (Gottlieb et al. 2014):
    1. Psychological support:
        1. Probably the most important aspect of medical care
        2. Psychologist or psychiatrist consultations to help adjust to child's condition, including support on how to inform the child, over time and in an age-appropriate manner
        3. Androgen Insensitivity Syndrome Support Group (http://www.medhelp.org/www/ais)
    2. CAIS:
        1. Gender assignment and sex of rearing: uniformly female (Hughes and Deeb 2006).
        2. Inguinal hernia repair.
        3. Remove testes (gonadectomy) as soon as the diagnosis is made: current recommendation, however, is for removal of gonads after puberty (Oakes et al. 2008).
        4. The rationale for postpubertal gonadectomy: testicular malignancy seldom occurs before puberty unlike that of usual crypt orchid testes.
        5. Estrogen replacement therapy necessary to initiate puberty, maintain feminization, and avoid osteoporosis.
        6. Dilatation of short vaginal length (vaginoplasty) to avoid dyspareunia.
        7. Systemic disclosure of the condition to parents and patients in an empathic setting.
    3. PAIS with predominantly female genitalia:
        1. Management issues similar to CAIS.
        2. Prepubertal gonadectomy helps avoid discomfort of increasing clitoromegaly at the time of puberty.
    4. PAIS with ambiguous genitalia or predominantly male genitalia:
        1. Sex of rearing based on the genital phenotype, genital reconstructive surgery, and hormone therapy.
        2. Sex assignment in infants with ambiguous genitalia requires delicate decision-making by parents and health-care personnel and should be resolved as early as is feasible.
        3. A male sex of rearing demands a therapeutic trial with pharmacologic doses of androgen to predict potential androgen responsiveness at puberty and to facilitate reconstructive surgery.
        4. Reduction mammoplasty for gynecomastia developing in puberty.

5. MAIS:
    1. Reduction mammoplasty often required for gynecomastia
    2. A trial of androgen pharmacotherapy to improve virilization

Angelman Syndrome

Contents

In 1965, Angelman (Angelman 1965) reported three children with a similar pattern of severe learning disability, seizures, ataxic jerky movements, easily provoked laughter, absent speech, and dysmorphic facial features. The syndrome, which bears his name, was originally called the "happy puppet" syndrome. The incidence is estimated to be 1 in 12,000 to 1 in 20,000 (Clayton-Smith and Pembrey 1992; Petersen et al. 1995; Steffenburg et al. 1996).

Synonyms and Related Disorders

Happy puppet syndrome

Genetics/Basic Defects

1. Inheritance (Chan et al. 1993)
    1. Sporadic in most cases
    2. Rare familial transmission (always transmitted through maternal lineage)
2. Caused by deficiency of gene expression from abnormality on the maternally derived chromosome 15 because of genomic imprinting
    1. The relevant region on chromosome 15q
        1. Normally expressed on the maternally derived chromosome
        2. Normally imprinted on the paternally derived chromosome
    2. Inability of the imprinted paternal allele to produce functional protein since the normally expressed maternal copy is often deleted in Angelman syndrome
3. Genetic mechanisms responsible for the disorder (Malzac et al. 1998; Buiting 2010; Bird 2014)
    1. Chromosome deletions and translocations
        1. Deletion (de novo) of the maternally derived chromosome region 15q11-q13 (about 70%): affects several imprinted genes including *UBE3A* (E6AP-3A ubiquitin-protein ligase gene) (Kishino et al. 1997) and *SNRPN* (small nuclear ribonucleoprotein polypeptide N)
        2. Maternal somatic and germline mosaicism for 15q11-q13 deletion: reported as the cause for AS (Sanchez et al. 2014)
        3. Rare families with deletion due to unique chromosome 15 rearrangement within 15q11-q13 (<1%)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_13

4. Diagnostic tests
    1. Abnormal methylation analysis with presence of paternal band only
    2. Other diagnostic tests: high-resolution cytogenetics or FISH analysis
2. *UBE3A* and other presumed single-gene mutations (20–25%)
    1. Imprinting of the *UBE3A* gene with paternal silencing in human brain (Rougeulle et al. 1997)
    2. Inability to degrade unwanted proteins
    3. Compromise cellular functions secondary to absence of *UBE3A*
    4. Result in abnormal cortical functioning with severe mental retardation
    5. Diagnostic tests for mutations
        1. Normal methylation analysis with presence of both maternal and paternal bands
        2. Other diagnostic tests: screening of *UBE3A* for mutations
3. Paternal uniparental disomy (UPD) (both copies of a chromosome come from the father) of the chromosome 15 (Fridman and Koiffmann 2000) (1–2%)
    1. Paternal UPD is isodisomic in almost all cases.
    2. Most likely origin of paternal UPD: maternal nondisjunction producing a monosomy 15 conception, with postzygotic rescue by duplication of the paternal chromosome 15 (Mutirangura et al. 1993).
    3. Chromosomal nondisjunction events in Angelman syndrome: mainly due to mitotic errors, but paternal meiosis II nondisjunction (Gyftodimou et al. 1999) can occur and give origin to an AS UPD15 individual by two different mechanisms (rescue of a trisomic fetus or fertilization of a nullisomic egg with the disomic sperm) (Fridman and Koiffmann 2000).
    4. Affected individuals having two alleles of all genes (both derived from the father) but remain silenced with no production of functional protein.
    5. Milder phenotypic manifestations (lower incidence of seizures).
    6. Diagnostic tests
        1. Abnormal methylation analysis with presence of paternal band only
        2. Other diagnostic tests: RFLP analysis
4. Imprinting defects (2–4%)
    1. A mutation within the "imprinting center," located within 15q11-q13 on chromosome 15, renders the imprinting center unable to function properly (2%). Normally, imprinting center regulates which segments of DNA are imprinted.
        1. Abnormal methylation analysis with presence of paternal band only
        2. Positive screening for imprinting center for mutation
    2. Imprinting defect without imprinting center mutation (2%).
        1. Abnormal methylation analysis with presence of paternal band only
        2. Negative screening for imprinting center for mutation
    3. Mosaic imprinting defect (frequency unknown).
        1. Abnormal methylation analysis with presence of faint maternal band
        2. Usually negative screening for imprinting center for mutation
    4. Microdeletions reported in the imprinting center.
5. No genetic abnormality identified: Patients with clinical features of Angelman syndrome but no demonstrable cytogenetic or molecular abnormality of chromosome 15q11-q13

Clinical Features

1. Consistent cardinal features (100%) (Williams et al. 1995a, b, 2006; Cassidy 2000; Clayton-Smith and Laan 2003; Bird 2014)
    1. Normal newborn phenotype
        1. Normal prenatal and birth history
        2. Normal head circumference
        3. Absence of major birth defects

2. Developmental delay
    1. Starting around 6 months of age
    2. Eventually classified as severe developmental delay and/or severe intellectual disability
3. Profound speech impairment
    1. Absent or minimal use of words
    2. Receptive and nonverbal communication skills better than verbal capability
4. Jerky movement (Van Lierde et al. 1990) or balance disorder
    1. Abnormal ataxic gait
    2. Puppet-like jerky movements of limbs
    3. Hand-flapping movement
5. Typical behavioral pattern
    1. An easily excitable personality, often with hand-flapping movements
    2. Short attention span
    3. A happy, sociable disposition
    4. Inappropriately happy affect
    5. Bouts of inappropriate laughter
    6. Hypermotoric behavior

2. Frequent features (>80%)
    1. Delayed, disproportionate growth in head circumference, usually resulting in microcephaly by age 2
    2. Seizures (80%)
        1. Onset usually before 3 years of age (1–5 years)
        2. Variety of seizures (tonic-clonic, atypical absences, complex partial, myoclonic, atonic, tonic seizures to status epilepticus)
    3. Characteristic EEG with large-amplitude slow spike waves and triphasic waves
3. Associated features (20–80%)
    1. Hypotonia at birth
    2. Characteristic craniofacial appearance
        1. Microcephaly
        2. Flat occiput
        3. Occipital groove
        4. Strabismus
        5. Tongue thrusting
        6. Prognathia
        7. Wide mouth
        8. Widely spaced teeth
        9. Frequent drooling
        10. Excessive chewing/mouthing behaviors
    3. Gastrointestinal difficulties
        1. Swallowing disorder
        2. Feeding problems during infancy
        3. Gastroesophageal reflux
        4. Constipation
    4. Hypopigmented skin
    5. Light hair and eye color, compared to other family members, seen only in deletion cases
    6. Refractive and alignment errors
    7. Hyperactive lower limb deep tendon reflexes
    8. Uplifted, flexed arm position especially during ambulation
    9. Increased sensitivity to heat
    10. Sleep disturbance
    11. Fascination with water or crinkly items
    12. Mouthing behavior
    13. Ankle pronation
4. Adolescent and adult phenotype (Smith 2001)
    1. More striking facial features
        1. Marked mandibular prognathism
        2. Pointed chin
        3. Macrostomia
        4. Prominent lower lip
        5. Deeply set eyes
        6. Keratoconus secondary to eye rubbing
    2. Scoliosis and joint contractures increasing with age
    3. Improved hyperactivity and concentration
    4. Persistent sociable disposition
    5. A good quality of life maintained despite the above problems
    6. Life span not greatly reduced
5. Phenotype-genotype correlations (Lossie et al. 2001; Bird 2014)
    1. Patients with chromosome 15 deletions: in general, the most severely affected
        1. Higher incidence of seizures, microcephaly, and hypopigmentation. Severe epilepsy seen in these patients is considered to be the result of the absence of one copy of the *GABA* receptor genes.
        2. Greater delay in motor milestones.
        3. Absent speech.
        4. Shorter and lighter than the general population.

5. Severe clinical features thought to be the result of haploinsufficiency for a number of genes within the 15q11-q13 region.
2. Phenotype in the non-deletion cases: milder than in the deletion cases
3. Phenotype in the paternal UPD: milder than that of the deletion cases
    1. A low incidence of seizures, microcephaly, and hypopigmentation
    2. Able to say a few words in many patients
    3. Better growth parameters
    4. Less obvious dysmorphic features
    5. Typical behavioral pattern
4. Imprinting defects
    1. Less likely to have microcephaly, hypopigmentation, or seizures
    2. More able than the deletion group with less delay in motor milestones and better communication skills
    3. Growth better than the deletion patients
    4. Obesity relatively common within this group
5. Milder phenotype associated with incomplete imprinting defect or cellular mosaicism (displayed as Angelman syndrome methylation pattern) (Fairbrother et al. 2015)
6. Point mutations in the *UBE3A*
    1. Phenotype between the deletion group and the UPD group
    2. Frequently with mild or absence of ataxia, epilepsy, and microcephaly
    3. Not hypopigmented
    4. Better motor and communication skills than the deletion group

6. Differential diagnosis (Williams et al. 2001, 2010a; Dagli et al. 2015)
    1. Nonspecific psychomotor delay and/or seizures including cerebral palsy, static encephalopathy, and mitochondrial encephalomyopathy: tremulousness and jerky limb movements seen in most infants with Angelman syndrome are not seen in these conditions.
    2. Mowat-Wilson syndrome (Please see the chapter of Mowat-Wilson syndrome)
        1. Findings suggesting Angelman syndrome
            1. Happy affect
            2. Prominent mandible
            3. Diminished speech
            4. Microcephaly
            5. Constipation
        2. Typically results from heterozygous mutations in *ZEB2*
    3. Christianson syndrome (Christianson et al. 1999; Gilfillan et al. 2008)
        1. An X-linked disorder
        2. Caused by mutations in the *SLC9A6* gene
        3. Clinical features
            1. Apparently happy disposition.
            2. Severe cognitive delays.
            3. Ataxia.
            4. Microcephaly.
            5. Seizure disorder.
            6. A rapid (10–14 Hz) background frequency EEG, compared to a generalized high-amplitude, slow spike-wave (1.5–3 Hz) pattern seen in patients with *SLC9A6* mutations.
            7. Cerebellar and brain stem atrophy in some cases.
            8. Individuals with *SLC9A6* disorder may have thinner body appearance and may lose ambulation beyond 10 years of age.
    4. Adenylosuccinate lyase deficiency (Spiegel et al. 2006; Gitiaux et al. 2009)
        1. Results in accumulation of succinylpurines leading to:
            1. Psychomotor retardation
            2. Autistic features
            3. Hypotonia
            4. Seizures
        2. The following behavior profile may mimic Angelman syndrome:
            1. Motor apraxia
            2. Severe speech deficits
            3. Excessive laughter
            4. A very happy disposition
            5. Hyperactivity
            6. A short attention span
            7. Mouthing of objects
            8. Tantrums
            9. Stereotyped movements

5. Pitt-Hopkins syndrome
    1. Characteristic features
        1. Mental retardation.
        2. Distinctive facial features including wide mouth.
        3. Intermittent hyperventilation followed by apnea (Zweier et al. 2007). Diurnal hyperventilation is a salient feature in some and occurs after 3 years of age (Peippo et al. 2006).
    2. Mutation and deletion screening for the *TCF4* gene: available
6. Rett syndrome (Please see the chapter.)
    1. Seizures and severe speech impairment of Rett syndrome: resemble infant girls with Angelman syndrome, but children with Angelman syndrome do not have a regressive course and do not lose purposeful use of their hands, as do girls with Rett syndrome.
    2. Testing for mutations of *MECP2*: clinically available.
7. Prader-Willi syndrome (Please see the chapter): Prader-Willi and Angelman syndromes shared a common chromosome 15 deletion but differ in parental origin of the deletion (Knoll et al. 1989). Infants with Angelman syndrome who present with feeding difficulties and muscle hypotonia may be misdiagnosed as having Prader-Willi syndrome because the 15q11.2-q13 deletion, detected by comparative genomic hybridization (CGH) or fluorescent in situ hybridization (FISH), was not proven by DNA methylation analysis to be of maternal origin.
8. Other microdeletion syndromes
    1. Microdeletion of 22q13.3 deletion (Phelan-McDermid) syndrome (Precht et al. 1998)
        1. Nondysmorphic facial features
        2. Absent or minimal speech
        3. Moderate to severe developmental delay
        4. Behavioral features in the autism spectrum
    2. Microdeletions of the 2q23.1 region (van Bon et al. 2010; Williams et al. 2010b)
        1. Severe speech delay.
        2. Seizures.
        3. Behavioral disorders.
        4. Microcephaly. Some individuals present with an AS-like phenotype.
    3. Other new microdeletion disorders, detected by CGH, may be associated with some features of Angelman syndrome (Brunetti-Pierri et al. 2008; Sharkey et al. 2009).

Diagnostic Investigations

1. Normal metabolic, hematologic, and chemical laboratory profiles
2. Normal brain imagings (MRI, CT) with occasional mild cortical atrophy and dysmyelination
3. Abnormal EEG
    1. High-amplitude slow spike-wave activities (most common)
    2. Hypsarrhythmia (infantile spasm)
4. Cytogenetic studies
    1. To detect visible chromosome rearrangement (<1%)
        1. Translocation
        2. Inversion
    2. High-resolution chromosome studies to demonstrate large del(15)(q11-q13)
    3. Fluorescence in situ hybridization (FISH) to identify 15q11-q13 microdeletions, using D15S10 and/or *SNRPN* probes: detects about 70% of patients
5. DNA methylation studies: to demonstrate characteristic DNA methylation pattern (i.e., paternal imprint only) of 15q11-q13 cloned DNA sequences using methylation-sensitive restriction endonucleases
    1. Diagnose about 80% of classic Angelman syndrome including patients with a deletion, uniparental disomy, or an imprinting defect (Glenn et al. 2000).
    2. Certain maternally inherited genes are extensively methylated and thus inactivated while the paternal alleles are unmethylated and active in normal individuals.
    3. Unmethylated *SNRPN* alleles in patients with Angelman syndrome, caused by:

1. Uniparental disomy
2. Imprinting center defects
3. Typical 15q11-q13 deletion

4. Inability to distinguish the molecular classes (15q11-q13 deletion, uniparental disomy, or imprinting center defect).

6. *UBE3A* mutation analysis
   1. Detect mutations in the E6-AP ubiquitin-protein ligase gene.
   2. Detect additional 11% of patients.
   3. Invaluable in clinically typical Angelman syndrome patients with a normal methylation analysis (Fang et al. 1999).
   4. Intragenic *UBE3A* mutations include (Malzac et al. 1998; Fang et al. 1999):
      1. Insertion
      2. Deletion
      3. Nonsense mutation
      4. Missense mutation
      5. Splice mutation
7. DNA polymorphisms to demonstrate absence of maternal alleles at 15q11-q13 loci, which may result either from maternal deletion or from paternal uniparental disomy
   1. Determined by analysis of simple sequence repeats (microsatellites) in the parents and affected individual.
   2. Determine parental origin of 15q11-q13 and the rest of chromosome 15.
   3. Detect patients with deletions and uniparental disomy but not the *UBE3A* mutation class of patients.
   4. Detect biparental inheritance of 15q11-q13 with abnormal DNA methylation in patients with imprinting center defects.
8. Simple algorithm for genetic testing in patients with clinical suspicion of Angelman syndrome (Clayton-Smith and Laan 2003; Williams et al. 2010a)
   1. Abnormal methylation analysis
      1. FISH analysis or array CGH if methylation analysis is abnormal
         1. Presence of del(15)(q11.3-q13) (5–7 Mb deletion)
         2. Absence of del(15)(q11-q13)
      2. RFLP analysis if FISH analysis is negative
         1. Presence of UPD
         2. Absence of UPD
      3. Angelman syndrome imprinting center deletion analysis (2–200 kb deletions) if UPD is absent
   2. Normal methylation analysis
      1. Screen *UBE3A* mutation (sequence analysis for sequence variants and gene or intragenic deletion study for partial or whole-gene deletions) in clinically typical patients
         1. If positive, check parents.
         2. If negative, keep on reviewing patient's findings; for patients with an AS phenotype, consider an alternative diagnosis such as Pitt-Hopkins syndrome, Mowat-Wilson syndrome, Kleefstra syndrome, Phelan-McDermid syndrome, Koolen-de Vries syndrome, Christianson syndrome, and MBD5 haploinsufficiency (Williams et al. 2001; Tan et al. 2014).
      2. No further testing required for clinical normal patients (not Angelman syndrome)
9. Currently, about 10% of patients with classic phenotypic features of Angelman syndrome are not amenable to diagnostic testing due to presently unidentified genetic mechanisms.
10. Consensus criteria for the diagnosis of Angelman syndrome by laboratory findings and genetic test abnormalities (Williams et al. 2006)
    1. Normal metabolic, hematologic, and chemical laboratory profiles.
    2. Structurally normal brain using MRI or CT (may have mild cortical atrophy or dysmyelination).
    3. Characteristic Angelman syndrome pattern of DNA methylation of the *SNURF-SNRPN* exon 1/promoter. Detects cases due to 15q11.2-q13 deletion, UPD, and imprinting defects (may have mosaic methylation pattern in non-deletion imprinting defects).
    4. Abnormal FISH indicates a deletion of 15q11.2-q13 DNA sequences within the common Angelman syndrome deletion overlap region.

1. Use of a pericentromeric FISH probe enhances the ability to detect subtle translocation.
2. Array CGH can be used to detect the deletion but confirmation by FISH is currently required.
3. Class I and II deletions can be distinguished by array CGH or FISH using appropriate clones.

5. DNA polymorphism analysis within 15q11.2-q13 showing paternal UPD.
6. Deletion in the imprinting center, demonstrated by real-time PCR, single-copy FISH, or other analysis methods of the Angelman syndrome imprinting center smallest region of overlap (SRO).
7. Pathogenic DNA sequence change in the *UBE3A* gene.

11. Diagnostic approach (van Buggenhout and Fryns 2009; Williams et al. 2010a)
    1. Cytogenetic study: large deletion/translocation/duplication: Rare (<1%)
    2. DNA methylation test
        1. Abnormal
            1. FISH and CGH: to demonstrate 5–7 Mb deletion of 15q11.2-q13 (about 68% of the patients)
            2. UPD study to demonstrate paternal UPD (about 7% of the patients)
            3. Imprinting center deletion study to demonstrate: imprinting center defect (about 3% of the patients)
        2. Normal
            1. Sequence analysis of the *UBE3A* gene detects mutations in about 11% of the patients.
            2. Gene or intragenic deletion study of *UBE3A* gene detects partial or whole-gene deletions (rare).

Genetic Counseling

1. Recurrence risks: depending on the genetic mechanism involved and on whether the mother is shown to carry genetic abnormalities of 15q11-q13 (Khan and Wood 1999; Laan 1999; Buiting 2010; Williams et al. 2010a; Dagli et al. 2015)
    1. Reasons of difficulty in providing recurrence risk estimation:
        1. Causal heterogeneity of Angelman syndrome
        2. Maternal germ cell mosaicism (Stalker et al. 1998)
    2. Patient's sib (Ramsden et al. 2010)
        1. Most cases (70–75%) of Angelman syndrome (resulting from de novo deletion of 15q11-q13 on the maternal chromosome) have a recurrence risk of <1% (Stalker and Williams 1998).
        2. For proband with a large deletion: <1% risk to sibs. However, germline mosaicism for these large deletions has been reported (Kokkonen and Leisti 2000).
        3. For proband with an inherited small interstitial deletion or an unbalanced chromosome translocation: The risk to sibs depends on whether the rearrangement is inherited or de novo (Horsthemke et al. 1996; Stalker and Williams 1998), possibly as high as 50%.
        4. For proband with paternal UPD of chromosome 15 (3–7% of cases) (in families in which Angelman syndrome is the result of paternal UPD and in which no Robertsonian chromosomal translocation is identified): The risk to sibs of having Angelman syndrome is <1% (the risk figure is based on the lack of recurrence among all known cases of UPD in Angelman syndrome with normal chromosomes).
        5. For proband with paternal UPD and with predisposing parental translocation: approaching 100% if father has a 15;15 Robertsonian translocation.
        6. For proband with imprinting defect:
            1. With an imprinting center deletion excluded (2–3% of cases): <1%
            2. With inherited imprinting center deletion (about 10–15% of patients with an imprinting defect): up to 50% (if present in the mother)

7. For proband with *UBE3A* mutation (about 10% of cases):
    1. De novo mutation: <1%
    2. With inherited mutation from mother: 50%
8. For families with familial structural chromosomal rearrangements, recurrence risk varies, depending upon the chromosomes that are involved (Yesodharan et al. 2014):
    1. Reported rare occurrence of two siblings with AS.
    2. Their karyotypes revealed monosomy of chromosome 15 and a derivative chromosome 1 leading to AS.
    3. Their mother was a balanced translocation carrier involving chromosomes 1p and 15p.
9. For proband without identifiable molecular abnormality (about 10% of cases): undetermined risk (up to 50%)

3. Patient's offspring: To date, only one individual with Angelman syndrome reported to have reproduced (Lossie and Driscoll 1999)
    1. Females with Angelman syndrome are fully capable of reproduction: The mother and fetus inherited large deletions of maternal 15q11-13.
    2. Demonstrated paternal-only DNA methylation imprints along 15q11-13.
    3. *UBE3A* was paternally expressed (not imprinted) in eye tissue from the fetus with Angelman syndrome.

2. Prenatal diagnosis
    1. Possible when the underlying genetic mechanism is as follows:
        1. A deletion
        2. Uniparental disomy
        3. An imprinting defect
        4. A *UBE3A* mutation
        5. A chromosome rearrangement
    2. Combined use of methylation analysis, chromosomal/FISH analysis, and DNA marker studies through analysis of fetal cells obtained by CVS or amniocentesis: to identify the common ~4-Mb deletion, paternal UPD, or imprinting mutation in about 70–80% of cases with Angelman syndrome.
    3. Mutation analysis for *UBE3A* (Tsai et al. 1998).
    4. Readily accomplished if a disease-causing mutation is identified and is present in the mother.
    5. Dilemmas associated with the molecular characterization of a fetus (Gilbert et al. 1997): DNA prepared from a 21-week fetal blood sample detected a fetus with normal maternal and paternal DNA methylation patterns but inherited the same maternal chromosome 15q11-q13 as the affected sibs. This is probably a result of germline mosaicism in the mother.
    6. Preimplantation genetic diagnosis:
        1. Available for families in which the underlying mechanism has been identified in the proband to be UBE3A mutations or imprinting center deletions.
        2. The relative hypomethylation of the early embryo makes PGD problematic for DNA methylation testing.

3. Management (Williams 2001)
    1. Routine management
        1. Feeding difficulties
        2. Constipation
        3. Gastroesophageal reflux
        4. Strabismus
    2. Seizure control difficult with antiepileptic drugs, especially in childhood
        1. Sodium valproate as monotherapy or in combination with clonazepam or other benzodiazepines
        2. Experience with the newer antiepileptic drugs: very limited
        3. Vagal stimulation needed for seizures refractory to pharmacological intervention (Thibert et al. 2009)
    3. Physical therapy for unstable or nonambulatory children
    4. Occupational therapy for improving fine motor and oral-motor control
    5. Speech and communication therapy

    1. Augmentative communication aids, such as picture cards or communication boards
    2. Sign language
6. Consistent behavioral modifications
7. Orthopedic management
    1. Subluxed or pronated ankles
    2. Tight Achilles tendons
    3. Scoliosis
8. Primary areas of clinical management in adults (Larson et al. 2015)
    1. Seizures
    2. Sleep
    3. Aspiration risk
    4. Gastroesophageal reflux disease
    5. Constipation
    6. Dental care
    7. Vision
    8. Obesity
    9. Scoliosis
    10. Bone density
    11. Mobility
    12. Communication

Apert Syndrome

Contents

Apert syndrome is named after the French physician who described the syndrome acrocephalosyndactylia in 1906. Apert syndrome is a rare autosomal dominant disorder characterized by craniosynostosis, craniofacial anomalies, and severe symmetrical syndactyly (cutaneous and bony fusion) of the hands and feet. It probably is the most familiar and best-described type of acrocephalosyndactyly. Prevalence is estimated at 1 in 65,000 (approximately 15.5 in 1,000,000) live births (Cohen et al. 1992; Cohen and Kreiborg 1992, 1993a). Apert syndrome accounts for 4.5% of all cases of craniosynostosis.

Synonyms and Related Disorders

Acrocephalosyndactyly types 1 and 2; Apert-Crouzon disease; Vogt cephalodactyly

Genetics/Basic Defects

1. Inheritance
   1. Autosomal dominant.
   2. Sporadic in majority (>98%) of cases, resulting from new mutations with a paternal age effect (Moloney et al. 1996).
   3. Rarity of familial cases can be explained by reduced genetic fitness of individuals because of severe malformations and the presence of mental retardation in many cases.
   4. Two sisters born to normal unrelated parents: the 1st known example of germinal mosaicism in Apert syndrome (Allanson 1986).
2. Cause
   1. Caused by specific missense substitution mutations, involving adjacent amino acids (i.e., Ser252Trp or Pro253Arg) in the linker between the second and third extracellular immunoglobulins domains of *FGFR2*, which maps to chromosome bands 10q25-q26 (more than 98% of cases with Apert syndrome).
   2. Remaining cases are caused by Alu-element insertion mutations in or near exon 9 of *FGFR2* (Oldridge et al. 1999).
3. Pathogenesis (Kreiborg and Cohen 1990; Chen 2014)
   1. Unique fibroblast growth factor receptor 2 (*FGFR2*) mutations (Lomri et al. 1998)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_14

1. Leading to an increase in the number of precursor cells that enter the osteogenic pathway
2. Ultimately leading to increased subperiosteal bone matrix formation and premature calvaria ossification during fetal development

2. Fusion of the cranial sutures
   1. The order and rate of suture fusion determine the degree of deformity and disability.
   2. Once a suture becomes fused, growth perpendicular to that suture becomes restricted, and the fused bones act as a single bony structure.
   3. Compensatory growth occurs at the remaining open sutures to allow continued brain growth.
   4. Complex, multiple sutural synostosis frequently extends to premature fusion of the sutures at the base of the skull, causing midfacial hypoplasia, shallow orbits, a foreshortened nasal dorsum, maxillary hypoplasia, and occasional upper airway obstruction.
3. Syndactyly of Apert syndrome
   1. A keratinocyte growth factor receptor (KGFR)-mediated effect, provided by the observation of the correlation between KGFR expression in fibroblasts and severity of syndactyly.
   2. Different phenotypic expressions in patients with Ser252Trp and those with Pro253Arg. The syndactyly is more severe with Pro253Arg mutation (Lajeunie et al. 1999) for both hands and feet, whereas cleft palate is significantly more common with Ser252Try mutation (Slaney et al. 1996).
4. During early infancy (younger than 3 months of age)
   1. Premature closure of the coronal suture area, evident by a bony condensation line beginning at the cranial base and extending upward with a characteristic posterior convexity.
   2. Widely patent anterior and posterior fontanelles.
   3. Presence of a gaping defect of the midline of the calvaria, extending from the glabellar area to the posterior fontanelle via the metopic suture area, anterior fontanelle, and sagittal suture area. The skull with gaping midline defect appears to permit adequate accommodation of the growing brain.
   4. Normal lambdoidal sutures in all cases.
5. During the first 2–4 years of life
   1. Obliteration of the midline defect by coalescence of the enlarging bony islands without evidence of any proper formation of sutures.
   2. Very early onset in fetal life of growth inhibition in the sphenofrontal and coronal suture area, suggested by an extremely short squama and orbital part of the frontal bone together with the posterior convexity of the coronal bone condensation line.

Clinical Features

1. History (Chen 2014)
   1. Headache and vomiting: signs of acute increase of intracranial pressure, especially in cases of multiple suture involvement.
   2. Stridor and sleep apnea indicate upper airway problems, due to craniosynostosis of the base of the skull.
   3. Visual disturbance due to exposure keratitis and conjunctivitis.
   4. Mental retardation in many patients, though patients with normal intelligence have been reported (Patton et al. 1988; Renier et al. 1996).
2. Skull
   1. Craniosynostosis
   2. Coronal sutures most commonly involved, resulting in acrocephaly, brachycephaly, turribrachycephaly, flat occiput, and high prominent forehead
   3. Large late-closing fontanels
   4. Gaping midline defect

5. Rare cloverleaf skull anomaly in approximately 4% of infants

3. Facial features (Cohen and Kreiborg 1996)
   1. Horizontal grooves above the supraorbital ridges that disappear with age
   2. A break in the continuity of the eyebrows
   3. A trapezoid-shaped mouth at rest
   4. Flattened, often asymmetric face
   5. Maxillary hypoplasia with retruded midface
   6. Eyes (Buncic 1991)
      1. Down-slanting palpebral fissures
      2. Hypertelorism
      3. Shallow orbits
      4. Proptosis
      5. Exophthalmos
      6. Lateral ptosis
      7. Widened palpebral fissures
      8. Tearing secondary to exposure keratitis
      9. Prolonged corneal exposure resulting in corneal scars and opacification
      10. Partially open eye during sleep
      11. Strabismus
      12. Amblyopia
      13. Optic atrophy
      14. Keratoconus
      15. Ectopic lentis
      16. Congenital glaucoma
      17. Lack of pigment in the fundi with occasional papilledema
      18. Rare luxation of the eye globes as an extreme complication of severe exorbitism, producing possible strangulation of the circulation of the globe and blindness
   7. Mouth: characteristic trapezoidal shape (Kreiborg and Cohen 1992)
      1. A prominent mandible
      2. Down-turned corners
      3. High arched palate
      4. Bifid uvula
      5. Cleft palate
      6. Crowded upper teeth
      7. Malocclusion
      8. Delayed dentition
      9. Ectopic eruption
      10. Shovel-shaped incisors
      11. Supernumerary teeth
      12. V-shaped maxillary dental arch
      13. Bulging alveolar ridges
   8. Ears (Gould and Caldarelli 1982)
      1. Apparent low-set ears
      2. Occasional conductive hearing loss
      3. Congenital fixation of stapedial footplate
4. Extremities and digits
   1. The upper limbs affected more severely than lower limbs.
   2. Coalition of distal phalanges and synonychia of the hands (never present in the feet).
   3. The glenohumeral joint and proximal humerus affected more severely than the pelvic girdle and femur.
   4. The elbow involved much less severely than the proximal portion of the upper limb.
   5. Syndactyly of the hands and feet with partial-to-complete fusion of the digits, often involving second, third, and fourth digits. These often are termed mitten hands and socked feet. In severe cases, all digits are fused, with the palm deeply concave or cup shaped and the sole supinated.
   6. Hitchhiker posture or radial deviation of short or broad thumbs resulting from abnormal proximal phalanx.
   7. Brachydactyly.
   8. Contiguous nail beds (synonychia).
   9. Subacromial dimples and elbow dimples during infancy.
   10. Limited mobility at the glenohumeral joint with progressive limitation in abduction, forward flexion, and external rotation.
   11. Limited elbow mobility common with decreased elbow extension, flexion, pronation, and supination.
   12. Short humeri, a constant finding beyond infancy.
   13. Limited genu valga present in many cases.
5. Other skeletal and cartilaginous segmentation defects
   1. Congenital cervical spinal fusion (68%), especially C5–C6 (Kreiborg et al. 1992)

2. Aplasia or ankylosis of shoulder, elbow, and hip joints
3. Tracheal cartilage anomalies
4. Rhizomelia (Cohen and Kreiborg 1993c)

6. CNS
   1. Intelligence varying from normal to mental deficiency, though a significant number of patients are mentally retarded. Malformations of the CNS may be responsible for most cases.
   2. Common CNS malformations (Cohen and Kreiborg 1990).
      1. Megalencephaly.
      2. Agenesis of the corpus callosum.
      3. Malformed limbic structures.
      4. Variable ventriculomegaly. Progressive hydrocephalus is uncommon.
      5. Encephalocele.
      6. Gyral abnormalities.
      7. Hypoplastic cerebral white matter.
      8. Pyramidal tract abnormalities.
      9. Heterotopic gray matter.
      10. Papilledema and optic atrophy with loss of vision in cases with insidious intracranial pressure increase.
7. Cardiovascular (10%) (Cohen and Kreiborg 1993b)
   1. Atrial septal defect
   2. Patent ductus arteriosus
   3. Ventricular septal defect
   4. Pulmonary stenosis
   5. Overriding aorta
   6. Coarctation of aorta
   7. Dextrocardia
   8. Tetralogy of Fallot
   9. Endocardial fibroelastosis
8. Genitourinary (9.6%) (Cohen and Kreiborg 1993b)
   1. Polycystic kidneys
   2. Duplication of renal pelvis
   3. Hydronephrosis
   4. Stenosis of bladder neck
   5. Bicornuate uterus
   6. Vaginal atresia
   7. Protuberant labia majora
   8. Clitoromegaly
   9. Cryptorchidism
9. Gastrointestinal (1.5%) (Cohen and Kreiborg 1993b)
   1. Pyloric stenosis
   2. Esophageal atresia and tracheoesophageal fistula
   3. Ectopic or imperforate anus
   4. Partial biliary atresia with agenesis of gallbladder
10. Respiratory (1.5%) (Cohen and Kreiborg 1993b)
    1. Anomalous tracheal cartilage
    2. Tracheoesophageal fistula
    3. Pulmonary aplasia
    4. Absence of right middle lobe of the lung
    5. Absence of interlobular lung fissures
11. Skin (Cohen and Kreiborg 1995b)
    1. Hyperhidrosis (common)
    2. Acneiform lesions frequent after adolescence
    3. Interruption of the eyebrows
    4. Hypopigmentation
    5. Hyperkeratosis in the plantar surface
    6. Paronychial infections more commonly affected in feet than hands and observed more commonly in institutionalized patients
    7. Excessive skin wrinkling of forehead
    8. Skin dimples at knuckles, shoulders, and elbows
12. At risk for complications resulting from elevated intracranial pressure despite surgical attempts to increase cranial capacity in infancy
13. Early death
    1. Upper airway compromise
       1. Reduction in nasophrynx size
       2. Choanal patency
       3. Obstructive sleep apnea
       4. Cor pulmonale
    2. Lower airway compromise due to anomalies of the tracheal cartilage
14. Differential diagnosis (Cohen 1977, 1988; Chen 2014; Jabs 1998)
    1. Beare-Stevenson syndrome
       1. Mental retardation
       2. Associated cutaneous disorders
          1. Cutis gyrata
          2. Acanthosis nigricans (hands and feet)
       3. Caused by *FGFR2* mutations

2. Carpenter syndrome (see the chapter)
    1. An autosomal recessive disorder
    2. A peculiar face
    3. Preaxial polydactyly of hands, feet, or both
    4. Absence of osseous fusion of hand bones
3. *FGFR3*-associated coronal synostosis syndrome
    1. Variable clinical presentation overlapping with Pfeiffer, Jackson-Weiss, or Saethre-Chotzen syndrome phenotypes.
    2. Some individuals with a disease-causing mutation may have no clinical problems.
4. Jackson-Weiss syndrome
    1. Caused by *FGFR2* mutations
    2. Enlarged or broad great toes with varus deviation
    3. Tarsal or metatarsal fusion
    4. Lack of thumb abnormalities
    5. Midface hypoplasia
5. Pfeiffer syndrome
    1. Identifiable mutations in *FGFR1* and *FGFR2* (∼67% of patients)
    2. Hand and foot abnormalities
        1. Broad thumbs and halluces
        2. Occasional cutaneous syndactyly
    3. Lack of osseous fusion of the phalanges
    4. Craniofacial features
        1. Turribrachycephaly
        2. Occasional cloverleaf skull
        3. Ocular hypertelorism
        4. Shallow orbits
        5. Sown-slanting palpebral fissures
        6. Proptosis
        7. Strabismus
        8. Low nasal bridge
        9. Small nose
        10. Maxillary hypoplasia
        11. Mandibular prognathism
6. Saethre-Chotzen syndrome (see the chapter)
    1. Characteristic facies
    2. Relatively mild cranial deformity
    3. Lack of osseous fusion of the hand bones
    4. Identifiable mutations in the *TWIST* gene (∼75% of patients).

Diagnostic Investigations

1. Psychometric evaluation
2. Hearing assessment
3. Imaging studies
    1. Skull radiography to evaluate craniostenosis, which usually involves coronal sutures and maxillary hypoplasia
        1. Sclerosis of suture line
        2. Bony bridging and beaking along the suture line
        3. An indistinct suture line
        4. Turribrachycephaly
        5. Shallow orbits
        6. Hypoplastic maxillae
    2. Spine radiography (Thompson et al. 1996)
        1. Spinal fusions, most commonly at the levels of C3–4 and C5–6, appearing to be progressive and occurring at the site of subtle congenital anomalies
        2. Small-sized vertebral body and reduced intervertebral disk space: indicators of subsequent bony fusion
    3. Limb radiography (Cohen and Kreiborg 1995a)
        1. Multiple epiphyseal dysplasia (Cohen and Kreiborg 1993d).
        2. Short humeri.
        3. Glenoid dysplasia.
        4. Cutaneous and osseous syndactyly.
        5. Complete syndactyly involving the second and fifth digits (mitten hands).
        6. Multiple progressive synostosis involves distal phalanges, proximal fourth and fifth metacarpals, capitate, and hamate.
        7. Progressive symphalangism of interphalangeal joints.
        8. Shortened and radial deviation of distal phalanx.
        9. Delta-shaped deformity of proximal phalanx of the thumbs.
        10. Complete syndactyly involving the second and fifth toes (socked feet).

11. Fusion of tarsal bones, metatarsophalangeal and interphalangeal joints, and adjacent metatarsals.
12. Delta-shaped proximal phalanx of the first toes.
13. Occasional partial or complete duplication of the proximal phalanx of the great toes and first metatarsals.

4. Computed tomography
    1. CT scan with comparative 3-dimensional reconstruction analysis of the calvaria and cranial bases: the most useful radiological examination in identifying skull shape and presence or absence of involved sutures
    2. Precise definition of the pathological anatomy, permitting specific operative planning
5. Magnetic resonance imaging
    1. Demonstration of the anatomy of the soft tissue structures and associated brain abnormalities
    2. Visualization of the spatial arrangement of the bones

4. Molecular analysis
    1. Exquisitely specific molecular mechanism with a narrow mutational spectrum
    2. More than 98% of cases: caused by specific missense substitution mutations, involving adjacent amino acids (Ser252Trp, Ser252Phe, or Pro253Arg) in exon 7 of *FGFR2*
    3. The remaining cases: due to Alu-element insertion mutations in or near exon 9.

Genetic Counseling

1. Recurrence risk
    1. Patient's sib.
        1. A negligible recurrence risk for patient's sib when parents are not affected except in the case of germinal mosaicism in which the risk for future sibs depends on the proportion of germ cells bearing the mutant allele.
        2. 50% risk, if a parent is also affected
    2. Patient's offspring: a 50% recurrence risk for an affected individual to have an affected offspring.
    3. Advanced paternal age effect in new mutations has been shown clinically and demonstrated conclusively at the molecular level.
2. Prenatal diagnosis (Hill et al. 1987; Kaufmann et al. 1997; Ferreira et al. 1999; Skidmore et al. 2003; Quintero-Rivera et al. 2006)
    1. Prenatal ultrasonography in low-risk pregnancies with finding of abnormal fetal skull shape
        1. Prenatal diagnosis of Apert syndrome suspected with findings of fetal "mitten hands" associated with abnormal skull shape and midfacial hypoplasia and confirmed by molecular diagnosis. Craniosynostosis is usually not detected until the third trimester.
        2. Low yield for testing mutations in the *FGFR2* gene.
        3. Mutation identification not helpful in determining the prognosis of a fetus, which is largely determined by the clinical diagnosis and not by the molecular diagnosis.
    2. Prenatal MRI: a useful and sometimes indispensable, additional diagnostic tool (Weber et al. 2010)
    3. Fetoscopy (Leonard et al. 1982) to visualize fetal anomalies comparable to Apert syndrome in a pregnancy at risk: an invasive procedure not used currently
    4. Molecular genetic analysis
        1. An affected parent with identified mutation of *FGFR2* gene: prenatal diagnosis available on fetal DNA obtained through amniocentesis or chorionic villus sampling
        2. An affected parent without identified mutation of *FGFR2* gene: linkage analysis available to an informative family with at least two affected family members based on an accurate clinical diagnosis and an accurate understanding of genetic relationships in the family
3. Management
    1. Treatment goals (Fearon and Podner 2013)

1. Prevention of avoidable developmental delays from raised intracranial pressure and sleep apnea.
2. Reducing operative interventions may potentially improve developmental outcomes.

2. Protection of the cornea
   1. Instill lubricating bland ointments in the eyes at bedtime to protect corneas from desiccation
   2. Artificial teardrops during the day
   3. Lateral or medial tarsorrhaphy in severe cases to narrow the palpebral fissure cosmetically and protect the corneas and the vision
3. Upper airway obstruction during the neonatal period
   1. Remove excessive nasal secretions
   2. Treat upper airway infection
   3. Humidification with added oxygen
   4. Judicious use of topic nasal decongestants
   5. Rarely requires orotracheal intubation
4. Sleep apnea
   1. Polysomography (a sleep recording of multiple physiologic variables), currently the most reliable method for determining the presence of sleep apnea
   2. Continuous positive pressure
   3. Tracheostomy indicated in severely affected children
5. Chronic middle ear effusion associated with bilateral conductive hearing deficit
   1. Antimicrobial therapy
   2. Bilateral myringotomy and placement of ventilation tubes: the most effective treatment
6. Craniofacial surgery (Marsh et al. 1991)
   1. Cranium
      1. Removes synostotic sutures
      2. Reshapes the calvaria
      3. Allows more normal cranial development to proceed with respect to shape, volume, and bone quality
      4. Relieves increased intracranial pressure
   2. Orbits
      1. Correction of ocular proptosis: the primary objective of orbital surgery
      2. Reduction of increased interorbital distance (hypertelorism)
      3. Correction of increased interior malrotation
   3. Nose
      1. Infants and child: nasal reconstruction focusing on correction of the excessively obtuse nasofrontal angle, flat nasal dorsum, and ptotic nasal tip
      2. Teenager and adult: reduction of the nasal tip bulk
   4. Midface
      1. Normalization of midface appearance
      2. Expansion of the inferior orbit
      3. Volumetric expansion of the nasal and nasopharyngeal airways
      4. Establishment of a normal dentoskeletal relationship
   5. Mandible: mandibular osteotomies to improve dentoskeletal relations for masticatory and esthetic benefit
7. Surgical reconstruction of syndactyly angiographic planning of a single-stage, 5-digit release for all classes of deformity (Harvey et al. 2012)
8. Psychological and social challenges confronted by individuals with Apert syndrome (Campis 1991)
   1. Emotional adjustment
   2. Body image development
   3. Impact of surgery and hospitalization on children with Apert syndrome.

Fig. 1 (**a**–**d**) An infant with Apert syndrome showing characteristic facial appearance and typical mitten hands and socked feet

Fig. 2 (**a**–**d**) A 13-year-old girl with Apert syndrome showing characteristic facial appearance and postoperative status of the fingers and toes

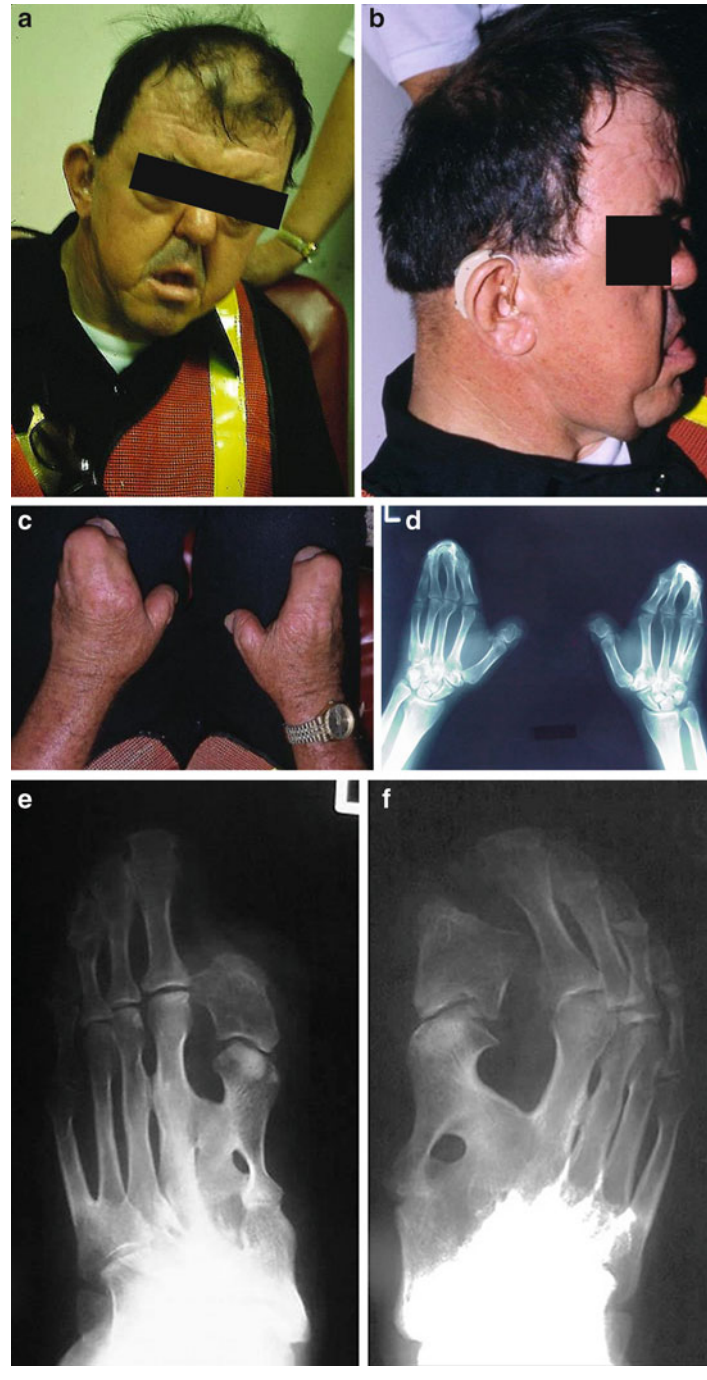

Fig. 3 (**a**–**f**) An adult with Apert syndrome showing typical craniofacial appearance, hearing loss (wearing hearing aids), and mitten hands. Radiographs showed cutaneous and osseous syndactyly, complete syndactyly involving the second through fifth digits (mitten hands), symphalangism of interphalangeal joints, delta-shaped proximal phalanx of the thumbs, complete syndactyly involving the second through fifth digits (socked feet), and partial duplication of the proximal phalanx of the great toes and first metatarsals

Fig. 4 (continued)

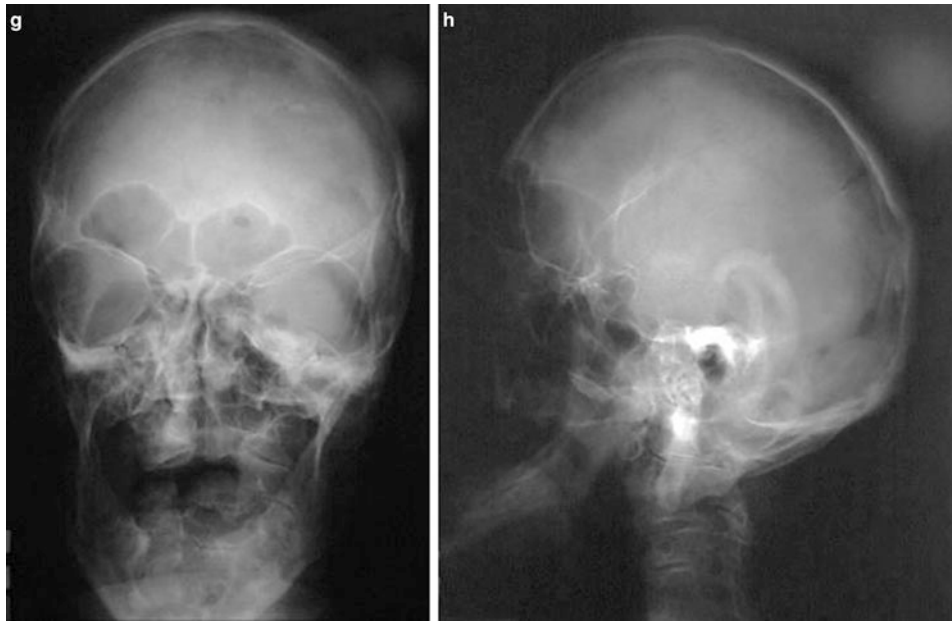

Fig. 4 (**a**–**h**) An adult with Apert syndrome showing typical craniofacial appearance with mitten hands and socked feet. Radiographs of hands and feet and skull showed cutaneous and osseous syndactyly, turribrachycephaly, shallow orbits, and hypoplastic maxilla

Fig. 5 (continued)

Fig. 5 (**a**–**h**) A daughter and a mother with Apert syndrome showing characteristic craniofacial features, mitten hands, and socked feet

Fig. 6 (**a**, **b**) A 6-month-old male infant was evaluated for Apert syndrome which was diagnosed prenatally. The fetus was noted to have abnormal craniofacial features with mitten hands by ultrasonography. Molecular testing from cultured amniocytes indicated the presence of a C > G transversion at nucleotide 755 (c.755 C > G) of the fibroblast growth factor receptor 2 (*FGFR2*) gene. This change substitutes a tryptophan for a serine at amino acid 252 (p. S252W). The presence of this mutation is consistent with a clinical diagnosis of Apert syndrome. The infant showed severe acrocephaly, palpable coronal suture ridge, ocular hypertelorism with proptotic eyes, low-set ears, depressed nasal bridge, small soft palate cleft, hitchhiker-like thumbs, mitten hands, and sock feet

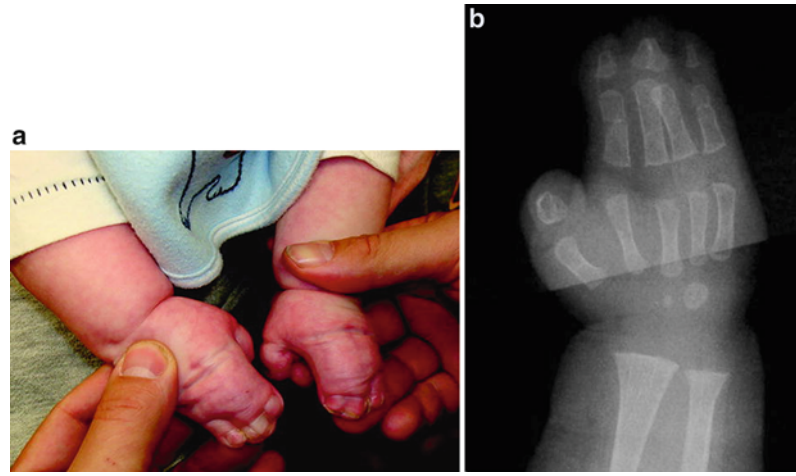

Fig. 7 (**a**, **b**) Mitten-shaped hands with cutaneous syndactyly and synonhychia (**a**) Radiograph of the right hand (**b**) showing coalition of distal phalanges, symphalangism, cutaneous and osseous syndactyly, and delta-shaped deformity of the proximal phalanx of the thumb

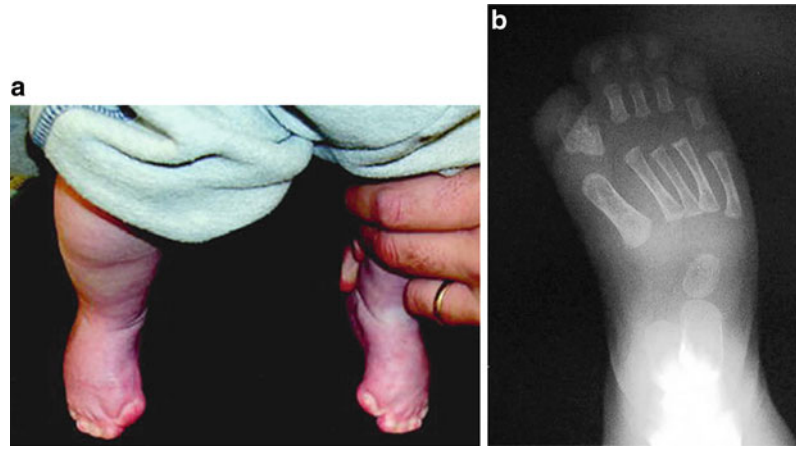

Fig. 8 (**a**, **b**) Both feet (**a**) showing socket-shaped feet, syndactyly of the feet with partial-to-complete fusion of the digits, involving second, third, and forth digits. Radiograph of the right foot (**b**) showing complete cutaneous syndactyly involving the second, third, and fourth digits and delta-shaped deformity of the proximal phalanx of the first toe

Fig. 9 (a-c) The 9-month-old girl was seen because of syndactyly of the hands and feet associated with craniofacial anomalies. The family and pregnancy histories were non-contributory. There were broad thumbs with 2-5 digit cutaneous syndactyly (**a, b**) (only right hand is shown here). The feet were characterized by brachydactyly and syndactyly of 2-5 toes (**c**). Genomic DNA analysis showed heterozygous for a C to G mutation at nucleotide 755 of fibroblast growth factor receptor 2 (FGFR2) gene (c.755C>G) that changes a codon for serine (TCG) to one for tryptophan (TGG) at amino acid position 252 (p. Ser252Trp). This mutation is diagnostic for Apert syndrome (Park et al, Am J hum Genet 57:321-328, 1995). (Courtesy of Dr. Grace Guo)

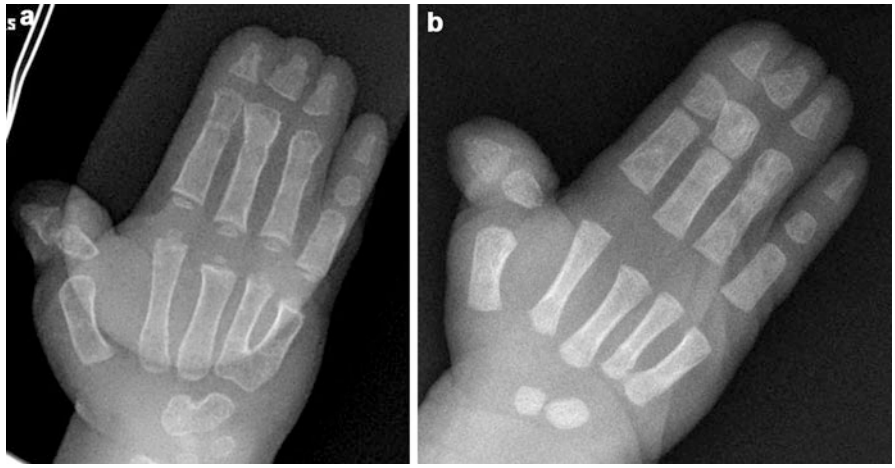

Fig. 10 (a, b) Right hand radiograph at 15 month of age (a) showed soft tissue fusion between the second through fourth digits and fusion of the proximal soft tissues between the fourth and fifth digit. Hypoplastic, deformed phalanges were present with fusion of the proximal and middle phalanges of the second through fourth digits. Bony fusion was also seen at the bases of the fourth and fifth metacarpals and fusion of the capitate and hamate. The thumb was pointing laterally with a sharp angulation at the 1st MCP joint. Right hand radiograph at 1 month of age (b) is provided here for comparison. Similar abnormalities are also seen in the left hand (not shown). (Courtesy of Dr. Grace Guo)

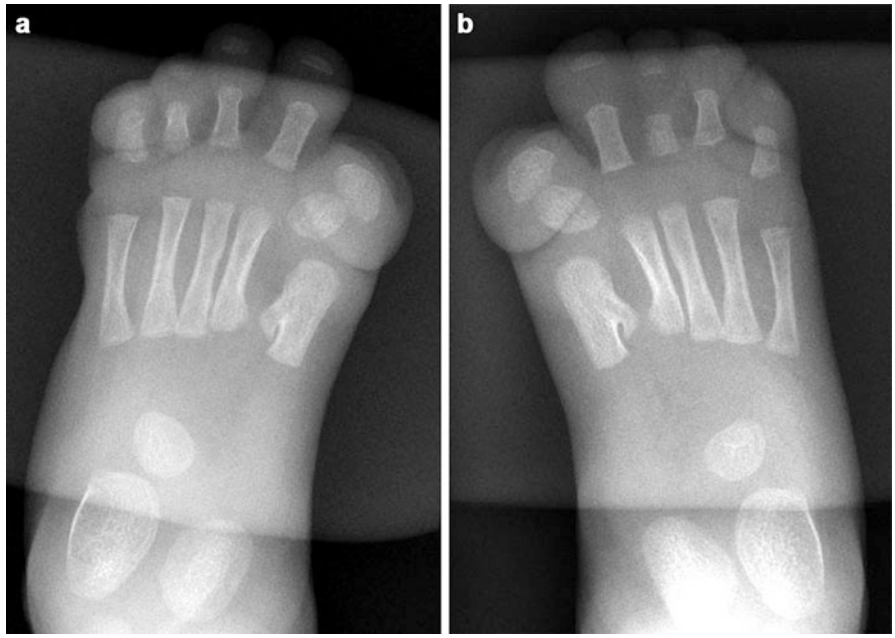

Fig. 11 (**a**, **b**) Radiographs of bilateral feet at 1 month of age (**a**, **b**) showed foreshortening of bilateral second metatarsals, right third proximal phalanx and left fourth phalanx, and distal phalanges of bilateral left second, third, fourth, and fifth digits. Bilateral great toes are bulbous and foreshortened with deformed phalanges and partially duplicated metatarsals. Soft tissue fusion was present in the bilateral second through fifth digits

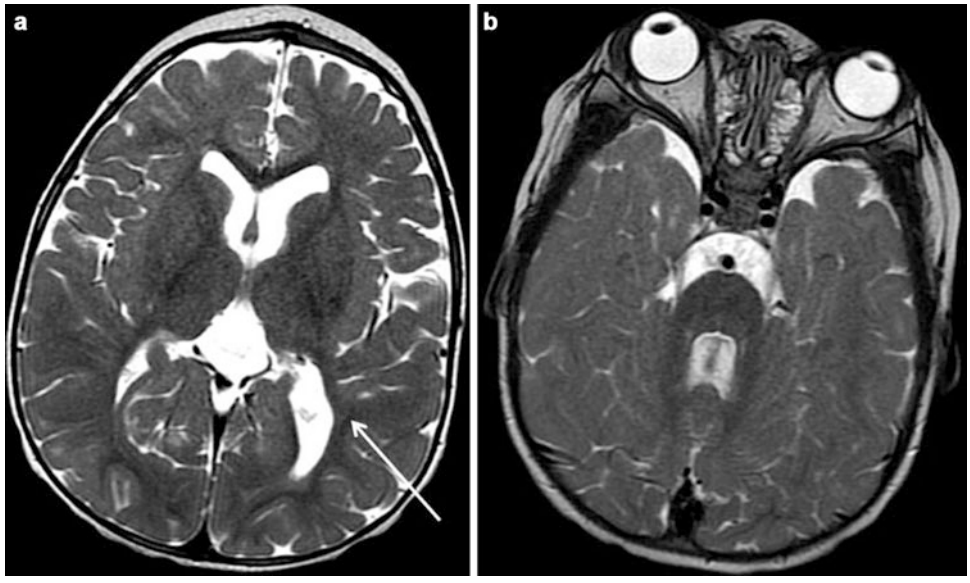

Fig. 12 (**a**, **b**) MRI images of the brain obtained at 16 month of age showed hypoplasia of the parietooccipital white matter with undulating bilateral lateral ventricle occipital horns (arrow) (**a**). Shallow orbits are appreciated bilaterally with ocular hypertelorism (**b**)

Aplasia Cutis Congenita

Contents

Aplasia cutis congenita (ACC) is a clinical description of the absence of the skin at birth, first described by Cordon in 1767. It is a heterogeneous group of disorders characterized by absence of epidermis, dermis, and, sometimes, subcutaneous tissue, muscle, or bone on one or more parts of the body. The incidence is estimated to be 1 in 10,000 births.

Synonyms and Related Disorders

Adams-Oliver syndrome; Aplasia cutis congenita associated with epidermolysis bullosa (simplex, junctional, dystrophic) (Bart syndrome); Congenital scalp defect; Congenital skull and scalp defect

Genetics/Basic Defects

1. Etiological theories
    1. Amniogenic theory (Frieden 1986)
        1. Adhesion of the amniotic membrane to the fetal skin might tear off, leaving absent areas of skin.
        2. Not supported by the study of placentas because most placentas are normal
    2. Vascular theory (Classen 1999): assumes thromboplastic material from a fetus papyraceus (mummified dead fetus) as the causes of skin damage
    3. Placental abnormalities
    4. Biomechanical forces on the vertex during the embryogenesis
    5. Intrauterine trauma: a history of trauma in only a minority of cases
    6. Intrauterine infections
        1. Varicella
        2. Herpes simplex
    7. Intrauterine involution of a hemangioma
    8. Teratogens
        1. Methimazole (Farine et al. 1988; Vogt et al. 1995; Rodriguez-Garcia et al. 2011)
        2. Misoprostol (Fonseca et al. 1993)
    9. Familial cases reported (Fisher and Schneider 1973; De Groot et al. 1978; Sybert 1985; Chitnis et al. 1996)
2. Frieden's classification of aplasia cutis congenita (Frieden 1986; Browning 2013; Brzezinski et al. 2015)
    1. Group I: ACC of the scalp without multiple anomalies: sporadic occurrence or autosomal dominant inheritance

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_15

2. Group II: ACC of the scalp with associated limb abnormalities (Adams-Oliver syndrome): autosomal dominant inheritance
3. Group III: ACC of the scalp with associated epidermal, organoid nevus, or epidermal nevus syndrome, ophthalmic, and neurologic problems (seizures, mental retardation, corneal opacities, and eyelid colobomas): sporadic occurrence
4. Group IV: ACC overlying embryologic malformations (meningomyelocele, porencephaly, leptomeningeal angiomatosis, cranial stenosis, spinal dysraphism, gastroschisis, or omphalocele): inheritance depending on underlying conditions
5. Group V: ACC with associated fetus papyraceous (results from the death of a twin fetus in the second trimester) (Mannino et al. 1977; Joshi et al. 1991; Boente et al. 1995; Classen 1999; Cambiaghi et al. 2001; Kelly et al. 2002; Pieretti et al. 2015) or placental infarcts; ACC is extensive on the trunk or limbs, linear or stellate configuration: sporadic occurrence
6. Group VI: ACC associated with epidermolysis bullosa (Bart syndrome): autosomal dominant or recessive inheritance depending on the type of the epidermolysis bullosa
7. Group VII: ACC localized to extremities without blistering: autosomal dominant or recessive inheritance
8. Group VIII: ACC caused by specific teratogens: scalp (methimazole treatment during pregnancy), any area (intrauterine infections with varicella-zoster virus, herpes simplex virus)
9. Group IX: ACC associated with malformation syndromes
    1. Trisomy 13
    2. Trisomy 18
    3. 4p- (Wolf-Hirschhorn syndrome)
    4. 46,XY gonadal dysgenesis
    5. Amniotic band disruption complex
    6. Ectodermal dysplasias
    7. Johanson-Blizzard syndrome
    8. Focal dermal hypoplasia (Goltz syndrome)
    9. Setleis syndrome
    10. Oculocerebrocutaneous (Delleman) syndrome
    11. Scalp-ear-nipple syndrome (Finlay-Mark syndrome)
    12. Kabuki syndrome
3. Aplasia cutis congenita associated with epidermolysis bullosa (Bart syndrome) (Achiron et al. 1992; Aygun et al. 2010)
    1. Simplex
        1. An autosomal dominant disorder
        2. Lysis of the epidermis occurring within the cytoplasm of the basal cell layer
    2. Junctional
        1. An autosomal recessive disorder
        2. Damage at the level of the lamina lucida
    3. Dystrophic (scarring) (Chiaverini et al. 2014)
        1. An autosomal dominant or recessive disorder.
        2. Defect situated in the anchoring fibrils attaching the basal lamina to the dermis.
        3. ACC is a frequent manifestation in patients with dystrophic epidermolysis bullosa (DEB) irrespective of the severity of the disease and is due to leg rubbing in utero.
        4. In children with a moderate form of DEB with no or moderate skin fragility, a glycine substitution near the triple helix domain interruption of the collagen VII leading to thermolabile protein could explain this phenomenon.
4. Summary of identified genes in ACC and syndromes with ACC (Marneros 2015)
    1. Familial ACC: *BMS1* mutation (Marneros 2013)
    2. Scalp-ear-nipple syndrome: *KCTD1* mutation (Marneros et al. 2013) (Please see the chapter)
    3. Adams-Oliver syndrome (AOS) (Please see the chapter)
        1. AOS-1: *ARHGAP31* mutation (Southgate et al. 2011)
        2. AOS-2: *DOCK6* mutation (Shaheen et al. 2011)

3. AOS-3: *RBPJ* mutation (Hassed et al. 2012)
4. AOS-4: *EOGT* mutation (Shaheen et al. 2013)
5. AOS-5: *NOTCH1* mutation (Stittrich et al. 2014)

Clinical Features

1. Aplasia cutis of the scalp (aplasia cutis vertices) (Cambiaghi et al. 1998)
   1. The most common form
   2. Single or multiple noninflammatory ulcers
   3. Occurrence at or near the scalp vertex
   4. Variable in shape and size
   5. Heals leaving a hairless scar
   6. Membranous aplasia cutis congenita of the scalp with the "hair collar sign" (growth of long dark coarse hair encircling the lesion) reported (Bassi et al. 2014)
   7. Occurrence
      1. An isolated condition
      2. Associated with other congenital abnormalities
2. Aplasia cutis with extracranial symmetrical involvement (a distinctive type of "non-scalp" aplasia cutis congenita)
   1. Linear lesions with a symmetrical pattern of distribution on the trunk and limbs
   2. Aplasia cutis with fetus papyraceous: usually associated with in utero death of a monozygotic twin during pregnancy, with or without the presence of a fetus papyraceous (persistence of a mummified dead fetus; vanishing twin) (Bourque and Preloger 2015)
   3. Other terms
      1. Truncal aplasia cutis
      2. Bilateral abdominal aplasia cutis
3. Associated congenital anomalies (Evers et al. 1995; Mesrati et al. 2015)
   1. Craniofacial anomalies
      1. Underlying skull bony defect (Kosnik and Sayers 1975): 15–20% of cases of scalp ACC and as high as 75% in cases of extensive scalp ACC (Burkhead et al. 2009)
      2. Microphthalmia
      3. Colobomas
      4. Myopia
      5. Epibulbar dermoid
      6. Cleft lip
      7. Cleft palate
      8. Ear malformations
   2. CNS malformation
      1. Hydrocephalus
      2. Mental retardation
      3. Spastic paralysis
   3. Ectodermal dysplasia
      1. Hypoplasia of the teeth
      2. Delayed dentition
      3. Nail hypoplasia
      4. Skin blisters
      5. Skin hyperpigmentation
      6. Cutis marmorata
   4. Gastrointestinal abnormalities (Al-Sawan et al. 1999; Lane and Zanol 2000)
      1. Tracheoesophageal fistula/esophageal atresia
      2. Omphalocele
      3. Gastroschisis
      4. Pyloric atresia (Carmi et al. 1982; Cowton et al. 1982): especially in association with junctional (atrophicans) type of epidermolysis bullosa
      5. Ileal atresia
      6. Mesenteric herniation
      7. Biliary atresia
      8. Midgut atresia
      9. Intestinal lymphangiectasia
   5. Musculoskeletal abnormalities
      1. Terminal transverse limb defects (Adams-Oliver syndrome) (Snape et al. 2009)
      2. Arthrogryposis
      3. Polydactyly
      4. Syndactyly
   6. Other malformations (Mesrati et al. 2015)
      1. Hemangiomas
      2. Terminal phalangeal hypoplasia
      3. Deviation of gluteal furrow
4. Prognosis (Burkhead et al. 2009)

1. Scalp lesion (1–3 cm): resolves spontaneously in majority of cases (85%)
2. Prognosis usually determined by underlying anomalies and extent of the lesions
3. Complications (Ribuffo et al. 2003)
    1. Hemorrhage
    2. Brain trauma
    3. Venous thrombosis
    4. Infection
    5. Meningitis
    6. Electrolyte abnormalities
    7. Seizures
4. Mortality rate (20–50%) (Basterzi et al. 2007)

Diagnostic Investigations

1. Imaging
    1. Radiography
        1. Scalp/skull
        2. Hands
        3. Feet
    2. CT scan or MRI of the brain
2. Karyotyping to detect chromosome abnormality
3. Histology: heterogeneous appearance of lesions
    1. Ulcerated lesions at birth
        1. Complete absence of all layers of skin
        2. Occasionally extending to the bone or dura
    2. In utero healing of some lesions
    3. Healed lesions
        1. Flattened epidermis
        2. Proliferation of fibroblasts in a loose connective tissue stroma
        3. Newly formed capillaries
        4. Complete absence of adnexal structures
4. Culture/serology
    1. Varicella zoster
    2. Herpes simplex virus
5. Amniotic fluid findings in some cases (Dror et al. 1994; Gerber et al. 1995)
    1. Elevated amniotic fluid AFP levels
    2. Positive acetylcholinesterase

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. Autosomal dominant: not increased unless a parent is affected
        2. Autosomal recessive: 25%
    2. Patient's offspring
        1. Autosomal dominant: 50%
        2. Autosomal recessive: not increased unless the spouse is a carrier
2. Prenatal diagnosis
    1. Ultrasound diagnosis of aplasia cutis congenita of the trunk (Liu et al. 2014)
        1. Absence of strong echoes (In normal fetus, the abdominal skin surrounding the trunk generates strong echoes)
        2. Absence of the skin over intra-abdominal organs: a typical finding
    2. Ultrasonography for at-risk family with aplasia cutis congenita associated with epidermolysis bullosa and pyloric atresia (Achiron et al. 1992)
        1. Hydramnios
        2. A dilated stomach
        3. A deformed external ear
        4. A contracted fisted hand
    3. Amniocentesis for associated chromosomal abnormality
3. Management
    1. Conservative treatment (Morrow et al. 2013; Puvabanditsin et al. 2015)
        1. Careful and standard wound treatment for small defects involving only epidermis: usually uneventful healing of the lesion (Kulali et al. 2015)
        2. Control of infection
        3. Control of electrolyte abnormalities, especially with larger wounds
    2. Requires a scalp flap for most lesions
    3. A split-thickness skin grafting or full-thickness pedicle grafts (for defects of the scalp extending to the dura mater)
    4. Reconstruction of skull and scalp for a large lesion involving scalp, skull, and dura (Argenta and Dingman 1986)
    5. Large-sized skin grafting (Liu et al. 2015)
        1. Ideal for treating large skin defects

2. A good option for treating small skin defects that do not heal or may heal with scarring after conservative treatment
6. Calvarial regeneration with use of acellular dermal matrix in aplasia cutis congenita (Mericli et al. 2015)
7. Emergency intervention to control life-threatening hemorrhage
8. Surgical intervention also useful later in life for revision of scars and correction of alopecia with rotation flaps, simple excision and closure, scalp reduction techniques, or local hair transplantation
9. Management of associated anomalies

Fig. 1 (**a**, **b**) An infant with aplasia cutis congenita with epidermolysis bullosa showing lesions on the face, trunk, and extremities

Fig. 2 (**a**, **b**) This 3-year-7-month-old girl was evaluated for scalp defect (**a**) and terminal transverse limb defect (**b**). For details of this case, please see the chapter of Adams-Oliver syndrome

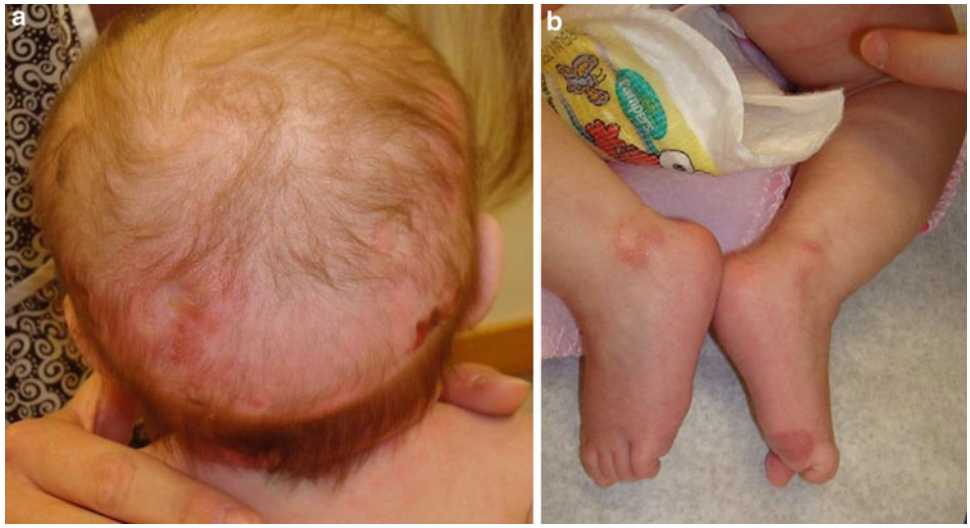

Fig. 3 (**a**, **b**) This 3-month-old infant was evaluated for blisters over the neck, trunk, and extremities (**b**) (only lower extremities are shown here). In addition, the baby has aplasia cutis congenita on the scalp (**a**)

Arthrogryposis Multiplex Congenita

Contents

Arthrogryposis multiplex congenita comprises nonprogressive conditions characterized by multiple joint contractures throughout the body at birth. The term encompasses a very heterogeneous group of disorders having the common feature of multiple congenital joint contractures. The overall prevalence of arthrogryposis is approximately 1 in 3,000 live births (Hall 1985a, b; Fahy and Hall 1990).

Synonyms and Related Disorders

Amyoplasia; Distal arthrogryposis (distotarlar dysmorphism, Freeman-Sheldon syndrome, Sheldon-Hall syndrome, Gordon syndrome, Hecht syndrome, Beals syndrome)

Genetics/Basic Defects

1. Major causes
    1. Arthrogryposis as a physical sign observed in many specific clinical conditions:
        1. Single-gene defects
        2. Chromosomal abnormalities
        3. Known or unknown syndromes or conditions
        4. Environmental effects: mutagenic agents, mitotic abnormalities, toxic chemicals or drugs, hyperthermia, neuromuscular blocking agents, and mechanical immobilization (Swinyard and Bleck 1985)
    2. Fetal akinesia due to fetal abnormalities:
        1. Neurogenic abnormalities: the most common cause of arthrogryposis
            1. Meningomyelocele
            2. Anencephaly
            3. Hydranencephaly
            4. Holoprosencephaly
            5. Spinal muscular atrophy
            6. Cerebro-oculo-facio-skeletal syndrome
            7. Marden-Walker syndrome
        2. Muscular abnormalities: relatively rare causes of arthrogryposis
            1. Congenital muscular dystrophies
            2. Congenital myopathies
            3. Intrauterine myositis
            4. Mitochondrial disorders
        3. Connective tissue abnormalities in tendon, bone, joint, or joint lining restricting fetal movements, resulting in congenital contractures. Examples include:
            1. Synostosis
            2. Lack of joint development

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_16

3. Aberrant fixation of joints (as in diastrophic dysplasia and metatropic dwarfism)
4. Aberrant laxity of joints with dislocations (as in Larsen syndrome)
5. Aberrant soft tissue fixations (as in popliteal pterygium syndrome)
6. Failure of normally developed tendon to attach to the appropriate place around the joint or bone in some forms of distal arthrogryposis, resulting in abnormal lack of movement of the joints with secondary contractures at birth

4. Mechanical limitations to movement. Limited space for fetal movement inside the uterus may contribute to development of contractures. Examples include:
   1. Multiple births
   2. Uterine structural abnormalities such as bicornuate uterus
   3. Umbilical cord wrapping
   4. Oligohydramnios in renal agenesis
   5. Early persistent leakage of amniotic fluid
5. Intrauterine vascular compromise resulting in loss of nerve and muscle function with development of fetal akinesia and secondary joint contractures. Examples include:
   1. Severe maternal bleeding during pregnancy
   2. Failed attempts at termination of pregnancy (Hall 1996)

3. Fetal akinesia due to maternal disorders, examples include:
   1. Infections
      1. Rubella
      2. Poliomyelitis
   2. Drugs/chemicals
      1. Methocarbamol
      2. Alcohol
      3. Carbon monoxide poisoning
   3. Trauma
   4. Vitamin deficiency
   5. Hyperthermia (e.g., prolonged sauna)
   6. Radiation
   7. Other maternal illnesses
      1. Maternal autoantibodies
      2. Diabetes mellitus
      3. Myotonic dystrophy
      4. Maternal multiple sclerosis

2. Pathophysiology
   1. Joint development
      1. Almost always normal during early embryogenesis
      2. Fetal motion essential for normal development of joints and their contiguous structures
   2. Lack of fetal movement (Hall 1989)
      1. Causing extra connective tissue to develop around the joint
      2. Resulting in fixation of the joint
      3. Limiting movement that further aggravates the joint contracture
      4. Contractures secondary to fetal akinesia: more severe in patients who are diagnosed early in pregnancy and who experience akinesia for longer periods of time during gestation

Clinical Features

1. Family history (Hall 1997, 2014):
   1. Presence of congenital contractures in the family
      1. Affected siblings
      2. Other affected family members
   2. Marked intrafamilial variability
      1. Mildly affected parent
      2. A parent with contractures early in infancy
   3. Consanguinity
      1. Increasing the chance that the parents will both carry the same disease gene
      2. Observed more frequently in families with rare recessive diseases than in those with common recessive diseases
   4. Increased parental age
      1. Some chromosomal abnormalities: increasing dramatically with advanced maternal age
      2. Single-gene dominant mutations: increasing with advanced paternal age

5. History of previous miscarriages or stillbirths
6. Multiple consecutively affected child: consider maternal antibodies to fetal neurotransmitter

2. Pregnancy history (Hall 2014)
    1. Diminished fetal movement
    2. Infants born to mothers affected with the following disorders:
        1. Myotonic dystrophy: A child who inherits the gene and is severely affected with resistant contractures.
        2. Myasthenia gravis and multiple sclerosis: Children may be born with congenital contractures.
        3. Diabetes.
    3. Maternal infections leading to CNS or peripheral nerve destruction with secondary congenital contractures:
        1. Rubella
        2. Rubeola
        3. Coxsackievirus
        4. Enterovirus
        5. Akabane
    4. Maternal fever or hyperthermia causing contractures due to abnormal nerve growth or migration
    5. Exposure to teratogens leading to decreased fetal movement
        1. Additive drugs
        2. Alcohol
        3. Curare
        4. Methocarbamol
        5. Misoprostol
        6. Phenytoin
        7. Radiation
        8. Robaxin
    6. Amniotic fluid volume
        1. Oligohydramnios, chronic leakage of amniotic fluid: causes fetal constraint and secondary deformational contractures
        2. Polyhydramnios, hydrops: indicating fetal compromise
    7. Uterine abnormalities
        1. Bicornuate uterus with a septum
        2. Uterine fibroid
    8. Other maternal complications
        1. Toxemia
        2. Severe hypotension at critical time
        3. Severe hypoxia (e.g., carbon monoxide poisoning) during pregnancy
        4. Abnormal fetal lies
        5. Threatened abortion
        6. Attempted termination
        7. Trauma such as trauma to the abdomen
        8. Early amniocentesis
3. Delivery history (Hall 2014)
    1. Breech or transverse fetal position.
        1. Relatively common
        2. Usually normal length of gestation
        3. Induction of labor often prolonged
        4. Fracture of a limb during traumatic delivery in 5–10% of cases
    2. Abnormal placenta, membranes, or cord insertion in case of amniotic bands or vascular compromise. The umbilical cord may be shortened or wrapped around a limb, leading to compression.
    3. Prematurity.
    4. Multiple births or twins.
        1. Lack of movement due to uterine crowding.
        2. The death of one twin may lead to vascular compromise in the remaining twin.
4. Common physical characteristics
    1. Involved extremities
        1. Fusiform or cylindrical in shape
        2. Thin subcutaneous tissue
        3. Absence of skin creases
    2. Deformities
        1. Usually symmetric
        2. Severity increasing distally
        3. Hands and feet typically being the most deformed
    3. Joint rigidity
    4. Associated joint dislocations, especially the hips and, occasionally, the knees
    5. Muscles
        1. Atrophy
        2. Absence
    6. Sensation
        1. Usually intact
        2. Diminished or absent deep tendon reflexes
5. Contractures
    1. Distal joints affected more frequently than proximal joints

2. Types of contractures
    1. Flexion versus extension
    2. Limitation of movement (fixed vs. passive vs. active)
    3. Complete fusion vs. ankylosis and soft tissue contracture
3. Intrinsically derived contractures
    1. Frequently associated with polyhydramnios
    2. Symmetric contractures
    3. Accompanied by taut skin
    4. Pterygia across joints
    5. Lack of flexion creases
    6. Recurrence risk and prognosis dependent on etiology
4. Extrinsically derived contractures
    1. Associated with positional limb anomalies, large ears, loose skin, and normal or exaggerated flexion creases
    2. Excellent prognosis
    3. A low recurrence risk

6. Deformities (Hall 2014)
    1. Limb deformities
        1. Pterygium (webbing)
        2. Shortening
        3. Cord wrapping
        4. Amniotic bands
        5. Compression (e.g., due to cord wrapping)
        6. Absent patella
        7. Dislocated radial heads
        8. Dimples
    2. Face deformities
        1. Asymmetry
        2. Flat nasal bridge
        3. Hemangioma
        4. Jaw deformities including micrognathia and trismus
    3. Other deformities
        1. Scoliosis/kyphosis (fixed or flexible)
        2. Genital deformities
            1. Cryptorchidism
            2. Microphallus
            3. Lack of labia
        3. Hernias
            1. Inguinal
            2. Umbilical
    4. Other features of the fetal akinesia sequence
        1. Intrauterine growth retardation
        2. Pulmonary hypoplasia
        3. Craniofacial anomalies
            1. Hypertelorism
            2. Cleft palate
            3. Depressed nasal tip
            4. High nasal bridge
        4. Functional short gut with feeding problems
        5. Short umbilical cord
    5. Absent or distorted crease abnormalities resulting from aberrant form or function in early hand or foot development
7. Malformations (Hall 2014)
    1. Craniofacial malformations
        1. CNS
            1. Structural malformations
            2. Seizures
            3. Mental retardation/intellectual disability
        2. Skull
            1. Craniosynostosis
            2. Asymmetry
            3. Microencephaly
        3. Eyes
            1. Small and malformed eyes
            2. Corneal opacities
            3. Ptosis
            4. Strabismus
        4. Palate
            1. High-arched
            2. Cleft
            3. Submucous cleft
    2. Respiratory problems affecting lung function
        1. Tracheal and laryngeal clefts and stenosis
        2. Hypoplasia or weak muscles of diaphragm
    3. Limb malformations
        1. Reduction anomalies
        2. Radioulnar synostosis
        3. Syndactyly
        4. Shortened digits
    4. Skin/vasculature abnormalities
        1. Hemangiomas and cutis marmorata
        2. Cold and blue distal limbs
    5. Cardiac problems
        1. Congenital heart defects
        2. Cardiomyopathy

6. Urogenital structural anomalies
    1. Kidneys
    2. Ureters
    3. Bladder
7. Nervous system problems
    1. Loss of vigor
    2. Lethargy
    3. Slow, fast, or absent deep tendon reflexes
    4. Sensory deficits
8. Muscle malformations
    1. Decreased muscle mass
    2. Soft muscle texture
    3. Fibrous bands
    4. Abnormal tendon attachments
    5. Muscle changing with time

8. Connective tissue abnormalities (Hall 2014)
    1. Skin webs (pterygia) across joints with limitation of movement
    2. Skin dimples observed frequently over joints where movement is limited
    3. Soft, doughy, thick, or extensible skin
    4. Decreased or increased subcutaneous fat
    5. Inguinal, umbilical, or diaphragmatic hernias
    6. Thickness in joints
    7. Symphalangism
    8. Abnormalities in tendon attachment and length
    9. Associated skin defects including scalp defects, amniotic bands on limbs, and nail defects
9. Disorders with mainly limb involvement (Hall 1997; Bamshad et al. 2009)
    1. Amyoplasia (Hall et al. 1983a, b, 2014; Sarwark et al. 1990; Sells et al. 1996; Bevan et al. 2007)
        1. The most common type of arthrogryposis seen in clinical practice and constitutes about one third of cases
        2. Incidence: about 1 in 10,000 live births
        3. A sporadic condition, not observed in siblings or offspring (recurrence risk not increased)
        4. Characterized by typical and symmetric congenital, rigid contractures of the limbs
        5. Internally rotated and adducted shoulders
        6. Fixed extended elbows
        7. Pronated forearms
        8. Flexed wrists and fingers
        9. A severe talipes equinovarus deformity
        10. Gracile, osteoporotic long bones
        11. Muscles: hypoplastic (marked decrease in limb muscle mass) and usually replaced by fibrous and fatty tissue
        12. Normal intelligence
    2. Distal arthrogryposes: Bamshad classification (Hall et al. 1982a; Bamshed et al. 1996; Hall 2014)
        1. Type 1A (distotarlar dysmorphism)
            1. An autosomal dominant disorder
            2. Medially overlapping fingers
            3. Tightly clenched fists at birth
            4. Ulnar deviation of fingers and camptodactyly in adults
            5. Positional foot contractures
            6. Usually normal intelligence
            7. Caused by mutations in TPM2, MYBPC1, TNN12, and MYH3
        2. Type 2A (Freeman-Sheldon syndrome, also known as whistling face syndrome)
            1. An autosomal dominant disorder
            2. A mask-like face with a small mouth, giving a whistling face appearance
            3. Deep-set eyes
            4. Small nose with a broad nasal bridge
            5. Epicanthal folds
            6. Strabismus
            7. High-arched palate
            8. Small tongue
            9. An H-shaped cutaneous dimpling on the chin
            10. Flexion of fingers
            11. Equinovarus feet with contracted toes
            12. Kyphoscoliosis
            13. Caused by MYH3 mutation
        3. Type 2B (Sheldon-Hall syndrome) (Toydemir et al. 2006; Toydemir and Bamshad 2009)
            1. An autosomal dominant disorder
            2. Contractures of the distal joints of the limbs
            3. Triangular face

4. Down-slanting palpebral fissures
5. Small mouth
6. High-arched palate
7. Caused by mutations in either *MYH3*, *TNNI2*, or *TNNT3* (~50% of cases)

4. Type 3 (Gordon syndrome)
   1. Short stature (90%)
   2. Cleft palate
   3. Bifid uvula
   4. Epicanthal folds
   5. Congenital ptosis
   6. Short neck
   7. Camptodactyly
   8. Caused by PIEZO2 mutation
5. Type 4 (may include Goodman syndrome)
   1. Scoliosis
   2. Finger contractures
6. Type 5
   1. Ophthalmoplegia (limited ocular motility)
   2. Ptosis
   3. Finger contractures
   4. Caused by PIEZO2 (AD) or ECEL1 (AR) mutations
7. Type 6
   1. Sensorineural hearing loss
   2. Finger contractures
   3. Caused by FGFR3 mutation
8. Type 7 (Hecht syndrome, Kentucky Dutch syndrome)
   1. Trismus pseudocamptodactyly
   2. Inability to fully open mouth
   3. Facultative camptodactyly
   4. Caused by MYH8 mutation
9. Type 8 (autosomal dominant multiple pterygium syndrome)
   1. Multiple pterygium
   2. Finger contractures
10. Type 9 (Beals syndrome, congenital contractural arachnodactyly)
    1. An autosomal dominant disorder
    2. Joint contractures
    3. A long, thin body builds
    4. Crumpling ears
    5. Lacking cardiovascular and ocular abnormalities of Marfan syndrome
    6. Caused by fibrillin 2 mutation
11. Type 10 (congenital plantar contractures)

3. Bony fusion likely to be confused with arthrogryposis
   1. Symphalangism (e.g., fusion of phalanges)
   2. Coalition (e.g., fusion of the carpals and tarsal bones)
   3. Synostosis (e.g., fusion of long bones)
4. Other associated syndromes and conditions
   1. Absence of dermal ridges
   2. Absence of distal interphalangeal (DIP) joint creases
   3. Amniotic bands
   4. Antecubital webbing
   5. Camptodactyly
   6. Congenital clasped thumbs
   7. Familial impaired pronation and supination of forearm
   8. Humeroradial synostosis
   9. Liebenberg syndrome
   10. Nail-patella syndrome
   11. Nievergelt-Pearlman syndrome
   12. Poland anomaly
   13. Radioulnar synostosis
   14. Tel-Hashomer camptodactyly

10. Disorders with involvement of limbs and other body parts (Hall 1997)
    1. Multiple pterygium syndrome (Chen et al. 1980)
       1. Autosomal recessive type: characterized by multiple joint contractures with marked pterygia, dysmorphic facies (flat, sad, motionless facial appearance), and cervical vertebral anomalies
       2. Autosomal dominant type: characterized by multiple pterygia with or without mental retardation
    2. Multiple pterygium syndrome (pterygia with flexion contractures) associated with scoliosis, cleft palate, and malignant hyperthermia
    3. Multiple pterygium syndrome, Escobar type (Escobar et al. 1978)
       1. Webbing of the neck that increases with age
       2. Webbing of the knees and elbows that develops before adolescence
       3. Multiple joint contractures

4. Lumbar lordosis
4. Lethal multiple pterygium syndrome (Chen et al. 1983, 1984; Hall 1984c; Porter 1995; Chen 2015)
    1. An autosomal recessive disorder
    2. Characteristic features
        1. Early lethality
        2. Hydrops fetalis
        3. Cystic hygroma
        4. Dysmorphic facies (hypertelorism, markedly flattened nasal bridge with hypoplastic nasal alae, cleft palate, micrognathia, and low-set ears)
        5. Marked webbing and flexion contractures of multiple joints
        6. Short neck
        7. Small chest
        8. Hypoplastic lungs
    3. Classification by Hall (1984a, b, c) and Entezami et al. (1998)
        1. Type I (Gillin-Pryse-Davis syndrome): multiple pterygia, pulmonary hypoplasia, genital anomalies, and marked flexed extremities with a reduced muscle mass
        2. Type II (Chen syndrome) (Chen et al. 1984): multiple pterygia, hygroma colli, facial anomalies, undermodeled long bones, cartilaginous fusion of joints and bony fusion of the spinous processes of the vertebrae, polyhydramnios, hypoplastic lungs and heart, and diaphragmatic hernia
        3. Type III (van Regemorter syndrome): multiple pterygia, pulmonary hypoplasia, facial anomalies, thin extremities with reduced muscle mass, and fusions of the long tubular bones
        4. Type IV (Herva syndrome): multiple pterygia, degeneration of the anterior horn cells of the spinal cord, and observed particularly in Finland
5. Popliteal pterygium syndrome
    1. An autosomal dominant disorder
    2. Popliteal webs
    3. Cleft lip or palate
    4. Webs in the mouth
    5. Unusual nails
6. Lethal popliteal pterygium syndrome (Bartsocas-Papas syndrome)
    1. An autosomal recessive disorder
    2. Severe webs across the knee
    3. Associated with facial clefting and fused digits (synostosis of the hand and foot bones) in the newborn period
    4. Usually lethal
7. Osteochondrodysplasias known to be associated congenital contractures
    1. Camptomelic dysplasia
    2. Conradi-Hünermann (chondrodysplasia punctata)
    3. Diastrophic dysplasia
    4. Focal femoral dysplasia
    5. Geleophysic syndrome
    6. Kniest dysplasia
    7. Metaphyseal dysplasia, Jansen type
    8. Metatropic dysplasia
    9. Larsen dysplasia
    10. Nail-patella syndrome
    11. Oculodentodigital syndrome
    12. Orocraniodigital syndrome
    13. Osteogenesis imperfecta type II
    14. Otopalatodigital syndrome
    15. Parastremmatic dysplasia
    16. Perinatal lethal osteogenesis imperfecta
    17. Pfeiffer syndrome
    18. Saul-Wilson syndrome
    19. Synspondylism
    20. Spondyloepiphyseal dysplasia congenita
    21. Otospondylomegaepiphyseal dysplasia
8. Other associated syndromes and conditions
    1. Hand muscle wasting and sensorineural deafness
    2. Holt-Oram syndrome
    3. Kuskokwim syndrome
    4. Leprechaunism
    5. Megalocornea with multiple skeletal anomalies
    6. Möbius syndrome
    7. Nemaline myopathy
    8. Ophthalmomandibulomelic dysplasia

9. Prader-Willi habitus/osteoporosis/hand contractures
10. Pseudothalidomide syndrome
11. Puretic-Murray syndrome
12. Sacral agenesis
13. Schwartz-Jampel syndrome
14. Sturge-Weber syndrome
15. Tuberous sclerosis
16. VATER (*v*ertebral defects, imperforate *a*nus, *t*racheo*e*sophageal fistula, *r*adial and *r*enal dysplasia) complex
17. Weaver syndrome
18. Winchester syndrome
19. X-trapezoidocephaly with midfacial hypoplasia and cartilage abnormalities

11. Disorders with limb involvement and CNS dysfunction (Hall 1997)
    1. Associated chromosome abnormalities.
        1. Sex chromosome anomalies (45,X, 47, XXY/48,XXXY, 49,XXXXX, 49, XXXXY)
        2. Autosomal trisomies (4p, 8, 8 mosaicism, 9, 9q, 10p, 10q, 11q, 13, 14, 15, 18, 21)
        3. Other chromosome anomalies
    2. Cerebro-oculo-facio-skeletal syndrome.
        1. A common lethal condition
        2. Contractures
        3. Brain anomalies
        4. Dysmyelination
        5. Microphthalmia
        6. Cataracts
        7. Renal anomalies
        8. Other visceral anomalies
    3. Neu-Laxova syndrome.
        1. A lethal autosomal recessive disorder
        2. Dramatic contractures
        3. Intrauterine growth retardation
        4. Microcephaly
        5. Open eyes
        6. Tight ichthyotic skin
        7. Severe CNS anomalies
    4. Restrictive dermopathy (Verloes et al. 1992).
        1. A lethal autosomal recessive disorder
        2. Contractures and failure of fetal skin to grow normally restricting fetal movement and leading to secondary contractures
    5. Pena-Shokeir phenotype (Chen et al. 1980; Moerman and Fryns 1990): Phenotype is caused by fetal akinesia rather than a specific syndrome.
        1. Short, fixed limbs
        2. Pulmonary hypoplasia
        3. Intrauterine growth retardation
        4. Polyhydramnios
        5. Short umbilical cord
        6. Unusual craniofacies

12. Other associated syndromes and conditions
    1. Adducted thumbs
    2. Bowen-Conradi syndrome
    3. C syndrome
    4. Congenital myotonic dystrophy
    5. Congenital myasthenia gravis
    6. Faciocardiomelic syndrome
    7. Fetal alcohol syndrome
    8. FG syndrome
    9. Marden-Walker syndrome
    10. Meckel syndrome
    11. Meningomyelocele
    12. Mietens-Weber syndrome
    13. Miller-Dieker syndrome
    14. Neu-Laxova syndrome
    15. Neurofibromatosis
    16. Popliteal pterygium with facial clefts
    17. Potter syndrome
    18. Pseudotrisomy 18
    19. Spinal muscular atrophy
    20. Syndrome of cloudy cornea, diaphragmatic defects, and distal limb deformities
    21. Syndrome of craniofacial and brain anomalies and intrauterine growth retardation
    22. Syndrome of cryptorchidism, chest deformity, and contractures
    23. Toriello-Bauserman syndrome
    24. Walker-Warburg syndrome
    25. X-linked lethal arthrogryposis (Hall et al. 1982b)
    26. Zellweger syndrome
13. Prognosis (Hall 1986)
    1. Poor prognosis for ventilator-dependent neonates (Bianchi and Van Marter 1994)

2. Prenatal factors that potentially predict respiratory insufficiency
    1. Decreased fetal movements
    2. Polyhydramnios
    3. Micrognathia
    4. Thin ribs
    5. Decreased fetal movement often resulting in delayed developmental milestones
3. Skeletal changes secondary to the original deformities
    1. Scoliosis
    2. Deformed carpal and tarsal bones
    3. Under growing of limbs after longstanding contractures
    4. External genitalia often abnormal (e.g., cryptorchidism, absent labia majora) because of abnormal hip position
4. Intrinsically or extrinsically derived defects
    1. Extrinsically derived contractures: an excellent prognosis
    2. Intrinsically derived contractures: a prognosis dependent on etiology
5. Prognosis depending on the condition's natural history
    1. Developmental landmarks (attainment of motor, social, and language milestones)
    2. Growth of affected limbs
    3. Progression of contractures
    4. CNS damage (lethal, stable, improving)
    5. Asymmetry of contractures (improving, worsening)
    6. Changes in trunk or limbs
    7. Intellectual ability
    8. Socialization
6. Prognosis depending on the patient's response to therapy
    1. Spontaneous improvement
    2. Response to physical therapy
    3. Response to casting
    4. Types of surgery at appropriate time
    5. Development of motor strength proportionate to limb size

Diagnostic Investigations

1. Laboratory evaluation (Hall 1981, 2014)
    1. Laboratory tests, in general, are not useful.
    2. Creatine phosphokinase (CPK) levels when the following conditions are present:
        1. Generalized weakness
        2. Doughy or decreased muscle mass
        3. Progressive worsening
    3. Viral cultures for an infectious process (intrauterine growth retardation, eye involvement, and hepatosplenomegaly)
    4. Immunoglobulin M levels and specific viral titers (e.g., coxsackievirus, enterovirus, Akabane virus) in the newborn for intrauterine infection
    5. Maternal antibodies to neurotransmitters in the infant indicating myasthenia gravis or recurrent affected pregnancies without diagnosis
    6. Video of movement including facial, range of movement, and strength repeat at regular intervals
    7. Cytogenetic study/comparative genomic hybridization (CGH) array indicated in the following situations:
        1. Multiple organ or system involvement
        2. Presence of CNS abnormalities, such as microcephaly, mental retardation, lethargy, degenerative changes, or eye anomalies
        3. Streaky or segmental involvement
        4. Fibroblast chromosome study if lymphocyte chromosomes are normal and the patient has mental retardation/intellectual disability without diagnosis
        5. Consider exome studies if family available
    8. Nuclear DNA mutation analysis to identify certain disorders
        1. Exome sequencing identifies aa dominant TNNT3 mutations in a large family with distal arthrogryposis (Daly et al. 2014)

2. Spinal muscular dystrophy
9. Mitochondrial mutation analysis to identify certain disorders, such as mitochondrial myopathy
10. Spinal muscular atrophy (SMN) DNA testing if accompanying hypotonia and intellectual disability
11. Metabolic screening if presence of organomegaly

2. Imaging studies
   1. Patient's photographs
      1. To document the extent of deformities (range of motion and position of arthrogryposis)
      2. To assess progress during treatment
   2. Radiographs to evaluate the following skeletal and joint abnormalities:
      1. Bony abnormalities (e.g., gracile bones, fusions, extra or missing carpals, and tarsals)
      2. Disproportionately short stature (i.e., skeletal dysplasias)
      3. Scoliosis
      4. Ankylosis
      5. Absence of patella
      6. Humeroradial synostosis
      7. Dislocations (hips, radial head, patella)
   3. Ultrasonography
      1. To evaluate the CNS and other viscera for anomalies
      2. To establish potential muscle tissue
   4. CT scan to evaluate the CNS and the muscle mass
   5. MRI to evaluate CNS (brain and spinal cord) and muscle mass obscured by contractures
   6. Ophthalmological evaluation for opacity and retinal degeneration
3. Histologic studies (Banker 1985, 1986)
   1. Neurogenic types
      1. Muscle fiber type predominance or disproportion is the most common neurogenic abnormality in arthrogryposis (26%). These are nonspecific alterations.
      2. Dysgenesis of the motor nuclei of the spinal cord and brainstem causes the replacement of fasciculi of muscle fibers by small muscle fibers and adipose tissue. Examples include Pierre Robin syndrome and Möbius syndrome.
      3. Dysgenesis of the CNS: the second most common neurogenic abnormality in arthrogryposis (23%), with disorganization and decrease in neurons of the cortex and motor nuclei of the brainstem and spinal cord. Clinical syndromes with this abnormality include trisomy 18, partial deletion of the long arm of chromosome 18 syndrome, and Zellweger syndrome.
      4. Dysgenesis of the anterior horn, another common neurogenic abnormality in arthrogryposis.
      5. Spinal muscular atrophy (e.g., Werdnig-Hoffmann disease): another neurogenic abnormality in arthrogryposis.
   2. Myopathic types
      1. Central core disease: a form of arthrogryposis in which the central portion of each muscle fiber contains a zone in which oxidative enzyme activity is absent.
      2. Nemaline myopathy indicated by abnormal thread-like structures in muscle cells. In type I nemaline myopathy, nemaline rods are present. In type II, the number of fibers with central nuclei is increased.
      3. Congenital muscular dystrophy indicated by muscle fibers that demonstrate a rounded configuration and conspicuous variation in diameter. Perimysial and endomysial connective tissues are increased markedly.
      4. Mitochondrial cytopathy indicated by numerous ragged red fibers on muscle biopsy. It is associated with CNS abnormalities consistent with mitochondrial disease (Gordon 1998).
      5. Myoneural junction abnormality (e.g., congenital myasthenia gravis): another myopathic type of arthrogryposis.

4. Procedures
    1. Eye examination for opacities and retinal degeneration.
    2. Skin biopsy for culture of fibroblasts to be used for chromosome analysis and metabolic studies.
    3. Muscle biopsy:
        1. Probably the most important diagnostic procedure (Thompson and Bilenker 1985). It should be included in all autopsies and at time of surgery.
        2. Do biopsy earlier and examine mitochondria, if elevated CPK or unusual muscle response present.
        3. Distinguish myopathic from neuropathic conditions by obtaining muscle specimens from normal and affected areas.
        4. Special histopathologic and electron micrographic studies to evaluate fatty and connective tissue replacement of muscle fibers and variations in fiber size, such as decreased fiber diameter. All are nonspecific signs of muscle atrophy.
    4. Electromyography (EMG) (Södergård et al. 1997) in normal and affected areas useful in differentiating neurogenic and myopathic causes (Gordon 1998).
    5. Nerve conduction tests to measure conduction velocities in motor and sensory nerves. These should be performed when a peripheral neuropathy is suspected.
    6. An autopsy to investigate the following:
        1. CNS (i.e., brain neuropathology)
        2. Spinal cord (number and size of anterior horn cells, presence or absence of tracts at various levels)
        3. Ganglia and peripheral nerves
        4. Eye (i.e., neuropathology)
        5. Muscle tissue from different muscle groups (i.e., electron microscopy and special stains)
        6. Fibrous bands replacing muscle
        7. Tendon attachments
        8. Other visceral anomalies, malformations, deformations, and disruptions

Genetic Counseling

1. Recurrence risk: Recurrence risk depends on whether the contractures are extrinsically or intrinsically derived. Extrinsically derived contractures have a low recurrence risk, while the recurrence risk for intrinsically derived contractures depends on etiology. Arthrogryposis may be inherited in the following ways with different recurrence risks:
    1. Patient's sib
        1. Autosomal recessive: 25%
        2. Autosomal dominant: not increased unless a parent is affected or having gonadal mosaicism
        3. X-linked recessive: 50% of male sibs affected if the mother is a carrier
    2. Patient's offspring
        1. Autosomal recessive: not increased unless the spouse is also a carrier.
        2. Autosomal dominant: 50%.
        3. X-linked recessive: All daughters of affected males will be carriers. All sons of an affected male will be normal.
    3. Multifactorial: Combined effects of multiple genes and environmental factors cause multifactorial traits. For most multifactorial diseases, empirical risks (risks based on direct observation of data) have been derived. For example, empirical recurrence risks of neural tube defects for siblings of an affected individual range from 2% to 5% in most populations.
    4. Mitochondrial: A small but significant number of diseases are caused by mitochondrial mutations. Because of the unique properties of mitochondria, these diseases display characteristic modes of inheritance (i.e., inherited exclusively through the maternal line) with wide phenotypic variability. Only females can transmit the disease mutation to their offspring (e.g., distal type IIB arthrogryposis).
    5. Sporadic: For those families in which a specific diagnosis cannot be made, the empiric recurrence risk to unaffected parents of an affected child, or to the affected

individual with arthrogryposis, is about 3–5%.

2. Prenatal diagnosis (Bendon et al. 1987; Baty et al. 1988; Hageman et al. 1988; Dimitraki et al. 2011):
    1. Prenatal ultrasonography to detect the following:
        1. Diminished fetal movement (main manifestation shared by various conditions with congenital contractures)
        2. Joint contractures (bilateral fixed flexion deformities of the hands, elbows, shoulders, hips and knees, or talipes)
        3. Detection of subcutaneous edema (fetal hydrops)
        4. Cystic hygroma
        5. Increased nuchal translucency (Madazli et al. 2002)
        6. Abnormal fetal lie
        7. Polyhydramnios or oligohydramnios
        8. Other associated anomalies (e.g., distended bladder in early urethral obstruction sequence; microcephaly, hydrocephaly, or hydranencephaly in "cerebral dysgenesis"-induced congenital contractures)
    2. Chromosome analysis by amniocentesis or CVS for chromosome disorders
    3. Molecular genetic analysis for certain genetic disorders with demonstrable mutations
3. Management (Shriner's Manual) (McCall and Gates, 1999, Personal communication):
    1. No completely successful approach to treatment
    2. Overall goals
        1. Proper alignment of the lower limbs
        2. Upper limb function for self-care
    3. Early vigorous physical therapy to stretch contractures
        1. To improve joint motion
        2. To avoid muscle atrophy
        3. Excellent functional outcome in patients with amyoplasia or distal arthrogryposis
        4. May be harmful in diastrophic dysplasia because it may lead to joint ankylosis
        5. Frequent recurrence of deformities following stretching, often requires surgery
    4. Splinting combined with physical therapy
        1. Preferable to continuous casting
        2. Night splinting after surgical procedures indicated to maintain increased range of motion
    5. Feeding assistance and intubation needed in patients with severe trismus
    6. Specific joint problems
        1. Should be addressed with regard to treatment of other joints and the goals for the patient
        2. Early soft tissue surgery with osteotomies when the growth is completed
        3. Tenotomies accompanied by capsulotomies in soft tissue release procedures
        4. Long-term bracing and assistive devices usually needed
    7. Feet
        1. A rigid talipes equinovarus deformity: the most common deformity (Guidera and Drennan 1985)
        2. Bilateral talectomy in the management of bilateral rigid clubfeet (Letts 1999)
        3. Goal of treatment: a plantigrade, braceable foot
    8. Knees (Thomas et al. 1985; Murray and Fixsen 1997)
        1. Goal of treatment: an extended knee for ambulation
        2. Fixed flexion knee deformities more common than fixed extension knee deformities and more resistant to treatment
    9. Hips (Huurman and Jacobsen 1985; Staheli et al. 1987)
        1. Hip surgery follows foot and knee surgery, especially in the presence of knee extension deformities.
        2. Hip surgery in patients younger than 1 year to facilitate ambulation. In some patients with bilateral hip dislocations and extremely mobile hips, open reduction may be attempted.

3. A one-stage open reduction and varus shortening femoral derotational osteotomy for all unilateral hip dislocations and those bilateral hip dislocations that have a less severe generalized involvement and an aggressive traction program with appropriate soft tissue releases during the neonatal period for patients with subluxation and/or marked limitation of motion of the hip (St. Clair and Zimbler 1985)

10. Upper extremities (Bennett et al. 1985; Williams 1985)
    1. Treatment involves development of self-help skills (e.g., feeding and toileting) (Bayne 1985) and mobility skills (e.g., pushing out of chair and using crutches).
    2. Consider overall function of the entire extremity rather than function of the individual joints in evaluating the upper extremities.
    3. Consider upper extremity surgery until the patient is older than 5–6 years.
    4. Emphasis is placed on evaluation of the disability by repeated testing and observation. In many cases, the deformities will be accepted and improvements in function will be gained by orthoses or attention to details of seating, dressing, and toileting.
    5. Surgery is indicated in some cases, especially at the elbow, to obtain mobility, flexor power, or both. Arthrodesing the wrist is also useful in some cases.
    6. When surgery is indicated, it is often desirable to rearrange all three levels – shoulder, elbow, and wrist.
11. Elbows
    1. Goals: passive or active flexion capability (feeding arm) and extension capability (toilet arm) (Axt et al. 1997).
    2. Achieve elbow mobility before correcting a wrist deformity because the elbow is crucial to hand function.
12. Wrists
    1. Stretching and splinting for the major wrist deformity (flexion with ulnar deviation)
    2. Proximal row carpectomy with or without fusion for a severe deformity
13. Fingers
    1. Passive stretching and splinting for minimal to moderate flexion deformities
    2. Soft tissue releases with proximal interphalangeal joint fusions for more severe deformities
    3. Thumb-in-palm deformity to be corrected to provide opposition-improved grasp
14. Spine
    1. The spine affected in about one third of patients.
    2. Scoliosis beginning early and progressing to become a long, severe, rigid, C-shaped curve. This curve responds poorly to orthoses, as it is progressive.
    3. Curves greater than 35°: treated with spinal fusion and instrumentation.
15. Complications
    1. Anesthesia: difficult to administer because vascular access often is restricted.
    2. Intubation: posing problems for patients with a small underdeveloped jaw, limited movement of the temporomandibular joint, or a narrow airway.
    3. Osseous hypoplasia associated with decreased mechanical use in developing bone: prone to fracture at multiple sites. Multiple perinatal fractures have been observed in osteopenic bones.
16. Feeding and toileting devices for a child with arthrogryposis (Hall and Hammock 1979)
17. Summary of the 2nd International Symposium on Arthrogryposis, St. Petersburg, Russia, September 17–19, 2014 (Hall et al. 2015)
    1. Ponseti type casting should begin by 1–2 months of age for clubfeet, and knee dislocations should be casted.
    2. Early imaging of muscle by ultrasound or MRI: important as a baseline for

determination of best therapy and long-term outcomes, for instance, as to whether or not walking can be anticipated.
3. Reports of dramatic improvement in the upper limbs of individuals with amyoplasia, utilizing vigorous physical therapy and muscle transfers.
4. Orthotics for adults with arthrogryposis for stabilization during walk and a carbon spring built into an ankle-foot orthosis may function as muscle when muscles are absent or very weak.
5. Use of the "8-plate": provides temporary hemiepiphysiodesis with a small plate and screws. It has revolutionized the treatment of malaligned knees in the older child, since it is less traumatic than osteotomies and spares muscle tissue.
6. Growing rods: very useful in individuals with arthrogryposis and scoliosis.
7. Adults with arthrogryposis should keep as active as possible, since immobilization in adults with arthrogryposis leads to disproportionate weakness and muscle atrophy.

18. Physical activity
    1. Limited because of existing orthopedic problems
    2. Passive motion therapy for infants with arthrogryposis (Palmer et al. 1985).
    3. As a group, patients cope well socially and participate in social activities corresponding to their needs.
    4. More restricted walking in patients with flexion contractures of the lower extremities than in those with extension contractures. Flexion contractures of the hips severely impair walking ability.
    5. Contracture of the elbow causing a significant degree of disability in hand function.
    6. Impossible to use crutches in patients with upper extremity involvement associated with severe spinal deformity.
    7. Dependent on help from other people to a higher degree in patients with more severe joint involvement than those with less severe joint involvement.
    8. Independent living with productive lives for most children with normal intelligence despite severe handicaps. However, many remain partially dependent on others, such as parents, relatives, and government subsidy. Dependency is related more closely to personality, education, and overall coping skills than to the degree of physical deformity.
    9. Good family support, a proper educational environment, and promotion of independence at an early age: required to achieve maximal function in addition to appropriate surgical correction (Carlson et al. 1985; Hahn 1985).

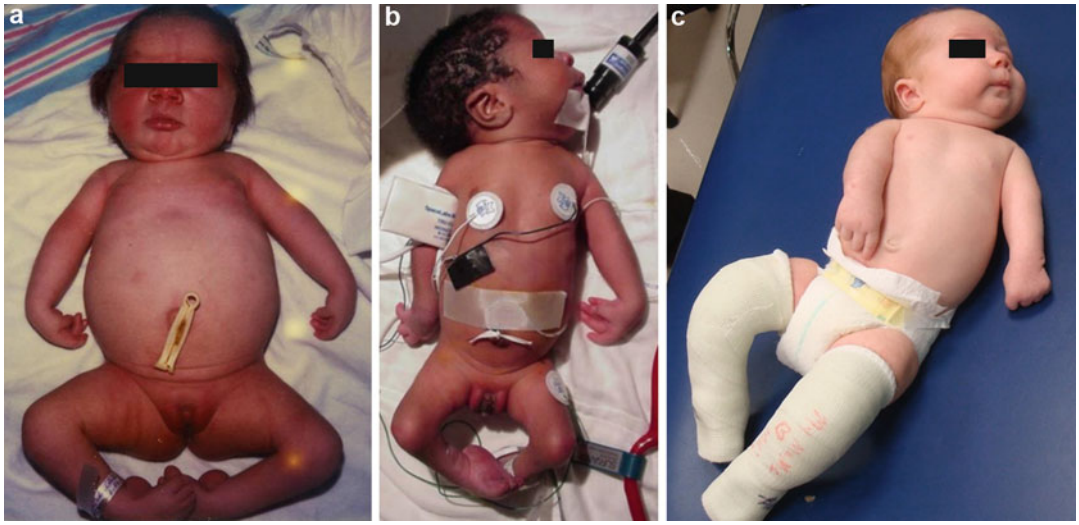

Fig. 1 (**a**–**c**) Three infants with amyoplasia congenita showing typical, symmetrical positioning of the limbs, internally rotated and adducted shoulders, fixed extended elbows, pronated forearms, flexed wrists and fingers, and severe talipes equinovarus deformity

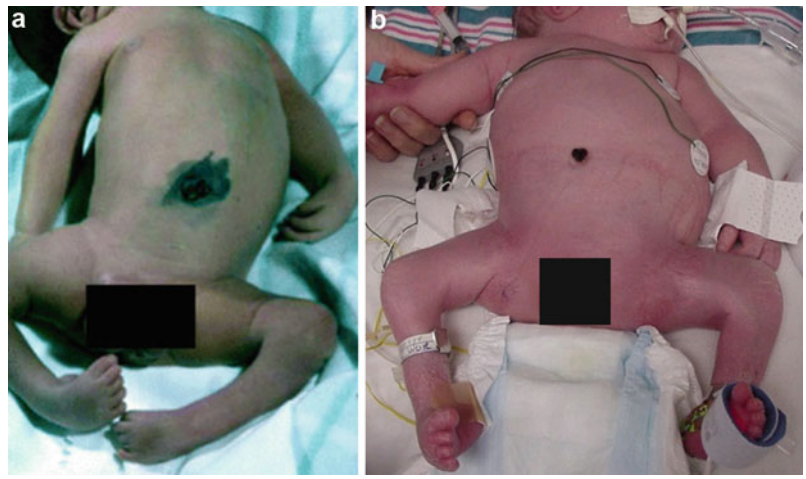

Fig. 2 (**a**–**b**) Two infants with arthrogryposis multiplex congenita characterized by flexion contractures of the knees and fingers and equinovarus deformities of the feet

Fig. 3 (**a**–**b**) An infant with distal arthrogryposis showing predominantly distal contractures with overlapping finger contractures, ulnar deviation of fingers, and clubfeet

Fig. 4 (**a**–**c**) A 33-year-old female was followed for arthrogryposis multiplex congenita. At birth, flexion contractures of the fingers and hands, dysplastic hips, bilateral rocker bottom feet, and "generalized stiffness" were noted. At recent visit, flexion contractures of the elbows, limitation of supination of the wrists, contractures of the thumbs and PIP joints, and operation scars of webbing release between 1st and 2nd fingers and Achilles tendon release were noted

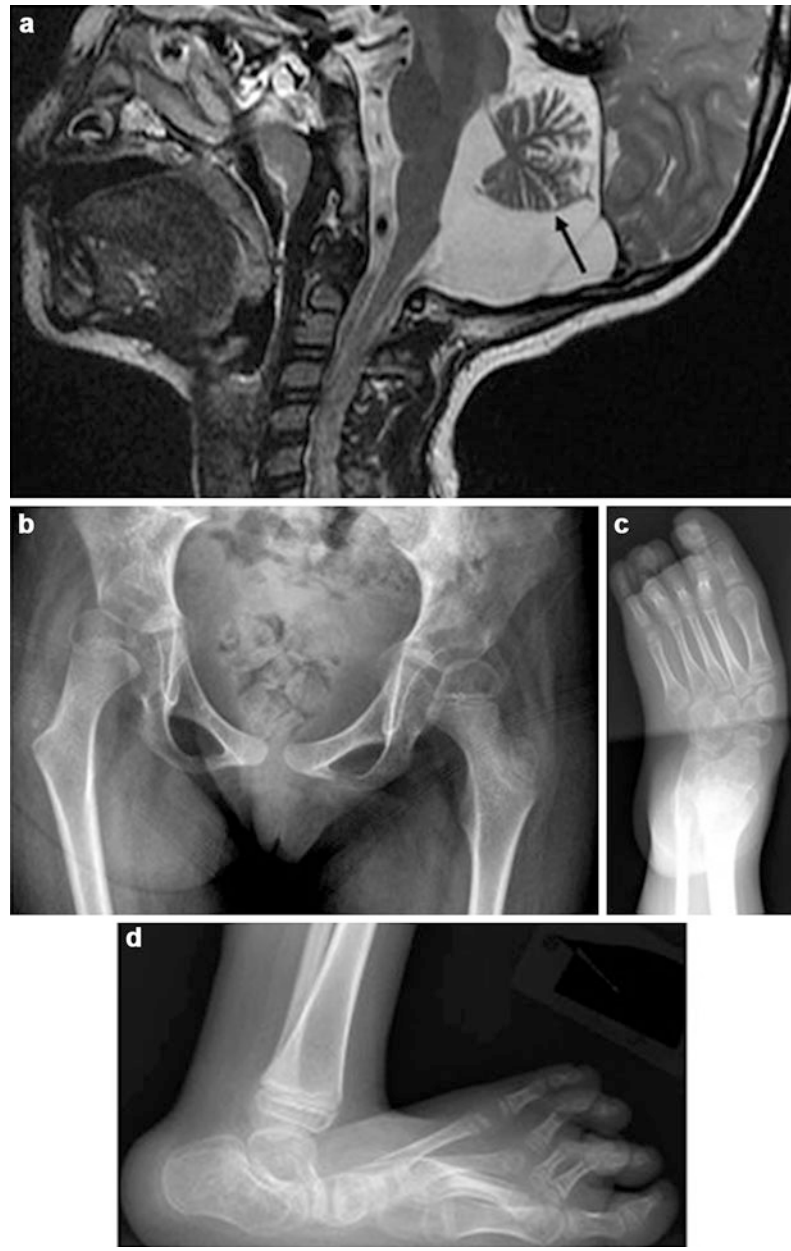

Fig. 5 (**a**–**d**) A 4-year-old girl was seen for arthrogryposis multiplex congenita. MRI image of the brain (**a**) demonstrates hypoplastic cerebellum, particularly the vermis (*black arrow*). This finding can be seen in the neurogenic arthrogryposis multiplex. Pelvic radiography (**b**) demonstrates generalize osteopenia, bilateral coxa valga, and mild lateral uncovering of the femoral heads. Radiographs of the left foot demonstrate osteopenia, exaggerated planovalgus deformity (**c**), and a rocker-bottom configuration (**d**). The right foot has similar deformities (not shown). The family and birth histories were not available since the patient was adopted. High-resolution chromosome study was normal. Molecular studies, including *TPM2*, *MYH3*, and *SMN1* (homozygous deletion of *SMN1*) genes, were negative (Courtesy of Dr. Grace Guo)

Asphyxiating Thoracic Dystrophy

Contents

In 1955, Jeune et al. described familial asphyxiating thoracic dystrophy (ATD) in a pair of siblings with severely narrow thoraxes. This condition is also known as Jeune syndrome. Incidence is estimated at 1 per 100,000–130,000 live births (den Hollander et al. 2001).

Jeune syndrome, a potentially lethal congenital dwarfism, is a rare autosomal recessive disorder characterized by typical skeletal dysplasias, such as a narrow thorax and micromelia, with respiratory and renal manifestations. Respiratory manifestations vary widely from respiratory failure and infantile death to a latent phenotype without respiratory symptoms.

Synonyms and Related Disorders

Jeune Syndrome; Thoracic-pelvis-phalangeal dystrophy/dysplasia

Genetics/Basic Defects

1. Inheritance: autosomal recessive
2. Genetically heterogeneous
    1. One locus mapped to chromosome 15q13 (Morgan et al. 2003).
    2. Families with both mild and severe forms of ATD mapped to 15q13.
    3. Five consanguineous families sharing a 1.2 cM region of homozygosity between D15S165 and D15S1010.
    4. Mutations in the intraflagellar transport 80 (*IFT80*) gene (Beales et al. 2007) have been recently identified in 3/39 families originating from Pakistan and Turkey, ascribing ATD to the ciliopathy group (Morgan et al. 2003). However, *IFT80* was excluded in a series of 26 fetuses and children belonging to 14 families diagnosed with either ATD or short rib-polydactyly syndrome, type III (SRP III) (Dagoneau et al. 2009).
    5. *DYNC2H1* Mutations: cause asphyxiating thoracic dystrophy (also cause SRP III) (Dagoneau et al. 2009).
        1. Studying a consanguineous family from Morocco, another locus was mapped to chromosome 11q14.3-q23.1 in a 20.4 Mb region and identified homozygous mutations in the cytoplasmic dynein 2 heavy chain

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_17

1 (*DYNC2H1*) gene in the affected children.
2. Compound heterozygosity for *DYNC2H1* mutations was also identified in four additional families.
3. Among the five families, three were diagnosed with ATD and two included pregnancies terminated for SRP type III.
4. *DYNC2H1* is a component of a cytoplasmic dynein complex and is directly involved in the generation and maintenance of cilia.
5. ATD and SRP type III are variants of a single disorder belonging to the ciliopathy group.

6. To date, mutations in IFT80, DYNC2H1, TTC21B, and WDR19 have been reported in ATD (Baujat et al. 2013). The identification of IFT80 mutations in ATD has first confirmed that ATD belongs to the spectrum of cilia disorders (Beales et al. 2007). More recently, mutations in DYNC2H1 (dynein cytoplasmic 2 heavy chain 1), TTC21B (Tetratricopeptide repeat-containing Hedgehog Modulator 1), and WDR19 (WD Repeat-Containing Protein 19) have been reported in ATD cases (Dagoneau et al. 2009; Merrill et al. 2009; Davis et al. 2011; Bredrup et al. 2011).

Clinical Features

1. Wide phenotypic variability (Oberklaid et al. 1977; Özçay et al. 2001; Tüysüz et al. 2009; de Vries et al. 2010)
2. Classification of ATD
    1. Lethal form
    2. Severe form
    3. Mild form (Giorge et al. 1990)
    4. Latent form (Kozlowski and Masel 1976)
3. Short-limbed dwarfism
4. Growth retardation
5. Respiratory distress
    1. Respiratory distress secondary to a small thorax.
        1. Motionless thorax
        2. Abdominal respiration
        3. Considerable supraclavicular, suprasternal, and intercostal space retraction on inspiration
    2. Severe dyspnea and extreme cyanosis in severe cases.
    3. Some infants with only respiratory symptoms in conjunction with infection.
    4. Some individuals lack respiratory symptoms in infancy or childhood.
6. Chest deformity of varying degree.
    1. A long, narrow, and abnormally small thorax with reduced thoracic cage capacity.
    2. Lung hypoplasia and respiratory distress usually leading to early death.
    3. The symptom of small thorax usually improves with age for those who survive early childhood.
7. Limbs.
    1. Variable micromelia and short digits with bulbous terminal phalanges
    2. Occasional postaxial polydactyly of the hands and feet
8. Eyes: occasional retinal degeneration (Allen et al. 1979; and retinal aplasia (Phillips et al. 1979).
9. Occasional intestinal malabsorption.
10. Renal lesions (Herdman and Lalnger 1968; Bernstein et al. 1974; Shah et al. 1980):
    1. Focal cystic change and severe cystic dysplasia
    2. Renal failure developing during infancty, early adolescence, or second decade of life
11. Polyuria, polydipsia, and hypertension occur during the second or third year of life.
12. Occasional involvement of the liver.
    1. Prolonged neonatal jaundice
    2. Polycystic liver disease
    3. Hyperplasia of the bile ducts
    4. Congenital hepatic cirrhosis
13. Occasional involvement of the heart.
    1. Cardiac failure secondary to increased pulmonary vascular resistance, thoracic constriction, and alveolar hypoplasia

2. Possible intrinsic myocardial disease
14. Cystic changes of pancreatic ducts and pancreatic exocrine insufficiency occur in long-term survivors.
15. Occasional involvement of the teeth, nails, and other organs.
16. Occasional association with Hirschsprung disease (Aurora and Wallis 1999)
17. Prognosis.
    1. Difficult to predict in each individual case because frequent pulmonary complications and cystic renal lesions are not always directly related to severity of skeletal changes.
    2. The skeletal dysplasia of this entity is compatible with life, though respiratory failure and infections are often fatal during infancy.
    3. Considerable variation in the severity of thoracic constriction: For those patients who survive infancy, the thorax tends to revert to normal with improving respiratory function. This suggests that the lungs have a normal growth potential and the respiratory problems are secondary to restricted rib cage deformity.
    4. Renal failure: Renal involvement is the major prognostic factor in those patients who survive the respiratory insufficiency during infancy.
    5. Short stature in survivors.
18. Morbidity and mortality.
    1. Alveolar hypoventilation
        1. The most common and prominent clinical presentation
        2. Caused by impaired chest expansion as a result of short horizontally placed ribs
    2. Bilateral microcystic renal disease gradually progressing to tubular atrophy and renal failure
    3. Most patients (approximately 60–70%) dying from respiratory failure in early infancy and early childhood
    4. Chronic renal failure ensuing in survivors
    5. Few patients reaching adolescence or adulthood
19. ATD overlapping with SRP III (Verma-Naumoff syndrome).
    1. Both conditions share the same radiological features (including the polydactyly).
    2. SRP type III (Ho et al. 2000; Superti-Furga and Unger 2007).
        1. More severe condition
        2. Early prenatal expression and lethality
        3. Variable malformations
            1. Cleft lip and/or palate
            2. Polycystic kidneys
            3. Gastrointestinal, urogenital, brain, and/or cardiac malformations
        4. Severely shortened tubular bones having round metaphyseal ends with lateral spikes

Diagnostic Investigations

1. Laboratory studies
    1. Urinalysis.
        1. Hematuria
        2. Proteinuria
        3. Defective urine-concentrating capacity
    2. Arterial blood gas (ABG): hypoxia and hypercarbia in room air reflecting severe restrictive lung disease.
    3. Whole-genome sequencing screen reveals *DYNC2H1* mutations as a frequent cause of Jeune asphyxiating thoracic dystrophy, affecting about a third of all families (Schmidts et al. 2013).
2. Imaging studies (Pirnar and Neuhauser 1966; Langer 1968; Cortina et al. 1979; Chen 2015)
    1. Newborn and infant radiography
        1. Small and bell-shaped thorax with reduced transverse and anterior-posterior diameter
        2. Abnormal clavicles (“bicycle handlebar shaped”)
        3. Short and horizontally oriented ribs with irregular costochondral junctions and bulbous and irregular anterior ends
        4. Abnormal pelvis
            1. Short squared iliac wings

2. Trident appearance of acetabular margin
5. Short limbs relative to trunk
6. Variable limb shortening
7. Short phalanges, metacarpals, or metatarsals with or without polydactyly
8. Premature ossification of the capital femoral epiphyses

2. Childhood radiology
1. Relatively larger thorax with growth of ribs compared to infancy
2. Short ilium with normal flaring of iliac wings
3. Striking cone-shaped epiphyses and early fusion between the epiphyses and metaphyses of the distal and middle phalanges
4. Short distal and middle phalanges
5. Varying shortening of extremities relative to trunk
6. Subtypes of ATD
1. Type I: irregular metaphyseal ends
2. Type II: smooth metaphyseal ends

3. Pulmonary function test to detect severe restrictive lung disease
4. Histology (Turkel et al. 1985; Chen 2015)
1. Lungs: Hypoplastic due to a marked reduction in the number of alveolar ducts and alveoli (hypoplasia of alveoli) (Finegold et al. 1971)
2. Cartilages (Yang et al. 1976, 1987): retarded endochondral ossification in both types
1. ATD type I: irregular cartilage-bone junction with patchy distribution of physeal growth zone of chondrocytes
2. ATD type II: smooth cartilage-bone junctions
3. Kidneys
1. Cystic renal dysplasia and hypoplasia
2. Nephronophthisis or interstitial nephritis
1. Diffuse interstitial and periglomerular fibrosis
2. Round cell lymphocytic infiltration
3. Hyalinized glomeruli
4. Pericapsular thickening
5. Thickened basement membrane
6. Dilated or atrophic tubules
3. Pyelonephritis with scarring
4. Distortion of renal parenchyma
4. Liver (Yerian et al. 2003)
1. Periportal hepatic fibrosis
2. Bile duct proliferation
3. Early cirrhosis

Genetic Counseling

1. Recurrence risk
1. Patient's sib: 25%
2. Patient's offspring: usually lethal, not surviving to reproductive age
2. Prenatal diagnosis by ultrasonography
1. Detection of affected second- and third-trimester fetuses of at-risk families
2. Characteristic ultrasonographic findings (Elejalde et al. 1985; Schinzel et al. 1985; Skiptunas and Weiner 1987; Chen et al. 1996; Hsieh et al. 1999; Tongsong et al. 1999; Das et al. 2002; Chen 2015)
1. Narrow thorax
2. Short hypoplastic ribs
3. Short tubular bones
4. Renal cystic changes
3. Other ultrasonographic findings
1. Polyhydramnios
2. Absent or feeble fetal respiratory movements
3. Increased nuchal translucency
4. With or without polydactyly
5. Ventriculomegaly
6. A single umbilical artery
3. Management (Chen 2015)
1. Medical care
1. Supportive care
2. Mechanical ventilation
1. Urgently required in the most severe cases, those when

respiratory distress develops immediately after birth
2. Less severe cases gradually progressing to respiratory failure as a result of multiple recurrent pulmonary infections
3. Treat respiratory infections vigorously with antibiotics, endotracheal suctioning, and postural drainage
4. Nasogastric or gastrostomy feedings if needed
5. Ursodeoxycholic acid used to control the progression of the hepatic dysfunction (Labrune et al. 1999)

2. Surgical care
1. Surgery indicated only in the most severe cases in which failure to intervene will result in progressive pulmonary damage and eventual death (Sharoni et al. 1998). No data is currently available on long-term follow-up care of patients who have been surgically treated.
2. Expansion thoracoplasty utilizing various surgical techniques (Barnes et al. 1971; Kaddoura et al. 2001).
1. Splitting the sternum or the rib cage and maintaining the separation with methacrylate (Todd et al. 1986; Sarimurat et al. 1998).
2. Rib grafts.
3. Homologous bone grafts.
4. Lateral rib cage expansion (Davis et al. 1995) using staggered superiosteal rib osteotomies and rigid titanium miniplate and screw augmentation and stabilization.
5. Modified Bailey rib approximator to provide a calibrated dynamic separation for the sternum after the primary procedure of midsternotomy and methylmethacrylate sternoplasty.
6. Treating Jeune syndrome patients with Dynamic Postero-Lateral Expansion Thoracoplasty, using 70 mm radius VEPTR, likely translates into improved respiratory function, decreasing mortality, and clinical respiratory morbidity (O'Brien et al. 2015).
3. Dialysis and renal transplantation (Amirou et al. 1998) indicated for renal failure. Recently, cadaver renal transplantation was successful in a 10-year-old boy with Jeune syndrome type 2 (Amirou et al. 1998).
4. Surgical complications.
1. Pneumothorax
2. Mucous plugging of a bronchus
3. Repeated infections
4. Progressive herniation of lung through sternal defect
5. Cardiac insufficiency

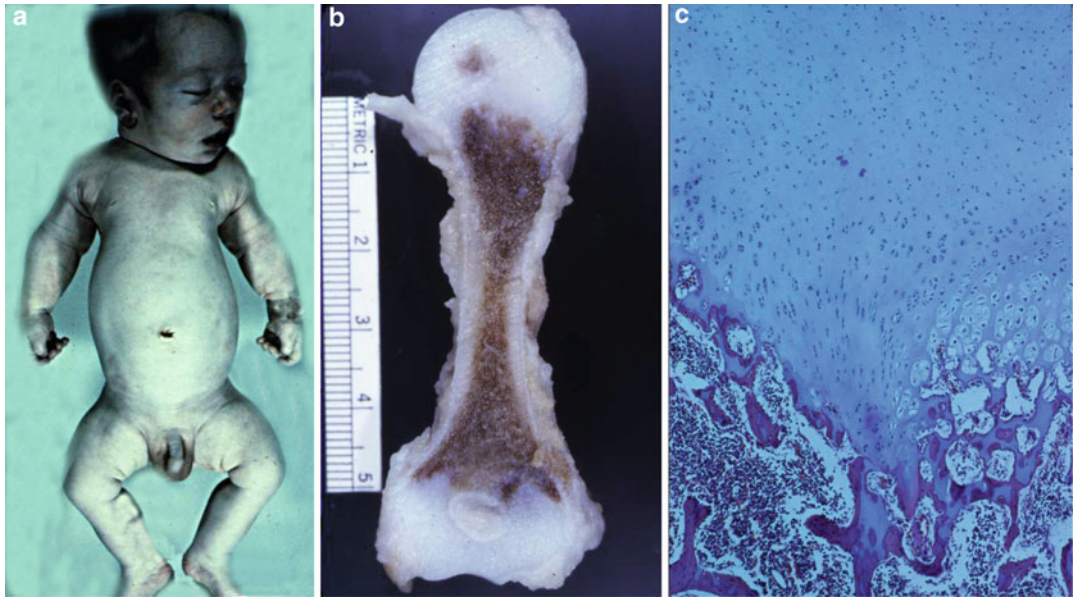

Fig. 1 (**a**–**c**) A neonate died of respiratory insufficiency. The chest is severely narrow and limbs mildly shortened (Yang et al. 1976). The longitudinal section of the humerus shows irregular cartilage-bone junctions. There is a premature ossification center in the proximal epiphysis. The photomicrograph of the physeal growth zone shows scattered areas (*left* two third of the picture) of severe retardation and disorganization. Consequently, the cartilage-bone junction is irregular

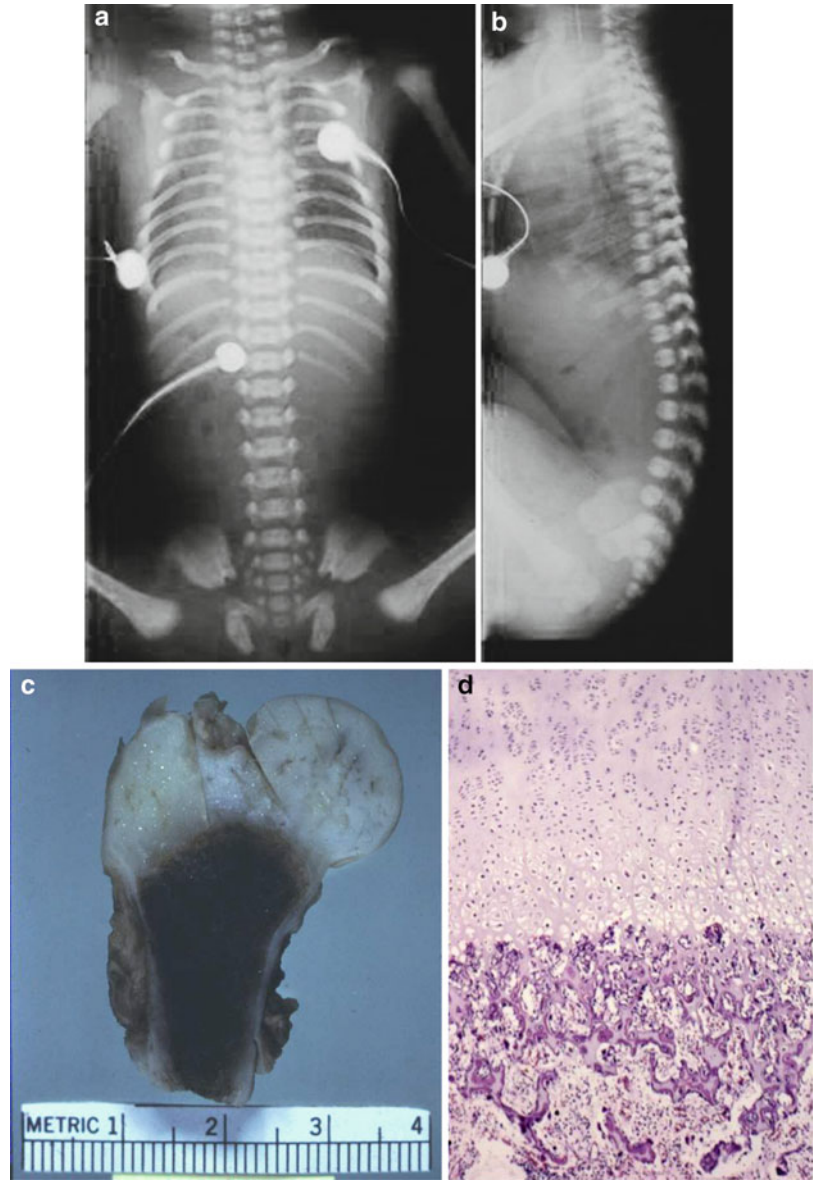

Fig. 2 (**a**–**d**) Radiographs of the skeletal system of a neonate with type II asphyxiating thoracic dystrophy. The ribs are short. The ilia are vertically shortened. The findings are similar in both types I and II. However, the metaphyseal ends of tubular bones do not show irregularity or spurs as in type I. Photomicrograph of the proximal femur shows generalized retardation and disorganization of the physeal growth zone. The cartilage columns in the metaphysis form a lattice-like meshwork

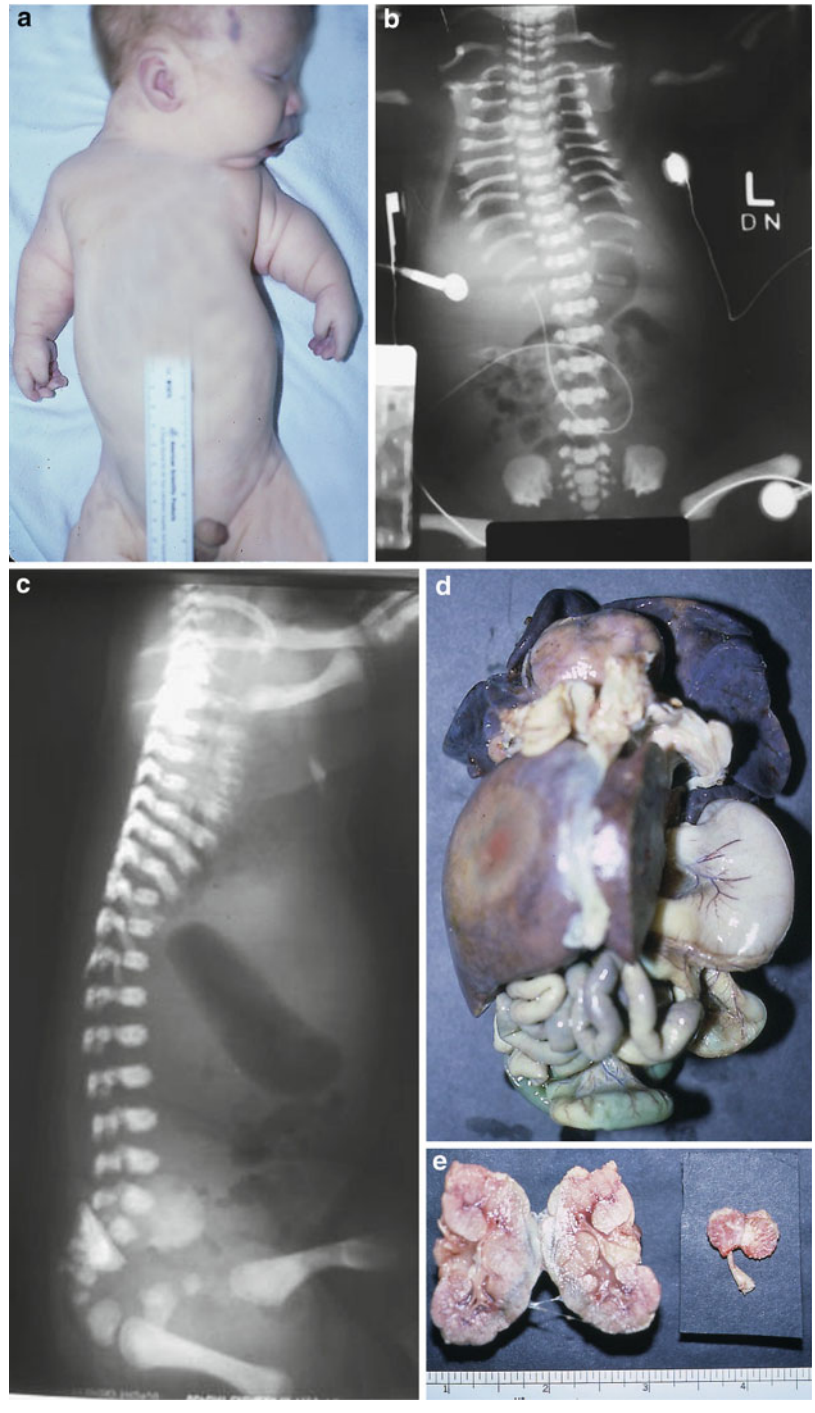

Fig. 3 (**a**–**e**) An infant with type II asphyxiating thoracic dystrophy showing a narrow thorax and short *upper* extremities. The radiographs showed the handlebar clavicles, short horizontal ribs with widened/cupped anterior rib ends, and *square-shaped* iliac bones with the medial spurs of both acetabular roofs. The necropsy showed lung hypoplasia and renal cystic dysplasia and hypoplasia

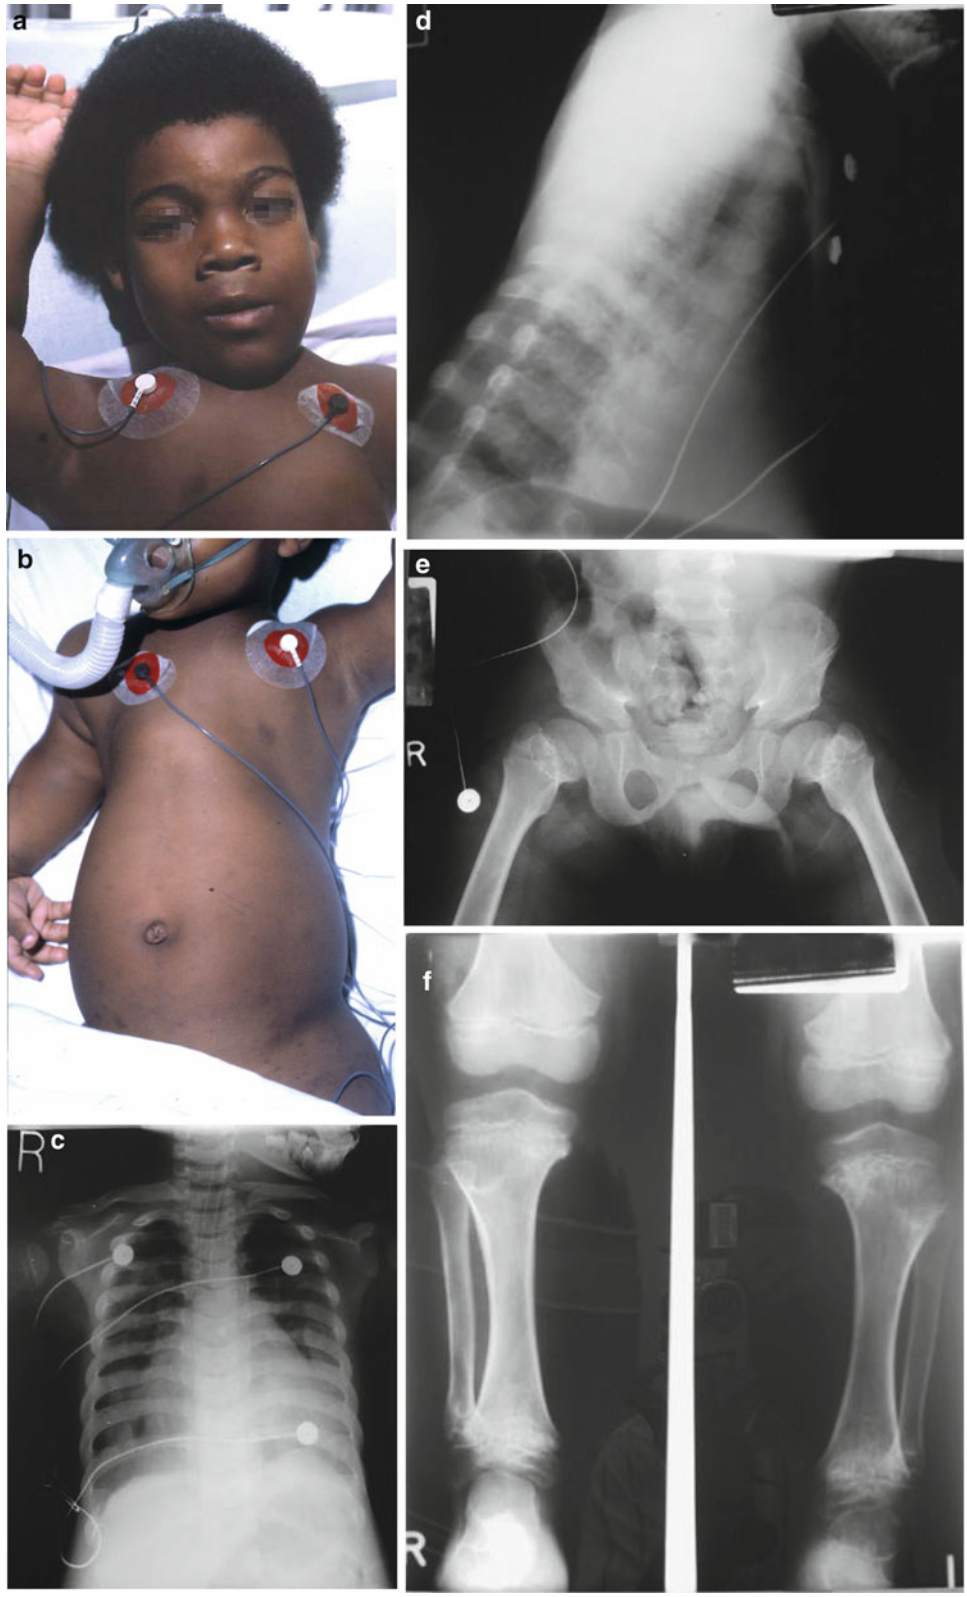

Fig. 4 (continued)

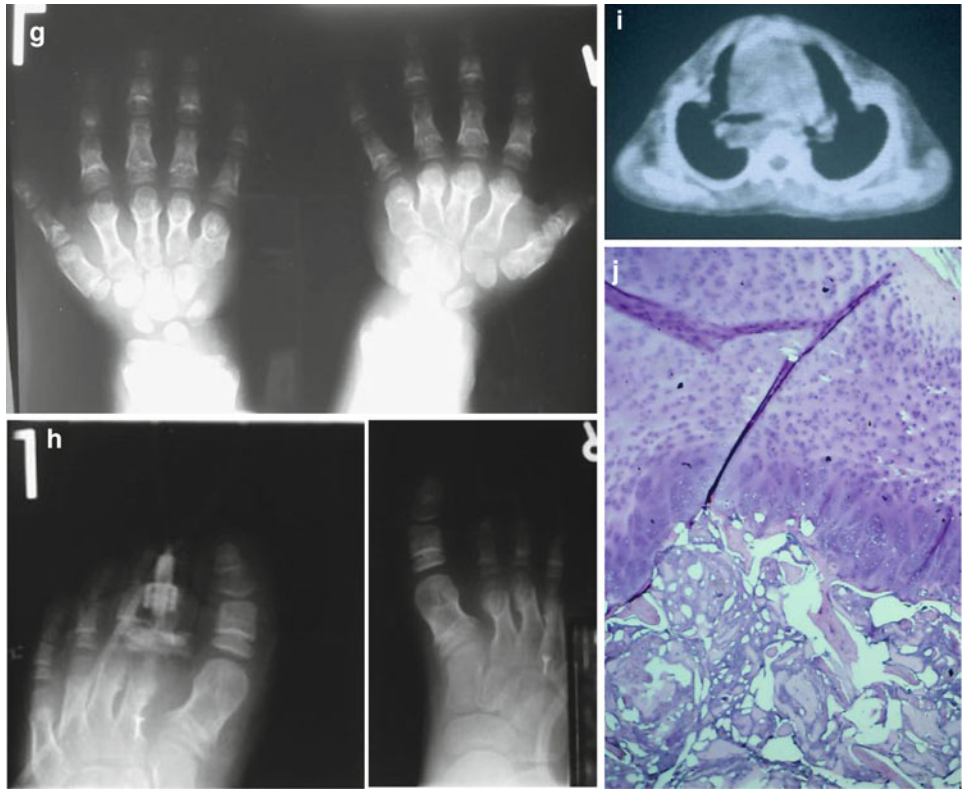

Fig. 4 (**a**–**j**) A 7-year-old boy with asphyxiating thoracic dystrophy showing a narrow thorax and short limbs. He had dwarfism, postaxial polydactyly, and respiratory distress since birth. Radiographs showed handlebar clavicles, short horizontal ribs, oblique superior acetabular margins, shortened tubular bones, shortened phalanges especially the middle and distal phalanges, and *cone-shaped* epiphyses. CT of the chest showed a narrow thorax, shortened ribs, and lung hypoplasia. Histology of the ribs showed that resting chondrocytes were widely separated by abundant cartilaginous matrix. Histology of a rib physeal growth zone shows greatly reduced number of chondrocytes. In some areas, they are completely nonexistent

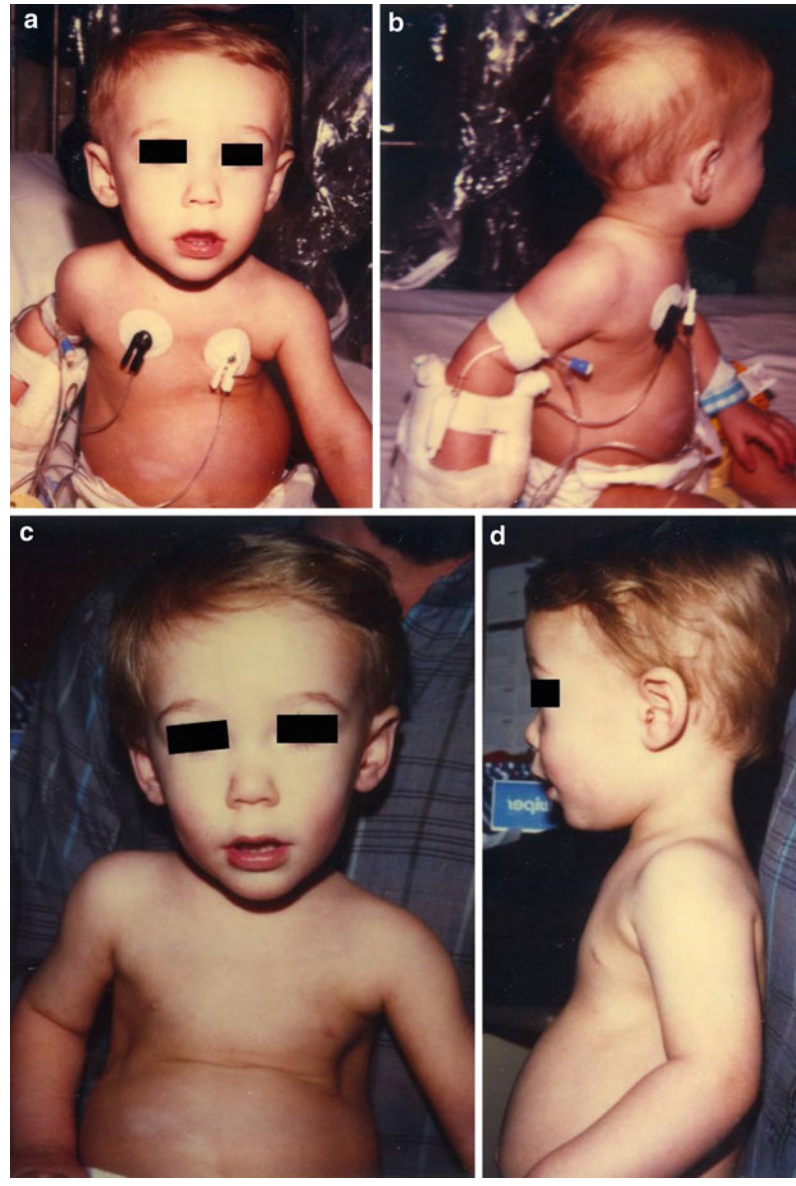

Fig. 5 (**a**–**d**) A boy with type II asphyxiating thoracic dystrophy at 7 months and 15 months

Fig. 6 (**a**–**f**) This 3-year-old Caucasian girl (**a**–**d**) was evaluated for short stature, short limbs, and a narrow chest. The prenatal ultrasonography at 16 weeks gestation showed short limbs and small rib cage. The fetus was suspected to have the same condition as the first female sibling, who died shortly after birth of asphyxiating thoracic dystrophy. On examination, the patient showed short-limb dwarfism and a long, narrow, and small thorax with history of respiratory distress. She required a PEG tube for feeding. Radiographs shortly after birth (**e**, **f**) showed the handlebar clavicles, short horizontal ribs with widened/cupped anterior rib ends, and square-shaped iliac bones with the medial spurs of both acetabular roofs (Courtesy of Dr. Eric Chen)

Ataxia-Telangiectasia

Contents

Ataxia-telangiectasia (A-T) is a rare hereditary disorder characterized by progressive cerebellar ataxia, conjunctival telangiectasias, recurrent sinopulmonary infections, radiosensitivity, and a predisposition to malignancy. It is the most common cause of progressive cerebellar ataxia in childhood. The prevalence is estimated to be 1 in 40,000–1 in 100,000 live births.

Synonyms and Related Disorders

Louis-Bar syndrome

Genetics/Basic Defects

1. Inheritance
   1. Autosomal recessive
   2. Genetic heterogeneity in at least five complementation groups (A–E)
2. Cause
   1. Mutations in the ataxia-telangiectasia mutated gene (*ATM*) which is mapped to 11q22.3
   2. Results from inactivation of the ATM kinase (Frappart and McKinnon 2006)
   3. Affected individuals completely lack functional ATM protein
   4. Diversity of ATM gene mutations (Concannon and Gatti 1997; Gatti 1997)
   5. A high prevalence of specific *ATM* mutations in certain ethnic groups (Amish, Mennonite, Costa Rican, Polish, British, Italian, Turkish, Iranian, Israeli) with a founder effect (Telatar et al. 1998), resulting in a small number of mutations that accounts for the majority of disease-causing mutant alleles
3. Pathophysiology
   1. Basic defect: abnormal sensitivity of A-T cells to X-rays and certain radiomimetic chemicals, leading to chromosome and chromatid breaks. However, sensitivity of A-T cells to ultraviolet irradiation is normal (Janniger 2015).
   2. Random distribution of breakpoints
   3. Nonrandom chromosome rearrangements selectively affect chromosomes 7 and 14 at sites that are concerned with T-cell receptors and heavy-chain immunoglobulin coding and with the development of hematologic malignancies
   4. Mechanisms responsible for neurologic disease, thymus aplasia, telangiectasias,

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_18

growth retardation, and impaired organ mutation
1. Have not been elucidated
2. Most likely linked to accelerated telomere loss

5. NADPH oxidase 4 (NOX4): involved in manifesting A-T disease (Weyemi et al. 2015)

4. Analyses of ATM mutations in A-T patients and in sporadic tumors suggest the existence of two classes of ATM mutation (Meyn 1999):
   1. Null mutations that lead to A-T
   2. Dominant negative missense mutations that may predispose to cancer in the heterozygous state
5. To date, more than 780 mutations in the *ATM* gene have been reported (Taylor and Byrd 2005; Chen et al. 2015)
   1. Truncating mutations
   2. Missense mutations
   3. Splice site mutations
   4. Founder mutations
   5. Small indels
   6. Large deletions
   7. Duplications
6. Genotype-phenotype correlations (Gatti 2010)
   1. 576ins137nt mutation
      1. Somewhat slower rate of neurological deterioration
      2. Later onset of symptoms
      3. Intermediate radiosensitivity
      4. Little or no cancer risk
   2. 8494C>T mutation
      1. Milder phenotype
      2. Longer life span
7. Genetic and clinical heterogeneity (Taylor et al. 2015)
   1. Allelic heterogeneity in *ATM* results in a striking clinical heterogeneity
   2. Locus heterogeneity: mutation of *MRE11* gene can cause an obvious A-T-like disorder both clinically and also at the cellular level and mutation of the *RNF168* gene results in a much milder clinical phenotype, neurologically, with the major clinical feature being an immunological defect

Clinical Features

1. CNS manifestations (Woods and Taylor 1992; Regueiro et al. 2000)
   1. Functional neurologic abnormalities rare in infancy
   2. Cerebellar ataxia
      1. A presenting symptom
      2. Slowly progressive
      3. Truncal ataxia preceding appendicular ataxia and peripheral incoordination
      4. Swaying of the head and trunk while standing and sitting: early sign of ataxia
   3. Diminished or absent deep reflexes by school age
   4. Hypotonia
   5. Dystonia and progressive spinal muscular atrophy affecting hands and feet in affected young adults, resulting in extension contractures
   6. Dysarthric speech
   7. Flexor plantar response
   8. Choreoathetosis in almost all patients
   9. Myoclonic jerking and intention tremors in about 25% of patients
   10. Drooling
   11. Oculomotor apraxia (total or partial loss of the ability to perform coordinated movement or manipulate objects in the absence of motor or sensory impairment) affecting reading (eye tracking) and writing (affected by 7–8 years of age)
   12. Intellectual function generally preserved
2. Telangiectasias (dilated small blood vessels)
   1. Ocular conjunctiva: most frequently observed
   2. Other sites: nose, ears, behind the knees, antecubital fossae, suprasternal notch, dorsum of the hands and feet, and hard and soft palate

3. Usually noticed during 3–6 years of age, i.e., a few years after ataxia
3. Immunodeficiency
   1. Frequent sinopulmonary infections
      1. Mucopurulent rhinitis, retropharyngeal discharge, otitis media, and sinusitis
      2. Bronchitis and pneumonia
      3. Progress to chronic lung disease: bronchiectasis, pulmonary fibrosis, respiratory insufficiency
   2. A small embryonic-like thymus
   3. Problems associated with defects in humoral and cellular immunity
      1. T-cell deficiency in about 30% of patients
      2. Severe immunodeficiency in about 10% of patients
      3. IgA and IgG_2 deficiency: most common
   4. Most frequent cause of death in adolescence: bronchiectasis complicated by pneumonitis
4. Malignancy
   1. The second most frequent cause of death
   2. Eventual malignancy during lifetime in 38% of patients
   3. Malignancy of hematologic origin most common (Taylor et al. 1996) (85% of patients)
      1. Predominance of malignant lymphomas, usually of B-cell type
      2. Acute lymphocytic leukemia of T-cell origin in younger patients
      3. T-cell prolymphocytic leukemia in older patients
   4. Other neoplasms (Swift et al. 1987, 1991)
      1. Breast cancer, even in female relatives who do not have ataxia telangiectasia
      2. Gastric cancer
      3. Melanoma
      4. Leiomyoma
      5. Sarcoma
5. Ectodermal changes
   1. Appearance of premature aging
      1. Diffuse graying of the hair
      2. Atrophic and hidebound facial skin
      3. Inelastic ears
      4. Facial wasting
   2. Frequent pigmentary changes (Greenberger et al. 2013)
      1. Hyper-/hypopigmentation with cutaneous atrophy and telangiectasia
      2. Partial albinism
      3. Vitiligo
      4. Hypopigmentary macules
      5. Café-au-lait spots
      6. Melanocytic nevi
   3. Hypertrichosis
   4. Seborrheic dermatitis
6. Respiratory manifestations (Bhatt et al. 2015)
   1. Recurrent respiratory tract infections including otitis media, sinusitis, bronchitis and pneumonia
   2. Bronchiectasis secondary to recurrent/chronic infection and aspiration
   3. Interstitial lung disease
   4. Obliterative bronchiolitis
   5. Aspiration syndromes due to incoordinate swallowing
   6. Opportunistic infections
   7. Restrictive lung disease due to scoliosis, neuromuscular disease or fibrosis
7. Endocrine manifestations
   1. Infertility has been described as a major feature of A-T; several reports of fertile A-T female patients have been reported (Stankovic et al. 1998; Worth et al. 2013; Dawson et al. 2015)
   2. Occasional female hypogonadism associated with ovarian hypoplasia or dysplasia
   3. Male hypogonadism with delayed puberty and characteristic high-pitched voice
8. Clubbing: Observed in 40% of Costa Rican patients not correlated with chronic lung disease, humoral immunodeficiency, or with a particular mutation
9. Other features
   1. Mild postnatal growth retardation
   2. Hypersensitivity to ionizing radiation
   3. Wheelchair-bound by 10 years of age
10. Clinical diagnosis (Gatti et al. 1991)

1. Presents with two diagnostic hallmarks of disease – the early-onset cerebellar ataxia and the oculocutaneous telangiectasia
2. Association of these hallmarks with the characteristic hypotonic cerebellar facies and posture: striking

11. A-T shares similar clinical symptoms and cellular characteristics with two other syndromes: A-T-like disorder (ATLD) and Nijmegen-breakage syndrome (NBS) (Lavin 2008)
    1. Defective protein
        1. A-T: ATM
        2. ATLD: MRE 11
        3. NBS: NBS1
    2. Appearance of symptoms
        1. A-T: infancy
        2. ATLD: first decade
        3. NBS: infancy
    3. Progression
        1. A-T: rapid
        2. ATLD: slow
        3. NBS: rapid
    4. Neurological defect
        1. A-T: cerebellar atrophy
        2. ATLD: cerebellar atrophy
        3. NBS: microencephaly
    5. Oculomotor apraxia
        1. A-T: present
        2. ATLD: present
        3. NBS: absent
    6. Immunodeficiency
        1. A-T: present
        2. ATLD: absent
        3. NBS: present
    7. Telangiectasia
        1. A-T: present
        2. ATLD: absent
        3. NBS: absent
    8. Alpha-fetoprotein
        1. A-T: high
        2. ATLD: normal
        3. NBS: normal
    9. Growth defect
        1. A-T: absent
        2. ATLD: absent
        3. NBS: present
    10. Radiosensitivity
        1. A-T: marked
        2. ATLD: present
        3. NBS: present
    11. Cell-cycle checkpoint defect
        1. A-T: present
        2. ATLD: present
        3. NBS: present
    12. DNA-repair defect
        1. A-T: present
        2. ATLD: questionable
        3. NBS: present
    13. Chromosomal instability
        1. A-T: present
        2. ATLD: present
        3. NBS: present
    14. Cancer predisposition
        1. A-T: present
        2. ATLD: absent
        3. NBS: present

Diagnostic Investigations

1. Immune workup: presence of significant humoral and cellular immune defects in most patients (Gatti 2010; Regueiro et al. 2000)
    1. Thymic hypoplasia
    2. Low numbers of circulating T-cells
    3. Functional impairment of T-cell-mediated immunity
    4. Selective deficiencies of IgA, IgE (Ammann et al. 1969), IgG_2, and IgG_4
    5. Low or absent serum levels of IgA in 60% of patients
    6. Low or absent serum levels of IgG2 in 80% of patients
    7. Hyper IgM in approximately 1% of patients, sometimes associated with myeloma-like gammopathy, lymphadenopathy, hepatosplenomegaly, and lymphocytic interstitial pneumonitis
    8. Poor in vivo response to pneumococcal polysaccharides (Sanal et al. 1999)
    9. Immunoblotting for ATM protein (Gatti 2010)
        1. Severely depleted intracellular ATM protein in most patients with A-T
            1. About 90% have no detectable ATM protein

   2. About 10% have trace amounts of ATM protein
   3. About 1% have a normal amount of ATM protein that lacks ATM serine/threonine kinase activity (so-called kinase-dead)
2. The most sensitive and specific clinical test, to date, for establishing a diagnosis of A-T
3. Small amounts of ATM protein: occasionally associated with a milder prognosis, although there are many exceptions to this and the association needs further validation

2. Increased serum levels of alpha-fetoprotein (AFP) levels in over 95% of A-T cases (Chun and Gatti 2004): a simple, rapid, and reliable screening test for A-T
3. Liver disease (Weiss et al. 2015)
   1. Elevated liver enzymes: frequent finding in A-T (43% of patients)
   2. Presence of positive correlation between dyslipidemia and elevated liver enzymes
   3. Patients with elevated liver enzymes should be evaluated for liver disease emphasizing hepatic steatosis.
   4. Progression to advanced liver disease may occur at a young age.
4. Increased plasma levels of carcinoembryonic antigen
5. Colony survival assay (Sun et al. 2002; Chun and Gatti 2004) by in vitro testing for radiosensitivity on lymphoblastoid cell line to measure the colony survival fraction after 1 Gy of in vitro radiation: sensitivity and specificity exceeding 95% but takes 2–3 months to complete
6. Western blot analysis to detect ATM protein in lysates of a lymphoblastoid cell line
7. DNA-based mutation analysis of the *ATM* gene available clinically
   1. Sequence analysis of the *ATM* coding region
   2. Deletion/duplication analysis
   3. Targeted mutation analysis
   4. Linkage analysis/ethnic haplotype analysis to identify carriers among family members at risk if direct DNA testing fails to identify two disease-causing mutations in the index case
8. Targeted next-generation sequencing (Chen et al. 2015): identification of causative variants of *ATM* gene
9. Chromosome analysis to identify genetic instability (Mavrou et al. 2008), a hallmark of the A-T phenotype
   1. Types of spontaneous in vitro chromosome aberrations, frequent in both lymphoid and non-lymphoid cells
      1. Chromosome breaks
      2. Acentric fragments
      3. Dicentric chromosomes
      4. Structural arrangements
      5. Telomeric fusions
      6. An increased rate of telomeric shortening (Metcalfe et al. 1996)
      7. Aneuploidy
   2. A-T lymphocytes
      1. Increased chromosome breaks. Common breakage points include 7p14, 7q35, 14q12, 14qter, 2p11, 2p12, and 22q11-q12
      2. Clonal rearrangements involving abnormalities of chromosome 14, especially tandem duplication of 14q at 14q11-q12 and characteristic t(7;14) (Chun and Gatti 2004)
   3. Non-lymphoid cells: break points randomly distributed
10. Radiography
    1. Decreased or absent adenoidal tissue in the nasopharynx
    2. Small or absent thymic shadow
    3. Decreased mediastinal lymphoid tissue
    4. Pulmonary changes similar to those seen in cystic fibrosis
11. EEG and nerve conduction velocities
    1. Frequently normal in children
    2. Showing denervation on EEG and reduced nerve conduction in the late stage of the disease, especially in sensory fibers
12. Electrooculography
    1. Shows characteristic oculomotor abnormality of A-T
    2. Differentiates A-T from Friedreich ataxia

13. MRI of the brain (Chun and Gatti 2004; Sauma et al. 2015)
    1. A small cerebellum (cerebellar atrophy)
    2. Multiple T1 and T2 hypointense foci suggestive of hemosiderin, probably related to thrombosis and vascular leaks from multiple capillary telangiectasias (Lin et al. 2014; Sahama et al. 2014)
    3. Widened sulci
    4. Enlargement of the fourth ventricle
14. Histology (Janniger 2015)
    1. Degeneration of Purkinje and granule cells in the cerebellum: the major pathological marker of A-T in the CNS
    2. Late degenerative gliovascular nodules in the white matter
    3. Lesions of the basal ganglia observed only occasionally
    4. Degeneration of spinal tracts and anterior horn cells often present in late stages
    5. Nucleocytomegaly, a feature of several cell types throughout the body

Genetic Counseling

1. Recurrence risk: counseling according to autosomal recessive inheritance
    1. Patient's sib
        1. A 25% recurrence risk
        2. Two thirds of unaffected sibs are carriers.
    2. Patient's offspring: most patients with A-T do not reproduce.
2. Prenatal diagnosis
    1. Elevated maternal serum alpha-fetoprotein levels
    2. Demonstration of chromosome breaks in amniocytes
    3. Molecular genetic analysis
        1. Direct DNA mutation analysis on fetal DNA obtained from amniocentesis (Mancebo et al. 2007) or CVS (Chessa et al. 1999) for pregnancies at risk with previously identified specific disease-causing mutation
        2. DNA-based testing with linkage analysis for at-risk family members if no specific disease-causing mutation identified
        3. Preimplantation genetic diagnosis may be available for families in which the disease-causing mutations have been identified
3. Management
    1. No specific treatment available
    2. Antibiotics for infections
    3. Prevention of infection by regular injection of immunoglobulins in patients with antibody deficiency
    4. IV IG replacement therapy for individuals with frequent and severe infections and very low IgG levels (Nowak-Wegrzyn et al. 2004)
    5. Aggressive pulmonary hygiene for individuals with chronic bronchiectasis before the final stages of the disease (Tangsinmankong et al. 2001)
    6. Supportive therapy to minimize drooling, choreoathetosis, and ataxia; individual responses to specific medications vary (Perlman et al. 2003)
    7. Beta-adrenergic blockers may improve fine motor coordination in some cases
    8. Controversial use and doses of radiation therapy and chemotherapy
    9. Avoid bleomycin, actinomycin D, and cyclophosphamide
    10. Regular cancer surveillance of heterozygotes essential. ATM heterozygosity is a risk factor for breast and lung cancers.
    11. Desferroxamine: recently shown to increase genomic stability of A-T cells and may present a promising tool in A-T treatment
    12. Early physical therapy, occupational therapy, and speech therapy
    13. A wheelchair: usually necessary by age 10
    14. Although steroids can temporarily improve the neurologic symptoms of A-T in children, the symptoms reappear within days of their discontinuation (Gatti and Perlman 2009)

Atelosteogenesis

Contents

In 1982, Maroteaux et al. proposed the term "atelosteogenesis" for a newborn skeletal dysplasia characterized by specific patterns of aplasia/hypoplasia of humeri, femora, spine, and other skeletal elements (Maroteaux et al. 1982). Atelosteogenesis encompasses a heterogeneous group of disorders with overlapping phenotypic features.

Synonyms and Related Disorders

Atelosteogenesis type I (giant cell chondrodysplasia, spondylohumerofemoral hypoplasia, boomerang dysplasia); Atelosteogenesis type II (neonatal osseous dysplasia I, de la Chapelle dysplasia); Atelosteogenesis III

Genetics/Basic Defects

1. Atelosteogenesis I (AOI)/boomerang dysplasia (BD)
    1. Inheritance: de novo autosomal dominant mutation, suggested by:
        1. Sporadic in all observed cases
        2. No familial cases reported
    2. Previously known as spondylohumerofemoral dysplasia and giant cell chondrodysplasia
    3. Caused by mutations in filamin B (*FLNB*) gene (Li et al. 2013), which also causes the following disorders (Krakow et al. 2004; Robertson 2013):
        1. Atelosteogenesis type III
        2. Autosomal recessive spondylocarpotarsal syndrome
        3. Autosomal dominant Larsen syndrome
    4. A common pathogenesis suggested for atelosteogenesis type I and boomerang dysplasia
        1. Forming a spectrum of findings within the same nosologic entity with boomerang dysplasia
        2. Similar histopathology in boomerang dysplasia
        3. Overlapping radiologic features with boomerang dysplasia
2. Atelosteogenesis II (AOII) (Karniski 2001)
    1. Inheritance: autosomal recessive suggested by:
        1. Recurrence in the subsequent pregnancy
        2. Parental consanguinity
    2. Synonymous with de la Chapelle dysplasia (Schrander-Stumpel et al. 1994).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_19

3. Phenotypic and radiographic overlap with atelosteogenesis I but with distinctive matrix histopathology with a major disturbance in cartilage matrix macromolecules.
4. Common pathogenetic features with disorders of sulfation of connective tissue matrix macromolecules. An overlap of phenotypic, radiographic, morphological, and cartilage histochemical features with the following conditions:
    1. Diastophic dysplasia
    2. Achondrogenesis type IB
5. Caused by mutated diastrophic dysplasia sulfate transporter (*DTDST*; *SLC26A2*) gene which also causes the following recessively inherited chondrodysplasias (Hastbacka et al. 1996; Rossi and Superti-Furga 2001; Dwyer et al. 2010):
    1. Diastrophic dysplasia (Rossi et al. 1996; Macias-Gomez et al. 2004)
    2. Multiple epiphyseal dysplasia
    3. Achondrogenesis IB (Cai et al. 1998)
6. The *DTDST* gene.
    1. Encodes a sulfate transporter that also accepts chloride and possibly bicarbonate as substrates
    2. Reduced sulfate transport in chondrocytes of individuals with *DTDST* mutations resulting in the under-sulfation of proteoglycans, which in turn leads to abnormal cartilage formation
7. Factors in addition to the intrinsic sulfate transport properties of the DTDST protein may influence the phenotype in individuals with *DTDST* mutations.

3. Atelosteogenesis III (AOIII)
    1. Inheritance: autosomal dominant (Schultz et al. 1999)
    2. Features overlapping with atelosteogenesis I and II but most similar to those of atelosteogenesis I
    3. Caused by mutations in *FLNB* gene
4. Genotype-phenotype correlation in a compound heterozygote (atelosteogenesis type II diastrophic dysplasia)
    1. Atelosteogenesis type II.
        1. R178X mutations of the *SLC26A2* gene
        2. Features typical of AO II
            1. Severe and progressive cervical kyphosis
            2. V-shaped distal humerus
            3. Bowed radii
            4. Horizontal sacrum
            5. Gap between the first and second toes
    2. Diastrophic dysplasia.
        1. R279W mutations of the *SLC26A2* gene
        2. Features suggestive of diastrophic dysplasia
            1. Cystic swelling of the external ears
            2. Cervical kyphosis
            3. Rhizomelia
            4. “Hitchhiker” thumbs
            5. Bilateral talipes equinovarus
            6. Short toes
    3. Combination of a severe and a mild mutation leads to an intermediate clinical picture, representing an apparent genotype-phenotype correlation.

Clinical Features

1. Atelosteogenesis I
    1. Stillborn or neonatal death due to respiratory distress
    2. Polyhydramnios
    3. Facial dysmorphism
        1. Depressed nasal bridge
        2. Eyelid edema
        3. Micrognathia
        4. Cleft soft palate
    4. Small chest
    5. Protuberant abdomen
    6. Deficient ossification of various bones
        1. Humerus
        2. Femur
        3. Thoracic spine
        4. Hand bones
    7. Rhizomelic micromelic dwarfism
        1. Short and broad hands
        2. Incurved legs
        3. Clubfeet
        4. Often dislocation of the elbows

8. Laryngeal hypoplasia (stenosis): an important role in the respiratory failure and death (Yang et al. 1983; Bejjani et al. 1998; Ueno et al. 2002)

2. Boomerang dysplasia (Kozlowski et al. 1985; Winship et al. 1990)
   1. Distinct facial features
      1. Horizontal palpebral fissures
      2. Broad nasal root
      3. Hypoplastic nasal septum
      4. Prominent philtrum
      5. Cleft palate
   2. Small chest
   3. Protuberant abdomen
   4. Marked rhizo-/mesomelic shortening of limbs
   5. Well-developed hands (broad, paddle shaped) and feet
   6. Bowed lower limbs
   7. Calcaneo-valgus deformities
3. Atelosteogenesis II (Whitley et al. 1986; Newbury-Ecob 1998)
   1. Lethal in neonatal period
      1. Pulmonary hypoplasia
      2. Tracheobronchomalacia
      3. Laryngeal stenosis
   2. Deficient ossification of parts of the skeleton
   3. Facial dysmorphism
      1. Midface hypoplasia
      2. Depressed nasal bridge
      3. Epicanthal folds
      4. Micrognathia
      5. Cleft palate
   4. Small chest
   5. Protuberant abdomen
   6. Extremities
      1. Severe rhizomelic limb shortening
      2. Talipes
      3. Abducted (hitch-hiked) thumbs and toes
      4. Ulnar deviation of the fingers
      5. Gap between the first and second toes
4. Atelosteogenesis III (Kuwashima et al. 1992; Schultz et al. 1999)
   1. Milder, usually nonlethal
   2. Limb anomalies
      1. Rhizomelic shortening
      2. Clubfeet
      3. Short broad thumbs and great toes
   3. Craniofacial abnormalities
      1. Ocular hypertelorism
      2. A flat nasal bridge
      3. Micrognathia
      4. Cleft palate
   4. Small chest
   5. Protuberant abdomen
   6. Multiple dislocations of elbows, hips, and knees
   7. Respiratory and feeding difficulties secondary to laryngomalacia
   8. Features overlapping 2 with oto-palato-digital syndrome type II (Stern et al. 1990)
   9. Apparent cause of death
      1. Respiratory complications
      2. Cervical spine instability
   10. Long survival possible

Diagnostic Investigations

1. Atelosteogenesis I (Sillence et al. 1997)
   1. Radiography: overlapping radiological features with boomerang dysplasia (Hunter and Carpenter 1991; Greally et al. 1993)
      1. Humeri: absent/geometric (AOI), absent (AOI/BD), absent (BD)
      2. Hand phalanges: presence of distal and absent middle (AOI), hypoplastic middle (AOI/BD), presence of distal and absent proximal/middle (BD)
      3. Femora: pointed distally (AOI), geometric (AOI/BD), absent (BD)
      4. Tibia: bowed (AOI), hypoplastic (AOI/BD), bowed/boomerang (BD)
      5. Fibula: absent (AOI), absent (AOI/BD), absent (BD)
      6. Spine: coronal clefts in the lumbar vertebrae (AOI), coronal clefts in the vertebrae, and uniform lack of ossification of the center of the vertebral bodies (BD)
      7. Pelvis: hypoplasia of the ischiopubis (AOI), lack of ossification of ischiopubis (BD), flared ilia with hypoplasia of the inferior one third (AOI, BD), producing a keyhole shape
      8. Foot: lack of ossification of the calcaneal centers (AOI, BD)
      9. Ribs: 10–13 pairs (BD)

2. Histopathology
    1. Uniformly abnormal
    2. Lack of ossification
    3. Nonhomogeneous cell distribution with hypocellular and acellular areas
    4. Occasional multinucleated giant chondrocytes in the relatively acellular areas of resting cartilage (alternatively named "giant cell chondrodysplasia") (Rimoin et al. 1980; Sillence et al. 1978, 1982)
    5. Disorganized growth plate in some cases
    6. Similar histopathology in boomerang dysplasia
3. Exome sequencing: a useful tool in identifying *FLNB* gene mutations (Jeon et al. 2014)

2. Boomerang dysplasia (Kozlowski et al. 1985)
    1. Radiography (Odent et al. 1999)
        1. Triangular, boomerang-shaped long bones, diagnostic of the syndrome
        2. Missing some tubular bone ossification centers
        3. Ossified fingers and toes from the periphery
        4. Characteristic shaped pelvis
        5. Retarded ossification of the spine, especially cervical and thoracic spine
        6. Coronal clefts in the lower thoracic and lumbar spine
    2. Histopathology
        1. Chondrocytes in the resting cartilage are irregularly reduced in number with focal acellularity. Multinucleated giant chondrocytes have been noted.
        2. The physeal growth zones are markedly retarded and disorganized.

3. Atelosteogenesis II (Bonafe et al. 2014)
    1. Radiography.
        1. Normal size skull with disproportionately short skeleton
        2. Spine
            1. Platyspondyly.
            2. Hypodysplastic vertebrae.
            3. Cervical kyphosis.
            4. Ossification of the upper thoracic vertebrae and coronal clefts of the lumbar and lower thoracic vertebrae may be incomplete.
        3. Pelvis
            1. Hypoplastic/flared ilia
            2. Flat/horizontal acetabula with a spicule at the medial border of the acetabula
            3. Often unossified pubic bones
        4. Long bones
            1. Shortened with metaphyseal flaring
            2. Distal humerus: sometimes bifid or V shaped, sometimes pointed and hypoplastic
            3. Femur: distally rounded, clubbed distally
            4. Tibia: bowed/hypoplastic
            5. Fibula: hypoplastic
            6. Radius: typically bowed
        5. Hands
            1. Hitchhiker thumbs
            2. Ulnar deviation of the fingers
            3. Hand phalanges: irregular size and shape
            4. Gap between the first and second toe
            5. Hypoplasia of the first metacarpal bone
    2. Histopathology (Sillence et al. 1987).
        1. Irregularly distributed resting cartilage chondrocytes
        2. Attenuation of cartilage matrix with concentric matrix condensation rings around degenerating chondrocytes
        3. Shortened proliferative and hypertrophic zones
        4. Histopathology of cartilage essentially similar to that of diastrophic dysplasia and achondrogenesis IB reflecting the paucity of sulfated proteoglycans in cartilage matrix
    3. Targeted mutation analysis (mutation detection rate about 60%), deletion/duplication analysis using (multi)exonic and whole-gene deletion/duplication (detection rate unknown), and sequence analysis (mutation detection rate >90%) of *DTDST* (*SLC26A2*) gene (Bonafe et al. 2014): Mutations in the *DTDST* gene can be found in more than 90% of patients with radiologic and histologic

features compatible with the diagnosis of atelosteogenesis II.
4. Carrier testing for AOII.
    1. Carrier testing available to at-risk family members once the mutation of the *DTDST* gene has been identified in the proband.
    2. For the partner of a heterozygous individual. The partners can be screened for the four most common pathogenic alleles, R279W, IVS1 + 2T > C, delV340, and R178X. When these four alleles are excluded, the risk of carrying *DTDST* mutation is reduced from the general risk of 1:100 to about 1:300.

4. Atelosteogenesis III
    1. Radiography
        1. Humeri: pointed distally
        2. Hand phalanges: tombstone-shaped proximal phalanges (Fallon et al. 1994), widened distal phalanges
        3. Femora: pointed distally
        4. Tibia: short
        5. Fibula: absent
        6. Spine: coronal clefts in the lumbar vertebrae, severe thoracolumbar kyphosis with an S-shaped cervical spine in lateral profile
        7. Pelvis: hypoplastic ischiopubis, banana-shaped pubic rami
    2. Histopathology: hypocellularity without clustering, acellular areas, or "giant cells"

Genetic Counseling

1. Recurrence risk
    1. AOI
        1. Patient's sib: low
        2. Patient's offspring: a lethal entity not surviving to reproduce
    2. AOII
        1. Patient's sib: 25%
        2. Patient's offspring: a lethal entity not surviving to reproduce
    3. AOIII
        1. Patient's sib: low
        2. Patient's offspring: 50%

2. Prenatal diagnosis
    1. Fetal ultrasonography (Herzberg et al. 1988; Bejjani et al. 1998; Luewan et al. 2009).
        1. Short limbs (micromelia)
        2. Abnormal facial profile (depressed nasal base, micrognathia, apparent hypertelorism)
        3. Absence of ossification in the humerus, radius, ulna, and cervical and upper thoracic vertebral bodies (Fryer and Carty 1996)
        4. Coronal clefts in the ossified vertebral bodies (Nores et al. 1992)
        5. Talipes equinovarus
    2. 3D helical computed tomography (Cordier et al. 2008).
        1. Not dependent on amniotic fluid volume and fetal position and not limited at specific fetal parts
        2. Theoretical fetal exposure to radioactivity similar to that of conventional fetal radiological examination
        3. Identifies more characteristic findings than 3D ultrasonography due to its advantage of being able to image the entire skeleton and its possibilities of rereading
    3. Fetal MRI using an ultrafast sequence.
        1. Dysmorphic features
        2. Pulmonary hypoplasia
        3. A large cisterna magna
    4. Fetal MRI of atelosteogenesis type II (Miller et al. 2008).
        1. Bilateral short upper extremities
        2. Short fingers and hitchhiker thumb
        3. Bilateral short and bowed lower extremities
        4. Bilateral severe equinovarus deformity
    5. Prenatal diagnosis by analysis of DNA extracted from fetal cells obtained by CVS or amniocentesis or preimplantation genetic diagnosis: Mutation analysis of *SLC26A2* gene for pregnancy at risk is possible for AOII for families in which the disease-causing mutations have been identified (Bonafe et al. 2014).

3. Management
    1. AOI and AOII: supportive measures for these two lethal conditions
    2. AOIII
        1. Ventilatory support and tracheostomy often necessary for respiratory distress due to laryngotracheomalacia
        2. Treat recurrent respiratory tract infections
        3. Cleft palate repair
        4. Conductive hearing loss evaluation and management
        5. Orthopedic care for clubfeet and joint dislocations

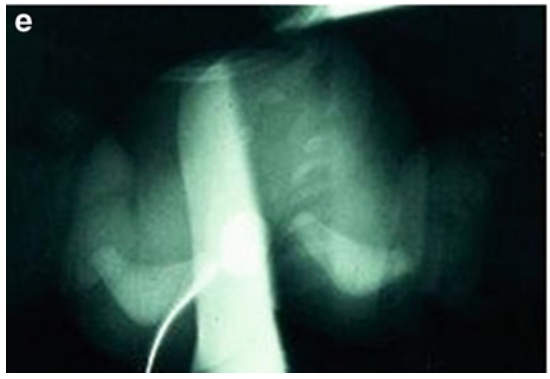
Fig. 1 (continued)



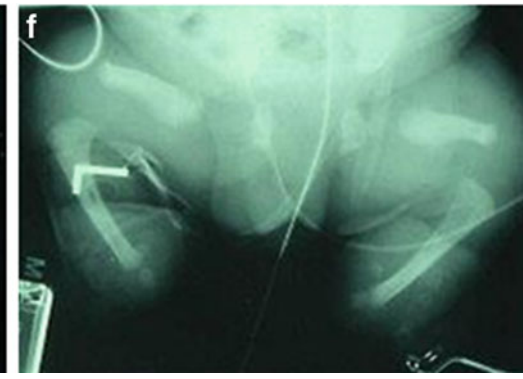


Fig. 1 (**a**–**f**) A male infant with atelosteogenesis I/boomerang dysplasia. Prenatal ultrasound showed polyhydramnios and a short limb dwarf. The infant died at 57 days. He showed relatively large head, hypertelorism, depressed nasal bridge, midfacial hypoplasia, micrognathia, cleft palate, short neck, relatively narrow chest, protuberant abdomen, severe "rhizomelic" micromelia, absent elbow joints, genu varus, and talipes equinovarus. Radiographic features included unossified vertebrae (T6–T9), single boomerang-like long bone (between acromion and wrist), short tapered femora, short bowed tibiae, absent fibulae, calcified distal phalanges, non-ossified carpals and metacarpals, proximal phalanges, and irregularly ossified tarsals and metatarsals. Histopathology of the cartilage showed disorganized physeal growth zones and irregular areas of hypocellularity in the resting cartilage. Multinucleated giant chondrocytes were not observed

Autism

Contents

Autism is a pervasive developmental disorder, defined by impairments in social and communication function and repetitive and stereotyped behavioral patterns. It occurs in approximately 7–40 out of 10,000 persons. Autism spectrum disorders (ASDs) represent a heterogeneous group of neurodevelopmental disorders, including autism, Asperger syndrome, childhood disintegrative disorder, and pervasive developmental disorder not otherwise specified, and are characterized by social and communication deficits accompanied by repetitive and stereotype behaviors, with onset before 3 years of age (American Psychiatric Association 2013; DiCicco-Bloom et al. 2006; Caglayan 2010). The prevalence of autism spectrum disorders is at least 5–6/1,000 and may be higher (Bryson and Smith 1998).

Synonyms and Related Disorders

Autism spectrum disorders (autism, Asperger syndrome, childhood disintegrative disorder, pervasive developmental disorder); Autistic disorder

Genetics/Basic Defects

1. Secondary autism (nongenetic and genetic conditions associated with autism): accounts for a small minority of individuals with autism (<10%) in population-based studies (Miles et al. 2005; Muhle et al. 2004)
   1. Obstetric complications including uterine bleeding, despite the absence of demonstrable causal relationship in many studies
   2. Intrauterine exposure to teratogenic drugs in a few affected children
      1. Thalidomide
      2. Valproate
   3. Elevated cord blood levels of the following substances:
      1. Neuropeptide substance P
      2. Vasoactive intestinal peptide
      3. Pituitary adenylate cyclase-activating polypeptide
      4. Calcitonin gene-related peptide
      5. Neurotrophin nerve growth factor

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_20

4. Various epidemiologic data
    1. Cerebral palsy (a static motor deficit of brain origin present from early life): present in 2.1–2.9% of individuals with autism and mental retardation
    2. Congenital rubella infection: present in 0.75% of cases
    3. Other pre- and postnatal infections (e.g., Haemophilus influenzae and cytomegalovirus): may cause autism when they significantly damage the immature brain
    4. No association between autism and inflammatory bowel disease or with a live MMR vaccination
    5. Epilepsy with the highest association with autism: reported in up to a third of individuals with an autistic spectrum disorder by adulthood
    6. Behavioral symptoms of autism: frequent in tuberous sclerosis complex and fragile X syndrome but account for only a minority of the total cases of autism
5. Genetic causes associated with autism: more than 25% of individuals with autism spectrum disorder have an identifiable genetic cause (Baker and Jeste 2015)
    1. Cytogenetically visible chromosomal abnormalities (~5%) (Gillberg 1998; Wassink et al. 2001)
        1. Angelman syndrome (more commonly associated with autism than Prader-Willi syndrome) can result from the loss or mutations of the maternally derived *UBE3A* or the *ATP10C* gene in 15q11-q13 region.
        2. Chromosomal duplication in the Prader-Willi/Angelman region of proximal 15q in about 3% of individuals with autism: more commonly a supernumerary isodicentric 15q chromosome detectable by routine cytogenetic studies or less commonly an interstitial duplication of the region detected by fluorescence in situ hybridization (FISH) analysis of the *SNRPN* gene.
        3. Other chromosome abnormalities in 3–5% of individuals with autism.
        4. A subtelomeric deletion detected by FISH telomere studies in 10% of unselected patients with autism.
        5. Down syndrome (Kent et al. 1999): autism was found in at least 7% in one study in children with Down syndrome.
        6. Turner syndrome: known to have specific cognitive and behavioral deficits that overlap with but are also distinct from those found in children with idiopathic autism (Caglayan 2010).
        7. Inv dup(15) or idic(15) syndrome: characterized by early central hypotonia, developmental delay and intellectual disability, epilepsy, and autistic behavior with no facial dysmorphic features (Battaglia 2008).
    2. Copy number variants (CNVs) (Miles et al. 2010): Array comparative genomic hybridization (aCGH)
        1. Steadily replacing high-resolution chromosome analysis and FISH in the evaluation of children with autism.
        2. Designed to test for known deletion/duplication syndromes on the entire genome plus assessment of subtelomeric regions.
        3. Currently, aCGH identifies clinically relevant de novo genomic imbalances in 7–10% of individuals with autism of unknown cause (Sebat et al. 2007; Christian et al. 2008; Kumar et al. 2008; Marshall et al. 2008; Weiss et al. 2008).
        4. Most common autism-related CNVs: 15q11.2-11.3 duplications and reciprocal 16p11.2 microdeletions and duplications (Miles 2011).
        5. Examples of CNVs associated with autism: 16p11.2 deletion syndrome in approximately 1% of individuals with autism (Marshall et al. 2008) and 15q13.3 deletion syndrome associated with mental retardation,

epilepsy, and ASDs (Ben Shachar et al. 2009; Miller et al. 2009; Pagnamenta et al. 2009).

3. Single gene causes of autism in which neurologic findings are associated with ASDs (~5%)
    1. Fragile X syndrome (Wassink et al. 2001) found in a few percent of children with autism: At least 50% of children with fragile X syndrome have autistic behaviors, including avoidance of eye contact, language delays, repetitive behaviors, sleep disturbances, tantrums, self-injurious behaviors, hyperactivity, impulsiveness, inattention, and sound sensitivities
    2. Rett syndrome: Children affected with both autism and Rett syndrome (almost universally female sex) have a period of normal development, followed by loss of language with stereotypic hand movements (hand-wringing behavior)
    3. Tuberous sclerosis complex: Mentally retarded individuals with tuberous sclerosis complex frequently have autism (almost 50% in some studies)
    4. Neurofibromatosis type 1: Much less frequently associated with autism than is tuberous sclerosis and fragile X syndrome
    5. Duchenne muscular dystrophy: An unexpectedly large proportion of boys with Duchenne muscular dystrophy have autistic spectrum
    6. Sotos syndrome: A number of affected individuals diagnosed to have ASDs or autistic features
    7. Joubert syndrome: A few affected children diagnosed with autism
    8. Other macrocephalic conditions with overgrowth (Simpson-Golabi-Behmel syndrome, Beckwith-Wiedemann syndrome)
    9. Autism and macrocephaly or autism with no other clinical features: Reported to have germline *PTEN* mutations (Herman et al. 2007)
    10. Timothy syndrome (an autosomal dominant disorder characterized by lethal cardiac arrhythmias, congenital heart disease, webbing of fingers and toes, immune deficiency, intermittent hypoglycemia, cognitive abnormalities, and autism) (Splawski et al. 2004)
    11. Williams syndrome: Individuals with Williams syndrome show an unusually strong interest in people, including strangers, warm and engaging, and highly empathetic toward others versus profound impairments in social functioning, including difficulties interacting with others, attending to people, and decoding nonverbal cures, and impairments in social emotional reciprocity (Caglayan 2010)
    12. Smith-Magenis syndrome: Autistic-type behaviors reported in many affected individuals (Dykens et al. 1997)
    13. Smith-Lemli-Opitz syndrome: ~75% of affected children met the criteria for some variants of ASDs (Sikora et al. 2006)
    14. Cohen syndrome (an autosomal recessive connective tissue disorder caused by COH1 gene mutations): Autistic features may be relatively common (Karpf et al. 2004).
    15. Duchenne muscular dystrophy: 3.1% of patients with ASDs (Hendriksen and Vles 2008).
4. Metabolic cause associated with autism
    1. Mitochondrial cytopathies: 7% of patients with ASDs (Oliveira et al. 2005)
    2. Untreated phenylketonuria: an autism frequency of 2.7–5.6% in affected

individuals (Baieli et al. 2003; Steiner et al. 2003)
3. Sanfilippo syndrome: prominent behavioral disturbance in affected individuals (Neufeld and Muenzer 2001)
4. Adenylosuccinate lyase deficiency: autistic features in about one-third of patients (Spiegel et al. 2006)

2. Idiopathic autism (inherited autism of unknown cause)
1. Family studies indicate genetics plays the major causative role in most individuals with "idiopathic" autism (90–95%).
2. Epidemiologic studies.
1. A prevalence of 5–10 cases of classic autism per 10,000 (3–6 per 1,000 if the entire spectrum of autism is included)
2. A male-to-female ratio of 3:1
1. The preponderance of males suggests an X-linked disorder.
2. Linkage to the X chromosome suggested by recent genome-wide screens, although the data are inconsistent.
3. Male-to-male transmission of autism in multiplex families (families with more than a single affected family member) ruled out X-linkage in these families.
4. No significant associations of autism to Y chromosome based on Y haplotype analysis, although Y chromosome abnormalities have been documented.
3. Classification of idiopathic autism.
1. Essential autism
1. Defined by the absence of physical abnormalities
2. Seen in about 70% of children with idiopathic autism
3. Associated with better outcome overall
4. More likely a male
5. A higher sibling recurrence risk
2. Complex autism
1. Defined by the presence of dysmorphic features (microcephaly and/or a structural brain malformation)
2. Seen in about 30% of children with idiopathic autism
3. Associated with a poorer prognosis
4. A lower male-to-female ratio
5. A lower sibling recurrence risk

4. Evidence suggesting genetic basis of autism without a diagnosable cause.
1. 25% rate of recurrence in siblings of affected individuals from family studies: much greater than the prevalence rate in the general population
2. Greater than 60% rate of concordance for classic autism in monozygotic twins compared with no concordance found between dizygotic twins

5. The identity and the number of genes involved in autistic disorders: remained unknown.
1. Multigenic
1. Similar autistic phenotypes may arise from different genes or gene combinations in different families (single-mutation genetic heterogeneity).
2. Example: tuberous sclerosis caused by *TSC1* on chromosome 9q in some families and *TSC2* on 16p in others.
2. Polygenic
1. Several synergistically acting genes in an affected individual's genome may be required to produce the full autistic phenotype.
2. Lowering of a theoretical threshold by certain sets of genes acting in concert to allow the development of autism, either by themselves or given the right set of environmental or immunologic modifiers.
3. Other related developmental disorders in family members presumed to have inherited some of the susceptibility genes found in the affected family member or to have the same set of

susceptibility genes without exposure to the same environmental "trigger factors" for autism.

3. Search for candidate genes
   1. Cytogenetics: scrutinize the region involved in visible breakpoints, translocations, duplications, inversions, and deletions for the presence of genes that potentially may be involved in the pathogenesis of autistic spectrum disorders.
   2. Whole genome search: microsatellite marker screening in multiplex family uncovers specific chromosomal regions that affected individuals inherit more often than predicted by chance.
4. Genes for a monogenic hereditable form of autism (Caglayan 2010; Lintas and Persico 2009)
   1. Neuroligins (*NLGN3*, *NLGN4*) (located at Xq13 and Xq22.33, respectively): gene mutations noted in 1% of individuals with ASDs (Jamain et al. 2003; Lintas and Persico 2009).
   2. *Shanks3* gene (located at 22q13.3): mutations cause ASDs with phenotype characterized mainly by severe verbal and social deficits (Moessner et al. 2007; Aneja and Tierney 2008).
   3. Neurexins (*NRXN1*) (located at 2p16.3): Exonic deletions involving *NRXN1* have been found in 0.4% of probands with ASD, and rarely in controls, in large-scale genomic screening studies (Devlin and Scherer 2012).
   4. Methyl-CpG-binding protein 2 gene (*MeCP2*) (located at Xq28): de novo mutations occur in 80% of female patients with Rett syndrome.
   5. The homeobox A1 gene (*HOXA1*) (located at 7p15.3): autism noted in some patients (Bosley-Salih-Alorainy syndrome) (Herman et al. 2007).
   6. The phosphatase and tensin homologue gene (*PTEN*) (located at 10q23): reported in individuals with macrocephaly and autism (Butler et al. 2005; Herman et al. 2007; Buxbaum et al. 2007).
   7. Deletions in the X-linked *PTCHD1* gene and in the upstream *PTCHD1AS1* non-coding RNA may be associated with intellectual disability with or without ASD (Pinto et al. 2010; Noor et al. 2010).

Clinical Features

1. Early signs of infants with autism (Miles et al. 2005).
   1. Do not care to be held or cuddled
   2. Do not reach out to be picked up
   3. Often "colicky" and hard to console
   4. Typically quieting more readily when left alone
   5. Avoid and fail to initiate eye contact
   6. Stare into space
   7. Sleep disturbances
   8. Usually do not come to medical attention until after the second year when language delays are evident
2. Natural history.
   1. Onset of autism: prior to age three.
   2. Gradual onset in most children with autism.
   3. "Regressive" onset in about 30% of children with autism.
      1. Initially begin to talk.
      2. Then often precipitously lose language and become distant.
      3. Refuse to make eye contact within a matter of days and no longer respond to his or her name.
      4. Repetitive movements may develop immediately or by 3 or 4 years of age.
   4. About 25% of children who fit diagnostic criteria for autism at age 2 or 3 years.
      1. Subsequently begin to talk and communicate
      2. Blend to varying degrees into the regular school population by 6 or 7 years
   5. Remaining 75% of children with autism continue to have a life-long disability requiring intensive parental, school, and societal support.

6. Fewer than 5% of children with autism completely recover.
3. Mental retardation by nonverbal IQ testing in 50–70% of children with autism.
4. Seizures develop in about 25% of children with autism.
5. Idiopathic autism.
    1. About 30% of children have complex autism, defined by the presence of the following features:
        1. Dysmorphic features
        2. Microcephaly
        3. Structural brain malformation
    2. About 70% of children have essential autism, defined by the absence of physical abnormalities.
6. Behavioral impairments (Bailey et al. 1996; Agency for Healthcare Research and Quality 2014).
    1. Impairments in social interaction: separates individuals with autism from individuals around them
        1. Unable to "read" other people, ignoring them, and often strenuously avoiding eye contact
        2. Do not comfort others or seek comfort and do not share interests with others
        3. Usually prefers to be by himself, engaging in his own, often repetitive, activities at home
        4. Fail to develop friendships with peers and siblings
        5. Demonstrate a marked deficit in imitating other's actions, which may impede the development of interpersonal synchrony, communication, symbolic play, and the learning of new behaviors
    2. Impairments in communication
        1. Fail to develop reciprocal communication either by speech, gestures, or facial expression in most children with autism
        2. Fail to use eye gaze to communicate and direct attention in young children
        3. Display stereotypic speech that may involve echolalia or unusual inflections and intonations when children with autism learn to talk
    3. Restrictive, repetitive, and stereotypic behaviors and activities
        1. Staring or rocking.
        2. Toddlers may have motor "stereotypies."
            1. Movements of fingers
            2. Twirling strings
            3. Flicking pages of books
            4. Licking
        3. Repetitive whole-body movements.
            1. Spinning
            2. Running back and forth
        4. Complex repetitive movements may last for hours.
        5. Develop elaborate rituals in which the order of events, the exact words, and the arrangement of objects must be followed.
    4. Other symptoms
        1. Hyper- and hyposensitivities to sensory stimulation of all types (e.g., visual, auditory, tactile, and pain)
        2. Odd behaviors around foods and their presentation
        3. Abnormal sleep patterns
        4. Tantrums and/or self-injurious and aggressive behaviors brought on by a change in routine, an offending touch, or no apparent reason
        5. Impaired motor development with toe walking early in life and general clumsiness
        6. Total disregard for danger, resulting in high risk of early death, most commonly from drowning
7. Behavioral characteristics/co-occurring diagnoses (Harrington and Allen 2014; Lai et al. 2014).
    1. Developmental
        1. Intellectual disability (~45%)
        2. Language disorders (variable)
        3. Attention-deficit/hyperactivity disorder (28–44%)
        4. Tic disorders (14–38%)
        5. Motor abnormality ($\leq$79%)
    2. General medical
        1. Epilepsy (8–30%)
        2. Gastrointestinal problems (9–70%)
        3. Immune dysregulation ($\leq$38%)

4. Genetic syndromes (~5%)
5. Sleep disorders (50–80%)

3. Psychiatric disorders
   1. Anxiety (42–56%)
   2. Depression (12–70%)
   3. Obsessive-compulsive disorder (7–24%)
   4. Psychotic disorders (12–17%)
   5. Substance use disorders (≤16%)
   6. Oppositional defiant disorder (16–28%)
   7. Eating disorders (4–5%)
4. Personality disorders
   1. Paranoid disorders (0–19%)
   2. Schizoid personality disorder (21–26%)
   3. Schizotypal personality disorder (2–13%)
   4. Borderline personality disorder (0–9%)
   5. Obsessive-compulsive personality disorder (19–32%)
   6. Avoidant personality disorder (13–25%)
5. Behavioral
   1. Aggressive behaviors (≤68%)
   2. Self-injurious behaviors (≤50%)
   3. Pica (~36%)
   4. Suicidal ideation or attempt (11–14%)

8. Diagnostic criteria for autistic disorder (adapted from DSM-V) (American Psychiatric Association 2013; Augustyn 2014).
   1. Persistent deficits in social communication and social interaction in multiple settings; demonstrated by deficits in all three of the following (either currently or by history):
      1. Social-emotional reciprocity (e.g., failure of back-and-forth conversation; reduced sharing of interests and emotions)
      2. Nonverbal communicative behaviors used for social interaction (e.g., poorly integrated verbal and nonverbal communication; abnormal eye contact or body language; poor understanding of gestures)
      3. Developing, maintaining, and understanding relationships (e.g., difficulty adjusting behavior to social setting; difficulty making friends; lack of interest in peers)
   2. Restricted, repetitive patterns of behavior, interests, or activities; demonstrated by ≥2 of the following (either currently or by history):
      1. Stereotyped or repetitive movements, use of objects, or speech (e.g., stereotypes, echolalia, ordering toys, etc.)
      2. Insistence on sameness, unwavering adherence to routines, or ritualized patterns of behavior (verbal or nonverbal)
      3. Highly restricted, fixated interests that are abnormal in strength or focus (e.g., preoccupation with certain objects; perseverative interests)
      4. Increased or decreased response to sensory input or unusual interest in sensory aspects of the environment (e.g., adverse response to particular sounds; apparent indifference to temperature; excessive touching/smelling of objects)
   3. The symptoms must impair function (e.g., social, academic).
   4. The symptoms must be present in the early developmental period. However, they may become apparent only after social demands exceed limited capacity; in later life, symptoms may be masked by learned strategies.
   5. The symptoms are not better explained by intellectual disability or global developmental delay.
9. Differential diagnosis with other pervasive developmental disorders (Cohen and Volkmar 1997).
   1. Asperger disorder (Asperger 1944; Frith 1991, 2004; Miles et al. 2010)
      1. A variant of autism typically occurring in high-functioning individuals without mental retardation.
      2. Whether Asperger syndrome is the expression of the high end of the autism spectrum or a discrete genetic entity is unclear.
      3. Language development.
         1. Develops better than classic autism
         2. Problems with the semantic and pragmatic use of language
      4. Requires all other DSM-IV diagnostic criteria for autism.

5. Other characteristics.
    1. Misdiagnosed early on and in adulthood as odd or eccentric.
    2. Generally loners.
    3. Uncomfortable in groups.
    4. Unable to empathize with others.
    5. Does not chat.
    6. Follow a literal interpretation of speech with no understanding of idioms or jokes.
    7. Maintain a sameness in routine and follow strict rules.
    8. Have an encompassing preoccupation with one domain, such as the weather or computers.
    9. Speech may be pedantic or repetitive with odd intonations.
    10. Clumsiness: common.
    11. IQ must be within the normal range to qualify for the diagnosis.
2. Childhood disintegrative disorder (Heller syndrome)
    1. Behavioral, cognitive, and language regression between ages 2 and 10 years after entirely normal early development.
    2. Lose previously acquired language, social, and play skills.
    3. Cognitive skills usually impaired significantly.
    4. The condition may resemble autism in clinical presentation but differs from autism in the pattern of onset, course, and outcome.
    5. No longer considered one of the pervasive developmental disorders.
3. Pervasive developmental disorder, not otherwise specified (PDD-NOS)
    1. Onset after age 3 years.
    2. Children with autistic symptoms who do not meet full criteria in all three diagnostic domains can be diagnosed with PDD-NOS.
        1. Includes children with milder symptoms of all three autism diagnostic criteria and those meeting full criteria for autism in two of the three domains
        2. Used as an initial or tentative diagnosis for younger children or before diagnostic evaluations are completed

Diagnostic Investigations

1. Cytogenetic studies and molecular genetic analyses (Filipek et al. 2000; Miles et al. 2010; Baker and Jeste 2015)
    1. High-resolution or multi-FISH telomere chromosome studies.
        1. Chromosomal abnormality involving the proximal long arm of chromosome 15 (15q11-q13) observed in more than 1% of autistic individuals. Duplication is usually maternally derived, with one or two extra copies of the area roughly corresponding to the typical Angelman syndrome/Prader-Willi syndrome deletion region:
            1. Pseudodicentric 15 (inverted duplication 15)
            2. Atypical marker chromosomes
        2. Other chromosome abnormality: Cytogenetic abnormalities have been found on virtually every chromosome in individuals with autism.
    2. Chromosome microarray analysis (CMA) (Malhotra and Sebat 2012; Baker and Jeste 2015).
        1. Has replaced high-resolution chromosome analysis as the test of choice for the evaluation of any child with an autism spectrum disorder.
        2. Cytogenetic analysis, in addition to aCGH, is recommended when the family history suggests transmission of a balanced chromosome rearrangement.
        3. Two types of CMA technologies: provide the first opportunity to perform relatively unbiased genome-wide surveys of chromosomal deletions and duplications with much greater resolution.
            1. Array-based comparative genomic hybridization (aCGH)

2. Single nucleotide polymorphism (SNP): advantage of being able to detect specific inheritance patterns, such as uniparental disomy, which cannot be detected by aCGH (Heil and Schaaf 2013)
3. Limitations: cannot detect point mutations and microdeletions

3. Molecular genetic testing (*FMR1*) for full mutations and premutations for fragile X syndrome: unlikely positive in the presence of high-functioning autism.
4. Whole exome and whole-genome sequencing technology: Recent advances in genetic method have led to the identification of contributory mutations in up to 30% of children with ASD (Neale et al. 2012; O'Roak et al. 2012; Sanders et al. 2012; Yu et al. 2013; Baker and Jeste 2015).
    1. Facilitate investigations at the level of the single base pair
    2. Allow analysis of single gene defects
    3. Allow identification of partial loss of gene function
    4. Most large-scale exome-sequencing studies based on data from simplex families, or families with only one affected child leading to a growing appreciation of the role of de novo mutations in the pathogenesis of ASD
        1. More than 500 candidate genes have been identified from these large cohorts of thousands of children.
        2. Each with 50% chance of being contributory or causative.
        3. Network analyses of the functions of the potentially causative genes find genes implicated in synaptic formation and integrity and in chromatin modulation (Pinto et al. 2014; Ronemus et al. 2014).

2. Metabolic studies: positive in probably less than 5% of children with autism
    1. Metabolic evaluation.
        1. Quantitative plasma amino acids
        2. Quantitative urine organic acids
        3. Purines, creatine, and guanidinoacetate in the urine
        4. Serum concentration of lactate, pyruvate, creatine kinase, and uric acid
    2. Increased serum serotonin in about one-third of individuals with autistic disorder.
    3. Toxicologic studies.
    4. Review of child's newborn screening test results.
    5. Further studies are needed to determine the prevalence of mitochondrial respiratory chain disorders in autism, especially those with recurrent setbacks, hypotonia, and failure to thrive.
3. Electrophysiologic studies: epileptiform EEG abnormalities in autistic children with a history of regression and seizures
4. Neuroimaging (MRI) of the brain
    1. Indicated when the history and physical examination or neurologic examination suggests a localized lesion, tuberous sclerosis complex, Joubert syndrome, or an early environmental insult.
    2. Its routine use is controversial because of the expense and need for sedation or anesthesia by an anesthesiologist.
5. Guideline for genetic testing in autism spectrum disorder (Baker and Jeste 2015)
    1. Guidelines on the screening and diagnosis of autism published by the American Academy of Neurology and Child Neurology Society in 2000: High-resolution chromosome studies (karyotype) and DNA analysis for fragile X should be performed in the presence of mental retardation or if dysmorphic features are present (Filipek et al. 2000)
    2. Revised guidelines for testing published by the American College of Medical Genetics in 2003 (Schaefer and Mendelsohn 2013)
        1. All children with ASD
            1. Three generation family history
            2. Detailed physical examination to identify known syndromes

3. Chromosomal microarray oligonucleotide array comparative hybridization or single-nucleotide polymorphism microarray
2. Specific testing
   1. Males: DNA testing for fragile X
   2. Females: MECP2 sequencing
   3. Macrocephaly (>2.5 standard deviation above the mean): PTEN gene sequence analysis
3. Genetic counseling for all families
   1. Negative test (no etiology identified): counseling about recurrence risk (up to 20% based on infant sib studies)
   2. Positive test (etiology identified): counseling about specific mutations and associated clinical features, including comorbidities, treatment, and prognosis

Genetic Counseling

1. Recurrence risk
   1. Patient's sib.
      1. Secondary autism: The recurrence risk is based on information relevant to the primary diagnosis. For example:
         1. Supernumerary isodicentric 15q chromosome: no increased recurrence risk since it is a de novo occurrence
         2. Duplication of proximal 15q: an increased recurrence risk since it may result from segregation of a parental chromosome translocation or a maternally derived interstitial 15q duplication
      2. Idiopathic autism
         1. The empiric aggregate risk to sibs of individuals with autism of unknown cause varies across studies but is generally considered to range from 5% to 10% for autism and 10–15% for milder symptoms, including language, social, and psychiatric disorders (Bolton et al. 1994; Lauritsen et al. 2005; Miles et al. 2005; Landa 2008; Selkirk et al. 2009).
         2. For families with ≥2 children: the recurrence risk approaches 35% (Ritvo et al. 1989).
      3. Essential autism (Miles et al. 2005)
         1. For male sibs (brothers) of a proband with essential autism: a 7% of risk for autism and an additional 7% risk for milder autism spectrum symptoms
         2. For female sibs (sisters) of a proband with essential autism: a 1% risk for autism and an unknown risk for a milder autism spectrum disorder
      4. Complex autism (Miles et al. 2005): the sib recurrence risk of a proband with complex autism
         1. One percentage for autism
         2. An additional 2% for a milder autism spectrum disorder
      5. Half-siblings or third-degree relatives: generally accepted that recurrent risk falls off dramatically with more distant family relationship (Carter and Scherer 2013)
   2. Patient's offspring: unknown but the risk is probably higher than for siblings (Carter and Scherer 2013).
   3. De novo pathogenic mutation or CNV is present in the proband: recurrence risk is typically quoted as 1%, taking account the rare cases of gonadal mosaicism in one of the parents, or the possibility that one parent carries a chromosomal rearrangement that predisposes to the CNV, with much higher recurrent risk (Carter and Scherer 2013).
2. Prenatal diagnosis: may be available for the specific etiology for families at risk of having a child with a chromosomal disorder, copy number variant, or a single gene disorder
3. Management (Agency for Healthcare Research and Quality 2014)
   1. General goals of treatment.
      1. Improve language and social skills
      2. Decrease stereotypic and disruptive behaviors
      3. Support parents and families in their adjustment and to educate their children
      4. Foster independence

2. Early intervention programs focused on developing the following areas:
    1. Language
    2. Cognitive and imitation skills
    3. Social responsiveness
    4. Appropriate behavior
3. Behavior modification programs (Prater 2002).
    1. Structure the environment
    2. Provide consistent responses to behaviors
    3. Reward a desired behavior (positive reinforcement)
    4. No reward for undesirable behavior (negative reinforcement)
    5. Apply an adverse stimulus to deter an unwanted response (punishment)
    6. Reinforcing closer and closer approximations to the desired behavior (shaping)
4. School-aged children with autism (Bennetto and Rogers 2001).
    1. Need a curriculum that is tailored to individual strengths and needs
    2. Effective education programs
        1. Well-structured, systematic teaching routines
        2. Consistency and repetition
        3. Concrete and functional learning objectives
5. Adolescents and adults with autism (Bennetto and Rogers 2001).
    1. Need specific help in vocations and avocations in adult life
    2. Social skills groups
    3. Recreational activities
    4. Individual psychotherapy
    5. Vocational coaching and assistance
6. Pharmacotherapy (Anagnostou et al. 2014; Ji and Findling 2015): No medications are autism-specific.
    1. Antidepressants: Selective serotonin reuptake inhibitors with some success in treating preoccupations, ritualized behaviors, and mood disorders and anxiety.
    2. Stimulant medications: Little or no clinical improvement to decrease the activity levels and to improve the attention span of some children.
    3. Antipsychotic medications: New atypical antipsychotic medications may be useful in treating aggressive and hyperactive behavior with fewer side effects.
    4. Anticonvulsant medications: Used to treat individuals with autism who suffer from seizures and may be effective in decreasing aggressive behavior and episodic behavioral outbursts, particularly in children with seizure disorder.
    5. Risperidone and aripiprazole: The only two FDA-approved medications for irritability (aggression, self-injury, and severe tantrums) in children with ASD.
    6. Methylphenidate, atomoxetine, and alpha-2 agonists for ADHD symptoms.
    7. Melatonin for initial insomnia.
7. Treatments for core symptoms of autism spectrum disorders (Levy et al. 2009).
    1. Socialization
        1. Educational curricula (Myers 2009)
        2. Communication and language (Paul 2008): didactic and intensive training and Milieu teaching
        3. Social skills training (Seida et al. 2009)
        4. Behavioral treatment (Rogers and Vismara 2008): discrete trial instruction, pivotal response training, and relationship development intervention
    2. Communication
        1. Communication intervention (Paul 2008): within a comprehensive program (e.g., pivotal response training or other center), social pragmatics approach, and parent training
        2. Augmentative and assistive communication (Schlosser and Wendt 2008): picture exchange communication system, sign language, and assistive technology (e.g., vocal output devices)
        3. Behavioral (e.g., play, reciprocal communication) (Ospina et al. 2008): floor time/developmental, individual

differences, relationship-based approach, applied verbal behavior
4. Educational (Myers 2009)

3. Behavior
   1. Behavioral intervention (Ospina et al. 2008): discrete trial instruction and other comprehensive programs using applied behavior analysis
   2. Psychopharmacology (King and Bostic 2006): selective serotonin reuptake inhibitors, anticonvulsants, atypical antipsychotics, α-2 agonists

8. Complementary and alternative medical treatments (Hess et al. 2008)
   1. Biological
      1. Supplements – e.g., vitamin B6 or magnesium ion, dimethyl glycine, and cod liver oil
      2. Anti-infectives – e.g., antibiotics, antifungals, and antivirals
      3. Immunoglobulins
      4. Off-label drugs – e.g., secretin
      5. Chelation medications
      6. Gastrointestinal medications
      7. Elimination or special diets – e.g., gluten-free or casein-free
      8. Hyperbaric oxygen administration
   2. Non-biological
      1. Auditory integration training
      2. Chiropractic therapy
      3. Craniosacral manipulation
      4. Facilitated communication
      5. Massage and qigong
      6. Interactive metronome
      7. Reiki
      8. Transcranial stimulation
      9. Yoga

Fig. 1 (**a**–**c**) A girl (at 4 years and 10 years) with autism (**a**, **b**). Her chromosome study showed a balanced translocation between the short arm of chromosome 3 and the long arm of chromosome 10 [t (5;10)(p13;q21)] (karyotype shown) (**c**). Her parents had normal chromosomes

Fig. 2 An 11-year-old girl with autism. During infancy, she did not pay attention to people or environment and was often staring into space. She had echolalia and smiled without reason. She walked in time, but had reported spinning, flapping, and rocking

Bannayan-Riley-Ruvalcaba Syndrome

Contents

In 1960, Riley and Smith described a mother and her four children with macrocephaly and pseudopapilledema due to a mutation in a single autosomal gene (Riley and Smith 1960). In 1971, Bannayan described a 3-year-old girl with macrocephaly and numerous subcutaneous lesions ranging from lipolymphangio-hemangiomas to vascular hamartomas (Bannayan 1971). This syndrome was felt to be related to the one reported earlier by Riley and Smith since both lipomatosis and hemangiomatosis are hamartomatous malformations. In 1980, Ruvalcaba, Myhre, and Smith described two patients with macrocephaly, mental retardation, pigmented spotting of the glans penis and shaft, and multiple polyps of the gastrointestinal tract (Ruvalcaba et al. 1980). The cases described by Bannayan, Riley, Ruvalcaba, Myhre, and Smith were later known as the Bannayan-Riley-Ruvalcaba syndrome (BRRS) when Gorlin and colleagues in 1992 coined the term based on evidence of overlap of these syndromes and later would be linked to mutations in the *PTEN* gene, which also causes Cowden syndrome (CS) (Gorlin et al. 1992).

Currently, BRRS and CS are considered to be a single entity, with a phenotypic spectrum caused by mutations of the *PTEN* gene, referred to as the *PTEN* hamartoma tumor syndrome.

Synonyms and Related Disorders

Cowden syndrome; Proteus-like syndrome; PTEN hamartoma tumor syndrome; PTEN-related Proteus syndrome

Genetics/Basic Defects

1. *PTEN* (Phosphatase and Tensin homolog deleted on chromosome 10), a tumor suppressor gene on 10q23.3 (Zigman et al. 1997), has been identified as the susceptibility gene for two hamartoma syndromes, BRRS and CS (allelic conditions with variable expression and age-related penetrance) (Longy et al. 1998; Lachlan et al. 2007). Although distinct phenotypically, these two disorders display partial clinical overlap (Arch et al. 1997).
2. *PTEN* encodes a dual specificity phosphatase with homology to the focal adhesion molecules tensin and auxilin.
3. Germline mutations in the *PTEN* (Liaw et al. 1997; Celebi et al. 1999) are found in approximately 85% of individuals with classic

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_21

Cowden syndrome and in 65% of individuals with BRRS and in other disorders (20%) (Proteus syndrome, Proteus-like syndrome) which are collectively referred to as the "*PTEN* hamartoma tumor syndrome" (PHTS) (Marsh et al. 1997, 1999; Eng 2000; Merks et al. 2003).
4. These phenotypically diverse disorders share several overlapping clinical features and a common genetic etiology, which has led to their gene-based classification of PHTS (Marsh et al. 1998, 1999). The broad, apparently difficult to predict, clinical manifestations of PHTS mandate thorough and meticulous phenomic analysis to ensure recognition and then proper diagnosis of patients who are at risk of developing neoplasia (Orloff and Eng 2008)

Clinical Features

1. Clinical features (Zonana et al. 1976; Gorlin et al. 1992).
    1. Macrocephaly with a normal ventricular system is common to all BRRS patients.
    2. Downslanting of the palpebral fissures (60%).
    3. Strabismus or amblyopia (15%).
    4. Schwalbe lines (35%).
    5. Birth weight above the mean and body length above the 97th percentile in most cases.
    6. Hypotonia, mild mental retardation, gross motor delay, autism spectrum disorder, and speech delay (50%).
        1. Motor delay is, for the most part, transient and improves with time.
        2. Irreversible myopathic disease in 60% of patients.
        3. Speckling of the glans penis and shaft, cutaneous angiolipomas, lymphangiomyomas, angiokeratomas, joint hyperextensibility, pectus excavatum, scoliosis, and accelerated growth of the metacarpals and of the first and second phalanges (50%).
    7. Subcutaneous lipomas (75%).
    8. Hemangiomas and café au lait spots of the trunk and lower extremities (10%).
    9. Hamartomatous polyps (45%): limited to the ileum and colon leading to rectal bleeding and intussusception.
    10. Posterior subcapsular congenital cataract due to altered function of the PTEN protein (Boccone et al. 2008).
2. Several clinical features common to CS (Marsh et al. 1999).
    1. Hashimoto's thyroiditis
    2. Vascular malformations
    3. Mental retardation
    4. Main differential features with BRRS
        1. Pigmented macules of the glans penis and shaft and delayed motor development: seen in BRRS but not seen in CS patients
        2. Lipomatosis common in BRRS: rarely seen in patients with CS
3. No agreed international criteria for the diagnosis of BRRS exist.
    1. Criteria of diagnosis by Marsh et al. (1999) with at least the following four features:
        1. Macrocephaly
        2. Lipomatosis
        3. Hemangiomas
        4. Speckled penis in males
    2. Criteria by Parisi et al. (2001) with at least two of the following three features:
        1. Macrocephaly
        2. Hamartomas (including at least one lipoma, hemangioma, or intestinal polyp)
        3. Penile macules in males
4. Differential diagnosis (Calva and Howe 2008; Eng 2014).
    1. Cowden syndrome (Lloyd and Dennis 1963; Starink et al 1986; Pilarski et al. 2011)
        1. A complex disorder with malignant and benign (hamartomatous) lesions affecting derivatives of all three germ cell layers, affecting the breast, thyroid, uterus, brain, and mucocutaneous tissues.
        2. Lhermitte-Duclos disease (adult) (dysplastic cerebellar gangliocytoma) (Zhou et al. 2003b; Riegert-Johnson et al. 2010): pathognomonic.
        3. By the third decade, 99% of affected individuals develop the mucocutaneous

stigmata (primarily trichilemmomas and papillomatosis papules) as well as acral and plantar keratoses: pathognomonic (Eng 2000).
4. Thyroid abnormalities (50–67%).
    1. Goiter
    2. Adenoma
    3. Thyroid cancer (typically follicular, but occasionally papillary) (approximately 10%), while the risk for endometrial cancer, although not well established, has been estimated to be 5–10%
5. Breast lesions.
    1. Fibroadenomas/fibrocystic disease (76% of affected females)
    2. Adenocarcinoma (25–50% of affected females), with an average age of diagnosis between 38 and 46 years old
6. Gastrointestinal lesions: hamartomatous polyps (40%).
7. Macrocephaly (38%).
8. Genitourinary abnormalities (44% of females).
9. Uterine leiomyoma (multiple, early onset).
10. Associated with germline mutations in *PTEN* (80% in Cowden syndrome probands ascertained by the strict operational diagnostic criteria for Cowden syndrome).

2. Proteus syndrome and Proteus-like syndrome
    1. A highly variable disorder involving congenital malformations, hamartomatous overgrowth of multiple tissues, connective tissue and epidermal nevi, and hyperostoses which affect patients in a mosaic pattern.
    2. Consensus diagnostic criteria available (Biesecker et al. 1999).
    3. While initially thought to be unrelated to Cowden syndrome or Bannayan-Riley-Ruvalcaba syndrome, at least two independent reports have identified germline *PTEN* mutations in approximately 20% of patients with Proteus syndrome (Zori et al. 1998; Smith et al. 2002).
    4. Furthermore, approximately 50% of patients with a Proteus-like syndrome (with significant features of Proteus syndrome, but not meeting diagnostic criteria) were also found to have germline *PTEN* mutations (Zhou et al. 2001).
    5. Thus, at least a subset of Proteus syndrome and Proteus syndrome-like conditions are allelic to Cowden syndrome and Bannayan-Riley-Ruvalcaba syndrome and are part of the *PTEN* hamartoma tumor syndrome spectrum.
3. Juvenile polyposis syndrome (JPS)
    1. An autosomal dominant disorder.
    2. Characterized by predisposition for hamartomatous polyps in the gastrointestinal tract, specifically in the stomach, small intestine, colon, and rectum.
    3. Untreated polyps lead to bleeding and anemia.
    4. Malignant transformation can occur though most juvenile polyps are benign.
    5. Approximately 20% of individuals with JPS have mutations in the *MADH4* gene, and approximately another 20% of individuals with JPS have mutations in the *BMPR1A* gene (Howe et al. 1998; 2001).
4. Peutz-Jeghers syndrome (PJS)
    1. An autosomal dominant disorder
    2. Characterized by the association of gastrointestinal polyposis and mucocutaneous pigmentation
    3. Characteristics of polyps
        1. Most prevalent in the small intestine but also occur in the stomach and large bowel.
        2. Often symptomatic with intussusception and rectal bleeding.
        3. The pigmentation of the perioral region is pathognomonic, particularly if it crosses the vermilion border.

4. Hyperpigmented macules on the fingers are also common.
5. Molecular genetic testing of *STK11/LKB1* reveals disease-causing mutations in approximately 70% of individuals who have a positive family history and 20–70% of individuals who have no family history of PJS.

Diagnostic Investigations

1. A yearly hemoglobin test from early infancy for the early detection of intestinal hamartomas (Hendriks et al. 2003)
2. Imaging studies to define extent of the neoplasms
3. *PTEN* molecular genetic diagnosis by full sequencing available on clinical basis (Eng 2014)
    1. Diagnosis of PHTS made only when a *PTEN* mutation is identified
    2. Detectable *PTEN* gene mutation
        1. Up to 65% of individuals meeting the diagnostic criteria of BRRS (Marsh et al. 1999; Zhou et al. 2003a).
        2. Up to 85% of individuals meeting the diagnostic criteria for CS (Marsh et al. 1998; Zhou et al. 2003a).
        3. Preliminary data available suggest that up to 50% of individuals with a Proteus-like syndrome and up to 20% of individuals with Proteus syndrome have *PTEN* mutations.

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. 50% if one parent is affected
        2. Recurrent risk probably negligible if neither parent has the *PTEN* mutation found in the proband since germline mosaicism has not been reported
    2. Patient's offspring: 50%
2. Prenatal diagnosis (Eng 2014)
    1. Possible for pregnancies at increased risk by analysis of DNA extracted from fetal cells obtained by amniocentesis usually performed at approximately 15–18 weeks' gestation or chorionic villus sampling at approximately 10–12 weeks' gestation if the disease-causing allele of an affected family member has been identified.
    2. Preimplantation genetic diagnosis may be available for families in which the disease-causing mutation has been identified in an affected family member.
3. Management
    1. Cancer surveillance: the most important aspect of management of an individual with a *PTEN* mutation
        1. Annual physical examination from age 18 years
        2. Annual urinalysis
        3. Baseline colonoscopy at age 50 years
    2. Molecular testing of asymptomatic at-risk relatives to identify those who have a family-specific *PTEN* mutation and ensure appropriate surveillance

Fig. 1 The patient, a 6-year-old Caucasian female, was seen for difficulty in walking. She complained significant pain in the *left* lower leg with prominent veins associated with intermittent swelling for the past 4 years. The physical examinations and various imaging studies revealed *left* lower extremity vascular malformation causing significant pain syndrome, swelling, limb dysfunction and gait disturbance, and multiple lipomas. The patient was found to have a PTEN deletion which was performed at other institution. The molecular testing confirmed the clinical diagnosis of Bannayan-Riley-Ruvalcaba syndrome. The family history revealed multiple family members affected with lipomatosis (mother, maternal great aunt, and a first cousin)

Fig. 7 A diffuse lipoma noted on the *left* side of the back

Beckwith-Wiedemann Syndrome

Contents

The Beckwith-Wiedemann syndrome (BWS) is the most common and the best-known congenital overgrowth syndrome. It was named after Beckwith who, in 1963, described three unrelated patients with exomphalos, hyperplasia of the kidneys and pancreas, and adrenal cytomegaly (Beckwith 1963). Wiedemann in 1964 (Wiedemann 1964) reported a familial form of omphalocele with macroglossia. The incidence is estimated to be about one in 13,700 births.

Synonyms and Related Disorders

Exomphalos-macroglossia-gigantism syndrome; Wiedemann-Beckwith syndrome

Genetics/Basic Defects

1. Genetics of BWS: complex (Engel et al. 2000)
    1. Pedigree data (Engstrom et al. 1988; Elliott et al. 1994)
        1. Sporadic (85%)
        2. Familial (15%): autosomal dominant inheritance with variable expressivity, incomplete penetrance (Pettenati et al. 1986), and preferential maternal transmission
    2. Karyotypic data
        1. Chromosome rearrangements influenced by the parent of origin (2%)
            1. Paternally derived 11p15.5 duplications exhibiting atypical clinical features as well as a significant risk of developmental delay
            2. Maternally derived translocations and inversions exhibiting typical features of Beckwith-Wiedemann syndrome
        2. Normal karyotype (98%)
    3. Molecular data: BWS is caused by alterations in growth regulatory genes on chromosome region 11p15.5, which is subjected to genomic imprinting (an epigenetic mechanism in which gene expression is altered according to the parental origin of the allele)
2. Pathogenesis (Li et al. 1997, 1998; Maher and Reik 2000; Ferry 2010; Soejima and Higashimoto 2013)
    1. Imprinted genes have been implicated in the pathogenesis of both familial and sporadic BWS (Hatada and Mukai 2000)
    2. A subgroup of BWS patients has loss of methylation at a differentially methylated region (KvDMR1) within the *KCNQ1* gene centromeric to the *IGF2* and *H19* genes

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_22

3. Maternally expressed 11p genes
    1. *CDKN1C* (also known as *P57KIP2*) (Hatada et al. 1996; Lam et al. 1999): a member of the cyclin-dependent kinase inhibitor family: a candidate for a maternally expressed growth inhibitory gene in BWS
        1. Germline mutations detected in >40% of familial cases
        2. Mutations infrequent (<5%) in sporadic cases
    2. *H19*: a maternally expressed gene encoding a biologically active nontranslated mRNA that may function as a tumor suppressor. Deletion of *H19* or transposition from its usual position relative to *IGF2* disrupts normal imprinting.
    3. *KCNQ1* (also known as *KvLQT1*): serves as an imprinting center, disruption of which could affect transcription and DNA replication through an effect on chromatin structure.
4. Paternally expressed 11p genes
    1. *IGF2* (the gene for insulin-like growth factor-2): a paternally expressed and maternally imprinted embryonic growth factor. Many sporadic cases show loss of imprinting of *IGF2* resulting in biallelic expression.
    2. *KCNQ1OT1* gene (also known as *LIT1*): The unmethylated paternal allele of *KvDMR1* permits transcription of the antisense transcript *KCNQ1OT1* and silencing of the *KCNQ1* and *CDKN1C* genes (Murrell et al. 2004).
5. Effect of multiple genes: combination of increased expression of paternally expressed growth promoter genes such as *IGF2* and loss of maternally expressed growth suppressor genes in some patients with paternal uniparental disomy of 11p15
6. Uniparental disomy (mosaic paternal isodisomy) for the band 11p15.5 (10–20% of sporadic cases)
    1. Two paternally derived copies of chromosome 11p15 and no maternal contribution for that chromosome region
    2. Resulting from postzygotic mitotic recombination and mosaic paternal isodisomy
    3. All patients with uniparental disomy exhibit somatic mosaicism
7. Opposite methylation defects, gain of methylation and loss of methylation, at H19DMR are known to cause clinically opposite disorders: BWS and Silver-Russell syndrome, respectively. Loss of function or gain of function of CDKN1C also causes clinically opposite disorders, BWS and IMAGe (intrauterine growth restriction, metaphyseal dysplasia, adrenal hypoplasia congenita, and genital anomalies) (Soejima and Higashimoto 2013)
8. Recent clinical studies have suggested a relationship between assisted reproductive technology and the risk of imprinting disorders, along with the existence of trans-acting factors that regulate multiple imprinted differentially methylated regions (Soejima and Higashimoto 2013)

3. Clinical findings relevant to molecular etiology (Weksberg et al. 2010)
    1. Tumor development
        1. Individuals with UPD of 11p15.5 or gain of methylation at the H19. Imprinting center (IC) carry the highest risk to develop Wilms tumor or hepatoblastoma.
        2. Individuals with loss of maternal methylation at IC2 carry a lower tumor risk; as well, the tumors in this molecular subgroup do not include Wilms tumor.
        3. Individuals with mutations in *CDKN1C* seem to have the lowest risk with only a small number of cases reported. In cases with *CDKN1C* mutation, only neuroblastoma has been reported to date.
    2. Hemihyperplasia in cases of BWS: Alterations have included mosaicism for UPD 11p15.5 with hemihyperplasia and or molecular alterations at IC2 or IC1.
    3. Positive family history: associated with mutations in *CDKN1C* or microdeletions of IC1 and very rarely IC2.

4. Omphalocele: associated with an IC2 defect or *CDKN1C* mutation.
5. Developmental delay: associated with cytogenetically detectable duplications involving the paternal copy of chromosome 11p15.5.
6. A severe BWS phenotype
    1. This seems to be associated, at least in certain cases, with very high levels of paternal chromosome 11p15.
    2. An increased frequency of female monozygotic twins discordant for BWS has been reported. These females usually show loss of methylation at IC2.
    3. In contrast, the less frequently observed male monozygotic twins show a broad spectrum of BWS-associated molecular alterations.
7. Sterility/assisted reproductive technologies (ART)
    1. This seems to be associated with an increased risk of BWS cases with loss of methylation at IC2.
    2. No specific aspect of subfertility or its treatment has been specifically associated with the increased risk of epigenetic defects associated with BWS after ART.

Clinical Features

1. Variable phenotypic expression (Shuman et al. 2010; Ibrahim et al. 2014)
2. Prenatal and postnatal overgrowth (gigantism) (cardinal feature)
    1. Fetus grows at an increased rate during the latter half of pregnancy
    2. Large or above normal size baby at birth
    3. Eventual somatic gigantism in most cases
    4. Advanced bone age
    5. Hemihyperplasia or hemihypertrophy (13%)
3. Performance
    1. Development
        1. Usually normal unless there is chromosome 11p15.5 duplication or serious perinatal complications such as prematurity or uncontrolled hypoglycemia.
        2. Mild-moderate mental retardation from undetected hypoglycemic episodes during infancy
    3. Hypoglycemia
        1. Reported in 30–50% of babies with BWS
        2. Likely caused by islet cell hyperplasia and hyperinsulinemia
    2. Seizures in some cases
4. A recognizable facial gestalt: common but often normalizes across childhood (Elliot and Maher 1994)
    1. Macroglossia (cardinal feature)
        1. Chronic alveolar hypoventilation
        2. Anterior open bite
    2. Earlobe grooves or indented ear lesions on the posterior rim of the helix or concha
    3. Facial nevus flammeus
    4. Midfacial hypoplasia
    5. Prominent eyes with infraorbital creases
    6. Maxillary hypoplasia
    7. Full lower face with a prominent mandible
    8. Prominent occiput
    9. Ear creases/pits
5. Abdominal wall defect
    1. Omphalocele (cardinal feature)
    2. Umbilical hernia
    3. Diastasis recti
6. Gastointestinal anomalies
    1. Malrotation anomalies
    2. Dome-shaped defect of the diaphragm
7. Visceromegaly
    1. Fetal adrenocortical cytomegaly: pathognomonic finding for BWS
    2. Hepatomegaly (frequent)
    3. Nephromegaly (frequent)
    4. Cardiomegaly that resolves spontaneously
    5. Occasional clitoromegaly
    6. Hyperplastic pancreas, bladder, uterus, and thymus
8. Neoplasms: overall risk for tumor development in children with BWS estimated at 7.5%
    1. Benign tumors
        1. Adrenal adenoma
        2. Carcinoid tumor
        3. Fibroadenoma
        4. Fibrous hamartoma

5. Ganglioneuroma
6. Myxoma

2. Malignant tumors: predisposition to embryonal malignancies
    1. Wilms tumor (most frequent) (3.7% incidence) (Borer et al. 1999)
    2. Hepatoblastoma: can be associated with elevated serum alpha-fetoprotein levels (Everman et al. 2000)
    3. Adrenocortical carcinoma
    4. Rhabdomyosarcoma
    5. Neuroblastoma
    6. Glioblastoma
    7. Malignant lymphoma
    8. Pancreatoblastoma
    9. Teratoma
3. Clinical findings associated with higher risks of tumor development
    1. Hemihyperplasia
    2. Nephromegaly
    3. Nephrogenic rests

9. Additional features
    1. Polyhydramnios
    2. Prematurity
    3. Enlarged placenta
    4. Hemangioma
    5. Congenital heart defects
    6. Other renal anomalies
        1. Medullary dysplasia
        2. Duplicated collecting system
        3. Nephrocalcinosis
        4. Medullary sponge kidney
        5. Cystic changes
        6. Diverticula
10. Adult phenotype
    1. Hemihyperplasia
    2. Prominent jaw
    3. Enlarge tongue
    4. Ear creases and pits
    5. Enlarged kidneys and other abdominal organs
    6. Normal height
11. Major and minor findings associated with BWS (Weksberg et al. 2010)
    1. Major findings
        1. Abdominal wall defect: omphalocele (exomphalos) or umbilical hernia
        2. Macroglossia
        3. Macrosomia (traditionally defined as height and weight >97th percentile)
        4. Anterior ear lobe creases and/or posterior helical pits (bilateral or unilateral)
        5. Visceromegaly of intra-abdominal organ(s); for example, liver, kidney (s), spleen, pancreas, and adrenal glands
        6. Embryonal tumor in childhood
        7. Hemihyperplasia
        8. Cytomegaly of adrenal fetal cortex, usually diffuse and bilateral
        9. Renal abnormalities, including medullary dysplasia and later development of medullary sponge kidney (MSK)
        10. Positive family history of BWS
        11. Cleft palate
    2. Minor findings
        1. Pregnancy-related findings of polyhydramnios, enlarged placenta, and/or thickened umbilical cord, premature onset of labor and delivery
        2. Neonatal hypoglycemia
        3. Nevus flammeus
        4. Cardiomegaly/structural cardiac anomalies/cardiomyopathy
        5. Characteristic facies
        6. Diastasis recti
        7. Advanced bone age
12. Simpson-Golabi-Behmel syndrome (clinical overlap with BWS) (Knopp et al. 2015)
    1. Clinical features overlap with BWS
        1. Pre- and postnatal overgrowth
        2. Macroglossia
        3. Umbilical hernia
        4. Organomegaly
        5. Ear lobe creases
        6. Occurrence of embryonic tumors
    2. Other features
        1. Distinctive craniofacial features (a wide mouth with an everted and thickening below the lower lip, epicanthal folds, and others)
        2. Supernumerary nipples
    3. A rare X-linked condition caused by glypican3 (GPC3) which encodes for a

membrane-associated heparan sulfate proteoglycan

Diagnostic Investigations

1. Transitory neonatal hypoglycemia (spontaneous regression during the first 4 months of life) (63%)
2. Neonatal polycythemia (20%)
3. Hypercholesterolemia, hyperlipidemia, hypothyroidism, thyroxine-binding globulin deficiency: rare occurrence
4. Periodic abdominal ultrasonography for organomegaly and embryonal tumors, followed by MRI or CT if indicated
5. Radiography
    1. Advanced bone age
    2. Chest radiography to rule out rare neural crest tumors such as thoracic neuroblastoma
6. Echocardiography for suspected cardiac abnormality
7. Chromosome analysis (high resolution and FISH studies)
    1. Normal chromosomes in most patients
    2. Chromosome abnormalities involving 11p15 in $\leq$1% of cases
        1. Partial duplication of chromosome 11p (Waziri et al. 1983)
        2. Paternally derived 11p15.5 duplication (Slavotinek et al. 1997)
        3. Maternally derived translocations and inversions
8. Molecular analysis (Shuman et al. 2010)
    1. Paternal uniparental disomy (UPD) of 11p15 in multiple tissues (10–20%)
        1. Restriction fragment length polymorphism (RFLP) analysis of multiple 11p15 loci
        2. Methylation studies of multiple imprinted genes on 11p15
    2. Mosaicism for paternal uniparental isodisomy of chromosome 11p15.5 om 28% of informative sporadic BWS patients (Slatter et al. 1994)
    3. Mutation analysis: *P57 KIP2* (5–10%) (screen for mutation by heteroduplex/SSCP analysis, followed by sequence of *P57 KIP2* exons)
    4. Molecular testing is typically not indicated for parents or other family members when UPD is found, as these cases arise through postzygotic somatic recombination.
    5. Parental studies are recommended if genomic alterations are found, that is, karyotype abnormalities, *CDKN1C* mutations, or microduplications or microdeletions of the 11p15.5 region (Weksberg et al. 2010).
    6. *CDKN1C* sequencing (after 11p15 methylation analysis) should be performed for (Brioude et al. 2015):
        1. Apparently sporadic cases in patients with abdominal wall defects (umbilical hernia or exomphalos), a cleft palate or a hypospadias, and without hemihyperplasia, or
        2. In familial cases of BWS even if the abdominal wall is normal
9. Molecular genetic results and relationship to clinical indications for referral (a total of 1,091 referrals) (Ibrahim et al. 2014)
    1. 46.5% had abnormal methylation profile at IC1 (distal imprinting centers) and/or IC2 (centromeric imprinting centers)
        1. 4.3% had hypermethylation at IC1 only
        2. 29.4% had isolated IC2 hypermethylation
        3. 12.4% had isolated IC1 and IC2 methylation from paternal UPD
    2. Low-level mosaicism may be missed
    3. Some cases with normal BWS methylation profiles may have *CDKN1C* mutations

Genetic Counseling

1. Recurrence risks (Shuman et al. 2010)
    1. Patient's sib: The risk to the sibs of a child with BWS depends on the genetic basis for BWS in the proband
        1. Probably a low recurrence risk in cases of negative family history, normal karyotype, and absence of identifiable molecular etiology

2. Up to 50% of recurrence risk in cases of positive family history and normal karyotype
3. Up to 50% recurrence risk in cytogenetically detected maternal 11p15 translocation or inversion
4. An undetermined recurrence risk in cytogenetically detected paternal 11p15 duplication
5. A low recurrence risk in cases of paternal 11p15 uniparental disomy as this event arises from a postzygotic somatic recombination
6. 50% recurrence risk if a *CDKN1C* mutation is present in a parent (usually maternally transmitted)
7. Four clinically relevant categories identified for approximately 85% of individuals with BWS who have a negative family history and a normal karyotype (Shuman et al. 2010):
    1. Proband with *KCNQ1OT1* hypomethylation (∼50–60%): very low recurrence risk since no recurrences of loss of methylation at *KCNQ1OT1* have been reported in first-degree relatives of individuals with BWS who have this molecular lesion.
    2. Proband with paternal uniparental disomy for 11p15 (∼10–20%): the recurrence risk is empirically very low because the UPD appears to arise from a postzygotic somatic recombination.
    3. Proband with a *CDKN1C* mutation (∼510%): Both parents should be tested for mutations. Several instances of transmission of *CDKN1C* mutations from clinically unaffected mothers to affected offspring have been reported as well as two instances of paternal transmission from clinically unaffected fathers. The recurrence risk for such parents may be as high as 50%.
    4. Proband with no identifiable primary etiology (∼13–15%): The risk to members in these families is unknown but empirically low.
    2. Patient's offspring (Shuman et al. 2010)
        1. Negative family history (10–20% of individuals with BWS and no known family history of BWS have paternal uniparental disomy of 11p15) and normal karyotype (5–10% of all individuals with BWS with a normal karyotype have identifiable mutations in *CDKN1C*): ∼85% of individuals with BWS
            1. *KCNQ1OT1* hypomethylation: a low recurrence risk
            2. Uniparental disomy for 11p15: likely a very low risk
            3. Identified *CDKN1C* mutation: The risk to offspring of a female with a *CDKN1C* mutation is 50%; the risk to offspring of a male with a *CDKN1C* mutation is <50%, but too few cases have been reported to generate a risk figure
        2. Positive family history and normal karyotype: ∼10–15% of individuals with BWS
            1. ∼50% if transmitting parent is female
            2. <50% if transmitting parent is male
        3. Monozygous twins (<1% of individuals with BWS): theoretically low
2. Prenatal diagnosis
    1. Indications (Weksberg et al. 2010)
        1. Families having a child with severe manifestations of BWS.
        2. If a cytogenetic or genomic abnormality (e.g., microdeletion, *CDKN1C* mutation) has been identified, prenatal testing may be indicated by CVS or amniocentesis. If such abnormalities are *de novo*, gonadal mosaicism remains a possibility. Epigenetic analysis of amniocytes can be undertaken by methylation-sensitive multiplex ligation probe analysis (MS-MLPA).
        3. Families, for whom UPD or methylation alterations have been detected in the absence of a transmissible genomic alteration, may also wish to consider

prenatal diagnostic testing even though the recurrence risk would be very low. Of note, a recent follow-up study of apparently isolated fetal omphalocele reported BWS in 20% of cases based on clinical or molecular findings (Wilkins-Haug et al. 2009).

2. Maternal serum screening (Kagan et al. 2015)
    1. Maternal serum alpha-fetoprotein: may be elevated in a fetus with omphalocele
    2. An excessive beta-hCG levels: may be related to the placentamegaly
3. Prenatal Ultrasonography (Weng et al. 1995a, b; Eckmann-Scholz and Jonat 2011; Kagan et al. 2015)
    1. Fetal overgrowth (macrosomia)
    2. Polyhydramnios
    3. Enlarged (hydropic) placenta
    4. A long umbilical cord
    5. Macroglossia
    6. Cleft palate
    7. Distended abdomen
    8. Abdominal wall defects including omphalocele (Winter et al. 1986)
    9. Organomegaly (hepatomegaly)
    10. Renal anomalies
    11. Cardiac anomalies
4. Cytogenetic studies
    1. Possible if a cytogenetic abnormality has been identified in the proband and one parent
    2. To identify translocations, deletions, inversions (Norman et al. 1992), and duplications involving 11p15 (Reish et al. 2002)
5. Molecular analysis
    1. Uniparental disomy
    2. Mutation analysis of *CDKN1C*, provided the mutation has been documented in the previously affected child

3. Management
    1. Early detection and close monitoring for hypoglycemia to reduce the risk of central nervous system complications
    2. Partial tongue resection for cosmetic purpose and to relieve severe airway obstruction
    3. Surgical risks related to hypoglycemia or difficulty in intubation secondary to macroglossia
    4. Management of abdominal wall defects, gastrointestinal malformations, and renal anomalies
    5. Orthopedic follow-up of hemihyperplasia
    6. Management of structural renal abnormalities
    7. Persistent congenital hyperinsulinism in BWS/11p overgrowth appears to be exclusive due to paternal UPD11p and may present to be either diazoxide-responsive or diazoxide-unresponsive. In cases of UPD-11p overgrowth that have also had a paternally transmitted KATP mutation, congenital hyperinsulinism may be particularly severe and difficult to control. Recognition of UPD-11p overgrowth in patients with congenital hyperinsulinism is of particular importance because of the need to monitor for potential tumors (Kalish et al. 2016).
    8. Management of embryonal neoplasms

Fig. 1 (**a**–**e**) Five infants with Beckwith-Wiedemann syndrome showing hemangioma, macroglossia, and umbilical hernia

Fig. 2 (**a**, **b**) An infant with Beckwith-Wiedemann syndrome showing macroglossia, ear crease, and umbilical hernia

Fig. 3 An infant with Beckwith-Wiedemann syndrome and a large omphalocele requiring surgical intervention

Fig. 4 An infant with Beckwith-Wiedemann syndrome prior to partial glossectomy

Fig. 5 A young adult with Beckwith-Wiedemann syndrome showing macroglossia and postsurgical status of umbilical and inguinal hernia repairs

Fig. 6 (**a**, **b**) A 2-month-old infant with macroglossia and posterior ear creases, suspected of having Beckwith-Wiedemann syndrome clinically. Southern blot analysis was utilized to detect abnormal methylation in the imprinting center DMR2, which is located within the BWS critical region on chromosome 1p15. The DNA probe LIT1 was used for the analysis. Hypomethylation of LIT1 was detected. The methylation index was 0.21 (Reference range: 0.40–0.58). The results are consistent with a diagnosis of Beckwith-Wiedemann syndrome

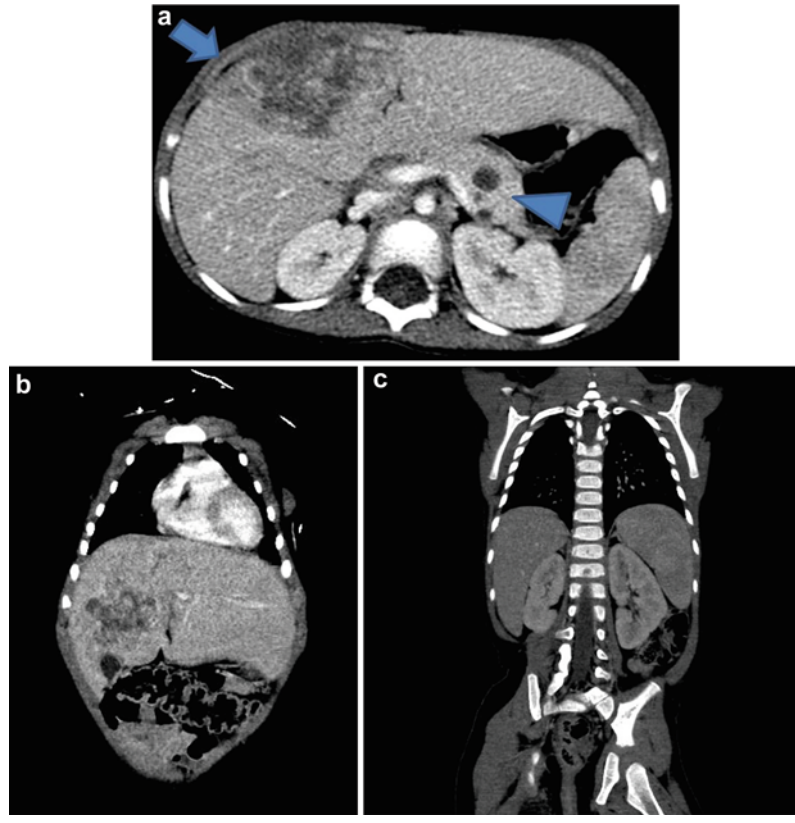

Fig. 7 (**a**–**c**) A 2-year-old girl with a diagnosis of Beckwith-Wiedemann syndrome. Enhanced axial CT image (**a**) demonstrated a large, heterogeneous hepatoblastoma (*arrow*) and multiple cystic lesions in the pancreas (*arrowhead*). The large, heterogeneous hepatoblastoma was also demonstrated in the second image (**b**). There was asymmetric enlargement of the left kidney with symmetric enhancement (**c**) (Courtesy of Dr. Grace Guo)

Behçet Disease

Contents

In 1937, Behçet (1937) first described three patients with oral and genital ulceration and hypopyon. It is most common in the Middle and Far East with a prevalence of 7–8 per 100,000 people, whereas in the USA the prevalence is estimated at 4 per 1,000,000 people.

Synonyms and Related Disorders

Behçet syndrome

Genetics/Basic Defect

1. A complex multisystem inflammatory disease of unknown cause
2. Considered a relapsing and remitting vasculitis of the small- to medium-sized vessels with following protean manifestations:
    1. Aphthous stomatitis
    2. Genital ulceration
    3. Uveitis
    4. Synovitis
    5. Gastrointestinal lesions
    6. Cutaneous lesions
    7. Central nervous system lesions
    8. Cardiac lesions
    9. Vessel lesions
3. Immunopathogenic aspects of Behçet disease (Direskeneli 2001; Krause and Weinberger 2008; Dalvi et al. 2012)
    1. Vascular injuries, hyperfunction of neutrophils, and autoimmune (Yazici 1997) responses: characteristics of Behçet disease (Sakane et al. 1999)
    2. Cellular and humoral immunity
    3. Antigenic stimuli
        1. Herpes simplex virus
        2. Streptococci and superantigens
        3. Heat shock proteins (65 kDa, αβ-crystallin)
    4. Genetic risk factor: most strongly associated with Behçet disease: human leukocyte antigen (HLA-B51) allele
        1. Genetic predisposition to HLA-B51 and antigen presentation
        2. Retinal-S antigen and HLA-B51 as autoantigens
    5. Vascular disease and antiendothelial cell antibodies
    6. Severity and sex: more severe in men
    7. Tumor necrosis factor-α-1031C allele: associated with disease susceptibility

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_23

8. Polymorphisms in interleukin-10 and CD28 genes: also associated with Behçet disease
9. Association with endothelial nitric oxide synthase gene polymorphism: ethnic related

Clinical Features

1. Highly variable clinical course with recurrences and remissions (Chajek and Fainaru 1975; Rizzi et al. 1997)
2. More prevalent in regions along the Silk Road from the Mediterranean to the Far East (Verity et al. 1999)
3. Recurrent attacks of oral, genital, ocular, and skin lesions (Kurokawa and Suzuki 2004; Alpsoy et al. 2007; Dalvi et al. 2012; Alnaimat 2015)
    1. Oral aphthous ulcers
        1. Keystones to diagnosis of Behçet disease according to the classification criteria
        2. Often an initial presenting sign
        3. Occurring on the buccal mucosa, tongue, gingiva, and the soft palate area
        4. Minor aphthous ulcers: superficial with a diameter of 2–6 mm, appearing as multiple lesions, and developing within 1–2 days. They heal without scarring within 7–10 days and recur at various frequencies.
        5. Major aphthous ulcers: deeper and painful lesions leaving scars after healing
        6. Herpetiform aphthous ulcers: numerous lesions grouped as small ulcers
    2. Genital ulcers
        1. Women: located on the vulva, vagina, and cervix uteri
        2. Men: located on the prepuce and scrotum
        3. Lesions resembling the oral aphthae but tend to be deeper and leaving scars
        4. Differential diagnosis from other genital ulcers (herpes simplex, syphilis, tropical ulcers, and skin infestations)
    3. Ocular lesions (70–85%) (Bashour 2014)
        1. Generally follow the genital and oral ulceration by a few years
        2. Characterized by severe vasculitis with arterial and venous occlusions
        3. Iridiocyclitis with hypopyon (presence of leukocytes in the anterior chamber of the eye) (one third of cases)
        4. Uveitis
        5. Retinal vasculitis (classic fundus findings) affecting both arteries and veins in the posterior pole
        6. Hemorrhagic and exudative retinal lesions (retinitis)
        7. Marked vitritis
        8. Choroiditis
        9. Bilateral nongranulomatous inflammation of the iris and ciliary body
        10. Intermittent blurring of vision and loss of vision
    4. Skin lesions
        1. Pustular vasculitic cutaneous lesions: may evolve as lesions of small vessel necrotizing vasculitis from a neutrophilic vascular reaction to a lymphocytic perivascular reaction
        2. Erythema nodosum-like lesions: usually occurring on the lower extremities but can be seen on the arms, neck, and face
        3. Pseudofolliculitis
        4. Papulopustular lesions: neutrophil-induced, vessel-based reaction
        5. Acneiform nodules
4. Myositis (Lang et al. 1990; Zen-nyoji et al. 2000)
    1. Pediatric onset of Behçet disease with myositis with calf pain and swelling
    2. Intestinal Behçet disease associated with generalized myositis
5. Articular manifestations
    1. Recurrent seronegative arthritis
        1. Common findings

    2. A nonspecific synovitis
  2. Monoarthritis
  3. Polyarthritis
6. Gastrointestinal manifestations (about 70% of patients) (Ebert 2009)
  1. Ulcerative lesions most frequently occurring in the terminal ileum, cecum, stomach, and intestine
  2. Symptoms
    1. Abdominal pain
    2. Diarrhea
    3. Melena
    4. Perforation
7. CNS manifestations (about 1% of patients)
  1. Headaches
  2. Meningitis
  3. Meningoencephalitis
  4. Cranial nerve palsies
  5. Peripheral nerve involvement with vasculitis
  6. Cerebellar ataxia
  7. Hemiplegia
  8. Benign intracranial hypertension
  9. Neurologic deficits
  10. Cerebral aneurysm
  11. Cerebral vasculitis and ischemic stroke (Krespi et al. 2001): unusual
  12. Personality changes and depression
  13. Dementia
  14. Hearing and vestibular disturbances
8. Pulmonary manifestations
  1. Tracheobronchial ulcerations
  2. Pleurisy
  3. Embolism
  4. Pulmonary arterial aneurysms
  5. Pneumonitis
  6. Fibrosis
9. Renal involvement: rare
  1. Glomerulonephritis
  2. Systemic amyloidosis
10. Cardiac manifestations
  1. Intracardiac thrombosis (Mogulkoc et al. 2000)
  2. Myocardial infarction
  3. Pericarditis
  4. Endocarditis
11. Vascular manifestations
  1. Superficial thrombophlebitis
  2. Deep thrombophlebitis
  3. Small- and large-vessel vasculitis
  4. Pulmonary artery aneurysms (PAI) (Seyahi and Yazici 2015)
    1. Strongly associated with venous thrombosis such as deep vein thrombosis of the legs, dural sinus thrombosis, and vena cava inferior thrombosis
    2. Thrombi on the right side of the heart occur in about one third of patients with PAI
12. Pregnancy in Behçet disease (Noel et al. 2013; Iskender et al. 2014)
  1. A higher rate of vascular complications during pregnancy
  2. The disease course: improves during pregnancy, mostly in patients who are treated with colchicine
  3. Rate for other obstetric complications: not increased
  4. Neonatal outcomes: not negatively influenced by Behçet disease
13. Neuro-Behçet disease (Serdaroglu 1998; Diri and Espinoza 2006)
  1. Defined as a constellation of neurologic manifestations with characteristic neuropathologic findings, usually confirmed by ancillary investigations, in patients who meet the diagnostic criteria for Behçet disease
  2. Neurologic involvement
    1. One of the most serious manifestations of Behçet disease
    2. More common in male patients and have been reported to occur in anywhere from 5% to 50% of Behçet disease patients, depending on their geographical region
  3. Two types of CNS involvement
    1. Primary parenchymal (neuro-Behçet disease; 82% of cases): pathological process within the CNS parenchyma (worse prognosis)
    2. Secondary or nonparenchymal (vascular-Behçet disease; 18% of cases):

pathological process resulting from a major vasculopathy (better prognosis if occluded)
4. Predominantly motor/mental picture
5. Peripheral neuropathy and myopathy: rare
6. MRI lesion extending from brain stem to basal ganglia
7. Immunosuppression: widely used for treatment

14. Prognosis (Ebert 2009)
    1. Runs a chronic, unpredictable course with exacerbations and remissions which decrease in frequency and severity over time
    2. Death: mainly due to major vessel disease and neurological involvement
    3. Prognosis for Behçet disease: worst for young males
    4. Prognosis for intestinal Behçet disease
        1. Complete remission: 38% of patients with intestinal Behçet disease after 8 weeks of medical treatment
        2. Rate of recurrence after surgery: 40–56%
        3. Recurrence: 49% of patients at 5 years, especially those with intestinal perforation or fistula formation
    5. Visual acuity: significantly improved after early treatment with chlorambucil (Pivetti Pezzi et al. 1985)
15. Criteria for clinical diagnosis of Behçet disease, proposed by O'Duffy and Goldstein in 1976, require the presence of recurrent oral or genital aphthae along with two additional systemic findings for diagnosis and only one for the diagnosis of the incomplete form (O'Duffy and Goldstein 1976):
    1. Criteria
        1. Aphthous stomatitis
        2. Aphthous genital ulceration
        3. Uveitis
        4. Cutaneous "pustular" vasculitis
        5. Synovitis
        6. Meningoencephalitis
    2. Diagnosis: At least three criteria present, one being recurrent aphthous ulceration
    3. Incomplete form: Two criteria present, one being recurrent aphthous ulceration
    4. Exclusion
        1. Inflammatory bowel disease
        2. Systemic lupus erythematosus
        3. Reiter's disease
        4. Herpetic infections
16. The International Study Group criteria (1990) included positive pathergy test as one of the criteria to establish the diagnosis of Behçet disease (Ghate and Jorizzo 1999):
    1. Recurrent oral ulceration: minor aphthous, major aphthous, or herpetiform ulceration observed by physician or patient that recurred at least three times in one 12-month period
    2. *Plus 2 of the following criteria* (findings applicable only in absence of other clinical explanations)
        1. Recurrent genital ulceration: aphthous ulceration or scarring observed by physician or patient
        2. Eye lesions: Anterior uveitis, posterior uveitis, or cells in vitreous on slit lamp examination; or retinal vasculitis observed by ophthalmologist
        3. Skin lesions: erythema nodosum observed by physician or patient, pseudofolliculitis or papulopustular lesions; or acneiform nodules observed by physician in postadolescent patients not receiving corticosteroid treatment
        4. Pathergy test (a nonspecific pustule that is an inflammatory reaction to needle pricks in approximately 40% of patients, especially during the exacerbation period): Pathergy test is positive when pricking a sterile needle into the patient's forearm results in an aseptic erythematous nodule or pustule that is more than 2 mm in diameter at 24–48 h.
17. Differential diagnosis (Dalvi et al. 2012)
    1. Reactive arthritis
        1. Conjunctivitis
        2. Urethritis
        3. Sacroiliitis
        4. Keratoderma blennorrhagicum

2. Inflammatory bowel disease
    1. Lesions seen in all parts of gastrointestinal tract, perianal, and rectal disease
    2. Fistula formation
3. Sarcoidosis
    1. Bilateral hilar lymphadenopathy
    2. Interstitial lung disease
4. Seronegative arthropathies
    1. Sacroiliitis
    2. Psoriatic skin lesions
    3. Aortic insufficiency
    4. Axial disease
5. Other systemic vasculitides
    1. Antineutrophilic cytoplasmic antibodies
    2. Mononeuritis multiplex
6. Sweet syndrome
    1. Moderate to high fever or upper respiratory infection preceding the skin lesions
    2. Neutrophilia

Diagnostic Investigations

1. Positive skin pathergy test
2. Laboratory findings (Önder and Gürer 2001)
    1. Acute-phase response
        1. Raised erythrocyte sedimentation rate
        2. Increased serum levels of C-reactive protein
        3. Elevated plasma complement components, such as C3, C4, C9, and factor B
    2. Disease exacerbations
        1. Elevated IgG, IgA, and IgM
        2. Elevated C-reactive protein
        3. Elevated 2-globulin
    3. Interleukin (IL)-8 as a serological marker
    4. Increased serum leptin concentration: correlated with disease activity (Evereklioglu et al. 2002)
3. HLA typing
4. Ultrasonography of lower extremity: to evaluate vein thrombosis (Seyahi et al. 2015)
5. Echocardiography: to detect valve vegetations and ventricular thrombi
6. Endoscopy of the GI tracts: to detect GI ulcerations
7. Radiography: show a wide spectrum of radiologic abnormalities (Chae et al. 2008; Rabinovich 2014)
    1. Barium studies with a double-contrast technique: demonstrate small ulcers in the bowel loop more effectively than do those with a single-contrast technique
    2. Fluorescein angiography, color Doppler imaging, and fundoscopic examination to detect retinal features
    3. Angiography: shows area of aneurysm formation and thrombosis
    4. CT scan (Ceylan et al. 2010)
        1. Effectively demonstrates vascular system involvement that is the main cause of mortality in these patients
        2. Also effective in detecting mediastinal, pleural, and pulmonary parenchymal findings related to the disease
    5. MRI and CT scan
        1. To identify cerebral vasculopathy and areas of acute/subacute ischemia
        2. Thorax CT: may disclose ground glass lesions, nodules, and pleural lesions, other than arterial lesions (Seyahi and Yazii 2015)
        3. Brainstem involvement with meningoencephalitis (T2-weighted images) (Rabinovich 2014)
    6. Electrocardiograph-gated cardiac CT and cardiac MRI: easily demonstrate periaortic pseudoaneurysms with their possible rupture into the cardiac chamber, as well as provide the detailed three-dimensional information required for surgery
    7. Single-photon emission computed tomography (SPECT): to identify areas of cerebral hypoperfusion
    8. Angiography: to evaluate aneurysms
8. Whole exome sequencing: identification of two rare putative protein-damaging genetic variants (*LIMK2* and *NEIK1*) associated with this disease (Ognenovski et al. 2015)
9. Neuropsychologic testing (Rabinovich 2014)
    1. Reveals memory impairment or personality changes
    2. Useful in monitoring neuropsychologic status

10. Histopathological features
    1. Pathergy lesions
        1. Leucocytoclastic vasculitis
        2. Neutrophilic vascular reaction
        3. Polymorphonuclear leucocyte infiltration
    2. Erythema nodosum-like lesions
        1. Neutrophilic vascular reaction or vasculitis in the dermis and subcutaneous tissue
        2. Perivascular lymphocytic dermal inflammation
    3. Common histopathological lesions in all organ systems
        1. Vasculitis
        2. Thrombosis
        3. Perivascular infiltrates of lymphomononuclear cells
        4. Neutrophilic vascular reaction
    4. Early cutaneous lesions: neutrophilic vascular reaction or leucocytoclastic vasculitis (Chen et al. 1997)
    5. Late cutaneous lesions: lymphocytic perivasculitis

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: not increased
    2. Patient's offspring: not increased
2. Prenatal diagnosis: no prenatal diagnosis reported
3. Management (Alpsoy and Akman 2009; Dalvi et al. 2012; Saleh and Arayssi 2014)
    1. Mucocutaneous lesions (Mangelsdorf et al. 1996)
        1. Topical corticosteroids: useful for oral and genital ulcers
        2. Colchicine
            1. Beneficial effects on the mucocutaneous symptoms, presumably by inhibiting neutrophil function
            2. The first choice for treatment of genital ulcers and/or erythema nodosum, especially in female patients
            3. Combination with benzathine penicillin: for patients who are ineffective with colchicine alone, or a male patient, or in the presence of oral ulcers with or without other mucocutaneous lesions
        3. Treatment with thalidomide in severe, refractory Behçet disease (Hamuryudan et al. 1998; Shek et al. 1999; Brik et al. 2001): effective for oral and genital ulcers, gastrointestinal manifestations, and pseudofolliculitis
        4. Dapson, zinc sulfate, and rebamipide can be other choices
        5. Immunosuppressive agents, such as azathioprine and cyclosporine, and biologicals, such as Interferon (IFN)-alpha (Georgiou et al. 1998) and antitumor necrosis factor (TNF)-α agents: to control the patients with severe mucocutaneous disease or unresponsive to the respected treatments
        6. Methotrexate
        7. Systemic corticosteroids: prescribed for erythema nodosum that is refractory to treatment with colchicine
    2. Ocular lesions
        1. Require special attention and aggressive treatment because of its highest morbidity
        2. About 25% of patients eventually develop blindness despite therapeutic intervention
        3. Topical mydriatic agents and corticosteroid drops: given for acute attacks of anterior uveitis
        4. Colchicine: prescribed to prevent both anterior and posterior uveitis because of its high degree of efficacy and relatively low toxicity
        5. Topical injection of corticosteroids, with systemic administration in some cases: used for acute attacks of posterior uveitis
        6. Cytotoxic agents (azathioprine, chlorambucil, and cyclophosphamide): help prevent ocular attacks in approximately 50–75% of patients; however, loss of useful visual acuity occur in 74% of eyes after intensive follow-up

and treatment (Benezra and Cohen 1986)
7. Cyclosporine: beneficial in 70–80% of patients with ocular lesions that have been refractory to the conventional therapies
8. Subcutaneous human recombinant interferon alpha: an effective and fairly well-tolerated therapy for Behçet disease
9. Systemic corticosteroids: generally given in acute attacks of posterior uveitis, panuveitis, and retinal vasculitis
10. Results from therapies: improved vision and decreased pain, saving the individual a potential enucleation
11. Retinal vasculitis: successfully treated with rituximab (Sadreddini et al. 2008)
12. Panuveitis or retinal vasculitis: effectively treated with gevokizumab or canakinumab (recombinant humanized anti-IL-1β antibody) (Gul et al. 2012; Ugurlu et al. 2012)

3. Arthritis
   1. Nonsteroidal anti-inflammatory drugs and colchicine: the first choice and are effective for most cases of arthritis
   2. Additional use of benzathine penicillin: the next step
   3. Low dose corticosteroids and azathioprine: used in patients whose arthritis is resistant to treatment with nonsteroidal anti-inflammatory drugs, colchicine, or sulfasalazine
   4. Interferon alfa: also highly effective
4. Gastrointestinal lesions (Skef et al. 2015)
   1. Goal of treatment
      1. Keeps patients in remission
      2. Reduces relapses
      3. Prevents surgical intervention
   2. Sulfasalazine, corticosteroids, and azathioprine: the principal drugs
   3. Anti-TNF-α treatments, especially infliximab: a new and effective alternative for more severe and/or refractory intestinal disease
   4. Bowel rest: obligatory in patients with an acute abdomen and bleeding
   5. Surgery: considered for patients with bowel perforation and intractable bleeding
5. CNS lesions
   1. High doses of corticosteroids
   2. Supplemented with cytotoxic agents
6. While the recurrence rate for PAI is about 20%, PAI may disappear in about 70% of the cases with immunosuppressive treatment. Yet, the disease can still be fatal in one fourth of patients despite all efforts (Seyahi and Yazici 2015)
7. Large-vessel lesions
   1. Treated with a combination of corticosteroids and cytotoxic agents
   2. Anticoagulants and antiplatelet agents: used for deep venous thrombosis
   3. Surgery for refractory large-vessel disease

Biotinidase Deficiency

Contents

In 1971, Gompertz and colleagues (1971) first described multiple carboxylase deficiency responsive to biotin administration. Wolf and colleagues (1981) further characterized the infantile form of multiple carboxylase deficiency as biotinidase deficiency (BTD) in 1981.

Based on the results of worldwide screening of biotinidase deficiency (Wolf 1991), the incidence of the disorder is one in 137,401 for profound biotinidase deficiency, one in 109,921 for partial biotinidase deficiency, and one in 61,067 for the combined incidence of profound and partial biotinidase deficiency. Carrier frequency in the general population is approximately one in 120.

Synonyms and Related Disorders

Juvenile-onset multiple carboxylase deficiency; Late-onset multiple carboxylase deficiency

Genetics/Basic Defects

1. An autosomal recessive disorder affecting the endogenous recycling and release of biotin (vitamin H) from dietary protein: consecutive biotin depletion resulting in low activities of biotin-dependent carboxylases and urinary excretion of organic acids characteristic of multiple carboxylase deficiency
2. Classification of biotinidase deficiency according to residual enzyme activity (Baumgartner and Suormala 1997; Wolf 2001)
    1. Profound biotinidase deficiency (residual activity $<10\%$ of mean normal value)
    2. Partial biotinidase deficiency (residual activity 10–30% of mean control value)
3. Caused by complete or partial absence of the enzyme biotinidase
4. The gene that encodes biotinidase is mapped at 3p25.
5. *BTD* (the gene encoding biotinidase) mutations
    1. 98-104del7ins3: the most common *BTD* mutation (about 50% of symptomatic children)
    2. Arg538 R → C: less common
    3. P.D444H (Wolf 2013)

DOI 10.1007/978-1-4939-2401-1_24

Clinical Features

1. Natural history (Wolf 2013)
    1. Biotinidase deficiency: a readily treatable inherited disorder (Wolf 2003)
    2. Individuals with biotinidase deficiency, diagnosed by newborn screening, who are treated with biotin before developing symptoms: develop normally
    3. Individuals with biotinidase deficiency who have recurrent symptoms and metabolic compromise prior to biotin treatment: develop neurologic problems
    4. Early onset of symptoms is predicted by the presence of zero residual activity as measured by sensitive assays and by homozygosity for the G98:d7i3 mutations (Mühl et al. 2001; Möslinger et al. 2003)
    5. Subtle neurologic abnormalities may appear as early as at 2 months of age and that developmental abnormalities may occur even in the absence of episodes of overt metabolic decompensation (Wolf et al. 1985a)
2. Untreated profound biotinidase deficiency
    1. Symptoms usually develop between ages 1 week and 10 years
    2. Clinical features, also observed in children with many other inherited metabolic disorders, include:
        1. Seizures (either alone or with other neurological or cutaneous findings): the most frequent initial symptoms (Wolf et al. 1985b)
        2. Hypotonia
        3. Developmental delay
        4. Breathing abnormalities
            1. Hyperventilation
            2. Laryngeal stridor
            3. Apnea
    3. More specific features
        1. Sensorineural hearing loss
        2. Optic atrophy
        3. Cutaneous symptoms
            1. Eczematous skin rash
            2. Alopecia
        4. Conjunctivitis
        5. Chronic and possibly lethal fungal infections (e.g., candidiasis)
        6. Ataxia
    4. Symptoms encountered by older children and adolescents
        1. Limb weakness
        2. Rare spastic paraparesis
        3. Scotomata
3. Children with untreated partial biotinidase deficiency: usually have mild symptoms which occur only when the child is stressed (e.g., prolonged infection, illness, fasting)
4. Prognosis for individuals diagnosed with biotinidase deficiency: good, provided they are treated before symptoms occur (Szymańska et al. 2015)

Diagnostic Investigations

1. New born screening (Wolf 2013)
    1. Utilizes a small amount of blood obtained from a heel prick for a colorimetric test for biotinidase activity (Heard et al. 1984, 1986; Wolf et al. 1985a; Wolf 1991)
    2. Detect virtually 100% of affected infants
    3. False positive test results in:
        1. Premature infants
        2. Samples placed in plastic prior to sufficient drying
    4. Measure biotinidase activity in serum/plasma in infants whose initial screening tests are abnormal
    5. Newborns should be screened for profound and partial biotinidase deficiency (Wolf 2015)
2. Other laboratory findings
    1. Decreased or low normal plasma biotin concentrations in individuals with profound biotinidase deficiency
    2. In most individuals
        1. Metabolic ketolactic acidosis
        2. Organic aciduria
        3. Metabolic ketoacidosis

3. Specific tests
    1. Biotinidase levels: Carriers (heterozygotes) usually have serum enzyme activity levels intermediate between those of affected and those of normal individuals (Wolf et al. 1983)
    2. Serum ammonia
    3. Urine organic acids
    4. Plasma amino acids
    5. Urine ketones
    6. Blood gas
    7. Serum chemistries
    8. Carnitine and acylcarnitine profiles
3. Imaging studies: MRI of the brain (Desai et al. 2008)
    1. Cerebral edema
    2. Low attenuation of white matter signal
    3. Cerebral atrophy
    4. Compensatory ventricular enlargement
4. Other tests
    1. Ophthalmologic testing
        1. Dilated fundoscopy to detect optic atrophy
        2. Visual field testing and visual evoked potentials to detect degree of optic nerve injury
    2. Audiologic testing
        1. To detect hearing deficits in symptomatic children which can be persistent after treatment
        2. Brainstem auditory evoked potentials to delineate the abnormality in younger children or in developmentally delayed patients
    3. EEG for seizure activities
5. Molecular Genetic testing: clinically available
    1. Targeted mutation analysis
        1. Real-time PCR of DNA from the blood spot of a newborn screen card can be used to identify a panel of common *BTD* mutations (p.Cys33PhefsX36, p.Gln456His, p.Arg538Cys, p.Asp444His, and p.Ala171Thr).
        2. These five mutations that cause profound biotinidase deficiency comprise approximately 60% of the abnormal alleles found in symptomatic individuals and in children identified by newborn screening.
    2. Sequence analysis
        1. Direct sequencing of *BTD* and its intron/exon junctions is available clinically.
        2. Almost all individuals with partial biotinidase deficiency have the mutation p.Asp444His in one allele of *BTD* in combination with a mutation for profound deficiency in the other allele.
    3. Deletion/duplication analysis: Although deletion testing is offered clinically, no large deletions have been reported in *BTD*.

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: 25%
    2. Patient's offspring: not increased unless the spouse is also a carrier
2. Prenatal diagnosis possible for pregnancies at increased risk
    1. Biochemical testing (measurement of biotinidase enzyme activity in cultured amniotic fluid cells and in amniotic fluid obtained by amniocentesis) (Secor McVoy et al. 1984; Chalmers et al. 1994)
    2. Molecular genetic testing (analysis of DNA extracted from fetal cells obtained by amniocentesis or CVS), provided both disease-causing alleles of an affected family member have been identified
    3. Request for prenatal diagnosis or preimplantation genetic diagnosis is not common since biotinidase deficiency can be treated and does not affect intellect.
3. Management
    1. Biotin treatment with supplementation with oral biotin in free form
        1. Children with biotinidase deficiency identified by newborn screening: remain asymptomatic with compliance to lifelong biotin therapy

2. Children with profound biotinidase deficiency should be treated with biotin regardless of their residual enzyme activity or genotype (Wolf 2002)
3. Effective in preventing symptoms (Möslinger et al. 2001; Weber et al. 2004)
4. Compliance with biotin therapy: improves symptoms in symptomatic individuals
5. Three children with partial deficiency discontinued biotin for varied lengths of time. Two of whom became symptomatic with abnormal gait, alopecia, skin rashes, and developmental delay (Gannavarapu et al. 2015)

2. Medical care for developmental delay, hypotonia, spasticity, and bulbar dysfunction

Fig. 1 A 11-month-old girl with biotinidase deficiency (0.41 nmol/mL/min) (normal, 3.66–9.21) detected by newborn screening. Her growth and development have been normal with oral biotin supplementation

Fig. 3 A 12-week-old infant boy was found to have a borderline biotinidase activity by newborn screening. DNA analysis showed a heterozygous D444H mutation and, therefore, he is a carrier

Fig. 2 A 26-month-old boy was found to have partial biotinidase deficiency by newborn screening with a biotin level of 6.3 (normal: >16). DNA analysis showed one copy of D444H mutation and one copy of G68:d7i3 mutations. His growth and development have been normal with oral biotin supplementation

Bladder Exstrophy

Contents

Bladder exstrophy is a rare developmental anomaly occurring as an isolated defect in about 1/25,000–1/40,000 births (Cacciari et al. 1999).

Synonyms and Related Disorders

Bladder exstrophy and epispadias complex

Genetics/Basic Defects

1. Genetics
    1. Usually an isolated defect
    2. Most likely a multifactorial trait (Messelink et al. 1994)
    3. Pure terminal 1q deletion [del(1)(q43q44)] in a patient with bladder exstrophy and extreme genital anomaly (Zaki et al. 2012)
    4. Microduplications at 22q11.21: associated with nonsyndromic classic bladder exstrophy (Draaken et al. 2010)
    5. Microduplication at 22q11.2: reported in two patients with bladder exstrophy and hearing impairment (Lundin et al. 2010)
2. Basic defects (Ives et al. 1980)
    1. Probably failure of fusion of the secondary mesoderm (from the primitive streak) in the midline of the anterior abdominal wall, with subsequent rupture of the thin wall consisting only of the ectoderm and endoderm
    2. Early rupture (fifth week) resulting in exstrophy of the cloaca and later rupture (seventh week) resulting in exstrophy of the bladder

Clinical Features

1. Classical bladder exstrophy (Higgins 1962; Ben-Chaim et al. 1996)
    1. Diagnosis easily made at birth
    2. Occupy 60% of the patients with the exstrophy-epispadias complex
    3. Bladder plate protruding just beneath the umbilical cord
    4. Posterior bladder wall is exposed through a midline abdominal wall defect
    5. Inferiorly displaced umbilicus located close to the superior margin of the exstrophic bladder
    6. Rectus muscles divergent on either side of the bladder

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_25

1. Leading to the separated pubic bones
2. Separation of the pubic bones caused by an outward rotation of the innominate bones and eversion of the pubic rami

7. Male patients (Pierre et al. 2014)
   1. A short epispadiac phallus with a dorsal urethral plate
      1. Caused by separation of the pubic bones
      2. Possibly caused by a true deficiency of corporeal tissue
   2. A splayed glans
   3. Dorsal chordee
   4. Exposed urethra
   5. Exposed bladder
   6. Umbilical stump
8. Female patients (Pierre et al. 2014)
   1. Genital defect analogous to the male but more easily reconstructed
   2. Separated mons pubis (both the hemiclitoris and labia and split clitoris and exstrophic vagina)
   3. Exposed urethra
   4. Exposed bladder
   5. Umbilical stump
   6. Predisposing to uterine prolapse (Burbige et al. 1986), especially after pregnancy and delivery, secondary to pelvic floor defect
9. Urinary tract abnormalities
   1. Generally normal upper urinary tract
   2. Occasional abnormalities
      1. Unilateral renal agenesis
      2. Horseshoe kidney
      3. Hydronephrosis
      4. Other renal anomalies
10. Internal genitalia: usually normal
11. Fertility and childbearing/pregnancy (Ledfors et al. 1966; Krisiloff et al. 1978)
    1. Documented in both sexes but less common in the males
    2. C-section advised to avoid injury to continence mechanism
    3. Postpartum uterine prolapse common because of aggravation of preexisting abnormal pelvic support
    4. Successful pregnancy and delivery (Bildircin et al. 2012)
12. Inguinal hernias
    1. Incidence: very common
       1. Fifty six to eighty two percent in boys
       2. Eleven to fifteen percent in girls
    2. Incidence of bowel incarceration below 1 year of age: 10–53%
    3. Causes
       1. Large internal and external inguinal rings
       2. Lack of obliquity of the inguinal canal
13. Anus
    1. Anteriorly placed
    2. Fecal continence adversely affected by the divergence of the pelvic musculature
14. Rectal prolapse
    1. Virtually always disappears after bladder closure or cystectomy
    2. Represents an indication for surgical management of the exstrophied bladder
15. Spinal abnormalities (6.7%) (Cadeddu et al. 1997)
    1. Myelomeningocele
    2. Lipomeningocele
    3. Scimitar sacrum
    4. Posterior laminal defects
    5. Vertebral fusion
    6. Hemivertebrae
16. Malignancies (Pierre et al. 2014)
    1. Rare late complication of bladder exstrophy, especially in untreated patients whose bladders are left exstrophic for many years
    2. Types of malignancies
       1. Adenocarcinoma: the most common type, arising from the precursor cystitis glandularis, a consequence of chronic irritation and inflammation of exposed bladder mucosa.
       2. Squamous cell carcinoma and rhabdomyosarcoma.
       3. Adenocarcinoma developing adjacent to the ureterointestinal anastomoses in patients with urinary

diversions that mix the urinary and fecal streams.
4. The risk of developing colon adenocarcinoma is increased 7,000-fold after ureterosigmoidostomy among patients younger than 25 years of age than the general population.

17. Psychological impact on children and on the lives of families (Stjernqvist and Kockum 1999)
18. Behavioral, social, and school competency problems observed in 70% of adolescents and 33% of school-aged children
19. Seventy percent of parents express concern about the children's sexual function or sexual disfigurement
20. Consider all patients with exstrophy-epispadias complex to be latex sensitive

2. Variants of exstrophy (Cerniglia et al. 1989)
   1. Pseudoexstrophy (exstrophic abdominal wall defect without bladder exstrophy)
   2. Duplicate exstrophy
   3. Superior vesical fistula and fissure
   4. Covered exstrophy and visceral sequestration
3. Exstrophy of the bladder and exstrophy of the cloaca: two different expressions of a primary developmental field (Martinez-Frias et al. 2001; Canning 2003)

Diagnostic Investigations

1. General assessment
2. Cardiopulmonary assessment
3. Renal ultrasound for baseline examination of the kidneys since increased bladder pressure after bladder closure can lead to hydronephrosis and upper urinary tract deterioration (Yerkes 2014).
4. Voiding cystourethrogram (Yerkes 2014)
   1. To rule out bilateral vesicoureteral reflux which is present in nearly all patients with classic bladder exstrophy
   2. Performed in early childhood to assess bladder capacity in preparation for continence reconstruction
5. Imaging of complications following bladder exstrophy repair (Pierre et al. 2014)
   1. Fluoroscopy for urethrocutaneous fistula, urethral stricture, bladder rupture/perforation, and complications of bladder augmentation
   2. Ultrasound for renal scarring and stone formation
   3. MRI: primarily utilized in a research capacity to evaluate pelvic anatomy changes following repair
   4. Combined high-end 2D and 3D MRI: the technique of choice for the evaluation of pediatric pelvic floor in the presurgical planning and for the postoperative evaluation of the various surgical approaches applied for repair of classic bladder exstrophy (Tekes et al. 2014)

Genetic Counseling

1. Recurrence risk (Ben-Chaim et al. 1996)
   1. Patient's sib: The risk of recurrence of exstrophy or epispadias in a given family is 1 of 275 births. Risk to sibs is low, probably $<1\%$ (Ives et al. 1980).
   2. Patient's offspring: The risk of a parent with exstrophy producing a child with exstrophy or epispadias is up to 1 of 70 or 500 times the risk of the general population.
2. Prenatal diagnosis
   1. Ultrasonography (Barth et al. 1990; Gearhart et al. 1995; Goldstein et al. 2001)
      1. Absence of bladder filling in the presence of normal kidneys (bladder never demonstrated on the ultrasound) (71%)
      2. A protuberance on the lower abdomen representing the exstrophied bladder (47%)
      3. A diminutive penis with anteriorly displaced scrotum (57% of the males)
      4. A low-set umbilical insertion (29%)
      5. Abnormal widening of the iliac crests (18%)
      6. Separation of the pubic rami
      7. Difficulty in ascertaining the sex of the fetus

2. Fetal MRI (Goldman et al. 2012)
    1. Shows a detailed scenario of the abnormality with advantages over the ultrasound evaluation in regard to excluding cloacal anomalies
    2. Allowed accurate sexual differentiation
3. Management (Megalli and Lattimer 1973; Mesrobian et al. 1988; Inouye et al. 2014)
    1. Supportive management
        1. Ligate umbilical cord with suture to avoid bladder mucosal damage by an umbilical clamp.
        2. Protect bladder
            1. With clear plastic wrap.
            2. Irrigate the bladder surface with sterile saline each time diaper is changed and the wrap replaced.
        3. Initiate prophylactic antibiotics
    2. Goals of the reconstruction of bladder exstrophy (Grady et al. 1999)
        1. Preservation of the kidney function
        2. Creation of urinary continence
        3. Reduction in the urinary tract infections
        4. Creation of functionally and cosmetically acceptable external genitalia
    3. Initial bladder closure
        1. Begin with closure of the bladder and abdominal wall by either the modern staged repair of exstrophy or complete primary repair of bladder exstrophy (combination of epispadias repair often performed at the time of primary bladder closure).
        2. Closure of the pelvic ring
            1. Important for the initial closure
            2. Important for the eventual attainment of urinary continence
        3. Pelvic osteotomy
            1. Two main approaches: posterior iliac osteotomy and the anterior innominate osteotomy
            2. Reduce the tension on the suture lines to help securing the bladder closure
            3. To restore the pelvic anatomy and thus increase the chances of eventual continence and reduce the likelihood of uterine prolapse
    4. Epispadias repair
        1. Usually performed at 2–3 years of age before the continence procedure
        2. Contributing significantly to the development of bladder capacity
        3. Goals
            1. Reconstruction of the urethra and glans penis
            2. Encourage the potential of penile length
            3. Correction of the dorsal chordee
            4. Achieving adequate skin coverage
        4. Penis is generally reconstructible to cosmetically and functionally acceptable form, despite a short phallus
    5. Bladder neck reconstruction
        1. Usually performed at age of 4–5 years (when toilet training is possible).
        2. Require anti-reflux procedure since all exstrophy patients have vesicoureteral reflux.
        3. Complete urinary drainage achieved with ureteral stents and suprapubic cystostomy tubes.
    6. Ureteral reimplantation
    7. Bladder augmentation and continent diversion for patients who have failed bladder neck reconstruction and have an inadequate bladder capacity
    8. Alternatives for exstrophy reconstruction
        1. For patients with very small bladder plates or hydronephrosis
        2. Ureterosigmoidostomies
            1. Allow children to achieve continence
            2. Protect upper urinary tracts
            3. Potential complications: recurrent acute and chronic pyelonephritis, urolithiasis, hyperchloremic hypokalemic metabolic acidosis, ureteral obstruction, and the late development of colonic malignancy
    9. Repair of inguinal hernias at the time of primary closure of bladder exstrophy
    10. Specialized experience in management allow demonstrable improvement in bladder exstrophy outcomes (Dickson 2014)

11. Professional mental health guidance with a developmental and family perspective and establishment of patient and parent support groups and family information services and seminars (Diseth et al. 1999)

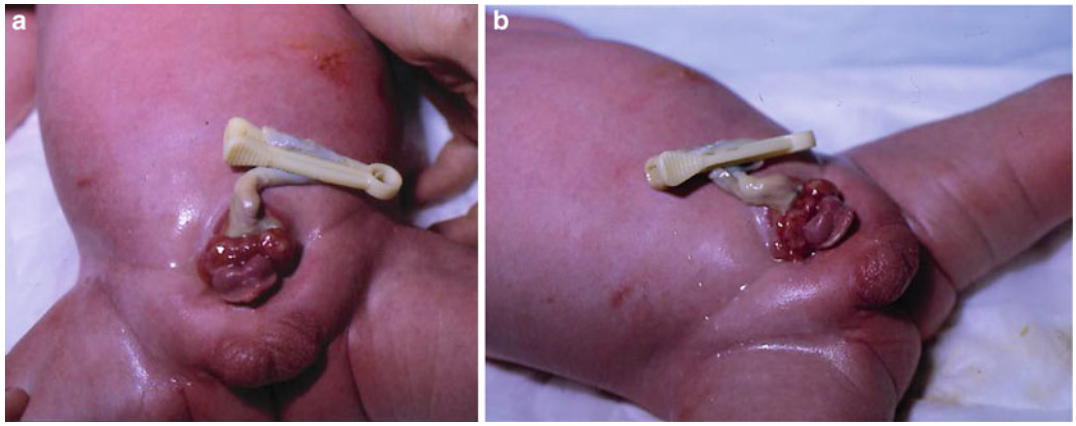

Fig. 1 (**a**, **b**) A newborn male with classic bladder exstrophy showing low insertion of the umbilical cord, a bulging mass of exstrophic bladder, and grossly abnormal external genitalia

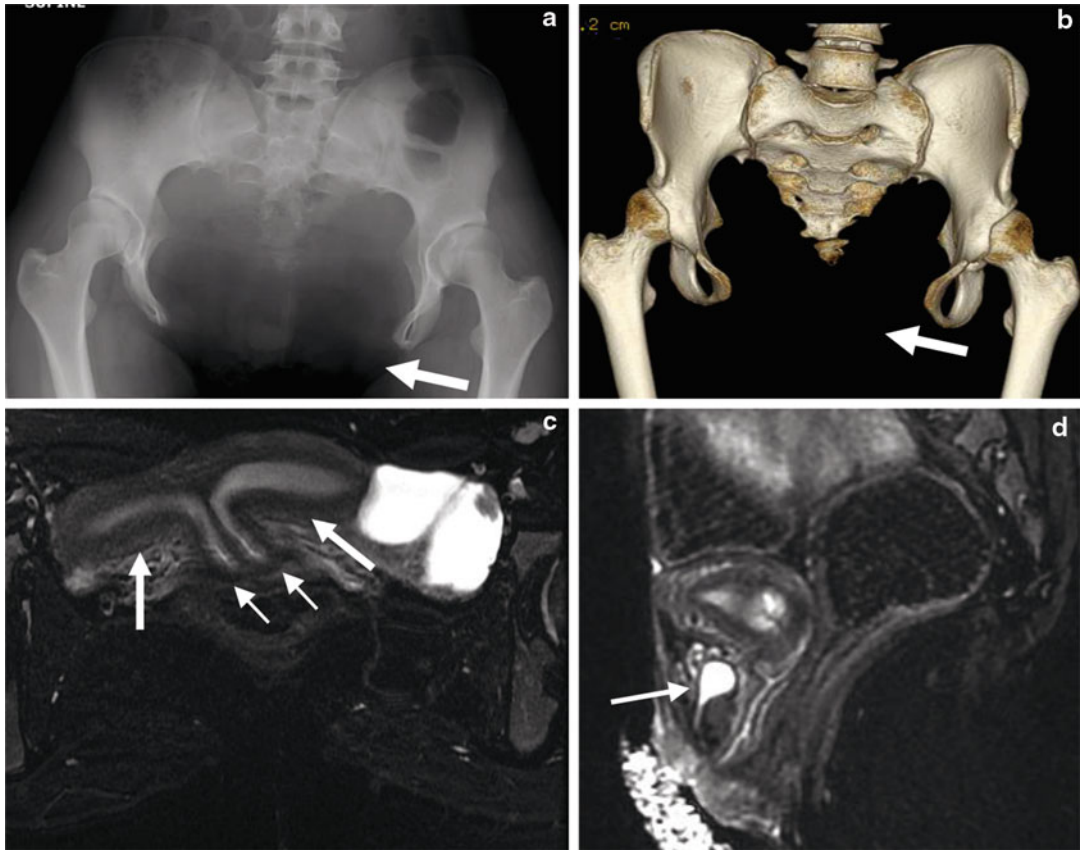

Fig. 2 (**a**–**d**) A 16-year-old female was evaluated for previous history of bladder exstrophy. The pelvic radiography (**a**) and 3D CT reconstruction image (**b**) showed the previous site of bladder exstrophy with substantial widening of the pubic rami and ischium (*arrows*). MRI image (**c**) demonstrated uterus didelphys (*large arrows*) with vaginal duplication (*small arrows*). The structures in the pelvis (**d**) (the bladder (*arrow*), the uterus, and the rectum) appear more anterior on the perineum than normally expected. No past medical history was available (Courtesy of Dr. Grace Guo)

Blepharophimosis, Ptosis, and Epicanthus Inversus Syndrome

Contents

In 1921, Komoto reported the first case known today as blepharophimosis, ptosis, and epicanthus inversus syndrome (BPES), with the triad of wide set eyes, ectropion, excessive brow hair, and hypoplasia of the caruncle and relatives with similar phenotypic features. Later that year, Dimitry described a family with the above triad and traced the pedigree of "blepharophimosis syndrome," apparently transmitted in an autosomal dominant manner for the first time. In 1971, Kohn and Komoto (1971) added telecanthus to the triad of this syndrome.

Synonyms and Related Disorders

BPES plus; BPES with Duane retraction syndrome; BPES with/without ovarian failure

Genetics/Basic Defects

1. An autosomal dominant disorder
    1. No known affected family members in about one quarter of cases
        1. New mutation cases
        2. Minimal expression in affected relatives
    2. A significant number of patients with no identifiable family history of BPES
2. BPES gene *FOXL2*
    1. Mapped to chromosome 3q23 (Amati et al. 1995)
    2. Recently mutation of *FOXL2* has been described as a cause of BPES
3. Two forms of BPES (Zlotogora et al. 1983; Krastinova and Jasinski 2003)
    1. BPES type I
        1. Characterized by hypogonadism and infertility in affected females
        2. Complete penetrance
        3. Transmission by males as fertility in affected females is reduced
    2. BPES type II
        1. Not associated with female infertility
        2. Incomplete penetrance
        3. Transmission occurs in both males and females
4. *FOXL2*
    1. The only gene known to be associated with BPES (Verdin and De Baere 2015)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_26

2. Encodes for a transcription factor that is expressed predominantly in the developing eyelid and in the ovary (Mari et al. 2006)
5. Mutations of *FOXL2*: detected in patients with both type I and type II BPES (De Baere et al. 2001)
6. Genotype-phenotype correlation
    1. BPES type I: predicted to be the result of a truncated protein either lacking or containing the forkhead domain (Crisponi et al. 2001)
    2. BPES type II: predicted to be the result of duplications, within or downstream of the forkhead domain, or other mutations resulting in an extended protein
7. MRI studies of BPES type I patients demonstrate the possible role of *FOX2* in the differentiation of the superior levator muscle of the eyelid

Clinical Features

1. Clinical triad (Oley and Baraitser 1988; Allen and Rubin 2008)
    1. Blepharophimosis (profound small and narrow horizontal palpebral fissure): morphologically defined as reduction of both the horizontal and vertical dimensions of the palpebral fissure
    2. Ptosis of the eyelids: severe, bilateral, and symmetric (Beaconsfield et al. 1991)
    3. Epicanthus inversus (a small skinfold which arises in the lower lids and runs upward)
2. Other ocular associations (Choi et al. 2006)
    1. Patients often assume a chin up, head tilt backward position to clear their visual axis.
    2. Patients often present with raised arched eyebrows because of recruitment of frontalis muscle to compensate for ptosis and visual field defect.
    3. Associated with telecanthus (normal interpupillary distance with abnormally wide intercanthal distance).
    4. Abnormalities of the eyelid margin and lacrimal drainage apparatus.
    5. A high incidence of amblyopia in BPES (39–56%) than general population (3.2%) (Beckingsale et al. 2003).
    6. Strabismus: much higher incidence in BPES (20–27%) than general population (2–4%) (Dawson et al. 2003).
    7. Microphthalmos/optic disc colobomas (Lee and Sullivan 1995).
3. Non-ocular associations (Cunniff et al. 1998)
    1. Infertility in women with type I BPES due to premature ovarian failure which is defined as the onset of menopause before the age of 40 years
        1. Normal menarche followed by oligomenorrhea and later amenorrhea in most women with BPES type I
        2. Fertile in early reproductive years
        3. Soon leading to either ovarian resistance to gonadotrophins or true premature ovarian failure
        4. Usually with normal secondary sexual characteristics
    2. Broad flat nasal bridge
    3. High-arched palate
    4. Protruding or cup-shaped ears
    5. Cardiac defects
    6. Mental retardation: microdeletions leading to contiguous gene syndrome, including mental retardation (De Baere et al. 2003)
4. Natural history of BPES
    1. Epicanthal folds and telecanthus: improve significantly with time
    2. Ptosis and blepharophimosis: do not improve with time
5. Differential diagnosis (Verdin and De Baere 2015)
    1. BPES plus (Yu et al. 2014)
        1. Facial anomalies: blepharophimosis, ptosis, and epicanthus inversus
        2. Neurological anomalies: global developmental delay
        3. Musculoskeletal anomalies: widely-spaced nipples, slight 2–3 syndactyly
        4. Genital anomalies: cryptorchidism, hydrocele
        5. Associated with *KAT6B* mutation

2. Blepharophimosis
    1. As an isolated clinical finding
    2. As part of a number of congenital syndromes
3. Ohdo blepharophimosis syndrome (Ohdo et al. 1986)
    1. Presumably an autosomal dominant condition
    2. Blepharophimosis
    3. Blepharoptosis
    4. Dental hypoplasia
    5. Partial deafness
    6. Congenital heart defects
    7. Intellectual disability
4. Michels syndrome (3MC syndrome 1)
    1. Presumably an autosomal dominant condition
    2. Blepharophimosis
    3. Blepharoptosis
    4. Epicanthus inversus
    5. Ophthalmic anterior segment (cornea) defects
    6. Cleft lip/palate
    7. Minor skeletal abnormalities
5. Ptosis with external ophthalmoplegia
    1. An autosomal recessive condition
    2. Ptosis
    3. Ophthalmoplegia
    4. Miosis
    5. Decreased accommodation
    6. Strabismus
    7. Amblyopia
6. Schwartz-Jampel syndrome (please see the chapter of Schwartz-Jampel syndrome)
    1. An autosomal recessive condition
    2. Intermittent ptosis
    3. Blepharophimosis
    4. Telecanthus
    5. Cataract
    6. Short stature
    7. Cartilage and skeletal anomalies
    8. Muscle hypertrophy
7. Dubowitz syndrome
    1. An autosomal recessive syndrome
    2. Ptosis
    3. Blepharophimosis
    4. Lateral telecanthus
    5. Short stature
    6. Intellectual disability
    7. Immunologic deficiencies
8. Smith-Lemli-Opitz syndrome (please see the chapter of Smith-Lemli-Opitz syndrome)
    1. Ptosis
    2. Epicanthus
    3. Cataract
    4. Growth retardation
    5. Intellectual disability
    6. Others: severe genitourinary, cardiac, gastrointestinal anomalies
9. KANSL1-related intellectual disability syndrome (Gijsbers et al. 2008)
    1. A 17q21.31 microdeletion syndrome
    2. Developmental delay with mild-to-moderate intellectual disability
    3. Characteristic facies: long face, high forehead, ptosis, blepharophimosis, large low-set ears, bulbous nasal tip, pear-shaped nose
    4. Nasal speech
    5. Friendly disposition
    6. Others: cardiac septal defects, seizures, cryptorchidism
10. Observed in several aneuploidies such as chromosome 3p deletion (blepharophimosis, ptosis, mental retardation) (Moncla et al. 1995)
11. Fetal alcohol effects (ocular involvement) (Stromland 1987)

Diagnostic Investigations

1. Diagnosis based on clinical findings which are present at birth
2. Detection of premature ovarian failure (Verdin and De Baere 2015)
    1. Secondary amenorrhea
    2. Endocrinologic evaluation of hypergonadotrophic hypogonadism
        1. Elevated follicle-stimulating hormone
        2. Elevated luteinizing hormone
        3. Decreased serum concentration of estradiol and progesterone
    3. Ultrasound studies
        1. Small hypoplastic uterus
        2. Streak ovaries

3. Early on, normal presence of primordial follicle but without normal follicular development
4. Later on, presence of scars in place of primordial follicles when progress into true premature menopause

3. Cytogenetic testing for chromosome rearrangement involving 3q23
   1. Unbalanced translocations and interstitial deletions (De Baere et al. 1999)
   2. Estimated to occur in a very small fraction of individuals with BPES (Beysen et al. 2005)
4. Molecular genetic testing of *FOXL2* gene mutations (Verdin and De Baere 2015)
   1. Sequence analysis
   2. Deletion/duplication analysis
   3. *FOXL2* mutations detectable in up to 75% of affected individuals (Beysen et al. 2005)
   4. Individuals with BPES without a *FOXL2* mutation should be tested for *KAT6B* mutations (Yu et al. 2014)

Genetic Counseling

1. Recurrence risk: autosomal dominant inheritance (Verdin and De Baere 2015)
   1. Patient's sib
      1. Low recurrence risk when parents are not affected and do not have a *FOXL2* mutation. However, Germline mosaicism has been observed in BPES and demonstrated at the molecular level.
      2. Fifty percent risk if a parent is also affected.
      3. Germline mosaicism: observed in autosomal BPES and demonstrated at the molecular level (Beysen et al. 2005): incidence unknown.
   2. Patient's offspring
      1. A 50% recurrence risk for an affected individual to have an affected offspring
      2. Affected female individuals with type I BPES may have infertility: crucial to distinguish the two types of BPES to address the infertility issues with patients and for genetic counseling of female patients of child-bearing age (Fokstuen and Antonarakis 2003)
      3. Possible presence of offspring risks to unaffected members of the families because of the presence of nonpenetrance or very minimal expression of BPES (Temple and Baraitser 1989)
2. Prenatal diagnosis (Verdin and De Baere 2015)
   1. Available by DNA analysis from fetal cells obtained via amniocentesis (during 15–18 weeks of gestation) and chorionic villus sampling (10–12 weeks of gestation).
   2. The disease-causing allele of an affected family member must be identified before prenatal testing can be performed.
   3. Preimplantation genetic diagnosis may be available for some families in which the pathogenic variant has been identified.
   4. These tests, however, are not commonly done for BPES.
3. Management
   1. Crucial to distinguish two types of BPES to address the infertility issues with patients and for genetic counseling of female patients of child-bearing age
   2. Endocrine and gynecologic evaluation and management recommended in affected females
      1. Hormone replacement therapy as needed
      2. Need to address concerns of infertility such as adoption or ovum donation for premature ovarian failure
      3. Referral to a clinical geneticist for an appropriate genetic workup and counseling
   3. Complex and requires coordination among several specialists, including pediatric ophthalmologist, oculoplastic surgeon, pediatric endocrinologist,

reproductive endocrinologist, gynecologist, and genetic counselor
4. Treatment goals for an ophthalmologist
    1. Promote normal visual development
    2. Improve cosmesis
    3. Alleviate abnormal chin-up posture
5. A comprehensive ophthalmic examination
    1. Visual acuity
    2. Refraction
    3. Ocular movements
6. Diagnosis and treatment of amblyopia and strabismus crucial
7. Ptosis repair: usually addressed after medial canthoplasty
8. Medial epicanthoplasty using the skin redraping for treatment of epicanthus inversus and telecanthus in patients with BPES (Sa et al. 2012)
9. Modified staged surgical intervention (Song et al. 2015)
    1. Medial canthoplasty
    2. Lateral canthoplasty
    3. Blepharoptosis correction surgery
10. Timing of surgery for congenital ptosis: controversial
    1. Weighing the balance of early surgery to prevent amblyopia
    2. Late surgery to allow for more reliable ptosis measurement, which provides a better surgical outcome

Body Stalk Anomaly

Contents

Body stalk anomaly, sometimes also called limb body wall complex, is a rare abdominal wall defect due to failure of the development of the body stalk. Prevalence is estimated to be 0.32 per 10,000 births.

Synonyms and Related Disorders

Limb body wall complex

Genetics/Basic Defects

1. Sporadic occurrence in most cases, although concordance in twins has been reported
2. Failure in body folding in cranial, caudal, and lateral axes during the embryonic stage of development (Hiett et al. 1992)
    1. Abnormalities of cranial folding leading to pentalogy of Cantrell et al. (1958) consisting of the following:
        1. Cardiac abnormalities
        2. Sternal cleft
        3. Upper abdominal defect
        4. Anterior diaphragmatic hernia
        5. Deficiency of the diaphragmatic pericardium
    2. Abnormalities of caudal folding leading to the following:
        1. Cloacal exstrophy
        2. Hypogastric omphalocele
        3. Imperforate anus
        4. Partial colonic agenesis
        5. Agenesis of one umbilical artery (Craven et al. 1997)
    3. Abnormalities of lateral folding leading to midline omphalocele
    4. Abnormalities of folding along all three axes resulting in a body stalk anomaly
        1. Failure to obliterate the extraembryonic cavity that continues to communicate with the intraembryonic cavity
        2. Creation of a large ventral wall defect that is covered by an amnioperitoneal membrane which contains the abdominal viscera and inserts directly into the chorionic plate
        3. The fetus appearing to be directly attached to the placenta as the umbilical cord is significantly shortened or absent.
        4. Frequent kyphoscoliosis due to limited truncal flexion
3. Possible causes of the anomaly (Becker et al. 2000):

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_27

1. Early amnion rupture before obliteration of the extraembryonic coelom
2. Abnormal splitting of the embryo at the fourth gestational week
3. Disturbance of the blood flow due to vascular rupture, as described in cocaine users (Martinez et al. 1994)
4. Monozygotic twinning: early cleavage disorder (Shih et al. 1996)
5. Maternal uniparental disomy of chromosome 16 in a fetus with body stalk anomaly suggesting placental insufficiency or imprinting effects as cause of this anomaly (Chan et al. 2000)

4. Pathogenesis (de Silva et al. 2001)
   1. The umbilical cord, derived from a small mass of mesoderm (body stalk), attaches the embryo to the wall of the blastocysts.
   2. Extreme maldevelopment of embryonic body folding resulting in incomplete fusion of the amnion to the chorion and failure to form an umbilical cord (Lockwood et al. 1986)
   3. Abnormal development of the body stalk resulting in an absent or rudimentary umbilical cord
   4. Vascular disruption during 4–6 weeks' gestation as an etiology for limb body wall complex (Van Allen et al. 1987)
   5. Consequences
      1. Direct attachment of fetus to the placenta
      2. Abdominal viscera lying in a sac outside the abdominal cavity covered by amnion
   6. OEIS (omphalocele, exstrophy of cloaca, imperforate anus, and spinal defect) and limb body wall complex (LBWC) (Mandrekar et al. 2014)
      1. Share congenital talipes equinovarus, hydroureter, and body stalk anomaly
      2. OEIS and LBWC may represent a continuous spectrum of abnormalities rather than separate conditions and may share a common etiology and pathogenetic mechanism as proposed by several authors.

Clinical Features

1. A large anterior abdominal wall defect with a large omphalocele
   1. Outside the abdominal cavity containing thoracic and/or abdominal organs
   2. Covered by amnion
   3. Appears continuous with (adherent to) the placental membranes
2. Absent, rudimentary, or extremely short umbilical cord. A severe type of short umbilical cord syndrome may be a variant of the body stalk anomaly.
3. Two-vessel cord
4. Severe kyphoscoliosis
5. Placenta directly attached to the amnioperitoneal sac
6. Extensive associated anomalies (Giacoia 1992)
   1. Hypoplasia of the lungs
   2. Anal atresia (imperforate anus)
   3. Agenesis of the colon
   4. Intestinal atresia
   5. Exstrophy of the cloaca
   6. Vaginal atresia
   7. Agenesis of uterus and gonads
   8. Absence of external genitalia
   9. Hypoplastic kidneys
   10. Absence of diaphragm
   11. Diaphragmatic hernia
   12. Spina bifida
   13. Dysplastic thorax
   14. Occasional coexistence of the syndrome with limb malformations (mostly lower extremities) and amniotic bands (Martínez-Frías et al. 2000)
7. Fetal death caused by abruptio placentae
8. Live-born infant dies shortly afterward

Diagnostic Investigations

1. Radiography to document skeletal anomalies
2. Cytogenetic analysis
   1. No specific anomaly

2. Placental karyotyping: report of a case with placental trisomy 16 and maternal uniparental disomy (UPD)

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: not increased
   2. Patient's offspring: not surviving to reproductive age
2. Prenatal diagnosis
   1. High maternal serum alpha-fetoprotein
   2. Ultrasonography (Goldstein et al. 1989; Daskalakis et al. 1997; Jauniaux et al. 1990; Takeuchi et al. 1995; Paul et al. 2001; Daskalakis and Nicolaides 2002; Smrcek et al. 2003; Rovida et al. 2014; Kocherla et al. 2015)
      1. Can be diagnosed as early as the first trimester by transvaginal sonography (Shalev et al. 1995; Ginsberg et al. 1997)
      2. A large abdominal anterior wall defect with abdominal organs in a sac outside the abdominal cavity in apparent continuity with (adherent to) the placental membranes
      3. An extremely short or absent umbilical cord
      4. Severe kyphoscoliosis
      5. Polyhydramnios
      6. Oligohydramnios
      7. Two-vessel cord
      8. Ectopic cordis (Shibata et al. 2014)
      9. Deformed lower limbs
      10. Sonographic signs alone expect an unequivocally poor prognosis.
   3. Amniocentesis
      1. Elevated amniotic fluid alpha-fetoprotein level
      2. Abnormal acetylcholinesterase
      3. Normal chromosomes
3. Management: newborn with the body stalk anomaly, uniformly fatal

Fig. 1 An extremely premature neonate with body stalk anomaly. Short umbilical cord (7.5 cm with 5 cm fused with placenta) and a large amnioperitoneal sac between the abdomen and the placenta are evident. The sac was filled with internal viscera. In addition, there were anal and urethral atresia, rectovesical fistula, left renal agenesis, lumbosacral meningomyelocele, severe scoliosis, and lumbosacral hypoplasia

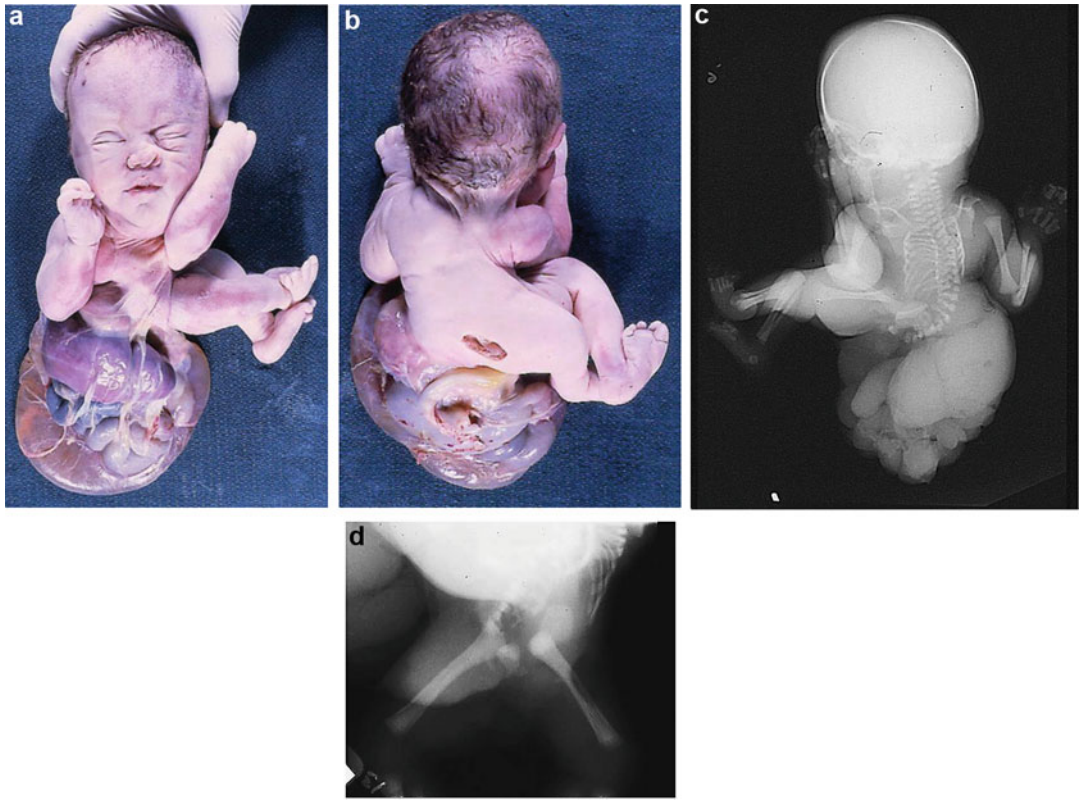

Fig. 2 (**a**–**d**) An infant with body stalk anomaly showing Potter facies, severe kyphoscoliosis, and a large amnioperitoneal sac outside the body. The sac contained abdominal organs. The umbilical cord was absent. Limb and vertebral defects illustrated in the radiographs

Fig. 3 (**a**, **b**) Another infant with body stalk anomaly showing anterior abdominal wall defect with a large sac containing abdominal organs, exstrophy of the bladder, and clubfeet

Brachydactyly

Contents

Brachydactyly, a general term for short digit, refers to disproportionately short fingers and toes and forms part of the group of limb malformations characterized by bone dysostosis. Dysostoses refer to abnormalities of individual bones, either in isolation or in combination with various abnormally formed bones. Dysostosis are usually static and arise during blastogenesis (first 8 weeks of embryonic life) versus osteochondrodysplasias that usually present at a later stage of development, typically affect the skeleton in general, and may continue to evolve as a result of continuous gene functioning throughout life.

Brachydactyly can occur either as an isolated malformation or as a part of a complex malformation syndrome. To date, many different forms of brachydactyly have been identified. Some forms also result in short stature. In isolated brachydactyly, subtle changes elsewhere may be present. Brachydactyly may also be accompanied by other hand malformations, such as syndactyly, polydactyly, reduction defects, or symphalangism.

Synonyms and Related Disorders

"Angel-shaped phalanx" brachydactyly; Brachydactyly type A1 (Farabee type); Brachymetatarsus IV; du Pan syndrome; Kirner deformity (dystelephalangy); Sugarman brachydactyly; Type 2 (Mohr-Wriedt type); Type A3 (brachydactyly-clinodactyly); Type A4 (Temtamy type); Type A5; Type B; Type C (Haws type); Type D (stub thumb); Type E

Genetics/Basic Defects

1. Isolated brachydactyly: the inheritance is mostly autosomal dominant with variable expressivity and penetrance.
2. Causative gene defect identified in the majority of isolated brachydactylies and some syndromic forms of brachydactyly.
3. Genomics of isolated brachydactyly (Hall 2002):
    1. Brachydactyly type A1 BDA1.
        1. Caused by mutations in the Indian hedgehog (*IHH*) gene located on chromosome 2q35-36 (Yang et al. 2000; Gao et al. 2001; Giordano et al. 2003). This supports the hypothesis that *IHH* plays a pivotal role in normal human skeletogenesis.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_28

2. Another locus for this phenotype, designated *BDA1B*, has been identified on chromosome 5p13.3-p13.2 (Armour et al. 2002; Kirkpatrick et al. 2003).

2. Brachydactyly type A2 (BDA2).
    1. Caused by mutation in the human bone morphogenetic protein receptor 1B gene (*BMPR1B*) (Majewski et al. 2003; Lehmann et al. 2006) on chromosome 4q21-q20, which affects cartilage formation in a dominant-negative manner.
    2. Sparing of the fourth finger distinguishes the Mohr-Wriedt type BDA2 from BDA2 caused by mutations in *BMPR1B* and concludes that the growth and differentiation factor 5 gene (*GDF5*) on chromosome 20q11.2 is a novel BDA2 causing gene (Kjaer et al. 2006; Ploger et al. 2008). Mutations in *GDF5* alter the receptor-binding affinities and can also cause symphalangism (Seemann et al. 2005).
3. Brachydactyly type A3 (BDA3): no gene or locus has yet been identified.
4. Brachydactyly type A4 (BDA4) (*HOXD13*, mapped on 2q31-q32).
    1. Mutations in the homeobox-containing gene (*HOXD13* on chromosome 2q31-q32) can give rise to limb malformations with variable expressivity and a wide spectrum of clinical manifestations including synpolydactyly and brachydactylies types D and E.
    2. The term "HOXD13 limb morphopathies" for the spectrum of limb disorders caused by *HOXD13* mutations was suggested based on a link between *HOXD13* and two additional limb phenotypes – syndactyly type V and brachydactyly type A4.
5. Brachydactyly type B (BDB) (Huang et al. 2014).
    1. Brachydactyly type B1 (Gong et al. 1999; Schwabe et al. 2000; Huang et al. 2014): caused mutations in the receptor kinase-like orphan receptor 2 gene (*ROR2*) on 9q22 in the majority of cases.
    2. Patients affected with the distal mutations have a more severe phenotype than those with the proximal mutations.
    3. Homozygous *ROR2* mutations are associated with an extreme form of brachydactyly, with extensive hypoplasia of the phalanges and metacarpals/metatarsals and absence of nails. In addition, there are vertebral anomalies, brachymelia of the arms, and ventricular septal defect, making up the manifestations of the Robinow syndrome, which also has been shown to be caused by mutations in *ROR2* (Stickler et al. 2006).
    4. Brachydactyly type B2: different mutations in the bone morphogenetic protein (*BMP*) antagonist *NOGGIN* (*NOG*, mapped on chromosome 4q23-q24) were identified in a subset of *ROR2*-negative patients with BDB and additional occurrence of proximal symphalangism and carpal synostosis (Lehmann et al. 2007).
    5. The BDB phenotype, as well as the location and nature of the BDB mutations, suggests a specific mutational effect that cannot be explained by simple haploinsufficiency.
6. Brachydactyly type C (BDC) (Baraitser and Burn 1983) (*CDMP1*, mapped on 20q11.2).
    1. Caused by heterozygous mutations of cartilage-derived morphogenetic protein 1 (*CDMP1*) (Polinkovsky et al. 1997), also known as growth/differentiation factor-5 (*GDF5*) gene, resulting in loss of function (Everman et al. 2002).
    2. Homozygous missense mutations in the GDF5 gene cause brachydactyly type C (Al-Qattan et al. 2015).

3. Factors other than locus heterogeneity, such as genetic modifiers and/or environmental factors, must play a role in phenotypic variability.
4. Non-penetrance in a mutation carrier of heterozygous mutations was identified in additional families with BDC.
5. A novel missense mutation was described in the prodomain of *CDMP1* indicating an important function of the prodomain for the folding, secretion, and availability of biologically active *CDMP1*.
6. Homozygous mutations of *CDMP1* cause the Hunter-Thompson form of chondrodysplasia, a recessive condition that is characterized by severe acromesomelic limb shortness.
7. A novel mutation in CDMP1, confirming that BDC and angel-shaped phalanx brachydactyly are part of the CDMP1 mutational spectrum (Gutiérrez-Amavizca et al. 2012).

7. Brachydactyly type D (BDD): associated with mutations in *HOXD13* (mapped on 2q31-q32) (Johnson et al. 2003).
8. Brachydactyly type E (BDE) (*HOXD13*, mapped on 2q31-q32).
    1. Mutations in parathyroid hormone-like hormone (*PTHLH*) (the gene coding for parathyroid hormone-related protein (PTHrP)): cause BDE (Thomas-Teinturier et al. 2015).
    2. The occurrence of brachydactyly type E was one feature of what appeared to be a contiguous gene syndrome due to a cytogenetically visible de novo deletion of 2q37.
    3. Missense and nonsense mutations (Jamsheer et al. 2012) in *HOXD13* with distinctive limb phenotypes exhibiting overlap with BDD and BDE have been described.
9. Brachymetatarsus IV: no gene or locus for Kirner deformity has yet been identified.
10. Sugarman brachydactyly: no gene or locus for Kirner deformity has yet been identified.

Clinical Features

1. Types of isolated brachydactyly (Temtamy and Aglan 2008)
    1. Brachydactyly type A: shortening is confined to middle phalanges.
        1. Brachydactyly type A1 (BDA1) (Farabee-type brachydactyly)
            1. Variable short or rudimentary middle phalanges of all digits which are occasionally fused with terminal phalanges
            2. Short proximal phalanges of the thumbs and big toes
            3. An autosomal dominant trait with significant intrafamilial phenotypic heterogeneity among the affected individuals (McCready et al. 2002)
        2. Brachydactyly type A2 (BDA2) (Mohr-Wriedt-type brachydactyly)
            1. Characterized by hypoplasia/aplasia of the second middle phalanx of the index finger and sometimes little finger
            2. Characteristic triangular-shaped middle phalanx ("delta phalanx") in the index fingers and second toes
            3. Radially curved index finger in severely affected cases
            4. Malformation of the proximal phalanx of big toes resulting in fibular deviation of the distal phalanx, while all other toes have rudimentary middle phalanges causing tibial deflection of their distal phalanges
            5. An autosomal dominant trait
        3. Brachydactyly type A3 (BDA3) (brachymesophalangy V, brachydactyly-clinodactyly)
            1. Characterized by shortening of the middle phalanx of the little finger.

2. Slanting of the distal articular surface of the middle phalanx leads to radial deflection of the distal phalanx.
3. Not always associated with clinodactyly. A single flexion crease of the little finger indicates a short or absent middle phalanx.
4. This type should be differentiated from other types of crooked little fingers, namely, Kirner deformity and camptodactyly; in the former, there is radial bowing of the terminal phalanx due to curving of its shaft. Camptodactyly is a flexure contracture deformity of the interphalangeal joints.
5. An autosomal dominant trait with reduced penetrance.

4. Brachydactyly type A4 (BDA4) (brachymesophalangy II and V, Temtamy-type brachydactyly)
   1. Brachymesophalangy affecting mainly the second and fifth digits.
   2. When the fourth digit was affected, it showed an abnormally shaped middle phalanx leading to radial deviation of the distal phalanx.
   3. The feet also showed absence of middle phalanges of the lateral four toes.
   4. Rare autosomal dominant trait.
5. Brachydactyly type A5 (BDA5) (absent middle phalanges of digits 2–5 with nail dysplasia):
   1. Absence of the middle phalanges and nail dysplasia with duplicated terminal phalanx of the thumb.
   2. This type can be included in type B brachydactyly.

2. Brachydactyly type B (BDB) (Gong et al. 1999)
   1. Absence or hypoplasia of the terminal parts of the index to little fingers with complete absence of fingernails
   2. Intact thumbs frequently showing flattening, splitting, or duplication of the distal phalanges
   3. Less severely affected digits on the radial side of the hand compared to those on the ulnar side
   4. Similarly but less severely affected feet
   5. Symmetric deformity
   6. Accompanied by soft tissue syndactyly, symphalangism, carpal and/or tarsal fusions, and shortening of metacarpals and/or metatarsals
   7. A rare hand malformation
   8. An autosomal dominant trait with variable severity (expressivity)
3. Brachydactyly type C (BDC) (brachydactyly with hyperphalangism, Haws-type brachydactyly)
   1. Characterized by brachymesophalangy of the index, middle, and little fingers and shortening of the first metacarpal
   2. The ring finger: usually the longest digit, longer than the index finger (hyperphalangism detected on radiological examination)
   3. The proximal phalanx of the index finger: an anomalous configuration resulting in its ulnar deflection
   4. Short metacarpals and symphalangism: occasionally present
   5. The feet: either normal or show ordinary brachydactyly
   6. Inheritance: autosomal dominant with variable expressivity
   7. Presence of considerable intra- and interfamilial variation (Debeer et al. 2001)
4. Brachydactyly type D (BDD) (stub thumb)
   1. Distal phalanx of the thumb alone: characteristically shortened.
   2. Various degrees of thumb shortening, either unilaterally or bilaterally.
   3. Base of the distal phalanx is broader than the surface of the proximal phalanx to which it articulates, and that the distal end of the bone often shows some hyperplasia.
   4. Short distal phalanx of the thumb results from early closure of its epiphyses.

5. An autosomal dominant trait with reduced penetrance.

5. Brachydactyly type E (BDE)
   1. Variable shortening of the metacarpals with more or less normal length of phalanges.
   2. Occasional shortening of the metatarsals, resulting from hypoplastic and partially fused metacarpal epiphyses, visible on radiographs.
   3. Often presence of short terminal phalanges.
   4. Hyperextensibility of the hand joints: frequently a striking feature.
   5. Often relatively high axial triradius.
   6. Mild short stature in affected individuals.
   7. An isolated type E brachydactyly is inherited as an autosomal dominant trait with variable expressivity and variable involvement of the metacarpals and/or metatarsals, with frequent bilateral asymmetry.
   8. Brachydactyly type E as a feature of a syndrome (Pereda et al. 2013):
      1. Pseudohypoparathyroidism
      2. Acrodysostosis with or without multihormonal resistance
      3. Bilfinturan BD or hypertension with brachydactyly syndrome
      4. BDE with short stature, parathyroid hormone-like hormone gene (*PTHLH*) type
      5. Brachydactyly mental retardation syndrome
      6. Trichorhinophalangeal syndrome
      7. Turner syndrome
6. Brachymetatarsus IV (metatarsus IV, short, toes, fourth, short)
   1. Short fourth metatarsi resulting in unilateral or bilateral short fourth toes were observed in 206 persons in Northeastern India with no instance of short metacarpals, distinguishing this form from BDE.
   2. An autosomal dominant trait with approximately 27% penetrance.
   7. Sugarman brachydactyly (brachydactyly with major proximal phalangeal shortening) (Sugarman et al. 1974)
      1. A new form of brachydactyly of which a conspicuous feature was a non-articulating great toe which was set dorsal and proximal to the usual position. The great toes were amputated.
      2. Very short fingers without motion at the proximal interphalangeal joints.
      3. The consanguinity in the family and the presence of seven other affected members among the patient's relatives made autosomal recessive inheritance likely.
   8. Kirner deformity (dystelephalangy) (David and Burwood 1972)
      1. Malformed little finger consists of radial bowing of the terminal phalanx.
      2. Tip of the little finger points toward the thenar eminence.
      3. Usually bilateral malformations.
      4. An autosomal dominant trait with incomplete penetrance.
2. Brachydactyly as part of a syndrome
   1. Angel-shaped phalango-epiphyseal dysplasia (ASPED) (Gutiérrez-Amavizca et al. 2012)
      1. An autosomal dominant skeletal abnormality.
      2. Characterized by a typical angel-shaped phalanx, brachydactyly, abnormal dentition, hip dysplasia, and delayed bone age.
      3. Brachydactyly and ASPED: both result from mutations in the *CDMP1* gene and are part of the CDMP1 mutational spectrum.
   2. Brachyphalangy, polydactyly, and tibial aplasia/hypoplasia syndrome (Shafeghati et al. 2010) (please see the chapter of Tibial Hemimelia)
   3. Autosomal recessive Robinow syndrome (see the chapter of Robinow Syndrome) (Stickler et al. 2006)
   4. "► Rubinstein-Taybi Syndrome" (see the chapter) (Roelfsema and Peters 2007)

5. Albright hereditary osteodystrophy (Davies and Hughes 1993)
6. Brachydactyly type E with hypertension
7. Du Pan syndrome (Faiyaz-Ul-Haque et al. 2002)

3. Prognosis
   1. Strongly dependent on the nature of the brachydactyly
   2. May vary from excellent to severely influencing hand function
   3. Often depends on the nature of the associated anomalies if brachydactyly forms part of a syndromic entity

Diagnostic Investigations

1. Radiographic studies (Temtamy and McKusick 1978)
   1. Brachydactyly type A1
      1. Short middle phalanges involving most digits bilaterally with absent middle phalanges in severely affected individuals
      2. Proximal phalanx of thumb: short in some patients
      3. Flattening of articular surface of metacarpals and short metacarpals in severely affected individuals
      4. Occasional small ossicles at metacarpocarpal joints and at metacarpophalangeal joints
      5. Short proximal phalanx of great toe and absent middle phalanges of the toes in some cases
   2. Brachydactyly type B (Gong et al. 1999)
      1. Middle and distal phalanges: shortened or missing.
      2. Cleft distal phalanx of the great toe.
      3. A single distal phalanx, in some instances, appears to articulate with the proximal phalanx.
      4. Metacarpal and proximal phalanges appear normal.
      5. Mild cutaneous syndactyly in the hands and feet may be present.
   3. Brachydactyly type C (Castriota-Scanderbeg et al. 2005)
      1. Striking shortening of several metacarpals (especially the thumb) and phalanges
      2. Absence ossification of the middle phalanges of the index, middle, ring, and little fingers
      3. "Angel-shaped" phalanges in the proximal phalanges of the index and middle fingers
      4. Ovoid thumb metacarpals
      5. Shortening of the ring and little finger metacarpals
   4. Brachydactyly type D
      1. Broad thumb without associated clinical findings
      2. More common in females than males
      3. Bilateral in about 75%
   5. Brachydactyly E
      1. Shortening of metacarpals and metatarsals due to premature closure of the growth plate, often symmetrical
      2. Often short distal phalanx of the thumb and less commonly of other distal phalanges
2. Mutation studies

Genetic Counseling

1. Recurrence risk: The nature of genetic counseling depends both on the pattern of inheritance of the type of brachydactyly present in the family and on the presence or absence of accompanying symptoms. In autosomal dominant inheritance, variability in severity and incomplete penetrance are common in several types of brachydactyly. In autosomal recessive inheritance, variability is usually smaller although variable symptoms may still be present in affected sibs. Clinically, the presence of a relatively long ring finger in a patient with brachydactyly should bring the attention to testing of candidate genes responsible for endochondral bone formation (Al-Qattan 2014). It is also important to realize that

brachydactyly type C may be inherited as either autosomal dominant or recessive. The dominant mutation may present as a "de novo mutation" (an alteration in a gene that is present for the first time in one family member). Hence, if apparently normal parents had a baby born with brachydactyly type C, genetic testing should include both the baby and parents to determine the risk in the next baby (autosomal recessive inheritance gives a 25% risk in each newborn).

1. Patient's sib
    1. Autosomal dominant inheritance
        1. Recurrence risk of 50% if a parent is affected
        2. Low recurrence risk if both parents are normal
    2. Autosomal recessive inheritance: risk of recurrence 25%
2. Patient's offspring
    1. Autosomal dominant inheritance: a 50% risk of offspring affected
    2. Autosomal recessive inheritance: low recurrence risk unless the spouse is affected or a carrier of brachydactyly mutation

2. Prenatal diagnosis
    1. Usually not indicated for isolated forms of brachydactyly, but may be appropriate in syndromic forms.
    2. Molecular studies of chorionic villus samples at 11 weeks of gestation and by amniocentesis after the 14th week of gestation can provide antenatal diagnosis if the causative mutation in the family is known.
    3. Prenatal diagnosis of a family affected by brachydactyly type A1 with a mutation in IHH (Palka et al. 2012).
3. Management
    1. No specific management or treatment applicable to all forms of brachydactyly.
    2. Plastic surgery:
        1. Only indicated if the brachydactyly affects hand function or for cosmetic reasons
        2. Typically not ordered
    3. Physical therapy and ergotherapy may ameliorate hand function.

Fig. 1 A 2-year-and-6-month-old boy was evaluated for brachydactyly and abnormal shaped thumbs and great toes. He had hitchhiker-shaped thumbs and great toes with short fingers and toes including clinodactyly of the fifth fingers. His sister, mother, and maternal grandmother are similarly but less severely affected. The brachydactyly present in this kindred is consistent with brachydactyly type A1

Fig. 2 His great toes showed hitchhiker-shaped deformities

Fig. 3 His thumbs showed hitchhiker-shaped deformities

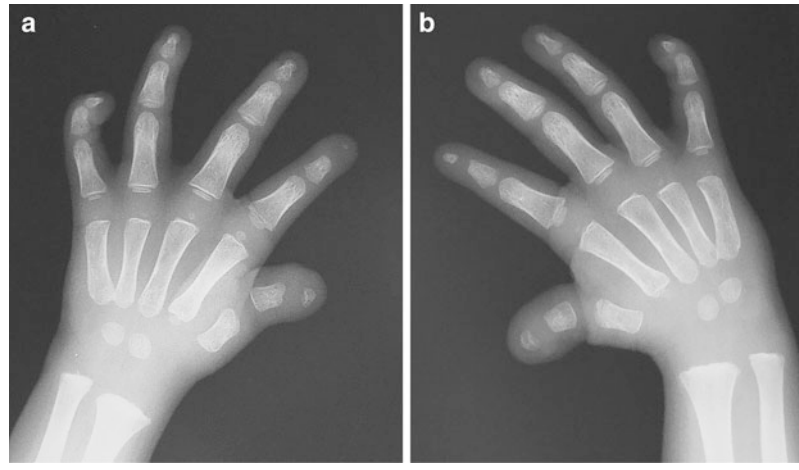

Fig. 4 (**a** and **b**) Radiographs of both hands showed short phalanges, especially short middle and distal phalanges in addition to deformities of the thumbs

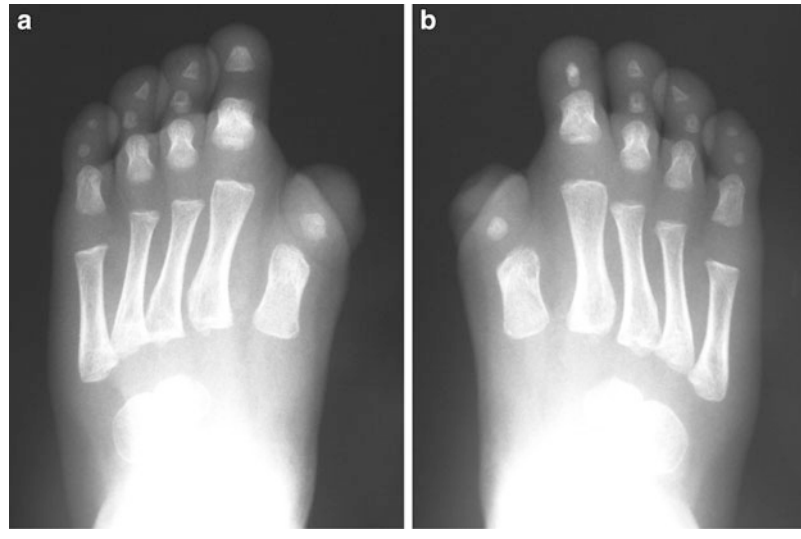

Fig. 5 (**a** and **b**) Radiographs of both feet showed short phalanges, especially middle and distal phalanges, in addition to deformities of the great toes

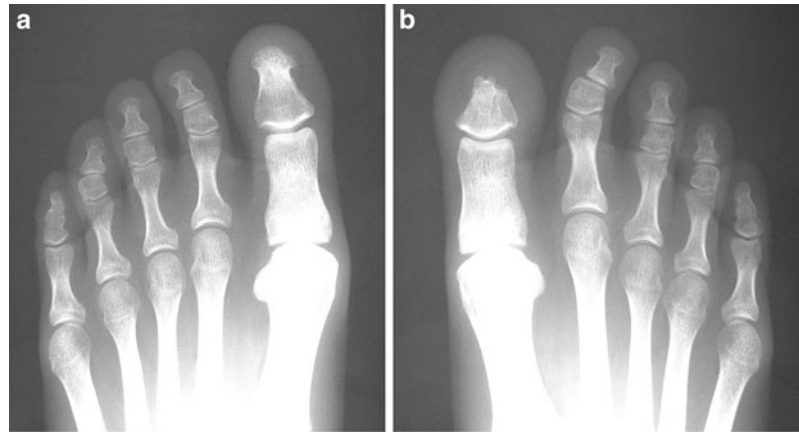

Fig. 6 (**a** and **b**) Radiographs of the feet of his mother

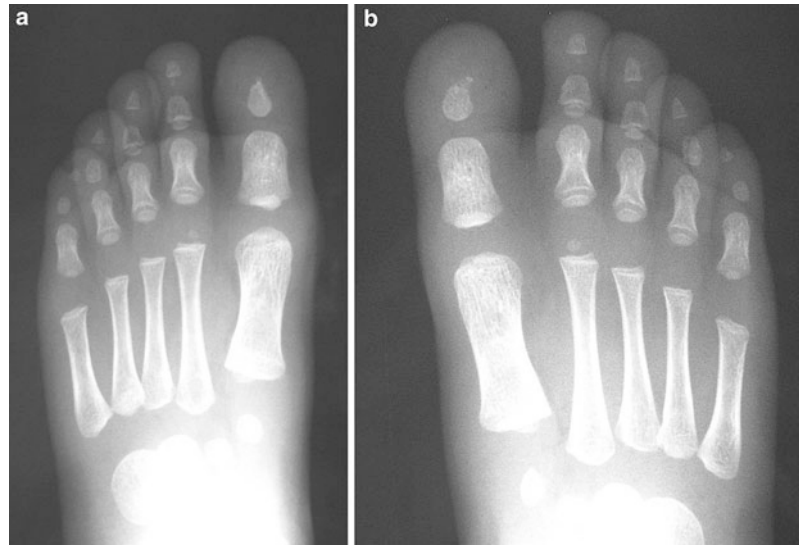

Fig. 7 (**a** and **b**) Radiographs of the feet of his sister

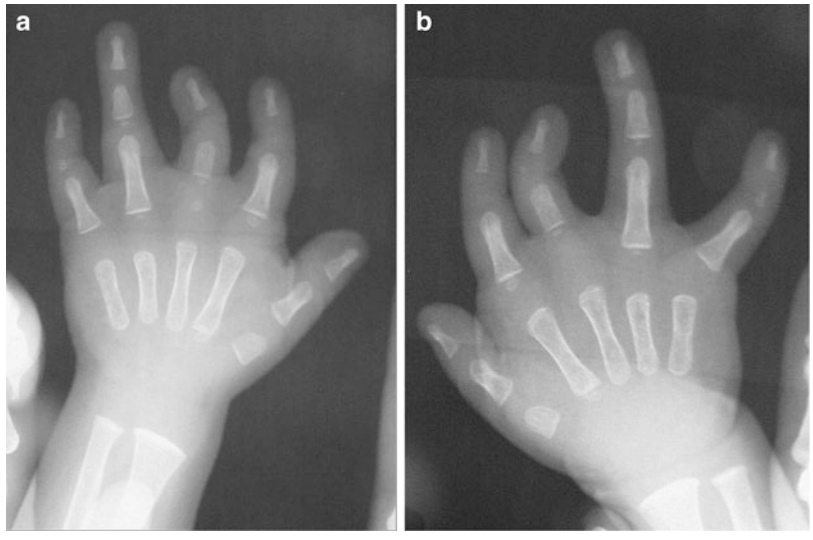

Fig. 8 (**a** and **b**) Radiographs of the hands of a 21-month-old boy, who was evaluated for hand anomalies, showed shortening of thumb metacarpals, ulnar deviation of the second to third fingers with deficient ossification of the middle phalanges, relatively normal fourth finger (the longest digit and longer than the middle finger), and clinodactyly of the fifth finger with hypoplastic middle phalanges. No carpal bones were apparent. The brachydactyly in this child appears to represent brachydactyly type C

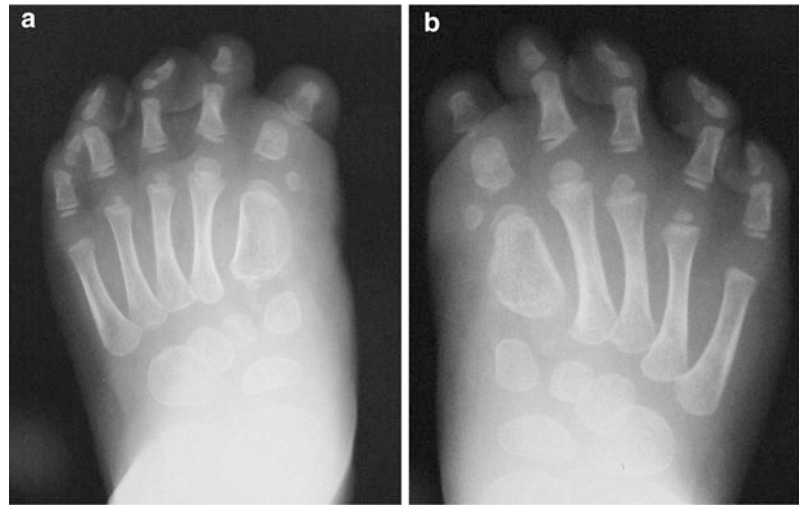

Fig. 9 (**a** and **b**) Radiographs of the feet showed abnormal shaped first metatarsals and short toes with absent or hypoplastic middle phalanges

Fig. 10 A 17-year-old female was evaluated for severe scoliosis and status post corrective surgery. She and her mother were noted to have brachydactyly. In the hands, there was evidence of brachydactyly with symmetric shortening of the bilateral 3rd and 4th metacarpals. The bilateral proximal and middle phalanges of the second digit and possibly the distal phalanges appeared also shortened (Courtesy of Dr. Grace Guo)

Branchial Cleft Anomalies

Contents

Abnormal persistence of branchial apparatus remnants results in branchial anomalies. Branchial cleft anomalies are the second most common head and neck congenital lesions seen in children (Bajaj et al. 2011).

Synonyms and Related Disorders

Branchial cyst; Branchial fistula; Branchial remnant presenting as skin tag; Branchial sinus

Genetics/Basic Defects

1. Embryology of the fetal branchial apparatus
    1. A derivative of a foregut, developed during the second fetal week
    2. Consisting of five paired pharyngeal arches, separated internally by four endodermal pouches and externally by four ectodermal clefts
2. Embryology of the branchial clefts (Benson et al. 1992; Prosser and Myer 2015)
    1. First branchial cleft (Arndal and Bonding 1996)
        1. Giving rise to the Eustachian tube, tympanic cavity, and mastoid antrum.
        2. Contributing to the formation of the tympanic membrane.
        3. The only cleft to contribute to the adult structure is the external auditory canal.
        4. Type I: thought to arise from the duplication of the membranous external ear canal and are composed of ectoderm only.
        5. Type II: composed of the ectoderm and mesoderm (Al-Mahdi et al. 2013).
    2. Second, third, and fourth branchial clefts
        1. Known as the cervical sinus of His (part of an ectodermally lined depression)
        2. Obliteration of the cervical sinus as the second and fifth branchial clefts merge
    3. Second branchial pouch
        1. Lined by the ectoderm
        2. Contributing to the palatine tonsil and tonsillar fossa
    4. Third branchial pouch: forming the following structures
        1. Inferior parathyroid gland
        2. Thymus
        3. Pyriform sinus
    5. Fourth branchial pouch: forming the following structures

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_29

    1. Superior parathyroid gland
    2. Apex of the pyriform sinus
3. Pathogenesis of branchial cleft anomalies: remains controversial
    1. Arising from incomplete obliteration of the cervical sinus of His
    2. Arising from buried epithelial cell rests
4. Genetics: autosomal dominant inheritance in some families (Wheeler et al. 1958; Anand et al. 1979; Clevens and Weimert 1995)

Clinical Features

1. Manifestation of branchial cleft anomalies (Muckle 1961; Maran and Buchanan 1978; Chandler and Mitchell 1981; Howie and Proops 1982; Doi et al. 1988; Ford et al. 1992; Choi and Zalzal 1995; Koeller et al. 1999)
    1. Cyst
        1. An epithelial-lined structure without an external opening
        2. Most common branchial cleft anomalies (75%)
    2. Sinus
        1. A blind tract with an opening externally through the skin on the side of the neck representing persistence of a branchial groove
        2. A blind tract with an opening internally into the foregut representing persistence of a branchial pouch
    3. Fistula
        1. A tract communicating between the skin externally (a patent abnormal canal opening externally on the neck surface) and the foregut internally (within the pharyngeal mucosa)
        2. Representing persistence of a branchial groove with its corresponding pouch and without branchial membrane between them
    4. Skin tag: a branchial remnant presenting in the lateral neck
    5. Bilateral branchial cleft anomalies
        1. Occurring in 2–3% of cases
        2. Often familial
2. First branchial cleft cyst (Triglia et al. 1998)
    1. Accounting for only 5–8% of all branchial cleft defects
    2. Most commonly seen in middle-aged women
    3. Usually manifesting as recurrent abscesses or other inflammation (sinus tract) either around the ear or at the angle of the mandible
    4. History of recurrent parotid abscesses unresponsive to antibiotics and drainage
    5. Cystic drainage into the external auditory canal
        1. Aural fistulas
        2. Auricular swelling
        3. Otitis
        4. Otorrhea
        5. A cervical skin tag at birth
    6. Occasional sinus tract extending to the hyoid bone
    7. Cyst related to the parotid gland
        1. Forming abscess and produce parotitis
        2. May be associated with facial nerve palsy
3. Second branchial cleft cyst (Ramirez-Camacho et al. 2001)
    1. Most common developmental anomalies arising from the branchial apparatus
    2. Cysts
        1. Accounting for at least three fourths of branchial cleft anomalies
        2. Typically occurring between 10 and 40 years of age
    3. Location of the cysts
        1. Most commonly in the submandibular space
        2. Anywhere along a line from the oropharyngeal tonsillar fossa to the supraclavicular region of the neck
    4. Signs and symptoms of second branchial cleft cyst
        1. Usually appearing as painless, fluctuant masses in the lateral portion of the neck adjacent to the anteromedial border of the sternocleidomastoid muscle at the mandibular angle.
        2. Enlarge slowly over time.
        3. Painful and tender if secondarily infected.

    4. Highly suggestive in a young patient with a history of recurrent inflammation in the region of the mandibular angle.
    5. Ostium usually noted at birth just above the clavicle in the anterior neck if a fistula is present.
  5. Fistulas and sinuses
    1. Almost always present at birth
    2. With a small pinpoint external opening
    3. May go unnoticed for years if there is no drainage
    4. Symptoms consisting of continuous or intermittent mucoid drainage and recurrent attacks of inflammation that often follow mild trauma or an infection of the upper respiratory tract
    5. Occasional formation of cellulitis and abscess
    6. Probing of the track producing irritation of the vagus nerve
    7. Usually unilateral
    8. Found in several members of the same family
4. Third branchial cleft cyst
  1. Extremely rare
  2. Most cysts located in the posterior cervical space posterior to the sternocleidomastoid muscle
  3. Constituting the second most common congenital lesion of the posterior cervical space of the neck after cystic hygroma
  4. Usually manifesting as a painless, fluctuant mass in the posterior triangle area of the neck
  5. Mass usually distending during a viral infection of the upper respiratory tract
5. Fourth branchial cleft cyst
  1. Extremely rare
  2. Usually manifesting as a sinus tract rather than a cyst or fistula
  3. Majority of the lesions occurring on the left side

Diagnostic Investigations

1. CT scans/MRI imagings (Koeller et al. 1999)
  1. First branchial cleft cyst
    1. Appearing as a cystic mass either within, superficial to, or deep to the parotid gland
    2. Variable wall thickness and enhancement: increase with recurrent infections
    3. Difficult to differentiate from other cystic mass of the parotid gland
  2. Second branchial cleft cyst
    1. Typically well-circumscribed, homogeneously hypoattenuated masses surrounded by a uniformly thin wall
    2. Increased mural thickness after infection
    3. "Beaked sign" (a curved rim of tissue or "beak" pointing medially between the internal and external carotid arteries) considered a pathognomonic imaging feature of a second branchial cleft cyst
  3. Third branchial cleft cyst
    1. Most commonly appearing as a unilocular cystic mass centered in the posterior cervical space
    2. Cyst fluid varying in signal intensity on T1-weighted images depending on the protein concentration and is typically hyperintense relative to muscle on T2-weighted images
  4. Fourth branchial cleft cysts
    1. Connected with the pyriform sinus
    2. Appearing similar to an external or mixed laryngocele
2. Ultrasonography
  1. A fluctuant, compressible, anechoic, or hypoechoic mass
  2. May have fine internal debris
3. Sinogram or fistulogram with radiopaque dye (Ramirez-Camacho et al. 2001)
  1. To help confirming the diagnosis
  2. To identify length and location of the fistulous tract
  3. To identify an associated cyst

Genetic Counseling

1. Recurrence risk
  1. Patient's sib

    1. Not increased in de novo case
    2. Fifty percent recurrence risk if a parent is affected with an autosomal dominant disorder
  2. Patient's offspring: 50% in autosomal dominant inheritance
2. Prenatal diagnosis by ultrasonography
  1. Demonstrate a cystic neck mass in the fetus with differential diagnosis including hemangioma, dermoid cyst, neuroblastoma, congenital cystic hygroma, teratoma, epignathus, esophageal duplication, goiter, and laryngocele
  2. Third branchial cleft anomaly detected in utero (Robichaud et al. 2000)
3. Management (Agaton-Bonilla and Gay-Escoda 1996)
  1. First branchial cleft cyst: complete surgical excision (only curative therapy) (Triglia et al. 1998)
  2. Second and third branchial cleft cysts: surgical excision recommended because of increased frequency of secondary infection
  3. Recurrence risk uncommon after surgical excision
  4. Antibiotics required for treating infections or abscess

Fig. 1 A branchial cleft cyst in the *left* side of the neck

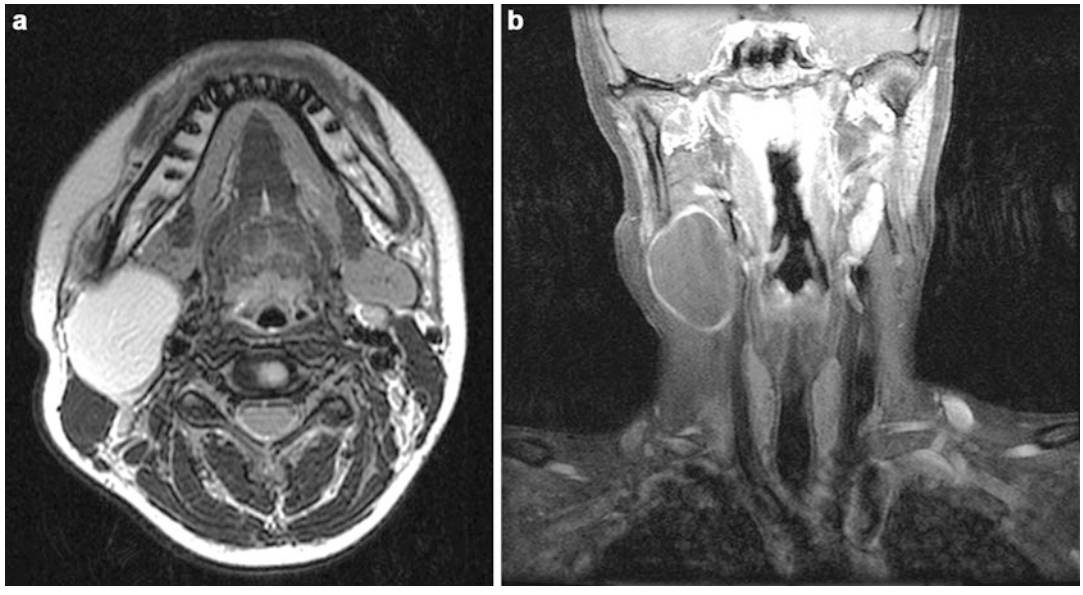

Fig. 2 (**a**, **b**) A 15-year-old female was evaluated for concerns of left neck swelling. Over the past 2 months, the swelling had decreased in size, but never returned to normal. The onset of the mass was gradual with complaints of left neck swelling with pain and upper respiratory tract infections. MRI Images (**a**, **b**) demonstrated a well-defined 4.4 cm lesion in the space posterior to the right angle of the mandible and anterior to the sternocleidomastoid muscle with mass effect on the surrounding structures. The axial image (**a**) showed the lesion with T2 hyperintensity. The coronal image (**b**) showed a mild thin peripheral enhancement. The findings are suggestive of a type II bronchial cleft cyst, which was confirmed with postsurgical pathology (Courtesy of Dr. Grace Guo)

Calcinosis Cutis

Contents

Calcinosis cutis is a group of disorders characterized by the deposition of crystals of calcium phosphate (hydroxyapatite) in the skin in various areas of the body (Ianello et al. 1998) and can be associated with both normal and elevated calcium levels. Classically, it is divided into dystrophic, metastatic, iatrogenic, and idiopathic types.

Synonyms and Related Disorders

Calcinosis cutis (dystrophic, metastatic, iatrogenic, or idiopathic types)

Genetics/Basic Defects

1. Dystrophic calcinosis cutis (Nunley and Jones 2009)
    1. A common form of calcinosis cutis
    2. Localized or generalized
3. Absence of calcium or phosphorus metabolic abnormalities
4. Depositions of calcium salts: secondary to local inflammation, tissue damage, and degeneration (Walsh and Fairley 1995)
5. Localized tissue damage
    1. Trauma
    2. Burn
    3. Inflammatory processes
        1. Acne
        2. Insect bites
    4. Varicose veins.
    5. Infections: Necrotic tissue produced by an infectious process may subsequently become calcified.
        1. Onchocerciasis
        2. Cysticercosis
        3. Histoplasmosis
        4. Cryptococcosis
        5. Intrauterine herpes simplex infection
    6. Tumors: Benign and malignant tumors may develop calcification.
        1. Pilomatrixoma
        2. Calcifying epithelioma of Malherbe
        3. Epithelial cysts
        4. Syringomas
        5. Basal cell carcinomas
        6. Rarely in melanocytic nevi, malignant melanoma, atypical fibroxanthoma, hemangioma, pyogenic granuloma, seborrheic keratoses, neurilemomas, and trichoepitheliomas

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_30

6. Generalized tissue damage (Reiter et al. 2011b)
    1. Connective tissue diseases (Balin et al. 2012)
        1. Dermatomyositis (Wu and Metz 2008)
        2. Scleroderma (Vereecken et al. 1998)
        3. Lupus erythematosus (Marzano et al. 1999)
        4. Lupus panniculitis
        5. Systemic sclerosis
        6. Mixed connective tissue disease
        7. Overlap connective tissue disease
        8. Mixed connective tissue disease
        9. Rheumatoid arthritis
        10. Calcinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasias (CREST) syndrome
    2. Porphyria cutanea tarda
    3. Subcutaneous fat necrosis of the newborn
    4. Inherited disorders
        1. Ehlers-Danlos syndrome
        2. Werner syndrome
        3. Pseudoxanthoma elasticum
        4. Rothmund-Thomson syndrome
2. Metastatic calcinosis cutis
    1. Precipitation of calcium salts in normal tissue due to increased serum calcium and phosphate levels as a result of an underlying defect in calcium and/or phosphate metabolism.
    2. Generally indicates chronic renal failure.
    3. Calcification usually widespread and affects predominantly the blood vessels, kidneys, lungs, and gastric mucosa.
    4. Cutaneous and subcutaneous tissues may be involved: a rare complication.
    5. Some of the factors involved are:
        1. Factors involved in increased serum calcium levels:
            1. Primary or secondary hyperparathyroidism
            2. Paraneoplastic hypercalcemia
            3. Albright hereditary osteodystrophy
            4. Destructive bone disease (malignancies, Paget disease)
            5. Excessive vitamin D intake
            6. Milk-alkali syndrome
            7. Sarcoidosis
            8. Chronic renal failure (Tan et al. 2006)
            9. Calciphylaxis
        2. Factor involved in increased serum phosphate levels: chronic renal failure
3. Iatrogenic causes: secondary to a treatment or procedure
    1. Parenteral calcium (Kagen et al. 2000; Puvabanditsin et al. 2005): extravasation of intravenously administered calcium chloride or calcium gluconate
    2. Parental inorganic phosphate
    3. Tumor lysis syndrome (Rodriguez-Cano et al. 1996)
    4. Repeated heel sticks in the newborn
    5. Prolonged use of calcium-containing electrode paste
        1. Electromyography
        2. Electroencephalography
        3. Brain auditory evoked potential
4. Idiopathic calcinosis cutis (Ogretmen et al. 2002)
    1. Also known as calcinosis cutis universalis
    2. Sporadic occurrence
    3. Characterized by calcium deposits in the dermis, subcutis, and muscles without any metabolic disorder or tissue injury
    4. An uncommon type and may be solitary of multiple
    5. Causes
        1. Idiopathic calcinosis of scrotum/penis/vulva
        2. “Milia-like” idiopathic calcinosis cutis with or without Down syndrome (Bécuwe et al. 2004; Goirtz et al. 2006)
        3. Subepidermal calcified nodule
        4. Tumoral calcinosis
        5. Calcinosis cutis circumscripta
        6. Transplant-associated calcinosis

Clinical Features

1. Dystrophic calcinosis cutis (Nunley and Jones 2009)

1. Most common type of calcinosis cutis
2. Large and widespread deposits: termed calcinosis universalis
3. Dystrophic calcification occurring locally and consists of only a few deposits of calcium salts termed "calcinosis circumscripta"

2. Metastatic calcinosis
   1. First manifestations
      1. Bone demineralization
      2. Non-visceral and/or visceral calcification, mostly with mural deposits in arteries and arterioles
   2. Calcium deposition
      1. Frequently widespread
      2. Large deposits frequently found around large joints, such as the knees, elbows, and shoulders, in a symmetrical distribution
      3. Visceral organs: deposition of calcium in the lungs, kidneys, blood vessels, and stomach occurring more frequently than deposition within the skin or muscle
      4. Calciphylaxis: characterized by progressive vascular calcification, soft tissue necrosis, and ischemic necrosis of the skin
3. Iatrogenic calcinosis cutis
   1. Calcification generally localized at the site of an invasive procedure
   2. Diffuse deposition may occur
4. Idiopathic calcinosis cutis
   1. Uncommon
   2. Calcification deposit
      1. Most commonly localized to one general area
      2. Observed in the dermis, subcutis, and muscles without any metabolic disorder or tissue injury

Diagnostic Investigations

1. Laboratory studies (Nunley and Jones 2009)
   1. Serum calcium, inorganic phosphate, alkaline phosphatase, and albumin levels.
      1. Elevated serum calcium and alkaline phosphatase levels with a decrease in the inorganic phosphate level: suggestive of hyperparathyroidism
      2. An albumin value: needed to interpret the significance of hypocalcemia or hypercalcemia
      3. Serum blood urea nitrogen and creatinine concentrations: needed to measure renal function
   2. Abnormal complete blood cell count with differential: suggest an underlying malignancy or lupus erythematosus.
   3. Abnormal plasma bicarbonate or arterial pH value: indicates the presence of a metabolic alkalosis (milk-alkali syndrome).
   4. Parathyroid hormone concentration: direct measurement for hyperparathyroidism.
   5. Abnormal creatine kinase and aldolase value.
      1. Dermatomyositis
      2. Myositis
      3. Rhabdomyolysis
   6. Serum amylase or lipase levels: to assess pancreatic disease.
   7. Antinuclear antibody testing: helpful in screening for lupus erythematosus.
   8. Presence of SCL-70 (topoisomerase) antibody: portends a poor prognosis for scleroderma patient.
   9. Vitamin D levels: to evaluate for excess vitamin D. A test of the 24-h urinary excretion of calcium and/or inorganic phosphate may be useful.
2. Imaging studies
   1. Radiographic examination (Shahi et al 2014): effective in detecting cutis and to demonstrate the extent of tissue calcification
   2. Bone scintigraphy with radiolabeled phosphate compounds (technetium Tc 99 m methylene diphosphonate [MDP]): to evaluate non-visceral soft tissue calcification (Bhattacharya et al. 2005)
   3. CT for the identification of visceral and non-visceral calcification, particularly in assessing tumoral calcinosis
   4. MRI: to evaluate characteristic patterns of calcific deposits, particularly in evaluating granulomatous foreign-body reaction in tumoral calcinosis

3. Biopsy and histopathologic examination of a cutaneous lesion
    1. Observation of granules and deposits of calcium in the dermis, with or without a surrounding foreign-body giant cell reaction
    2. Massive calcium deposits: may be located in the subcutaneous tissue
    3. Calcium deposition: frequently found within the walls of small- and medium-sized blood vessels in areas of necrosis
    4. Calcium deposition: may be confirmed on Von Kossa and alizarin red stains
    5. Fine needle aspiration cytology: amorphous calcium salts in subcutaneous fibrofatty tissue (Aggawal and Shrestha 2013; Choudhury et al. 2015)

Genetic Counseling

1. Recurrence risk:
    1. Patient's sib
        1. No increase in sporadic cases
        2. Autosomal recessive: a 25% recurrence risk (e.g., Rothmund-Thomson syndrome, Ehlers-Danlos syndrome types VI–VII, and familial hyperphosphatemic tumoral calcinosis)
        3. Autosomal dominant: not increased unless a parent is affected, in which case a 50% recurrence risk (e.g., pseudoxanthoma elasticum, Ehlers-Danlos syndrome types I–IV)
        4. X-linked recessive: 50% of male sibs affected if the mother is a carrier (e.g., Ehlers-Danlos syndrome type V)
    2. Patient's offspring:
        1. Autosomal recessive: not increased unless the spouse is also a carrier
        2. Autosomal dominant: a 50% risk
        3. X-linked recessive: all daughters of affected males will be carriers. All sons of an affected male will be normal.
2. Prenatal diagnosis: not reported
3. Management (Reiter et al. 2011a)
    1. Medical management: limited with variable benefit; should attempt to correct the underlying problems
        1. Intralesional corticosteroids: may be beneficial because of their anti-inflammatory and inhibitory effects on fibroblast activity.
        2. Probenecid and colchicines: beneficial in some individuals with extensive calcification related to juvenile dermatomyositis.
        3. Magnesium or aluminum antacids: may be effective phosphate binders in patients with hyperphosphatemia but the use of these agents in patients with renal insufficiency may result in magnesium or aluminum toxicity.
        4. Sodium etidronate and bisphosphonates: may reduce bone turnover and inhibit the growth of ectopic hydroxyapatite crystals. Paradoxical hyperphosphatemia may result from prolonged treatment. Improvement has been observed in extended soft tissue calcification in dermatomyositis.
        5. Minocycline: successfully treated calcinosis cutis in limited systemic sclerosis (reduction of size and decrease of inflammation/ulceration).
        6. Myoinositol hexaphosphate is a dietary substance shown to inhibit the crystallization of calcium salts in animal studies and potentially could be of benefit in humans.
        7. Diltiazem: successfully treated calcinosis cutis in dermatomyositis.
        8. Ceftriaxone: effectively treated morphea profunda with calcinosis cutis.
        9. Alminum hydroxide: size reduction and softening of subcutaneous calcification in a patient with systemic lupus erythematosus after oral aluminum hydroxide.
        10. Systemic warfarin: has shown benefit in small calcified deposits but no improvement in larger, longer-standing calcinosis cutis lesions.

11. The use of the calcium-channel blocker diltiazem over at least 5 years has variable benefits. The therapeutic effect is believed to be the antagonism of the calcium-sodium ion pump.
12. Response to intravenous immunoglobulin in some patients with dystrophic calcification (Schanz et al. 2008).

2. Carbon dioxide laser: effective in small, digital calcified deposits
3. Surgical removal (Hussman et al. 1995)
    1. Indications
        1. Pain
        2. Recurrent infection
        3. Ulceration
        4. Functional impairment
    2. Initial test removal of a test site before pursuing a large excision because the surgical trauma may stimulate calcification
    3. Recurrence common after excision
4. Electric shock wave lithotripsy
    1. Anecdotally successful in dermatomyositis-induced tissue calcification
    2. Complete relief of associated pain although reduction in the size of the calcification is minimal

Fig. 1 (**a–d**) A 4-year-old boy has had numerous hard nodules in his neck, arms, legs, and trunk since early infancy. The subcutaneous hard nodules were tender and began to multiply and eventually became ulcerated. Recently he complained restricted arm and leg movement

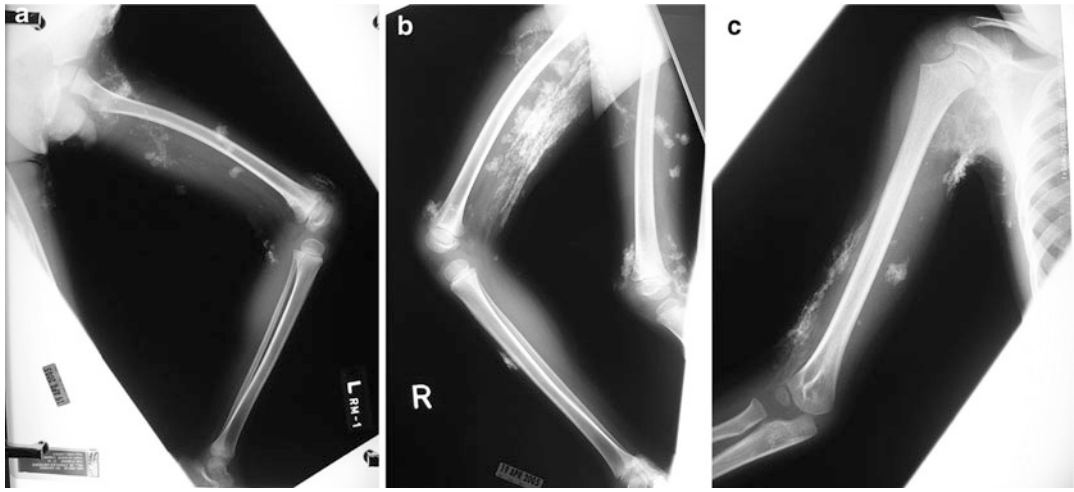

Fig. 2 (**a**–**c**) Radiologic studies revealed numerous subcutaneous calcifications throughout the body (only arm and legs are illustrated here). *GNAS1* gene mutation testing revealed no sequence variation

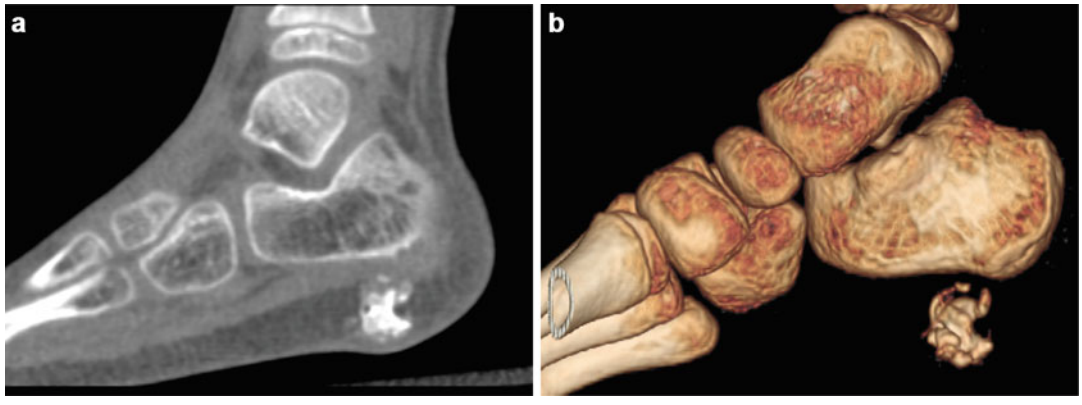

Fig. 3 (**a**, **b**) The patient was a healthy 3-year-old female with a history of a small mass on her right heel pad for over a year. Recently, she had intermittently complained of pain associated with slightly increased mass size. Plain CT (**a**) and 3D reconstruction CT (**b**) images of the right foot demonstrated an irregular calcification centered in the subcutaneous fat plantar and slightly medial to the posterior body of the calcaneus. There was an accompanying soft tissue component, with the mass being contiguous with and inseparable from the adjacent plantar musculature and overlying dermis. There was no evidence of periosteal reaction or cortical destruction of the adjacent calcaneus. The bones of the foot demonstrated normal osseous mineralization and no suspect sclerotic or lytic lesion was seen (Courtesy of Dr. Grace Guo)

Campomelic Dysplasia

Contents

Campomelic dysplasia is a rare, often lethal congenital osteochondrodysplasia associated with skeletal malformations and sex reversal. The term "campomelia" derives from Greek, meaning bent or curved limb. Since most patients die in the neonatal period due to respiratory distress, patients with campomelic dysplasia are most often sporadic but few familial cases have been reported. The incidence of campomelic dysplasia is reported to be 0.05–0.9 per 10,000 births (Iravani et al. 2000).

Synonyms and Related Disorders

Acampomelic campomelic dysplasia; Campomelic dysplasia with autosomal sex reversal; Camptomelic dysplasia

Genetics/Basic Defects

1. Inheritance
    1. Autosomal recessive (Hall and Spranger 1980)
    2. Autosomal dominant (Thurmon et al. 1973; Lynch et al. 1993) with variable expression (Savarirayan et al. 2003)
2. Etiology (Kwok et al. 1995): can be caused by heterozygous intragenic *SOX9* mutations or chromosomal aberrations (translocations, inversions, or deletions) affecting *SOX9* or the putative enhancer region (Wada et al. 2009)
    1. Assignment of a locus *CMPD1* to 17q24.3-q25.1 was based on characterization of three independent de novo chromosome 17 translocations in campomelic dysplasia patients (Tommerup et al. 1993).
    2. XY sex reversal of two of these translocation patients placed an autosomal sex-determining locus, *SRA1*, in the same region.
    3. *SOX9*, a gene related to the mammalian Y chromosome sex-determining gene SRY, was mapped to this region and found to be near the translocation breakpoint of a sex-reversed campomelic dysplasia patient.
    4. Subsequent identification of de novo mutations in sex-reversed campomelic patients

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_31

demonstrated that SOX9 is the gene responsible for both campomelic dysplasia and autosomal sex reversal (Foster et al. 1994; Schafer 2001).

5. SOX9 mutations
    1. Disrupt skeletogenesis and chondrocytic differentiation
    2. Produce defective testicular development often resulting in sex reversal with female phenotype in chromosomal XY males
6. Proof of *SOX9* being responsible for both campomelic dysplasia and XY sex reversal: demonstration of de novo heterozygous loss-of-function mutations within the SOX9 coding region in non-translocation campomelic dysplasia patients (Iravani et al. 2000).
7. Isolation of the *SOX9* gene on chromosome 17q by positional cloning in combination with positional candidate information from the vicinity of breakpoints in campomelic dysplasia patients with reciprocal de novo translocations (Meyer et al. 1977).
8. Acampomelic campomelic dysplasia (ACD) (Gopakumar et al. 2014; Castori et al. 2016)
    1. Represents about 10% of individuals with *SOX9* coding region mutations: affected by an attenuated form of campomelic dysplasia without bent bones and can be associated with a longer survival (Mansour et al. 2002).
    2. A familial acampomelic dysplasia: caused by an inherited deletion mapping upstream of the *SOX9* gene (Lecointre et al. 2009).
    3. Can result from translocations and inversions involving the long arm of chromosome 17 that disrupt the coding region of *SOX9* (Leipoldt et al. 2007).
    4. Babies with acampomelic dysplasia frequently have missense mutations within the HMG domain, as in the present case, suggesting that the mutant SOX9 protein may retain some binding activity, in contrast to nonsense or frameshift mutations (Friedrich et al. 2000; Thong et al. 2000; Moog et al. 2001).

Clinical Features

1. Clinically a heterogeneous disorder (Khajavi et al. 1976; Houston et al. 1983; Iravani et al. 2000)
    1. Long-limbed variety
        1. Bent bones of normal thickness, may be slightly shortened
        2. Rarely involves the upper limbs
    2. Short-limbed variety
        1. Bent bones that are short and wide
        2. Two skull types
            1. Craniosynostotic type with cloverleaf skull
            2. Normocephalic type
    3. Acampomelic campomelic dysplasia
        1. The eponymous feature "campomelia" (the bending of the long bones): not an obligatory feature of the syndrome
        2. Absence of campomelia in about 10% of campomelic dysplasia cases
2. Prenatal history
    1. Polyhydramnios (30% of cases) in the third trimester common
    2. Growth retardation
3. Extreme hypotonia at birth
4. Characteristic craniofacial features
    1. Frequent macro-dolichocephaly
    2. Cloverleaf skull
    3. Wide fontanel
    4. Short, narrow, and upslanted palpebral fissures
    5. Ocular hypertelorism
    6. Flat nasal bridge
    7. Long philtrum
    8. Micrognathia (Pierre Robin sequence)
    9. Cleft palate in two thirds of the cases
    10. Low-set and posteriorly rotated ears
    11. Prominent nuchal folds
    12. Hearing loss (deaf) in survivors
5. Prominent and characteristic musculoskeletal features

1. Congenital bowed lower limbs (anterior bowing of the tibiae) with pretibial skin dimples. Pretibial dimples that appear to result from the loss of subcutaneous tissue secondary to marked stretching of the skin overlying the apexes of the bony curvatures during fetal life
2. Short limbs
3. Short neck
4. Pterygium colli
5. Narrow thorax
6. Kyphoscoliosis
7. Talipes equinovarus
8. Hand anomalies
    1. Brachydactyly
    2. Clinodactyly
    3. Camptodactyly
9. Congenital dislocation of the hips
10. Winging of the scapula
11. Fewer ribs

6. Genitalia
    1. Genotypic XY males (three fourths of karyotypic males with sex reversal) (Mansour et al. 1995)
        1. External genitalia: range from an unambiguous female external genitalia to hypospadias with a bifid scrotum and an enlarged clitoris
        2. Internal genitalia: various combinations of internal Müllerian and Wolffian duct structures
    2. Genotypic XX females: remain phenotypic female
7. CNS
    1. Mental retardation in survivors
    2. Large brain
    3. Hydrocephalus (25%)
    4. Polygyria
    5. Absent olfactory bulbs and/or tracts
    6. Dysgenesis of the corpus callosum
    7. Gross cellular disorganization, especially of the cerebral peduncle, thalamus, and caudate nucleus
8. Respiratory insufficiency secondary to:
    1. Robin sequence
    2. Narrow airways due to laryngotracheobronchomalacia (the most characteristic finding)
    3. Hypoplastic lungs
    4. A small bell-shaped thorax
9. Occasional abnormalities
    1. Congenital heart diseases
        1. Patent ductus arteriosus
        2. Ventricular septal defects
        3. Coarctation of the aorta
        4. Tetralogy of Fallot
    2. Renal anomalies
        1. Hydronephrosis
        2. Hydroureter
        3. Renal hypoplasia
        4. Renal cortical and medullary cysts
    3. Ear anomalies
        1. Hypoplastic cochlea and semicircular canals
        2. Anomalies in incus and stapes
10. Diagnostic criteria (Mansour et al. 1995)
    1. Clinical
        1. Seven or more of the following: macrocephaly, micrognathia, cleft palate, flat nasal bridge, low-set ears, talipes equinovarus, congenital dislocation of hips, bowed femora, bowed tibiae, pretibial skin dimples, and respiratory distress
        2. Sex reversal and bowed lower limbs
    2. Radiological
        1. Hypoplastic scapulae
        2. Bowed femora (marked or mild)
        3. Bowed tibiae (marked or mild)
        4. Vertically narrow iliac wings
        5. Non-mineralized thoracic pedicles
11. Cause of death
    1. Usually due to respiratory insufficiency
        1. Primarily owing to airway and pulmonary defects, lack of laryngotracheobronchial cartilages and hypotonia
        2. Resulting in apneic spells, atelectasis, aspiration, and pneumonia
    2. A high rate of neonatal death
        1. Most deaths occurring neonatally (77%)
        2. 90% of deaths before 2 years
12. Life expectancy that varies depending on the severity of the phenotype
    1. Young infants who survive
        1. Feeding difficulties

2. Stridor
3. Retractions
4. Frequent otitis media
5. Bronchitis
6. Poor growth

2. Infants who survive several years
   1. May be mentally retarded
   2. May show variable breakpoints within the vicinity of chromosome 17 (q21-q25)
   3. Oldest reported survivor: 17 years of age with an IQ of 45
3. Complications of survivors of campomelic dysplasia (Mansour et al. 2002)
   1. Recurrent apnea
   2. Upper respiratory infections
   3. Progressive kyphoscoliosis
   4. Mild to moderate learning difficulties
   5. Short stature
   6. Dislocation of the hips
4. Possible explanations for the survival of patients with campomelic dysplasia
   1. Mosaicism of the *SOX9* mutations
   2. Chromosomal rearrangements involving chromosome 17q (q23.3-q25.1) shown to cause campomelic dysplasia without disrupting the *SOX9* gene, resulting in a milder phenotype (Staffler et al. 2010)

Diagnostic Investigations

1. Radiography (skeletal survey)
   1. Affected infants (Khoshhal and Letts 2002)
      1. Tubular bones
         1. Bowed femora and tibiae
         2. Short fibulae
         3. Radioulnar dislocation
      2. Thorax
         1. Severe hypoplastic, bladeless scapulae
         2. Thin short clavicles
         3. Non-mineralized sternum
         4. Small thoracic cage with slender and/or decreased number of ribs (usually 11 pairs)
      3. Spine
         1. Abnormal cervical vertebrae
         2. Kyphoscoliosis
         3. Non-mineralized thoracic pedicles
      4. Pelvis
         1. Dislocation of the hips
         2. Narrow iliac wings
         3. Poorly developed ischiopubic rami
         4. Coxa vara
      5. Hands and feet
         1. Short first metacarpal bone
         2. Talipes equinovarus
      6. Skeletal maturation
         1. Delayed bone age
         2. Delayed ossification of proximal tibial and distal femoral epiphysis and talus
   2. Survivors
      1. Hypoplastic scapulae
      2. Defective ischiopubic ossification
      3. Absent or hypoplastic patellae
      4. Spinal dysraphism
   3. Considerable radiographic overlap with ischiopubic-patella syndrome
2. Hearing screening
3. Gonadal histology (Cameron et al. 1996)
   1. Similar to XY gonadal dysgenesis
   2. Ranging from dysplastic testicular tissue to poorly differentiated ovarian tissue with a few primordial follicles
4. Histology of growth plate: unremarkable epiphyseal resting cartilage
5. Cytogenetic analysis
   1. Abnormal in about 5% of patients (Unger et al. 2013)
      1. A de novo reciprocal translocation with one breakpoint in chromosome region 17q24.3-q25.1 where SOX9 is located: rarely the translocation may be familial, thus parental karyotypes should be obtained.
      2. A de novo interstitial deletion of 17q.

2. Identification of the sex reversal (fetal karyotype does not match fetal phenotype) (Gentilin et al. 2010)

6. Molecular analysis of *SOX9* mutation (Unger et al. 2013; Carvajal et al. 2016)
    1. Molecular testing is important as affected individuals with aberration of the regulatory domain of SOX9 and chromosome rearrangement tend to have better clinical outcomes.
    2. Sequence screening of the three *SOX9* exons: to detect coding regions and splice mutations (positive in about 90%).
    3. Deletion analysis: to detect partial or whole-gene deletions by quantitative PCR, MLPA, or array CGH and by cytogenetic analyses to detect translocations or larger inversions (positive in about 5%) (Scherer et al. 2013).

Genetic Counseling

1. Recurrence risk (Unger et al. 2013)
    1. Patient's parents: risk of recurrence considered to be as low as 1% for parents in whom a negative molecular test result is obtained (Gentilin et al. 2010)
    2. Patient's sib
        1. An affected parent (non-mosaic): a 50% risk
        2. Not increased unless somatic or gonadal mosaicism or *SOX9* deletion is present in one of the parent
            1. Unaffected mother with somatic mosaicism for the *SOX9* mutation has been reported (Wagner et al. 1994).
            2. An unaffected father of three affected children was reported to have germline, but not somatic, mosaicism (Cameron et al. 1996).
            3. A *SOX9* deletion in a mildly/minimally affected father of two affected children has been reported (Smyk et al. 2007).
            4. There is an estimated recurrence risk of 5% due to the possibility of germline mosaicism in either of the parents (Cameron et al. 1996).
        3. Proband with an unbalanced chromosome constitution
            1. If neither parent has the chromosome rearrangement: a negligible risk
            2. If a parent has a balanced chromosome rearrangement: an increased risk, dependent on the specific chromosome rearrangement and the possibility of other variables
    3. Patient's offspring: provided the patient survives to the reproductive age
        1. A 50% risk to offspring when the proband has a non-mosaic *SOX9* mutation.
        2. Risk to offspring depends on the proband's cytogenetic abnormality involving *SOX9*.
2. Prenatal diagnosis (Unger et al. 2013)
    1. Possible by ultrasonography as early as 18 weeks of gestation
        1. Ultrasonographic findings (Cordone et al. 1989; Tongsong et al. 2000)
            1. Symmetrical anterior bowing of femurs and tibiae
            2. Hypoplastic or absent scapulae
            3. Small thorax compared to the abdomen
            4. Bilateral talipes equinovarus
            5. External genitalia not compatible with 46,XY karyotype
            6. Polyhydramnios
            7. Fetal growth retardation
            8. Large head with internal hydrocephalus
            9. Sagittal scan of the face showing a flat nasal bridge, elongated philtrum, and micrognathia
        2. 3D ultrasound allowing better capture of facial dysmorphic features (Promsonthi and Wattanasirichaigoon 2006)
            1. Telecanthus
            2. Depress nasal bridge
            3. Bowing of forearm
            4. Skin dimpling over the anterior surface of the bowed legs
            5. Fanlike position of the toes

3. Ultrasound findings of acampomelic campomelic dysplasia
    1. Bowing of long bones: evident until the 18th week of gestation (Preiksaitiene et al. 2015)
    2. Some fetuses may manifest with straight bones (acampomelic campomelic dysplasia) (Barone et al. 2014)
4. Major differential diagnosis of ultrasonographic features
    1. Osteogenesis imperfecta
    2. Hypophosphatasia
    3. Unclassifiable varieties of congenital bowing of the long bones
2. Amniocentesis result of 46,XY with ultrasonographic finding of female external genitalia
3. Identification of *SOX9* mutation in the fetus (Barone et al. 2014) by sequence analysis or deletion/duplication analysis: Prenatal diagnosis for pregnancies at risk as a result of a mildly affected parent or potential somatic or germline mosaicism that requires prior identification of the disease-causing mutation in a previously affected child or the mildly affected parent
4. Preimplantation genetic diagnosis for pregnancies at risk as a result of a result of a mildly affected parent or potential somatic or germline mosaicism that requires prior identification of the disease-causing mutation in a previously affected child or the mildly affected parent

3. Management
    1. Supportive medical care.
    2. Orthopedic treatment of the musculoskeletal malformations to prevent additional morbidity.
        1. Hip dislocation
        2. Bracing or spinal fusion for spinal deformity
        3. Serial casting or surgical correction for foot deformity
    3. Gonadodectomy advocated in surviving phenotypic females with Y chromosome fragments owing to the increased risk of gonadoblastoma.
    4. In mothers with severe kyphoscoliosis and preexisting ventilatory failure, nocturnal noninvasive ventilation can assist in maintaining respiratory stability during pregnancy with close observation for consideration of early delivery to avoid overt ventilatory failure (Khor et al. 2014).

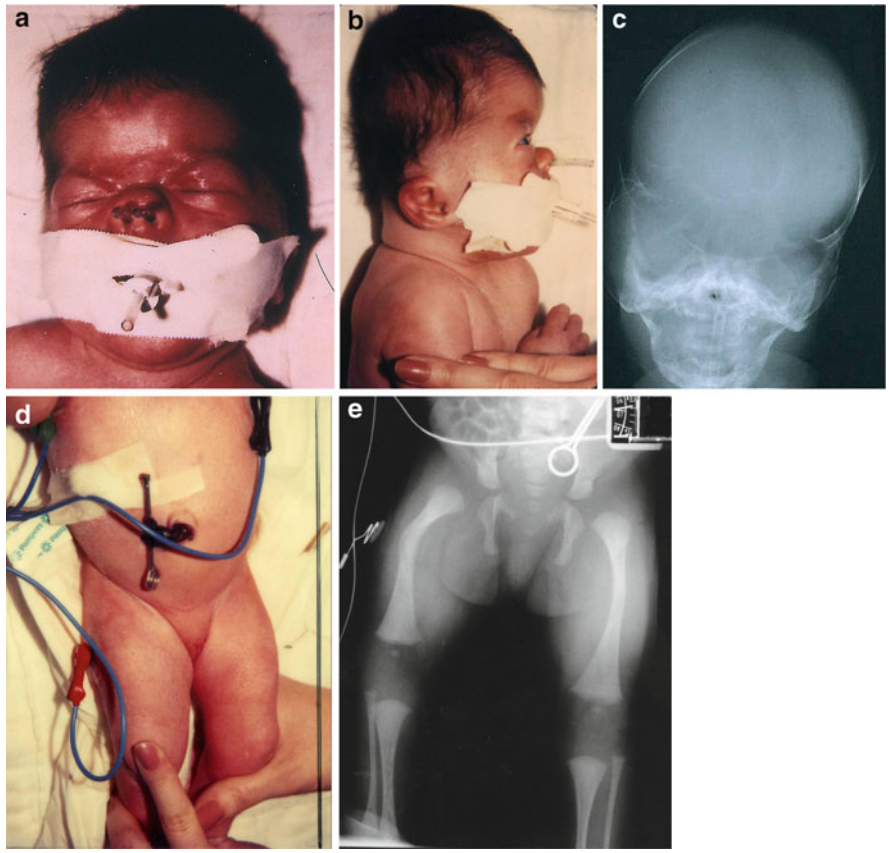

Fig. 1 (**a**–**e**) A neonate with campomelic dysplasia showing cloverleaf skull and bowed femurs, illustrated by radiographs

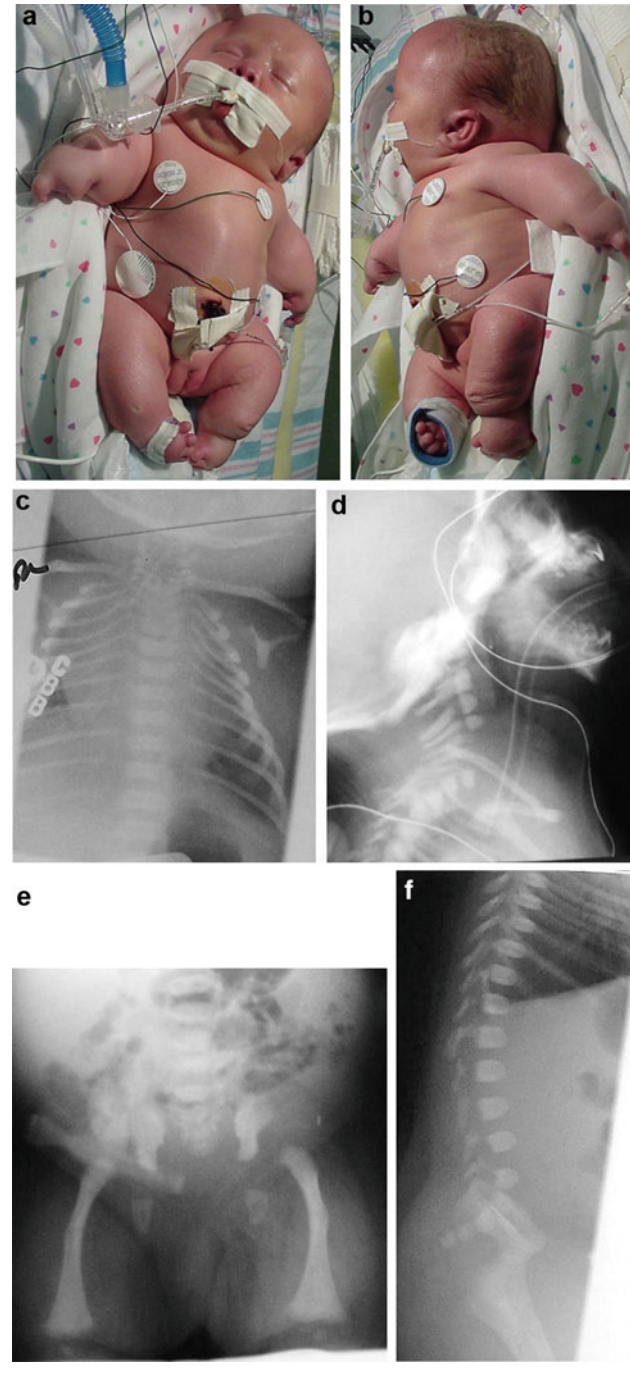

Fig. 2 (**a**–**f**) An infant with campomelic dysplasia showing bowing of the limbs with pretibial skin dimples, hypoplasia of cervical vertebra and scapula, 11 pairs of ribs, non-mineralized pedicles, *vertical*/*narrow* iliac wings, and bowing of femurs

Fig. 3 (**a**–**c**) A neonate with campomelic dysplasia showing large head, flat face, flat nasal bridge, low-set ears, micrognathia, and bowed lower legs with pretibial dimples. The radiograph showed bowing of the femora, tibia, and fibulae

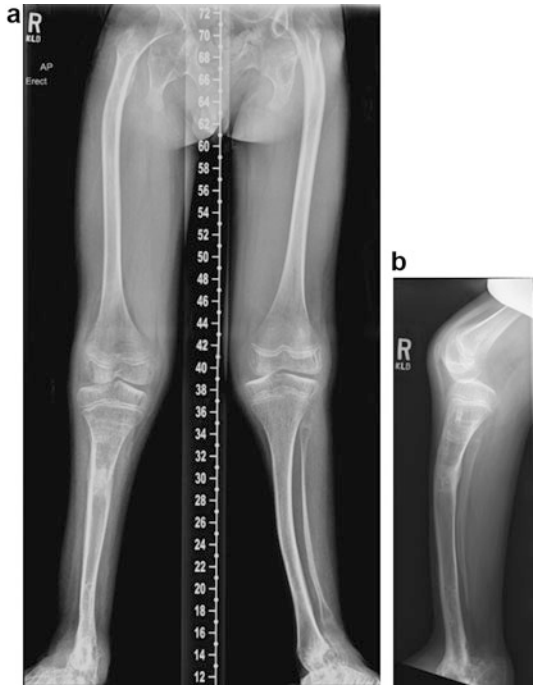

Fig. 4 A 13-year-old male was diagnosed to have camptomelic dysplasia shortly after birth. According to the mother, the diagnosis was confirmed by the genetic testing. The radiography of bilateral lower extremities demonstrated bilateral hip dislocation. There was generalized osteopenia. The femurs were mildly bowed laterally, but appeared normal. The tibiae were shortened and thin bilaterally with medial bowing on the left (**a**). Lateral view of the right tibia (**b**) showed mild anterior bowing of the tibia and partial deficiency of the distal right fibula. There was fusion of the ankle joints bilaterally. Sclerotic focus identified in the proximal third of the right tibial diaphysis corresponds to a healing lengthening osteotomy. Diffuse muscular atrophy was present (Courtesy of Dr. Grace Guo)

Carpenter Syndrome

Contents

Carpenter in 1901 (Carpenter 1901) described two living siblings and one stillborn sibling with peculiar facies, acrocephaly, brachydactyly, syndactyly of the hands, and preaxial polydactyly and syndactyly of the toes. Temtamy in 1966 (Temtamy 1966) documented 12 additional cases (ten of which were familial) and proposed the eponymous designation "Carpenter syndrome."

Synonyms and Related Disorders

Acrocephalopolysyndactyly type II; Goodman syndrome; Summit syndrome

Genetics/Basic Defects

1. An autosomal recessive inheritance: unlike other acrocephalosyndactyly syndromes or acrocephalopolysyndactyly syndrome
2. Caused by mutations in ras-like rat brain 23 (*RAB23*), a negative regulator of hedgehog signaling involved in cranial suture development (Jenkins et al. 2007; Cohen 2009)
3. Caused by mutations in the multiple epidermal growth factor-like-domains 8 (*MEGF8*) in some cases (Jenkins et al. 2007; Cohen 2009; Twigg et al. 2012)

Clinical Features

1. Marked intrafamilial variability (Cohen et al. 1987; Gershoni-Baruch 1990)
2. Marked phenotypic variability within this disorder (Perlyn and Marsh 2008)
3. Craniofacial anomalies (Perlyn and Marsh 2008)
    1. Craniosynostosis (abnormal fusion of the cranial sutures) (Cohen 2009): the basic abnormality of the craniofacial skeleton in Carpenter syndrome
        1. Premature closure of the sagittal, metopic, and lambdoid sutures, with coronal suture often remaining patent until the remaining sutures became synostotic (Marsh and Vannier 1995)
        2. Pattern of craniosynostosis at birth may vary among affected siblings.
    2. Cranial configuration (Marsh and Vannier 1995)
        1. Acrocephalic
        2. Often asymmetric

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_32

3. Marked absence or underdevelopment of the anterior cranial fossa and bulging of the middle cranial fossa
4. Maxillofacial manifestations (Carpenter 1901; Temtamy 1966; Der Kaloustian et al. 1972; Eaton et al. 1974; Poole 1993; Puri et al. 1980)
    1. Brachycephaly
    2. Flat facies with midface hypoplasia
    3. Eyes
        1. Hyper/hypotelorism
        2. Shallow orbits
        3. Epicanthal folds
        4. Corneal opacity
        5. Microcornea
        6. Optic atrophy
    4. Fat nasal bridge
    5. High-arched palate
    6. Teeth
        1. Missing teeth
        2. Delayed loss of deciduous teeth
    7. Ears
        1. Low-set/malformed ears
        2. Preauricular pits
        3. Conductive hearing loss
        4. Sensorineural hearing loss
    8. Short muscular neck
4. Acral anomalies
    1. Preaxial polydactyly of the feet: allowing differentiation from other autosomal-recessive acrocephalopolysyndactyly syndromes (Robinson et al. 1985)
    2. Clinodactyly of the fingers
    3. Brachydactyly of the hands and feet
    4. Syndactyly of the hands and feet
5. Neurologic findings: presence of phenotypic variability
    1. Dilatation of ventricles
    2. Discernible brain abnormalities
6. Growth
    1. Short stature
    2. Obesity
7. Other features
    1. Cardiovascular defects
        1. Atrial septal defect
        2. Ventricular septal defect
        3. Pulmonic stenosis
        4. Tetralogy of Fallot
        5. Transposition of the great vessels
        6. Patent ductus arteriosus
    2. Abdomen
        1. Umbilical hernia
        2. Omphalocele
    3. Genitourinary tract anomalies
        1. Cryptorchidism
        2. Hydronephrosis
        3. Hydroureter
    4. Other skeletal anomalies
        1. Spine
            1. Pilonidal dimple
            2. Absent coccyx
            3. Spina bifida occulta
            4. Scoliosis
        2. Pelvis
            1. Coxa valga
            2. Decreased hip joint mobility
            3. Flared ilia
        3. Limbs
            1. Genu valgum
            2. Lateral displacement of patellae
    5. Endocrine features
        1. Hypogenitalism
        2. Precocious puberty
    6. Learning disability
8. Cohen syndrome, Goodman syndrome, and Summit syndrome: fall within the clinical spectrum of the same disorder (Cohen et al. 1987; Gershoni-Baruch 1990)

Diagnostic Investigations

1. Radiography/CT scan of the skull
    1. Craniosynostosis
        1. Sagittal suture
        2. Metopic suture
        3. Lambdoidal suture
        4. Coronal suture
    2. Cranial configuration: acrocephalic and often asymmetric
2. Radiography of the hands and feet
    1. Polysyndactyly
    2. Brachydactyly
    3. Clinodactyly
3. Molecular genetic testing of *RAB23* and *MEGF8* mutations: not available clinically at present

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: 25%
    2. Patient's offspring: not increased unless the spouse is also a carrier, in which case there is a 50% risk of having an affected offspring
2. Prenatal diagnosis (Haye et al. 2014)
    1. Ultrasonography: abnormal craniofacial shape with polysyndactyly of the hands and feet
    2. Fetal CT scan: preaxial hexadactyly of the feet and bowed femora
    3. Fetal bone CT scan: abnormal shape of the skull with partial synostosis of the sagittal and left lambdoid sutures
    4. Molecular genetic diagnosis: A novel *RAB23* mutation in a fetus with Carpenter syndrome (Haye et al. 2014)
3. Management
    1. Correction of skull malformations within the first year of infancy
    2. Reconstructive management for cranial abnormalities, hypotelorism and hypertelorism, ear abnormalities, and maxillary and mandibular hypoplasia (Kadakia et al. 2014)
    3. Correction of other anomalies
        1. Congenital heart defects
        2. Polysyndactyly
    4. Care for eyes, vision, and hearing impairments
    5. Intervention programs
        1. Speech therapy
        2. Occupational therapy
    6. Dietary control for obesity

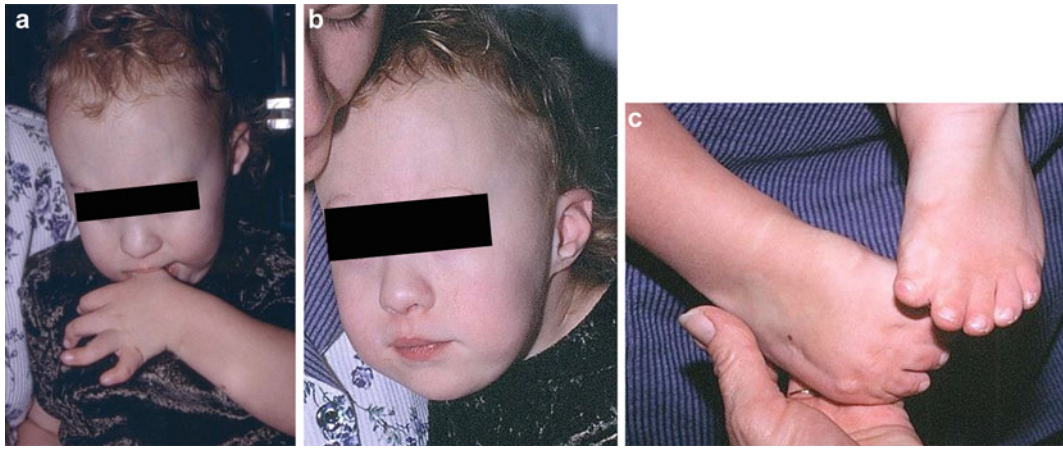

Fig. 1 (**a**–**c**) A two-and-a-half-year-old girl had a cone-shaped head, clinodactyly of the 5th fingers, and extra big toes of both feet (surgically excised at 1 month of age). The patient also had no opening of the anterior fontanel which was surgically repaired. She was noted to have brachycephaly, shallow orbits, high forehead, scanty eyebrows, lateral displacement of inner canthi, operation scars on the coronal sutures and sagittal suture, low-set malformed ears, small chin, high-arched palate, and operation scar for the umbilical hernia. Fingers and toes were abnormal with brachydactyly, clinodactyly, syndactyly, and polydactyly (surgically excised)

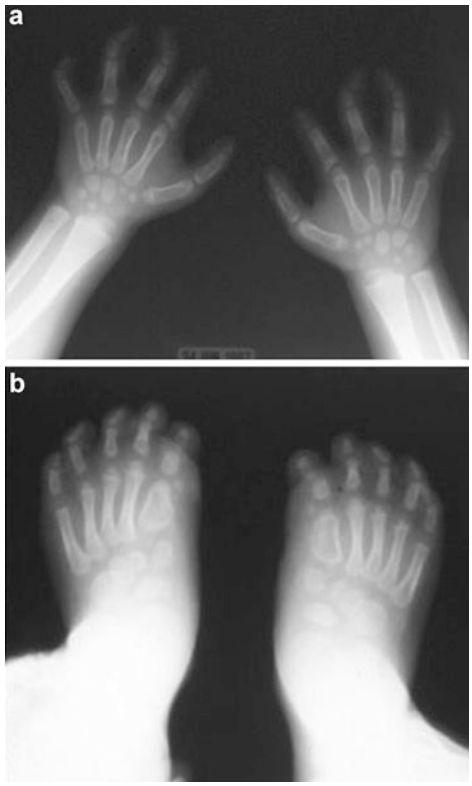

Fig. 2 (**a**, **b**) X-ray of hands and feet

Fig. 3 Patient at 10 years of age

Cat Eye Syndrome

Contents

Cat eye syndrome is a clinically recognizable congenital malformation syndrome consisting primarily of colobomas, anal anomalies, preauricular anomalies, cardiac and renal defects, and mild to moderate mental retardation. The name "cat eye" was introduced because of iris colobomas resembling the pupils of the cat.

Synonyms and Related Disorders

Chromosome 22 partial tetrasomy inv dup(22)(q11); Schmid-Fraccaro syndrome

Genetics/Basic Defects

1. Historic background
   1. In 1965, an extra bisatellited marker chromosome was described in patients with cat eye syndrome phenotype (Schachenmann et al. 1965).
   2. Later in 1981, the marker was determined to be an inverted dicentric duplication of a part of chromosome 22 [inv dup(22)(pter → q11::q11 → pter)].
2. Molecular and cytogenetic bases
   1. Associated with the presence of three copies (partial trisomy) or four copies (partial tetrasomy) (Schinzel et al. 1981; Wilson et al. 1984; McDermid et al. 1986; Liehr et al. 1992) of a segment of chromosome 22q11.2, usually in the form of a bisatellited, isodicentric supernumerary chromosome (Footz et al. 2001).
   2. Formation of transient or unstable dic r (22) during early fetal development, which subsequently are lost from most cells, resulting in cat eye syndrome features.
   3. The minimal common duplication required to produce features of cat eye syndrome (the cat eye syndrome critical region) (Mears et al. 1995): defined by the dic r(22) patient, breakpoints between proximal locus ATP6E and distal locus D22S57, and covering approximately 2 Mb of 22q11.2.
   4. Maternal origin of the supernumerary chromosome in cases studied (Magenis et al. 1988).
   5. Direct correlations between the extent of duplicated chromosome 22 materials and the severity of the cat eye syndrome remain difficult (McTaggart et al. 1998).
   6. Human homolog of insect-derived growth factor, *CECR1*: a candidate gene for

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_33

features of cat eye syndrome (Riazi et al. 2000).
7. Occurrence of direct transmission of supernumerary marker chromosome (Kvarnung et al. 2012):
    1. Presence of a direct correlation between the degree of mosaicism and the symptoms, varying from no obvious symptoms to classical cat eye syndrome
    2. Examination of parental epithelial cells: preferred to blood cells in order to exclude a recurrence risk in parents of a child with cat eye syndrome
    3. Interphase FISH analysis of spermatozoa: the most sensitive method to exclude paternal germ line mosaicism
3. 22q11.2 region (Jezela-Stanek et al. 2009)
    1. Highly susceptible to chromosomal rearrangement: mediated by low-copy repeats causing nonallelic homologous recombination (Stankiewicz and Leepski 2002).
    2. A variety of clinical disorders are associated with either increased or decreased gene dosage (McDermid and Morrow 2002).
        1. Most common: DiGeorge/velocardiofacial syndrome caused by microdeletion of 22q11.2
        2. Other well characterized but less frequently recognized disorders:
            1. Cat eye syndrome (CES) because of 22pter-q11 trisomy/tetrasomy
            2. Emanuel syndrome – the result of unbalanced 11, 22 chromosomal translocation, resulting in der (22) (22pter-22q11: 11q23-11qter) (Zackai and Emanuel 1980)
        3. Other 22q11.2 rearrangements have been recognized recently.
            1. Microduplication 22q11.2 (Yobb et al. 2005; Kriek et al. 2006; Courtens et al. 2008)
            2. Triplication 22q11.2 (Yobb et al. 2005)
            3. Deletion of CES critical region (Kriek et al. 2006)
            4. 22q11.2 distal deletion (Ben-Shachar et al. 2008)
            5. Aberrations resulting in CES phenotype: proximal 22q duplication (Lindsay et al. 1995; Feenstra et al. 2006) or interstitial duplication 22q11 (Ensenauer et al. 2003)

Clinical Features

1. Marked phenotypic variability (Guanti 1981; Berends et al. 2001; Rosias et al. 2001)
2. Major features
    1. Preauricular skin tags and/or pits: most consistent features
    2. Ocular coloboma
    3. Congenital heart defect (Freedom and Gerald 1973)
        1. Ventricular septal defect
        2. Total anomalous pulmonary venous connection
        3. Atrial septal defect
        4. Patent ductus arteriosus
        5. Pulmonary stenosis
        6. Aortic malformation
        7. Tricuspid atresia
        8. Hypoplastic left heart syndrome
    4. Anorectal malformations
        1. Anal atresia or imperforate anus
        2. Anal stenosis
        3. Anorectal atresia
        4. Ectopic anus
        5. Associated rectal fistulas
    5. Urogenital malformations
        1. Male external genital malformation
        2. Renal agenesis/hypoplasia
        3. Hydro(uretero)nephrosis
        4. Vesicoureteral reflux
        5. Female genital malformation
        6. Renal dysplasia or polycystic kidney
        7. Bladder defects
        8. Renal cystic malformation
        9. Ectopic/horseshoe kidney
3. Minor features
    1. Craniofacial abnormalities
        1. Microcephaly
        2. Ocular abnormalities
            1. Downslanting palpebral fissures

2. Hypertelorism
3. Ocular motility defect
4. Epicanthal folds
5. Microphthalmia

3. Oral abnormalities
1. Micrognathia
2. Cleft palate or absent uvula

4. Low-set or dysplastic ears

2. Skeletal abnormalities
1. Arm or hand deformity
2. Leg or foot deformity
3. Scoliosis or chest deformity
4. Vertebral anomaly
5. Congenital dislocation of the hip
6. Rib or sternal anomaly

3. Abdominal abnormalities
1. Umbilical hernia
2. Malrotation of the gut
3. Hirschsprung or megacolon
4. Biliary atresia or choledochal cyst
5. Volvulus
6. Meckel diverticulum

4. Neurodevelopmental outcome
1. Growth and development
1. Short stature
2. Mental development: markedly variable
1. Normal-borderline normal
2. Mild-moderate retardation
3. Severe mental retardation

2. Neurological abnormalities
1. Dysregulation of muscle tone
2. Visual defect
3. Hearing impairment
4. Ventricular dilatation
5. Abnormal slow EEG
6. Seizures
7. Spasticity
8. Cerebral or cerebellar atrophy
9. Hyperactive behavior
10. Ataxia
11. Facial nerve palsy

Diagnostic Investigations

1. Chromosome analysis from blood and other tissues (Crolla et al. 1997)
1. Conventional cytogenetic study
2. Molecular (array comparative genomic hybridization) (Córdova-Fletes et al. 2012; Haltlrich et al. 2014) and FISH studies to determine small supernumerary marker (22) chromosomes

2. Radiography for limb defect
3. Echocardiography for congenital heart defects
4. Renal ultrasonography for renal anomalies
5. Developmental evaluation

Genetic Counseling

1. Recurrence risk
1. Patient's sib: a small recurrence risk because of possible presence of germ line mosaicism
2. Patient's offspring
1. Patients with an inv dup(22): 50%
2. Patients with mosaic form of an inv dup (22): lower than 50%, depends on the percentage of the marker chromosomes
3. A review of sporadic and familial cases illustrate the heterogeneity of the syndrome and the challenge to genetic counseling (Bofinger and Soukup 1977)

2. 2D/3D ultrasonography; may show severe prenatal presentation of cat eye syndrome such as microretrognathia and low-set ears (Jedraszak et al. 2013)
3. Prenatal diagnosis by amniocentesis or CVS
1. Presence of a bisatellited, dicentric supernumerary chromosome
2. FISH with a chromosome 22-specific cosmid probe to identify chromosome 22 (Beeser et al. 1994)
3. Molecular characterization of mosaicism for a small supernumerary marker chromosome derived from chromosome 22 associated with cat eye syndrome (Chen et al. 2013)

4. Management
1. Supportive
2. Surgery
1. Congenital heart defect
2. Anorectal anomalies
3. Urogenital anomalies

4. Gastrointestinal anomalies
5. Skeletal anomalies

3. Potential anesthetic risks (Devavaram et al. 2001)
   1. Potential difficult airway management
   2. Congenital heart disease
   3. Renal and hepatic dysfunction

The radiographs (**c**, **d**) show bilateral radial aplasia/hypoplasia with missing thumbs. The patient has a supernumerary marker chromosome 22 (*circled*), illustrated by the chromosome spread (**e**)

Celiac Disease

Contents

Celiac disease is a gastrointestinal disorder characterized by chronic inflammation of the small intestine that can develop in genetically susceptible individuals ingesting proteins in wheat (gliadin), rye (secalin), and barley (hordein), collectively called gluten. The prevalence of celiac disease in the United States and Canada is as high as 0.5–1%, similar to earlier estimates outside North America (Hill et al. 2000).

Synonyms and Related Disorders

Celiac sprue; Gluten-sensitive enteropathy

Genetics/Basic Defects

1. Pathogenesis
    1. Celiac disease occurs in genetically susceptible individuals who ingest gluten, a protein found in certain grains.
    2. Caused by a combination of adaptive and innate immune responses that both are triggered by gluten (Koning 2005).
    3. Gluten causes an abnormal T-cell-mediated immune response and inflammatory injury to the mucosa of the small intestine, resulting in malabsorption of nutrients in these individuals.
    4. Gliadin fraction of gluten is mainly responsible for this intestinal damage.
    5. Approximately 97% of individuals with celiac disease have genetic markers on chromosome 6 called human leukocyte antigen (HLA) DQ2 and HLA DQ8, compared with 40% of the general population.
    6. T-cell and B-cell immunity in celiac disease (du Pré and Sollid 2015).
        1. T cells and B cells
            1. Heavily involved in the pathogenesis of celiac disease.
            2. Their cooperation may be crucial for the generation of antibodies as well as the amplification of the gluten-reactive T-cell response.
        2. T-cell epitopes: generated as a result of resistance to proteolytic digestion, substrate affinity to the deamidating enzyme TG2, and their binding to HLA-DQ2.5, HLA-DQ2.2, and HLA-DQ8 molecules
        3. Presence of limited number of mutations in TG2 (transglutaminase 2)- and gluten-reactive IgA plasma cells

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_34

7. An individual's intolerance to gluten is lifelong and self-perpetuating because of this genetic predisposition.

2. A multifactorial disorder with complex genetics (Sollid 2002; Sollid and Lie 2005)
    1. Interplay between genetic and environmental factors
        1. Gluten (consisting of the gliadin and glutenin subcomponents): a critical environmental component
        2. Both HLA and non-HLA genes: considered to be predisposing genetic factors
        3. HLA as a necessary but not sufficient genetic factor for celiac disease development
            1. HLA-DQ as the chief locus mediating the HLA-linked effect in celiac disease.
            2. The great majority of the patients carry a variant of DQ2 (*DQA1*05/DQB1*02*).
            3. A minority of the patients carry DQ8 (*DQA1*03/DQB1*0302*).
    2. HLA molecules
        1. The role of the molecules: to bind and present peptide fragments to T cells.
        2. Different HLA molecules thus present different sets of peptides.
        3. Gluten-reactive T cells of the celiac intestinal mucosa uniquely recognize gluten peptides in the context of DQ2 and DQ8, suggesting that these HLA molecules predispose to celiac disease by preferentially presenting gluten peptides to CD4 T cells (Lundin et al. 1994).
    3. Genetic variants associated with disease risk (Dieli-Crimi et al. 2015)
        1. Six MHC (major histocompatibility complex) and 39 non-MHC loci plus additional regions: recently implicated in the disease.
        2. The firmly described genetic variants: account for roughly 31% of celiac disease heritability, being 25% explained by the MHC influence.
        3. Forty-one different loci have been identified, explaining 47% of the genetic variation (Ricaño-Ponce et al. 2015).
3. Metabolomics investigation of celiac disease: accounts for following three different but complementary components (Calabrò et al. 2014)
    1. Malabsorption
    2. Energy metabolism
    3. Alterations in gut microflora and/or intestinal permeability
4. Prevalence of the disease (Fersano et al. 2003)
    1. 4.54% among first-degree relatives of patients with celiac disease
    2. 0.75% in the not-at-risk subjects

Clinical Features

1. Variable clinical presentations may lead to difficulty in diagnosis (Poon and Nixon 2001; Farrell and Kelly 2002; Westerberg et al. 2006; Fasano and Catassi 2012; Ediger and Hill 2014; Guandalini and Assiri 2014).
    1. Signs and symptoms of celiac disease in children
        1. Onset: classically between the ages of 4 and 24 months
        2. Abdominal distention/bloating
        3. Chronic or recurrent diarrhea (more typical)
        4. Constipation
        5. Vomiting
        6. Pallor and edema
        7. Iron deficiency (alopecia, pruritus, aphthous ulceration, angular stomatitis, glossitis, and koilonychia)
        8. Zinc deficiency (alopecia)
        9. Vitamin B_{12} (folic acid) deficiency (angular stomatitis, glossitis, aphthous ulcers, pigmentation)
        10. Rickets
        11. Delayed puberty
        12. Growth failure (failure to thrive)
        13. Behavioral disturbances (depression, irritability, may perform poorly in school)

2. Signs and symptoms of celiac disease in adults (Cranney et al. 2007)
    1. Abdominal pain (83%)
    2. Chronic diarrhea (76%)
    3. Infertility or recurrent spontaneous abortion
    4. Iron deficiency anemia
    5. Irritable bowel syndrome (29%) (Verdu et al. 2009)
    6. Peripheral neuropathy
    7. Persistent fatigue/malaise
    8. Weight loss (69%)
3. Nongastrointestinal manifestations of celiac disease
    1. Anemia or iron deficiency
    2. Aphthous stomatitis
    3. Ataxia
    4. Behavioral problems
    5. Dental enamel defects
    6. Depression
    7. Dermatitis herpetiformis
    8. Epilepsy with intracranial calcifications
    9. Headaches
    10. Hypotonia
    11. Infertility
    12. Neuropathy
    13. Osteopenia
    14. Osteoporosis
    15. Pubertal delay
    16. Short stature
    17. Transaminase elevation
4. Associated conditions
    1. Alopecia areata
    2. Autoimmune disorders
    3. Chronic alopecia
    4. Cutaneous vasculitis
    5. Diabetes mellitus (type I) (3–12%)
    6. Dermatitis herpetiformis
    7. Down syndrome
    8. Epilepsy
    9. Erythema elevatum diutinum
    10. Idiopathic dilated cardiomyopathy
    11. Immunoglobulin A deficiency (2–8%)
    12. Immunoglobulin A nephropathy
    13. Microscopic colitis
    14. Osteoporosis or other bone diseases
    15. Rheumatoid arthritis
    16. Sjögren syndrome
    17. Systemic lupus erythematosus
    18. Thyroiditis
    19. Turner syndrome
    20. Williams syndrome
    21. Turner syndrome
    22. Type I diabetes mellitus
2. Causes of persistent symptoms in celiac disease (Mooney et al. 2014)
    1. Continued exposure to gluten
    2. Bacterial overgrowth of the small bowel
    3. Exocrine pancreatic insufficiency
    4. Microscopic colitis
    5. Irritable bowel syndrome
    6. Lactose intolerance
    7. Refractory celiac disease
    8. Cancer (small bowel lymphoma or adenocarcinoma)
3. Complications (Farrell and Kelly 2002)
    1. Refractory sprue
    2. Enteropathy-associated T-cell lymphoma
    3. Carcinoma of the oropharynx, esophagus, and small bowel
    4. Ulcerative jejunoileitis
    5. Collagenous sprue
4. Differentiation from non-celiac gluten sensitivity (Rubio-Tapia et al. 2013)
    1. Symptoms or symptom response to a gluten-free diet alone should not be used to diagnose celiac disease, as these do not differentiate celiac disease from non-celiac gluten sensitivity.
    2. A diagnosis of non-celiac gluten sensitivity should be considered only after celiac disease has been excluded with appropriate testing.
5. Changing celiac disease pattern
    1. Less frequent so-called classic/typical celiac disease with a malabsorption syndrome in childhood. The symptomatic cases (about 10%) are considered to be the tip of the iceberg (Kaukinen et al. 2002).
    2. Increasingly common to diagnose children who have subtle or no gastrointestinal or nongastrointestinal symptoms (Ravikumara et al. 2006).

Diagnostic Investigations

1. Initial serology tests before eliminating gluten from diet (Hill et al. 2005; Rostom et al. 2006; Westerberg et al. 2006).
    1. IgA-tissue transglutaminase (tTG) antibody and endomysial antibody (EMA) (performed to identify candidates for duodenal biopsy)
    2. Total serum IgA (performed to identify individuals with IgA deficiency)
2. Serologic tests are helpful in screening at-risk populations for celiac disease (Rashid et al. 2009).
    1. Helpful in screening at-risk populations for celiac disease, such as:
        1. First- and second-degree relatives of patients with celiac disease (Gudjónsdóttir et al. 2004)
        2. Individuals with type 1 diabetes mellitus and other autoimmune endocrinopathies
        3. Individuals with atypical symptoms
    2. Serum antigliadin antibody (AGA) assay (IgG and IgA) for the general population screening feasible (Catassi et al. 1994).
    3. Anti-deamidated gliadin-related peptide (a-DGP) antibodies IgA and IgG: detect antibodies binding synthetic deamidated gliadin-related peptides (DGPs) (Liu et al. 2007; Niveloni et al. 2007).
    4. An over-the-counter home self-testing kit for celiac disease has recently been marketed in Canada. Using a tiny blood sample obtained by a pinprick of the fingertip, the home blood test identifies the tTG antibodies present in the blood of those with celiac disease. This test is for screening only and should not replace a medical diagnosis.
    5. Serum tests for the diagnosis of celiac disease (Fasano and Catassi 2012).
        1. IgA anti-tTG (tissue transglutaminase) antibodies
        2. IgG anti-tTG antibodies
        3. IgA antiendomysial antibodies
        4. IgG DGP (deamidated gliadin peptides)
        5. *HLA-DQ2* or *HLA-DQ8*
3. The diagnosis of celiac disease still requires upper gastrointestinal endoscopy (Balaban et al. 2015) and the biopsy findings of typical histologic alterations of the small intestinal mucosa of patients eating gluten (Rodrigues and Jenkins 2008).
4. Histopathology of celiac mucosa (Sollid 2002):
    1. Villus atrophy
    2. Enlarged hyperplastic crypts
    3. Increased infiltration of lymphoid cells in the lamina propria and epithelium
5. A clinical response on a gluten exclusion diet: considered to be important in diagnosis.
6. Recent recommendations also include HLA genotyping as a diagnostic adjunct (Hill et al. 2005).
    1. DQ2 heterodimer (encoded by specific *HLA-DQA1**05 alleles and specific *HLA-DQB1**02 alleles)
    2. DQ8 heterodimer (encoded by specific *HLA-DQA1**03 and *HLA-DQB1**0302 alleles)
    3. Clinical molecular testing by targeted mutation analysis to determine *HLA-DQA1* and *HLA-DQB1* genotypes to detect the presence or absence of the celiac disease-associated alleles, *HLA-DQA1**0501, *HLA-DQA1**0505, *HLA-DQB1**0201, *HLA-DQB1**0202, and *HLA-DQB1**0302 (Taylor et al. 2015)
7. Diagnosis of celiac disease: "four out of five rule" (Catassi and Fasano 2010; Sapone et al. 2012)
    1. Typical symptoms of celiac disease
    2. High-titer elevated celiac disease antibodies
    3. A compatible HLA haplotype (DQ2 or DQ8)
    4. Enteropathy found on small bowel biopsy
    5. Response to a gluten-free diet
8. Informing an individual that she or he is the carrier of predisposing genes has an ethical aspect, and the possibility of a psychological impact of an HLA test in relation to celiac disease must be considered (Sollid and Lie 2005). The presence of celiac disease predisposing HLA alleles means little, whereas

the absence of the same HLA alleles makes celiac disease an improbable disorder for that patient.

Genetic Counseling

1. Recurrence risk (Taylor et al. 2015)
    1. Patient's sib
        1. The overall empiric risk for celiac disease in sibs of a proband is 7–20% if the HLA haplotype is not known (Treem 2004).
        2. If the HLA haplotype of the parents is known, the risk to the sibs can be refined.
        3. Sibs who share the same celiac disease-susceptibility HLA haplotype with the proband have a risk of developing celiac disease that approaches 40% (Treem 2004).
        4. The risk to a sib of having celiac disease is estimated at 23.6% when multiple family members are affected (Gudjónsdóttir et al. 2004).
        5. If a parent of the proband has the DQ2 celiac disease-susceptibility haplotype in *cis* configuration or the DQ8 celiac disease-susceptibility HLA haplotype, the risk to each sib of inheriting the celiac disease-susceptibility HLA haplotype is 50%.
        6. If one parent of the proband has half of the DQ2 heterodimer (*HLA-DQA1**0501 or *0505) and the other parent has half of the DQ2 heterodimer (*HLA-DQB1**0201 or *0202), the risks to sibs are as follows:
            1. Risk of inheriting both HLA haplotypes and having the full DQ2 heterodimer encoded in *trans* configuration: 25%
            2. Risk of inheriting half of the DQ2 heterodimer (*HLA-DQA1**0501 or *0505) or (*HLA-DQB1**0201 or *0202): 50%
            3. Risk of inheriting neither the *HLA-DQA1**0501 or *0505 nor the *HLA-DQB1**0201 or *0202 celiac disease-susceptibility haplotype: 25%
    2. Patient's offspring
        1. The overall risk for celiac disease in offspring of a proband is 5–10% if the celiac disease-susceptibility HLA haplotype is not known.
        2. The risk increases when the offspring has the DQ2 celiac disease-susceptibility HLA haplotype and/or the DQ8 celiac disease-susceptibility HLA haplotype (Treem 2004).
        3. The risk is lower when only half of the DQ2 heterodimer (i.e., the *DQA1* sequence variant **or** the *DQB1* sequence variant, but not both) is present (Qiao et al. 2005).
        4. Each child of an individual with the DQ2 celiac disease-susceptibility HLA haplotype or the DQ8 celiac disease-susceptibility HLA haplotype has a 50% chance of inheriting the celiac disease-susceptibility HLA haplotype.
        5. The child of a proband who has the DQ2 celiac disease-susceptibility HLA haplotype in the *trans* configuration will inherit one of the celiac disease-susceptibility HLA haplotypes from the affected parent.
        6. Because the DQ2 or DQ8 heterodimer is found in 30–40% of the general population, testing the proband's reproductive partner is appropriate.
2. Prenatal diagnosis: While technically possible, prenatal testing of celiac disease-susceptibility HLA haplotypes does not seem relevant in this complex disorder (Taylor et al. 2015)
    1. The genetic change is common in the general population.
    2. The genetic change is predisposing to, but not predictive of, celiac disease.
    3. A highly effective treatment is available.
3. Management
    1. Gluten-free diet (Ediger and Hill 2014).
        1. All those with a confirmed diagnosis of celiac disease should follow a strict gluten-free diet for life.

2. A gluten-free diet involves complete elimination of all foods that contain gluten, including, but not limited to, wheat, barley, and rye ingredients.
3. Oats should not be ingested unless they are guaranteed pure and free of contamination with wheat flour.
4. Gluten-free grains and starches:
    1. Amaranth
    2. Arrowroot
    3. Buckwheat
    4. Corn
    5. Flax
    6. Nuts, bean, and seed flour
    7. Millet
    8. Potato starch, potato flour
    9. Quinoa
    10. Rice, rice bran
    11. Sago
    12. Sorghum
    13. Soybean
    14. Tapioca flour
    15. Teff
5. Avoid all beers, lagers, ales, and stouts.
6. Wine, liqueurs, most ciders, and other spirits, including whiskey and brandy, are allowed.
7. Give essential medications parenterally initially if malabsorption is severe.
8. All patients with celiac disease should be referred to a nutritionist with specialized knowledge of celiac disease and the gluten-free diet.
9. Many patients cope easily.
10. Some patients may find that the dietary restrictions are laborious, negatively influencing their quality of life.
11. Requires strict adherence to a gluten-free diet for life for symptomatic and asymptomatic children with characteristic histological findings on small bowel biopsy.
12. Compliance with the gluten-free diet is often incomplete among celiac disease patients.
13. When maintained on a long-term gluten-free diet (including wheat starch-based gluten-free flours), there is probably no increase in mortality, morbidity, or malignancies (Holmes et al. 1989) in patients with celiac disease over the population in general, although there are conflicting reports whether gluten-free food completely eliminates all risks (Green et al. 2003).
2. Treat nutritional deficiencies and osteoporosis.
3. Future therapeutic options (Sollid and Khosla 2005):
    1. Oral enzyme supplementation is designed to accelerate gastrointestinal degradation of proline-rich gluten, especially its proteolytically stable antigenic peptides.
    2. Complementary strategies aiming to interfere with activation of gluten-reactive T cells include the inhibition of intestinal tissue transglutaminase activity to prevent selective deamidation of gluten peptides and blocking the binding of gluten peptides to the HLA-DQ2 or HLA-DQ8 molecules.
    3. Other possible treatments include cytokine therapy and selective adhesion molecule inhibitors that interfere with inflammatory reactions, some of which are already showing promise in the clinic for other gastrointestinal diseases.

Fig. 1 A 3-year-old girl was healthy until 1 year of age when she developed severe watery diarrhea and abdominal distention for approximately a year and 9 months. She was diagnosed to have gluten-induced gastroenteropathy. The diarrhea stopped immediately upon withdrawal of gluten. She has been healthy since then. Her 18-month-old brother was admitted to a local hospital at 11 days of age for 6 days including 3 days of intensive care stay for a respiratory syncytial virus bronchiolitis. He again developed RSV infection at 2 months of age. In addition, he developed severe watery diarrhea with abdominal distention which improved upon discontinuation of gluten from his diet. He has since been healthy. HLA allelic variants associated with celiac disease were detected in both siblings: DQ2 heterodimer (HLA DQA1*05/DQB1*02). These alleles are present in 96–99% of confirmed celiac disease

Cerebral Palsy

Contents

Cerebral palsy (CP) is currently considered as a clinically defined symptom complex applied to individuals with a static, nonprogressive motor impairment of early onset that is cerebral in origin. It describes a group of motor impairment syndromes secondary to genetic and acquired disorders of the developing brain. Therefore, it is not a single entity with respect to pathogenesis but rather an etiologically heterogeneous entity with multiple possible causes that result in an aberration or injury to the maturing central nervous system. The motor disorders of cerebral palsy are often accompanied by disturbances of sensation, cognition, communication, perception, and/or behavior and/or by a seizure disorder. The prevalence is estimated between 1.5 and 2.5 per 1,000 live births (Ferriero 1999).

Synonyms and Related Disorders

Ataxic–hypotonic CP; Dyskinetic CP; Mixed CP; Monoplegic/hemiplegic CP; Spastic diplegic CP; Spastic quadriplegic CP; Spastic triplegic CP

Genetics/Basic Defects

1. Components of CP classification (Bax et al. 2005)
    1. Motor abnormalities
        1. Nature and typology of the motor disorder
            1. Tonal abnormalities assessed on examination (e.g., hypertonia or hypotonia)
            2. Diagnosed movement disorders (e.g., spasticity, ataxia, dystonia, or athetosis)
        2. Functional motor abilities: motor function in all body areas, including oromotor and speech function
    2. Associated impairments
        1. Presence or absence of associated non-motor neurodevelopmental or sensory problems
            1. Seizures
            2. Hearing or vision impairments
            3. Attentional, behavioral, communicative, and/or cognitive deficits

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_35

2. The extent to which impairments interact in individuals with cerebral palsy
3. Anatomic and radiological findings
    1. Anatomic distribution (the parts of the body affected by motor impairments or limitations), e.g.:
        1. Limbs
        2. Trunk
        3. Bulbar region
    2. Radiological findings: the neuroanatomic findings on computed tomography or magnetic resonance imaging, e.g.:
        1. Ventricular enlargement
        2. White matter loss
        3. Brain anomaly
4. Causation and timing
    1. Clearly identified cause
        1. Usually postnatal CP (e.g., meningitis or head injury)
        2. Brain malformations (Garne et al. 2008; Krägeloh-Mann and Cans 2009)
    2. Presumed time frame during which the injury occurred, if known

2. Common etiologies of cerebral palsy (Paneth 1986; Kuban and Leviton 1994; Shevell et al. 2003; Russman and Ashwal 2004; Dodge 2008)
    1. Before pregnancy
        1. History of fetal wastage
        2. Long menstrual cycles
    2. Prenatal onset
        1. Low social class
        2. Brain malformations
        3. Intrauterine infection such as cytomegalovirus infection
        4. In utero stroke
        5. Toxemia
        6. Placental abruption
        7. Low birth weight
        8. Fetal growth retardation
        9. Twin gestation
        10. Abnormal fetal presentation
    3. Perinatal onset
        1. Hypoxic-ischemic encephalopathy (birth asphyxia)
        2. Viral encephalitis
        3. Meningitis
        4. Kernicterus
        5. Trauma
    4. Postnatal onset
        1. Newborn encephalopathy
        2. Infection
        3. Accidental head trauma
        4. Anoxic insult
        5. Child abuse
        6. Progressive hydrocephalus
3. Occurrence of CP phenotype has been seen in a variety of recognizable genetic syndromes including (Fisher and Russman 1974)
    1. Coffin–Lowry syndrome
    2. Cerebro-oculo-facio-skeletal syndrome
    3. Rett syndrome
    4. Angelman syndrome
    5. Hereditary spastic paraplegia
    6. Pelizaeus–Merzbacher spectrum
    7. West syndrome (infantile spasm and status dystonicus)
4. Recently described metabolic conditions associated with cerebral palsy phenotype (Schaefer 2008)
    1. Glucose transport disorders
    2. Molybdenum cofactor deficiency (sulfite oxidase deficiency)
    3. Serine biosynthesis disorder
    4. Glycine cleavage encephalopathy
    5. Creatine biosynthesis disorder
    6. Neurotransmitter disorders
    7. Nonlactic acidemia Leigh syndrome
    8. Adenylosuccinate lyase deficiency
    9. Congenital disorders of glycosylation
    10. Glutamate transporter EAAT1
    11. 2-methylbutyryl-CoA dehydrogenase deficiency
    12. Mitochondrial disorders (Fryer et al. 1994)
        1. Report of a family, affected with Leigh's encephalopathy and the mitochondrial DNA (mtDNA) mutation 8993, presented with nonspecific delayed development or cerebral palsy.
        2. There was some correlation in this family between the disease severity and the proportion of mutant mtDNA in the blood.

3. This mutation appears to segregate to high levels of mutant mtDNA rapidly within pedigrees.
4. The mother of a severely affected child has a high risk of having further children with a high proportion of mutant mtDNA and a severe phenotype.

5. Physiological classification of cerebral palsy (Agarwal and Verma 2012)
   1. Spastic (80%)
      1. Velocity-dependent increase in muscle tone with passive stretch
      2. Joint contractures: common
   2. Athetoid
      1. Dyskinetic, purposeless movements
      2. Joint contractures: common
   3. Choreiform: continual purposeless movements
   4. Rigid: hypertonicity occurring in the absence of hyperreflexia, spasticity, and clonus
   5. Ataxic
      1. Disturbance of coordinated movement, most commonly walking
      2. Normal head/neck control
   6. Hypotonic
      1. Low muscle tone
      2. Normal deep tendon reflexes
   7. Mixed
      1. Features of more than one type
      2. No head/neck control
6. Geographical classification of cerebral palsy (Agarwal and Verma 2012)
   1. Monoplegia: one extremity involved, usually lower
   2. Hemiplegia (30%)
      1. Both extremities on same side involved
      2. Usually upper extremity involved more than lower extremity
   3. Paraplegia: both lower extremities equally involved
   4. Diplegia (50%)
      1. Lower extremities more involved than upper extremities
      2. Fine motor/sensory abnormalities in upper extremity
   5. Quadriplegia
      1. All extremities involved equally
      2. Normal head/neck control
   6. Double hemiplegia: all extremities involved, upper more than lower
   7. Total body
      1. All extremities severely involved
      2. No head/neck control

Clinical Features

1. Prenatal and perinatal history (Green et al. 2003)
   1. Prenatal history: potential pregnancy complications
      1. Maternal illnesses during pregnancy
      2. Exposure to toxins (e.g., alcohol or drugs)
      3. Prenatal care
      4. Fetal movements
      5. History of trauma
   2. Perinatal history
      1. Gestational age at delivery
      2. Delivery type and presentation
      3. Length of labor
      4. Birth weight
      5. Apgar scores
      6. Cord gas pH
      7. Presence of intraventricular hemorrhage
      8. Procedures done during hospitalization
      9. Ability to feed
      10. Degree of tone
2. Developmental history
   1. Age of attainment of developmental milestones
   2. Age-appropriate developmental function
   3. Assessment of gross motor function
      1. Head control
      2. Trunk control
      3. Rolling
      4. Sitting
      5. Crawling
      6. Standing
      7. Cruising
      8. Walking

4. Assessment of fine motor function
    1. Handedness
    2. Hand-to-mouth movements
    3. Bimanual activities
    4. Grasping
    5. Writing
    6. Feeding
5. Assessment of language ability
    1. Babbling
    2. Size of vocabulary
    3. Ability to string words together
    4. Counting
    5. Naming of body parts, colors, alphabet, and comprehension
6. Current social and personal skills

3. Other histories
    1. Nutritional status, including feeding style, ability, and content
    2. Medications and allergies
    3. Past surgeries
    4. Presence of seizures
    5. Tone and body movement patterns
    6. Bowel and bladder concerns
    7. Visual and hearing concerns
    8. General health
    9. Immunization history
    10. Positioning devices
    11. Bathing equipment
    12. Wheelchair and seating equipment
    13. Adaptive devices
    14. Communication devices
    15. Computers
    16. Environmental control units
    17. Transportation systems
    18. Educational information
        1. Early intervention programs
        2. School environment
        3. Special services
        4. Individualized education plan
        5. Adaptive physical education and recreation
        6. Vocational and vocational activities in adults

4. Criteria for diagnosis (Paneth 2008): presence of one or more of the following four types of neurologic impairment of the motor system (in order of frequency)
    1. Spasticity
        1. Commonest neurologic abnormality
        2. Characterized by increased muscle tone manifesting as increased resistance to stretch that is velocity dependent
        3. Generally accompanied by hyperreflexia, which may include prolonged or sustained clonus, as well as pathologic reflexes such as an abnormal Babinski response (Sanger et al. 2003)
        4. When spasticity affects the lower limbs:
            1. Internal rotation and adduction of the hips is often seen, leading to the typical flexed posture and pigeon-toed gait of CP.
            2. Spasticity of the gastrocnemius muscle in the calf leads to another characteristic finding of toe walking due to plantar flexion.
    2. Dyskinesia
        1. Stereotyped, involuntary movements accentuated with effort
        2. Presence of two forms of dyskinesia
            1. Dystonia in which abnormal postures due to sustained muscle contractions are the essential feature.
            2. Choreoathetosis, in which abnormal movements predominate, consists of two related motor disorders: choreiform movements are rapid and jerky, whereas athetoid movements have a writhing quality. Athetoid CP is characteristic of children who suffered kernicterus in the neonatal period. With control of rhesus hemolytic disease, and better management of all forms of neonatal hyperbilirubinemia, this form of cerebral palsy has become very rare. Patients with the dystonic form of cerebral palsy generally have spasticity as well, whereas patients with choreoathetoid cerebral palsy often have varying tone, with hypertonia and hypotonia both found.
    3. Hypotonia
        1. More often in combination with spasticity than alone.

2. Truncal hypotonia with spasticity of the extremities is not unusual.
4. Ataxia
   1. Usually the presence of both truncal and gait ataxia, which can both be observed (e.g., wide-based gait) and elicited by examination (e.g., inability to accurately place finger on nose).
   2. Intention tremor commonly seen.
   3. Fine motor skills are particularly limited.
   4. Tone is usually hypotonic in this form of cerebral palsy.

5. Musculoskeletal features
   1. Hip assessment should include evaluation for contractures involving flexion, internal and external rotation, adduction, and leg length discrepancies.
   2. The knee should be tested for hamstring contracture.
   3. The foot and ankle should be tested for contractures and tibial torsion.
   4. The back should be examined for posture, spinal curves, or asymmetries.
   5. The upper extremities should be assessed for resting posture and spontaneous movement.
   6. An occupational therapy evaluation of grip and fine motor coordination often is beneficial.
6. Neurologic features
   1. CP is a disorder of movement resulting in a delay in the development of gross motor skills.
   2. Focus on tone.
      1. If movement has a velocity-dependent component, it is spastic.
      2. Deep tendon reflexes: often increased in spastic CP.
      3. Babinski, or plantar, response: often upgoing.
7. Spastic cerebral palsy
   1. Spasticity.
      1. Definitions
         1. An increase in the physiologic resistance of muscle to passive motion
         2. Hypertonicity that increases with increased velocity of movement (or having an increased stretch reflex)
      2. Most common of cerebral palsy (70–80% of children who have cerebral palsy are spastic) (Panteliadis 2004)
      3. A part of the upper motor neuron syndrome characterized by:
         1. Hyperreflexia
         2. Clonus
         3. Extensor plantar responses
         4. Persistent primitive reflexes
   2. Cause: damage to the pyramidal parts of the brain.
   3. Subdivision of spastic cerebral palsy: according to the area of the body involved.
      1. Diplegia
         1. Fifty percent of children with spastic cerebral palsy have diplegia (Berker and Yalçin 2008).
         2. The most common type seen in premature infants (Schaefer 2008).
         3. Greater involvement of legs than arms.
         4. Children with spastic diplegia are late in attaining all gross motor skills, but the delay in standing and walking is most notable. Generally, there is only mild functional impairment of the upper extremity. In a prospective study, being able to sit independently at 2 years was a good predictive sign of future ambulation. Children who could not sit by age 4 did not ambulate.
      2. Quadriplegia
         1. Thirty percent of children with spastic cerebral palsy have quadriplegia (Berker and Yalçin 2008).
         2. The only type associated with asphyxia in term infants (Schaefer 2008).
         3. All four extremities, the trunk, and muscles that control the mouth, tongue, and pharynx get affected.
         4. Children with spastic quadriplegia present a much broader spectrum of disability.

5. The severity of motor involvement affects the delay in developmental milestones.
6. About one-fourth of children with spastic quadriplegia have only mild involvement, with minimal functional limitation with regard to mobility or self-care.
7. About one-half are moderately impaired.
8. These patients are unable to achieve complete independence but are able to function reasonably well.
9. About one-quarter of patients are severely involved, require total care, and are unable to ambulate.
10. Independent sitting at 2 years and suppression of obligatory reflexes are good prognostic signs for eventual ambulation.

3. Hemiplegic/monoplegia
   1. Most likely causes (focal traumatic, vascular, or infectious lesion).
   2. Not typically associated birth asphyxia (Schaefer 2008).
   3. Twenty percent of children with cerebral palsy have hemiplegia (Berker and Yalçin 2008).
   4. One-sided (unilateral) involvement: a unilateral brain infarct with posthemorrhagic porencephaly apparent on MRI.
   5. Upper extremity generally more affected than the lower.
   6. Exhibit definite hand preference before 1 year of age, compared with most children who display handedness at about age 2.
   7. Display either an asymmetric crawl or no crawl at all.
   8. Almost all children with spastic hemiplegia do ambulate. Most become independent with activities of daily living, using some aids.
   9. Seizures, mild mental retardation, learning difficulties, and behavioral disturbances may complicate the management and integration into society.
   4. Double hemiplegic: both sides, arms > legs
4. Children with spastic syndromes, in general, often show white matter injury on imaging.
5. Most closely linked to periventricular leukomalacia but may also be secondary to congenital human immunodeficiency virus, dopa-responsive dystonia, hereditary spastic paraplegia, or spinal pathology, arginase deficiency, and Sjögren–Larsson syndrome, with characteristic appearances on imaging.

8. Dyskinetic cerebral palsy
   1. Dyskinetic cerebral palsy accounts for approximately 10–15% of all cases of cerebral palsy (Berker and Yalçin 2008).
   2. The most probable etiology: hyperbilirubinemia or severe anoxia that causes basal ganglia dysfunction.
   3. Choreoathetoid (hyperkinetic) and chorea: the main movement disorders seen in dyskinetic children.
   4. Dysarthria, dysphagia, and drooling accompany the movement problems.
   5. Children with dyskinetic cerebral palsy typically suffer from severe neuromuscular dysfunction. The abnormal movements are first noticed in the hands and fingers, but abnormal movements are usually noted in all extremities by 18 months of age. The writhing, involuntary movements give way to dystonia. As a result, all of their gross motor milestones are significantly delayed. Only about one-half of these children are able to walk, and they normally do not walk until after 3 years of age. Children who are able to walk usually develop the coordination necessary to perform their activities of daily living. Those who do not walk typically require almost total care.
   6. Abnormal movements that are most obvious when a patient initiates a movement. These abnormal movements are caused by

inadequate regulation of muscle tone and coordination.
7. When the patient is relaxed, there is usually full range of motion with decreased tone.
8. The patient often has a "cogwheel"-type resistance, without changes in the deep tendon reflexes. Tone decreases when the patient is supine, and tone may "shake loose."
9. There are two main types of dyskinetic movement.
    1. The first is dystonia, in which abnormal shifts of general muscle tone are induced by movement. These patients tend to retain abnormal posture in the same stereotyped patterns.
    2. The second main type of dyskinetic movement is choreoathetoid, in which the initiation of movement in one extremity leads to movement of other muscle groups. These patients exhibit slowly writhing involuntary movements in combination with abrupt, irregular, jerky movements.

9. Ataxic cerebral palsy
    1. Ataxic CP is the disturbance in the coordination of voluntary movements caused by muscle dyssynergia.
    2. Usually caused by cerebellar dysfunction.
    3. Ataxia becomes apparent toward the age of 2–3 years.
    4. Generally seen in association with spastic diplegic cerebral palsy.
    5. Now often categorized in the group of dyskinetic CP.
10. Mixed cerebral palsy
    1. Ataxia and dystonia occurring together with spasticity.
    2. The damage, usually, is more global, and the patients are quadriplegic.
11. Extrapyramidal cerebral palsy syndromes
    1. Characterized by rigidity, elicited clinically by passive stretch independent of velocity or dystonia, which is often action-induced twisting or fixed postures.
    2. Arm use is typically more affected than leg function.
    3. Children with extrapyramidal syndromes, in general, frequently have basal ganglia abnormalities on imaging.
    4. May result from genetic metabolic disorders such as glutaric aciduria type 1 (caudate/putamen), mitochondrial disorders such as Leigh syndrome (globus pallidus/caudate/putamen), kernicterus (globus pallidus), or hypoxic-ischemic encephalopathy (putamen/thalamus).
12. Associated conditions in children with cerebral palsy (Ashwal et al. 2004)
    1. Mental retardation (52%)
        1. Cognitive and neuropsychological function in children with CP are commonly impaired.
        2. In general, no absolute relation between the type of CP and severity of cognitive impairment. However, the following correlations are noted:
            1. Greater degree of mental impairment in spastic quadriplegia than in spastic hemiplegia.
            2. Severity of cognitive deficits appears to correlate with motor deficits associated with spastic cerebral palsy in contrast to dyskinetic cerebral palsy where this relation is lacking.
            3. Greater intellectual impairment in cerebral palsy in the presence of epilepsy, abnormal EEG, or abnormal neuroimagings.
    2. Speech and language disorders (38%)
        1. Anarthric or dysarthric speech and other impairments related to oral motor dysfunction are common due to bilateral corticobulbar dysfunction (i.e., articulation disorders and impaired speech intelligibility present in 38%).
        2. Inability to develop the linguistic skills necessary to develop more complex speech patterns due to impaired mobility which causes

limited interaction with individuals in the environment.
3. Language (as opposed to speech) deficits in CP closely related to verbal intellectual limitations associated with mental retardation.
4. Oral motor problems may lead to potential serious impacts on nutrition and growth, oral health, respiration, and self-esteem.
1. Feeding difficulties
2. Swallowing dysfunction
3. Drooling

3. Ophthalmologic defects (28%)
1. Visual impairments and disorders of ocular motility are common.
1. Strabismus
2. Amblyopia
3. Nystagmus
4. Optic atrophy
5. Refractive errors
2. Visual perceptual problems more likely in those due to periventricular leukomalacia.

4. Hearing impairment (12%)
1. More commonly in children with following etiologies:
1. Low birth weight
2. Kernicterus
3. Neonatal meningitis
4. Severe hypoxic-ischemic insults
2. Greater risk in children with CP who have mental retardation or abnormal neuroimaging studies

5. Epilepsy (43%)

13. Clues to the so-called cerebral palsy of unknown etiology (Dodge 2008)
1. Family history (familial spastic paraplegia)
2. Normal deep tendon reflexes (transient toe walking)
3. Calf hypertrophy with positive Gower sign (muscular dystrophy)
4. Regression, lethargy, and unusual vomiting
1. Ichthyosis (Sjögren–Larsson syndrome)
2. Severe self-mutation (Lesch–Nyhan syndrome)
5. Recurrent stroke, cardiomyopathy, and hypoglycemia (mitochondrial disorders)
6. Multiple anomalies
7. Lissencephaly (Miller–Dieker syndrome)
8. Acquired microcephaly, hand wringing (Rett syndrome)

14. Medical complications associated with cerebral palsy (Dougherty 2009)
1. Spasticity
2. Joint contractures, misalignment secondary to muscle spasticity
3. Hip dislocation
4. Osteoporosis
5. Intellectual disability (seen in 30–50% of individuals)
6. Seizures
7. Gastroesophageal reflux
8. Dysphagia or aphagia
9. Failure to thrive/malnutrition
10. Hearing loss

15. Possible source of pain (Dodge 2008)
1. Cranial
1. Increased intracranial pressure
2. Migraines and other headaches
2. Ophthalmologic
1. Corneal abrasion
2. Glaucoma
3. Dental
1. Abscesses
2. Temporomandibular joint pain
4. Gastrointestinal
1. Gastroesophageal reflux
2. Constipation
5. Musculoskeletal
1. Hip dislocation
2. Scoliosis
6. Neuromuscular (muscle spasms)
7. Urologic
1. Urolithiasis
2. Bladder spasms
8. Other (decubitus ulcers)

16. Proposed diagnostic criteria of cerebral palsy (Kavčič and Vodušek 2005)
1. Possible CP
1. Mandatory inclusion criteria
1. Disorder of movement and posture manifesting as spastic diplegia, spastic hemiplegia, spastic

tetraplegia, ataxia, dystonia, choreoathetosis – alone or in any combination
2. Onset early in life
3. No evidence of progression
2. Mandatory exclusion criteria
1. Active disease that could explain the foregoing features
2. Chromosomal disorders
3. Supportive features
1. Other signs of brain dysfunction that could be caused by the same pathological process as the foregoing disorders of movement and posture (epilepsy, learning disorders, disorders of speech, vision, or hearing)
2. Born after multiple pregnancy
3. Vanishing twin syndrome
4. Intrauterine growth retardation
5. Major antenatal placental abruption
6. Preterm birth
7. Acute intrapartum hypoxia
8. Reduced fetal heart rate variability from the onset of labor
9. Extensive chorioamnionitis
10. Congenital coagulation disorders
11. Autoimmune disease of the mother
12. No child with the same/similar clinical picture in a family
2. Probable CP: Mandatory inclusion criteria:
1. Disorder of movement and posture as in possible CP
2. Onset early in life
3. No evidence of progression or other disease that could explain the foregoing features at school age
3. Definite CP: Mandatory inclusion criteria:
1. Disorder of movement and posture as in probable CP
2. Plus still no evidence of progression unrelated to aging or other disease that could explain the foregoing features at age 18 or older

17. Prognosis (Blair et al. 2001)
1. Most severely affected persons with cerebral palsy (spastic quadriplegia, dyskinetic, and "mixed" cerebral palsy) survive to adulthood (Evans et al. 1990).
2. Survival strongly associated with degree of intellectual deficit.
3. Mortality declines with age during childhood.
4. Cause of death usually due to respiratory problems such as aspiration pneumonia.

Diagnostic Investigations

1. EEG
1. For features suggesting the presence of epilepsy or epileptic syndrome
2. Probably not very helpful in determining the etiology of cerebral palsy
2. Neonatal audiometric screening
3. Neuroimaging (Shimony et al. 2008)
1. Cranial ultrasound
1. Performed through open fontanelle (its use is restricted to the first 6 months of life)
2. Sensitive to detect the following:
1. Blood products
2. Ventricular size
3. Gross brain malformations
4. Cystic changes in the brain parenchyma
2. Computed axial tomography (CT) with the following advantages:
1. Acute blood products
2. Bone abnormalities
3. Short examination time
4. Wide availability
3. MRI (preferred to CT scanning) (Russman and Ashwal 2004)
1. Higher yield of suggesting an etiology and timing of insult leading to CP
2. Acquired lesions
1. Periventricular leukomalacia with other areas of injury
2. Diffuse encephalopathy (cortical/subcortical atrophy/ventriculomegaly)
3. Focal ischemic/hemorrhagic (e.g., infarct porencephaly)
4. Multicystic encephalomalacia

5. Trauma (at birth or later)
6. Infection

3. Malformations
   1. Cortical dysplasia/polymicrogyria
   2. Schizencephaly
   3. Pachygyria/lissencephaly
   4. Complex brain malformation
   5. Agenesis/hypoplasia of the corpus callosum
   6. Arachnoid cyst
   7. Vermian/cerebellar hypoplasia
   8. Hydrocephalus/holoprosencephaly/hydranencephaly
4. Miscellaneous or unknown
   1. Miscellaneous etiologies
   2. Delayed/abnormal myelination
5. Normal

4. Metabolic and genetic testing (Russman and Ashwal 2004; Schaefer 2008)
   1. Features of family history that might prompt a genetics/metabolic workup.
      1. Thromboses/vascular accidents
      2. Mental retardation/developmental disabilities
      3. Seizures
      4. Cerebral palsy
      5. Neuromotor disorders
      6. Tumors
      7. Neurobehavioral disorders
      8. Joint contractures/stiffness
      9. Congenital anomalies
      10. Infertility
      11. Recurrent miscarriages/stillborns
      12. Adult-onset neurodegenerative conditions
   2. Features on medical history and physical examination prompting a genetics/metabolic workup (Schaefer 2008).
      1. Neuroregression
      2. Seizures/change in seizure type
      3. Late onset/acquired microcephaly
      4. Macrocephaly
      5. Pigmentary changes
      6. Major and minor dysmorphic features
      7. Congenital anomalies
   3. Metabolic or genetic causes for CP to occur infrequently (0–4%; true incidence unknown).
   4. Neuroimaging studies showing 7–11% of children with cerebral palsy have a brain malformation suggest the presence of additional risk for genetic and possibly a metabolic etiology.
   5. Metabolic studies.
   6. High-resolution chromosome analysis.
   7. Chromosome microarray analysis.
5. Recognizable genetic syndromes known to be associated with a cerebral palsy phenotype
   1. MECP2 mutation study for Rett syndrome
   2. Chromosome 15 anomaly and UBE3A mutation studies for Angelman syndrome
   3. L1CAM mutation study for hereditary spastic paraplegia (Finckh et al. 2000)
   4. PLP1 mutation study for Pelizaeus–Merzbacher spectrum
   5. ARX (X-linked aristaless-related homeobox gene) mutation study for West syndrome (triad of infantile spasms, hypsarrhythmia, and mental retardation) (Guerrini et al. 2007)

Genetic Counseling

1. Recurrence risk: depends on the underlying genetic disorders (rare) of cerebral palsy
   1. Patient's sib
      1. Recurrence risk is low in most cases caused by hypoxic or ischemic injury to the brain.
      2. Autosomal recessive: 25%.
      3. Autosomal dominant: not increased unless a parent is affected or having gonadal mosaicism.
      4. X-linked recessive disorder: 50% of male sibs affected if the mother is a carrier.

5. Mitochondrial: all sibs are at risk of being affected if the mother has the mitochondrial DNA mutation.

2. Patient's offspring
   1. Autosomal recessive: not increased.
   2. Autosomal dominant: 50%.
   3. X-linked recessive: all daughters of affected males will be carriers. All sons of an affected male will be normal.
   4. Mitochondrial:
      1. Offspring of males with a mtDNA mutation are not at risk.
      2. All offspring of females with a mtDNA mutation are at risk of inheriting the mutation.
      3. A female harboring a heteroplasmic mtDNA point mutation may transmit a variable amount of mutant mtDNA to her offspring, resulting in considerable clinical variability among sibs within the same nuclear family (Poulton and Turnbull 2000; Chinnery 2014).

2. Prenatal diagnosis: not reported to date
3. Management
   1. Management strategy and rehabilitation of the child with cerebral palsy (Berker and Yalçin 2008)
      1. Support growth and nutrition
      2. Therapy for vision
         1. Rehabilitation
         2. Glasses
         3. Surgery
      3. Dental hygiene
      4. Gastrointestinal problems
         1. Medications for reflux
         2. Gastrostomy
         3. Antireflux surgery
      5. Therapy for motor function
         1. Physical therapy
         2. Occupational therapy
         3. Adaptive seating
         4. Bracing
         5. Wheeled motility
         6. Orthopedic surgery
         7. Sports–recreation
      6. Oromotor therapy
         1. Chewing
         2. Swallowing
         3. Speech
      7. Seizure prevention
      8. Spasticity and dyskinesia
         1. Medical treatment
         2. Botulinum toxin
   2. Timing of rehabilitative measures
      1. Infancy
         1. Goal: supportive measures for prolonging and optimizing physical status and life
         2. Methods: nutritional support and infant stimulation and positioning
      2. Childhood
         1. Goal: strategies to obtain maximum independent mobility
         2. Methods: medication to minimize spasticity, exercise, botulinum toxin, bracing
      3. Preschool
         1. Goal: maximum independent mobility
         2. Methods: minimize deformity, medication, exercise, botulinum toxin, bracing, orthopedic surgery
      4. Adolescence
         1. Goal: education, vocation, and integration into the community
         2. Methods: schooling, sports, psychosocial support
   3. Effects of physiotherapy (Berker and Yalçin 2008)
      1. Physiotherapy to improve:
         1. Postural control: decreasing spasticity and contracture
         2. Muscle strength: increasing muscle elasticity and joint laxity
      2. Range of motion
         1. Joint alignment: increasing coordination/agility
         2. Motor control: balance
         3. Muscular/cardiovascular endurance and mobility skills: transitions, use of assistive devices

4. Oral sensorimotor therapy
    1. May be effective in promoting oral motor function
    2. Not shown to be effective in promoting oral feeding efficiency, caloric intake, weight gain, or pharyngeal motility and airway protection during feedings
5. Gastrostomy tube feeding (Rogers 2004)
    1. An important alternative nutritional source for children with cerebral palsy
    2. Relative indications
        1. Dysphagia resulting in undernutrition
        2. Aspiration with associated respiratory disease
        3. Insufficient fluid intake and/or refusal of oral medications
        4. Excessive effort or stress during oral feedings.
6. Early intervention programs
    1. Work to optimize development.
    2. Goals: improve function and encourage independence.
    3. Improve family interaction.
    4. Provide family support.
    5. Provide education in how to promote development.
    6. The Individuals with Disabilities Education Act mandates early intervention for all children 0–3 years old who demonstrate developmental delay.
        1. These programs are typically multidisciplinary and may take place in centers or in the family's home.
        2. The therapists directly provide hands-on therapy to the child or educate the family on how to provide the interventions themselves.
7. Orthopedic treatment of cerebral palsy (Aversano et al. 2015)
    1. Lower extremity muscle imbalance leading to gait abnormalities in spastic cerebral palsy
        1. Ankle equinus: gastrocnemius recession procedure.
        2. Stiff knee gait: rectus femoris (RF) lengthening provides a viable alternative to RF tendon transfer.
        2. Knee flexion contracture: distal femoral osteotomies
        3. Single-event multilevel surgery of the lower extremity
        4. Foot and ankle deformity
            1. Calcaneal lengthening for correction of pes planovalgus deformities in children with cerebral palsy
            2. Additional medial stabilization procedures (posterior tibialis reefing or talonavicular arthrodesis)
            3. Intra-articular subtalar fusion technique for surgical correction of pes planovalgus
        5. Acetabular dysplasia and hip displacement
            1. Early detection and management of hip subluxation and dislocation
            2. Osteotomies
            3. Salvage hip procedures
8. Management of spasticity
    1. The management of spasticity is a large part of the treatment of children with cerebral palsy.
    2. Daily range of motion shown to decrease muscle tone for several hours after it is done and may delay or prevent contractures.
    3. The use of heat or cold can modify tone in the short term, but either modality is impractical for long-term use.
    4. Casting and splinting often used as adjuncts to regular range of motion: Casting for 2–3 weeks can decrease tone and improve range of motion for several months.
    5. Cyclical use of electrical stimulation has been found to decrease upper extremity contractures and improve agonist/antagonist balance, but these affects last only for hours.
    6. Medications.
9. Management of seizures
10. Complemental and alternative therapies (Liptak 2005)
    1. Hyperbaric oxygen (delivery of 100% oxygen)

    1. Theory/benefits: awakens dormant brain tissue surrounding the original injury.
    2. Adverse effects: ear trauma, pneumothorax, fire, and explosions.
    3. Evidence: improvements in the treated children in uncontrolled studies, improvement in treated, and controls in controlled study.
    4. Comments: more evidence is required.
2. Adeli suit (originally developed for Russian cosmonauts to counteract the adverse effects of zero gravity, including muscle atrophy and osteopenia)
    1. Theory/benefits: resistance across muscles improves strength, posture, and coordination
    2. Adverse effects: discomfort from suit, expense for intensive therapy, and travel to centers that prescribe the suit
    3. Evidence: no conclusive evidence
3. Patterning (passively putting children through certain repeated normal motions)
    1. Theory/benefits: passively repeating steps in normal development overcome brain injuries.
    2. Adverse effects: time, energy, and expenses required.
    3. Evidence: results of uncontrolled studies are inconsistent; controlled trials show no benefits.
    4. Comments: not recommended.
4. Electrical stimulation (elicits muscle contraction): more evidence required
5. Threshold electrical stimulation
    1. Theory/benefits: increased blood flow from electrical current leads to stronger muscles.
    2. Adverse effects: expense for units, generally safe.
    3. Evidence: subjective improvements in some uncontrolled trials and inconclusive in controlled trials.
6. Functional neuromuscular stimulation
    1. Theory/benefits: increased muscle contraction improves strength and function.
    2. Adverse effects: expense, infection from needles, and discomfort.
    3. Evidence: somewhat more positive than for threshold stimulation but still inconclusive.
7. Conductive education (interventions including promoting independent functioning using repetition and verbalization by the child)
    1. Theory/benefits: problems with motor skills are due to problems of learning. New abilities are created out of teaching.
    2. Adverse effects: not known.
    3. Evidence: benefit shown in uncontrolled trials and mixed results in controlled trials.
    4. Comments: conductive education implemented in many different ways making generalizations from a single program difficult.
8. Hippotherapy (equine-assisted therapy)
    1. Theory/benefits: riding a horse improves muscle tone, head and trunk control, mobility in the pelvis, and equilibrium.
    2. Adverse effects: trauma from a fall and allergies.
    3. Evidence: beneficial effects on body structures and functioning shown by uncontrolled and controlled trials.
    4. Comments: increases social participation.
9. Craniosacral therapy (a cranial rhythm linked with movements in the sacrum transmitted through the dura of the spinal cord by light corrective pressure applied to various points along the craniosacral axis)
    1. Theory/benefits: used to remove impediments to the flow of cerebrospinal fluid within the cranium and spinal cord.

2. Adverse effects: none known.
3. Evidence: no studies showing efficacy; some question the basis of the intervention.

10. Feldenkrais intervention method
    1. Theory/benefits: gentle change of position and directed attention to relax muscles and improve movement, posture, and functioning
    2. Adverse effects: none known
    3. Evidence: no studies showing efficacy
11. Acupuncture
    1. Theory/benefits: help to restore the normal flow of Qi (energy)
    2. Adverse effects: forgotten needles, pain, bruising, and infection
    3. Evidence: improvements in several areas shown by uncontrolled and some controlled studies
    4. Comments: appears promising, but more studies needed
12. Potential future nanotherapeutic approaches in cerebral palsy (Balakrishnan et al. 2013)
    1. Dendrimer-based drug delivery to pregnant mothers with infection/inflammation may reduce inflammatory response in the mother and the fetus.
    2. Prenatal therapies may involve systemic treatment of the mother to modulate the maternal immune response and/or treatment of the fetus by intra-amniotic administration of the nanodevices.
    3. Postnatal therapies would involve treatment of ongoing injury after birth.
    4. Therapies may potentially involve the use of stem cells in combination with drugs or after modification by nanoparticles to promote differentiation, delivery of trophic and growth factors, or delivery of combination therapies using nanoparticles.

Fig. 1 A 10-year-old girl with cerebral palsy secondary to anoxic encephalopathy

Fig. 2 The patient, a 14-year-old boy, was diagnosed with diplegia cerebral palsy. He was born 27 weeks gestation by C-section and was one of the fraternal twins. He had a grade IV intraventricular bleed. Birth weight was 2 lbs. 1 oz. He was in NICU for 2 months

Fig. 3 The patient, a 14-year-old boy, was diagnosed with triplegia cerebral palsy. He was born 32 weeks gestation and on the ventilator for several weeks

Cerebrocostomandibular Syndrome

Contents

Cerebrocostomandibular syndrome (CCMS), a rare congenital syndrome, consists of severe micrognathia, often with the Pierre Robin anomaly, posterior rib-gap defects, and developmental delay (Smith et al. 1966). It is also known as "rib-gap syndrome," "rib-gap defect with micrognathia syndrome," and "Smith-Theiler-Schachenmann syndrome."

Synonyms and Related Disorders

Rib-gap defects with micrognathia; Rib-gap syndrome; Smith-Theiler-Schachenmann syndrome

Genetics/Pathogenesis

1. Caused by heterozygous mutation in the SNRPB gene on chromosome 20p13 (Lynch et al. 2014; Bacrot et al. 2015; Tay 2015)
2. Inheritance
    1. Sporadic in majority of cases
    2. Familial occurrence in a few instances
        1. Autosomal recessive pattern (Clarke and Nguyen 1985; Hennekam et al. 1985; Trautman et al. 1985; McNicholl et al. 1970; Drossou-Agakidou et al. 1991)
        2. Autosomal dominant pattern (Leroy et al. 1981; Merlob et al. 1987; Flodmark and Wattsgård 2001; Morin et al. 2001)
3. Pathogenesis of the rib gaps (Megier et al. 1998)
    1. Not well understood.
    2. Rib abnormality results from a lack of fusion between two mesenchymal tissues derived from the somatic mesoderm (posteriorly) and the lateral plate mesoderm (anteriorly).
    3. Defective organization of the somite results in discontinuities of the ribs.

Clinical Features

1. Variable inter- and intrafamilial expression (Plötz et al. 1996)
2. Cardinal signs
    1. Rib abnormalities
        1. Posterior rib gaps
            1. Present in almost all affected newborn infants
            2. Showing great variability in severity

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_36

   3. Disappear in time
   4. Sometimes replaced by callus or pseudo-arthroses
2. Segmentation defects and rudimentary rib development, fusion of most ribs to the vertebrae, and absence of any normal costovertebral articulations
3. Thin ribs
4. Agenetic ribs (Hennekam and Goldschmeding 1998)

2. Micrognathia/Pierre Robin anomaly (Miller et al. 1972)
3. Cerebral abnormalities
   1. Microcephaly
   2. Agenesis of the corpus callosum
   3. Dilated lateral ventricles
   4. Porencephalic cyst
   5. Variable degree of mental retardation probably secondary to hypoxia following respiratory distress

3. Other skeletal anomalies
   1. Vertebral anomalies including hemivertebrae
   2. Hip dislocation
   3. Subluxation of the elbows
   4. Pectus carinatum
   5. Hypoplasia of the sternum, clavicles, and pubic rami
   6. Epiphyseal stippling
   7. Abnormal phalanges and toes
   8. Clubfoot
4. Intrauterine growth retardation
5. Postnatal growth deficiency
6. Respiratory distress
7. Feeding difficulties
8. Language delay
9. Conductive deafness
10. Palatal defect
    1. Short soft palate
    2. Cleft palate
11. Dental defects
12. Laryngeal and tracheal abnormalities
13. Pterygium coli
14. Renal anomalies
    1. Renal cysts
    2. Ectopia
15. Congenital heart defects (Kuhn et al. 1975)
16. Prognosis (Ramaswamy et al. 2016)
    1. Mental retardation: often among the late survivors
    2. High mortality (40% in the first year of life, 50% in the first month of life) mostly due to respiratory insufficiency secondary to rib abnormalities and flail chest
    3. General development progresses well once the initial respiratory problems are survived.

Diagnostic Investigations

1. Radiography
   1. Rib malformations
      1. Multiple gaps consisting of fibrous or cartilaginous tissue
      2. Thin ribs
      3. Agenetic ribs
   2. Vertebral anomalies
   3. Other associated skeletal anomalies
   4. Micrognathia
2. Serial radiographs: demonstrate a progressive diminution of the characteristic posterior rib-gap defects (Williams and Sane 1976)
3. Thoracic CT studies
   1. Three-dimensional CT of costothoracic skeleton: demonstration of variable gaps in the posterior ribs and absence of ribs (Su et al. 2010)
   2. Multidetector thoracic CT: rib gaps and failure of costovertebral separation (Watson et al. 2014)
4. Cranial ultrasonography for cerebral abnormalities
5. Exome sequencing and Sanger sequencing: detection of heterozygous variants in the small nuclear ribonucleoprotein polypeptides B and B1 (*SNRPB*) gene (Bacrot et al. 2015)
6. Histology of rib gaps: fibrovascular tissue (Kang et al. 1992) and muscles, instead of cartilage and bone

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Not increased in sporadic cases and in a fresh mutation case of an autosomal dominant disorder
      2. 25% in an autosomal recessive disorder
   2. Patient's offspring: not increased unless the patient survives and is affected with an autosomal dominant disorder in which case there is a 50% risk of having an affected child
2. Prenatal diagnosis by ultrasonography (Ibba et al. 1997; Morin et al. 2001)
   1. Increased fetal nuchal translucency thickness detectable at 11 weeks
   2. Micrognathia at 12 weeks
   3. A narrow and short (bell-shaped) chest and defective ribs (with lack of rib display) at 18 weeks
   4. Growth retardation
   5. Vertebral anomalies
   6. Limb anomalies
   7. Cystic hygroma
   8. Polyhydramnios
3. Management (Hosalkar 2000)
   1. Ex utero intrapartum treatment (EXIT) at 36 weeks 6 days of gestation for prenatally diagnosed CCMS (Ogasawara et al. 2014)
   2. Treatment of respiratory distress
   3. Nasogastric tube feeding
   4. Tracheostomy may be required
   5. Management of recurrent infections
   6. Surgery for cleft palate
   7. Early intervention and multidisciplinary team approach.
   8. Orthopedic care for skeletal anomalies.

Fig. 1 (**a**–**f**) An infant with cerebrocostomandibular syndrome (at birth and 12 weeks of age) showing severe micro/retrognathia and malformations of the ribs with multiple gaps and segmentation defects

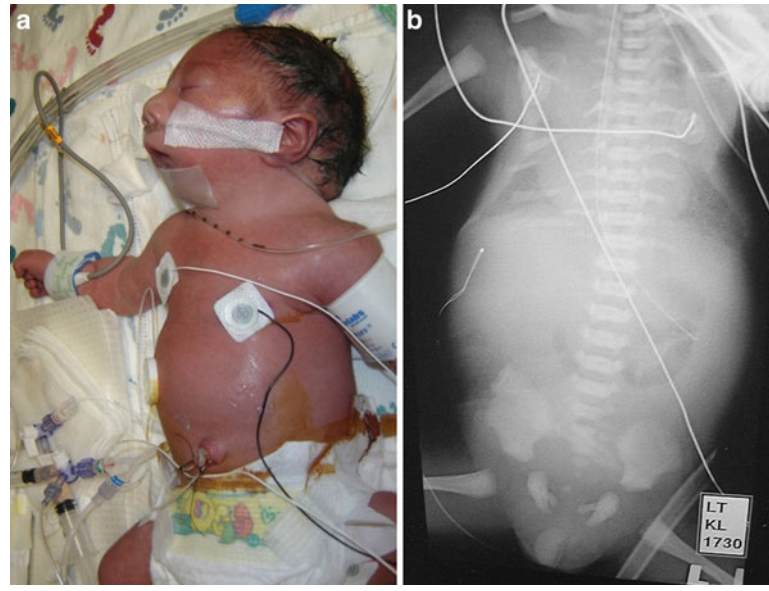

Fig. 2 (**a**, **b**) Another infant with cerebrocostomandibular syndrome showing severe micro/retrognathia, a narrow chest, and rib malformations with multiple gaps

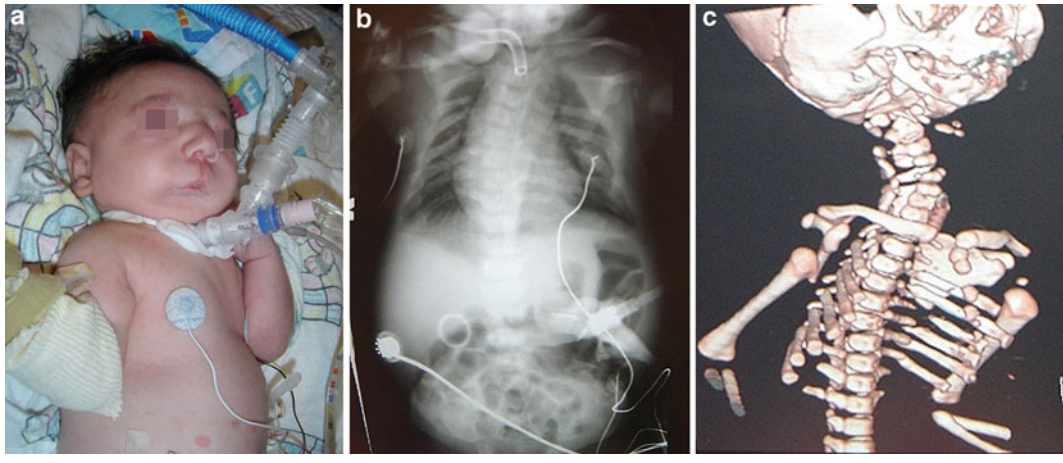

Fig. 3 (**a**–**c**) A neonate presented with severe respiratory distress, requiring tracheostomy. He has severe retromicrognathia and a small chest. Radiographs showed malformations of the ribs with multiple gaps and segmentation defects. A 3-D CT showed variable gaps in the posterior ribs and absence of several ribs

Charcot-Marie-Tooth Disease

Contents

Charcot-Marie-Tooth (CMT) disease is the most common inherited peripheral neuropathy. It is a pathologically heterogeneous group of hereditary motor and sensory neuropathies (HMSN), characterized by slowly progressive weakness and atrophy, primarily in the distal leg muscles. The incidence is estimated to be approximately 1 in 2,500.

Synonyms and Related Disorders

Hereditary motor and sensory neuropathy

Genetics/Basic Defects

1. Charcot-Marie-Tooth disease type 1 (CMT1) (Berger et al. 2002; Barisic et al. 2008; Banchs et al. 2009; Pareyson and Marchesi 2009; Szigeti and Lupski 2009; Harel and Lupski 2014; Rossor et al. 2013; Bird 2015b, d)
   1. Also called hereditary motor and sensory neuropathy type I (HMSN I)
   2. The most common subtype (accounting for about 50% of CMT)
   3. A demyelinating neuropathy
   4. Autosomal dominant demyelinating form of CMT1
      1. CMT1A (90% of CMT1 patients): caused by *PMP22* duplication or point mutations (17p11.2-12)
      2. CMT1B (5–10%): caused by mutations of the myelin protein zero (*MPZ/PO*) gene (1q22)
      3. CMT1C: caused by mutations of *SIMPLE/LITAF* gene (16p13.1-p12.3)
      4. CMT1D: caused by mutations of early growth response gene 2 (*EGR2*) gene (10q21.1-q22.1)
      5. CMT1E: *PMP22* (17p11.2)
      6. CMT1F: *NEFL* gene (8p21)
      7. CMT1 plus: FBLN5
2. Charcot-Marie-Tooth disease type 2 (CMT2) (Vance 2000; Rossor et al. 2013; El-Abassi et al. 2014; Harel and Lupski 2014; Saporta 2014; Bird 2015c, d)
   1. Also called hereditary motor and sensory neuropathy type II (HMSN II)
   2. An axonal neuropathy
   3. Accounting for 20–40% of CMT
   4. Autosomal dominant axonal form of CMT2: disease gene loci

5. CMT2D: *GARS* (7p15)
6. CMT2E: *NEFL* (8p21)
7. CMT2F: *HSPB1* (*HSP27*) (7q11-q21)
8. CMT2G: unknown (12q12-q13.3)
9. CMT2H/K: *GDAP1* (8q13-q21.1)
10. CMT2I/J: *MPZ* (1q22-q23)
11. CMT2L: *HSPB8*/*HSP22* (12q24.3)
12. CMTM: *DNM2*
13. CMT2N: *AARS*
14. CMT2O: *DYNC1H1*
15. CMT2P: *LRSAM1*
16. CMP2Q: *DHTKD1*
17. CMT2S: *IGHMBP2*
18. CMT2T: *DNAJB2*
19. CMT2U: *MARS*
20. Hereditary motor and sensory neuropathy with proximal dominance: *TFG*
21. Hereditary spastic paraplegia type 10: *KIF5A*

5. Autosomal recessive axonal form CMT2 (Tazir et al. 2013)
   1. CMT2B1: *LMNA* (1q21.2)
   2. CMT2B2: *Med25* (19q13.3)
   3. CMT2H/2 K: *GDAP1* (8q13-q21.1)
   4. CMT2R: *TRIM2*
   5. Neuromyotonia and axonal neuropathy: *HINT1*

3. Intermediate form of autosomal dominant CMT (rare) (Rossor et al. 2013; El-Abassi et al. 2014; Harel and Lupski 2014; Bird 2015d)
   1. DI-CMTA: unknown (10q24.1-q25.1)
   2. DI-CMTB: *DNM2* (19p12-p13.2)
   3. DI-CMTC: *YARS* (1p34-p35)
   4. DI-CMTD: *MPZ* (1q22)
   5. DI-CMTE: *IFN2*
   6. DI-CMTF: *GNB4*
4. Recessive form of autosomal recessive CMT (Rossor et al. 2013; Harel and Lupski 2014; El-Abassi et al. 2014)
   1. RI-CMTA: *GDAP1*
   2. RI-CMYB: *KARS*
   3. RI-CMT: *PLEKHG5*
5. Autosomal recessive demyelinating form of CMT4 (Tazir et al. 2013; Harel and Lupski 2014; Bird 2015d, e)
   1. CMT4A: the first locus identified: 8q13-q21.1 (corresponding gene, *GDAP1*)
   2. CMT4B1: *MTMR2* (11q22)
   3. CMT4B2: *MTMR13*/*SBF2* (11p15)
   4. CMT4C: *KIAA1985*/*SH3TC2* (5q32)
   5. CMT4D (HSMN-Lom): *NDRG1* (8q24.3)
   6. CMT4E: *EGR2* (10q21.1-q22, 17p)
   7. CMT4F: *PRX* (19q13.1-q13.2)
   8. CMT4G: unknown (10q23.2)
   9. CMT4H: *FGD4* (12p11.21-q13.11)
   10. CMT4J: *FIG4* (6q21)
6. Autosomal recessive axonal form of CMT4
   1. CMT4C1 (AR CMT2B1): lamin A/C (1q21.2-q21.3)
   2. CMT4C2 (AR-CMT2C or AR-CMT2H): unknown (8q21.3)
   3. CMT4C3 (AR-CMT2B2): *ARC92*/*ACID1* (MED25) (19q13.3)
   4. CMT4C4 (AR-CMT2K): *GDAP1* (8q13-q21.1)
7. X-linked dominant form of CMT (CMTX1) (Harel and Lupski 2014; Bird 2015a, d; Wang and Yin 2015): accounting for 10–20% of CMT (the second most common form of inherited demyelinating neuropathy, next to CMT1A)
   1. CMTX1: caused by mutations in the gene for the gap junction protein 1 (*GJB1*) or connexin 32 (*Cx32*) on Xq13.1
   2. CMT3A(Dejerine-Sottas syndrome): PMP32 (17p11.2-12)
      1. Also called hereditary motor and sensory neuropathy type III (HMSN III).
      2. A severe demyelinating neuropathy.
      3. Autosomal dominant new mutations (*PMP22* mutations).
      4. Clinical symptoms overlapping with CMT1: these two disorders may represent a spectrum of related clinical phenotypes that can arise from allelic missense point mutations in the *PMP22* gene.
      5. Allelic mutations in the *MPZ* gene similarly identified in sporadic patients

with DSS, also implying that CMT type 1 and DSS constitute a spectrum of peripheral neuropathy phenotypes with common genetic bases.
3. CMT3B: *MPZ* (1q22-q23)
4. CMT3C: unknown (8q23-q24)
5. DSS-EGR: *EGR2* (10q21-q22)
6. CMT3D or CMT4F: *periaxin* (19q13.1-q13.2)
7. CMTX6: *PDK3* (Xp22.11)

8. X-linked recessive form of CMT (Bird 2015a, d; Wang and Yin 2015)
   1. CMTX2: unknown (Xp22.2)
   2. CMTX3: unknown (Xq26.3-q27.1)
   3. CMTX4 (Cowchock syndrome): *AIFM1* (Xq24-q26.1)
   4. CMTX5: *PRPS1* (Xq22.3) (Kim and Kim 2013)
9. Autosomal dominant distal hereditary motor neuropathy (HMN) form of CMT
   1. Distal HMN I: unknown (7q34-q36)
   2. Distal HMN II: *HSP22*, *HSP27* (12q24.3, 7q11-q21)
   3. Distal HMN V (HMN 5A): *GARS* (7p15)
   4. Distal HMN V (Silver syndrome, HMN 5B): *BSCL2* (11q12-q14)
   5. Distal HMN VII A: unknown (2q14)
   6. Distal HMN VII B: *DCTN1* (2p13)
   7. Distal HMN ALS4: *SETX* (9q34)
10. Autosomal recessive distal HMN form of CMT
    1. Distal HMN III: unknown (11q13)
    2. Distal HMN IV: unknown (11q13)
    3. Distal HMN VI: *IGHMBP2* (11q13.2-q13.4)
    4. Distal HMN-Jerash: unknown (9p21.1-p12)
11. Autosomal dominant hereditary sensory and autonomic neuropathy (HSAN)
    1. HSAN I: *SPTLC1* (9q22.1-q22.3)
    2. HSAN 1B associated with cough and gastroesophageal reflux: unknown (3p22-p24)
12. Autosomal recessive HSAN form
    1. HSAN II: *HSN2* (12p13.33)
    2. HSAN III (Riley-Day syndrome): *IKBKAP* (9q31)
    3. HSAN IV: *TRKA*/*NGF* (1q21-q22)
    4. HSAN V: *TRKA*/*NGF* (1q21-q22), *NGFβ* (1p13.2-p11.2)
    5. HSAN with deafness and global delay: unknown
    6. HSAN with spastic paraplegia: unknown (5q15.31-q14.1)
    7. X-linked HSAN associated with deafness: unknown (Xq23-q27.3)
13. Problems in classification of inherited neuropathies
    1. *PMP22* deletion causes HNPP.
    2. PMP22 duplication causes CMT1A.
    3. Deletion and duplication of *PMP22* causes HNPP and CMT1A, respectively, establishing a singular genetic mechanism as the cause of the two most common inherited neuropathies.
    4. *PMP22* mutations cause DSS, CMT1A, and HNPP.
    5. *MPZ* mutations cause DSS, CMT1B, and a CMT2-like phenotype.
    6. *GJB1* mutations cause CMT1X.
    7. *EGR2* mutations cause CMT1 and DSS.

Clinical Features

1. Family history (Jani-Acsadi et al. 2008)
   1. Autosomal dominant
      1. Multiple generations affected
      2. Male-to-male transmission
      3. Females and males affected
   2. Sporadic: only one member in the family affected
   3. Autosomal recessive
      1. Consanguinity
      2. Multiple children affected
      3. Parents unaffected
   4. X-linked
      1. No male-to-male transmission.
      2. Males may be more severely affected than females.
2. Clinical phenotype of all forms of CMT
   1. Generally similar
   2. Clinical presentation with distal leg weakness and atrophy

3. Followed by hand involvement
3. Presence of a wide range of variation and severity of symptoms in the affected areas and in the rate of progression of symptoms
4. CMT1A (Garcia 1999; Bird 2015b)
    1. Accounting for 90% of CMT1 patients
    2. A wide range of variation in clinical presentation and severity among affected members of large families with CMT1A
    3. CMT1A *PMP22* duplication
        1. Asymptomatic patients
            1. Observed in some family members in large pedigrees
            2. No symptoms
            3. Normal neurologic examination including ability to walk on their heels and normal stretch reflexes
            4. Slow MNCV
            5. Duplication of *PMP22* confirming the diagnosis of CMT1A
        2. Symptomatic patients
            1. Onset: first decade or early in the second decade
            2. Presenting symptoms in infants and children: walking on their toes and have severe tightness of the heel cord
            3. Occasional patients born with foot deformities including clubfeet
            4. Other symptoms: abnormal gait, foot deformities, or loss of balance
            5. Muscle weakness starting in the feet and legs
            6. Frequently trip over objects on the floor and sprain ankles as a result of weakness of the dorsiflexor muscles of the feet, innervated by the peroneal nerves
            7. Difficulty or inability to walk on heels
            8. Tight heel cords
            9. Foot drops with each step, forcing the patient to flex the hip, giving the steppage or equine gait
            10. Pes cavus deformity developing with age
            11. Atrophy of the legs, due to wasting of the peroneal muscles giving the stork legs or "inverted champagne bottle" appearance
            12. Weakness of the intrinsic hand muscles usually occurring late in the course of the disease
            13. Claw hands
            14. Mild sensory loss to pricking pain in the legs in some patients
            15. Frequently decreased vibratory sense
        3. Associated symptoms
            1. Enlarged (auricular, ulnar, and peroneal) nerves in 20–25% of the patients, not related to the age of the patient or the severity of the disease.
            2. Tremor in 40% of the patients.
            3. Hip dysplasia with hip pain and a limp.
            4. Restrictive lung disease usually not a major problem in patients with CMT1.
            5. Other associated features: spastic paraparesis, deafness, optic atrophy, Marfan-like appearance, and absence of eyebrows.
            6. Exacerbation of the weakness in 50% of the patients with early-onset disease during pregnancy and delivery.
            7. Certain medication and neurotoxic substances may aggravate the neuropathy in patients with CMT.
    4. CMT1A point mutations in *PMP22*
        1. Show severe disease in childhood.
        2. Found in patients that have been diagnosed with the Dejerine-Sottas syndrome.
5. CMT1B (Bird 2015b)
    1. Accounting for less than 10% of CMT1 patients
    2. *MPZ* mutations identified in CMT1B, DDS, or congenital hypomyelination phenotype
    3. Differentiating from CMT1A
        1. An earlier onset of the symptoms manifested by delayed ability to walk
        2. Proximal leg weakness without decreasing ambulation

3. Slower motor NCVs

6. Pregnancy and delivery in CMT1 (Rudnik-Schöneborn et al. 1993)
   1. Rate of obstetric complications: same as in the normal population
   2. No deleterious effect on fetal outcome
7. CMT2 (Bird 2015c)
   1. Neuronal type (a progressive peripheral motor and sensory neuropathy)
   2. Clinical phenotype similar to the type 1 CMT
      1. Symptoms
         1. Tingling
         2. Numb feeling
         3. Pain
         4. Muscle cramp
         5. Slow deterioration of muscle strength (distal weakness with feet involvement first) and increase in disability (Teunissen et al. 2003)
         6. Walking instability
         7. Increased loss of strength
         8. Increased sensory loss
      2. Signs
         1. Atrophied hands
         2. Atrophied legs
         3. Postural tremors
         4. Fasciculations
         5. Pes cavus
         6. Claw toes
         7. Steppage gait
         8. Leg atrophy
         9. Short calf muscles
         10. Abnormal Romberg sign
         11. Absent biceps, triceps, knee, and ankle jerks
   3. Other characteristics
      1. Generally a later onset of the symptoms than seen in type 1
      2. Pes cavus and short calf muscles: predominantly present in patients with early-onset disease
      3. Less involvement of the hand muscles
      4. No clinical evidence of palpable enlarged nerves
      5. No sensory deterioration
      6. Normal or slightly diminished motor nerve conduction velocities
8. Autosomal recessive CMT (CMT4) (Bird 2015e)
   1. Progressive motor and sensory neuropathy
   2. Rare heterogeneous forms with a broad spectrum of clinical severity
   3. Presentation of symptoms in infancy by delay in walking
   4. Early and rapidly progressive deformities of the feet and spine
   5. A high incidence of associated features such as sensorineural hearing loss
   6. Weakness beginning in the feet but affecting both distal and proximal muscles
   7. No enlargement of superficial nerves
   8. Presence of three pathologic forms
9. X-linked CMT (CMTX) (Bird 2015a)
   1. The second most frequent form of CMT (Dubourg et al. 2001)
   2. Inheritance
      1. Dominant form in 90% of cases
      2. Recessive form in 10% of cases
   3. A disease-causing mutation and a family pedigree consistent with X-linked dominant inheritance
      1. Presence of a disease-causing mutation in the *GJB1* (*Cx32*) gene
      2. Lack male-to-male transmission
   4. Males and females with peripheral motor and sensory neuropathy
      1. Affected males
         1. More severe phenotype than the affected females
         2. More severe progressive peripheral motor and sensory neuropathy than that seen in CMT1A
         3. Moderately slow median nerve MNCV: 34.5 ± 6.2 m/s
         4. Reduced motor and sensory nerve amplitudes (median nerve CMAP): 3.7 ± 3.7 mV
      2. Affected females
         1. Normal or mild to moderate signs and symptoms
         2. Moderately slow MNCV: 45.8 ± 7.3 m/s
         3. Reduced motor and sensory nerve amplitudes (median nerve CMAP): 7.8 ± 3.4 mV

5. Signs and symptoms
    1. Typical presenting symptom: weakness of the feet and ankles
    2. Initial physical findings: depressed or absent tendon reflexes with weakness of foot dorsiflexion at the ankle
    3. Typical adult patients
        1. Bilateral foot drop
        2. Symmetrical atrophy of muscles below the knee with stork leg appearance
        3. Pes cavus
        4. Atrophy of intrinsic hand muscles especially the thenar muscles of the thumb
        5. Absent tendon reflexes in both upper and lower extremities
        6. Proximal muscles usually remaining strong
        7. Mild to moderate sensory loss (deficits of position, vibration, and pain/temperature) commonly occurring in the feet
6. Other characteristics
    1. Symptoms typically develop between ages 5 and 25 years.
    2. Onset commonly within the first decade in males.
    3. Earlier onset with delayed walking in infancy as well as later onset beyond the fourth decades possible.
    4. Mild symptoms may be overlooked by patient and physician.
    5. Severe motor slowing in most families, consistent with a demyelinating form of the disease.
    6. A predominant axonal type has also been described.
10. Dejerine-Sottas syndrome (DSS) (Pareyson 1999)
    1. The syndrome still used to define the rare cases of severe hypo-demyelinating neuropathy of early onset.
    2. Criteria for diagnosis:
        1. Early onset of the disease by age 2 years with delayed motor milestones.
        2. Severe motor, sensory, and skeletal muscle deficits, frequently extending to proximal muscles. Sensory ataxia and scoliosis also present.
        3. Very low conduction velocities, usually <12 m/s.
        4. Nerve biopsy reveals severe hypomyelination and basal lamina reduplication, with multiple onion bulb formation.
        5. Presence of the enlarged nerves.
    3. De novo point mutations in either *MPZ* or *PMP22* found in most DSS cases.
    4. May be a variant of CMT1A or CMT1B.
11. Congenital hypomyelination (CH) (Pareyson 1999)
    1. An ill-defined and extremely rare disease merging into Dejerine-Sottas disease.
    2. A clinical syndrome characterized by infantile hypotonia due to distal muscle weakness and very slow NCVs. Severe weakness may lead to early death.
    3. Severe contractures of joints or arthrogryposis multiplex congenita in severe cases.
    4. Mutation analysis showing *MPZ* mutations, suggesting some of the DSS and CH are part of a spectrum of the demyelinating form of CMT1B.
12. Hereditary neuropathy with liability to pressure palsies (HNPP) (Pareyson 1999)
    1. Also called familial recurrent polyneuropathy or tomaculous neuropathy
    2. Clinical manifestations
        1. Periodic/transient/recurrent episodes of numbness, muscular weakness, and atrophy
        2. Palsies after relatively minor compression or trauma of the peripheral nerves (the axillary, median, radial, ulnar, and peroneal nerves)
    3. Nerve conduction abnormalities mainly localized at common entrapment sites
    4. Nerve biopsy: occurrence of focal myelin thickenings (tomacula) in several fibers
    5. Commonly associated with deletion of *PMP22* gene (De Jonghe et al. 1997)
13. Genotype-phenotype classification of CMT disorders
    1. CMT demyelinating types

1. CMT1A PMP22 duplication
    1. Roussy-Levy syndrome: a phenotypic variant of the CMT1A (pes cavus, distal limb weakness, areflexia, tremor in the upper limbs, gait ataxia, and distal sensory loss)
    2. Dejerine-Sottas syndrome or HMSN III: an interstitial hypertrophic neuropathy of infancy, characterized by early onset, severe clinical features, and the presence of the enlarged nerves
    3. CMT1A with calf hypertrophy
    4. Scapuloperoneal form of muscular atrophy, associated with pes cavus, areflexia and distal sensory loss (Davidenkow syndrome)
2. CMT1A PMP22 point mutations: Dejerine-Sottas syndrome
3. CMT1B
    1. Dejerine-Sottas syndrome
    2. Congenital hypomyelination: characterized by infantile hypotonia due to distal muscle weakness, areflexia, very slow NCVs, and hypomyelination (few thin myelin lamella)
4. CMT1C
5. Autosomal recessive demyelinating CMT
6. Hereditary neuropathy with liability to pressure palsies (HNPP)
7. CMTX: Cx32 mutations

2. CMT type 2 neuronal types
    1. CMT2A (1p36)
    2. CMT2B (ulcerations and limb amputations, linkage on chromosome 3)
    3. CMT2C (diaphragm weakness and vocal cord paralysis)
    4. CMT2D (a locus on chromosome 1)

14. Genotype/phenotype correlation in X-linked dominant CMT disease (Hahn et al. 1999)
    1. Cx32 missense mutations located within the second transmembrane domain and/or cytoplasmic loop might be associated with milder clinical phenotype.
    2. Missense, chain-terminating, or deletion mutations in all other locations of the connexin 32 protein caused severe forms of CMTX and disease onset in the first decade.

Diagnostic Investigations

1. Two types of CMT, currently distinguishable by the value of motor nerve conduction velocity (MNCV) of median nerve on electrophysiologic examination and nerve biopsy findings
    1. Demyelinating form (CMT1)
        1. Slowing of MNCV (15–30 m/s)
        2. Hypertrophy of peripheral nerves with onion bulb formation and segmental demyelination
    2. Axonal form (CMT2)
        1. Normal or mildly slow MNCV (>40 m/s)
        2. Normal size nerves
        3. No evidence of segmental demyelinations
2. Motor nerve conduction velocity of the median nerve (MNCV) of inherited demyelinating neuropathies (Lewis et al. 2000)
    1. Uniform conduction slowing
        1. CMT1A
        2. CMT1B
        3. CMT4
        4. Dejerine-Sottas syndrome
        5. Metachromatic leukodystrophy
        6. Cockayne disease
        7. Krabbe disease
    2. Multifocal conduction slowing
        1. CMTX
        2. Hereditary neuropathy with liability to pressure palsies (HNPP)
        3. Adrenomyeloneuropathy
        4. Pelizeus-Merzbacher disease with proteolipid protein null mutation
        5. Refsum disease (retinitis pigmentosa, deafness, ataxia, and ichthyosis)
    3. Incompletely characterized electrophysiology
        1. *PMP22* point mutations
        2. *MPZ* point mutation
        3. *EGR2* mutations

4. *P0* point mutations
5. Adult-onset leukodystrophies
6. Merosin deficiency

4. Usually normal in CMT2

3. EMG testing: evidence of an axonal neuropathy in CMT2
   1. Positive waves
   2. Polyphasic potentials
   3. Fibrillations
   4. Reduced amplitudes of evoked motor and sensory responses
4. Compound motor action potentials (CMAP): greatly reduced in CMT2
5. Muscle biopsy (Ericson et al. 1998)
   1. CMT1 (demyelinating form): angular atrophic fibers that were scattered or in small groups, findings commonly described as neuropathic
   2. CMT2 (with normal or near-normal MNCV)
      1. Atrophic fibers that were rounded or elongated in groups and hypertrophic fibers with central nuclei and fiber splitting
      2. Increased amounts of connective tissue, "whorled fibers," degeneration, and signs of regeneration, findings commonly regarded as myopathic.
6. Nerve biopsy (Bassam 2014)
   1. CMT1A
      1. Regression of onion bulb
      2. Significantly increased ratio of axon diameter/total fiber diameter, indicating arrested remyelination
   2. CMT1B
      1. Demyelinating process with onion bulb formation (sural nerve biopsy).
      2. Ultrastructural finding of uncompacted myelin is consistent with the accepted function P0 as a homophilic adhesion molecule.
   3. CMT2
      1. No histological evidence of well-formed onion bulbs on the nerve biopsies
      2. Loss of myelinated fibers with signs of regeneration, axonal sprouting, and atrophic axons with neurofilaments
   4. Autosomal recessive demyelinating CMT with three pathologic forms
      1. Classical onion bulbs
      2. Basal laminar onion bulbs
      3. Focally folded myelin sheaths
   5. CMTX
      1. Nerve hypertrophy or onion bulb formation: rare
      2. A primary axonal neuropathy with axonal sprouting in most affected individuals
      3. Prominent demyelination consistent with a CMT1 phenotype in some cases
   6. Congenital hypomyelination: hypomyelination (few thin myelin lamella) without active myelin breakdown products and early onion bulb formations
   7. Hereditary neuropathy with liability to pressure palsies (HNPP): demyelination and remyelination with tomacula or sausage-like thickening on the myelin sheath
7. Molecular genetic testing
   1. CMT1
      1. CMT1A
         1. Sequence analysis for point mutations in the *PMP22* gene
         2. Mutation scanning for point mutations in the *PMP22* gene
      2. CMT1B
         1. Sequence analysis for point mutations in the *MPZ* gene
         2. Mutation scanning for point mutations in the *MPZ* gene
      3. CMT1C: direct DNA/linkage analysis for point mutation in *LITAF*
      4. CMT1D
         1. Sequence analysis for point mutations in the *EGR2* gene
         2. Mutation scanning for point mutations in the *EGR2* gene
   2. CMT2E: sequence analysis for mutations in *NEFL*
   3. CMT4
      1. CMT4E: molecular genetic testing for *EGR2*
      2. CMT4F: molecular genetic testing for *PRX*

4. CMTX: sequence analysis to detect mutations in the *GJB1* coding region (accounting for about 90% of mutations in patients with CMTX)
5. Molecular genetic testing approach
    1. In cases of HNPP
        1. Test for the *PMP22* deletion (since this is by far the major cause).
        2. If negative, then sequence *PMP22*.
    2. In CMT patients with uniform slowing of motor NCVs between 10 and 35 ms
        1. Test for the *PMP22* duplication (since this is the major cause of CMT1).
        2. If negative, sequence *PMP22*, *MPZ*, *GJB1*, and *EGR2*.
    3. In DSS with appropriately slowed NCVs
        1. Test for the duplication: usually negative.
        2. Sequence *PMP22*, *MPZ*, *GJB1*, *EGR2*, and *PRX* genes.
    4. In cases where CMT1X is the most likely diagnosis (based on intermediate slowing of NCVs, no male-to-male transmission)
        1. Sequence *GJB1* alone: the appropriate initial test.
        2. If negative, sequence *MPZ* and *NEFL*.
    5. In cases of suspected CMT2
        1. Probably premature to test for *MPZ* and *NFEL* mutations alone (the only commercially available tests).
        2. Await a comprehensive battery in the future.
8. Targeted testing strategies (Hoyle et al. 2015)
    1. Conduction velocity less than 15 m/s and severe phenotype: *PMP22* duplication most common, but *MPZ* with a sizable minority
    2. Conduction velocity 15–35 m/s and classic phenotype: *PMP22* duplication testing (as high as 89% sensitivity in this category)
    3. Conduction velocity 35–45 m/s and classic phenotype: *GJB1* with high sensitivity with no male-to-male transmission. *MPZ* next most frequent
    4. Conduction velocity greater than 45 m/s or responses unobtainable: *MPZ* approximately 20% of cases (highest sensitivity with severe phenotype or unobtainable responses)
9. Next-generation sequencing: boosted the identification of CMT associated genes (Timmerman et al. 2014)
    1. Targeted next-generation sequencing and its limitation in CMT gene finding
    2. Whole-exome sequencing as a successful approach in CMT gene finding
    3. First whole-genome sequencing of a CMT patient (Lupski et al. 2010)
    4. Future perspectives and the need to share large datasets and genetic variants
10. Presymptomatic diagnosis from newborn cord blood for those couples who decide not to test prenatally (Lebo 1998)

Genetic Counseling

1. Recurrence risk (Bird 2015a, b, c, d)
    1. Patient's sib
        1. Autosomal dominant CMT
            1. Majority of CMT1 patients carry the *PMP22* duplication and represent de novo mutation cases (De Jonghe et al. 1999): recurrence risk to sib not increased unless a parent is affected, in which case the recurrence risk is 50%.
            2. Patients with de novo *MPZ* mutation: recurrence risk to sibs not increased unless a parent is affected, in which case the recurrence risk is 50%.
        2. Autosomal recessive CMT: 25%
        3. X-linked dominant CMT (patients with Cx32 mutation)
            1. A carrier mother has a 50% risk of transmitting the disease-causing mutation with each pregnancy. Sons who inherit the mutation will be affected. Daughters who inherit the

mutation will be carriers and may or may not be affected.
2. A noncarrier mother: recurrence risk to sibs low but not zero since the risk of germ line mosaicism in mothers is not known.

2. Patient's offspring
1. Autosomal dominant CMT: patients with *PMP22* duplication, *PMP22* deletion, or *MPZ* mutation will have a 50% risk of transmitting the disease to the offspring.
2. Autosomal recessive CMT: not increased unless the spouse is a carrier or affected.
3. X-linked dominant CMT (patients with *Cx32* mutation):
1. All the daughters of an affected male inherit the mutation but may or may not have symptoms.
2. None of his sons will be affected.

2. Prenatal diagnosis: available to pregnancies at risk for CMT1A, CMT1B, CMT2E, CMT4E, CMT4F, and CMTX
1. Identify the disease-causing allele of an affected family member before prenatal diagnosis.
2. Mutation analysis of fetal DNA obtained from amniocentesis or CVS.
3. CMT1
1. Prenatal diagnosis of CMT1A by FISH (Lebo et al. 1993; Kashork et al. 1999a, b)
1. Parental blood samples confirmed to be duplicated for *PMP22* by FISH.
2. Interphase FISH assay performed on amniotic fluid specimens and chorionic villus samples to detect a submicroscopic 17p12 duplication in the fetus with CMT1A.
2. Preimplantation diagnosis for CMT1A (De Vos et al. 1998, 2003): selection of healthy embryos is made based on the presence of the nonduplicated haplotype and heterozygosity of a marker (Löfgren et al. 1999)
4. CMT2E: molecular genetic testing of DNA extracted from fetal cells obtained from amniocentesis or CVS for testing of *NEFL* mutation when both disease-causing alleles of an affected family member are identified
5. CMT4E and CMT4F: molecular genetic testing of DNA extracted from fetal cells obtained by amniocentesis or CVS for testing of *EGR2* and *PRX* mutations, respectively, when both disease-causing alleles of an affected family member are identified
6. CMTX
1. Prenatal diagnosis: available to pregnancies of women who are heterozygotes for a disease-causing *GJB1* mutation that has been identified in an affected family member.
2. Amniocentesis or CVS:
1. Determination of the fetal sex
2. DNA extracted from cells from male fetuses tested to determine if a disease-causing mutation is present

3. Preimplantation genetic diagnosis (Sharapova et al. 2004; Lee et al. 2013; Bird 2015d) may be available for some families in which the pathogenic variant(s) have been reported.
4. Management:
1. No specific treatment to reverse or slow the natural disease process
2. Supportive care (Jani-Acsadi et al. 2008)
1. Musculoskeletal dysfunctions: scoliosis, foot deformities, and hand atrophy
1. Evaluation by physiatry
2. Physical therapy
3. Occupational therapy
4. Orthotics and assistive devices
5. Corrective surgery
2. Respiratory dysfunction
1. Pulmonary evaluation
2. Continuous positive airway pressure (CPAP)
3. Bi-level positive airway pressure (BiPAP)
4. Scoliosis correction
3. Sensory dysfunction
1. Pain control
2. Topical medications (lidocaine patch)
3. Antidepressants: tricyclics (amitriptyline, nortriptyline, desipramine)

4. Anticonvulsants: gabapentin, pregabalin
5. Lamotrigine, carbamazepine

4. Iatrogenic neurology
   1. Avoid medications that are known to cause nerve damage: chemotherapeutic drugs (vincristine, cis-platinum, mivacurium), Taxol, cisplatin, isoniazid, and nitrofurantoin.
   2. Refer to CMTA Web site regarding updated lists of medication (www.charcot-marie-tooth.org).

Fig. 1 (**a**, **b**) Two patients with Charcot-Marie-Tooth disease showing stork-like legs and pes cavus deformities

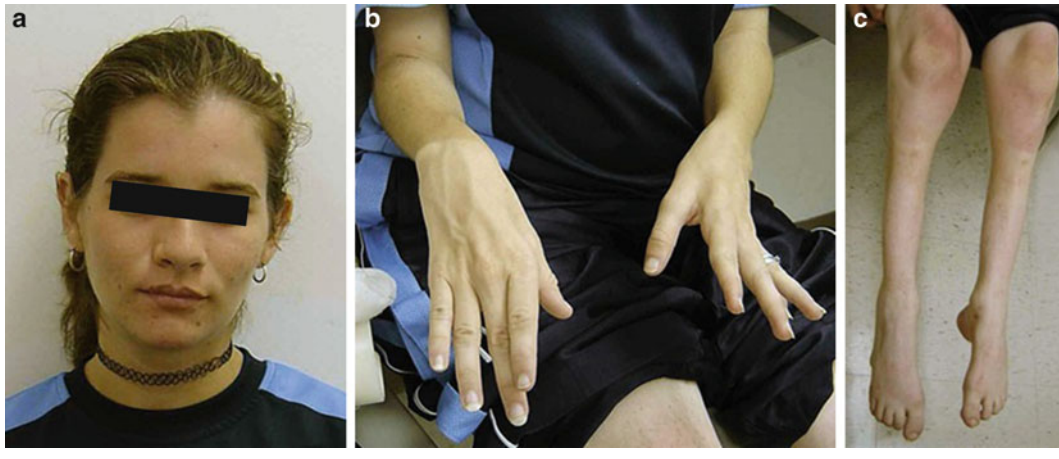

Fig. 2 (**a**–**c**) A 23-year-old female with Charcot-Marie-Tooth disease showing stork legs with muscle wasting, pes cavus deformities, and foot drop. She has absent deep tendon reflexes. Her onset of disease began in the third grade with a history of tripping, falling, and clumsiness. Family history revealed affected individuals in three generation

Fig. 3 An 11-year-old girl was evaluated for "stork-like legs." She was noted to have loss of balance, tip-toe walking, and muscle weakness, particularly in her lower extremities. On examination, she was noted to have claw hands (finger contractures at PIP), "stork-like" legs, muscle weakness in the lower extremities, tight heel cord, pes cavus, and absent deep tendon reflexes. The motor nerve and sensory nerve conduction tests showed severe prolonged latency and severe reduced amplitude. The left median, radial, tibial, and peroneal motors and median, ulnar, radial, and sural sensories were absent. The study showed electrophysiologic evidence of a severe sensorimotor polyneuropathy. A complete CMT molecular evaluation showed her to possess one known recessively inherited mutation in the *GDAP1* gene and one or more DNA variants of unknown significance

Fig. 4 A 26-year-old mother was diagnosed to have Charcot-Marie-Tooth disease type 1A at 15 years of age with complaints of weakness and pain in the arms, shoulders, hips, and neck and had a slight decrease in the pulmonary function test. Her DNA testing showed duplication of peripheral myelin protein (*PMP22*) gene, inherited from her father. The 5-month-old daughter is asymptomatic and carries no *PMP22* gene mutation

Fig. 5 A 31-year-old man with Charcot-Marie-Tooth disease type 1A, confirmed molecularly to have *PMP22* gene mutation associated with 17p12 microduplication. A son died at 3 month of age of ACTA1-related nemaline myopathy. The baby's chromosome microarray analysis showed 17p12 and 16q23.1 microduplications. Duplication of *PMP22* gene on 17p12 is associated with Charcot-Marie-Tooth disease type 1A. The clinical significance of 16q23.1 is unclear

CHARGE Syndrome

Contents

CHARGE syndrome is a genetic disorder characterized by a specific and a recognizable pattern of anomalies, namely, *c*oloboma, *h*eart defects, *a*tresia of choana, *r*etardation of growth and/or development, *g*enitourinary defects, and *e*ar anomalies and/or deafness. The pattern of anomalies associated with CHARGE syndrome was described independently by Hall and Hittner et al. in 1979 (Hall 1979; Hittner et al. 1979). However, the acronym "CHARGE association" was coined by Pagon in 1981 (Pagon et al. 1981). At present, with its recognizable pattern and definition, CHARGE is referred to as a syndrome (Pampal 2010; Zentner et al. 2010). The prevalence is estimated to be approximately 1 in 10,000 (Jongmans et al. 2006; Lalani et al. 2006).

Synonyms and Related Disorders

CHARGE association; Coloboma, heart defects, atresia of choana, retardation of growth and/or development, genitourinary defects, and ear anomalies and/or deafness; Hall-Hittner syndrome (Graham 2001)

Genetics/Basic Defects

1. Sporadic in almost all cases (Zentner et al. 2010)
2. Familial in a small number of cases with parent-to-child transmission of *CHD7* mutations (Mitchell et al. 1985; Metlay et al. 1987; Lalani et al. 2006; Delahaye et al. 2007; Jongmans et al. 2008; Vuorela et al. 2008; Wincent et al. 2008; Pauli et al. 2009)
    1. Parents generally have a mild CHARGE phenotype or are asymptomatic
    2. Their children display more severe defects (a full spectrum of CHARGE features)
    3. Somatic mosaicism for a CHD7 mutations has been described in an asymptomatic mother of two affected siblings (Jongmans et al. 2008)
    4. Germ-cell mosaicism has also been described in an asymptomatic father of two affected children (Pauli et al. 2009)
3. Cause: De novo mutations in the gene encoding chromodomain helicase DNA

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_38

binding protein 7 (*CHD7*), located on chromosome 8q12.1, are the major cause of CHARGE syndrome.

4. Individuals with *CHD7* mutations: more commonly have the following findings compared to those without the mutations:
    1. Ocular colobomas
    2. Temporal bone anomalies (semicircular canal hypoplasia/dysplasia)
    3. Facial nerve paralysis
5. Pathogenetic mechanism: Haploinsufficiency for *CHD7* is the most likely pathogenic mechanism underlying CHARGE syndrome:
    1. Nonsense or frameshift mutations: majority of *CHD7* disruptions
    2. Chromosomal abnormalities (Sanlaville et al. 2002)
        1. Interstitial deletion of 8q11.2-q13 (Arrington et al. 2005)
        2. A balanced translocation disrupting 8q12 (Hurst et al. 1991; Johnson et al. 2006)
        3. Several chromosomal abnormalities not involving CHD7 have been reported to confer a phenotype similar to those seen in CHARGE patients (Clementi et al. 1991; North et al. 1995; Wieczorek et al. 1997; Lev et al. 2000)
    3. Recently, CHARGE patients without detectable single-base mutation were found to have heterozygous deletions of CHD7 (Wincent et al. 2009). In fact, CHD7 deletion was originally detected by array-CGH (Vissers et al. 2004). Alterations in copy number have been reported but represent only a small fraction of the reported disruptions of CHD7 (Bergman et al. 2008).
    4. Other conditions with CHD7 mutations having significant clinical overlap with CHARGE syndrome
        1. Kallmann syndrome (Ogata et al. 2006; Kim et al. 2008; Jongmans et al. 2009)
        2. Omenn-like syndrome (Gennery et al. 2008)
        3. 22q11.2 deletion syndrome: more often than anticipated (Sanka et al. 2007; Corsten-Janssen et al. 2013)

Clinical Features

1. Major criteria (Lalani et al. 2012)
    1. Eye anomalies (Chestler and France 1988; Russell-Eggitt et al. 1990)
        1. *C*oloboma (80–90%) of the iris, choroid disc, and optic nerve
        2. Microphthalmia/anophthalmia
        3. Secondary retinal detachments and cataracts
        4. Total or partial vision loss
        5. Superior palpebral ptosis, epicanthus, and telecanthus
    2. Choanal *a*tresia (50–60%) (Kaplan 1985; Harris et al. 1997)
    3. *E*ar anomalies/deafness (90%) (Morgan et al. 1993)
        1. External ears (Dhooge et al. 1998)
            1. Asymmetry
            2. Posteriorly rotated
            3. Dystopia
            4. Prominent
            5. Increased width
            6. Decreased height
            7. Cup-shaped
            8. "Snipped-off" helical fold
            9. Prominent antihelix discontinuous with the antitragus
            10. Triangular concha
            11. Small or absent lobes
        2. Middle ears
            1. Chronic serous otitis media approaching 100%
            2. Eustachian tube anomalies associated with choanal atresia or palatal cleft
            3. Ossicular malformations
            4. Conductive hearing loss
        3. Inner ears
            1. Cochlear defects
            2. Sensorineural hearing loss (Thelin et al. 1986; Edwards et al. 1995)
        4. Temporal bone malformations
    4. Cranial nerve dysfunction (70–90%)
        1. Cranial nerve I: anosmia
        2. Cranial nerve II: unilateral or bilateral facial palsy
        3. Cranial nerve VIII: sensorineural deafness and vestibular problems

4. Cranial nerves IX and/or X: velopharyngeal incoordination and swallowing problems with aspiration

2. Minor criteria
   1. *H*eart disease (cardiovascular malformations) (75–85%)
      1. Conotruncal defects (e.g., tetralogy of Fallot)
      2. AV canal defects
      3. Aortic arch anomalies
      4. Others
         1. Double outlet right ventricle
         2. Hypoplastic left/right heart
   2. Growth and mental *r*etardation (70–100%)
      1. Growth deficiency
      2. Short stature
      3. Delayed motor milestones
      4. Hypotonia
      5. Mental retardation
   3. *G*enital anomaly (70–80%)
      1. Hypogonadotropic hypogonadism and delayed puberty
      2. Males: micropenis, cryptorchidism, delayed/incomplete pubertal development
      3. Females: hypoplastic labia, delayed/incomplete pubertal development
   4. Orofacial cleft (15–20%)
      1. Cleft lip/palate
      2. Laryngeal cleft
   5. Tracheoesophageal fistula/esophageal atresia (15–20%)
   6. Distinctive face (70–80%)
      1. Broad forehead
      2. Square face
      3. Facial asymmetry
      4. Ptosis
      5. Arched eyebrows
      6. Shallow supraorbital ridges
      7. Iris coloboma
      8. High nasal bridge
      9. Full nasal tip
      10. Microretrognathia
      11. Cleft lip/palate
      12. Laterally protruding ears
      13. Prognathism, prominent mandibular mentum, and generalized facial narrowing with advancing age
      14. Occasional broad or webbed neck with sloping shoulders
3. Occasional findings
   1. Thymic/parathyroid hypoplasia: DiGeorge sequence without chromosome 22q11 deletion (rare)
   2. Renal anomalies (15–25%)
      1. Dysgenesis
      2. Horseshoe/ectopic kidney
      3. Hydronephrosis
   3. Hand anomalies
      1. Polydactyly, ectrodactyly, thumb hypoplasia (rare)
      2. Altered palmar flexion creases (50%)
   4. General appearance
      1. Webbed neck (rare)
      2. Sloping shoulders (occasional)
      3. Accessory or hypoplastic nipples (rare)
   5. Abdominal defects
      1. Omphalocele (rare)
      2. Umbilical hernia (15%)
   6. Spine anomalies (rare)
      1. Scoliosis
      2. Hemivertebrae
   7. CNS malformations
      1. Midline defects (corpus callosum agenesis, arhinencephaly, septal agenesis, meningoencephalocele, partial vermis agenesis) (22%)
      2. Asymmetry (cerebral, ventricular, cerebellar) (18%)
      3. Hindbrain anomalies (brain stem hypotrophy demonstrated by CT scan or MRI, vermian agenesis) (14%)
4. Different diagnostic criteria for CHARGE syndrome (Sanlaville and Verloes 2007; Pampal 2010)
   1. Clinical criteria (Pagon et al. 1981): presence of four criteria out of six, and at least one major
      1. Major criteria
         1. Choanal atresia
         2. Ocular coloboma
      2. Minor criteria
         1. Heart defects of any type
         2. Retardation (of growth and/or of development)
         3. Genital anomalies

4. Ear anomalies (abnormal pinnae or hearing loss)

2. Diagnosis criteria of CHARGE (Verloes 2005): typical CHARGE (presence of either all three major signs or two major signs with two minor signs), partial CHARGE (two majors plus one minor), and atypical CHARGE (two majors but no minors or one major plus two minors)
    1. Major signs
        1. Ocular coloboma
        2. Choanal atresia
        3. Hypoplastic semicircular canals
    2. Minor signs
        1. Rhombencephalic dysfunction (brain stem and cranial nerve III-XII anomalies, including sensorineural deafness)
        2. Hypothalamo-hypophyseal dysfunction (including growth hormone and gonadotrophin defects)
        3. Mental retardation
        4. Malformation of mediastinal organs (heart, esophagus)
        5. External or middle ear malformations
3. Diagnostic criteria of CHARGE (Blake et al. 1998; Blake and Prasad 2006): presence of either all four major signs or three major signs plus three minor signs
    1. Major signs (classical four Cs)
        1. Coloboma (of iris, retina, choroid, disc, microphthalmia)
        2. Choanal atresia/stenosis (unilateral or bilateral, membranous, or bony)
        3. Cranial nerve dysfunction: facial palsy (unilateral or bilateral), sensorineural deafness, and/or swallowing problems
        4. Characteristic ear anomalies: external ear (lop or cup-shaped); middle ear (ossicular malformations, chronic serous otitis), mixed deafness, cochlear defects
    2. Minor signs
        1. Characteristic CHARGE facies (sloping forehead, flattened nasal tip)
        2. Orofacial cleft (cleft lip and/or palate)
        3. Cardiovascular malformations: all types, especially conotruncal defects (e.g., tetralogy of Fallot), AV canal defects, and aortic arch
        4. Tracheoesophageal fistula: all types
        5. Genital hypoplasia: males (micropenis, cryptorchidism); females (hypoplastic labia); both males and females (delayed, incomplete pubertal development)
        6. Developmental delay: delayed motor milestones, language delay, mental retardation
        7. Growth deficiency: short stature, growth hormone deficiency
    3. Occasional signs
        1. Renal anomalies: duplex system, vesicoureteric reflux
        2. Spinal anomalies: scoliosis, osteoporosis
        3. Neck/shoulder anomalies: sloping, Sprengel deformity, kyphosis
        4. Hand anomalies: fifth finger clinodactyly, camptodactyly, cutaneous syndactyly
4. Another major diagnostic criteria by Amiel et al. (2001): emphasized the importance of temporal bone imaging in the diagnosis of the disease along with characteristic clinical findings
5. Neonatal brain dysfunction (Tellier et al. 1998)
    1. Severe sucking and swallowing problems
    2. Pharyngo-esophageal dysmotility
    3. Respiratory problems
    4. Cranial nerve palsies or anomalies (VI, VII, VIII, IX, X)

Diagnostic Investigations

1. Audiology, tympanometry, BAER, and CT of temporal bones for evaluation of hearing loss (Blake and Prasad 2006)
2. Auditory brain stem responses (ABR): an effective tool for early assessment of hearing function in children with multisystem involvement (Edwards et al. 2002)

3. Visual analysis and electroretinogram and functional vision testing: to identify and document severity of visual loss
4. Dilated fundoscopic exam for colobomas
5. Nasal pharyngeal feeding tube passage and CT scan of upper airway for evaluation of choanal atresia
6. Blood urea nitrogen, creatinine, electrolytes, and calcium: to evaluate renal function and exclude hypocalcemia (if present, evaluate T-cells for signs of DiGeorge sequence)
7. Hormonal studies (Hsu et al. 2014)
    1. Luteinizing hormone-releasing hormone and human chorionic gonadotropin tests in cases of hypogenitalism
    2. Growth hormone (GH) stimulation levels to exclude GH deficiency as a cause of growth retardation
    3. Prepubertal bone age X-ray, followed by screening for hypogonadotrophic hypogonadism in early puberty for growth
8. Echocardiography for cardiovascular malformations
9. Holter monitoring: to detect cardiac rhythm abnormalities
10. Abdominal ultrasound and voiding cystourethrogram: to exclude renal anomalies
11. Skeletal survey: to exclude skeletal anomalies, especially cervical spine anomalies, and scoliosis
12. Head CT scan and/or MRI for brain malformations and defective formation of the ossicles of the middle ear, cochlear, and semicircular canals. Olfactory bulbs and tracts imaging may be pathognomonic for CHARGE syndrome (Chalouhi et al. 2005).
13. Chromosome analysis for associated chromosomal anomalies
14. FISH to exclude 22q11 deletion
15. *CHD7* gene mutation testing available clinically
16. Multiple ligation-dependent probe amplification (MLPA) and comparative genomic hybridization (CGH): for patients with clinical suspect of CHARGE syndrome (Pisaneschi et al. 2015)
17. Whole exome sequencing (Martin et al. 2016)
    1. Identification of CHD7 mutations in some cases
    2. Other genes: likely to be the underlying cause of their CHARGE-like syndrome
    3. May be helpful to some patients, particularly those who are negative for CHD7 mutations and present with atypical findings
18. Strongly recommend performing *CHD7* analysis in any patients with a 22q11.2 deletion phenotype but without TBX1 haploinsufficiency and performing a genome-wide array for 22q11.2 deletions in clinical CHARGE patients without a *CHD7* mutation (Corsten-Janssen et al. 2013)

Genetic Counseling

1. Recurrence risk (Lalani et al. 2012)
    1. Patient's sib
        1. A parent affected or with a CHD7 mutation: a 50% risk
        2. Neither parent affected: the empiric risk is approximately 1–2% due to germ-line mosaicism. Typically, CHARGE syndrome is caused by a *CHD7* de novo mutation; the risk to the sibs is small. However, several sib pairs born to unaffected parents have been reported (Jongmans et al. 2006; Lalani et al. 2006), likely due to germ-line mosaicism confirmed in a report (Pauli et al. 2009).
    2. Patient's offspring
        1. Severely affected individuals do not reproduce
        2. Each child of a mildly affected individual: a 50% risk of inheriting the mutations
2. Prenatal diagnosis (Lalani et al. 2012)
    1. Ultrasonography: difficult unless in the pregnancy at risk
    2. Molecular genetic testing: possible for pregnancies at increased risk by analysis of DNA extracted from fetal cells obtained by amniocentesis or CVS, provided the disease-causing allele of an affected family

member has been identified prior to prenatal diagnosis
3. Preimplantation genetic diagnosis: possible for families in which the disease-causing mutation has been identified

3. Management
   1. Neonatal brain stem dysfunction (Tellier et al. 1998)
      1. Feeding problems/failure to thrive (use of antispasmodics, Nissen fundoplication, gastrostomy tube feeding, gastrostomy)
      2. Oxygen therapy
      3. Tracheostomy
   2. Developmental delay/mental retardation
      1. Early infant intervention
      2. Special education
   3. Neonatal surgeries (Morgan et al. 1993)
      1. Respiratory problems: may require tracheostomy for aspiration of secretions
      2. Choanal stenosis/atresia (choanoplasty): airway stabilization and circulatory support; requires surgical opening for the posterior choanae by placing stents to keep the nasal passages open if there is obstructed breathing
      3. Laryngotracheal abnormalities (tracheoesophageal fistula, laryngomalacia, tracheomalacia, subglottic stenosis, laryngeal clefts, vocal cord/bulbar palsy)
      4. Congenital heart defects: corrective surgery when indicated
      5. Inguinal hernia
      6. Imperforate anus
   4. Colobomas: requires ophthalmologic care
   5. External ear anomalies/hearing loss
      1. Hearing aids for deafness
      2. Surgery for ear canal and temporal bone abnormalities
   6. Congenital absence of vestibular function: gradually develop motor function, and presumably improve equilibrium by using visual and proprioceptive inputs (Murofoshi et al. 1997)
   7. Cochlear implant surgery: an effective technological resource to provide information on hearing as one source for language construction (Cardoso et al. 2013)
   8. Management of other associated anomalies

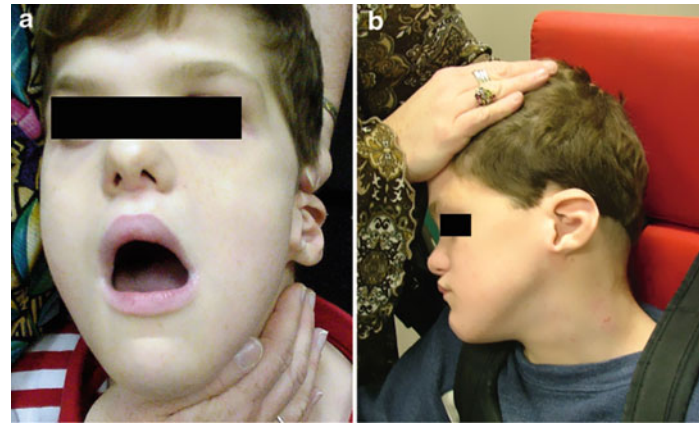

Fig. 1 (**a**, **b**) A boy with typical CHARGE association at ages 11 (*front view*) and 15 (*lateral view*). The patient had bilateral colobomas, choanal atresias, growth and mental retardation, hypogonadism, and ear anomalies with hearing loss

Cherubism

Contents

In 1933, Jones (1933) first described familial occurrence of painless enlargement of the jaws in three siblings. Later in 1938, Jones (1938) reported observations on the same family under the title "familial multilocular cystic disease of the jaws" and coined the term "cherubism" after the cherubs of Renaissance art for the full round cheeks and the upward cast of the eyes giving the children a peculiarly grotesque, cherubic appearance.

Cherubism is a benign maxillary bone dysplasia of childhood, usually showing an autosomal dominant inheritance with variable penetrance and spontaneously resolving after puberty. The prevalence of cherubism is 1 or less in 10,000.

Genetics/Basic Defects

1. Inheritance (Faircloth et al. 1991):
    1. Autosomal dominant with variable penetrance (Peters 1979; Caballero Herrera and Vinals Iglesias 1998; Zohar et al. 1989; Kömerik et al. 2014)
    2. Familial (Jones et al. 1950, 1965; Caffey and Williams 1951) in 80% of cases
    3. Males affected twice as often as females
    4. 80% overall penetrance:
        1. 100% in males
        2. 50–70% in females
    5. Variable expressivity
2. Cause (Ueki et al. 2001; Lo et al. 2003):
    1. Gene responsible for cherubism: mapped to chromosome region 4p16.3 (Southgate et al. 1998; Mangion et al. 1999).
    2. Caused by mutations in the gene encoding SH3-binding protein *SH3BP2*:
        1. Familial cherubism: all mutations are present in exon 9 and affect three amino acids within a conserved six amino acid sequence (Hatani and Sada 2008).
        2. Sporadic cherubism: description of a *SH3BP2* mutation in a case of nonfamilial case (Imai et al. 2003) and in an aggressive case of sporadic cherubism (Carvalho et al. 2008).
        3. Novel mutations in the *SH3BP2* gene have been described in sporadic central giant-cell lesion (which is indistinguishable histologically from cherubism), suggesting that both conditions share the same genetic alteration (Carvalho et al. 2009).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_39

3. SH3BP2 cherubism mutation potentiates TNF-α-induced osteoclastogenesis via NFATc1 and TNF-α-mediated inflammatory bone loss (Mukai et al. 2014).

Clinical Features

1. Variable size of the jaw lesions in cherubism:
    1. Minor lesions of both jaws
    2. Massive involvement of both jaws
2. Natural history:
    1. Classically normal at birth.
    2. Onset usually between 14 months and 5 years. However, the severe cases are evident at birth.
    3. Progresses until puberty.
    4. Usually progression stops after puberty.
    5. Regression of the bone lesions (involution of the disease) without treatment in some cases.
    6. Rapidly growing and extensively deforming lesions of the maxilla and the mandible including the coronoids and condyles in severely affected individuals.
3. Characteristic "eyes raised to heaven" cherubic appearance: an appearance of the cherubs portrayed in Renaissance art:
    1. Fullness of the lower half of the face (cheeks and jaw).
    2. Retraction of the lower lids by the stretched skin over the cheeks pulling down the lower eyelids. Consequently, a thin line of sclera is exposed beneath the iris, and the eyes appear to be raised heavenward in a manner reminiscent of "the cherubs in Renaissance paintings."
4. Painless hard enlargement of the jaws
5. Exclusively affecting the maxilla and mandible:
    1. The mandible usually involved.
    2. Involvement of the maxilla in 60% of cases.
    3. Painless lesions.
    4. Bilateral enlargement with loss of bone in the jaws and its replacement with large amount of fibrous tissue.
    5. Dental effect by bone lesion:
        1. Premature loss of deciduous teeth
        2. Displacement of permanent dentition
    6. Swelling usually abates by the third decade, whereas radiographic changes commonly persist into the fourth decade.
6. Submandibular lymph node enlargement in 45% of cases
7. Ocular manifestations (Carroll and Sullivan 2001; Yoo et al. 2015):
    1. Lower lid retraction
    2. Proptosis
    3. Strabismus with diplopia
    4. Globe displacement
    5. Visual loss due to compressive optic neuropathy (optic nerve atrophy)
    6. Retinal vein occlusion
    7. Macular folds and scarring (Ahmadi et al. 2003)
    8. Rare extension of lesion into the orbits (Colombo et al. 2001)
8. Rare upper airway involvement:
    1. Displaced tongue affecting speech, mastication, swallowing, and respiration
    2. Obstructive apnea (complete nasal obstruction) (Battaglia et al. 2000)
9. Extremely rare extrafacial skeletal involvement:
    1. Upper humerus
    2. Bilateral triquetral bones
    3. Anterior ribs
    4. Upper femoral necks
10. Modified clinical classification for cherubism (Raposo-Amaral et al. 2007; Pérez-Sayáns et al. 2013; Jiao et al. 2015):
    1. Grade 0: existence of the mutation without expression of the disease
    2. Grade I: lesion of the mandible without signs of root resorption
    3. Grade II: lesions involving the mandible and maxilla without signs of root resorption
    4. Grade III: aggressive lesion of the mandible with signs of root resorption
    5. Grade IV: lesions involving the mandible and maxilla with signs of root resorption
    6. Grade V: the rare, massively growing, aggressive, and extensively deforming

juvenile lesions involving the maxilla and mandible
7. Grade VI: the rare, massively growing, aggressive, and extensively deforming juvenile lesions involving the maxilla, mandible, and orbits

11. Rare associated syndromes:
    1. Noonan syndrome
    2. Ramon syndrome (Baskin et al. 2011):
        1. Cherubism
        2. Short stature
        3. Mental retardation
        4. Gingival fibromatosis
        5. Epilepsy
    3. Fragile X syndrome
    4. Craniosynostosis
12. Functional impairment (Tiziani et al. 1999):
    1. Mastication problems
    2. Speech difficulty
    3. Tooth alteration
    4. Loss of normal vision
13. Psychological consequences
14. Prognosis:
    1. Normally a self-limiting condition.
    2. Unusually extensive cases of cherubism have been reported (Ramon and Engelberg 1986), and even a fatal case is reported due to pulmonary and gastrointestinal infection as a result of aspiration given the gross deformity of the child (Silver et al. 2002).
15. Differential diagnosis (Baskin et al. 2011):
    1. Four main types of fibrous dysplasia:
        1. Monostotic fibrous dysplasia: only one bone is affected.
        2. Polyostotic: multiple bones are affected.
        3. McCune-Albright syndrome:
            1. Polyostotic form
            2. Accompanied by pigmentary lesions
            3. Endocrine dysfunction presenting as precocious puberty in females
        4. Craniofacial form of fibrous dysplasia:
            1. Only bones of the craniofacial complex are affected.
            2. Onset in the second decade in majority of patients.
            3. Generally unilateral lesions tend to become static once skeletal maturity is reached.
            4. Clinically difficult to differentiate from cherubism if the skeletal abnormalities are localized to the jaws.
            5. Molecularly different from cherubism.
    2. Infantile cortical hyperostosis:
        1. Diagnosed in the first 6 months of life
        2. Radiographically does not produce cystic areas
        3. Characterized by thickening of the mandibular lower border
        4. Does not have bilateral expression
    3. Osteitis fibrosa cystica secondary to hyperparathyroidism:
        1. Increased serum alkaline phosphatase
        2. Increased serum calcium
        3. Decreased serum phosphorus
        4. Increased urinary phosphorus
    4. Congenital infiltrating lipomatosis of the face (please see the chapter "► Congenital Infiltrating Lipomatosis of the Face")
    5. Noonan-like/multiple giant-cell lesion syndrome (Dunlap et al. 1989; Jafarov et al. 2005; Lee et al. 2005):
        1. Phenotypic overlap and frequently misdiagnosed with cherubism.
        2. Mutations in PTPN11 and SOS1 have been described in both familial and simplex cases (Hanna et al. 2009).
    6. Central giant-cell granuloma:
        1. Histologically cannot be distinguished from cherubism (Kaugars et al. 1992; De Lange and Van den Akker 2005)
        2. A somatic mutation in SH3BP2: identified in one individual (Carvalho et al. 2009)
    7. Odontogenic myxoma of the face: mimicry of cherubism (Kleiber et al. 2014)
    8. Ramon syndrome:
        1. Cherubism: a part of the syndrome
        2. Short stature
        3. Intellectual disability
        4. Gingival fibromatosis

Diagnostic Investigations

1. Orthodontic assessment, commonly required as the jaw distortion leads to permanent dental abnormalities:
   1. Malocclusive bite
   2. Premature loss of deciduous teeth
   3. Wide-spaced, misplaced, unerupted, or absent permanent teeth
2. Ophthalmologic examination, for rare individuals who may have:
   1. Lower lid retraction
   2. Proptosis
   3. Diplopia
   4. Globe displacement
   5. Visual loss caused by optic atrophy
3. Serum alkaline phosphatase levels may be elevated (Kozakiewicz et al. 2001).
4. Radiography (Jones et al. 1950; Hitomi et al. 1996; Tiziani et al. 1999; Agrawal et al. 2014):
   1. Extensive involvement of the mandible and the maxilla
   2. Multilocular radiolucent areas in the mandible and maxilla with expansion of the bony cortex:
      1. Often very extensive
      2. With a few irregular bony septa
      3. Multilocular rarefactions replaced by sclerosis with progressive calcification in the adult
   3. Absent and displaced teeth in the involved areas
5. CT scan:
   1. Superior in making the diagnosis
   2. Determining the degree of severity
6. Histological changes in cherubism:
   1. Replacement of the normal bony architecture with proliferating fibrous tissue containing numerous giant cells (Ayoub and El-Mofty 1993)
   2. Mononuclear fibroblastic stroma:
      1. Nonneoplastic fibrous lesions rich in multinucleated giant cells identified as osteoclasts
      2. Irregular bone formation
   3. A peculiar perivascular cuffing of collagen: considered by some to be pathognomonic for the condition (Adante and Breen 1996)
   4. Histological resemblance to the following disorders (Mangion et al. 1999):
      1. Giant-cell tumor
      2. Giant-cell granulomas
      3. Ossifying fibroma
      4. Fibrous dysplasia of the jaw
      5. Paget disease of bone
7. Molecular genetic testing (Baskin et al. 2011):
   1. To confirm the diagnosis in a proband with the suggestive clinical findings and typical radiologic and/or histologic manifestations.
   2. Sequence analysis: *SH3BP2* sequence variants in exon 9 detect an estimated 80% of mutations.

Genetic Counseling

1. Recurrence risk (Baskin et al. 2011):
   1. Patient's sib. The risk depends on the genetic status of the parents:
      1. An affected parent: a 50% risk
      2. Clinically unaffected parents and/or the parents not detected to have a disease-causing mutation: a low recurrence risk but greater than that of the general population because of the possibility of germ-line mosaicism
   2. Patient's offspring: a 50% risk of inheriting the mutation.
2. Prenatal diagnosis (Baskin et al. 2011):
   1. Ultrasonography: not possible since the lesion is postnatal in nature
   2. Molecular analysis possible on fetal DNA obtained by amniocentesis or CVS if the disease-causing mutation (*SH3BP2*) has been identified in an affected family member
   3. Preimplantation genetic diagnosis: possible for families at risk in which the disease-causing mutation has been identified
3. Management:
   1. Although cherubism represents a benign and localized maxillary dysplasia, it requires prompt surgical but conservative treatment and careful follow-up to avoid permanent lesions (malocclusion and/or edentulism) (Mortellaro et al. 2009).

2. Observation:
    1. Generally self-limiting lesions and subside with age (Katz et al. 1992)
    2. Surgical intervention required only in cases with esthetic or functional problems
3. Tracheostomy to secure the airway for upper airway obstruction.
4. Teeth extraction from the sites of fibrous changes.
5. Curettage alone or in combination with surgical contouring: considered the treatment of choice.
6. Resection of the orbital lesions may be required to improve visual impairment.
7. Prompt recurrence is likely if surgery is performed at an early age.
8. Radiation therapy is ineffective and contraindicated in view of the following risks:
    1. Osteoradionecrosis
    2. Interference with dentofacial growth and development
    3. Effect on future surgical procedures
9. Tacrolimus (calcineurin inhibitor) as a new therapy for cherubism enhances bone formation by stimulating osteogenesis and inhibiting osteoclastogenesis (Kadlub et al. 2015).

Chiari Malformation

Contents

In 1891, Chiari first described a dysplasia of the nervous system consisting of herniation of the cerebellar tonsils into the foramen magnum. There are three types of Chiari malformations. The commonest ones are type I and type II, and the latter has been named the Arnold-Chiari malformation (De Reuck and Theinpont 1976).

Synonyms and Related Disorders

Chiari malformation type I with syringomyelia; Chiari malformation type II (Arnold-Chiari malformation); Chiari malformation type III

Genetics/Basic Defects

1. Classification of Chiari malformations according to the severity (Cesmebasi et al. 2015)
    1. Chiari type I (CMI) malformations (the milder malformation)
        1. Ectopia of the cerebellar tonsils (caudal herniation of the cerebellar tonsils and inferior cerebellum through the foramen magnum).
        2. Usually an isolated feature encountered in adults.
        3. The anomaly occurs sporadically but can be transmitted genetically in some families (Milhorat et al. 1999; Schanker et al. 2011).
    2. Chiari type II (CMII) malformations (also called the Arnold-Chiari malformation) (the more severe malformation)
        1. Downward displacement of the cerebellar medulla and fourth ventricle into the spinal canal
        2. Almost always associated with meningomyelocele
        3. May be associated with polygyria, cortical heterotopia, and dysgenesis of the corpus callosum
    3. Chiari type III (CMIII) malformations (the most severe malformation) (Caldarelli et al. 2002)
        1. Downward displacement of most of the cerebellum into a high cervical/low occipital encephalocele
        2. Malformation consisting of anatomical anomalies typical of Chiari type II malformation with those of a high cervical/occipital encephalocele

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_40

4. Chiari type IV (CM IV) malformations
    1. Absence of hindbrain herniation
    2. Defined as hypoplasia or aplasia of the cerebellum
    3. Occasionally associated with tentorial hypoplasia (Wellons et al. 2005)
5. Chiari type 1.5 (CM 1.5) malformations
    1. Recently coined to specifically address patients with Chiari type I malformation with an added component of brainstem and fourth ventricle elongation/caudal descent (Iskandar and Oakes 1999)
    2. Have symptoms similar to Chiari type I patients
    3. May have a higher incidence of developing syringomyelia
6. Chiari type 0 (CM 0) malformations
    1. Used to describe a particular subset of patients.
    2. Have syringomyelia but no associated findings of hindbrain herniation.
    3. Patients' symptoms improve following posterior cranial fossa decompression.
    4. Presence of craniocervical anomalies such as those seen in Chiari type I malformation in many patients.
    5. Crowding of the foramen magnum and obstruction of the median aperture (of Magendie) by arachnoid veils and adhesions are seen (Wellons et al. 2005).
    6. By definition, Chiari type 0 patients present with symptoms associated with syringohydromyelia (these symptoms are like those seen in patients with Chiari type I malformation and syringomyelia).

2. Acquired Chiari I malformation caused by conditions leading to increased intracranial pressure
    1. Head injury
    2. Hydrocephalus
    3. Craniosynostosis
3. Brainstem dysfunction, sensory disturbance, and motor loss caused by impaction of the tonsils against the cervicomedullary structures

Clinical Features

1. Patients with Chiari I malformation
    1. Asymptomatic in majority of patients
    2. General symptoms (Thomas et al. 1999)
        1. Headache (Weinberg et al. 1998)
        2. Fatigue
        3. Memory loss
        4. Pressure on the neck
        5. Back pain
        6. Insomnia
        7. Poor circulation
        8. Nausea
        9. Menstrual problems
        10. Sexual alterations
        11. Hypothermia
        12. Bronchial aspirations
        13. Respiratory alterations
        14. Drop attacks
        15. Rare reports of sudden death
    3. Ocular symptoms
        1. Loss of vision
        2. Intolerance of bright light
        3. Diplopia
    4. Otolaryngologic symptoms (Naya Galvez et al. 2002)
        1. Vestibular manifestations
            1. Imbalance
            2. Swaying
            3. Dizziness
            4. Positional vertigo
            5. Spontaneous vertigo
            6. Nystagmus
            7. Hearing loss
            8. Tinnitus
        2. Alterations of cranial pairs
            1. Dysphagia
            2. Dysphonia
            3. Alterations in tongue mobility
            4. Loss of smell
            5. Facial hypoesthesia
        3. Sleep apnea
    5. Cerebellum compression symptoms
        1. Ataxia
        2. Nystagmus
        3. Gait difficulties
        4. Opisthotonos

5. Horner's syndrome
6. Paralysis of the last cranial nerves
7. Hypotonia
8. Trembling
9. Dysarthria
10. Dysmetria

6. Associated CNS anomalies
    1. Stenosis of the aqueduct of Silvia
    2. Meningomyelocele
    3. Syringomyelia (cystic dilation of the spinal cord)
7. Symptoms associated with syringomyelia
    1. Known to accompany 50–70% of patients with Chiari I malformations.
    2. Obstructed cerebrospinal fluid at the site of cerebellar tonsillar herniation shows perivascular movement of CSF from the spinal subarachnoid space into the spinal cord with each Valsalva maneuver and causes syringomyelia.
    3. Tingling, hypoesthesia, and burning sensation in the extremities.
    4. Thermalgesic anesthesia.
    5. Alteration in muscular reflexes.
    6. Areflexia.
    7. Alteration of kinesthesia.
    8. Motor skill dysfunction.
    9. Headache or nonradicular pain in the shoulder, back, and limbs
    10. Headache usually suboccipital and upper cervical in location and is exacerbated by Valsalva maneuvers.
    11. Associated with the development of a painful, rapidly progressive, or left-curving scoliosis.
    12. Recent reports of spontaneous radiographic improvement of childhood Chiari malformations and syringomyelia.
8. Chiari I malformation in children and adolescents (Genitori et al. 2000)
    1. Natural history of an asymptomatic Chiari I malformation in children
        1. Not well understood
        2. Rarely reported to resolve spontaneously
        3. Asymptomatic at the time of diagnosis in many children
        4. Degree of tonsillar ectopia correlating well with the presence of neurologic signs and symptoms
        5. Rare reports of sudden death
    2. Group I (asymptomatic)
        1. Age at diagnosis: 3 months to 17 years
        2. Associated conditions: hydrocephalus, craniofacial syndromes, epilepsy, and occult spinal dysraphism
    3. Group II (brainstem compression)
        1. Age at diagnosis: 7 months to 26 years
        2. Associated conditions: craniofacial syndromes, hydrocephalus (Di Rocco et al. 2011), and precocious puberty
        3. Symptoms: neck pain, vertigo, headache, numbness, swallowing difficulties, apnea, opisthotonos, brachialgia, hyposthenia, spasticity, and hemifacial pain
    4. Group III (presence of syringomyelia) (Paul et al. 1983; Dauser et al. 1988; Dure et al. 1989; Dyste et al. 1989). Symptoms are:
        1. Numbness
        2. Sensory loss
        3. Neck pain
        4. Vertigo
        5. Scoliosis
        6. Hyposthenia
        7. Headache
        8. Muscle hypotrophy
        9. Swallowing difficulties
        10. Limb pain
    5. Associated disorders of Chiari type I malformations (Loukas et al. 2011)
        1. Craniostenosis (e.g., Apert syndrome)
        2. Endocrinopathy (e.g., acromegaly)
        3. Hyperostosis (e.g., craniometaphyseal dysplasia)
        4. Bone mineral deficiency (e.g., familial vitamin D-resistant rickets)

5. Cutaneous disorders (e.g., acanthosis nigricans)
6. Spinal defects (e.g., atlantoaxial assimilation)
7. Space-occupying lesions (e.g., brain tumors)
8. Others (e.g., Beckwith-Wiedemann syndrome)

6. Prognosis (Nagib 1994)
   1. The clinical presentation of younger children (less than 6 years old) appeared similar to older children (over 6 years of age), except for sleep apnea, which was limited to the younger age group.
   2. Patients with pronounced motor and sensory deficits had the worst prognosis for recovery.

2. Patients with Chiari II malformation (Rauzzino and Oakes 1995)
   1. Almost invariably associated with myelomeningocele (90%)
   2. Brainstem signs in 20% of patients with Chiari II malformation in children and adolescence
      1. Vertigo
      2. Bioccipital headache
      3. Cerebellar dysfunction
      4. Progressive paresis of the arms
3. Patients with Chiari III malformation (Caldarelli et al. 2002)
   1. Rarest of the Chiari malformations
   2. Associated with a high cervical or occipital encephalocele (Häberle et al. 2001; Ivashchuk et al. 2015)
   3. Prognosis for nearly all reported patients
      1. Various degree of developmental delay
      2. Epilepsy
      3. Hypotonia
      4. Spasticity
      5. Upper and/or lower motor neuron deficits
      6. Lower cranial nerve dysfunction
   4. CNS anomalies usually observed in an occipital encephalocele
      1. A small cranial fossa
      2. Caudal displacement of cerebellar tonsils and vermis
      3. Medullary kinking
      4. Tectal beaking
      5. Obvious hydrocephalus

Diagnostic Investigations

1. CT or MRI
   1. Chiari I malformation
      1. Incidental detection in asymptomatic individuals (Elster and Chen 1992)
      2. Herniation of the tonsils >5 mm below the foramen magnum on MRI considered diagnostic
   2. Chiari II malformation (Naidich 1981; El Gammal et al. 1988; Chapman et al. 2015)
      1. Caudal cerebellum (100%)
      2. A small posterior fossa and pointed morphology of the herniating inferior cerebellar tonsil, cervical cord syrinx, and corpus callosal dysgenesis
         1. Kinking of medulla on spinal cord (79%)
         2. Elongation of brainstem and low medulla, stretched aqueduct, and fourth ventricle (75%)
         3. Beaking of quadrigeminal plate (60%)
         4. Large massa intermedia (55%)
         5. Large fourth ventricle (25%)
         6. Hydromyelia (15%)
         7. Calvarial three-dimensional surface-shaded reconstructions from a CT: lacunar skull seen in Chiari II malformation with numerous calvarial pits and thinning
   2. Chiari III malformation (Castillo et al. 1992; Aribal et al. 1996; Caldarelli et al. 2002)
      1. An occipitocervical meningoencephalocele protruding through a bony defect involving the lower occipital squama and/or the posterior arch of the first cervical vertebrae
      2. A small posterior cranial fossa with low tentorial attachment
      3. Scalloping of the clivus

4. Massive herniation of the hypoplastic cerebellar structures into the malformation
5. Beaking of the tectal plate
6. Dysgenesis of the corpus callosum
7. Severe ventricular dilatation (hydrocephalus)

2. Cranial and spinal magnetic resonance (MR) imaging: used to identify the degree of tonsillar descent and document the presence of syringohydromyelia (McVige and Leonardo 2014)
3. Cine flow MRI (Ventureyra et al. 2003)
   1. Understand the dynamics of cerebrospinal fluid at the craniocervical junction
   2. Understand pathophysiology of the Chiari I malformation
4. Brainstem auditory evoked potentials (BAEP) (Koehler et al. 2001)
   1. Consistently abnormal in symptomatic Chiari II malformation
   2. Showing a positive predictive value of 88% in predicting central neurologic sequelae in newborns and infants

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: not increased
   2. Patient's offspring: not increased
2. Prenatal diagnosis
   1. Prenatal ultrasound diagnosis of Chiari I malformation (Iruretagoyena et al. 2010).
      1. A lip of cerebellum is downwardly displaced with the tonsils, but the fourth ventricle remains in the posterior fossa.
      2. Enlarged third ventricle.
      3. Cerebellar hypoplasia with marked cystic enlargement of the fourth ventricle.
      4. This condition may coexist with syringomyelia, which is a cyst formation on the cervical portion of the spinal cord.
   2. Prenatal diagnosis of Chiari II malformation (Chapman et al. 2015).
      1. Fetal ultrasound
         1. "Lemon sign": altered fetal calvarium with concave scalloping of the frontal bones
         2. "Banana sign": effaced cisterna magna and compressed fetal cerebellum which has an unusual elongated morphology
         3. Classic "lemon and banana" signs: the gold standard in the early screening of Chiari II malformation
         4. Demonstrate the myelomeningocele, occurring most often in the lumbar region
         5. A triangular shaped of the posterior horn of the lateral ventricle in coronal plane imaging
         6. Ventriculomegaly
      2. Fetal MR imaging: will show following additional key prognostic factors (Righini et al 2011)
         1. Degree of herniation
         2. Brainstem dysmorphology
         3. Corpus callosal dysgenesis
         4. Cerebral cortical or white matter abnormalities
   3. Strategy for fetal sonographic and MRI diagnosis of CMII when ultrasound study shows ventriculomegaly/hydrocephalus
      1. Presence of myelomeningocele by ultrasound: suspect CMII
      2. Absence of myelomeningocele by ultrasound: proceed to MRI
      3. Presence of tight posterior fossa by MRI (Ando et al. 2007)
         1. Presence of myelomeningocele: suspect CMII
         2. Absence of myelomeningocele: suspect CMII (with open defect) or conditions other than CMII, such as craniosynostosis, swollen hindbrain, and tumor
      4. Absence of tight posterior fossa by MRI: CMII not likely
   4. Prenatal ultrasound/MRI diagnosis of Chiari III malformation (Smith et al. 2007)
      1. Repeat US at 19 weeks demonstrated neural tissue in the cyst, consistent with an encephalocele.

2. MR imaging at 23 weeks confirmed the presence of an occipital encephalocele, demonstrated additional bony defect in the upper cervical spine, and identified abnormal morphology and position of the brainstem consistent with the diagnosis of Chiari III.
3. Postnatal MRI and CT confirmed the fetal MRI findings and demonstrated the utility of fetal MRI in the early evaluation of sonographically detected posterior fossa abnormalities.

3. Management
   1. Chiari I malformation (Bindal et al. 1995; Siasios et al. 2012)
      1. Conservative treatment for asymptomatic patients.
      2. Surgical treatment should be individualized for each patient.
      3. Main treatment consisting of decompressing the structures trapped in the foramen magnum.
         1. Suboccipital craniectomy with or without dural patch grafting and cervical laminectomies: the most often used procedure
         2. Syringosubarachnoid shunt when indicated
      4. Posterior fossa decompression as first-line treatment in symptomatic syringomyelia patients.
      5. Shunting of hydrocephalus.
      6. Major preexisting sensory or motor deficits: poor prognosticators for functional recovery.
   2. Chiari II (Arnold-Chiari) malformation
      1. Seen most often in children with myelomeningocele.
      2. Shunting of hydrocephalus often resolves brainstem symptoms and surgical decompression may not be necessary.
      3. Surgical decompression of posterior fossa and upper cervical spine may be required if brainstem compression symptoms remain after shunting.
      4. Surgical intervention indicated to prevent further deterioration of the motor function and to diminish the progress of spasticity and scoliosis from tethered cord syndrome.
   3. Chiari III malformation (Caldarelli et al. 2002)
      1. Primary closure of the malformation: usually the treatment of choice.
      2. CSF shunting of the associated hydrocephalus postponed to a later phase.
      3. Neonates often require intensive care treatment for the associated severe respiratory distress.

Fig. 1 Sagittal section of a neonate with a large ruptured lumbar meningomyelocele. Arnold-Chiari malformation is evident: the brainstem and lower portion of cerebellum herniate through the foramen magnum and overlap the cervical cord which is severely flattened. The brain shows hydrocephalus

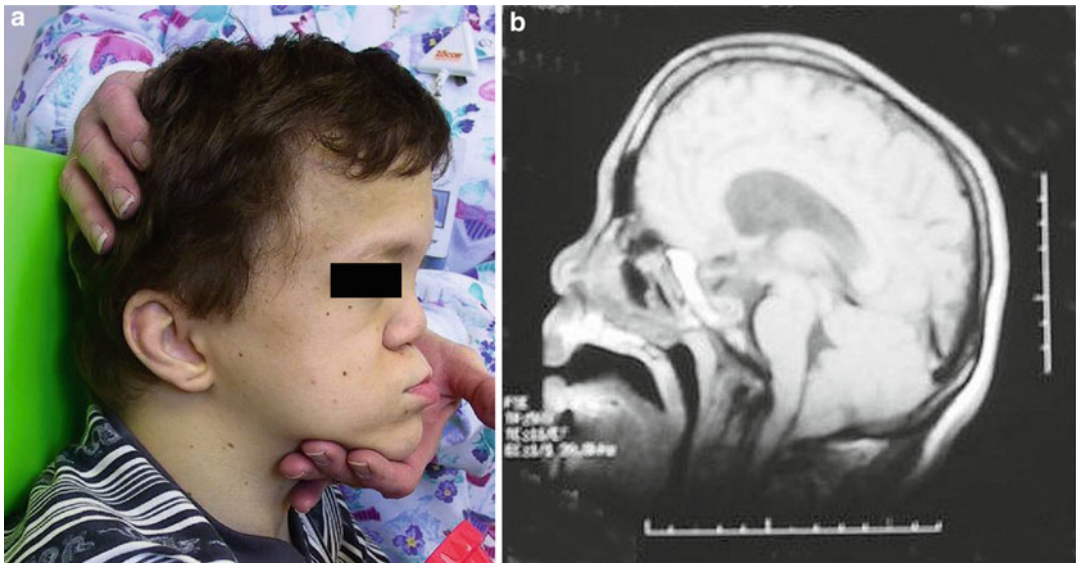

Fig. 2 (**a**, **b**) A patient with multiple congenital anomalies (mental retardation, flat facial plane, epicanthus inversus, blepharophimosis, cataracts, nystagmus, elbow flexion contractures, and vertical talus) with Chiari I malformation (MRI of the brain)

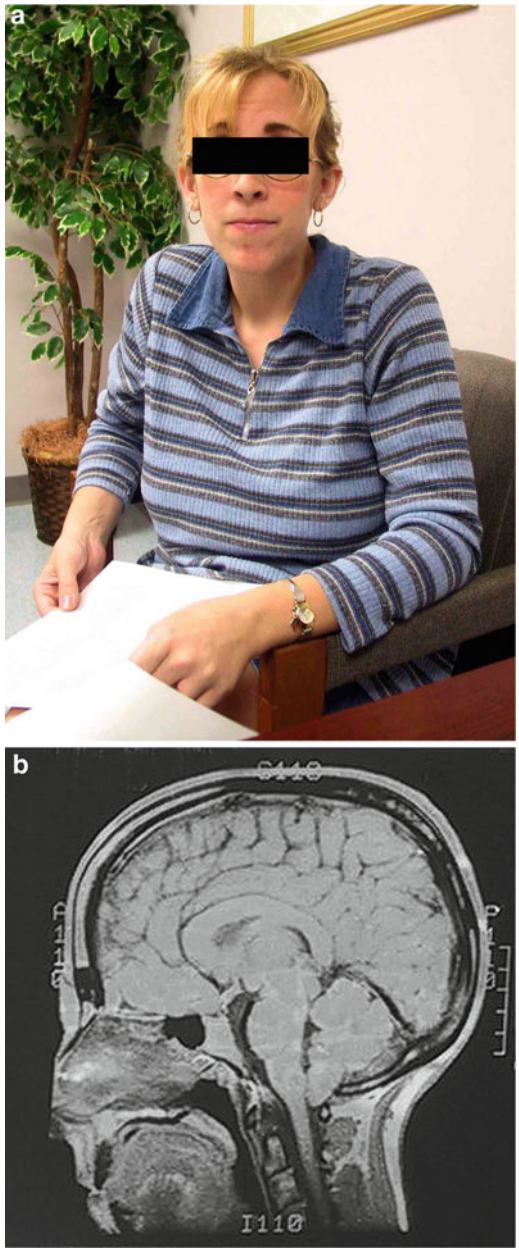

Fig. 3 (**a**, **b**) A 28-year-old female with Chiari I malformation with normal phenotype but complaining headache, dizziness, and neck pain worsened by pregnancy

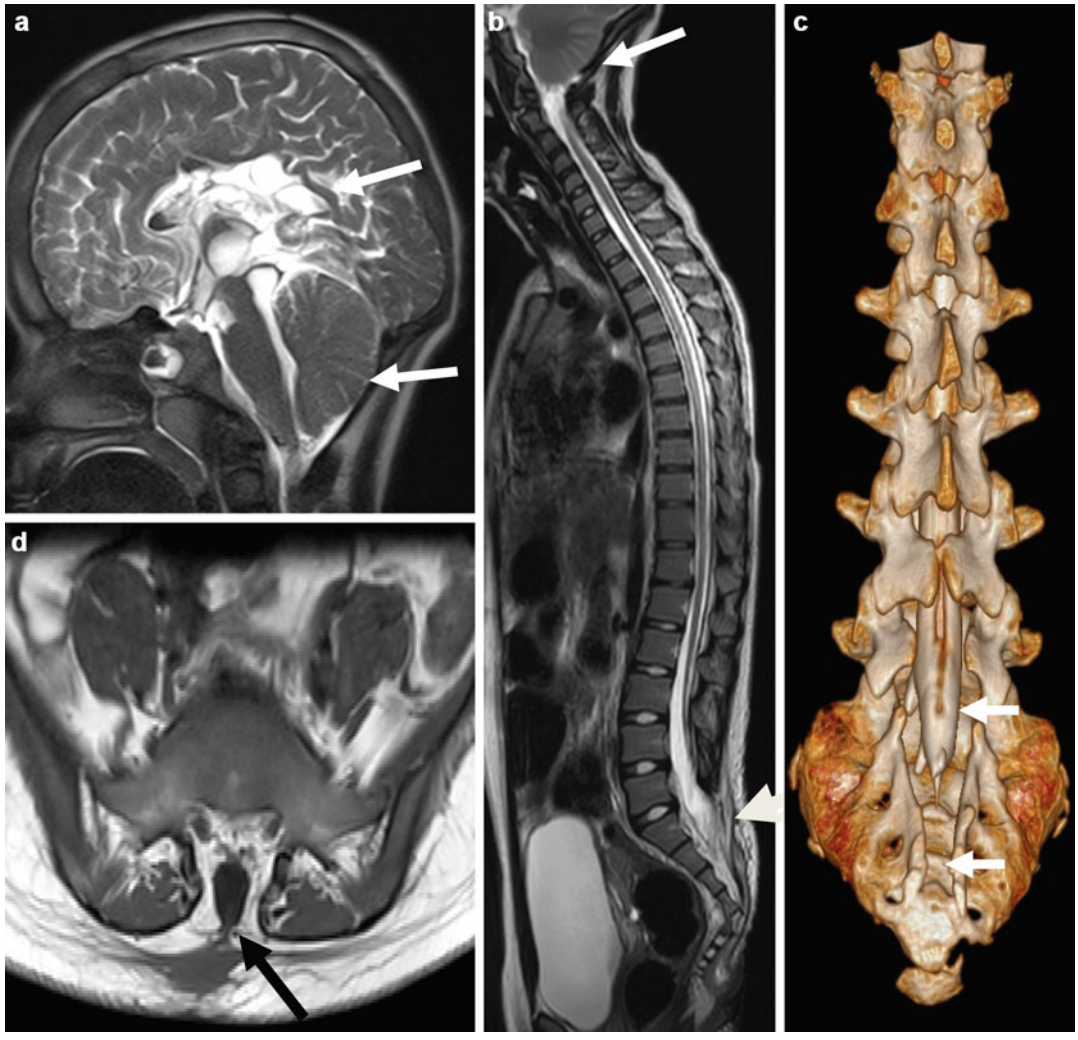

Fig. 4 (**a**–**d**) An 11-year-old female with Chiari II malformation. MRI images of the brain showed cerebellar tonsil located below the foramen of magnum (**a**) (*lower arrow*) and (**b**) (*upper arrow*) with absent corpus callosum (**a**) (*upper arro*w) and mild ventriculomegaly. There is a syrinx from T2–L4 (**b**) (lower arrow) and posterior spinal defect at L5/sacrum (b) (*lower arrow*) and (**d**) (*arrow*). CT 3D reconstruction image (**c**) showed the spina bifida (*arrows*) (Courtesy of Dr. Grace Guo)

Chondrodysplasia Punctata

Contents

Chondrodysplasia punctata (CDP) refers to the radiographic appearance of punctate calcifications, due to abnormal cartilaginous stippling, the result of calcium deposition in the areas of enchondral bone formation, described in a variety of chondrodysplasias.

Synonyms and Related Disorders

Chondrodystrophia calcificans punctata; Conradi-Hünermann syndrome; Conradi-Hünermann-Happle syndrome; Happle syndrome; Rhizomelic form of chondrodysplasia punctata

Genetics/Basic Defects

1. Genetic heterogeneity of chondrodysplasia punctata
    1. Rhizomelic chondrodysplasia punctata type I (RCDP1) (Braverman et al. 1997, 2002)
        1. Autosomal recessive disorder
        2. Caused by mutations in peroxisome biogenesis factor 7 (*PEX7*) gene, mapped at 6q22-q24, which encodes the cytosolic peroxisomal targeting signal type 2 (PTS2)-receptor protein peroxin 7
        3. Genotype-phenotype correlations
            1. Classic RCDP1: all patients homozygous for the L292X mutation (Brites et al. 1998)
            2. Phenotype determined by the other allele if the patients are compound heterozygotes for L292X and another mutation
            3. A milder phenotype associated with several *PEX7* alleles
    2. Rhizomelic chondrodysplasia punctata type 2 (RCDP2)
        1. Autosomal recessive disorder
        2. Caused by mutations in the gene that encodes peroxisomal dihydroxyacetone phosphate acyltransferase (DHAPAT) (Barr et al. 1993)
    3. Rhizomelic chondrodysplasia punctata type 3 (RCDP3)
        1. Autosomal recessive disorder
        2. Caused by mutations in the gene (mapped at 2q31) that encodes peroxisomal alkyl-dihydroxyacetone phosphate synthase (ADHAPS)
    4. Rhizomelic chondrodysplasia punctata type 4 (RCDP4)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_41

1. *FAR1* encodes fatty acyl-CoA reductase 1, producing fatty alcohols used in plasmalogen biosynthesis
2. Mutations in *FAR1* were recently shown to cause peroxisomal fatty acyl-CoA reductase 1 disorder (MIM 616154) (Buchert et al. 2014), also referred to as RCDP4 (Wanders and Poll-The 2015)

5. Rhizomelic chondrodysplasia punctata type 5 (RCDP5) (Barøy et al. 2015)
   1. Mutations in *PEX5* resulting in a selective loss of PEX5L isoform represent a fifth type of RCDP
   2. A novel c.722dupA mutation in *PEX5* gene, the first to exclusively affect PEX5Lexpression, and that unlike previous mutations in *PEX5* gene, results in RCDP instead of Zellweger spectrum disorders
   3. The peroxisomal dysfunction: due to an isolated defect in import of peroxisomal targeting signal 2 (PTS2)-tagged proteins, previously described from mutations in *PEX7* only
6. Relatively mild autosomal dominant Conradi-Hünermann syndrome
   1. Chondrodysplasia punctata, tibia-metacarpal type
   2. Chondrodysplasia punctata, humero-metacarpal type
7. X-linked dominant type only seen in females (Conradi-Hünermann-Happle syndrome) (CDPX2) (Braverman et al. 1999; Kelley et al. 1999; Has et al. 2000; Ikegawa et al. 2000; Becker et al. 2001; Herman et al. 2002)
   1. Lethal in males
   2. Caused by mutations of the 3β-hydroxysteroid-Δ^8-Δ^7-isomerase (also called emopamil-binding protein, EBP)
   3. The gene encoding EBP mapped to Xp11.22-p11.23
   4. EBP: which catalyzes an intermediate step in the conversion of lanosterol to cholesterol
   5. Presence of gonadal and somatic mosaicism in CDPX2
   6. Single gene mosaicism giving rise to CDPX2 in a male (Aughton et al. 2003)
8. X-linked recessive type (Parenti et al. 1997; Brunetti-Pierri et al. 2003) with a deletion of the short arm of the X chromosome (CDPX1)
   1. Caused by defects in arylsulfatase E, a vitamin K-dependent enzyme
   2. The locus of the disease identified through the characterization of patients with chromosomal abnormalities involving the Xp22.3 region
   3. The gene of CDPX1, named *ARSE*, encoding a new sulfatase (arylsulfatase E), showing a high-sequence homology to steroid sulfatase
   4. Point mutations of the *ARSE* gene detected in the DNA of karyotypically normal patients with chondrodysplasia punctata

2. Causes of stippled cartilaginous calcifications (Borochowitz 1991)
   1. Peroxisomal disorders
      1. Zellweger syndrome
         1. A peroxisomal disorder
         2. An autosomal recessive inheritance
         3. Associated stippled calcifications of the epiphyses, particularly common in the patella
         4. Severe hypotonia
         5. Characteristic facies with a high forehead, hypertelorism, epicanthal folds, Brushfield spots, and shallow supraorbital ridges
         6. Club foot deformity
         7. The affected infants that usually die early in infancy
         8. Involvement of other organ systems, especially the brain (migrational disorders) and kidneys (cortical cystic disease of the kidneys)
      2. Rhizomelic chondrodysplasia punctata
   2. Genetic disorders
      1. Conradi-Hünermann chondrodysplasia punctata

2. X-linked dominant chondrodysplasia punctata
3. Smith-Lemli-Opitz syndrome
4. Greenberg dysplasia (cholesterol biosynthesis disorder)
    1. An autosomal recessive disorder
    2. Appears to be caused by an error of sterol metabolism at the level of 3β-hydroxysteroid-Δ14 reductase
    3. Nonimmune hydrops fetalis
    4. Midface hypoplasia
    5. Micrognathia
    6. Rhizomesomelic dwarfism with relatively long and broad hands and feet
    7. Narrow thorax
    8. Protuberant abdomen
    9. Radiographic findings of grossly irregular and deficient ossification of the short tubular bones, fragmented ossification at the ends of the long tubular bones, small pelvic bones with irregular "moth-eaten" contours, platyspondyly with multiple ossification centers of the vertebral bodies, and deficient ossification of the calvaria
5. CHILD syndrome
    1. Congenital hemidysplasia
    2. Ichthyosiform erythroderma
    3. Limb defects (unilateral hypomelia with ipsilateral epiphyseal stippling)
6. Dappled diaphyseal dysplasia (lethal short-limbed dysplasia, type Carty) (Carty 1989)
    1. An autosomal recessive disorder
    2. All cases stillborn or died in utero
    3. Fetal hydrops
    4. Polyhydramnios
    5. Short limbs with relatively long hands and feet
    6. Small thorax
    7. Protuberant abdomen
    8. Radiographic findings of fragmented appearance of the ribs, small islands of ossification from disruption of the facial bones, axial and appendicular skeleton, and absent ossification of the calvaria
7. Acrodysostosis
8. Binder syndrome
9. De Barsy syndrome
    1. Cutis laxa
    2. Corneal clouding
    3. Mental retardation
    4. Stippled epiphysis
10. GM1 gangliosidosis
11. Galactosialidosis
12. Fibrochondrogenesis
13. Mucolipidosis II
14. De Lange syndrome
15. X-linked ichthyosis
16. Keutel syndrome
    1. Stippled epiphysis (knees, elbows)
    2. Brachytelephalangism
    3. Pulmonary stenosis
17. Osebold-Remondini syndrome
18. Hypothyroidism
19. Chromosome translocation
20. Trisomy 21 and 18
21. Turner syndrome
22. Brachytelephalangic chondrodysplasia punctata (CDP-B)
    1. An X-linked recessive disorder
    2. Male infants affected with a very small nose, anteverted and grooved nares
    3. Benign type of chondrodysplasia punctata
    4. Also observed in a patient with Xp terminal deletion with ichthyosis and mental retardation
    5. Distal phalangeal hypoplasia: the most characteristic radiological sign of this form
    6. Cervical canal stenosis with cervical cord compression leading to

serious morbidity and early mortality in a small number of patients (Ochiai et al. 2013)

23. Chondrodysplasia punctata, metacarpal type
    1. Including tibia-metacarpal type and humero-metacarpal type
    2. An autosomal dominant disorder
    3. Named for a specific long bone but with overlap in the long bone involved
    4. All having short metacarpals
    5. Affected children with a hypoplastic midface, a depressed nasal bridge, small mouth, micrognathia, short neck, and short limbs
    6. Radiographically, with short metacarpals associated with short tibias in the tibia-metacarpal type and short humeri in humero-metacarpal type
24. Sheffield-type chondrodysplasia punctata
    1. Heterogeneous group of patients with punctate epiphyses, particularly in the calcaneus and spine
    2. A benign course
    3. Distal phalangeal hypoplasia
    4. Probably not a specific entity but rather a heterogeneous group of disorders that can be included in other entities
25. Pacman dysplasia
    1. A single-case report with peculiar bone dysplasia, stippling in many areas, short bowed bones, and periosteal cloaking
    2. Osteoclasts with an unusual appearance reminiscent of the Pacman figures in computer games on bone histology
    3. The entire coccygeal and sacral regions replaced by stippling
    4. Dense stippling also observed in the thoracic region
    5. Considerable stippling also observed in the epiphyses of the proximal femur, talus, calcaneus, cuboid, and the bones of the hand
    6. Wide periosteal cloaking of many bones and poor ossification
    7. Bowed femora
    8. Superior inferior sagittal clefting in the AP views in the upper spine

3. Vitamin K disorders
    1. Warfarin embryopathy (Collins et al. 1977; Pauli et al. 1987)
        1. Associated with maternal use of warfarin sodium
        2. Consistent features: saddle nose deformity, hypertelorism, frontal bossing, high-arched palate, short neck, and short stature
        3. Other features: rhizomelia, micromelia, flexion contractures, optic atrophy, psychomotor retardation, cataracts, congenital heart disease, and renal anomalies
    2. Vitamin K epoxide reductase deficiency
4. Acquired in utero
    1. Fetal alcohol syndrome
    2. Phenacetin intoxication
    3. Fetal hydantoin syndrome
    4. Femoral hypoplasia unusual facies syndrome
    5. Maternal diabetes
    6. Maternal systemic lupus erythematosis
    7. Febrile illness
5. Other conditions involving unusual calcification that may be confused with punctata
    1. Amelia and other absence deficiencies
    2. Cerebrocostomandibular syndrome
    3. Dysplasia epiphysealis hemimelica
    4. Calcifying arthritis
    5. Metachondromatosis

3. Etiological classification of chondrodysplasia punctata to aid clinician to reach an accurate diagnosis when CDP is detected (Irving et al. 2008)

1. Group 1 (inborn errors of metabolism)
    1. Group 1a (abnormalities of peroxisomal function)
        1. Rhizomelic CDP1 (*PEX7*, 6q22-q24)
        2. Rhizomelic CDP2 (*DHAPAT*, 1q42)
        3. Rhizomelic CDP3 (*AGPS*, 2q31)
        4. Zellweger syndrome (*PEX1*, *PEX2*, *PEX3*, *PEX5*, *PEX6*, *PEX10*, *PEX12*, *PEX13*; 7q21, 8q, 6q, 12p13.3, 6p21.1, 1p36, 17q11.2, 2p15 respectively)
    2. Group 1b (abnormalities of cholesterol synthesis)
        1. Greenberg dysplasia/HEM (*LBR*, 1q42.1)
        2. CDP Conradi-Hunermann (CDPX2) (*EBP*, Xp11.23-p11.22)
        3. CHILD syndrome (*NSDHL*, *EBP*; Xq28, Xp11.23-p11.22 respectively)
    3. Group 1C (other metabolic disorders)
        1. Mucolipidosis type II
        2. Mucopolysacharidosis type III
        3. GM1 gangliosidosis
2. Group 2 (disruption of vitamin K metabolism)
    1. Warfarin embryopathy
    2. Familial multiple coagulation factor deficiency (*VKORC1*, *GGCX*: 16p11.2, 2p12, respectively)
    3. Maternal vitamin K deficiency
    4. Fetal phenytoin exposure
    5. Keutel syndrome (Keutel et al. 1972; Monroe et al. 1999) (*MGP*, 12p13.1-p12.3)
        1. Abnormal calcification with cartilaginous calcification of the ears, nose, trachea, bronchi, and ribs
        2. Peripheral pulmonary stenosis
        3. Sensorineural hearing loss
        4. Short-terminal phalanges
        5. Developmental delay and seizures, secondary to intracerebral calcification
    6. CDP X-linked recessive/brachytelephalangic (CDPX1) (*ARSE*, Xp22.3)
3. Group 3 (chromosomal abnormalities)
    1. Trisomy 21
    2. Trisomy 18
    3. Other chromosomal aberrations
4. Unknown etiology
    1. Maternal systemic lupus erythematosus
    2. Fetal alcohol syndrome
    3. CDP-TM (tibia-metacarpal type) (Rittler et al. 1990)
    4. Dappled diaphyseal dysplasia
    5. Astley-Kendall dysplasia (Astley and Kendall 1980)
    6. Pacman dysplasia (Miller et al. 2003)

Clinical Features

1. Recessive rhizomelic form
    1. Classic RCDP1
        1. Skeletal abnormalities
            1. Severe symmetric shortening of the proximal limb segments (more severe in humeri than femora)
            2. Stippled (punctate) epiphyses involving knees, hips, elbows, shoulders, hyoid bone, larynx, sternum, and ribs
        2. Peripheral calcifications
        3. Facial dysmorphism
            1. Frontal bossing
            2. A short, saddle nose
        4. Ocular features
            1. Cataracts: the most common ocular defect developing in virtually all patients, usually present at birth or appear in the first few months of life and are progressive
            2. Optic atrophy
            3. Posterior embryotoxon
            4. Strabismus
            5. Adhesions between iris and cornea in the ring of Schwabe
        5. Severe failure to thrive with profound postnatal growth deficiency
        6. Gross developmental retardation
        7. Contractures and stiff, painful joints, causing irritability in infancy
        8. Other complications

1. Seizures
2. Recurrent respiratory tract infections caused by neurological compromise, aspiration, immobility, and a small chest with restricted expansion
3. Spastic quadriplegia
4. Ichthyotic skin changes
5. Cleft soft palate
6. Cervical spine stenosis
7. Congenital heart disease
8. Ureteropelvic junction obstruction

9. A high mortality
    1. About 60% survive the first year.
    2. About 39% survive the second year.
    3. Only a few survive beyond age 10.

2. Mild RCDP1
    1. Only a few patients reported
    2. Consistent features
        1. Chondrodysplasia
        2. Cataracts
    3. Variable expression
        1. Punctate calcifications
        2. Rhizomelia
        3. Mental and growth deficiency

2. X-linked dominant form (CDPX2) (Happle 1979; DiPreta et al. 2000)
    1. Phenotype
        1. Usually a mild form of the disease identified in adult females
        2. May be a stillborn
        3. Occurring almost only in females
        4. Presumably lethal in males, although a few affected males have been reported
    2. Lyonization (skewed X-chromosome inactivation) in females resulting in phenotypic variability and asymmetric findings (Shirahama et al. 2003)
    3. Showing increased disease expression in successive generations (anticipation): another striking clinical feature of CDPX2 that may be associated with skewed methylation
    4. Skin lesions
        1. The hallmark of the X-linked dominant form
        2. Congenital ichthyosiform erythroderma, distributed in a linear or blotchy pattern
        3. Systematized atrophoderma mainly involving the fair follicles
        4. Circumscribed alopecia
        5. Sparse eyebrows and lashes
        6. Nails: flattened and split into layers
    5. Epiphyseal calcification in the first year of life
    6. Limb shortening
        1. Rhizomesomelic
        2. Usually asymmetric
        3. Severely affected infants with bilateral findings resembling those of RDCP1
    7. Other later signs
        1. Palmoplantar keratosis
        2. Follicular atrophoderma
        3. Cataracts (Happle 1981): usually asymmetric and often unilateral- versus rhizomelic-type cataracts tend to be symmetric and bilateral
        4. Tooth and bone abnormalities
3. X-linked recessive chondrodysplasia punctata, brachytelephalangic type (CDPX1) (Braverman et al. 2014)
    1. Clinical reports available so far are mainly those of patients who are nullisomic for Xp22.3 in which chondrodysplasia punctata is part of a complex phenotype due to a "contiguous gene syndrome"
    2. Wide spectrum of manifestations, ranging from aborted fetus, neonatal death, midfacial hypoplasia, and brachytelephalangy (Brunnetti-Brunetti-Pierri et al. 2003)
    3. Facial anomalies with severe nasal hypoplasia
    4. Short stature
    5. Cardinal manifestations
        1. Epiphyseal stippling
        2. Hypoplasia of the distal phalanges
    6. Abnormalities of proximal and middle phalanges after healing of the punctate calcifications: typical diagnostic signs
    7. Without limb shortening or cataracts
    8. Presence of ichthyosis attributed to the involvement of the STS gene in the patients with Xp deletion
    9. Mild ichthyosis that improves with age: may be part of the CDPX phenotype

4. Chondrodysplasia punctata, tibia-metacarpal type (Rittler et al. 1990; Shukla and Phadke 2015)
    1. Short tibia
    2. Sort metacarpals
    3. Punctate epiphyseal calcifications noted at birth
    4. Abnormal face (flattened midface and nose)
    5. Short hands
    6. Normal height
    7. Normal mentation

Diagnostic Investigations

1. Radiography (Spranger et al. 2002)
    1. Classic RCDP1
        1. Bilateral shortening of the humerus and to a lesser degree the femur
        2. Punctate calcifications in the epiphyseal cartilage at the knee, hip, elbow, shoulder, hyoid bone, larynx, sternum, and ribs
        3. Radiolucent coronal clefts of the vertebral bodies that represent unossified cartilage
        4. Abnormal epiphyses and flared and irregular metaphyses secondary to resolved punctate calcification after age 1–3 years
    2. Tibia-metacarpal type
        1. Shortened and bowed tibia and radii
        2. Overgrowth of the fibulae
        3. Ulnar hypoplasia
        4. Calcific stippling of the proximal bones
        5. Punctate calcifications of the trachea, thyroid cartilage, entire spine, and sacrum
        6. Clefting (coronal and/or sagittal) of the vertebral bodies
        7. Symmetrical brachymetacarpy: shortened 2nd, 3rd, and 4th metacarpals
        8. Shortened radial head
        9. Patella dislocation
    3. Chondrodysplasia punctata brachytelephalangic type (Ochiai et al. 2013)
        1. Skeletal survey
            1. Hypoplastic distal phalanges
            2. Diffuse stippling of the spine and proximal femora
        2. 3D CT scan: subluxation and multiple punctata in the cervical spine and atlantoaxial subluxation
    4. X-linked recessive CDPX2 (Mundinger et al. 2009; Jurkiewicz et al. 2013)
        1. Chondrodysplasia (symmetrical or asymmetrical shortening of long bones)
        2. Nasal/midface hypoplasia
        3. Epiphyseal stippling
            1. Punctate calcification of cartilage, including airway
            2. Diffuse paravertebral calcifications as well as around joints, in the cartilages of larynx, trachea, and nose
        4. Articular contractures
        5. Scoliosis
        6. Vertebral anomalies
        7. Platyspondylia
        8. Deformed feet
        9. Distal phalangeal hypoplasia
2. Biochemical/molecular studies
    1. RCDP1 (Braverman et al. 2010)
        1. Deficiency of red blood cell plasmalogens
        2. Increased plasma concentration of phytanic acid
        3. Deficiencies in plasmalogen biosynthesis and phytanic acid hydroxylation in cultured skin fibroblasts
        4. PEX7 receptor defect in RCDP1 predicted by the following:
            1. Deficiency of plasmalogens in red blood cells
            2. Increased plasma concentration of phytanic acid
            3. Normal plasma concentration of very long-chain fatty acids
        5. Molecular genetic analysis: *PEX7* gene mutation analysis and sequencing (Motley et al. 2002)
    2. RCDP2
        1. Deficiency of the peroxisomal enzyme dihydroxyacetone phosphate acyltransferase (DHAPRT) in cultured skin fibroblasts
        2. *DHAPRT* gene mutation analysis by sequencing of coding regions
    3. RCDP3: deficiency of the peroxisomal enzyme, alkyl-dihydroxyacetone phosphate

synthase (ADAPS) in cultured skin fibroblasts
1. Deficiency of the peroxisomal enzyme, alkyl-dihydroxyacetone phosphate synthase (ADAPS) in cultured skin fibroblasts
2. *ADHAPS* gene mutation analysis

4. X-linked dominant form (CDPX2)
1. Diagnosis confirmed by measuring the plasma concentration of sterols which show accumulation of precursors, 8(9)-cholesterol and 8-dehydrocholesterol
2. Identify molecular defect in human *EBP* in CDPX2 patients

5. X-linked recessive form (CDPX1): ARSE gene mutation analysis

Genetic Counseling

1. Recurrence risk
1. Patient's sib
1. Autosomal recessive RCDP1: 25%
2. Autosomal dominant form: not increased unless one of the parents is affected
3. X-linked recessive form: 50% of brothers affected when the mother is a carrier (Braverman et al. 2014)
4. X-linked dominant form
1. 50% of sisters and brothers (lethal) affected when the mother is a carrier
2. Possibility of an apparently normal mother being a carrier to be considered when examining seemingly sporadic cases

2. Patient's offspring
1. Autosomal recessive RCDP1: do not reproduce
2. Autosomal dominant form: 50%
3. X-linked recessive form: 50% risk of daughters to be carriers; none of sons will be affected
4. X-linked dominant form: affected mother; 50% of sons affected (lethal in male), 50% of daughters affected

2. Prenatal diagnosis
1. Radiography
1. Stippling of the bones of the extremities and pelvis
2. Abnormalities of the vertebral bodies

2. Ultrasonography (Argo et al. 1996)
1. Rhizomelic form
1. Severe rhizomelic limb shortening
2. Punctuate epiphyseal calcifications
3. Associated sonographic findings: profound hypoplasia of the humeri, metaphyseal flaring, a flattened midface, joint contracture, clubfoot deformity, and hydramnios

2. Nonrhizomelic form (Pradhan et al. 2002)
1. Asymmetric, variable limb shortening without a clear pattern of rhizomelia or mesomelia
2. Calcifications in the long-bone epiphyses, which may be recognizable in the second trimester or may not be recognizable even in the third trimester
3. Other sonographic findings: spinal deformities, frontal bossing, a depressed nasal bridge, ascites, and polyhydramnios

3. X-linked dominant form
1. Polyhydramnios
2. Growth retardation
3. Prenatal detection of asymmetric shortening and bowing of the long bones and cartilage stippling should raise the possibility of CPDX2 in female fetuses, especially because the majority of such cases involve de novo mutations (Lefebvre et al. 2015)

3. Biochemical studies
1. Assays of plasmalogen biosynthesis in cultured chorionic villi or amniocytes for pregnancies at 25% risk for RCDP1
2. Enzyme activity of alkyl-dihydroxyacetone phosphate synthase (ADHAPS) and subcellular localization of peroxisomal thiolase performed on uncultured chorionic villi

3. Biochemical test of DHAPAT synthase deficiency in amniotic fluid at 13 weeks gestation in RCDP family (Brookhyser et al. 1999)
4. Fetal MRI: shows cervical spinal cord compression in a fetus with CDP-B (Ochiai et al. 2013)
5. Molecular prenatal diagnosis in X-linked dominant chondrodysplasia punctata to identify disease-causing *EBP* mutation in the fetus (Whittock et al. 2003)

3. Management
   1. Health supervision for children with rhizomelic chondrodysplasia congenita (White et al. 2003)
   2. Mainly supportive
   3. G-tube placement for poor feeding and recurrent aspiration
   4. Cataract extraction to preserve vision
   5. Orthopedic procedures to correct contractures to improve function
   6. X-linked dominant form
      1. Emollients for ichthyosis
      2. Splinting for clubbed feet
      3. Surgery for polydactyly
      4. Ophthalmological care for cataracts

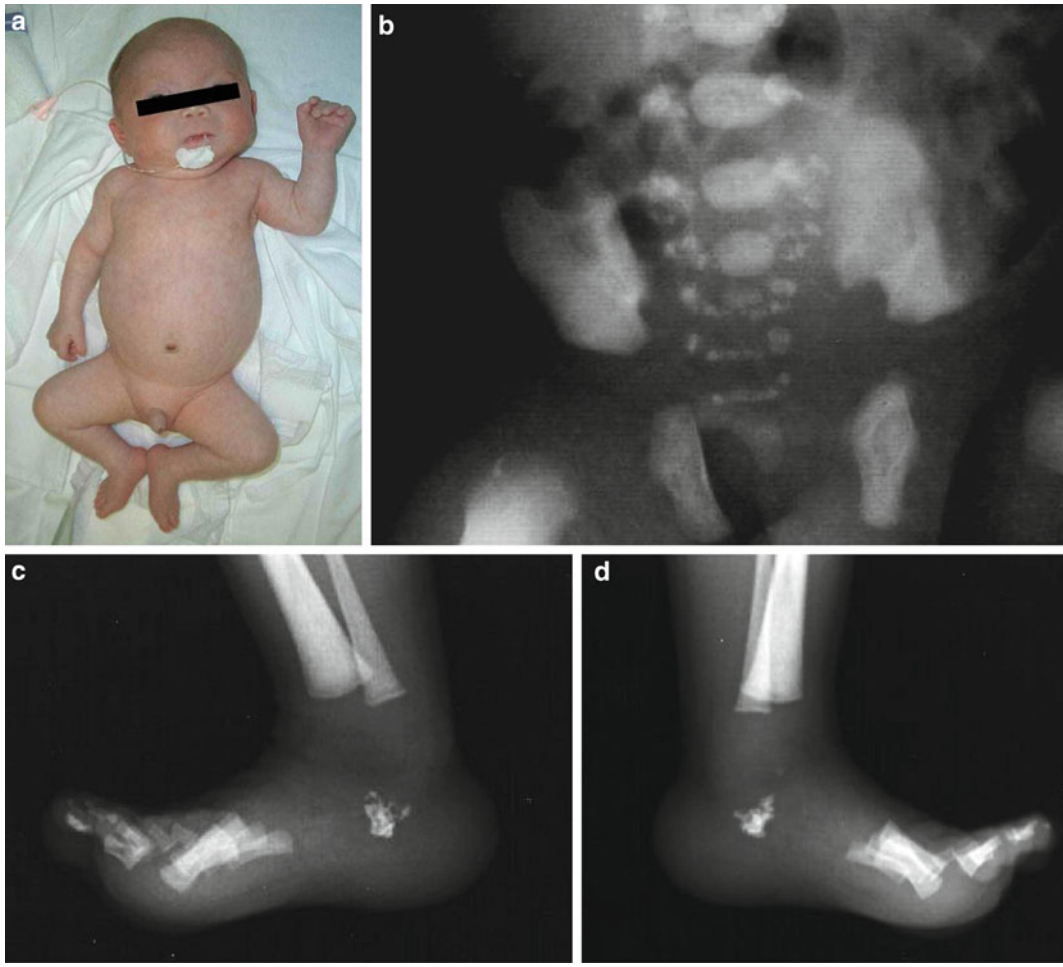

Fig. 1 (**a**–**d**) Patient 1 (a Japanese newborn boy) with X-linked recessive form of chondrodysplasia punctata. Radiographs show paravertebral and calcaneus punctate calcification

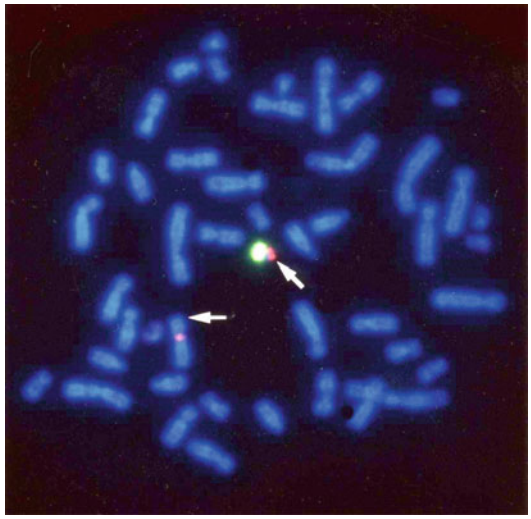

Fig. 2 FISH (patient 1) with a SHOX (short stature homeobox-containing gene) probe for Xp22.3 (*a pink signal*) and Yp11.3 (*a pink signal*) showing a deleted pink Xp22.3 signal. The *pink signal* in the X chromosome is an X peri-centromere probe (SXZ1) and the *green signal* is a Yq12 probe (DXZ1)

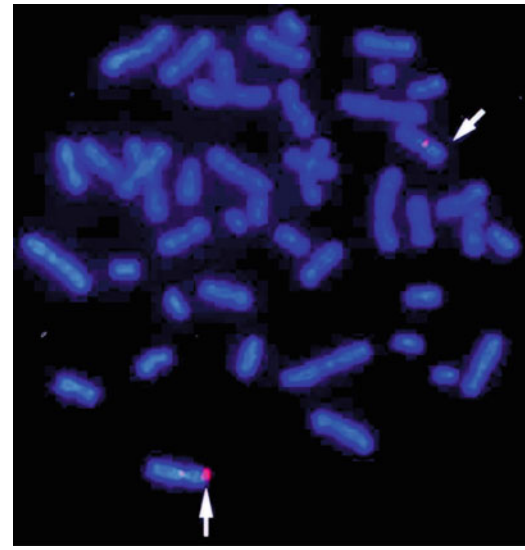

Fig. 3 The mother of patient 1 is a carrier of del(X) (p22.3p22.3) (SHOX-). Her FISH showed that a red signal (a probe for Xp22.3; SHOX gene) is deleted in one of her X chromosomes

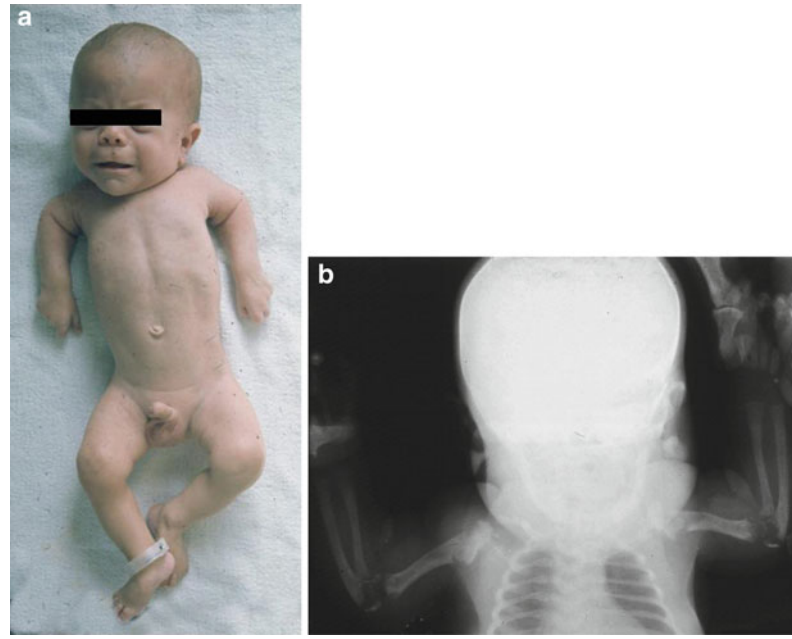

Fig. 4 (**a**, **b**) A neonate with rhizomelic form of chondrodysplasia punctata, showing short humeri and punctate calcifications in the shoulder and/or elbow joints illustrated by radiograph

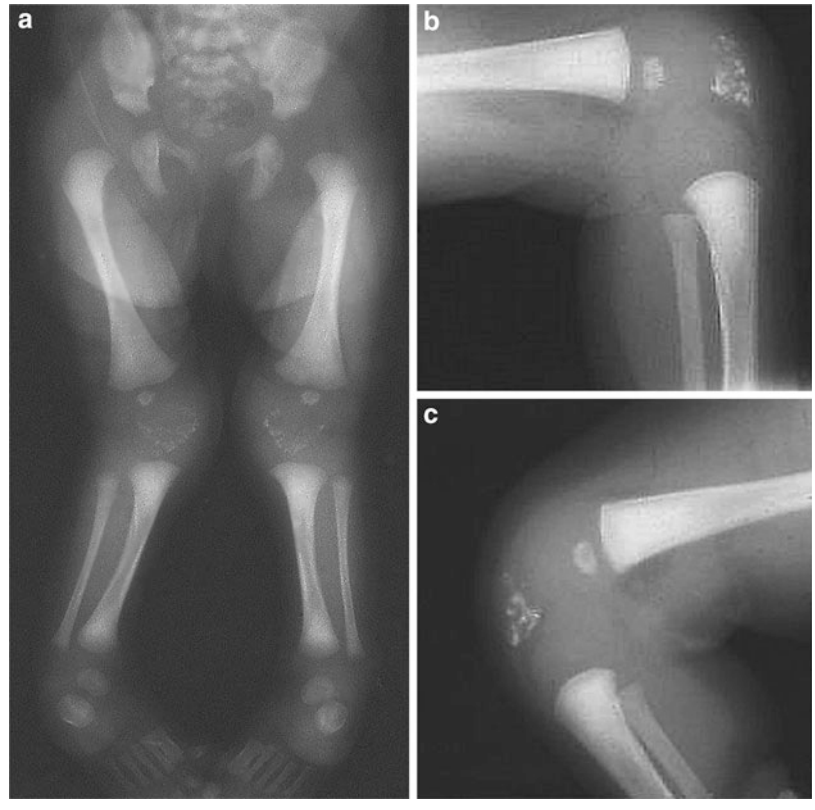
Fig. 5 Radiograph of another neonate with rhizomelic form of chondrodysplasia punctata, showing similar radiographic features

Fig. 6 (**a**, **b**) Another neonate with chondrodysplasia punctata showing depressed nasal bridge and underdeveloped nasal cartilage. The infant has punctate calcifications in the proximal femoral heads



Figs. 7 (**a**–**c**) Radiographs of a child with an autosomal dominant chondrodysplasia punctata showing punctate calcifications in the knees

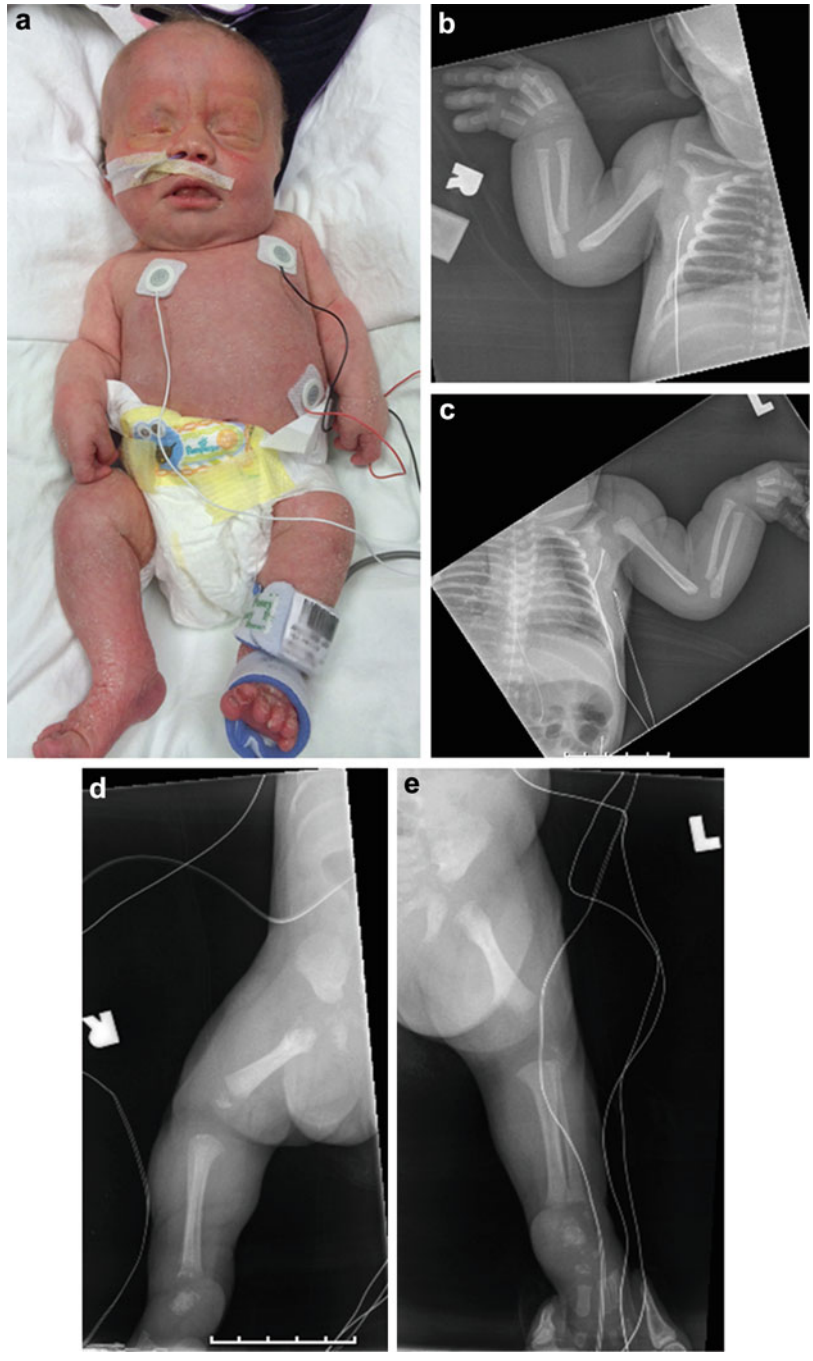


Fig. 8 (**a**–**e**) This Caucasian newborn baby girl (**a**) was born at 36 weeks' gestation secondary to polyhydramnios. The baby was noted to have rhizomelic shortening of the extremities. The radiographs (**b**–**e**) showed multiple punctuate calcifications (stipplings) throughout spinal column and in the epiphyses of the long bones such as proximal humerus and proximal and distal femurs and calcaneus and other tarsal bones. The skin showed congenital ichthyosiform erythroderma. EBP sequencing performed by Prevention Genetic Laboratory showed that the patient is heterozygous in the *EBP* gene for a sequence variant defined as c.328 C > T that is predicted to result in the premature protein termination (p.R110X). This variant was previously reported to be pathogenic for chondrodysplasia punctata (Grange et al. 2000; Hellenbroich et al. 2007). EBP is the only gene currently known to be associated with Conradi-Hunermann syndrome (CDPX2) (chondrodysplasia punctata X-linked dominant form) (Courtesy of Dr. Gerald Whitton)

Fig. 9 (**a**–**i**) The infant was evaluated again at 10 months of age with the surrogate mother who had implanted an embryo from an unknown couple donor. She was short with rhizomelic shortening of the extremities, extremely short neck, and severe kyphoscoliosis. The wrists were pronated with ulnar deviation. The head was large and misshaped (plagiocephaly) with frontal bossing, flat and broad nasal root, and a large occipital hemangioma. The scalp hairs were coarse and twisted (**a**–**c**). Radiographs at 10 months of age showed rhizomelic shortening of the long bones, short neck, kyphoscoliosis, and loss of characteristic stippled epiphyses (**d**–**i**)

Chromosome Abnormalities in Pediatric Solid Tumors

Contents

Consistent chromosome abnormalities have been described in many pediatric solid tumors. These findings led to direct molecular investigation and a better understanding of tumor pathogenesis. Clinical correlation often produced useful prognostic information (Karnes et al. 1992).

Synonyms and Related Disorders

CNS primary tumor; Ewing sarcoma; Fibrosarcoma; Neuroblastoma; Osteosarcoma; Other pediatric solid tumors; Rhabdomyosarcoma; Retinoblastoma; Sarcomas; Wilms' tumor

Genetics/Basic Defects

1. Somatic mutation theory of cancer (Mertens et al. 1994):
    1. Resulting from the accumulation of specific genetic changes
    2. Several lines of evidence:
        1. Monoclonal origin of most tumors, suggesting that they derive from a single progenitor cell
        2. Several tumors occurring not only sporadically but also as familial hereditary traits
        3. Mutagenic nature of most carcinogenic agents, at least in experimental systems
        4. Acquired genetic changes in the tumor cells, many of which are detectable at the chromosome level and several of these mutations have been shown to be tumorigenic in experimental animals
2. Chromosome abnormalities in neoplastic cells:
    1. Technical improvement in basic cytogenetic techniques:
        1. Use of colchicine to arrest dividing cells in metaphase and hypotonic solutions to improve spreading of the chromosomes:
            1. Description of the correct chromosome number in humans
            2. The first specifically neoplasia-associated chromosome aberration, the Ph1 chromosome in chronic myeloid leukemia
        2. Introduction of chromosome banding techniques:
            1. Possible to identify individual chromosome pairs
            2. To detect and characterize even subtle rearrangements

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_42

2. Clonal chromosome aberrations in neoplasms:
    1. Primary aberrations:
        1. Nonrandomly associated with particular tumor types.
        2. Sometimes observed as the sole karyotypic deviation.
        3. Thought to constitute early and essential events in carcinogenesis.
        4. Increased genomic instability thought to be one of the consequences of the acquisition of a primary cancer chromosome rearrangement.
        5. Many primary aberrations affect cellular oncogenes, often fusing them with other genes to encode hybrid proteins or disrupting the normal control sequences of the oncogene, causing its inappropriate expression.
    2. Secondary aberrations:
        1. Occurrence of new abnormalities facilitated by primary aberrations
        2. Nonrandom
        3. Distribution of the secondary aberrations dependent on both the primary abnormality and the tumor type in which they occur
    3. Cytogenetic noise:
        1. Resulting from acquired instability
        2. Random changes with little or no selective value
3. Mechanisms by which chromosomal aberrations arise (Albertson et al. 2003):
    1. Aberrations that lead to aneuploidy:
        1. Polyploidy
        2. Aneuploidy
        3. Reciprocal translocation
        4. Nonreciprocal translocation
        5. Amplification (double minutes)
        6. Amplification (HSR)
        7. Amplification (distributed insertions)
    2. Aberrations that leave the chromosome apparently intact:
        1. Loss of heterozygosity (LOH) (somatic recombination)
        2. Loss of heterozygosity (duplication/loss)
4. Identification of specific chromosome rearrangements in neoplasms:
    1. Leukemia and lymphoma:
        1. Crucial for more detailed studies utilizing molecular genetic techniques
        2. Possible to compare cytogenetic findings with morphologic, immunologic, and clinical parameters such as the response to therapy and survival
        3. Diagnostic and prognostic implications of karyotyping
    2. Solid tumors:
        1. In general, more complex karyotypes observed in solid tumors
        2. Have distinct patterns of primary and secondary aberrations closely associated with histopathologic entities
        3. Identification of only a few genes as a consequence of recurrent structural rearrangements
        4. Fusion of transcription factor gene with other loci, a common feature
        5. Tumor suppressor genes:
            1. Important in solid tumors
            2. Thought to encode inhibitors of unrestrained growth
            3. Behave in a recessive manner at the cellular level (i.e., loss or structural disruption of both wild-type alleles is required to unleash a neoplastic phenotype)
5. A new unifying concept called cellular pliancy as a possible explanation for susceptibility to cancer and the developmental origin of pediatric solid tumors (Chen et al. 2015):
    1. Diversity of pediatric solid tumors:
        1. Cellular diversity:
            1. Remarkably diverse in histologic features
            2. To define the genetic lesions in different pediatric solid tumors, the inter- and intra-tumor heterogeneity, and the order of events that cause malignant transformation during the development of the retina, bone, neural crest, muscle, and other cellular lineages
        2. Clinical diversity: can provide important clues about the developmental origins of pediatric solid tumors

3. Genetic diversity
4. Reprogramming the tumor genome: needs a detailed understanding of the genomic landscape of pediatric solid tumors that has emerged with next-generation sequencing over the past 5 years

2. Epigenetics: emerged as a major focus area in pediatric solid tumor research because of:
   1. Striking changes in the epigenetic landscape after inactivation of tumor suppressor genes such as *RB1*
   2. Identification of recurrent mutations in epigenetic modulators such as *BCOR* and *ATRX*
3. Cellular pliancy (unify the findings in pediatric solid tumor genomic and integrate them with our understanding of developmental competence and lineage specification)
4. Clinical genomics: important to incorporate whole-genome sequencing, whole-exome sequencing, and RNA sequencing in future clinical genomics efforts to identify potentially druggable mutations and to advance our understanding of the genetic underpinnings of pediatric solid tumors

6. Retinoblastoma (RB) (Mertens et al. 1994):
   1. A prototype tumor for understanding basic concepts in cancer genetics
   2. Genetics of retinoblastoma:
      1. Thought to be a single-gene disorder caused by mutation of the *RB1* gene (Carlson and Desnick 1979)
      2. Sporadic, nonhereditary form in most cases:
         1. Unilateral or unifocal retinoblastoma
         2. A mutation in the RB1 locus which occurred later in embryogenesis
      3. Hereditary form (one third of tumors):
         1. Bilateral or multifocal retinoblastoma
         2. Predisposition inherited as an autosomal dominant trait
         3. Mutations inherited from a carrier parent in 25% of the cases
         4. A new mutation occurring very early in embryogenesis in 75% of cases
         5. Overall estimates of the penetrance of the trait: 85–95%
   3. Retinoblastoma gene, *RB1*:
      1. The first cancer predisposition gene to be cloned
      2. Chromosome map: 13q14
      3. More than 100 different mutations reported to date:
         1. Missense mutations
         2. Nonsense mutations
         3. Splice-site mutations
         4. Small and large deletions
   4. Knudson's "two-hit hypothesis" of tumorigenesis (Knudson 1971; Horsthemke 1992):
      1. In the unaffected individual, both RB1 genes are intact and serve as guardians of the retina.
      2. Retinoblastoma develops as a result of two separate mutations.
      3. Sporadic tumors: two separate mutations occurring somatically in the same retinal cell.
      4. Heritable retinoblastoma: the first mutation is germinal and the second somatic.
   5. Inherited form of retinoblastoma:
      1. Critical gene for retinoblastoma located in band 13q14, suggested by cytogenetic analyses of tumor cells and lymphocytes
      2. Homozygous loss of DNA markers from 13q14 in tumor cells from individuals with familial retinoblastoma versus heterozygous loss of these DNA markers in normal cells, suggested by molecular genetic investigations
7. Neuroblastoma (NB):
   1. A malignant tumor derived from undifferentiated neural crest cells that are committed to differentiate into the sympathetic nervous system
   2. Inheritance:
      1. Sporadic in most cases
      2. A few clustered familial cases reported indicating an autosomal dominant inheritance with incomplete penetrance
   3. Molecular biology (Lee et al. 2003):
      1. The amplification (i.e., increased number of DNA copies) of the oncogene MYCN (N-myc), located on

chromosome 2p24, and changes in the normal diploid chromosomal content:
1. Both are correlated with disease prognosis and disease recurrence.
2. The amplification can be in the form of the double-minute chromosomes, which are extragenomic segments of DNA, or in homogeneously staining chromosomal regions.

2. Variable DNA content of neuroblastoma:
1. Near-triploid DNA index regardless of any clinical or biologic features predicts a smaller risk of progression to higher-stage diseases.
2. Diploid/tetraploid index tends to predict higher risk of progression or multiple relapses.

3. Other molecular markers (receptors for nerve growth factors) associated with neuroblastoma:
1. Trk A: associated with favorable neuroblastomas
2. Trk B: expressed in unfavorable neuroblastomas

8. Wilms' tumor (WT):
1. Biological pathways leading to the development of Wilms' tumor:
1. Complex
2. Involvement of several genetic loci:
1. Two genes on chromosome 11p: one on chromosome 11p13 (the Wilms' tumor suppressor gene, *WT1*) and the other on chromosome 11p15 (the putative Wilms' tumor suppressor gene, *WT2*)
2. Loci at 1p, 7p, 16q, 17p (the *p53* tumor suppressor gene), and 19q (the putative familial Wilms' tumor gene, *FWT2*)

2. Inheritance:
1. Sporadic in majority of cases (>95%).
2. Familial predisposition to Wilms' tumor is rare, affecting only1.5% of patients with Wilms' tumor.

3. Association with specific genetic disorders or recognizable syndromes:
1. WAGR syndrome:
1. Large constitutional deletions of chromosome 11p13
2. Tumor suppressor gene: *WT1*
3. Mechanism of gene inactivation: hemizygous deletion
4. Wilms' tumor incidence: >30%
5. Associated features: aniridia and genitourinary abnormalities
6. Mental retardation
7. Associated aniridia: caused by deletion of the *PAX6* gene in the 11p13 region in close proximity to *WT1* gene

2. Denys-Drash syndrome:
1. Chromosomal loss: 11p13
2. Tumor suppressor gene: *WT1*
3. Mechanism of gene inactivation: mutation (DNA-binding domain)
4. Wilms' tumor incidence: >90%
5. Associated features: pseudohermaphroditism, mesangial sclerosis, and renal failure

3. Beckwith-Wiedemann syndrome:
1. Chromosomal loss: 11p15
2. Tumor suppressor gene: (*WT2*/*BWS*)
3. Mechanism of gene inactivation: unknown
4. Wilms' tumor incidence: 5%
5. Associated features: organomegaly, hemihypertrophy, umbilical hernia, neonatal hypoglycemia, and other tumors such as hepatoblastoma

4. Perlman syndrome:
1. Renal dysplasia
2. Multiple congenital anomalies
3. Gigantism
4. Wilms' tumor

5. X-linked Simpson-Golabi-Behmel syndrome:
1. Overgrowth disorder
2. Caused by mutations in the *GPC3* gene located on Xq26
3. Overlapping physical features with Beckwith-Wiedemann syndrome
4. Wilms' tumor and other embryonal tumors

9. Primary tumors of the central nervous system (Mertens 1994):
    1. Primitive neuroectodermal tumors (PNETs):
        1. Homozygous inactivation of the *TP53* gene, a tumor suppressor gene located in 17p, secondary to i(17p): implicated in the development of several tumor types
        2. Molecular analyses indicating the existence of a second tumor suppressor gene, distinct from and distal to the *TP53* locus, which might be pathogenetically involved in a subset of primitive neuroectodermal tumors
    2. Gliomas:
        1. A tumor suppressor gene in 22q implicated as an essential event in the genesis of a number of neurogenic neoplasms.
        2. A candidate for such a role is *NF2*, thought to be mutated in neurofibromatosis type 2, a dominantly inherited disorder predisposing for gliomas, neurinomas, and meningiomas.

Clinical Features

1. Only retinoblastoma, neuroblastoma, and Wilms' tumor will be discussed here:
2. Retinoblastoma (Mertens 1994; Aerts et al. 2006):
    1. The most common malignant ocular tumor in childhood that affects approximately 1 in 18,000 children under 5 years of age in the USA (Devesa 1975)
    2. A rare malignant tumor arising from cells of the embryonal neural retina
    3. Develops only in infants and young children
    4. Unifocal retinoblastoma: presence of a single retinoblastoma
    5. Multifocal retinoblastoma: presence of more than one tumor (Lohmann and Gallie 2013):
        1. Unilateral: occurrence of multiple RB tumors in one eye
        2. Bilateral: occurrence of RB tumors in both eyes
        3. "Trilateral" retinoblastoma: occurrence of bilateral retinoblastoma plus a pinealoma
    6. Presenting signs:
        1. White papillary reflex (leukocoria): the most common presenting sign
        2. Strabismus: the second most common presenting sign
        3. Less common signs:
            1. Poor vision
            2. Orbital swelling
            3. Unilateral mydriasis
            4. Heterochromia iridis
            5. Glaucoma
            6. Orbital cellulitis
            7. Uveitis
            8. Hyphema or vitreous hemorrhage
            9. Nystagmus
    7. Retinoma-associated eye lesions ranging from retinal scars to calcified phthisical eyes resulting from spontaneous regression of retinoblastoma (include benign retinal tumors called retinocytoma or retinoma)
    8. Patients with germline RB1 mutations: at an increased risk of developing tumors outside the eye:
        1. Pinealomas
        2. Osteosarcomas
        3. Soft tissue sarcomas
        4. Melanomas
3. Neuroblastoma (Davidoff and Hill 2001; Lee et al. 2003):
    1. The most frequently occurring solid tumor in children
    2. Responsible for 8–10% of all cancers in children and approximately 15% of all pediatric cancer deaths
    3. 40% of cases diagnosed in children under 1 year of age who have a very good prognosis
    4. 60% in older children and young adult who have a poor prognosis despite advanced medical and surgical management

5. Amplification of *MYCN* gene found in neuroblastomas:
    1. A powerful prognostic indicator
    2. Associated with:
        1. Advanced stages of disease
        2. Rapid tumor progression
        3. Poor outcome
6. Clinical presentation:
    1. Variable presentation (Brodeur et al. 1997):
        1. Localized disease (one third to one fourth of cases)
        2. Metastatic disease (two thirds to three fourths of cases)
        3. Asymptomatic in a small number of patients
    2. Retroperitoneal and abdominal tumors (62–65%):
        1. A palpable mass
        2. Abdominal pain (34%)
        3. Weight loss (21%)
        4. Anorexia
        5. Vomiting
        6. Symptoms related to mass effect
    3. Thoracic tumors (14%):
        1. Dysphagia
        2. Cough
        3. Respiratory distress
    4. Pelvis (5%) and paraspinal tumors that compress the spinal cord:
        1. Urinary dysfunction
        2. Constipation
        3. Fetal incontinence
        4. Lower extremity weakness
    5. Neck tumors:
        1. Horner syndrome: present in patients with lesions in the cervical or upper thoracic sympathetic ganglia (1.7%)
        2. Airway distress
    6. Liver metastasis:
        1. Hepatomegaly
        2. Jaundice
        3. Abnormal liver function tests
        4. Abdominal pain
    7. Bone metastases and bone marrow involvement:
        1. Bone pain
        2. Palpable bony nodules
        3. Anemia
        4. Purpura
    8. Fever (28%)
    9. Lymph node metastases: palpable lymphadenopathy
    10. Retrobulbar and orbital metastases: periorbital ecchymoses
    11. Severe diarrhea refractory to standard treatment due to production of vasoactive intestinal peptide by tumor cells (4%)
    12. Acute cerebellar encephalopathy (2%):
        1. Cerebellar ataxia
        2. "Dancing eyes and dancing feet syndrome" (involuntary eye fluttering and muscle jerking)
        3. Myoclonic jerks
    13. Symptoms related to high catecholamine levels (0.2%):
        1. Hypertension
        2. Palpitations
        3. Flushing
        4. Sweating
        5. Malaise
        6. Headache
4. Wilms' tumor (Mertens 1994):
    1. The most common kidney cancer in childhood
    2. Represents about 6% of all childhood cancers in the USA
    3. Clinical presentation (Paulino 2014):
        1. Presence of an asymptomatic abdominal mass – the most common presentation:
            1. Usually affects one kidney with multiple tumor foci in 8% of cases
            2. Bilateral in 6% of cases
        2. Hypertension, gross hematuria, and fever observed in 5–30% of patients
        3. Hypotension, anemia, and fever in a small number of patients who have hemorrhaged into their tumor
        4. Rare respiratory symptoms related to the presence of lung metastases in patients with advanced-stage disease
    4. Association with congenital malformations:
        1. Found in 60% of the bilateral cases and 4% of the unilateral cases
        2. WAGR

3. Denys-Drash syndrome
4. Beckwith-Wiedemann syndrome
5. Perlman syndrome
6. X-linked Simpson-Golabi-Behmel syndrome

5. Likelihood of developing Wilms' tumor in aniridia patients:
   1. Aniridia patients without other anomalies: 1–2%
   2. Aniridia patients with WAGR syndrome: 25–40%

Diagnostic Investigations

1. Cytogenetic and molecular genetic techniques used in analyzing tumor materials from patients (Cooley et al. 2009):
   1. Conventional and molecular cytogenetic techniques most commonly used (Varella-Garcia 2003):
      1. Metaphase cytogenetics or karyotyping (G-, Q-, and R-bandings):
         1. Protein digestion and/or special dye generating banding pattern specific for each chromosome
         2. Identification of numerical and structural chromosomal anomalies
      2. Fluorescence in situ hybridization (FISH):
         1. A small, labeled DNA fragment used as a probe to search for homologous target sequences in chromosome or chromatin DNA
         2. Identification of the presence, number of copies per cell, and localization of probe DNA
         3. Applicable to interphase cells
      3. Comparative genomic hybridization (CGH):
         1. Comparative hybridization of differentially labeled total genomic tumor DNA and normal reference DNA to normal human metaphases used as templates
         2. Detection of variant DNA copy numbers at the chromosome level
         3. Applicable to fresh or preserved specimens
      4. Multicolor karyotyping (M-FISH, SKY):
         1. Hybridization with 24 differentially labeled, chromosome-specific probes allowing the painting of every human chromosome in a distinct color
         2. Detection of rearrangements involving one or more chromosomes within individual metaphase spreads
         3. Accurate origin identification of all segments in complex rearrangements
         4. Clarification of marker chromosomes
   2. Other techniques:
      1. Flow cytometry
      2. Reverse transcriptase-polymerase chain reaction (RT-PCR)
      3. Quantitative PCR
      4. Southern blot analysis of gene rearrangements
      5. Loss of heterozygosity (LOH) analysis
      6. Clinical utilization of high-resolution single-nucleotide polymorphism (SNP)-based oligonucleotide arrays in diagnostic studies of pediatric patients with solid tumors (Dougherty et al. 2012)
      7. Restriction landmark genome scanning
      8. Representational difference analysis
      9. cDNA gene expression microarrays
      10. Proteomic methods:
          1. Matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF)
          2. Surface-enhanced laser desorption/ionization-time of flight (SELDI-TOF)
2. Cytogenetic studies in retinoblastoma:
   1. Cytogenetically visible changes of 13q14: infrequent in retinoblastoma
   2. Deletions or unbalanced translocations leading to loss of 13q14 band (10%)
   3. Monosomy 13 (10%)

4. i(6p), mostly detected as a supernumerary isochromosome (one third of cases)
5. Gain of 1q material (one third of cases)
6. Bone marrow cytogenetic (Barros et al. 2012):
    1. Del(13q), i(6p), +1, monosomy 16, dup (5q), dic(15;22), and add(14q).
    2. These complex chromosome abnormalities may be related to the aggressiveness of the disease.
7. Cytogenetic aberrations in retinoblastoma:
    1. Secondary to *RB1* mutations
    2. More related to tumor progression than to tumor establishment

3. Other studies for retinoblastoma:
    1. Indirect ophthalmoscopy to examine the fundus of the eye to detect retinomas, preferably by a retinal specialist
    2. Imaging studies (CT, MRI, ultrasonography) to support the diagnosis and stage the tumor
    3. Histopathological examination to confirm the diagnosis
    4. Direct DNA testing of the RB1 gene in WBC DNA:
        1. Identify a germline mutation in about 80% of individuals with a hereditary predisposition to retinoblastoma
        2. Probability of detection of the RB1 gene mutation in an index case dependent on the following:
            1. Whether the tumor is unifocal or multifocal
            2. Whether the family history is positive or negative
            3. The sensitivity of the testing methodology
4. Cytogenetic studies in neuroblastoma (Maris and Matthay 1999; Davidoff and Hill 2001; Lee et al. 2003; Schwab et al. 2003):
    1. Identification of multiple cytogenetic abnormalities in neuroblastoma:
        1. Allelic losses on chromosomes 1p (particularly 1p36), 11q, 14q, 7q, 2q, 3p, and 19q.
        2. Allelic gains on chromosomes 17q, 18q, 1q, 7q, and 5q.
        3. Aberrations involving chromosomes X,3, 19, and del(1p) could be considered early events, whereas those involving chromosomes 9, 13, 15, 18, 20, and 21 were often late events (Betts et al. 2005).
    2. Hyodiploid, triploid, or "near-triploid", or "near-tetraploid" in modal chromosome number:
        1. Majority (55%) with triploid or "near-triploid" (a chromosome number between 58 and 80)
        2. Remainder with "near-diploid" (35–57 chromosomes) or "near-tetraploid" (81–103 chromosomes)
    3. Frequent partial 1p monosomy (70–80% of cases) with most commonly deleted region being between 1p32 and 1p36
    4. Gain on the long arm of chromosome 17 (17q):
        1. Probably the most common genetic abnormality in neuroblastomas
        2. Occurring in approximately 75% of primary tumors
        3. Most often resulting from an unbalanced translocation of this region to other chromosomal sites, most frequently 1p or 11q
        4. A powerful independent finding of adverse outcome
    5. Deletions of the long arms of chromosomes 11 (11q) and 14 (14q):
        1. Appears to be common in neuroblastomas
        2. Both inversely related to *MYCN* amplification
    6. Frequent presence of extrachromosomal double-minute chromatin bodies (DMs) or homogeneously staining regions (HSRs):
        1. Cytogenetic evidence of gene amplification
        2. Amplified region derived from the distal short arm of chromosome 2 (2p24) that contains the *MYCN* proto-oncogene
    7. Chromosome imbalances and alterations of AURKA and MYCN genes in children

with neuroblastoma (İnandıklıoğlu et al. 2012):

1. Some 72% of the cells had structural aberrations and only 28% had numerical changes in patients.
2. Structural aberrations consisted of deletions, translocations, breaks, and fragility in various chromosomes, 84% and 52% of the patients having deletions and translocations, respectively.
3. Among these expressed chromosome abnormalities, there was a higher frequency at 1q21, 1q32, 2q21, 2q31, 2p24, 4q31, 9q11, 9q22, 13q14, 14q11.2, 14q24, and 15q22 in patients.
4. Thirty two percent of the patients had chromosome breaks, most frequently in chromosomes 1, 2, 3, 4, 5, 8, 9, 11, 12, 19, and X.
5. Aneuploidies in chromosomes X, 22, 3, 17, and 18 were most frequently observed.
6. Numerical chromosome abnormalities were distinctive in 10.7% of sex chromosomes.
7. Fragile sites were observed in 16% of patients.

5. Other studies for neuroblastoma:
   1. Imaging studies:
      1. Chest radiography
      2. Ultrasound
      3. CT
      4. MRI
      5. Radionucleotide bone scan
   2. Blood tests:
      1. Elevated urinary and serum catecholamine metabolites:
         1. Homovanillic acid (HVA)
         2. Vanillylmandelic acid (VMA)
      2. Abnormal liver function tests
   3. Molecular genetic testing (Castel et al. 2007):
      1. Array CGH analysis: a pangenomic technique allowing insights into gains and losses with high resolution
      2. Multiplex ligation-dependent probe amplification (MILPA)

6. Cytogenetic studies in Wilms' tumor:
   1. A near-diploid chromosome count.
   2. Triploid-tetraploid karyotypes in a few cases with tendency to have an anaplastic morphology.
   3. Numerical aberrations:
      1. Trisomy 12: particularly frequent
      2. Followed by trisomies 8, 6, 7, 13, 20, and 17
   4. Structural rearrangements:
      1. Involve all chromosomes except the Y chromosome
      2. Recombinations of 11p (>20%):
         1. Vast majority of the breakpoints assigned to 11p13 and 11p15, indicating these loci are important in sporadic Wilms' tumor
         2. Loss of heterozygosity studies indicating that alleles from 11p13 and 11p15 are often lost in Wilms' tumor
      3. Loss of the long arm of chromosome 16 occurring in about 20% of Wilms' tumors: associated with poor prognosis independent of stage or tumor histology
   5. SNP-based arrays complement classic cytogenetics in the detection of chromosomal aberrations in Wilms' tumor (Zin et al. 2012).
7. Other studies in Wilms' tumor:
   1. Renal ultrasound to monitor Wilms' tumor
   2. Abdominal CT scanning to determine the tumor's origin, lymph node involvement, bilateral kidney involvement, and invasion into major vessels (e.g., inferior vena cava or liver metastases)
   3. Chest radiography to detect lung metastases
   4. Histopathological examination to confirm the diagnosis
   5. Further studies of certain patients with either Wilms' tumor or associated anomalies (Coppes and Egeler 1999):
      1. Hemihypertrophy/Beckwith-Wiedemann syndrome: uniparental disomy studies to evaluate constitutional or somatic alterations of 11p15.

2. WAGR syndrome: molecular evaluation of the 11p13 region if chromosomal studies do not reveal a deletion:
    1. Fluorescence in situ hybridization (FISH)
    2. Pulsed-field electrophoresis
3. Denys-Drash syndrome: molecular evaluation of *WT1* to determine whether the patient indeed carries a constitutional mutation. If the mutation is present, family members need to be screened.
4. Aniridia:
    1. Cytogenetic analysis and molecular evaluation of the WAGR region by FISH or pulsed field to rule out contiguous deletion of *Pax6* and *WT1*
    2. No further screening for Wilms' tumor if *Pax6* mutation is identified in isolated cases of aniridia

8. Cytogenetic studies of primary tumors of the central nervous system (Mertens 1994):
    1. Primitive neuroectodermal tumors:
        1. Near-diploid in most tumors
        2. I(17q): the most consistent rearrangement
    2. Gliomas:
        1. Mostly astrocytomas and ependymomas
        2. No specific structural rearrangement found
        3. Loss of 1p and gain of 1q found in a subset of tumors
        4. Loss of chromosome 22 common in childhood gliomas
        5. Loss of material from chromosome 22, either numeric or structural aberrations, found recurrently in rhabdoid tumors, meningiomas, and neurinomas
        6. Single-nucleotide polymorphism (SNP) arrays (Paxton et al. 2015):
            1. Allow for a whole-genome view of complex copy number changes and loss of heterozygosity
            2. Enable observations of the genomic landscape beyond 1p19q deletions and EGFR amplification
9. Cytogenetic studies in hepatoblastoma (Mertens et al. 1994):
    1. Trisomy 2 or duplications of part of 2q: detected in half of the cases
    2. Trisomy 20
    3. Duplication of 8q through either i (8q) formation or trisomy 8
10. Cytogenetic studies in sarcomas (Bennicelli and Barr 1999; Esparza 2012):
    1. Ewing sarcoma/primitive neuroectodermal tumor (Davidoff and Hill 2001):
        1. Reciprocal translocation t(11;22)(q24;q12):
            1. Characteristic primary rearrangement.
            2. Found in nearly 90% of the tumors.
            3. Causing a fusion of the transcription factor gene *FLI1* on chromosome 11 with *EWS* on chromosome 22 (*FLI1-EWS*, a fusion transcript). Only the chimeric gene expresses on the derivative chromosome 22 which contains a sequence encoding a DNA-binding domain from *FLI1*.
        2. t(21;22)(q22;q12) and *ERG-EWS*
        3. t(7;22)(p22;q12), *ETV1-EWS*
        4. t(17;22)(q12;q12), *E1AF-EWS*
        5. t(2;22)(q33;q12), *FEV-EWS*
    2. Additional chromosome changes:
        1. Trisomy 8
        2. Der(16)t(1;16)(a10-q21;q10-13), leading to gain of 1q and loss of 16q
    3. Congenital or infantile fibrosarcoma (Mertens et al. 1994):
        1. t(12;15)(p13;q25), *ETV6-NTRK3*
        2. Hyperdiploid with few or no structural rearrangements
        3. Nonrandom numerical changes:
            1. Trisomies 11 and 20, the most frequent changes
            2. Trisomies 17 and 8
    4. Osteosarcoma (Mertens et al. 1994):
        1. Highly complex karyotypes in the majority of cases
        2. Chromosome number in the triploid-tetraploid range
        3. Most common numeric aberrations involving −3, −10, −13, and −15

4. Structural rearrangements involving chromosome arms 1p, 1q, 3p, 3q, 7q, 11p, 17p, and 22q
5. Presence of many undefined chromosome markers

5. Rhabdomyosarcoma (Mertens et al. 1994):
   1. The most common soft tissue sarcoma in childhood
   2. Alveolar subtype:
      1. Most contain one or two recurring translocations, namely, t(2;13)(q35-37;q14) or the rare t(1;13)(p36;q14), shown to juxtapose the *PAX3* gene on chromosome 2 with the *FKHR* gene on chromosome 13, leading to the formation of a hybrid transcription factor (*PAX3-FKHR*).
      2. Found in about 70% of the alveolar tumors.
      3. Only occasionally described in other subtypes.
   3. Embryonal subtype: numerical changes with +2, +8, +11, and +20, found in 35–50% of cases

11. Other common, recurrent translocation/chromosome abnormalities in solid and soft tissue tumors of childhood (Davidoff and Hill 2001; Tien et al. 2014):
    1. Alveolar soft part sarcoma: t(X;17)(p11;q25), *ASPL-TFE3*
    2. Inflammatory myofibroblastic tumor: 2p23 translocations, *ALK-TPM3*
    3. Desmoplastic small round cell tumor:
       1. t(11;22)(p13;q12), *WT1-EWS*
       2. t(11;22)(q24;q12), *FLI1-EWS*, *ERG-EWS*
    4. Synovial sarcoma:
       1. t(X;18)(p11.23;q11.2), *SSX1-SSXT*
       2. t(X;18)(p11.21;q11), *SSX2-SSXT*
    5. Malignant melanoma of soft part (clear cell sarcoma): t(12;22)(q13;q12), *ATF1-EWS*
    6. Myxoid liposarcoma:
       1. t(12;16)(q13;p11), *CHOP-TLS*(*FUS*)
       2. t(12;22)(q13;q12), *CHOP-EWS*
    7. Ewing sarcoma:
       1. t(11;22)(q24;q12)
       2. t(2;11;22)(q35;q24;q12), add(17)(p11.2)
       3. +12
    8. Extraskeletal myxoid chondrosarcoma: t(9;22)(q22;q12), *CSMF-EWS*
    9. Dermatofibrosarcoma protuberans and giant cell fibroblastoma: t(17;22)(q22;q13), *COLIAI-PDGFB*
    10. Lipomas: t(2;12)(q23;q15)
    11. Leiomyomas: t(12;14)(q13;15), *HMGI-C* (Cooper 1996)

12. Other primary chromosome changes in solid tumors (Sandberg and Turc-Carel 1987; Sandberg 1988):
    1. Benign tumors:
       1. Meningioma and acoustic neuroma:
          1. −22
          2. 22q−
       2. Mixed tumors of salivary glands:
          1. t(3;8)(p21;q12)
          2. t(9;12)(p13-22;q13-15)
       3. Colonic adenomas:
          1. 12q− and/or +7
          2. 12q− and/or +8
       4. Cortical adenoma of the kidney:
          1. +7
          2. +17
          3. −Y
    2. Adenocarcinomas:
       1. Bladder:
          1. i(5p)
          2. +7
          3. −9/9q−
          4. 11p−
       2. Prostate: del(10)(q24)
       3. Lungs (small cell carcinoma): del(3)(p14p23)
       4. Colon:
          1. 12q−
          2. +7
          3. +8
          4. +12
          5. 17(q11)
          6. 17p-
       5. Kidney: del(3)(p11p21)
       6. Uterus: 1q−
       7. Ovary:
          1. 6q−
          2. t(6;14)(q21;q24)

8. Endometrium:
   1. Trisomy 1q
   2. +10
3. Embryonal and other tumors:
   1. Testicular (germ cell tumors): i(12p)
   2. Malignant melanoma:
      1. Del(6)(q11q27)
      2. i(6p)
      3. Del(1)(p11p22)
      4. t(1;19)(q12;q13)
   3. Mesothelioma: del(3)(p13p23)
   4. Glioma: −22

13. Potential prognostic markers of neoplastic disease (Barcus et al. 2000):
   1. Breast cancer: allelic loss at 1p22-p31 (lymph node metastasis and tumor size >2 cm)
   2. Bladder cancer:
      1. LOH RB (high grade/muscle invasion)
      2. Genomic alterations (2q−, 5p+, 5q−, 6q−, 8p−, 10q−, 18q−, 20q+) (higher grade)
   3. Cervical carcinoma: LOH on chromosome (advanced stage)
   4. Colorectal cancer:
      1. LOH at 18q21 or p53 expression (recurrence/poor survival)
      2. *MSI* (microsatellite instability) and *K-ras* mutations in normal-appearing colonic mucosa (predictive of colorectal cancer)
      3. P16 hypermethylation (shorter survival in Stage T3N0M0 tumors)
   5. Gastric cancer:
      1. LOH p53 (invasive disease)
      2. LOH of 7q (D7S95) (poor prognosis (in Stage III/IV))
   6. Glioma: chromosome 22q loss (astrocytoma progression)
   7. Head and neck squamous cell carcinoma:
      1. LOH of 14q (poor outcome)
      2. LOH on 2q (poor prognosis)
      3. LOH on 17p (chemoresistance)
   8. Melanoma: LOH in plasma (advanced stage/tumor progression)
   9. Neuroblastoma:
      1. N-myc amplification (poor prognosis)
      2. TrkA expression (good prognosis)
      3. High telomerase expression (aggressive behavior)
   10. Neuroblastomas, 4s: N-myc amplification, 1p deletion, 17q gains, and elevated telomerase activity (poor prognosis)
   11. Non-small cell lung cancer:
      1. Allelic imbalances on 9p (poor prognosis)
      2. LOH of 11p (poor prognosis)
   12. Primitive neuroectodermal tumor:
      1. LOH of 17p (metastatic disease)
      2. C-myc amplification (poor prognosis)
   13. Prostate cancer: LOH on 13q (advanced stage)
   14. Retinoblastoma: LOH at RB1 locus (tumoral differentiation, absence of choroidal invasion)

14. Chromosome abnormalities observed in some solid tumors (Cooley et al. 2009):
   1. Genitourinary:
      1. Renal:
         1. Renal cell carcinoma (RCC): −3 or del(3p), del(3p) with gain 5q, del (3p) with loss 5q, and −14/del(14q)
         2. Papillary RCC: +7, +17, −Y, and 9p−
         3. t(Xp11.2) RCC: (X;17)(p11.2;q25), t(X;17) (p11.2;q23), and t(X;1) (p11.2;p34)
         4. t(6;11) RCC: t(6;11)(p21;q12)
         5. Chromophobe RCC: losses 1, 2, 6, 10, 13, 17, and 21
         6. Oncocytoma: 1p− and t(11q13)
         7. Rhabdoid: −22/22q−
         8. Congenital mesoblastic nephroma: t(12;15)(p12;q25), +11, +17, and +20
      2. Bladder, papillary: del(9)(p21), 8p−, +7, and +17
      3. Wilms' tumor: 16q−, +1q, 1p−, −22, and 17p−
      4. Prostate: +17q31, 8p22−, +8q24, 10q−, and 17p13−
   2. Gastrointestinal:
      1. Liver:
         1. Hepatoblastoma: +20, +2, +8, and t(1q12q21)

2. Hepatic mesenchymal hamartoma: t(11;19)(q13;q13.4) and t(19q-13.4)
2. Salivary gland:
1. Pleomorphic adenoma: t(3;8)(p21;q12)
2. Mucoepidermoid cancer: t(11;19)(q21;p13)
3. Warthin tumor: t(11;19)(q21;p13)

3. Breast:
1. Invasive intraductal: dmin (double minute) and HSR (homogeneously staining region)
2. Secretory breast: t(12;15)(p13;q25)

4. CNS:
1. Astrocytic tumors: +7, −10/10q−, 9p21−, and 19q−
2. Glioblastoma: +7, 10q−, and 9p−
3. Anaplastic: 1p−, 19q−, and der(1;19)(q10;p10)
4. Mixed oligoastrocytoma: +7, −10/10q−, and 15q−
5. Oligoastrocytoma: 19q− and 1p−

5. Ependymoma:
1. Spinal: +7, −22q, and 14q−
2. Intracranial: +1q, 6q−, +7, and 9p−

6. Mudulloblastoma: i(17q), 17p−, −10/10q−, and +7
7. Supratentorial primitive neuroectodermal tumor: +1q, 16q−, and 19p−
8. Atypical teratoid/rhabdoid tumor: −22 or del(22q11.23)
9. Meningioma: −22 or del(22q11.2), 1p−, and −14/14q−
10. Choroid plexus tumors:
1. Carcinoma: losses 2, 3, 4, 5, 6, 8, 10, 11, 13, 14, 15, 16, 17, 18, 19, and 22
2. Papilloma: gains 7, 8, 9, 12, 14, 15, 17, 18, 19, and 20

11. Small round cell tumors:
1. Alveolar RMS: t(2;13)(q37;q14), t(1;13)(p36;q14), t(X;2)(q13lq35), and t(2;2)(q35;p23)
2. Embryomal rhabdomyosarcoma: gains 2, 7, 8, 11, 12, 13, and 20; losses 1p, 3p, 9q, 10q, 16q, 17p, and 22
3. Neuroblastoma: del(1p), del(11q) without *MYCN* amp, del(1p), +17q, *MYCN* amp, and triploidy without above abnormalities
4. Ewing sarcoma/peripheral neuroectodermal tumor: t(11;22)(q24;q12) and variants, t(21;22)(q22;q12), del(9p), 17p−, and der(1;16)(q10;p10)
5. Desmoplastic small round cell tumor: t(11;22)(p13;q12)
6. Clear cell sarcoma: t(12;22)(q13;q12)
7. Retinoblastoma: del(13q14) and gains 1q and 6p
8. Lymphomas: specific translocations

12. Bone and soft tissue:
1. Congenital fibrosarcoma/congenital mesoblastic nephroma: t(12;15)(p12;q25), +11, +17, and +20
2. Synovial sarcoma: t(X;18)(p11.2;q11.2)
3. Lipoma: t(3;12)(q27-28;q14-15) and variants
4. Liposarcoma:
1. Myxoid, round cell: t(12;16)(q13;p11)
2. Myxoid: t(12;22)(q13;q12) and variant
3. Well differentiated: rings, markers, and dmin

13. Leiomyoma: t(12;14)(q15;q24):
1. Alveolar soft part sarcoma: der(17)t(X;17)(p11.2;q25)
2. Extraskeletal myxoid chondrosarcoma: t(9;22)(q22;q12), t(9;17)(q22;q11.2), t(9;15)(q22;q21), and t(3;9)(p11;q22)

14. Dermal tumors:
1. Dermatofibrosarcoma protuberans: der(22)t(17;22)(q22;q13.1) or r(22)t(17;22)
2. Giant cell fibroblastoma: t(17;22)(q22;q13.1)
3. Bednar tumor: der (22)t(17;22) (q22;q13.1) or r(22)t(17;22)
4. Hidradenoma: t(11;19)(q21;p13)

15. Non-small cell lung cancer: 3p−, +7, and *EGFR* high copy number or amplification
16. Dysgerminoma, ovary: i(12p) and 12p overrepresentation

17. Testicular germ cell tumors, seminoma, and nonseminoma: i(12p) and 12p amplification

Genetic Counseling

1. Recurrence risk:
    1. Retinoblastoma:
        1. Predisposition to retinoblastoma which is caused by germline mutations in the *RB1* gene: transmitted in an autosomal dominant fashion.
        2. Use *RB1* mutation analysis to clarify the genetic status of at-risk sibs and offspring when a previously characterized germline cancer-predisposing mutation is available.
        3. Use indirect testing using polymorphic loci linked to the *RB1* gene in some families to clarify genetic status of at-risk family members if *RB1* direct DNA testing is not available or is uninformative.
        4. Use empiric recurrence risk estimates in all families in which direct DNA testing of *RB1* and linkage analysis are unavailable or uninformative.
        5. Risk to patient's siblings:
            1. When there is an existing family history: a 45% chance for siblings of bilaterally affected cases and a 30% chance for siblings of unilaterally affected cases to develop disease.
            2. When there is absence of any family history: 2% risk for siblings of bilaterally affected cases and 1% for siblings of unilaterally affected cases to develop disease (Draper et al. 1992).
            3. There is an additional risk to siblings in the absence of any family history or documented mutation in parental leukocyte DNA because of germline mosaicism. If neither parent has the cancer-predisposing *RB1* germline mutation that was identified in the index case, germline mosaicism in one parent is possible, and the risk to each sib of having retinoblastoma is 3–5%.
            4. If the index case has mosaicism for an *RB1* cancer-predisposing mutation (the mutation arose as a post-zygotic event) and neither parent has an *RB1* germline mutation, the risk to the sibs is not increased, and thus it is not warranted to test the sibs for the *RB1* mutation identified in the index case.
        6. Risk for patient's offspring:
            1. About 45% by the age of 6 years (consistent with an autosomal dominant inheritance with 90% penetrance) for the offspring of survivors of hereditary (multifocal, bilateral) retinoblastoma.
            2. About 2.5% for the offspring of survivors of unilateral retinoblastoma.
            3. The low (~1%), but not negligible, risk to the offspring of index cases with unifocal disease and a negative family history reflect the possibility of a germline *RB1* mutation with low penetrance or mutational mosaicism.
    2. Implications of somatic and germline mosaicism in retinoblastoma for genetic counseling (Sippel et al. 1998):
        1. In a unilateral, simplex case of retinoblastoma, the absence of a detected mutation in leukocytes does not reliably predict that no tumors will arise in the fellow eye in the future.
        2. Some bilateral simplex retinoblastoma patients and unilateral, multifocal simplex retinoblastoma patients have a recurrence risk among their offspring that is much less than 45–50%.
        3. It is possible – but not yet proven – that every bilateral or unilateral retinoblastoma patient in whom an initial mutation is identified in tumor cells, but not in leukocytes, has a recurrence risk of zero.

4. If unaffected parents with no previous family history of retinoblastoma have an affected child, DNA-based estimates of the recurrence risk for future children should include, whenever possible, an analysis of paternal germline DNA.
5. The risk that a patient with unilateral simplex retinoblastoma will have mutant germ cells may be much higher than 12%; however, some will be mosaics, and <50% of their germ cells will be mutant.

3. Genetic counseling for retinoblastoma in the presence of positive family history (Vogel 1979; Isidro et al. 2011):
   1. Multiplex disease (>2 affected members) – the index patient had retinoblastoma and one or more close relatives are also affected:
      1. Affected individuals definitely carry a germline mutation.
      2. A 50% chance exists that a known carrier will pass the mutant copy of the retinoblastoma gene to each child and there is 50% penetrance and there is a 50% × 90% = 45% chance that each child will develop retinoblastoma.
   2. Multiplex disease (>2 affected members) – the index patient did not develop retinoblastoma as a child, but a parent is known to be a carrier:
      1. Approximately 10% risk that an asymptomatic son or daughter of a known carrier is also a carrier.
      2. The risk that his or her offspring will inherit a mutation is about 5%, and the risk of the disease is 90% × 5% = 4.5%.
   3. Simplex disease (only one family member affected) – the index patient had multifocal retinoblastoma:
      1. The patient very likely has a germline mutation.
      2. The risk to each offspring is 50% for being a carrier and 45% for developing the disease.
   4. Simplex disease (only one family member affected) – the index patient had unifocal retinoblastoma (one tumor in one eye only):
      1. A 12% risk exists that the patient carries a germline mutation (i.e., has hereditary retinoblastoma) and an 88% risk that he or she does not (nonhereditary retinoblastoma).
      2. The risk for the first child of the index patient is 6% for being a carrier and 5.4% for developing the disease.
      3. If the first child does not develop retinoblastoma, the risk for the next child is less.
      4. If at least one child develops retinoblastoma, the index patient definitely has the hereditary type of the disease, and the risk for family members is as described for multiplex families.
   5. Simplex disease (only one family member affected) – two unaffected parents have one child with retinoblastoma:
      1. The risk of the parents' second child's developing retinoblastoma is about 1% if the first child had unifocal disease and about 6% if the first child had multifocal disease.
      2. These risks decrease with every unaffected child that passes the years of highest risk (years 0–5) without developing the disease.
   6. Simplex disease (only one family member affected) – the index patient is an adult of childbearing age who did not develop retinoblastoma, but a sibling had retinoblastoma:
      1. A small risk exists that one of the parents is an asymptomatic carrier and the index patient is also an asymptomatic carrier.
      2. The carrier risk for the index patient is 0.1% if the affected sibling had unilateral retinoblastoma and 0.6% if the

affected sibling had bilateral retinoblastoma.
3. The risk that the first child of the index patient will develop retinoblastoma is approximately half of these numbers, i.e., 0.05% or 0.3%, respectively.

4. Neuroblastoma:
1. Risk for patient's sibling: low unless a parent has hereditary form of neuroblastoma
2. Risk for patient's offspring: 50%

5. Wilms' tumor:
1. Risk for patient's sibling: low unless a parent has hereditary form of Wilms' tumor
2. Risk for patient's offspring: 50%

2. Prenatal diagnosis:
1. Retinoblastoma:
1. Prenatal testing is possible if the germline *RB1* mutation in the parent is known or if *RB1* linkage analysis is informative in the family.
2. Mutation analysis on fetal DNA obtained from amniocentesis or CVS.
3. Use prenatal ultrasonography to detect intraocular tumors if the disease-causing RB1 mutation is identified in the fetus.

2. Adrenal neuroblastoma (Kesrouani et al. 1999):
1. Prenatal diagnosis adrenal neuroblastoma by ultrasonography usually made in the third trimester.
2. Sonographic appearance of the adrenal neuroblastoma varies:
1. Solid
2. Purely cystic (50%)
3. Mixed echo pattern (related to necrosis, hemorrhage, or spontaneous tumoral involution)
4. Fetal hydrops
5. Hydropic placenta with metastases in the placenta

3. Needle biopsy for selection of the group with favorable biological parameters (N-myc, DNA index).
4. Frequently producing catecholamines and hence maternal symptoms could aid the diagnosis.
5. Elevated catecholamines in the amniotic fluid.

3. Wilms' tumor (Vadeyar et al. 2000):
1. Prenatal ultrasonography:
1. Maternal hydramnios.
2. Fetal hydrops.
3. A solid echogenic mass with a clearly defined capsule.
4. Areas of hemorrhage and necrosis may be seen within the mass.

2. Fetal renal biopsy (nephroblastoma by histology)

3. Management:
1. Surgeries for most solid tumors
2. Determining the genetic changes present in the tumor of an individual patient: becoming increasingly important for managing the oncology patient
3. Retinoblastoma (Chintagumpala et al. 2007):
1. Goals of treatment: preservation of sight and life.
2. Management of intraocular disease:
1. Enucleation
2. External beam radiation (EBR) therapy
3. Brachytherapy: involves the placement of a radioactive implant
4. Thermotherapy
5. Chemothermotherapy
6. Laser photocoagulation
7. Cryotherapy
8. Chemotherapy

3. Management of extraocular disease: Patients with extraocular disease, having a very poor prognosis with respect to survival, may benefit from a combination of conventional chemotherapy and EBR, and those with distant metastatic disease may benefit from high-dose chemotherapy and EBR in conjunction with bone marrow stem cell transplantation.

4. Neuroblastoma (Lee et al. 2003):
1. Localized, low-risk disease:
1. Primary curative surgery
2. Minimal therapy: low-dose radiation or chemotherapy
3. Supportive care with surveillance

2. Intermediate-risk patients: combination therapy with radiation, chemotherapy, and surgery
3. High-risk patients:
   1. Combination of radiation, myeloablative chemotherapy, and surgery (delayed)
   2. Autologous bone marrow transplant
   3. Research protocols

5. Wilms' tumor: The usual approach in most patients is nephrectomy followed by chemotherapy with or without postoperative radiotherapy.

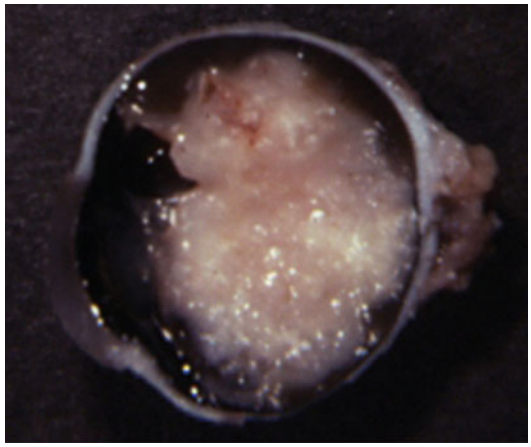

Fig. 1 Notice the *white* firm neoplasm (retinoblastoma) filling the vitreous space of the eye

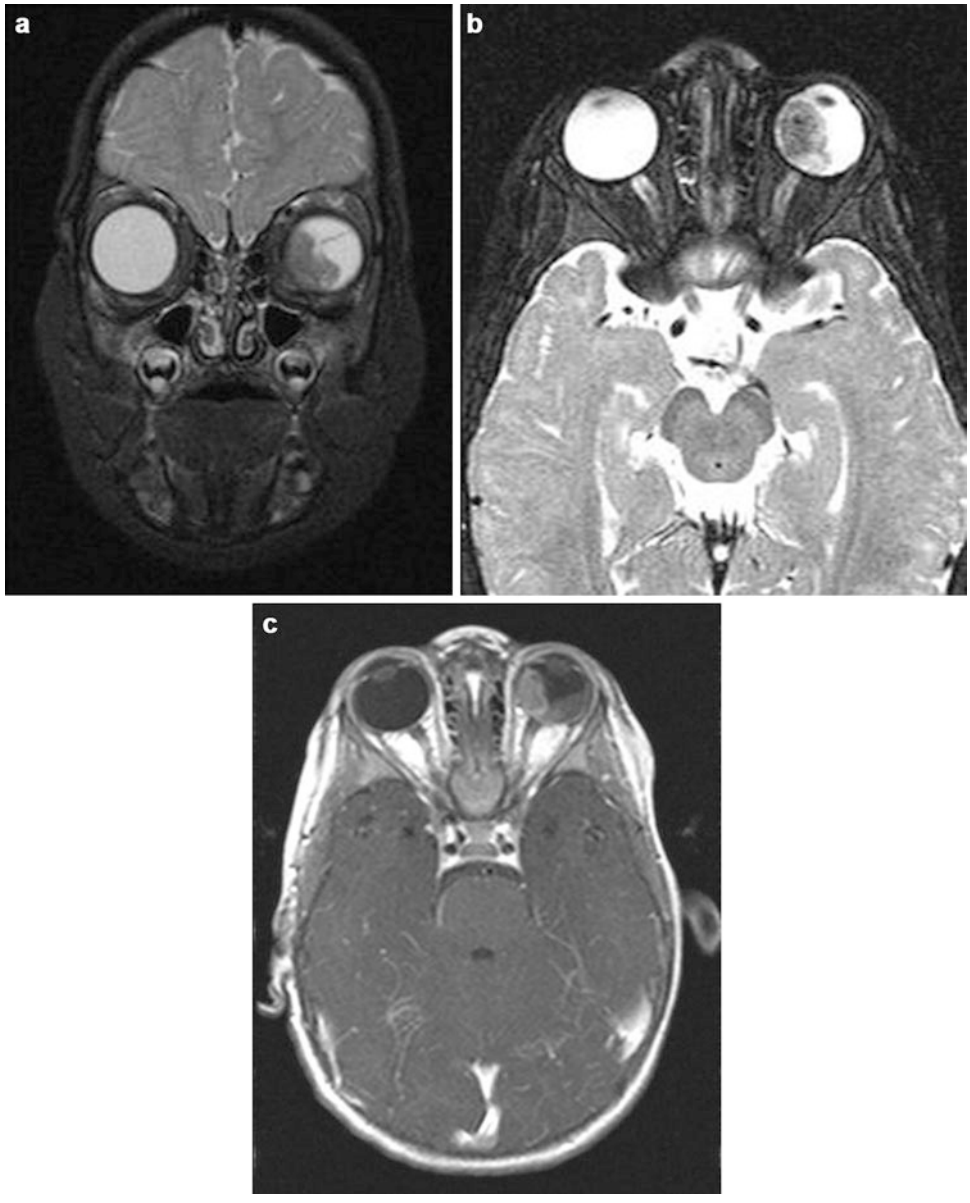

Fig. 2 (**a**–**c**) A 12-month-old boy was seen because of a 3-month history of a lazy left eye. One month previously, he was noted to have a white reflex in his left eye. He was seen by an ophthalmologist who diagnosed him to have group E retinoblastoma of the left eye. The right eye was normal. MRI of orbits demonstrated a calcified mass (**a**, **b**) with mild enhancement (**c**) in the posterior aspect of the left globe. The findings are compatible with retinoblastoma. Mutation screening of RB1 gene on DNA isolated from lymphocytes demonstrated heterozygous for a single-base substitution, g.162367G > A, in the last nucleotide of exon 23 of the coding sequence of the RB1 gene. This single-base substitution translates to a missense mutation, p.Arg830Lys. Although this novel change has not been reported in the RB1 mutation database, it has been seen in one other child with unilateral retinoblastoma in the performing molecular laboratory own database (Courtesy of Dr. Grace Guo)

Fig. 3 Large, well-circumscribed ovoid Wilms' tumor in the upper pole of the kidney. Barely identifiable small areas of hemorrhage and necrosis are present

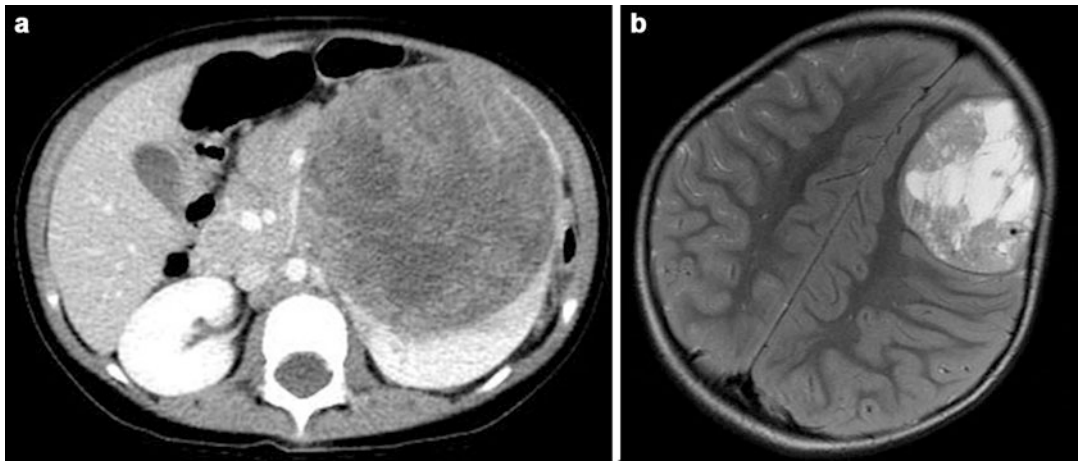

Fig. 4 (**a**, **b**) A 2-year-old female with a left renal mass was seen on the recent ultrasound. CT scan demonstrated a large heterogeneous mass arising from the left kidney (**a**). A heterogeneous metastatic lesion was present in the right front lobe of the brain (**b**). The masses were confirmed as Wilms' tumors (Courtesy of Dr. Grace Guo)

Cleft Lip and/or Cleft Palate

Contents

Cleft lip and/or cleft palate (CL/CP) is the most common craniofacial malformation with an estimated incidence from approximately 1 in 700 to 1 in 1,000 live births among Caucasians (Carinci et al. 2000). CL/CP may occur as an isolated finding or may be found in association with other congenital malformations.

Genetics/Basic Defects

1. Etiological heterogeneity (Fraser 1970; Wyszynski et al. 1996)
2. Environmental agents (De La Pedraja et al. 2000):
    1. Cleft lip and cleft palate (Habib 1978a; Wyszynski and Beaty 1996):
        1. Alcohol
        2. Anticonvulsants (phenytoin, sodium valproate) (Jackson et al. 2015)
        3. Isotretinoin
        4. Steroids
        5. Methotrexate
        6. Maternal infections in the first trimester:
            1. Rubella
            2. Toxoplasmosis
        7. Maternal smoking
    2. Isolated clefts:
        1. Little evidence linking to any single teratogenic agent, except anticonvulsant phenytoin.
        2. Use of phenytoin during pregnancy is associated with a tenfold increase in the incidence of cleft lip.
    3. Cleft lip: incidence of cleft lip in infants in mothers who smoke during pregnancy is twice that of those born to nonsmoking mothers.
3. Genetic factors:
    1. Syndromic clefts associated with malformations involving other developmental regions:
        1. About 25% of neonates with CL/CP show associated malformations, syndromes, or aneuploidy (Bergé et al. 2001).
        2. Van der Woude syndrome (van der Woude 1954): the most commonly recognized syndrome associated with CL/CP, an autosomal dominant disorder characterized by CL/CP and blind sinuses or pits of the lower lip.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_43

3. Microdeletion of chromosome 22q11.2 (velocardiofacial syndrome, DiGeorge syndrome, and conotruncal anomaly face syndrome): currently the most common syndromic diagnosis among patients with clefts of the secondary palate alone.
4. Other syndromes associated with clefts of the secondary palate alone:
    1. Stickler syndrome
    2. Ectrodactyly-ectodermal clefting (EEC) syndrome
    3. Popliteal pterygium syndrome

2. Nonsyndromic cleft of the lip and/or palate (Carinci et al. 2000; Mehrotra 2015):
    1. An embryopathy derived from failure in fusion of the nasal process and/or palatal shelves.
    2. Genetic factors play an important role in the etiology of cleft lip and/or palate since one in five patients in different populations has a positive family history of CL/CP.
    3. Isolated CL/CP is considered multifactorial in origin and demonstrates strong familial aggregation with a significant genetic component.
    4. No evidence of classic Mendelian inheritance attributable to any single gene, although a number of genes or loci have been implicated, including transforming growth factor-alpha (*TGFA*, 2p13), *TGFB3* (14q24), retinoic acid receptor alpha (*RARA*, 17q12), B-cell leukemia/lymphoma 3 (*BCL3*, 19q13) (Stein et al. 1995), *MSX-1* (4p16, 4q31, 6p23), interferon regulatory factor-6 (*IRF6*), runt-related transcription factor 2 (*RUNX2*), and several regions on chromosomes 1p36 (*SKI*/*MTHFR*), 6p23-24 (*OFC1*), 2q13 (*OFC2*), and 19q13.2 (*OFC3*) and other loci such as 4q25-4q31.3 and 17q21 (Hibbert and Field 1996; Prescott et al. 2001; Murray 2002; Mehrotra 2015).

3. Molecular signaling events in embryonic palatal development (Yu et al. 2009):
    1. Failure of palatal shelf formation:
        1. Recent studies have identified several molecular networks operating between the palatal shelf epithelium and mesenchyme during different steps of palatogenesis.
        2. These networks include signaling molecules and growth factors such as sonic hedgehog (Shh); members of the transforming growth factor-β (TGFβ) superfamily, including bone morphogenetic proteins (BMPs) and TGFβs; and fibroblast growth factors (FGFs) and their receptors (FGFR), effectors, and targets.
    2. Fusion of the palatal shelf with the tongue or mandible:
        1. Severe reduction of the expression of *Jagged 2* (*Jag2*), thereby encoding a ligand for the Notch family receptors and ectopic TGFβ3 production in the nasal epithelia of mice.
        2. Mutations in TBX22 have been reported in families with X-linked cleft palate and ankyloglossia.
    3. Failure of palatal elevation:
        1. Mutations of *Pax9, Pitx1*, or *Osr2* can lead to failed palatal shelf elevation and cleft palate defect.
        2. The implication of GABA in palate development was demonstrated by genetic studies of mice lacking the β3 subunit of the GABA receptor that developed CP without other craniofacial malformations.
    4. Failure of palatal shelves to meet after elevation: mutations in *Msx1* and *Lhx8* and conditional inactivation of *TGFbr2* in CNC cells or *Shh* in the epithelium all result in retarded palatal shelf development.
    5. Persistence of the middle edge epithelium: mutations of *CDH1*/E cadherin, which deletes the extracellular cadherin repeat domains required for cell–cell adhesion, have recently been associated with CL/CP in families with hereditary diffuse cancer.

Clinical Features

1. Classification of different types of orofacial clefting:
   1. Cleft lip with or without cleft palate (CL/CP):
      1. Unilateral cleft lip
      2. Unilateral cleft lip and cleft palate
      3. Bilateral cleft lip
      4. Bilateral cleft lip and cleft palate
   2. Cleft palate only:
      1. Cleft palate
      2. Submucous cleft palate
      3. Velopharyngeal insufficiency
      4. Robin sequence and robin complexes
   3. Median clefts:
      1. Median cleft lip
      2. Persistent infranasal furrow
      3. Median frenular cleft
      4. Median mandibular cleft
   4. Alveolar (oral–facial–digital syndromes)
   5. Tessier-type clefts including lateral and oblique facial clefts
2. Racial difference in CL/CP (De La Pedraja et al. 2000):
   1. Whites: approximately 1 in 1,000 births
   2. African Americans: 0.41 per 1,000 births
   3. Asians: approximately twice of whites
3. Sex difference in CL/CP and isolated clefts of the secondary palate (De La Pedraja et al. 2000):
   1. Children born with CL/CP: 60–80% are males.
   2. Isolated clefts of the secondary palate: more frequently in females.
4. Sites of clefts:
   1. Isolated cleft lip: 21%
   2. CL/CP: 46%
   3. Clefts of the secondary palate alone: 33%
   4. Unilateral clefts:
      1. More common in the left than the right (2:1)
      2. Much more common than bilateral (9:1)
      3. Associated with palatal clefts in 68% of cases
   5. Bilateral clefts of the lip: associated with palatal clefts in 86% of cases
5. Types of cleft lip:
   1. Microform:
      1. Presence of a vertical groove and vermilion notching
      2. Associated with varying degrees of lip shortening
   2. Unilateral incomplete cleft lip:
      1. Present with varying degrees of lip disruption
      2. Associated with an intact nasal sill or Simonart band (a band of fibrous tissue from the edge of the red lip to the nostril floor)
   3. Complete cleft lip: characterized by disruption of the lip, alveolus, and nasal sill
6. Incidence of cleft lip +/− palate (CL/CP) and cleft palate alone (CPA) (Robin et al. 2006):
   1. Overall incidence of CL/CP and CPA: 1–2/1,000 children.
   2. CPA incidence is about 1/1,500:
      1. More common if submucous CP/CA is included.
      2. Bifid uvula occurs in 1 of 80 patients and often occurs in isolation, with no clefting of the palatal muscles.
   3. Incidence of CL/CP varies by race:
      1. Highest among American Indians, at 3.6 cases per 1,000 live births.
      2. Lowest among African Americans, with 0.3 cases per 1,000 live births.
      3. The incidence of CPA does not vary by race.
   4. Of all CL/CP and CPA:
      1. Twenty percent of all clefts are isolated cleft lip (18% unilateral, 2% bilateral).
      2. Fifty percent are CL/CP (38% unilateral, 12% bilateral).
      3. Thirty percent are CPA.
   5. CL/CP is twice as common in males; CPA is twice as common in females.
7. Secondary medical problems with the presence of cleft palate:
   1. Difficulty in sucking
   2. Inadequate intake of formula
   3. Aspiration
   4. Deviated nasal septum (airway obstruction)
   5. Hearing impairment
   6. Recurrent ear infections

7. Malocclusion
8. Abnormal craniofacial growth
9. Inability to generate a pressure gradient between the oral and nasal chambers (hinders sucking in most infants)
10. Speech dysfunction:
    1. The most serious untoward consequence associated with cleft palate
    2. Hypernasality or escape of sound into the nasal cavity associated with the production of many consonant phonemes and vowels in the English language except m, n, and ng
11. Cosmetic disfigurement associated with orofacial clefting

Diagnostic Investigations

1. Speech and hearing evaluation
2. Echocardiography for associated cardiac anomalies
3. Karyotyping if indicated, especially to detect del(22)(q11.2)
4. Molecular genetic analysis for a known mutation in a syndromic CL/CP
5. Multiple ligation probe-dependent amplification (MLPA) analysis: to detect chromosomal rearrangements (22q11.2 microduplications among patients with cleft lip and/or cleft palate) (Sedghi et al. 2015)

Genetic Counseling

1. Recurrence risk (Chen 1988; Tolarova 1972):
    1. Recurrence risk for nonsyndromic CL +/− CP (Curtis et al. 1961; Cockell and Lees 2000):
        1. Unaffected parent:
            1. No previously affected child: about 0.1% (general population risk) (Bonaiti-Pellie and Smith 1974; Kirschner and LaRossa 2000)
            2. With one previously affected child: about 4%
            3. With two previously affected children: about 9%
        2. One affected parent:
            1. No previously affected child: about 4%
            2. With one previously affected child: about 17%
            3. With two previously affected children: about 25%
        3. Two affected parents:
            1. No previously affected child: about 35%
            2. With one previously affected child: about 45%
            3. With two previously affected children: about 50%
        4. Risks to first-, second-, and third-degree relatives: 4%, 0.7%, and 0.4%, respectively (Habib 1978b)
    2. Recurrence risk for nonsyndromic CP:
        1. Unaffected parent:
            1. No previously affected child: about 0.04% (general population risk) (Kirschner and LaRossa 2000)
            2. With one previously affected child: about 3.5%
            3. With two previously affected children: about 13%
        2. One affected parent:
            1. No previously affected child: about 3.5%
            2. With one previously affected child: about 10%
            3. With two previously affected children: about 24%
        3. Two affected parents:
            1. No previously affected child: about 2.5%
            2. With one previously affected child: about 40%
            3. With two previously affected children: about 45%
3. Van der Woude syndrome (presence of lip pits in addition to the cleft anomaly): if lip pits are identified in either parent, the recurrence risk would increase to 50% (Cockell and Lees 2000).

4. Presence of a microform such as a forme fruste cleft lip, submucous cleft palate, or bifid uvula suggests genetic factors within the family, which would alter the inheritance risks (e.g., striking association with lower-lip pits in the van der Woude syndrome).
5. Recurrence risk for CL/CP with associated anomalies:
    1. Mendelian diseases and syndromes:
        1. Autosomal dominant inheritance (e.g., Apert syndrome)
        2. Autosomal recessive inheritance (e.g., Smith–Lemli–Opitz syndrome)
        3. X-linked inheritance (e.g., oto-palato-digital syndrome)
    2. Chromosome disorders (e.g., trisomy 13)

2. Prenatal diagnosis:
    1. Prenatal ultrasonography (2D, 3D) (Lee et al. 2000):
        1. 3D ultrasonography:
            1. Enhances 2D ultrasonography
            2. Provides more precise image of the defect
        2. CL/CP not reliably diagnosed until the soft tissues of the fetal face become distinct by 13–14 weeks by transabdominal (TA) sonography and by transvaginal (TV) sonography slightly earlier
        3. Fetal palate best seen in the axial plane
        4. Fetal lips optimally visualized in the coronal view
        5. To demonstrate isolated cleft lip (Mulliken and Benacerraf 2001):
            1. Unilateral versus bilateral
            2. Incomplete (the labial cleft does not extend through the nasal still or floor) versus complete (no tissue connection between the alar base and medial labial element or premaxilla)
            3. Microform (tiny) cleft on the "normal" side of a unilateral labial cleft
            4. Alveolar cleft: extent and degree of premaxillary proclination
            5. Cleft of the secondary palate if any
        6. To demonstrate associated anomalies (limb and spine anomalies, most common with 33%; cardiovascular anomalies, 24%)
    2. Fetal MRI: useful for detecting fetal deformities with valuable information and supplying higher diagnostic accuracy (Wang et al. 2011; Kim et al. 2015)
    3. Fetal echocardiography in case of fetal cardiac anomalies
    4. Fetal karyotyping in case of associated fetal anomalies
3. Management:
    1. Medical:
        1. A highly specialized multidisciplinary approach from birth to adulthood
        2. Airway management
        3. Establishment of feeding
        4. Speech, hearing, and language therapies
    2. Cleft lip repair (Shaye 2014; Shaye et al. 2015):
        1. Timing of repair: usually carried out around at the age of 3 months followed by palatal repair at around 6 months
        2. Unilateral cleft lip:
            1. Objectives: to approximate the medial and lateral lip elements with preservation of natural landmarks, to align a functional concentric orbicularis, and to establish symmetry and proportionality
            2. Straight-line closure
            3. Triangular (geometric) cleft lip repair
            4. Rotation-advancement technique
        3. Bilateral cleft lip:
            1. Two-stage repair with columellar elongation as the second procedure between the ages of 1 and 5 years.
            2. One-stage approach with primary rhinoplasty at the time of cleft lip repair.
            3. Nasoalveolar molding.
            4. Lip adhesion surgery.
            5. Alveolar bone grafting.
            6. Primary cleft rhinoplasty: improves nasal appearance and possibly decreases the number of revision surgeries in the future.

7. Postoperative nasal stents.

3. Cleft palate repair (Shaye 2014; Shaye et al. 2015):
   1. Goals: closure of the soft palate and reorientation of the levator veli palatini to obtain normal velopharyngeal closure and speech.
   2. Closure of the hard palate cleft separates the oral and nasal cavities.
   3. Palatoplasty:
      1. Von Langenbeck palatoplasty
      2. Veau–Wardill–Kilner palatoplasty
      3. Two-flap palatoplasty
      4. Furlow double-opposing Z-plasty
   4. Preventative and restorative dental care
   5. Orthodontics
   6. Pharyngeal flap or sphincter pharyngoplasty for velopharyngeal incompetence
4. Psychological issues (Endrica and Kapp-Simon 1999):
   1. Parental stress
   2. Parent–child relationship
   3. Behavioral and emotional adjustment
   4. Self-concept and personality
   5. Cosmetic disfigurement
   6. Social functioning
   7. Cognitive development and adjustment
   8. Cleft Lip and Palate Association (CLAPA), a helpful source of support and information for both families and professionals
5. Recent observation suggests beneficial effects of folic acid supplementation during pregnancy in the prevention of facial clefting (Tolarova and Harris 1995; Hartridge 1999).

Cleidocranial Dysplasia

Contents

Cleidocranial dysplasia is a generalized skeletal dysplasia affecting not only the clavicles but almost the entire skeletal system. It is characterized by aplasia or hypoplasia of the clavicles, enlarged calvaria with frontal bossing, multiple Wormian bones, delayed tooth eruption, supernumerary unerupted teeth, distal phalanges with abnormally pointed tufts, hypoplasia of the pelvis, and numerous other abnormalities (Jensen 1990).

Synonyms and Related Disorders

Cleidocranial dysostosis

Genetics/Birth Defects

1. Inheritance: autosomal dominant
2. About 20–40% of cases represent new mutations (Martinez-Frias et al. 1988)
3. Cause (Mundlos et al. 1997; Quack et al. 1999; Cohen 2001)
    1. Caused by mutations in *CBFA1* (*RUNX2*) gene resulting in haploinsufficiency. Types of mutations identified are:
        1. Deletion
        2. Insertion
        3. Missense (Golan et al. 2000)
        4. Nonsense
    2. The gene for cleidocranial dysplasia called core-binding factor A1 (*CBFA1*) (a member of the runt family of transcription factors), mapped to 6p21 (Feldman et al. 1995; Gelb et al. 1995). The alternative gene name is called *RUNX2*
    3. *CBFA1* encodes a transcription factor that activates osteoblast differentiation and plays a role in differentiation of chondrocytes (Otto et al. 1997)
4. Germline mosaicism has been reported (Zackai et al. 1997; Pai et al. 2007)
5. No significant genotype/phenotype correlations observed

Clinical Features

1. Significant intra- and interfamilial variability of phenotypic expression (Chitayat et al. 1992; Mundlos 1999)
2. Abnormal craniofacial growth
    1. The head

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_44

1. Abnormally large, wide-open fontanels at birth
2. A large brachycephalic head
3. A broad forehead with frontal bossing
4. Delayed closure of the fontanels and sutures
5. Poorly developed midfrontal area showing a frontal groove owing to incomplete ossification of the metopic suture
6. Soft skull in infancy

2. The face
   1. Frontal and parietal bossings, separated by a metopic groove
   2. A depressed nasal bridge
   3. Hypertelorism with possible exophthalmos
   4. A small, flattened facial appearance (midface hypoplasia) with mandibular prognathism
   5. An anatomic pattern of dentofacial deformity consistent with the diagnosis of vertical maxillary deficiency (short face syndrome, type 2)
3. Oral/dental (Jensen and Kreiborg 1990)
   1. High-arched palate
   2. Clefts involving soft and hard palates
   3. Persistence of the deciduous dentition with delayed eruption of the permanent teeth: a relatively constant finding
   4. Impaction of supernumerary permanent teeth
   5. Crowding/malocclusion
   6. Dentigerous cysts
3. Otolaryngologic manifestations (Segal and Puterman 2007)
   1. Hypoplasia of the maxilla and zygoma resulting in small face and sometimes asymmetric.
   2. Small or absent mastoid air cells.
   3. A high rate of Eustachian tube dysfunction.
   4. A higher prevalence of submucosal cleft palate.
   5. Narrow external auditory canals.
   6. Increase rates of recurrent childhood ear infections and various degrees of hearing loss.
   7. Clumping of the ossicles, stapes fixation, and sclerosis of the footplate have been described (Hawkins et al. 1975).
4. Shoulders and thorax
   1. Ability to bring shoulders together.
   2. Dimplings in the skin secondary to mild hypoplasia of the clavicles.
   3. Sloping, almost absent shoulders secondary to severe hypoplasia or the absence of the clavicles.
   4. A narrow thorax may lead to respiratory distress during early infancy.
5. Mildly disproportionate short stature with short limbs comparing to the trunk and more apparent in the upper limbs than the lower
6. The spine
   1. Scoliosis
   2. Kyphosis
7. Hands
   1. Brachydactyly
   2. Short distal phalanges
   3. Tapering fingers
   4. Nail dysplasia/hypoplasia
   5. Short, broad thumbs
   6. Clinodactyly of the fifth fingers
8. Other abnormalities
   1. Hearing loss (Dhooge et al. 2001)
   2. Abnormal gait
   3. Joint hypermobility
   4. Muscular hypotonia
9. Intelligence: normal
10. Cesarean section often required in the pregnant female due to dysplastic pelvis

Diagnostic Investigations

1. Radiographic findings: generalized failure of midline ossification (Jarvis and Keats 1974).
   1. The skull
      1. Delayed closure of the anterior fontanel (open fontanel) and sagittal and metopic sutures, often open for life
      2. Unossified areas of the skull becoming smaller with increasing age
      3. Multiple Wormian bone formation, particularly around the lambdoid suture
      4. Small or absent nasal bones

5. Segmental calvarial thickening
6. Underdeveloped maxilla
7. Delayed union of the mandibular symphysis
8. Platybasia
9. Small cranial base
10. A large foramen magnum
11. Hypoplastic sinuses (paranasal, frontal, mastoid)

2. Clavicles
   1. Absent clavicles: rare
   2. Pseudarthrosis of one or both clavicles
   3. Hypoplasia of the acromial end: common
   4. Two separate fragments
   5. Absent sternal end with the presence of the acromial end
   6. Bilaterality is the rule but not always the case
3. The chest
   1. Small bell-shaped thoracic cage
   2. Short, oblique ribs
   3. The presence of cervical ribs
   4. The scapula often hypoplastic with deficient supraspinatus fossae and acromial facets
   5. Associated deficiency in musculature
4. The pelvis
   1. Widened pubis symphysis resulting from delay in ossification during adulthood
   2. Hypoplasia and anterior rotation of the iliac wings
   3. Wide sacroiliac joints
   4. Delayed ossification of the pubic bone
   5. Large femoral epiphyses
   6. Unusual shape of a femoral head reminiscent of a "chef's hat" (Aktas et al. 2000)
   7. Broad femoral necks
   8. Frequent coxa vara
5. The spine
   1. Hemivertebrae
   2. Posterior wedging
   3. Spondylolysis and spondylolisthesis
   4. Syringomyelia
   5. Spina bifida occulta of the cervical, thoracic, or lumbar region
6. Tubular bones
   1. The presence of both proximal and distal epiphyses in the second metacarpals and metatarsals leading to excessive growth and length
   2. Frequent cone-shaped epiphyses and premature closure of epiphyseal growth plates leading to shortening of bones
   3. Wide epiphyses
   4. Unusually short distal phalanges and the middle phalanges of the second and fifth fingers
   5. Poorly developed terminal phalanges giving a tapered appearance to the digit
   6. Occasional hypoplasia, dysplasia, and aplasia of nails
7. Dentition: impacted, supernumerary teeth

2. Panoramic radiology.
   1. Provide an overview of over-retained deciduous teeth
   2. Demonstrate multiple impacted permanent and supernumerary teeth
3. Cone-beam computed tomography can study the location, alignment, proximity of teeth to vital structures, as well as quality and quantity of basal bone available (Gupta et al. 2015).
4. Cytogenetic study: visible complex chromosome rearrangements occasionally seen (Purandare et al. 2008).
5. Molecular genetic studies of mutations involving *RUNX2* (Mendoza-Londono and Lee 2013).
   1. Sequence analysis
   2. Deletion/duplication analysis

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: not increased unless a parent is affected with the disorder or has germline mosaicism
   2. Patient's offspring: 50%
2. Prenatal diagnosis
   1. Ultrasonography (Stewart et al. 2000; Hermann et al. 2009)

   1. Absent or hypoplastic clavicles (Hamner et al. 1994; Hassan et al. 1997)
   2. Less calcified cranium than expected for gestational age
   3. Other craniofacial and skeletal anomalies
2. Prenatal diagnosis and preimplantation genetic diagnosis: direct DNA testing possible for those families with a known mutation in the *RUNX2*

3. Management (Cooper et al. 2001)
   1. Hearing evaluation
   2. Evaluation of the presence of submucous cleft palate
   3. Evaluation of obstructive sleep apnea
   4. Medical and surgical therapy for upper airway obstruction, recurrent and chronic sinusitis, and otitis
   5. Monitoring of skeletal and orthopedic complications
   6. Early surgical and orthodontic intervention of unerupted permanent teeth to induce eruption (Farrar and Van Sickels 1983)
   7. Orthognathic surgery to correct midface hypoplasia to reduce or correct significant upper respiratory complications and malocclusions
   8. Surgical and orthodontic management of vertical maxillary deficiency (Dann et al. 1980)
   9. Women with cleidocranial dysplasia at risk for a cesarean section delivery

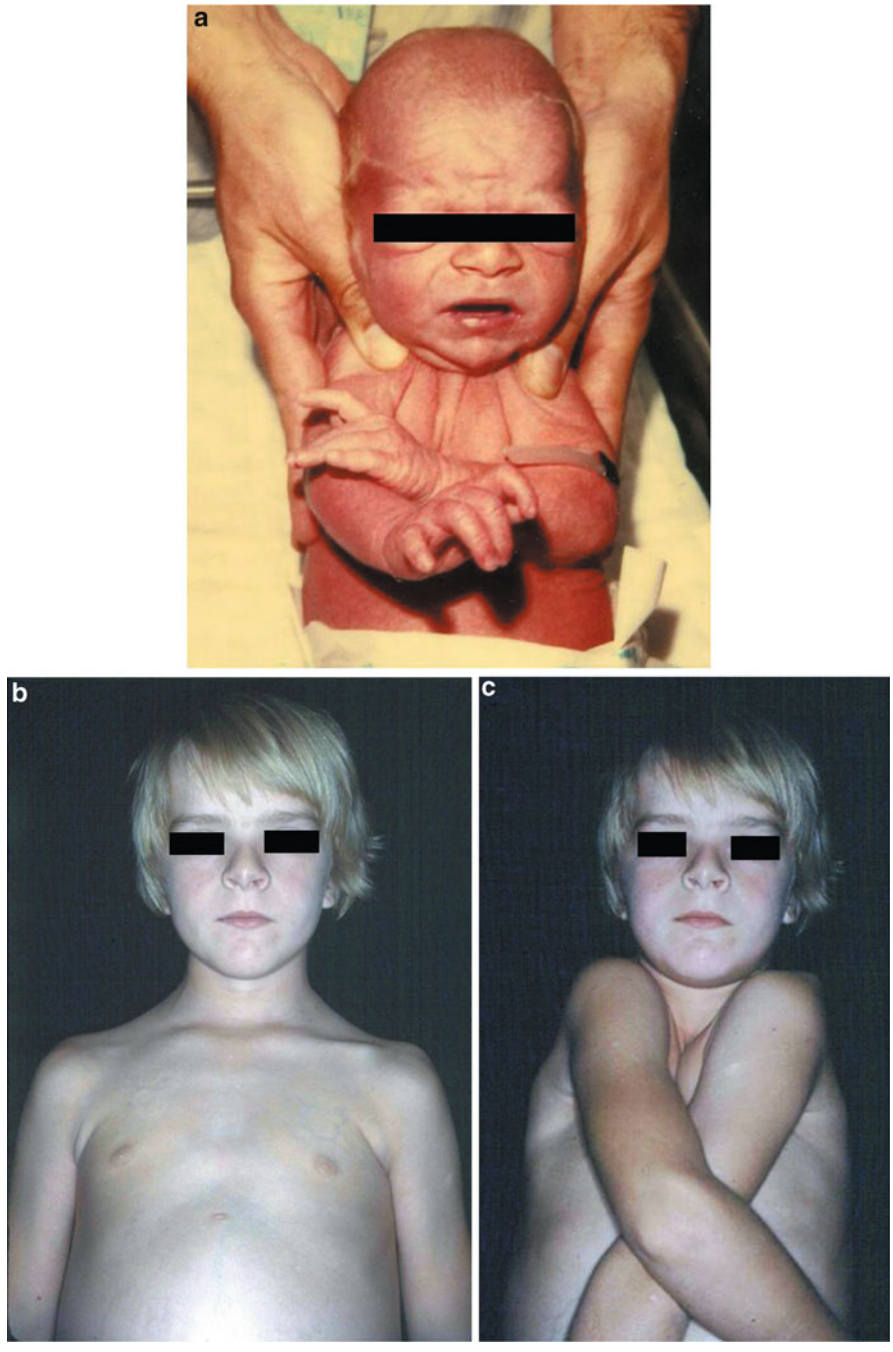

Fig. 1 (**a**–**c**) An infant and a child with cleidocranial dysplasia showing a large brachycephalic skull, frontal bossing, large anterior fontanel, widely spaced eyes, flat nasal bridge, and easily proximated shoulders

Fig. 2 (**a**–**c**) A child with cleidocranial dysplasia showing a prominent forehead, wide anterior fontanel and cranial sutures, wide eyes, depressed nasal bridge, and easily proximated shoulders. Radiographs show a poorly ossified skull, wide fontanels, cone-shaped thorax, and the absence of clavicles

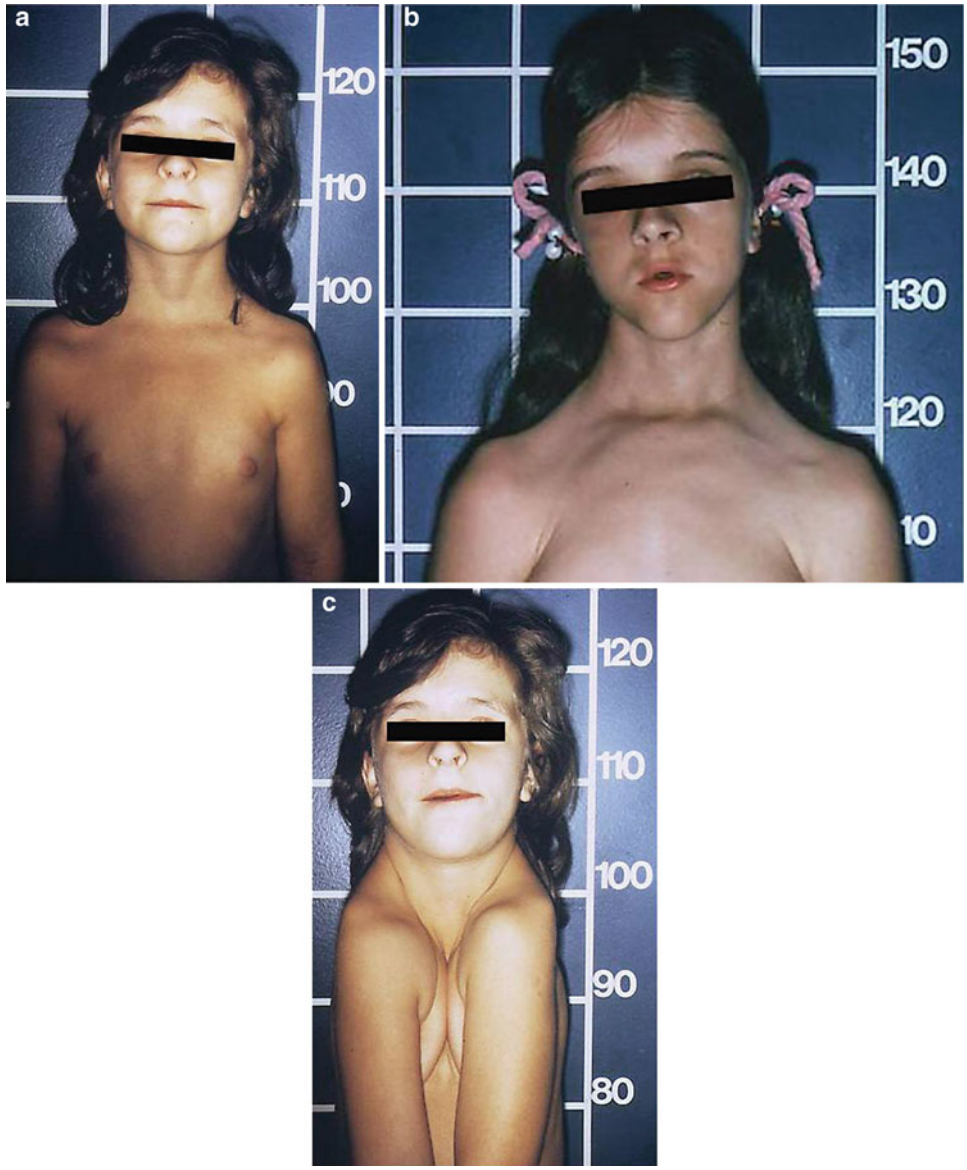

Fig. 3 (**a**–**c**) A girl with cleidocranial dysplasia at different ages showing short stature, frontal bossing, wide cranial sutures, wide set eyes, depressed nasal bridge, and sloping and easily proximated shoulders

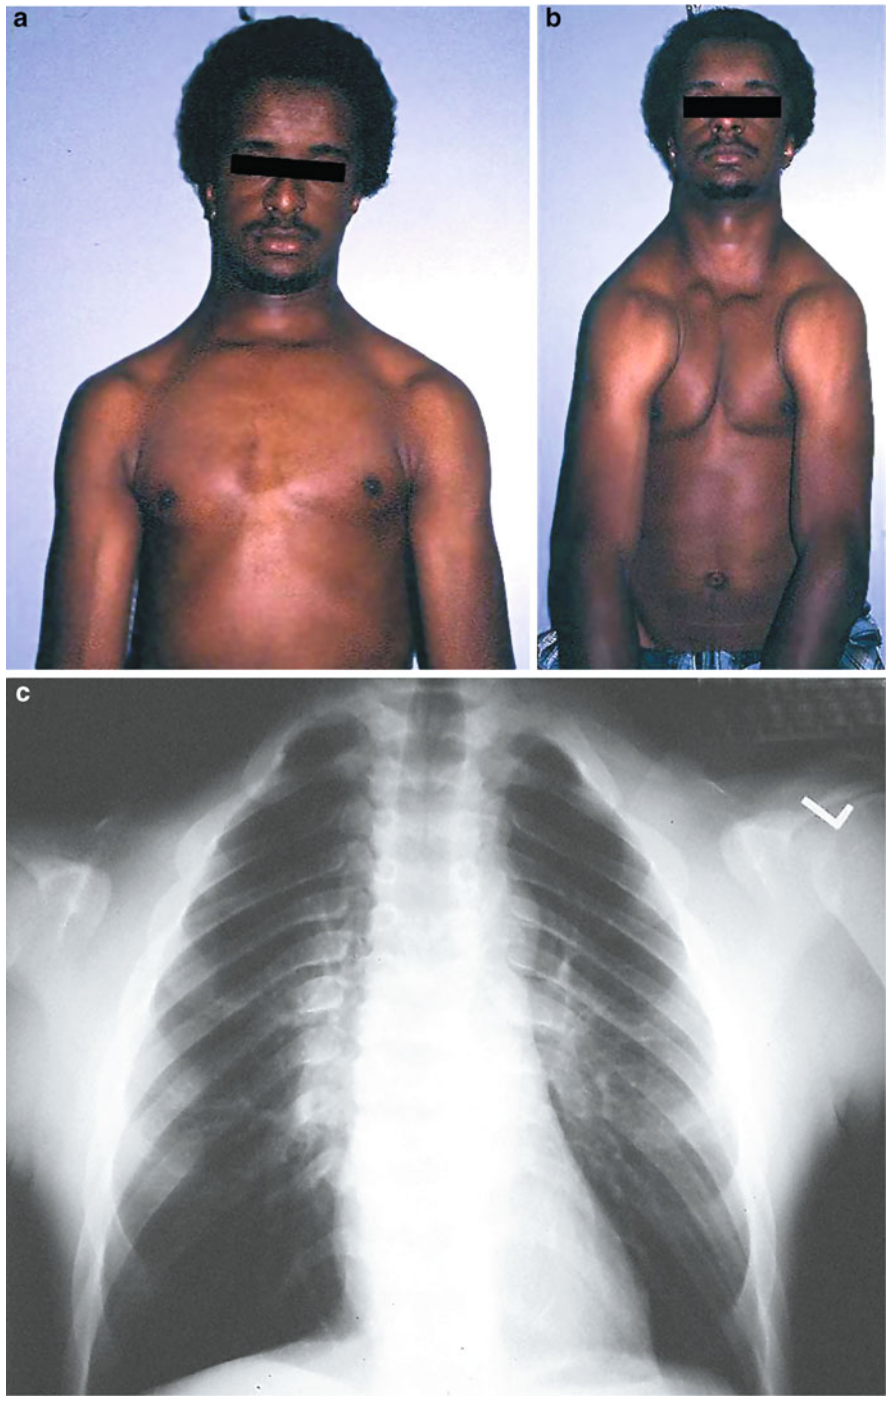

Fig. 4 (**a**–**c**) An adult with cleidocranial dysplasia showing widened cranial sutures, a characteristic face, and sloping and easily proximated shoulders. Radiograph showed a cone-shaped thorax with absent clavicles

Fig. 5 (**a**–**e**) A father and a son with cleidocranial dysplasia showing characteristic clinical findings and a dysplastic left clavicle presenting as two separate fragments, illustrated by radiograph

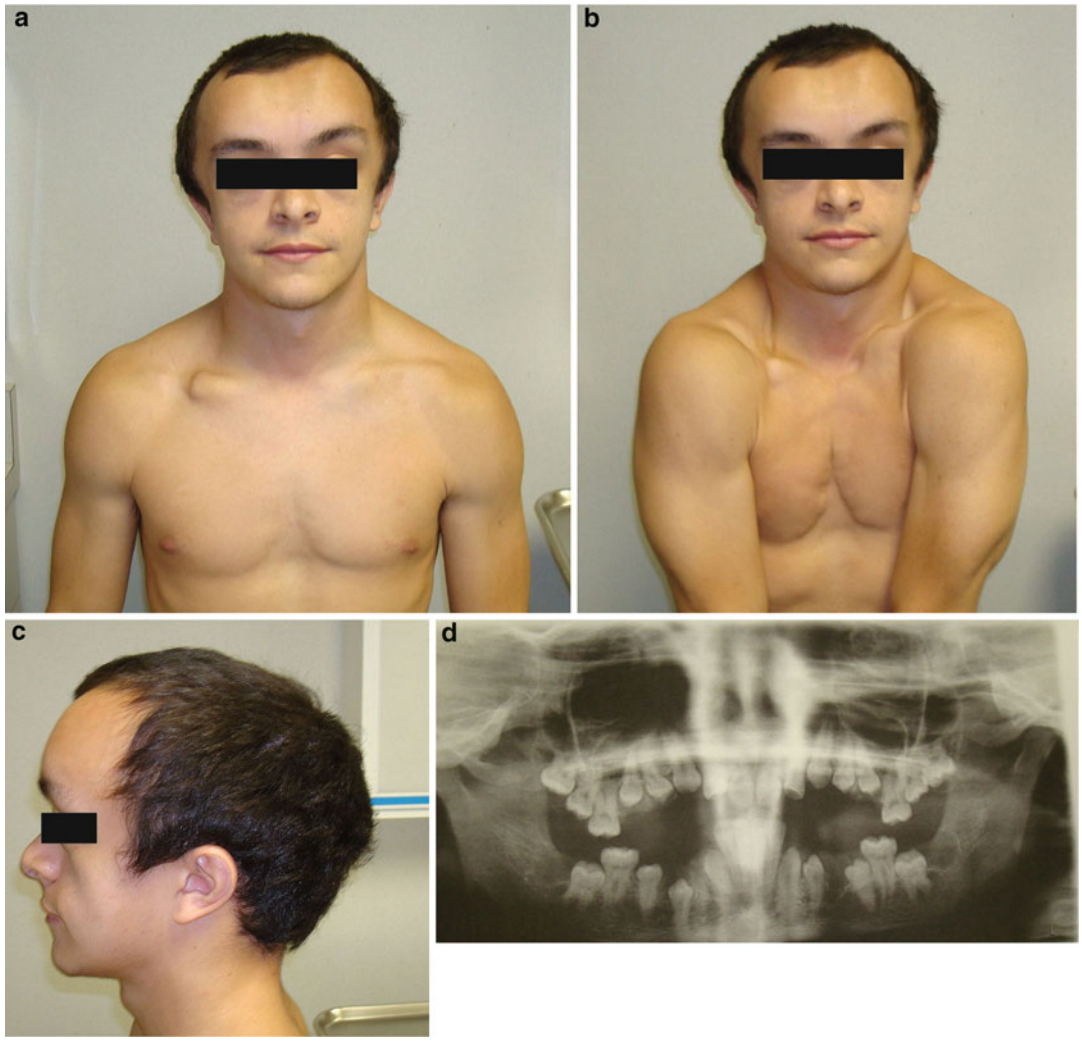

Fig. 6 (**a**–**d**) Another adult patient with cleidocranial dysplasia, showing typical clinical and dental features (radiograph)

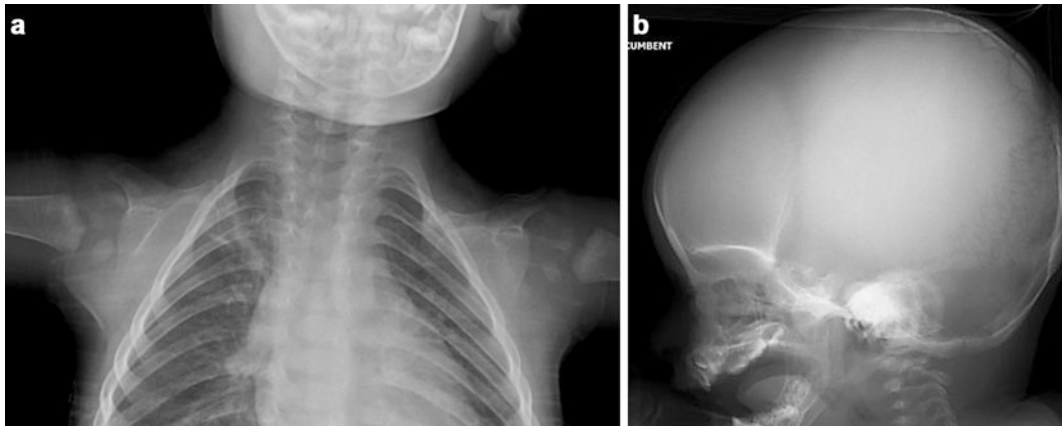

Fig. 7 (**a, b**) A 10-month-old female was seen with a large fontanel and absent clavicles. Her mother, maternal grandfather, and maternal uncle are known to have cleidocranial dysplasia. Chest X-ray showed absent bilateral clavicles (**a**). Skull radiograph (**b**) showed enlargement of the skull with Wormian bones in the lambdoidal sutures. There was widening of the sagittal and coronal sutures and prominent frontal bossing (Courtesy of Dr. Grace Guo)

Cloacal Exstrophy

Contents

Cloacal exstrophy is a rare congenital malformation resulting in exstrophy of the urinary, intestinal, and genital systems and is associated with anomalies of other organ systems. The term OEIS complex (*o*mphalocele, *e*xstrophy of the bladder, *i*mperforate anus, and *s*pinal defects) is used to describe the spectrum of malformations in cloacal exstrophy (Carey et al. 1978; Kaya et al. 2000). The incidence of cloacal exstrophy is estimated to be 1/200,000–1/400,000 live births (Carey et al. 1978; Hurwitz et al. 1987; Dick et al. 2001), although the true incidence may be as high as 1 in 10,000–50,000, taking into account the lack of diagnosis in stillborn infants (Keppler-Noreuil 2001).

Synonyms and Related Disorders

Covered cloacal exstrophy; OEIS complex (omphalocele-exstrophy of the bladder-imperforate anus-spinal defects)

Genetics/Basic Defects

1. Genetics
    1. Recurrence of OEIS complex in siblings (Smith et al. 1992) can be explained by the following mechanisms:
        1. Autosomal recessive inheritance
        2. Multifactorial determination
        3. Gonadal mosaicism for a dominant mutation
        4. Environmental factors
        5. Subclinical maternal disorder
        6. An unbalanced translocation between 9q and Y chromosome resulting in a 9q34.1-qter deletion, as a potential cause (Thauvin-Robinet et al. 2004)
        7. Mutations in a group of homeobox genes such as HLXB9 and HOX family which are involved in the development of embryonic mesoderm (Manner and Kluth 2005)
    2. Higher incidence of OEIS complex in monozygotic twins than in dizygotic twins suggests a possible genetic contribution to the occurrence of these defects
2. Basic defects of OEIS complex (Lee et al. 1999)
    1. Resulting from a single localized defect in the early caudal mesoderm at approximately 29 days of development
    2. Resulting in the following sequence of events:

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_45

1. Failure of cloacal septation leading to a persistence of the cloaca with a rudimentary mid-gut and imperforate anus
2. Failure of breakdown of the cloacal membrane leading to exstrophy of the cloaca, omphalocele, and lack of fusion of the pubic rami
3. The lumbosacral somites giving rise to abnormal vertebrae in which there is protrusion of the dilated spinal cord (hydromyelia) and a cystic, skin-covered mass in the lumbosacral region

3. Cloaca and cloacal exstrophy
   1. Cloaca
      1. A transient embryological structure
      2. The term "cloaca" literally means "sewer" in Latin
      3. The term used to represent the emptying of the gastrointestinal and urogenital tracts into a common sinus
      4. Defined as a common chamber (orifice) in the perineum into which the urinary, genital, and intestinal tract drain
   2. Cloacal exstrophy: The common orifice empties onto the anterior abdominal wall

Clinical Features

1. Classic exstrophy of the cloaca (Lee et al. 1999)
   1. Lower abdominal defect
   2. Exposure of intestinal and bladder mucosa
   3. Accompanied by the following anomalies
      1. Omphalocele
      2. Imperforate anus
      3. Urogenital anomalies
2. Gastrointestinal malformations (Woo et al. 2010)
   1. Omphalocele
   2. Imperforate anus, anal atresia/stenosis
   3. Rectovestibular/rectovesical fistula
   4. Small bowel anomalies (short gut syndrome)
      1. Foreshortened small bowel
      2. Rotational anomalies
      5. Intestinal duplication
      6. Meckel diverticulum
      7. Inguinal hernias
3. CNS malformations
   1. Spina bifida: the most common CNS malformation
      1. Leptomeningocele
      2. Myelomeningocele
      3. Meningocele
      4. Spina bifida occulta
      5. Cord tethering
   2. Craniosynostosis
4. Skeletal malformations
   1. Vertebral anomalies (Loder and Dayioglu 1990)
      1. Abnormal lumbosacral segmentation
      2. Congenital scoliosis and kyphosis
      3. Partial sacral agenesis
      4. Interpedicular lumbar widenings
   2. Pubic diastasis
   3. Lower extremity anomalies
      1. Clubfoot deformities
      2. Limb deficiencies
5. Genitourinary malformations
   1. Bladder anomaly
      1. Open
      2. Separated into two halves
      3. Flanking the exposed interior of the cecum
      4. Openings to the remainder of the hindgut
      5. Prolapse of the terminal ileum as a "trunk" of bowel onto the cecal plate
   2. Renal anomalies
      1. A single kidney
      2. Rudimentary kidney
      3. Pelvic ectopic kidney
      4. Ureteropelvic junction obstruction
      5. Malrotation
      6. Crossed renal ectopia
   3. Ureteral anomalies
      1. Duplication
      2. Ectopic insertion
      3. Distal stricture and megaureter
   4. Male genitalia anomalies
      1. Diminutive or absent penis (30% of males) (Schober et al. 2002)
      2. Bifid penis

3. Hemiglans located caudal to each hemibladder
5. Female genitalia anomalies
   1. Bifid clitoris
   2. Uterine duplication
   3. Vaginal duplication
   4. Vaginal agenesis
6. Prognosis (Lund and Hendren 2001)
   1. Used to be uniformly fatal malformation in its worst form
   2. Currently with an 80–100% survival rate due to early surgical repair but accompanied by lifelong severe morbidity
7. Covered cloacal exstrophy: frequently misdiagnosed condition (Bischoff et al. 2013)
   1. Low implantation of the umbilicus
   2. A single large perineal orifice
   3. Separation of the pubic bones
   4. Imperforate anus
   5. Intraabdominal anatomic abnormalities: resemble those observed in cases of cloacal exstrophies
   6. Considered as part of the cloacal exstrophy spectrum, even when the majority of the patients have an intact abdominal wall

Diagnostic Investigations

1. Evaluation of associated malformations
2. Karyotyping for genetic sex
3. Renal ultrasonography for renal and upper urinary tract anomalies
4. Voiding cystourethrography to assess bladder capacity in early childhood in preparation for continence reconstruction
5. Radiologic features (Meglin et al. 1990)
   1. Symphysis pubis diastasis: a prerequisite for diagnosis of cloacal exstrophy
   2. Hip subluxations/acetabular dysplasia
   3. Posterior element dysraphism with hemivertebrae, vertebral fusions, or absence of vertebral bodies
   4. Sacral dysplasia with posterior element dysraphism, widened neural foramina, axial torsion, and marked underdevelopment
   5. Scoliosis/gibbus deformity
   6. Hypoplasia of the thoracic cage
   7. Limb anomalies: clubfoot and hypoplastic lower extremity
   8. Bladder anomaly: classic cloacal exstrophy (bladder is separated into two hemi-bladders by a portion of interposed bowel)
   9. Renal anomalies: pelvic kidneys, renal ectopia, renal agenesis, renal atrophy, bifid collecting systems, and upper tract anomalies
   10. Genital anomalies: cryptorchidism (in genotypic males), duplication of internal genitalia with duplicated or bicornuate uterus, double cervix, duplicated vagina, and hypoplastic fallopian tube (in genotypic females)
   11. CNS anomalies: spinal dysraphism associated with lumbar lipomyelomeningocele, cord lipoma, meningocele, and myelomeningocele
   12. Gastrointestinal anomalies: bladder bisection by the ileocecal portion of the bowel, blind-ending colon with imperforate anus, malrotation or nonrotation, large-bowel duplication, appendiceal duplication, anatomically short small bowel, and hypoplastic superior half of the anterior abdominal wall
   13. Pelvic floor evaluated by MRI and 3D CT: hypoplasia of the levator musculature
6. Radiographic studies to demonstrate spinal dysraphism (Dick et al. 2001)
   1. Plain spinal radiographs
   2. Myelography
   3. CT
   4. CT myelography
   5. Spinal MRI to identify occult abnormalities that predispose to symptomatic spinal cord tethering (Lund and Hendren 1993)

Genetic Counseling

1. Recurrence risk (Mathews et al. 1998)
   1. Patient's sib: recurrence in subsequent pregnancies noted in one report

2. Patient's offspring: Lack of offspring from patients with cloacal exstrophy making the determination of inheritance difficult

2. Prenatal diagnosis by ultrasonography
   1. Elevated maternal serum α-fetoprotein (AFP) in OEIS complex. The open ventral wall defect likely results in AFP leakage (Gosden and Brock 1981; Kutzner et al. 1988).
   2. Ultrasonography (Chitrit et al. 1993; Austin et al. 1998; Keppler-Noreuil et al. 2007)
      1. Major ultrasound criteria
         1. Nonvisualization of the bladder (91%)
         2. A large midline infraumbilical anterior wall defect or cystic anterior wall structure (persistent cloacal membrane) (82%)
         3. Omphalocele (77%)
         4. Lumbosacral myelomeningocele (68%)
      2. Minor (less frequent) ultrasound criteria
         1. Lower limb defects (23%)
         2. Renal anomalies (23%)
         3. Ascites (14%)
         4. Widened pubic arches (18%)
         5. A narrow thorax (9%)
         6. Hydrocephalus (9%)
         7. A single umbilical artery (9%)
      3. Despite these criteria, often the full extent of anomalies cannot be identified prenatally
      4. The elephant trunk-like US finding as a new criterion for the prenatal diagnosis (Hamada et al. 1999; Clements et al. 2014)
      5. Prenatal ultrasound findings can be confused or difficult to differentiated with the following conditions:
         1. Limb–body wall complex
         2. Pentalogy of Cantrell
         3. Gastroschisis
         4. Amniotic band sequence
3. Fetal MRI (Gobbi et al. 2008; Bischoff et al. 2012; Calvo-Garcia et al. 2013)
   1. Absence of a normal bladder despite normal amniotic fluid volume (in the form of persistently absent bladder or thin-walled protruding anterior pelvic cyst)
   2. Protuberant anterior pelvic contour representing the exstrophy
   3. Lack of meconium in the rectum and colon supporting a primitive blind-ending hindgut
   4. Omphalocele (usually small and low)
   5. Additional findings: potential visualization of the prolapsed terminal ileum and the lateral bladder plates, distal ureters extending to the anterior abdominal wall, closed neural tube defects, and genitourinary abnormalities (hydronephrosis, hydroureter)
   6. Incompletely formed external genitalia
   7. Vaginal hydrocolpos (expanded fluid filled vaginal cavity)
   8. Infraumbilical anterior abdominal wall defect (omphalocele, bladder exstrophy)
   9. Midline structure corresponding to the "elephant trunk-like" (representing the intussuscepted ileum) image that is a characteristic feature of cloacal exstrophy
4. Management (Lund and Hendren 1993; Mathews et al. 1998)
   1. Appropriate parental counseling and referral to a center with significant expertise in the management of cloacal exstrophy when prenatal diagnosis is made (Bischoff et al. 2012)
   2. Medical stabilization of the infant
      1. Fluid and electrolyte replacement
      2. Parenteral nutrition
      3. Moisten the exstrophied bladder and bowel with saline and cover them with a protective plastic dressing
      4. Daily prophylactic antibiotics
   3. Gender assignment
      1. Evaluation of the genitalia
      2. Decision limited to the genetic male patients with cloacal exstrophy
         1. Male gender assignment appropriate for male patients with adequate bilateral or unilateral phallic structures
         2. Male neonates with minimal phallic structures: appropriate to raise as female subjects with early excision of the gonads

3. Appropriate hormonal manipulation to improve psychosexual dysfunction
4. Improvements in phallic reconstruction eventually allow most genetic male patients to be assigned male gender

3. Initial sexual reassignment to be done in conjunction with extensive family counseling as well as continued counseling for the parents and children

4. Management of gastrointestinal malformations
   1. Closure of omphalocele
   2. Combined with gastrointestinal diversion or reconstruction
      1. Ileostomy with resection of the hindgut remnant
      2. Colostomy
5. Management of genitourinary malformations
   1. Bladder closure (Diamond and Jeffs 1985)
   2. Initial bladder excision and urinary diversion (Smith et al. 1997)
   3. Further augmentation or urinary diversions to achieve continence
   4. Initial stages of surgery (Jeffs 1978)
      1. Should be undertaken at birth when the pelvic ring can be approximated without osteotomy and the bladder mucosa has not deteriorated from inflammatory changes
      2. Parental attitudes toward the child as well as successful reconstruction may both be best served by immediate surgery to begin reconstruction and reduce the visible defect
   5. Pelvic osteotomy: a well-established method of obtaining a successful cloacal exstrophy closure (Cervellione 2011)
6. Management of CNS malformations
   1. Closure of myelomeningocele
   2. Cord untethering
   3. Spinal fusion
   4. Cranial expansion for craniosynostosis
7. Management of orthopedic malformations
   1. Manage myelodysplasia
   2. Pelvic osteotomies
   3. Various orthopedic devices to assist with ambulation

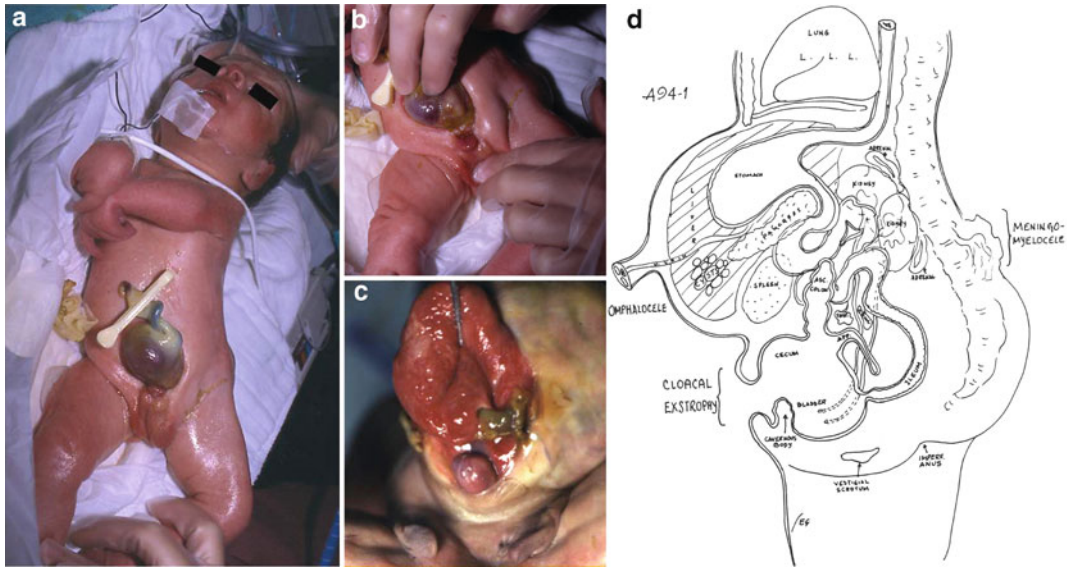

Fig. 1 Two infants (**a**, **b**, **c**) with cloacal exstrophy. The schematic diagram (**d**) illustrates the anatomy of Cloacal exstrophy, including omphalocele, exstrophy of the bladder, imperforate anus, and Meningomyelocele in the second infant (**c**)

Clubfoot

Contents

Clubfoot, or talipes equinovarus, is one of the most common congenital deformities affecting the lower limbs in approximately 1–2 in 1,000 live births. The incidence is higher in Hispanics and lower in Asians. Although clubfoot is recognizable at birth, the severity of the deformity can vary from mild to an extremely rigid foot that is resistant to manipulation (Dobbs and Gurnett 2009).

Synonyms and Related Disorders

Congenital talipes equinovarus; Syndromic clubfoot; TARP syndrome

Genetics/Basic Defects

1. Pathogenesis:
    1. Genetic cause: suggested because it tends to run in families (Lochmiller et al. 1998).
    2. Oligohydramnios: suggested as a cause from early amniocentesis data (CEMAT Group 1998).
    3. Osseous deformities (Shapiro and Glimcher 1979), muscle abnormalities (Herceg et al. 2006), and arrested fetal development (Fukuhara et al. 1994): hypothesized to play a role in pathogenesis.
    4. Beta-catenin mediates soft tissue contracture in clubfoot (Poon et al. 2009).
2. Etiology (Dobbs and Gurnett 2009):
    1. Most commonly as an isolated birth defect and considered idiopathic (Wynne-Davies 1964). Various theories on etiologies include:
        1. Vascular deficiencies (Hootnick et al. 1982)
        2. Environmental factors:
            1. Early amniocentesis (<13 weeks gestation): associated with an increased risk in talipes equinovarus (an uncommon risk factor), compared to midgestational amniocentesis or chorionic villus sampling (Philip et al. 2004)
            2. Partially associated with amniotic fluid leakage: suggesting that oligohydramnios occurring at a critical gestational period may be detrimental to foot development (Tredwell et al. 2001)
            3. Environmental exposure to cigarette smoke in utero: an independent risk factor (Honein et al. 2000)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_46

3. In utero positioning (Dunn 1972)
4. Abnormal muscle insertions (Bonnell and Cruess 1969)

2. Genetic factors suggested by:
   1. Thirty-three percent concordance of identical twins and the fact that nearly 25% of all cases are familial (Lochmiller et al. 1998)
   2. Differences in clubfoot prevalence across ethnic populations with the lowest prevalence in Chinese (0.39 cases per 1,000 live births) and the highest in Hawaiians and Maoris (seven per 1,000) (Beals 1978; Chung et al. 1969)
3. Prevalence of additional congenital anomalies (Gurnett et al. 2008b):
   1. Chromosomal abnormalities:
      1. Trisomy 18 syndrome in patients with clubfoot (24–50%) (Bakalis et al. 2002; Gurnett et al. 2008b).
      2. Other numerous cytogenetic abnormalities produce individuals with multiple congenital anomalies including clubfeet.
   2. Distal arthrogryposis
   3. Myelomeningocele
   4. Orthopedic abnormalities:
      1. Fibular hemimelia
      2. Polydactyly
      3. Hip dysplasia
      4. Ulnar longitudinal deficiency

3. Part of a genetic syndrome:
   1. An autosomal recessive inheritance of clubfoot, for example:
      1. Diastrophic dwarfism
      2. Larsen syndrome
      3. Smith-Lemli-Opitz syndrome
   2. An autosomal dominant inheritance of clubfoot, for example:
      1. Distal arthrogryposis type 2A (whistling face syndrome)
      2. Distal arthrogryposis type 1
      3. Freeman-Sheldon syndrome
   3. An X-linked recessive inheritance of clubfoot: for example, Pierre-Robin syndrome
   4. Other syndromic clubfoot, for example:
      1. Meningomyelocele/spina bifida
      2. Sacral agenesis
      3. Constriction band syndrome
      4. Congenital myopathy
4. Specific involvement of the foot also appears to exclude many of the skeletal muscle contractile genes that are responsible for distal arthrogryposis (Sung et al. 2003a, b; Toydemir et al. 2006; Veugelers et al. 2004) in the causation of idiopathic clubfoot, as mutations in these genes cause both upper and lower extremity involvement and were not identified in idiopathic clubfoot patients (Gurnett et al. 2009).
5. Genes and proteins involved in congenital talipes equinovarus (Bacino and Hecht 2014):
   1. Paired-like homeodomain 1 (*PITX1*):
      1. Recent identification of a rare mutation in the transcription factor PITX1 in a large family with idiopathic clubfoot: importance of genes involved in early limb development (Gurnett et al. 2008a)
      2. The first gene implicated in clubfoot that explains the specific involvement of the foot, since *PITX1* is expressed nearly exclusively in the hindlimb and is responsible for rapid evolutionary changes in pelvic morphology in lower vertebrates (Shapiro et al. 2004)
   2. Transcription factor (*TBX4*):
      1. Expressed in the hindlimb
      2. Involved in limb muscle and tendon patterning
      3. A 17q23.1q23.2 2.2 Mb microduplication (Alvarado et al. 2010; Lu et al. 2012):
         1. Segregated in three different families in an autosomal dominant fashion with reduced penetrance in 30% of individuals and variable expression
         2. A common cause for familial isolated clubfoot
         3. Deletion in the same region involving *TBX4* in one of the families with two siblings affected with clubfeet
         4. A small 350 kb 17q23.1q23.2 microduplication identified in one multiplex family: encompassed *TBX4*, *NACA2*, and part of *BRIP1*

3. RNA-binding motif protein 10 (*RBM10*) mutation:
    1. Associated with a syndromic form of congenital talipes equinovarus known as TARP syndrome (De Marco et al. 2012; Janda et al. 2012)
    2. Acronym for TARP:
        1. *T*alipes equinovarus
        2. *A*trial septal defect
        3. *R*obin sequence (micrognathia, glossoptosis, and cleft palate)
        4. *P*ersistence of left superior vena cava
4. Muscle contraction genes:
    1. Mutations in *TPM2*, *MYH3*, *TNNT3*, *TNNI2*, *MYH3*, *MYH3*, and *PIEZO2* gene cause distal arthrogryposis (DA1, DA2A, DA2B, DA7 (Bamshad et al., 1996), and DA5 (Coste et al., 2013)).
    2. *ZC4H2* gene mutation causes X-linked Wieacker-Wolff syndrome (pes equinovarus, hip dislocations, and scoliosis) (Wieacker et al. 1985; Hennekam et al. 1991; Hirata et al. 2013).
5. Homeobox A and D genes:
    1. Chromosomal abnormalities, deletions, and duplications in syndromic clubfoot (Brewer et al, 1998, 1999).
    2. 2q31-33 deletion region identified association with *CASP8*, *CASP10*, and *CFLAR*: these genes are involved in the mitochondria-mediated apoptotic pathway which is consistent with the key role that apoptosis plays in limb and muscle development (Ester et al. 2009; Heck et al. 2005).
6. Vascular and muscular abnormalities:
    1. Deficiency or absence of the anterior tibial artery, and of its derivative, the dorsalis pedis artery, has been reported in clubfeet and other lower limb malformations like fibular deficiency and tibial hypoplasia.
    2. Arterial dysgenesis may play a role in the etiology of clubfoot (Sodre et al. 1990; Kruse et al. 2009).
    3. MRI: showed abnormalities of the anterior tibial artery and dorsalis pedis artery in clubfoot and abnormalities of posterior tibial artery in vertical talus (Kruse et al. 2009).
    4. Vascular involvement can perhaps be secondary to environmental exposures like maternal smoking in pregnancy, use of misoprostol, and early amniocentesis.
    5. *PITX1* mutations may lead to decreased muscle volume development and vascular maldevelopment with narrowing of anterior peroneal and tibial arteries.
6. Multifactorial inheritance:
    1. Multifactorial and possibly polygenic causation suggested (Lochmiller et al. 1998; Wynne-Davies 1972).
    2. Most infants with clubfoot (idiopathic congenital clubfoot) have no identifiable genetic, cytogenetic, syndromal, or extrinsic cause. The idiopathic congenital clubfoot is primarily caused by a multifactorial inheritance.
    3. The observed percentages of talipes equinovarus in relatives of an affected child are consistent with a multifactorial mode of inheritance (Wynne-Davies 1965, 1972):
        1. Monozygotic twins with about 32.5% rate of concordance (both twins affected with clubfoot)
        2. First-degree relative (parents and siblings) occurrence rate:
            1. 2.14%
            2. About 17 times as high as the population rate
        3. Second-degree relative (aunts and uncles) occurrence rate:
            1. 0.61%
            2. About six times as high as the population rate
        4. Third-degree relative (cousins) occurrence rate:
            1. 0.2%
            2. Near the incidence in the general population
7. Extrinsic causes:
    1. Teratogenic agents:
        1. Sodium aminopterin

   2. Position in utero at the time of d-tubocurarine paralysis
2. Loss of amniotic fluid during gestation
3. Mechanical forces or positional influence (restriction of fetal foot movement by the uterus)
4. Drugs

Clinical Features

1. Bilateral in about 50% of cases
2. Three major components of talipes equinovarus:
   1. Equinus (limitation of extension) of the ankle and subtalar joint
   2. Hindfoot and midfoot varus
   3. Forefoot adduction
3. Evaluation of the foot, ankle, and leg:
   1. "Down and in" appearance
   2. Shorter and wider than the normal foot
   3. Flexible, softer heel due to hypoplastic calcaneus
   4. Concave medial border
   5. Transverse plantar creases or clefts at the midfoot and at the posterior part of the ankle
   6. Highly convex lateral border
   7. Internally rotated heel making the soles of the feet facing each other in cases of bilateral deformities
   8. Internal rotation of the leg
   9. Variable rigidity of the foot
   10. Calf and foot atrophy (more obvious in older child than in infant)
   11. Mild hypoplasia of the tibia, fibula, and bones of the foot
   12. Pronounced tightness of the Achilles tendon with very little dorsiflexion
   13. Range of motion of the joints
4. Idiopathic clubfoot:
   1. An isolated deformity of the foot and leg:
      1. Identifiable in utero
      2. Consists of four components:
         1. Equinus
         2. Hindfoot varus
         3. Forefoot adductus
         4. Cavus
   2. When untreated, children with clubfoot walk on the sides and/or tops of their feet, resulting in (Dobbs and Gurnett 2009):
      1. Callus formation
      2. Potential skin and bone infections
      3. Inability to wear standard shoes
      4. Substantial limitations in mobility and employment opportunities
   3. By far the most common form.
   4. Occurring more common in males than in females (2 ~ 2.5:1).
   5. Normal upper limbs.
   6. Associated features:
      1. Joint laxity
      2. Congenital dislocation of the hip
      3. Tibial torsion
      4. Ray anomalies of the foot (oligodactyly)
      5. Absence of some tarsal bones
      6. A history of other foot anomalies in the family
5. Various associated anomalies in syndromic talipes equinovarus

Diagnostic Investigations

1. Plain radiography (Chung 2015):
   1. Talocalcaneal parallelism: radiographic feature of clubfeet (Patel 2015)
   2. Limitations:
      1. Risk of ionizing radiation
      2. Proper positioning difficult
      3. Lack of ossification in some involved bones:
         1. Only talus, calcaneus, and metatarsals are ossified in neonates.
         2. Cuboid ossification at 6 months.
         3. Cuneiform ossification at 1 year.
         4. Navicular ossification after 3 years.
   3. Assessment:
      1. Hindfoot equinus (plantar flexion of the anterior calcaneus)
      2. Hindfoot varus (calcaneus rotated around the talus into a varus, i.e., toward midline, position)
      3. Forefoot varus (increased forefoot supination on dorsoplantar view)

4. Common measurements:
    1. Anteroposterior talocalcaneal angle (typically $<20^\circ$ in a clubfoot)
    2. Talar-first metatarsal angle:
        1. Up to about 30° of valgus in a normal foot
        2. Mild-to-severe varus in a clubfoot
    3. Medial displacement of the cuboid ossification center on the axis of the calcaneus representing either of the following:
        1. Angular deformity of the calcaneus
        2. Medial subluxation of the cuboid on the calcaneus
2. CT scan (Chung 2015):
    1. Limitations:
        1. Risk of ionizing radiation
        2. Lack of ossification of the tarsal bones
        3. Susceptible to motion artifact
    2. Advantage: better assessment of complex three-dimensional deformity by three-dimensional reconstructions
3. MRI (Chung 2015):
    1. Limitations:
        1. Need for patient sedation
        2. Loss of signal caused by ferromagnetic effects of fixation devices
    2. Advantages:
        1. Capability of multiplanar imaging
        2. Excellent depiction of following:
            1. Ossific nuclei
            2. Cartilaginous anlage
            3. Surrounding soft tissue structures
    3. Findings:
        1. Plantar flexion
        2. Varus angular deformity of the talus, calcaneus, and cuboid
4. Ultrasonography (Chung 2015):
    1. Limitation: inability of the beam to penetrate all of the bones, particularly if a post-operative scar is present
    2. Advantages:
        1. Lack of ionizing radiation
        2. No need for sedation
        3. Ability to depict non-ossified portions of bone
        4. Capacity for dynamic imaging
    3. Findings:
        1. Interosseous relationship in normal feet and clubfeet.
        2. Multiple views can be obtained through a dynamic range of motion.

Genetic Counseling

1. Recurrence risk depends on underlying etiology:
    1. Patient's sib:
        1. Multifactorial trait: approximately 2.1% (first-degree relatives)
        2. Autosomal recessive: 25%
        3. Autosomal dominant: not increased unless a parent is affected
        4. X-linked recessive: 50% of male sibs affected if the mother is a carrier
        5. Chromosomal: increased risk, especially a parent is a translocation carrier
    2. Patient's offspring:
        1. Multifactorial: approximately 2.1%.
        2. Autosomal recessive: not increased unless the spouse is also a carrier.
        3. Autosomal dominant: 50%.
        4. X-linked recessive: All daughters of affected males will be carriers. All sons of an affected male will be normal.
        5. Chromosomal: increased risk.
2. Prenatal diagnosis by ultrasonography: (Bar-On et al. 2005)
    1. Wide variation in the accuracy of ultrasonography:
        1. Isolated clubfoot:
            1. Better prognosis especially detected in the 3rd trimester of pregnancy
            2. Poor correlation between the prenatal appearance of the foot on ultrasound findings and the severity of the talipes at birth
        2. Complex clubfoot: associated with syndromic, neuromuscular, or chromosomal conditions.
        3. Overall prognosis is related to the presence of associated abnormalities (Treadwell et al. 1999).

2. The abnormalities detected at 20 weeks: present to some degree at birth (Tillett et al. 2000)

3. Management (Cummings and Davidson 2002):
   1. Traditional nonoperative approach: stretching and manipulations:
      1. Proper manipulation technique: the most important for treatment of clubfoot (Ippolito et al. 2003).
      2. Appropriate initial management for all children with clubfoot.
      3. Splintage begins at 2–3 days after birth.
      4. Order of correction:
         1. Forefoot adduction
         2. Forefoot supination
         3. Gentle correction of equinus
      5. Two methods most widely performed and with highest reported long-term success rates:
         1. Kite and Lovell method
         2. Ponseti method (Scher 2006)
      6. "Montpellier" method: remains popular in France.
   2. Ponseti method (Ponseti 1992): currently widely utilized with high success rate in treating clubfoot:
      1. Goal:
         1. To reduce or eliminate deformity (equinus, hindfoot varus, forefoot adductus, and cavus)
         2. To attain functional, pain-free, plantigrade foot with good mobility and without calluses and without need to wear modified shoes
      2. Techniques:
         1. Serial manipulation
         2. A specific technique of cast application
         3. Possible percutaneous Achilles tenotomy
      3. Significant risk factors for the recurrence of clubfoot deformity after correction with the Ponseti method (Dobbs et al. 2004):
         1. Noncompliance of the parents
         2. Lower educational level of the parents
      4. Outcome:
         1. A safe, effective, and low-cost treatment for neglected idiopathic club foot presenting after walking age (Lourenço and Morcuende 2007)
         2. Effective long-term clinical outcome (Hulme 2005)
         3. Requires only a reasonable amount of time out of the lives of the patient and his or her parents
         4. Frequently include some minimal invasive surgery without extensive correction surgery (Morcuende et al. 2004)
         5. Results of treatment: good in 71% of feet, slight residual deformity persisted in 28%, and one foot with a poor result (Ponseti and Smoley 2009)
         6. Anterior tibial tendon transfer to the third cuneiform: a useful operation for the treatment of cases of severe relapsing clubfoot (Ponseti and Campos 2009)
   3. Kite and Lovell method:
      1. Starting with stretching of the foot through longitudinal traction applied to the foot
      2. Less often requires minimally invasive surgery
      3. More time consuming
   4. "Montpellier" method:
      1. Requires fairly extensive physical therapy
      2. Demands substantial parental time and attention
      3. Long-term results yet to be confirmed
   5. Operative approach:
      1. Should be considered only after a suitable trial of manipulating the foot and holding it in a suitable cast or other device has failed
      2. Operative treatment:
         1. Incisions
         2. Medial plantar release
         3. Posterior release
         4. Lateral release

5. Reduction and fixation
6. Intraoperative assessment
7. Wound closure
8. Revision surgery
9. Postoperative evaluation

3. Treatment of residual deformity:
   1. Residual forefoot adduction
   2. Residual cavus
   3. Angulation of the heel for residual varus or valgus
   4. Dynamic forefoot supination
   5. Residual toeing-in
   6. Dorsal bunion (a painful swelling of the bursa of the first joint of the big toe)
   7. Overcorrected foot
   8. Skin problems

6. Complications of treatment:
   1. Failure to correct (undercorrection) resulting from:
      1. Selection of inappropriate procedure
      2. Inadequate performance of an appropriate procedure
   2. Overcorrection resulting from:
      1. Selection of an inappropriate procedure
      2. Overzealous release of appropriate structures
      3. Inappropriate release of normal structures
   3. Recurrence of deformity

Collodion Baby

Contents

Collodion baby is a descriptive term for infants born encased in a membrane-like thick scale resembling oiled parchment or collodion. The presence of a collodion membrane at birth represents a defect in skin barrier function and is usually the initial presentation of a congenital ichthyosiform disorder, most often autosomal recessive congenital ichthyosis (ARCI). Thus, neonates born with the features of collodion baby subsequently develop lamellar ichthyosis (LI), nonbullous congenital ichthyosiform erythroderma (NCIE), or other forms of ichthyosis (Akiyama 2006). However, in 10% of neonates, spontaneous healing occurs (Raghunath et al. 2003). Collodion baby is a rare congenital condition accounting for 1 in 50,000 to 1 in 100,000 deliveries. Neonatal presentations of selected ichthyoses (Craiglow 2013) include collodion baby, "▶ Harlequin Ichthyosis" (please see the chapter of Harlequin Ichthyosis), "▶ X-Linked Ichthyosis" (please see the chapter of X-linked Ichthyosis), epidermolytic ichthyosis, and "▶ Netherton Syndrome" (please see the chapter of Netherton Syndrome (line 31)).

Synonyms and Related Disorders

Collodion fetus; congenital ichthyosis; epidermolytic ichthyosis; harlequin ichthyosis; lamellar exfoliation of newborn; lamellar ichthyosis; Netherton syndrome; X-linked ichthyosis

Genetics/Basic Defects

1. Etiology (Taïeb and Labrèze 2002)
    1. The presence of a collodion membrane at birth (Hackett et al. 2010)
        1. Represents a defect in skin barrier function.
        2. Usually the initial presentation of a congenital ichthyosiform disorder is most often autosomal recessive congenital ichthyosis.
    2. Major forms: common severe phenotype (severe congenital ichthyoses in the neonatal period) (Akiyama 1998; Rodríguez-Pazos et al. 2013)
        1. Autosomal recessive nonbullous congenital erythrodermic ichthyosis (50% of cases) including harlequin fetus. Harlequin ichthyosis represents the most severe end of the phenotypic spectrum.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_47

2. Autosomal recessive lamellar ichthyosis (10%) with mutations in the gene for keratinocyte transglutaminase (*TGM1*) (Huber et al. 1995; Russell et al. 1995; Cserhalmi-Friedman et al. 2001) on chromosome 14q11 in many patients. Mapping of a second locus for lamellar ichthyosis to chromosome 2q33-q35 (Permentier et al. 1996). Rare reports of autosomal dominant lamellar ichthyosis.
3. Nonbullous congenital ichthyosiform erythroderma.
4. Bullous congenital ichthyosiform erythroderma.
5. Sjögren-Larsson syndrome.
6. Netherton syndrome.
7. Neural lipid storage disease.

3. Minor forms: common milder phenotypes (Rodríguez-Pazos et al. 2013)
   1. Mild form of ichthyosis vulgaris (10%)
   2. Recovery without sequelae: self-healing collodion babies, described in a minority of collodion babies (10%)
      1. Self-healing collodion baby: compound heterozygous transglutaminase 1 mutations G278R and D490G in two siblings (Raghunath et al. 2003); two cases of autosomal recessive congenital ichthyosis due to *CYP4F22* mutations (Noguera-Morel et al. 2015)
      2. An acral self-healing collodion baby caused by a new *TGM1* mutation (Mazereeuw-Hautier et al. 2009)
      3. Genotypic heterogeneity of *TGM1* mutations: can lead to nonbullous congenital ichthyosiform erythroderma, self-healing collodion baby (localized or generalized), lamellar ichthyosis, and bathing suit ichthyosis (Petit et al. 1997; Oji et al. 2006; Arita et al. 2007; Hackett et al. 2010)
4. Associated congenital ichthyosis
   1. Trichothiodystrophy
   2. Poorly documented true collodion membrane
      1. Sjögren-Larsson syndrome (ichthyosis, spastic paraplegia, mental retardation, and retinopathy with abnormal levels of fatty aldehyde dehydrogenase activity in cultured fibroblasts)
      2. Netherton syndrome
      3. Gaucher disease type II (Stone et al. 2000)
      4. Congenital hypothyroidism
      5. Conradi syndrome
      6. Dorfman-Chanarin syndrome
      7. Ketoadipic aciduria
      8. Koraxitrachitic syndrome
      9. Ichthyosis variegata
      10. Palmoplantar keratoderma with anogenital leukokeratosis

2. Genes known to be associated with autosomal recessive congenital ichthyosis (ARCI) (Bale and Richard 2009; Hackett et al. 2010)
   1. *TGM1*: Mutations in *TGM1* account for 50–60% of all ARCI and 90% or more of severe LI.
   2. *ALOXE3* and *ALOX12B* genes: Mutations in the two *ALOX* genes are present in an estimated 10% of individuals with NCIE or intermediate LI/NCIE phenotypes.
   3. *NIPAL4* (*ICHTHYIN*): *NIPAL4* mutations appear to be less common.
   4. *ABCA12*: The vast majority of individuals with harlequin ichthyosis and a few individuals with LI have mutations in *ABCA12*, including partial-gene deletions.
   5. *CYP4F22*.
3. Pathogenesis (Akiyama 1999)
   1. The term "collodion baby" is considered a descriptive term for infants born encased in membrane-like thick scale and includes several heterogeneous conditions.
   2. Several disorders of cornification showing this phenotype at birth.
   3. A mutation of keratinocyte transglutaminase may play a role in lamellar ichthyosis, although lamellar ichthyosis is still considered genetically heterogeneous.

4. Keratinocytes lacking specific transglutaminase will not cause cross-linked envelopes.

Clinical Features

1. Collodion babies are often the initial presentation of an autosomal recessive ichthyosis (Sandler and Hashimoto 1998).
2. Major clinical features (Sybert 1997)
    1. Newborn covered with a taut, shiny membrane resembling plastic wrap
    2. The membrane often fissured and cracked at birth.
    3. Lamellar exfoliation cracks and peels over the course of several weeks to reveal underlying normal skin or skin with mild scaling that goes on to resolve.
    4. Red-/ivory-colored (erythematous) underlying skin.
    5. Persistence of mild ichthyosis in some patients.
    6. Ectropion (eversion of the eyelids).
    7. Eclabium (eversion of the lips).
    8. Crumpled pinnae.
    9. Resolved tapered fingertips and partially flexed hands with shedding of the encasing membrane.
    10. Self-healing collodion baby in some cases (Frenk and de Techtermann 1992).
    11. The membrane eventually detaches in 3–4 weeks, usually revealing a permanent ichthyosis phenotype (Nguyen et al. 2015).
3. Minor clinical features
    1. Secondary skin infections in the cracks and fissures
    2. Scarring in the areas of deep fissuring
4. Complications
    1. Difficulties in temperature regulation (hypothermia)
    2. Increased insensible water loss predisposing to hypernatremic dehydration (Buyse et al. 1993)
    3. Secondary infections from gram-positive organisms and *Candida albicans*
    4. Septicemia
    5. Pneumonia secondary to aspiration of squamous material in the amniotic fluid
    6. Respiratory difficulty due to restricted chest wall movement
    7. Possible loss of vision caused by corneal damage
    8. Constrictive bands of the extremities resulting in vascular compromise and edema (Van Gysel et al. 2002; Roberts and Adelson 2010)
5. Prognosis
    1. Long-term prognosis is difficult to address at birth.
    2. Infrequently, a collodion baby may have normal skin after exfoliation of the membranes.

Diagnostic Investigations

1. Skin biopsy
    1. Reduced transglutaminase enzymatic activity in the epidermis (Akiyama et al. 2001)
    2. Conventional and electron microscopy (Akiyama et al. 1997)
        1. Hyperkeratosis with thick compact cornified layer (orthokeratotic stratum corneum).
        2. Aberrant keratinized/cornified cells.
        3. Irregularly convoluted horny cells and numerous intercellular Odland bodies (lamellar granules) and nuclear debris in distal layer of the stratum corneum.
        4. Presence of lipid inclusions within the cornified cells.
        5. Abnormal lamellar granules in the granular layer keratinocytes.
        6. Lack of extracellular lamellar structure between the first cornified cell and the granular cell.
        7. Cornified cell envelope appeared to be normally formed.
        8. Compact collodion membrane from a self-healing collodion baby showed a very compact keratin without the normal elimination of corneocytes, a thick horny

layer, and the structure of lower corneocytes with polygonal contour (De Almeida et al. 2015).

2. Molecular genetic analysis
    1. *TGM1* sequence analysis: identification of mutation of keratinocyte transglutaminase 1 gene for severe form of autosomal recessive lamellar ichthyosis and self-healing collodion baby.
    2. *TGM1* mutations include missense, nonsense, and splice site.
    3. Carrier testing available to at-risk family members on a clinical basis once the mutation in *TGM1* has been identified in the proband.
    4. Other gene mutations.
3. Studies for other associated conditions
    1. Polarized light examination of hair and eyebrows
        1. Trichothiodystrophy
        2. Netherton syndrome
    2. Leukocyte lipid inclusions
        1. Dorfman-Chanarin syndrome
        2. Neonatal Gaucher disease
    3. Thyroid hormone level: congenital hypothyroidism
    4. Skeletal study: Conradi syndrome
    5. Neurosensory evaluation

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. Autosomal recessive inheritance: 25% recurrence risk
        2. Autosomal dominant inheritance: not increased unless a parent is affected
    2. Patient's offspring
        1. Autosomal recessive inheritance: not increased unless the spouse is a carrier or affected
        2. Autosomal dominant inheritance: 50%
2. Prenatal diagnosis: direct mutation analysis of the keratinocyte transglutaminase 1 gene on fetal DNA obtained from amniocentesis or CVS (Schorderet et al. 1997; Pigg et al. 2000) for severe form of autosomal recessive lamellar ichthyosis, provided the mutation in *TGM1* or other disease-causing mutations has been identified in the proband
3. Management: requiring intensive care (Shareef et al. 2000)
    1. Maintain skin integrity.
        1. Assess open skin lesions.
        2. Minimal handling with precaution.
        3. Prevent secondary infection and avoid prophylactic use of antibiotics.
    2. Maintain body temperature.
        1. Avoid radiant heat.
        2. Use humidified incubator for dehydration and hypothermia.
        3. Pre-warm all linen used to absorb weeping.
    3. Ophthalmological management of ectropion important for the prevention of conjunctivitis and keratitis.
    4. Sedation with opioids indicated for severe pain.
    5. Petrolatum-based creams/ointments to keep the skin soft, supple, and hydrated.
    6. Retinoids in case of delayed shedding of the collodion membrane beyond 3 weeks.
    7. Use keratolytic agents (e.g., alpha-hydroxy acid preparations) or urea preparations to promote peeling and thinning of the stratum corneum as the child becomes older.
    8. Release of collodion membrane on digits, when necessary, to maintain circulation and on the thorax for adequate respiration.

Congenital Adrenal Hyperplasia

Contents

Congenital adrenal hyperplasia (CAH) refers to a family of inherited disorders of adrenal steroidogenesis. The common functional defect in each disorder is impaired cortisol secretion, resulting in hypersecretion of corticotropin-releasing hormone (CRH) and adrenocorticotropic hormone (ACTH) and consequent hyperplasia of the adrenal glands (Antal and Zhou 2009).

More than 90% of cases of CAH are caused by a defect in the enzyme 21-hydroxylase (White and Speiser 2000). Four other enzyme deficiencies in the steroid biosynthesis pathway, along with one cholesterol transport protein defect, account for the remaining cases. Depending on the severity of the enzyme deficiency, 21-hydroxylase deficiency is defined as classic (severe form) or nonclassic (mild form). Approximately, 75% of patients who have the classic form also have salt wasting due to inadequate aldosterone production, further subdividing the classification into classic simple virilizing and classic salt-wasting forms. This chapter will discuss 21-hydroxylase deficiency in detail with a brief discussion of the other forms of CAH.

21-hydroxylase deficiency is the most common type of congenital adrenal hyperplasia (CAH). The incidence of classic 21-hydroxylase deficiency is estimated to be 1/12,000–1/15,000 births. The nonclassical form of the disease, also called "late-onset" CAH, occurs in approximately 1 in 1,000 of the general population depending on the ethnic group and in up to 6% of hirsute women (Deneux et al. 2001). Carrier frequencies for nonclassic disease range from 1:5 to 1:16, depending on the ethnic population sampled (Baumgartner-Parzer et al. 2005). Nonclassic CAH is especially common in Ashkenazi Jews, with a disease frequency as high as 1 in 27 individuals (Sherman et al. 1988).

Synonyms and Related Disorders

11-beta-hydroxylase deficiency; 17-alpha-hydroxylase deficiency; 21-hydroxylase deficiency; 3-beta-hydroxysteroid dehydrogenase deficiency; Lipoid congenital adrenal hyperplasia

Genetics/Basic Defects

1. Inheritance: autosomal recessive
2. Molecular biology of steroid hormone synthesis: five groups of steroid hormones are

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_48

generally recognized according to their physiological behavior (Miller 1988)
1. Mineralocorticoids: instruct the renal tubules to retain sodium
2. Glucocorticoids: named for their carbohydrate mobilizing properties but have many other effects as well
3. Estrogens: induce female secondary sexual characteristics
4. Progestins: essential for reproduction
5. Androgens: induce male secondary sexual characteristics

3. Biochemical and molecular basis
   1. Deficient 21-hydroxylase activity : the most common form (>90% of cases) of CAH
   2. Caused by mutations of *CYP21* (*CYP21A2*) gene, mapped on the short arm of chromosome 6 (6p21.3), present in duplicate
   3. A highly homologous pseudogene (*CYP21P*)
      1. Located in the same chromosomal region as the active gene
      2. Severe mutations of the pseudogene incompatible with coding for a functional enzyme
   4. About 95% of mutant alleles generated by recombination events between *CYP21* and *CYP21P* (Forest et al. 1998)
   5. Relatively common exchange of genetic material between these two homologous genes, the major reason for the high incidence of 21-hydroxylase deficiency compared to other forms of CAH
4. Pathophysiology (Cutler and Laue 1990; New 1995; New and Wilson 2002)
   1. Classic form of 21-hydroxylase deficiency
      1. Prenatal exposure to potent androgens (testosterone and delta4-androstenedione) at critical stages (8–12 weeks) of sexual differentiation resulting in virilization of the external genitalia in genetic females, resulting in varying degrees of genital ambiguity (female pseudohermaphroditism) at birth
      2. Subdivision of classic form
         1. Simple virilizing form (about 25%): sufficient aldosterone is produced, in response to elevated levels of renin and angiotensin, to prevent a salt-losing crisis
         2. Salt-wasting form (>75%) in which aldosterone production is inadequate and at risk of life-threatening salt-wasting crises
   2. Nonclassic "late-onset" form of 21-hydroxylase deficiency
      1. Has only moderate enzyme deficiency
      2. Present postnatally with signs of hyperandrogenism
      3. Females with the nonclassic form differing from the classic form: cortisol deficiency and virilization of newborn girls are absent (Turcu and Auchus 2015)
   3. Phenotype of congenital lipoid adrenal hyperplasia: result of the following two separate events (Bose et al. 1996):
      1. An initial genetic loss of steroidogenesis that is dependent on steroidogenic acute regulatory protein
      2. A subsequent loss of steroidogenesis that is independent of the protein due to cellular damage from accumulated cholesterol esters
5. CAH due to 21- hydroxylase deficiency
   1. 21-hydroxylase
      1. A microsomal cytochrome P450 enzyme
      2. Required to convert:
         1. 17-hydroxy-progesterone to 11-deoxycortisol
         2. Progesterone to deoxycorticosterone
   2. 21-hydroxylase deficiency
      1. Impairs the metabolism of cholesterol to cortisol, generating excessive level of 17-hydroxyprogesterone
      2. Produces androstenedione and other androgens from the precursor (17-hydroxyprogesterone) via an alternative metabolic pathway
      3. Aldosterone deficiency
         1. Inability to synthesize adequate amounts of aldosterone due to severely impaired 21-hydroxylation of progesterone in about 75% of patients

2. Resulting in sodium loss via the kidney, colon, and sweat glands and excrete potassium from the renal tubules
3. Cortisol deficiency
   1. Glucocorticoids
      1. Increase cardiac contractility
      2. Increase cardiac output
      3. Increase cardiac and vasculature sensitivity to the pressor effects of catecholamines and other pressor hormones
   2. Absence of glucocorticoids
      1. Decrease in cardiac output
      2. Decrease in glomerular filtration leading to an inability to excrete free water and consequently to hyponatremia
4. Shock and severe hyponatremia much more likely in 21-hydroxylase deficiency in which both cortisol and aldosterone biosynthesis are affected

6. Phenotype-genotype correlations (Wedell 1996, 1998; White 2001; Hughes 2002b)
   1. Mutations in CYP21, such as deletions, frameshifts, or nonsense mutations
      1. Totally ablate enzyme activity
      2. Most often associated with salt wasting
   2. Mutations mainly consisting of the missense mutation Ile172Asn (Il72N)
      1. Yielding enzymes with 1–2% normal activity
      2. Carried predominantly by patients with simple virilizing disease
   3. Mutations such as Val281Leu (V281L) and Pro30Leu (P30L)
      1. Producing enzymes with 20–60% of normal activity
      2. Most often associated with the nonclassical disorder
   4. Two different CYP21 mutations
      1. Producing compound heterozygotes
      2. Most often with a phenotype compatible with that of the less severe gene defects
   5. All patients homozygous or compound heterozygous for large deletions or gene conversions have a salt-wasting classic form
   6. A strong correlation exists between genotype and phenotype: mutational analysis can be used to predict disease severity in affected individuals
7. Characteristics of other forms of CAH (Speiser 2001; Antal and Zhou 2009)
   1. 11-beta-hydroxylase deficiency
      1. Incidence: 1:100,000
      2. Gene involved: *CYP11B1*
      3. Chromosome location: 8q24.3
   2. 17-alpha-hydroxylase deficiency
      1. Incidence: rare
      2. Gene involved: *CYP17*
      3. Chromosome location: 10q24.3
   3. 3-beta-Hydroxysteroid dehydrogenase deficiency
      1. Incidence: rare
      2. Gene involved: *HSD3B2*
      3. Chromosome location: 1p13.1
   4. Lipoid CAH
      1. Incidence: rare
      2. Gene involved: steroidogenic acute regulatory protein (*STAR*)
      3. Chromosome location: 8p11.2
8. Affect of CAH (steroidogenic disorders) on female fertility (Reichman et al. 2014)
   1. Classic CAH due to 21-hydroxsylase deficiency: virilization
      1. Anatomic distortion leading to impaired sexual functioning
      2. Delayed gender assignment
      3. Elevated, noncyclic progesterone (P4) impacting endometrium and hypothalamic-pituitary-ovarian (HPO) axis
      4. Alter psychosocial development
      5. Elevated androgens disturbing HPO axis, leading to anovulation
   2. Classic CAH due to 11β-hydroxylase deficiency: as above, with exception of significant P4 elevation
   3. Nonclassic CAH due to 21-hydroxylase deficiency: hyperandrogenemia affecting HPO axis, leading to anovulation and polycystic ovary syndrome-like phenotype
9. Simple classification of intersex: type, cause, and result (Hughes 2002c)
   1. Masculinized female

1. Fetal androgens resulting in:
   1. CAH
   2. Placental aromatase deficiency
2. Maternal androgens resulting in:
   1. Adrenal tumors
   2. Ovarian tumors

2. Undermasulinized male
   1. Abnormal testis determination resulting in:
      1. Gonadal dysgenesis
      2. X/XY mosaicism
   2. Defects in androgen biosynthesis and metabolism resulting in:
      1. 17β-OH-dehydrogenase deficiency
      2. 5α-reductase deficiency
   3. Resistance to androgen resulting in partial androgen insensitivity syndrome
3. True hermaphroditism: presence of both testicular and ovarian (with follicles) tissues resulting in XX, XY, or XX/XY

Clinical Features

1. Neonatal presentation of CAH (Hughes 1986)
   1. Either virilization of females or
   2. Salt loss in both sexes
2. Typical signs and symptoms of acute adrenal crisis (Antal and Zhou 2009)
   1. Decreased activity/fatigue
   2. Altered sensorium/unresponsiveness
   3. Poor feeding/weak suck
   4. Dry mucous membranes
   5. Hyperpigmentation
   6. Abdominal pain
   7. Vomiting
   8. Hyponatremia
   9. Hyperkalemia
   10. Hypoglycemia
   11. Metabolic acidosis
   12. Hypothermia
   13. Hypotension
   14. Dehydration
   15. Lack of weight gain
3. Clinical manifestations of 21-hydroxylase deficiency (Hughes 1988; New 2001b)
   1. Newborn
      1. Ambiguous genitalia
      2. Cryptorchid/hypospadic "male"
      3. Salt wasting
   2. Later in life
      1. Pseudoprecocious puberty
      2. Isolated pubarche
      3. Isolated clitoromegaly
      4. Rapid growth
      5. Hirsutism (Kuttenn et al. 1985)
      6. Menstrual disorders
      7. Infertility
      8. Cryptic cases
4. Classic CAH phenotype (Levine 2000; White 2001; New and Wilson 2002; Speiser and White 2003)
   1. Simple (complete) virilizing form (about 25% of patients): can present later in life with abnormalities of somatic or sexual development (Woelfle et al. 2002)
   2. Salt-wasting form (>75% of patients)
      1. Adrenal crises present at 1–4 weeks of age in severely affected patients
         1. Severe dehydration
         2. Hypotension
         3. Severe hyponatremia, hyperkalemia, and hyperreninemia
         4. Progression to adrenal crisis (azotemia, vascular collapse, hypovolemic shock, and death) if adequate medical care is not provided
         5. Affected infant boys who are not detected in a newborn screening program are at high risk of a salt-wasting crisis since their normal genitalia fail to alert physicians to the diagnosis of congenital adrenal hyperplasia
      2. Nonspecific symptoms
         1. Poor appetite/feeding
         2. Vomiting
         3. Hypotension
         4. Lethargy
         5. Failure to gain weight (weight loss)
      3. Improved sodium balance and more efficient aldosterone synthesis with age in patients known to have severe salt-wasting episodes in infancy and early childhood

4. Siblings may be discordant for salt wasting
5. The degree of salt wasting may vary in individuals carrying identical mutations
6. Patients with 3β-hydroxysteroid hydrogenase deficiency, aldosterone synthase deficiency, or lipoid hyperplasia
    1. Unable to synthesize aldosterone
    2. May present with salt-wasting crises

3. Children with classic CAH
    1. Lack of sufficient amounts of cortisol to mount a stress response and frequently succumb to minor illnesses
    2. Premature closure of the epiphyses resulting in short stature even though these children grow at an accelerated rate when young
4. Growth disturbances
    1. Accelerated skeletal maturation in untreated patients due to high levels of androgen
    2. Growth retardation in patients treated with excessive doses of gluco-corticoids
    3. Final height, despite careful monitoring and good patient compliance, usually averaging one to two standard deviations below the population mean or the target height based on parental heights
5. Behavioral and physical masculinization in girls with CAH (Hall et al. 2004)
    1. Related to each other and to genotype
    2. A consequence of prenatal androgen exposure
6. Reproductive problems in affected females (White 2001)
    1. Ambiguous genitalia typically present in the neonatal period
        1. Clitoromegaly (mild)
        2. With or without partial fusion of the labioscrotal folds (intermediate)
        3. Complete fusion of the labioscrotal folds with the appearance of a penile urethra (severe)
    2. Internal genitalia
        1. Normal ovaries, fallopian tubes, and uteri
        2. Normal upper third of the vagina but urogenital sinus may be present distally with one opening on the perineum
    3. Signs of androgen excess in affected females without glucocorticoid replacement therapy (New and Wilson 2002)
        1. Clitoral enlargement
        2. Excessive linear growth
        3. Advanced bone age
        4. Acne
        5. Early onset of pubic and axillary hair
        6. Hirsutism
        7. Male pattern baldness
        8. Menstrual abnormalities
        9. Reduced fertility
    4. Adolescence (White 2001)
        1. Late menarche in inadequately treated girls
        2. Sonographic finding of multiple ovarian cysts similar to patients with polycystic ovarian syndrome
        3. Anovulation/oligo-ovulation (Garner 1998)
        4. Irregular bleeding
        5. Hyperandrogenic symptoms
    5. Pregnancy and live-birth rates
        1. Severely reduced in salt-wasting patients
        2. Mildly reduced in simple virilizing patients
        3. Normal in nonclassical patients
    6. Factors suggested responsible for the impaired fertility (Stikkelbroeck et al. 2003)
        1. Adrenal overproduction of androgens and progestins (17-hydroxyprogesterone, progesterone, and androstenedione)
        2. Ovarian hyperandrogenism
        3. Polycystic ovary syndrome
        4. Ovarian adrenal rest tumors
        5. Neuroendocrine factors
        6. Genital surgery
        7. Psychosocial factors (delayed psychosexual development, reduced sexual activity, low maternal feelings)
    7. No evidence of an excess of congenital malformations in offspring of women

with 21-hydroxylase deficiency (White 2001)

8. Other types of congenital adrenal hyperplasia (White 2001)
    1. 11β-hydroxylase deficiency: similar to 21-hydroxylase deficiency
    2. 17α-hydroxylase deficiency: remains sexually infantile due to inability to synthesize sex hormones unless supplemented with estrogen
    3. 3β-hydroxysteroid hydrogenase deficiency: slightly virilized due to high levels of dehydroepiandrosterone

7. Reproductive function and problems in affected males (New and Wilson 2002; White 2001)
    1. Signs of androgen excess in affected males without glucocorticoid replacement therapy
        1. Penile enlargement
        2. Small testes
        3. Excessive linear growth
        4. Advanced bone age
        5. Acne
        6. Early onset of pubic and axillary hair
    2. Ability to father children
    3. Testicular adrenal rests
        1. Most often benign
        2. Manifest as testicular enlargement
        3. Seen most often in inadequately treated patients, particularly those with the salt-wasting form of 21-hydroxylase deficiency
    4. Other types of congenital adrenal hyperplasia
        1. Men with 11β-hydroxylase deficiency: similar to those with 21-hydroxylase deficiency
        2. Genetic males with 3-β-hydroxysteroid hydrogenase deficiency, 17α-hydroxylase deficiency, or lipoid hyperplasia: usually raised as females and castrated during or before adolescence to prevent malignant transformation of abdominal testes

8. Effects on gender role, sexual orientation, and identity (Meyer-Bahlburg 2001; White 2001)
    1. Gender role
        1. Referring to gender-stereotyped behaviors such as choice of play toys by young children
        2. Girls with 21-hydroxylase deficiency may show low interest in maternal behavior, extending from lack of doll play in early childhood to lack of interest in childrearing in women.
    2. Sexual orientation
        1. Referring to homosexual versus heterosexual preferences
        2. Heterosexuality in most adult women with 21-hydroxylase deficiency
        3. Homosexuality or bisexuality or increased tendency to homo-erotic fantasies in a small but significant proportion in women with 21-hydroxylase deficiency
    3. Gender identity
        1. Referring to self-identification as male or female
        2. Self-reassignment to the male sex is unusual in women with 21-hydroxylase deficiency
        3. Severely virilized females are more likely to be raised as males in cultures that value boys more highly and/or in third world countries in which the diagnosis is likely to be delayed

5. Nonclassic (late-onset) CAH phenotype (White 2001; Wichel 2013)
    1. Nonambiguous external genitalia, with normal or mild clitoromegaly, in females affected with mild, nonclassical form of 21-hydroxylase deficiency
    2. Signs of androgen excess
        1. Wide spectrum of symptoms and signs
        2. Asymptomatic in many affected individuals
        3. Children: premature pubarche

4. Young women
    1. Severe cystic acne
    2. Hirsutism
    3. Oligomenorrhea
3. Signs and symptoms suggesting mild CAH (Deaton et al. 1999; Miller 1999)
    1. Children
        1. Moderate to severe recurrent sinus or pulmonary infections
        2. Severe acne
        3. Hyperpigmentation, especially of the genitalia
        4. Tall for age
        5. Early onset of puberty
    2. Adults
        1. Childhood history as described above
        2. Syncope or near-syncope
        3. Shortened stature compared with either parent
        4. Hypotension (21-hydroxylase deficiency)
        5. Hypertension (11β-hydroxylase deficiency)
    3. Women
        1. Clitoromegaly
        2. Poorly developed labia
        3. Premature adrenarche
        4. Hirsutism
        5. Menstrual disturbances
        6. Infertility
        7. Polycystic ovary syndrome
6. Clinical characteristics of other forms of CAH (Antal and Zhou 2009)
    1. 11-beta-Hydroxylase deficiency
        1. Ambiguous genitalia in females
        2. Rare adrenal crisis
    2. 17-alpha-ydroxylase deficiency
        1. Ambiguous genitalia in males
        2. No adrenal crisis
    3. 3-beta-hydroxysteroid dehydrogenase deficiency
        1. Ambiguous genitalia in males
        2. Adrenal crisis present
    4. Lipoid CAH
        1. Ambiguous genitalia in males
        2. Severe adrenal crisis

Diagnostic Investigations

1. Newborn screening (Pang 1997; Pang and Shook 1997; Therrell 2001; Joint LWPES/ESPE CAH Working Group 2002; New and Wilson 2002; White 2001, 2009)
    1. Objectives
        1. Detect a common and potentially fatal childhood disease (classic form of CAH)
        2. Prevent serious morbidity and mortality by early recognition and treatment
        3. Prevent incorrect male sex assignment of affected female infants with ambiguous genitalia
        4. Detect most, but not all, cases of the nonclassic form of 21-hydroxylase deficiency
    2. Filter paper blood spot sample (White 2001)
        1. Markedly elevated 17- hydroxyprogesterone by radioimmunoassay
        2. False positives
            1. Samples taken in the first 24 h of life (elevated in all infants)
            2. Variation of weight-adjusted cutoff values among newborn screening programs
            3. Infants with low birth weight or prematurity
    3. Early diagnosis is based on elevated levels of 17-hydroxyprogesterone (Hughes 1986), the preferred substrate for steroid 21-hydroxylase
    4. Initial testing usually involves dissociation-enhanced lanthanide fluorescence immunoassay that has a low positive predictive value (about 1%), leading to many follow-up evaluations that have negative results
    5. Second level of screening based on detection of actual mutations on DNA extracted from the same dried blood spots or liquid chromatography followed by tandem mass spectrometry

6. Main benefits of newborn screening
    1. Reduced morbidity and mortality
    2. Reduced time to diagnosis of infants with 21-hydroxylase deficiency
    3. Infants ascertained through screening
        1. Less severe hyponatremia
        2. Tend to be hospitalized for shorter periods of time

2. Intersex: initial investigation (Hughes 2002c)
    1. Chromosomes
        1. Fluorescent in situ hybridization on interphase spreads with X, Y specific probes
        2. Full karyotype
    2. Hormones
        1. Serum 17OH-progesterone at 24–48 h after birth
        2. Serum testosterone
        3. Plasma renin
        4. Save serum, DNA, urine
    3. Biochemistry
        1. Serum electrolytes
        2. Plasma glucose
    4. Imaging
        1. Pelvic ultrasonography for uterus/cervix
        2. Renal ultrasonography
3. Diagnosis of CAH
    1. Female neonates
        1. With genital ambiguity
            1. Genital ambiguity highly distressing to the family
            2. Require urgent expert medical attention
            3. Need immediate comprehensive evaluation by a multidisciplinary team including specialists from pediatric endocrinology, psychosocial services, pediatric surgery/urology, and genetics
        2. With or without salt loss
        3. Presence of elevated concentration of serum 17-hydroxyprogesterone
            1. Only diagnostic of CAH when measured after the 3rd day of life
            2. Presence of relatively high concentrations in the immediate neonatal period in normal infants
        4. Normal internal female genitalia on pelvic ultrasonography
        5. Normal female karyotype (46,XX)
    2. Male neonates
        1. Salt-losing crises
        2. Presence of elevated 17-hydroxyprogesterone concentration
4. Clinical chemistry
    1. Important initial laboratory evaluation for patients suspected of experiencing adrenal crisis due to 21-hydroxylase deficiency (Antal and Zhou 2009)
        1. Glucose/dextrose stick at bedside
        2. Chem-20 (including electrolytes and liver function panel): critical to assure that the potassium concentration is obtained from a nonhemolyzed sample to minimize the likelihood of a falsely elevated potassium value
        3. Arterial blood gas/serum pH
        4. Cortisol
        5. ACTH
        6. 17-OHP
        7. Pelvic ultrasonography
        8. Karyotype
    2. ACTH stimulation test: necessary to evaluate adrenal function and differentiate among the various potential enzymatic defects (Antal and Zhou 2009)
    3. Comparison of baseline and cortrosyn-stimulated serum concentrations of the steroid precursor 17-hydroxyprogesterone (nonclassical)
    4. Increased serum levels of progesterone, 17-hydroxyprogesterone, and androstenedione in affected males and females with classic 21-hydroxylase deficiency
    5. Elevated serum levels of testosterone and adrenal androgen precursors in affected girls
    6. Salt losers
        1. Low serum bicarbonates, sodium, and chloride levels
        2. Elevated levels of serum potassium and serum urea nitrogen
        3. Hyponatremia and hyperkalemia usually not present before 7 days of age

4. Inappropriately increased urine sodium levels
5. Elevated plasma rennin levels
6. Serum aldosterone level inappropriately low for the rennin level

5. Karyotyping or fluorescence in situ hybridization for sex chromosome material
   1. 46,XX in females with 21-hydroxylase deficiency
   2. 46,XY in males with 21-hydroxylase deficiency
6. Careful monitoring of linear growth
7. Imaging studies (Wilson 2015)
   1. Transabdominal pelvic sonography (Chertin et al. 2000)
      1. Perform in patients with CAH undergoing vaginal reconstruction
      2. Provide adequate information about the anatomy of the vagina and urogenital sinus
      3. Demonstrate presence or absence of a uterus or associated renal anomalies
   2. Urogenitogram helpful to define the anatomy of the internal genitalia
   3. Adrenal ultrasonography to detect enlarged, lobulated adrenals with stippled echogenicity invariably associated with CAH (Al-Alwan et al. 1999)
   4. CT scanning of adrenal gland: helps exclude bilateral adrenal hemorrhage in patients with signs of acute adrenal failure without ambiguous genitalia or other clued to adrenal hyperplasia (Purandare et al. 2001)
   5. Sonography or MRI for testicular adrenal rest tumors
   6. Bone age radiography: useful in evaluating for advanced skeletal maturation in a child who develops precocious public hair, clitoromegaly, or accelerated linear growth
8. Carrier detection (New and Wilson 2002)
   1. Carriers: asymptomatic individuals who have one normal allele and one mutant allele
   2. ACTH stimulation test
      1. Resulting in slightly elevated serum concentrations of deoxycortisol and 17-hydroxyprogesterone
      2. Overlap in serum concentration of 17-hydroxyprogesterone between carriers and noncarriers
      3. No longer the preferred method of carrier detection
   3. Molecular genetic testing
      1. Molecular genetic testing of the *CYP21A2* gene available to at-risk relatives, given that the disease-causing mutation(s) have been identified in the proband
      2. The preferred method of carrier detection
9. Molecular genetic testing (New and Wilson 2002)
   1. Molecular genetic analysis for *CYP21A2* gene for a panel of 9 common mutations and gene deletions detect about 90–95% of disease-causing alleles in affected individuals and carriers
   2. Complete gene sequencing detects more rare alleles in affected individuals in whom the panel of nine mutations and deletions reveals only one or neither disease-causing allele
   3. Applications
      1. Primarily used in genetic counseling for carrier detection of at-risk relatives and for prenatal diagnosis
      2. Can be used for diagnosis in newborns with slight to moderate elevations of 17-hydroxyprogesterone
10. Laboratory characteristics of other forms of CAH (Antal and Zhou 2009)
    1. 11-beta-Hydroxylase deficiency
       1. Glucocorticoid values: decreased
       2. Mineralocorticoid values: elevated
       3. Androgens: elevated
       4. Sodium concentrations: elevated
       5. Potassium concentrations: decreased
       6. Elevated metabolites
          1. Deoxycorticosterone (DOC)
          2. 11-deoxycortisol
    2. 17-alpha-hydroxylase deficiency
       1. Glucocorticoid values: decreased
       2. Mineralocorticoid values: elevated
       3. Androgens: decreased
       4. Sodium concentrations: increased

5. Potassium concentrations: decreased
6. Elevated metabolites
    1. Deoxycorticosterone
    2. Corticosterone

3. 3-beta-Hydroxysteroid dehydrogenase deficiency
    1. Glucocorticoid values: decreased
    2. Mineralocorticoid values: decreased
    3. Androgens
        1. Elevated in females
        2. Decreased in males
    4. Sodium concentrations: decreased
    5. Potassium concentrations: elevated
    6. Elevated metabolites
        1. Dehydroepiandrosterone (DHEA)
        2. 17-hydroxypregnenolone
4. Lipoid CAH
    1. Glucocorticoid values: decreased
    2. Mineralocorticoid values: decreased
    3. Androgens: decreased
    4. Sodium concentrations: decreased
    5. Potassium concentrations: elevated
    6. Elevated metabolites: none

Genetic Counseling

1. Recurrence risk (Nimkarn and New 2013)
    1. Genetic counseling according to autosomal recessive inheritance
        1. Most parents: heterozygotes with one normal allele and one mutated allele
        2. One percentage of probands having only one parent who is heterozygous since 1% of mutations occur de novo
        3. In some instances, a parent, who was previously not known to be affected, was found to have the nonclassic form of 21-hydroxylase deficiency
        4. For individuals with CAH, the risk of having a child with CAH depends on the probability that the partner is a carrier; this is typically about 1 in 60. Thus, the risk of having a CAH fetus is 1:120 and the risk of having a female infant with CAH is 1:240 (Wichel 2013)
        5. Prevalence of CAH among children of women with nonclassic adrenal hyperplasia is higher than predicted, presumably because affected individuals tend to marry within their own ethnic background (Moran et al. 2006)
    1. Patient's sib
        1. When the parents of a proband are both obligate heterozygotes
            1. Twenty-five percent risk of inheriting both altered alleles and being affected
            2. Fifty percent risk of inheriting one altered allele and being an unaffected carrier
            3. Twenty-five percent risk of inheriting both normal allele and being unaffected
            4. Two-third chance of unaffected sibs of a proband being a carrier
        2. When a parent of a proband has 21-hydroxylase deficiency and the other is heterozygous
            1. Fifty percent risk of inheriting both mutant alleles and being affected
            2. Fifty percent risk of inheriting one mutant allele and being a carrier
    2. Patient's offspring for a woman with classic 21-hydroxylase deficiency
        1. When the spouse status is unknown (Lo and Grumbach 2001)
            1. Risk of having an infant with the same disorder: approximately 1 in 120 births
            2. Risk of having an affected female infant: approximately 1 in 240 births
            3. Risk figures are based on an estimated 1 in 60 incidence of heterozygous individuals with a *CYP21* mutation, derived from newborn screening data
        2. When the spouse is not a carrier or not affected: risk is not increased
        3. Appropriate to offer molecular genetic testing of the *CYP21A2* gene to the spouse given the high carrier rate for 21-hydroxylase deficiency
    3. Patient's offspring for a woman with nonclassic CAH and are compound

heterozygotes with one severe *CYP21A2* mutation: risk of having an affected infant with classic CAH is 1 in 4 pregnancies (or 1 in 8 pregnancies for an affected female infant) when the spouse is a known carrier of the severe form of *CYP21A2* deficiency

2. Prenatal diagnosis and preimplantation genetic diagnosis for pregnancies require prior identification of the disease-causing mutations in the family (New 2001b; Nimkarn and New 2013)
    1. Noninvasive prenatal diagnosis (Khattab et al. 2016)
        1. Utilization of cell-free fetal DNA in mothers carrying at-risk fetuses as early as 6 gestational weeks by targeted massively parallel sequencing of the genomic region including and flanking the CYP21A2 gene
        2. Should permit the diagnosis of CAH before genital development begins, therefore restricting the purposeful administration of dexamethasone to mothers carrying affected females
    2. Determination of amniotic fluid (AF) hormone levels
        1. Elevated 17α-hydroxyprogesterone
        2. Elevated Δ^4-androstenedione
    3. Human leukocyte antigen (HLA) typing on cultured chorionic villus cells and cultured AF cells
        1. Basis for prenatal diagnosis: the gene for 21-hydroxylase has been linked to the HLA system on chromosome 6
        2. HLA type
            1. Fetus with an HLA type identical to that of the proband with 21-hydroxylase deficiency predicted to be affected
            2. Fetus sharing 1 parental haplotype with the proband predicted to be a heterozygous carrier
            3. Fetus with both haplotypes different from the index case predicted to be homozygous normal
    4. Molecular DNA diagnosis
        1. Molecular genetic testing of the proband and both parents should be undertaken prior to conception:
            1. To identify the two disease-causing mutations
            2. To confirm both parents are carriers
        2. Analysis of both parents
            1. To determine the phase of different mutations (whether they lie on the same or opposite alleles)
            2. To distinguish homozygotes and hemizygotes (individuals who have a mutation on one chromosome and a deletion on the other)
        3. De novo mutations, found in patients with CAH but not in parents, observed in 1% of disease-causing CYP21B mutations
        4. Before 10 weeks of gestation and prior to any prenatal testing, administer dexamethasone to the pregnant mother to suppress excess fetal adrenal androgen secretion and to prevent virilization of an affected female
        5. Obtain fetal cells to determine fetal sex by chromosome analysis or FISH using Y-chromosome specific probes
            1. Chorionic villus sampling in the 10th–12th week of gestation (preferable because of early result)
            2. Amniocentesis at 16–18 weeks of gestation
        6. If the fetus is a female and if the two *CYP21A2* disease-causing mutations have been identified in the proband:
            1. Perform molecular genetic testing to determine whether the fetus has inherited both disease-causing alleles
            2. Female fetus known to have 21-hydroxylase deficiency by DNA analysis or having an indeterminant status: continue dexamethasone treatment to term
        7. If the fetus is a male or unaffected female by DNA analysis: discontinue dexamethasone treatment

3. Management (White 2001; Turcu and Auchus 2015)
    1. Replacement with glucocorticoids (hydrocortisone, prednisone, dexamethasone)
        1. Indicated in all patients with classic and symptomatic nonclassical patients with 21-hydroxylase deficiency
        2. To suppress the excessive secretion of CRH and ACTH by the hypothalamus and pituitary
        3. To reduce the abnormal blood levels of adrenal sex steroids
        4. Situations in which increased hydrocortisone dose is needed in patients with classic 21-hydroxylase deficiency
            1. Febrile illness
            2. Surgery under general anesthesia
        5. Increase dose of hydrocortisone or prednisone in pregnancy due to pregnancy-induced alterations in steroid metabolism and clearance
        6. Glucocorticoid replacement also required in patients with CAH caused by other enzymatic deficiencies
    2. Mineralocorticoid replacement
        1. Mineralocorticoid (fludrohydrocortisone) and sodium chloride supplements required in infants with the salt-wasting form of 21-hydroxylase deficiency
        2. Treat patients with simple virilizing form of the disease by fludrohydrocortisone to aid in adrenocortical suppression and reduce the dose of glucocorticoid required to maintain acceptable 17-hydroxyprogesterone levels
        3. Signs of overtreatment with mineralocorticoid and sodium replacement
            1. Hypertension
            2. Tachycardia
            3. Suppressed plasma rennin activity
        4. Other indications of fludrohydrocortisone replacement
            1. 3β-hydroxysteroid hydrogenase deficiency
            2. Aldosterone synthase deficiency
            3. Lipoid hyperplasia
    3. Other pharmacological approaches
        1. A novel 4-drug regimen for 21-hydroxylase deficiency
            1. Flutamide (an androgen receptor blocking drug), testolactone (an aromatase inhibitor), and low dose of hydrocortisone and fludrocortisone can achieve short-term normalization of growth rate, weight gain, and bone maturation (Merke and Cutler 1997)
            2. Benefit: produces less bone age advancement and attain more appropriate linear growth velocity than standard treatment
            3. Side effect: occurrence of central precocious puberty requiring treatment with gonadotrophin-releasing hormone analog
        2. Experimental treatment with carbenoxolone, an inhibitor of 11β-hydroxysteroid dehydrogenase
    4. Corrective surgery
        1. Decision about surgery
            1. Made by the parents, together with the clinical team
            2. After disclosure of all relevant clinical information and all available options
            3. Obtain informed consent
        2. Objectives
            1. Genital appearance compatible with gender
            2. Unobstructed urinary emptying without incontinence or infections
            3. Good adult sexual and reproductive function
        3. Clitoroplasty, rather than clitoridectomy, done in infancy
        4. Vaginal reconstruction
            1. Often postponed until the age of expected sexual activity
            2. Single-stage corrective surgery in children
    5. Adrenalectomy
        1. Questionable therapeutic alternative
        2. Likely to be used, if at all, in patients with severe 21-hydroxylase deficiency refractory to standard medical management

6. Management of testicular adrenal rests
    1. Effective adrenal suppression with dexamethasone since many of these tumors are ACTH-responsive
    2. Testis-sparing surgery for cases unresponsive to dexamethasone after imaging the tumor by sonography and/or MRI
7. Management of adolescence with classical and nonclassical CAH (Clayton et al. 2002)
    1. Psychological assessment and support of the patient
    2. Counseling
        1. Sexual function
        2. Future surgeries
        3. Gender role
        4. Issues related to living with a chronic disorder
        5. Low risk of women with CAH or nonclassic CAH having an affected fetus
8. Management of pregnancy in women with classic 21-hydroxylase deficiency (Lo and Grumbach 2001)
    1. Factors contributing to lower fertility rates
        1. Masculinization of the external genitalia
        2. An inadequate introitus
        3. Factors relating to genital reconstructive surgery (poor surgical repair, vaginal stenosis, and clitoral dysfunction)
        4. Hormonal factors (increased levels of adrenal androgens and progestational steroid, and ovarian hyperandrogenism)
    2. Recent improvement of fertility prognosis
        1. Earlier detection and treatment of 21-hydroxylase deficiency
        2. Surgical advances in genital reconstruction (Schnitzer and Donahoe 2001)
        3. Higher patient compliance rates
    3. Preconception issues for all women with classic 21-hydroxylase deficiency who desire pregnancy
        1. Need for glucocorticoid treatment
        2. Careful endocrine monitoring throughout gestation
        3. Ovulation induction with clomiphene citrate or gonadotropin therapy or in vitro fertilization for patients who do not achieve normal ovulatory cycles and fertility despite effective glucocorticoid therapy
        4. Most pregnancies are successful in carrying to term with a healthy outcome
        5. Preconceptional counseling about the risk of having a child affected with 21-hydroxylase deficiency
    4. Gestational management (Lo and Grumbach 2001)
        1. Regular assessment of maternal clinical status, serum electrolytes, and circulating adrenal androgen levels during gestation to determine the need for increased glucocorticoid or mineralocorticoid therapy
        2. Signs of adrenal steroid insufficiency (excessive nausea, salt craving, and poor weight gain)
        3. Monitor hypertension and fluid retention in patients receiving mineralocorticoid therapy, particularly in the third trimester
    5. Labor and delivery (Lo and Grumbach 2001)
        1. Require stress doses of glucocorticoid therapy during labor and delivery
        2. Elective cesarean section considered for pregnant women with virilizing CAH, for cephalopelvic disproportion due to android pelvic characteristics and especially for those who have had reconstructive surgery of the external genitalia
    6. Evaluation of the infant (Lo and Grumbach 2001)
        1. Clinical signs of adrenal suppression (hypotension, hypoglycemia), particularly in cases in which dexamethasone was administered during pregnancy

2. Sign of ambiguous external genitalia
3. Female pseudohermaphroditism secondary to either maternal hyperandrogenism or fetal 21-hydroxylase deficiency (if the father is a carrier)

9. Prenatal therapy (Speiser and New 1994; Pang 1997; Ritzén 2001; Turcu and Auchus 2015)
   1. Encouraging results from prenatally treating congenital adrenal hyperplasia due to 21-hydroxylase deficiency (David and Forest 1984)
      1. Hydrocortisone treatment: fetal adrenal suppression was only partial with slightly abnormal external genitalia
      2. Dexamethasone treatment: fetal adrenal suppression was achieved with normal external genitalia at birth (New 2001a)
   2. Prenatal treatment significantly reduces or eliminates virilization in the newborn female (New et al. 2001) and spares the newborn female the consequences of genital ambiguity, genital surgery, sex misassignment, and gender confusion (New 2001b)
   3. Inclusion criteria (Clayton et al. 2002)
      1. A previously affected sibling or first-degree relative with known mutations causing classic CAH, proven by DNA analysis
      2. Reasonable expectation that the father is the same as the father of the proband
      3. Availability of rapid, high-quality genetic analysis
      4. Therapy started less than 9 weeks after the last menstrual period
      5. No plans for therapeutic abortion
      6. Reasonable expectation of patient compliance
   4. Dexamethasone
      1. No salt-retaining activity
      2. Not significantly metabolized by placental 11β-hydroxysteroid dehydrogenase
      3. Able to cross the placenta
   5. Administer oral dexamethasone to the mother in pregnancies at risk for a female child affected with virilizing adrenal hyperplasia
      1. To suppress fetal adrenal androgen production, beginning after conception and before the 7–8th week of gestation, to prevent ambiguity of the external genitalia in the female fetus with classic CAH
      2. To prevent progression of virilization on therapy after 7–8th week of gestation
      3. Short-term outcomes of children exposed to dexamethasone in utero indicate no significant adverse effects (Hughes 2002a)
      4. Chromosome analysis from fetal cells obtained from either CVS at 10–12 weeks of gestation or amniocentesis at 14–18 weeks of gestation
      5. If the fetus is a female, additional molecular genetic testing is performed on the sample to determine if she has 21-hydroxylase deficiency (Antal and Zhou 2009)
      6. If the fetus is affected, maternal dexamethasone administration is continued to term; if not, it can be discontinued
   6. Outcome of prenatally treated females (American Academy of Pediatrics 2000)
      1. Approximately 70% born with normal or only slightly virilized genitalia with clitoromegaly, partial labial fusion, or both
      2. Approximately 30% born with marked genital virilization
   7. Disadvantage: 7 out of 8 fetuses unnecessarily treated since CAH is inherited as an autosomal recessive disease and only affected girls benefit from the treatment
   8. Prompt discontinuation of dexamethasone therapy to minimize potential risks of glucocorticoid toxicity if (White 2001):
      1. Male sex determination by prenatal genetic diagnosis

2. *CYP21* genotype indicating that the fetus is unaffected
9. Refer patient to centers with expertise in the prenatal management of pregnancies at risk for CAH
10. Long-term follow-up studies still needed for prenatally treated children
11. Side effects of women treated to term (10%)
    1. Features of Cushing syndrome (excessive weight gain, severe striae, hypertension, hyperglycemia)
    2. Resolved when the treatment is discontinued
12. Side effects of women treated for a shorter time (10–20%)
    1. Edema
    2. Gastrointestinal upset
    3. Mood fluctuations
    4. Acne
    5. Hirsutism
13. Similar therapeutic approaches: effective in families at risk for 11-β-hydroxylase deficiency, in which affected female fetuses may also suffer severe prenatal virilization
14. Prenatal therapy not appropriate for nonclassic CAH
15. Parents of affected girls
    1. Many opting for prenatal medical treatment because of severe psychological impact of ambiguous genitalia on the child and on the family
    2. Obtain informed consent as to the potential fetal and maternal risks, some of which may yet to be recognized

Fig. 1 (**a**–**c**) Female infants (46,XX) with classic form of CAH showing varying degree of virilization

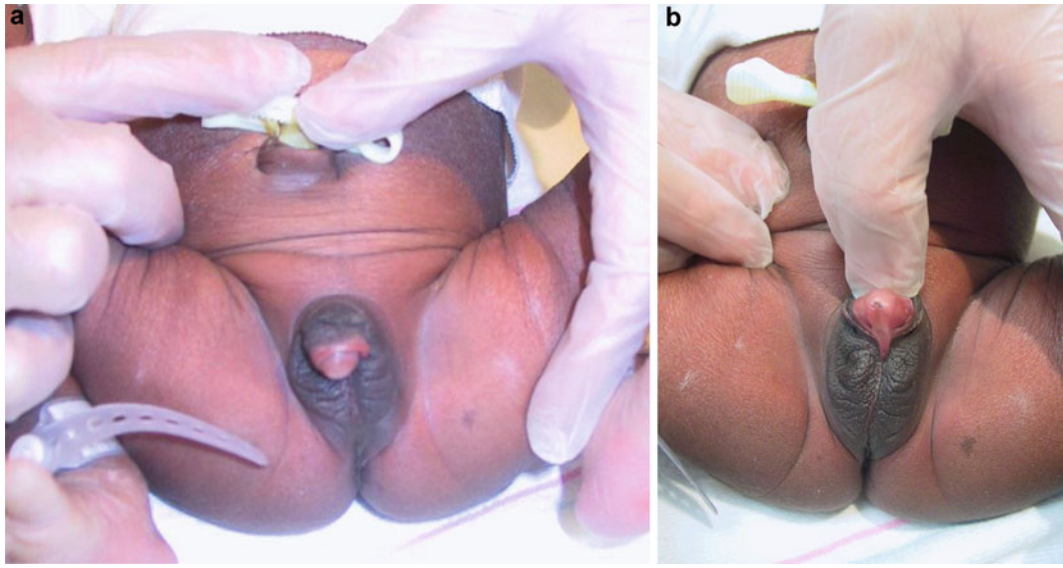

Fig. 2 (**a**, **b**) A newborn with congenital adrenal hyperplasia showing ambiguous genitalia. Newborn screening from filter paper showed total 17OHP of >240 ng/mL (normal <33). A pair of intron 2 mutations were detected by PCR

Congenital Cutis Laxa

Contents

Congenital cutis laxa is a rare inherited connective tissue disorder manifested by inelastic, loose, pendulous skin, giving the appearance of premature aging (Andiran et al. 2002).

Synonyms and Related Disorders

Arterial tortuosity syndrome; Cutis laxa with or without congenital disorder of glycosylation; Cutis laxa, Debre type (cutis laxa with growth and developmental delay); Macrocephaly, alopecia, cutis laxa, and scoliosis syndrome; Occipital horn syndrome/Menkes syndrome; Progeroid syndrome of De Barsy (cutis laxa-corneal clouding-mental retardation syndrome; Urban-Rifkin-Davis syndrome (cutis laxa with severe pulmonary, gastrointestinal, and urinary abnormalities)

Genetics/Basic Defects

1. Genetic heterogeneity of congenital cutis laxa (Beighton 1972, 1974; Berk et al. 2012)
    1. Autosomal recessive cutis laxa (ARCL), a genetically heterogeneous condition: the most common type
        1. Type I (ARCL-I): less frequent than type II
        2. Type IIA (ARCL-IIA) (cutis laxa, Debre type; cutis laxa with growth and developmental delay (Patton et al. 1987); cutis laxa with or without congenital disorder of glycosylation)
        3. Type IIB (ARCL-IIB): cutis laxa with progeroid features
        4. Type III (ARCL-III) (also known as De Barsy syndrome)
        5. Urban-Rifkin-Davis syndrome
        6. Macrocephaly, alopecia, cutis laxa, and scoliosis syndrome
        7. Arterial tortuosity syndrome
    2. Autosomal dominant cutis laxa (ADCL) (Damkier et al. 1991; Fischer-Zimsak et al. 2015)
    3. X-linked recessive cutis laxa (XLCL)
        1. Previously called occipital horn syndrome
        2. At present, best termed as Ehlers-Danlos syndrome type IX
        3. XLCL and Menkes syndrome are allelic, existing along a spectrum, with XLCL,

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_49

representing the mildest form (Tumer and Moller 2009)

2. Biochemical and molecular defects of congenital cutis laxa (Loeys et al. 2002; Berk et al. 2012)
    1. ARCL-I: Molecular studies in a large consanguineous Turkish family demonstrated the presence of a homozygous missense mutation (T998C) in the fibulin-5 (*FBLN5*) gene, resulting in a serine-to-proline (S227P) substitution in the fourth calcium-binding epidermal growth factor-like domain of fibulin-5 protein
    2. ARCL-IIA
        1. Caused by mutation in the ATPase, H + transporting, lysosomal, V0 subunit A2 gene (*ATP6V0A2*)
        2. A combined disorder of N- and O-linked glycosylation has been described in children with congenital cutis laxa in association with severe central nervous system involvement, brain migration defects, seizures, and hearing loss (Morava et al. 2008).
    3. ARCL-IIB: caused by mutation in the *PYCR1* gene (Dimopoulou et al. 2013)
    4. ARCL-III (Fischer et al. 2014)
        1. ARCL-IIIA: caused by mutations in *ALDH18A1*
        2. ARCL-IIIB: caused by mutations in *PYCR1*
    5. URDS: caused by *LTBP4* mutations (Urban et al. 2009)
    6. MACS syndrome: caused by homozygous mutation in the *RIN2* gene (Basel-Vanagaite et al. 2009)
    7. ATS: caused by inactivating mutations in SLC2A10, which encodes GLUT10, a member of the glucose transporter family (Coucke et al. 2006; Callewaert et al. 2008)
    8. Autosomal dominant cutis laxa (Fischer-Zimsak et al. 2015)
        1. Can be caused by mutations in the elastin gene (*ELN*) (Graul-Neumann et al. 2008)
        2. Due to deficiency of lysyl oxidase (Byers et al. 1976, 1980)
        3. Autosomal dominant cutis laxa with progeroid features (ADCL): proposed by Fischer-Zimsak et al. (2015) to distinguish it from *ELN*-ADCL (ADCL2) (Urban et al. 2005; Callewaert et al. 2011) and *FBLN5*-ADCL (ADCL2) (Markova et al. 2003)
    9. X-linked recessive cutis laxa (Byers et al. 1980; Gorlin and Cohen 1990)
        1. Caused by mutations in the *ATP7A* gene
        2. Characterized by diminished activity of lysyl oxidase in the skin from affected males
        3. Reduced serum copper and ceruloplasmin in affected males, suggesting that the lysyl oxidase deficiency may be secondary to a defect in copper metabolism
3. Acquired cutis laxa (Banks et al. 2003)
    1. Drug ingestion: generalized skin involvement associated with the following:
        1. Penicillamine
        2. Penicillin
        3. Isoniazid
        4. Melphalan
        5. Phenacetin
    2. Paraneoplastica: skin manifestation of paraneoplastic syndromes associated with solid or hematogenous neoplasias
        1. Chronic neutrophilic leukemia
        2. Chronic myelogenous leukemia
    3. Postinflammatory: hyperextensible skin lesions with inflammatory infiltrates
        1. Sweet syndrome
        2. Bowel bypass syndrome
        3. Postinflammatory elastolysis and cutis laxa
        4. Marshall syndrome

Clinical Features

1. Autosomal recessive cutis laxa (Gorlin and Cohen 1990; Berk et al. 2012)
    1. More common than the autosomal dominant form
    2. ARCL-I
        1. Abundant facies
        2. Redundant folds around the face and neck

3. An aged appearance
4. Associated with severe systemic complications
    1. Pulmonary emphysema
    2. Diaphragmatic defects
    3. Arterial tortuosity
    4. Aneurysms
    5. Poorest prognosis: Many patients die from pulmonary or cardiac complications in early childhood
5. Muscular hypotonia
6. Joint laxity
7. Umbilical and inguinal hernias
8. Gastrointestinal and vesicourinary tract diverticuli
9. Normal mental and motor development

3. ARCL-II: also called cutis laxa with joint laxity and developmental delay
    1. ARCL-IIA (Van Maldergem et al. 2015)
        1. Furrowing of the skin of the whole body, particularly obvious in neck, axillae, and groin
        2. Droopy skin on the cheeks of the face and marked nasolabial folds, giving rise to distinctive facial features that also include prominent large nasal root, downslanted palpebral fissures, and delayed closure of the fontanelles
        3. Skin when extended does not display marked hyperelasticity but rather maintains its consistency and pretibial pseudo-ecchymotic skin lesions (as is observed in the Ehlers-Danlos syndromes) (Greally et al. 2014)
        4. Frequent motor nervous system abnormalities
        5. Cardiovascular abnormalities
        6. Patent anterior fontanel
        7. Congenital hip dislocation
        8. Inguinal hernias
        9. High myopia
        10. Bruch's membrane rupture
        11. Female predominance
    2. ARCL-IIB (Dimopoulou et al. 2013)
        1. Wrinkled inelastic skin, especially on the dorsal acral surfaces and abdomen
        2. Thin/translucent skin
        3. Triangular dysmorphic facies with progeroid appearance, bulbous nose, prognathism, hypotelorism, epicanthal folds, blue sclera, large ears, and microcephaly
        4. Intrauterine and postnatal growth retardation and developmental delay
        5. Hypotonia
        6. Microcephaly
        7. Blue sclera
        8. Cataract/corneal clouding
        9. Joint hyperlaxity
        10. Hip dislocation
        11. Osteoporosis/osteopenia
        12. Finger contractures
        13. Athetoid movements
4. ARCL-III (De Barsy syndrome) (de Barsy et al. 1968; Gorlin and Cohen 1990; Andiran et al. 2002; Morava et al. 2009; Fischer et al. 2014)
    1. The most severe disease of the autosomal recessive cutis laxa spectrum
    2. Thin and translucent skin, visibility of the veins
    3. A specific facial gestalt with triangular face and prognathism resulting in a progeroid appearance. Additionally, affected individuals show skeletal abnormalities
    4. Ophthalmological abnormalities
        1. Corneal clouding due to degeneration of the tunica elastica of the cornea
        2. Bilateral corneal opacification
    5. Intrauterine growth retardation
    6. Considerable intellectual disability in the majority of cases [9,10].
    7. Muscular hypotonia
    8. Reduced subcutaneous fat
    9. Athetoid movements early in life
    10. Hypermobility of small joints
5. Urban-Rifkin-Davis syndrome (Urban et al. 2009)
    1. Cutis laxa
    2. Severe respiratory complications: often fatal during infancy including emphysema, atelectasis, tracheomalacia, and diaphragmatic hernia

3. Gastrointestinal distension, diverticulosis, stenoses, and tortuosities
6. Macrocephaly, alopecia, cutis laxa, and scoliosis (MACS) syndrome (Basel-Vanagaite et al. 2009; Albrecht et al. 2010; Syx et al. 2010)
   1. Caused by mutations in the *RIN2* gene
   2. Very characteristic, discriminatory facial features with sagging chin and severe developmental delay.
   3. Described in an Israeli-Arab family with age-dependent redundant skin, macrocephaly, down-slanting palpebral fissures, droopy eyelids, everted lips, gingival hypertrophy, dental anomalies, sparse hair, joint hypermobility, scoliosis, and high-pitched voice
   4. There were no ocular, neurologic, or respiratory abnormalities.
7. Arterial tortuosity syndrome
   1. Characterized by elongation and tortuosity of major arteries and variable skin laxity. (Beuren et al. 1969; Gardella et al. 2004)
   2. Distinctive complications include vascular aneurysms, dissections, and stenoses (Zaidi et al. 2005; Callewaert et al. 2008)
   3. Death may occur in early childhood (Wessels et al. 2004) although milder phenotypes have been described (Callewaert et al. 2008)

2. Autosomal dominant cutis laxa (Hadj-Rabia et al. 2013)
   1. Less common than the autosomal recessive form
   2. Skin laxity (100%)
   3. Clinical features presenting in infancy (Andiran et al. 2002)
      1. Intrauterine growth retardation
      2. Delayed fontanelle closure
      3. Ligamental laxity
      4. Episodes of edema may precede the skin changes, usually within the first 2 months of life.
      5. Aging appearance by the end of the second year
      6. Pulmonary emphysema common (37%) due to a loss of elastic tissue in the lungs
      7. Aortic root dilatation (55%)
      8. Inguinal hernias (51%)
   4. Skin changes presenting in adulthood
      1. Usually no internal defects
      2. Having a normal life expectancy
   5. Aging appearance
      1. Drooping of eyelids
      2. Sagging facial skin
      3. Accentuation of the nasolabial and other facial folds
      4. Often hooked nose with everted nostrils
      5. Long philtrum
   6. Few complications
      1. Hoarseness
      2. Pulmonary artery stenosis
      3. Mitral valve prolapse
      4. Bronchiectasis
      5. Joint dislocations
      6. Tortuosity and dilatation of carotid arteries and aorta
      7. Dilatation of sinuses of Valsalva
      8. Coarctation of the aorta
   7. Normal life span
3. X-linked recessive cutis laxa (Brown et al. 1982; Berk et al. 2012)
   1. Known as occipital horn syndrome, formerly classified as Ehlers-Danlos syndrome type IX (Please see the chapter on "► Ehlers-Danlos Syndrome"), and allelic to Menkes syndrome (Please see the chapter on "► Menkes Disease")
   2. Hyperextensible wrinkled skin with droopy facies at birth
   3. Mainly with connective tissue problems
      1. Long and thin face, neck, and trunk
      2. Mild hyperelastic (but not lax) and bruisable skin with resultant atrophic scars
      3. Inferior cranial spurs (occipital horns)
         1. A constant feature
         2. May be palpated or found on radiographs
         3. May become larger with age
         4. May represent ectopic bone formation within the trapezius and sternocleidomastoid aponeuroses
      4. Skeletal dysplasia most prominent at the wrists and elbows

5. Limitation of extension of the elbows, shoulders, knees
6. Hypermobility of the finger joints
7. Pes planus
8. Genu valga
9. Pectus excavatum or carinatum (40%)

4. Obstructive uropathy secondary to bladder diverticula with bladder neck obstruction (60–70%)
5. Various hernias (hiatal, femoral, and inguinal) (35%)
6. Chronic diarrhea (40%)
7. Coarse, kinky hair with pili torti can be observed

4. Clinical and biochemical features guiding the diagnostics in neurometabolic cutis laxa (Gardeitchik et al. 2014)
   1. Abnormal glycosylation and gyration abnormalities: mostly, but not always associated with *ATP6V0A2* mutations
   2. Epilepsy: most common in *ATP6V0A2* defects
   3. Corpus callosum dysgenesis: associated with *PYCR1* and *ALDH18A1* mutation
   4. Dystonic posturing: discriminatory for *PYCR1* and *ALDH18A1* defects
   5. Metabolic markers of mitochondrial dysfunction: found in one patient with *PYCR1* mutations
   6. White matter abnormalities: associated with *GORAB* and *RIN2* mutations
   7. Migration defects and corpus callosum hypoplasia: not always diagnostic for a specific genetic defect in cutis laxa
   8. All patients with *ATP6V0A2* defects had abnormal glycosylation
   9. Central nervous system and metabolic abnormalities in cutis laxa: discriminatory in this genetically heterogeneous group, although not always diagnostic for a certain genetic defect
5. Differential diagnosis: syndromes featuring lax or wrinkled skin (Berk et al. 2012)
   1. Wrinkling skin syndrome
      1. A rare autosomal recessive disorder of the connective tissue: *ATPV0A2* mutations
      2. Cutaneous findings
         1. Wrinkled skin over abdomen and on the dorsum of the hands and feet
         2. Poor skin elasticity in affected areas
         3. Increased palmar and plantar creases
         4. A prominent venous pattern on the chest
      3. Other predominant findings
         1. Mental retardation
         2. Microcephaly
         3. Hypotonia
         4. Musculoskeletal abnormalities
   2. Geroderma osteodysplasticum
      1. An autosomal recessive disorder: caused by mutations in *SCYL1BP1*
      2. Also caused by *GORAB* mutations involving Golgi apparatus function
      3. Cutaneous findings
         1. Lax, nonhyperelastic skin, most prominent over extremities
         2. Premature aging
      4. Other predominant findings
         1. Frequent bone fractures
         2. Joint luxations
   3. Cantu syndrome
      1. An autosomal dominant disorder
      2. Cutaneous findings
         1. Hypertrichosis
         2. Wrinkled palms and soles
      3. Other predominant findings
         1. Delayed psychomotor development
         2. Short stature
         3. Large head
         4. Peculiar facies
         5. Cardiac abnormalities
         6. Mild mental retardation
         7. Osteochondrodysplasia
   4. Costello syndrome (Davies and Hughes 1994)
      1. An autosomal recessive disorder: caused by *HRAS* mutations
      2. Cutaneous findings
         1. Cutis laxa most prominent over palms, soles, and neck
         2. Coarse craniofacial appearance

3. Papillomata around mouth, nares, and anus
3. Other predominant findings
1. Postnatal growth retardation
2. Cardiovascular abnormalities
3. Mental retardation

5. SCARF syndrome (Koppe et al. 1989)
1. An X-linked recessive disorder
2. Cutaneous findings
1. Cutis laxa
2. Webbed neck
3. Other predominant findings
1. Facial abnormalities: multiple hair whorls, epicanthal folds, ptosis, high and broad nasal root, low-set and posteriorly rotated ears, and small chin
2. Mild to moderate psychomotor retardation
3. Wide-spaced nipples
4. Diastasis recti
5. Umbilical and inguinal herniae
6. Craniostenosis
7. Enamel hypoplasia and hypocalcification of the teeth
8. Short sternum
9. Pectus carinatum
10. Abnormally shaped vertebrae
11. Abnormal modeling of long tubular bones
12. Ambiguous genitalia: micropenis, perineal hypospadias

6. Williams syndrome (Please see the chapter of "► Williams Syndrome")

7. Patterson syndrome (pseudoleprechaunism)
1. Cutaneous findings
1. Cutis gyrata of hands and feet
2. Bronze hyperpigmentation
2. Other predominant findings
3. Hyperadrenocorticism
4. Diabetes mellitus
5. Bladder diverticuli
6. Severe mental retardation
7. Major bony deformities

8. Hutchinson-Gilford syndrome
1. An autosomal dominant disorder: caused by *LMNA* mutations
2. Cutaneous findings
1. Wrinkled aged-looking skin
2. Loss of subcutaneous fat
3. Alopecia
3. Other predominant findings
1. Progeria
2. Short stature
3. Micrognathia
4. Craniofacial disproportion
5. Joint stiffness

9. Kabuki syndrome (Please see the chapter of "► Kabuki Syndrome")

10. Barber-Say syndrome
1. Cutaneous findings
1. Redundant, lax skin
2. Generalized hypertrichosis
3. Ectopion of eyelids
2. Other predominant findings
1. Ambiguous genitalia
2. Macrostomia

11. Congenital hemolytic anemia with emphysema and cutis laxa
1. An autosomal recessive disorder
2. Cutaneous finding: cutis laxa
3. Other predominant findings
1. Hemolytic anemia
2. Emphysema
3. Hemorrhagic necrosis of adrenals

12. Hereditary gelsolin amyloidosis (amyloidosis V)
1. An autosomal dominant disorder
2. Cutaneous finding: skin laxity
3. Other predominant findings
1. Corneal lattice dystrophy
2. Cranial and peripheral polyneuropathy

13. Ablepharon macrostomia syndrome
1. An autosomal recessive disorder
2. Cutaneous findings
1. Redundant, lax skin
2. Absence or hypoplasia of eyelids
3. Other predominant findings
1. Ambiguous genitalia
2. Abnormal ears
3. Rudimentary nipples
4. Macrostomia

14. Lenz-Majewski hyperostotic dwarfism
1. An autosomal dominant disorder

2. Cutaneous findings
    1. Thin, wrinkled, and atrophic skin
    2. Prominent cutaneous veins
3. Other predominant findings
    1. Delayed closure of fontanelle
    2. Mental retardation
    3. Progressive skeletal sclerosis with severe growth retardation

15. GAPO (growth retardation, alopecia, pseudoanodontia (failure of tooth eruption), and progressive optic atrophy) syndrome (Tipton and Gorlin 1984)
    1. An autosomal recessive disorder
    2. Cutaneous finding: redundant skin
    3. Other predominant findings
        1. Growth retardation
        2. Alopecia
        3. Pseudoanodontia
        4. Optic atrophy
        5. Facial dysmorphism
        6. Short stature
        7. Glaucoma
16. Ehlers-Danlos syndrome (classic type) (Please see the chapter of "▶ Ehlers-Danlos Syndrome")
17. Pseudoxanthoma elasticum
    1. An autosomal recessive disorder: caused by *ABCC6* mutations
    2. Cutaneous findings
        1. Lax skin with redundant folds in affected areas
        2. Yellowish papules coalescing to plaques on neck and flexural areas
    3. Other predominant findings
        1. Angioid streaks
        2. Cardiovascular disease

Diagnostic Investigations

1. Radiography
    1. Autosomal recessive cutis laxa
        1. Presence of a variety of hernias
            1. Femoral
            2. Inguinal
            3. Obturator
            4. Hiatal
        2. Eventrations of the diaphragm
        3. Rectal and uterine prolapse
        4. Common intrathoracic abnormalities
            1. Hyperexpansion of the lungs
            2. Emphysema which may lead to cor pulmonale and death in childhood
            3. Upper airway obstruction caused by excessively lax vocal cords, leading to congestive heart failure
            4. Frequent peripheral pulmonary artery stenosis and aortic dilatation
        5. Diverticula involving the entire bowel but no functional significance
        6. Diverticula of the urinary tract predisposing to infection or causing obstruction
        7. Arteriographic changes
            1. Peripheral pulmonary stenosis
            2. Dilatation and tortuosity of the aorta
            3. A peculiar corkscrew appearance of the peripheral systemic arteries, similar to the arterial changes seen in Menkes syndrome
    2. X-linked recessive cutis laxa (Gorlin and Cohen 1990)
        1. Occipital exostosis (horns) symmetrically located on each side of the foramen magnum
        2. Short clavicles with a widened medullary cavity
        3. Hammer-shaped distal extremities
        4. Focal hyperostosis of the femora at sites of tendon and ligament insertion
        5. Carpal fusion involving capitate-hamate and trapezium-trapezoid coalescence (over 50%)
        6. Deformation of humerus, radius, ulna, tibia, and fibula (90%)
        7. Osteoporosis (70%)
        8. Narrowing of rib cage (65%)
        9. Dislocation of radial head (40%)
        10. Mild platyspondyly
        11. Coxa valga
        12. Flattening of acetabular roofs
    2. Histopathological abnormality: fragmentation and paucity of elastic fibers in the skin

3. X-linked cutis laxa
    1. Nonmolecular testing
        1. Low serum copper concentration
        2. Low serum ceruloplasmin concentration
        3. Copper transport studies in cultured fibroblasts: impaired cellular copper exodus demonstrated by increased cellular copper retention in pulse-chase experiments with radiolabeled copper
        4. Plasma and CSF catecholamine analysis: abnormal levels reflecting partial deficiency of dopamine-beta-hydroxylase, a copper-dependent enzyme critical for catecholamine biosynthesis
        5. Low activity of a copper-dependent enzyme, lysyl oxidase
    2. Molecular genetic testing
        1. Mutation analysis: multiplex PCR analysis, available on a clinical basis, to detect large *ATP7A* deletions
        2. Sequence analysis: direct sequence analysis of the *ATP7A* coding region and flanking intron sequences, available on a clinical basis
        3. Mutation scanning: heteroduplex analysis, available on a clinical basis, to detect small mutations

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. Autosomal recessive cutis laxa: 25%
        2. Autosomal dominant cutis laxa: not increased unless a parent is affected
        3. X-linked recessive cutis laxa:
            1. When the mother is a carrier: 50% risk of brother will be affected and 50% of sisters carriers
            2. When mother is not a carrier: the recurrence risk is low but greater than that for the general population because the risk of germline mosaicism in mother is not known.
    2. Patient's offspring
        1. Autosomal recessive cutis laxa: not increased unless the spouse is a carrier or affected
        2. Autosomal dominant cutis laxa: 50%
        3. X-linked recessive cutis laxa: Males with occipital horn syndrome will pass the disease-causing gene to all of their daughters and none of their sons.
2. Prenatal diagnosis
    1. DNA-based analysis on fetal DNA obtained from amniocentesis or CVS for the previously characterized disease-causing mutation
    2. Fetal sex determination for X-linked recessive cutis laxa (occipital horn syndrome)
    3. Preimplantation genetic diagnosis may be an option for some families in which the pathogenic variants have been identified (Van Maldergem et al. 2015)
3. Management (Nahas et al. 1999; Strohecker 1995)
    1. Supportive therapy: antibiotic prophylaxis for bladder infection
    2. Surgery for bladder diverticula
    3. Plastic surgery (Beighton et al. 1970) to improve aging appearance
        1. Serial excisions of the skin
        2. Blepharoplasty
        3. Rhytidectomy
        4. Rhinoplasty
        5. Shortening of the upper lip
        6. Earlobe reduction
        7. Neck lift
        8. Correction of lower eyelid laxity, epiphora, and upper eyelid ptosis

Congenital Cytomegalovirus Infection

Contents

Congenital cytomegalovirus infection is the most common congenital infection in neonates in the USA, affecting approximately 0.5–1.5% of all live births and 30,000–40,000 newborns annually. Congenital infections result from transplacental transmission of cytomegalovirus (CMV).

Synonyms and Related Disorders

Intrauterine cytomegalovirus infection of fetus

Genetics/Basic Defects

1. Human cytomegalovirus (HCMV) (Griffiths et al. 2015)
    1. A DNA virus belonging to the herpesvirus group (herpes simplex, varicella zoster, Epstein-Barr) (Brown and Abernathy 1998).
    2. Ability of the virus (Pass 2002).
        1. To destroy host cells (lytic infection)
        2. To infect a wide range of cells and tissues
        3. To evade and interfere with host defense mechanisms
        4. To persist indefinitely in the host
        5. To infect and destroy cells during productive infection (with release of progeny virus)
    3. HCMV: a recognized cause of disease in the fetus, the allograft recipient, and AIDS patients.
    4. More recently, it has been recognized as a pathogen for those admitted to intensive care units, for the elderly, and for the general population.
2. Transmission of CMV (Del Pizzo 2011)
    1. Horizontal transmission: close intimate contact with another person shedding the virus in body fluids (saliva, blood, cervical secretions, semen, urine, or respiratory droplets)
    2. Vertical transmission: from mother to infant
        1. In utero by transplacental passage of maternal blood-borne virus.
        2. At birth by passage through an infected maternal genital tract.
        3. Postnatally by ingestion of CMV-positive human milk from seropositive mothers.
        4. Mothers who have been exposed to CMV before pregnancy are still at risk for transmitting the infection to the fetus by way of reactivation or infection with a

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_50

new strain. However, maternal infection before pregnancy and subsequent development of immunity significantly decrease the risk of congenital CMV.
   3. Infected organ or bone marrow transplantation
   4. Infected blood transfusion from CMV-seropositive donors
3. Primary sources of CMV infection for women of childbearing age
   1. Young children
   2. Sexual contacts
4. Classifications of CMV (Mestas 2016)
   1. Primary CMV (first experience): primary maternal CMV infection during pregnancy presents the greatest danger to the fetus.
   2. Secondary CMV (recurrent or reactivated CMV infection): In secondary maternal CMV infection during pregnancy the presence of maternal anti-CMV antibodies offers substantial protection against congenital infection and presents much less danger to the fetus with much lower transmission rates (Guerra et al. 2000).
   3. Congenital CMV: CMV that has been transmitted from the mother to the fetus during pregnancy.
   4. Perinatal CMV: CMV acquired during the intrapartum period such as during delivery, via cervical secretions or maternal blood exposure.
   5. Postnatal CMV: CMV acquired after delivery, such as that acquired via maternal breast milk.
5. The most common vertically transmitted viral infection from mother to fetus in pregnancy
   1. Recurrent infection: 1% risk of vertical transmission
   2. Primary infection
      1. Pose a 30–40% risk of vertical transmission, and adverse outcome is more likely when infection occurs within the first half of gestation (Stagno et al. 1986).
      2. Congenital CMV infection resulting from primary maternal infection: more likely to be serious than that resulting from recurrent infection (Stagno et al. 1982).
      3. Congenital CMV infection acquired from primary maternal infection with normal fetal imaging: associated with a high rate of subtle signs and symptoms after birth (Amir et al. 2016).
6. Greatest risk occurring with infection during the first 22 weeks of gestation
7. Congenitally infected newborns: may shed the virus for many years
8. Perinatal CMV infection acquired during birth or from mother's milk: not associated with newborn illness or CNS sequelae, except perhaps in very preterm newborns who have very low levels of passively acquired CMV antibody at the time of infection

Clinical Features

1. Symptomatic at birth in 5–10% of congenital CMV infections (Enders et al. 2001).
   1. Approximately 20% of these will die.
   2. Ninety percent of survivors will develop major neurological sequelae.
2. Asymptomatic or "silent" congenital infections at birth in vast majority (85–90%) of cases. Ten to fifteen percent of the asymptomatic newborns will be afflicted by late sequelae such as mental retardation, deafness, or hearing defects, usually during the first 2 years of life (Enders et al. 2001).
3. Non-neurologic symptoms at birth.
   1. Prematurity
   2. Small size for gestation
   3. Petechiae (most common non-neurologic symptom)
   4. Blueberry muffin rash
   5. Thrombocytopenia
   6. Purpura
   7. Ecchymoses
   8. Hepatosplenomegaly
   9. Jaundice
   10. Intrauterine growth retardation
   11. Chorioretinitis
   12. Pneumonitis
   13. Anemia
   14. Nonimmune hydrops

4. Neurologic symptoms at birth.
    1. Hypotonia
    2. Lethargy
    3. Jitteriness
    4. Split sutures
    5. Immature primitive reflexes
    6. Feeding difficulties
    7. Microcephaly: the most specific predictor of mental retardation and major motor disability
    8. Seizures
5. Eye manifestations (Coats et al. 2000; Metz 2001).
    1. Chorioretinitis resulting in a chorioretinal scar
    2. Corneal opacities
    3. Bilateral anterior polar cataracts
    4. Optic nerve hypoplasia and optic nerve coloboma
    5. Strabismus
    6. Visual impairment
    7. Cyclopia (Byrne et al. 1987) and anophthalmia
6. Later neurologic symptoms.
    1. Sensorineural hearing loss
        1. Likely caused by asymptomatic congenital CMV infection (Fowler et al. 1997)
        2. Underscores the importance of congenital cytomegalovirus as a cause of sensorineural hearing loss in childhood (Goderis et al. 2014)
    2. Learning disability
    3. Mental retardation
    4. Cerebral palsy
7. Atypical findings in preterm infants rarely reported in term infants (Perlman and Argyle 1992).
    1. Hypotonia
    2. Multiple contractures
    3. Periventricular leukomalacia
    4. Optic atrophy
8. Prognosis.
    1. Neonatal clinical abnormalities expected to resolve spontaneously within weeks, except for those involving the CNS and hearing.
    2. Neonates with symptomatic congenital CMV infection have a multisystem disease with significant morbidity and mortality (Boppana et al. 1992).
    3. A leading cause of mental retardation and sensory impairment (50–90% of symptomatic newborns) and sensorineural hearing loss (7–15% of asymptomatic infants).
    4. An important cause of cerebral palsy and retinal damage.
    5. Children with postnatal microcephaly, postnatal seizures, and an abnormal central nervous system imaging study: more likely to have severe developmental sequelae (Bale et al. 1990).
9. Long-term sequelae of congenital cytomegalovirus infection in children with and without symptoms at birth (Sharon and Schleiss 2007; Schleiss 2008).
    1. Overall incidence
        1. Symptomatic: 50–90%
        2. Asymptomatic: 10–15%
    2. Hearing loss
        1. Symptomatic: 50–60%
        2. Asymptomatic: 7–15%
    3. Cognitive deficits
        1. Symptomatic: 50–70%
        2. Asymptomatic: ~4%
    4. Microcephaly
        1. Symptomatic: 35–40%
        2. Asymptomatic: ~2%
    5. Ocular abnormalities
        1. Symptomatic: 25–50%
        2. Asymptomatic: ~3%
    6. Seizures
        1. Symptomatic: 15–20%
        2. Asymptomatic: ~1%
    7. Mild to moderate motor deficits
        1. Symptomatic: 25–30%
        2. Asymptomatic: <1%
    8. Severe motor deficits
        1. Symptomatic: 15–25%
        2. Asymptomatic: <1%
10. Maternal primary CMV infection.
    1. Asymptomatic: vast majority of pregnant women
    2. Symptomatic (mononucleosis-like syndrome) in approximately 10% of infected pregnant patients
        1. Fever
        2. Fatigue/malaise
        3. Myalgia

4. Pharyngitis
5. Cough
6. Nausea
7. Headache

Diagnostic Investigations

1. Children with symptomatic congenital CMV infection (Istas et al. 1995; Pass 2002; Bonalumi et al. 2011)
    1. Virus detection by PCR amplification in the urine or saliva samples (Joseph et al. 2013)
    2. Elevated alanine aminotransferase (ALT >80 IU/mL)
    3. Thrombocytopenia (<100,000 cells/mcL)
    4. Conjugated hyperbilirubinemia (direct bilirubin >2 mg/dL)
    5. Anemia
    6. Elevated CSF protein (>120 mg/dL)
2. Diagnostic tests for identification of CMV infection in mother, fetus, and newborn infants (Naing et al. 2016)
    1. Prenatal
        1. Maternal CMV: IgM positivity
        2. IgM/IgG serology: IgG seroconversion, low IgG avidity
        3. Qualitative CMV-PCR (amniotic fluid): CMV-DNA positive
        4. Real-time PCR (amniotic fluid): CMV-DNA positive, with high viral load ($>10^4$ copies/mL)
        5. Fetal ultrasound: fetal abnormalities (cerebral ventriculomegaly, echogenic bowel, intrauterine growth restriction)
    2. At birth
        1. Maternal CMV-IgM/IgG serology: IgM detection, IgG seroconversion, and low IgG avidity
        2. Qualitative CMV-PCR (cord blood, infant urine, placenta/infant saliva): CMV-DNA positive
        3. Real-time PCR (cord blood, infant urine, placenta/infant saliva): CMV-DNA positive, with high viral load ($>10^4$ copies/mL)
3. Ultrasonography (Crino 1999; Lipitz et al. 2002; Malinger et al. 2003, 2011; Bonalumi et al. 2011)
    1. Fetal growth restriction
    2. Cerebral ventriculomegaly
    3. Increased periventricular echogenicity
    4. Periventricular pseudocysts and intraventricular synechiae
    5. Ascites
    6. Intracranial calcifications
    7. Abnormality of amniotic fluid volume (usually oligohydramnios)
    8. Microcephaly
    9. Hyperechogenic bowel
    10. Hydrops fetalis
    11. Pleural effusion
    12. Liver calcifications
4. Radiography
    1. Intracranial calcification: usually periventricular (Roach et al. 1983)
    2. Microcephaly
5. CT scan
    1. Intracerebral calcification: the most frequent finding (Boppana et al. 1997)
    2. Microcephaly: the most specific predictor of poor cognitive outcome in children with symptomatic congenital CMV infection (Noyola et al. 2001)
    3. White matter lucencies
    4. Ventriculomegaly
    5. Destructive encephalopathy
    6. Brain atrophy
    7. Neuronal migration disorders
6. Fetal MRI (Doneda et al. 2010; Averill et al. 2015)
    1. Anterior temporal cysts and occipital horn septations, as dilation of these areas may decrease later in development.
    2. Cortical migration abnormalities.
    3. White matter abnormalities.
    4. Cerebellar dysplasia.
    5. Periventricular calcifications.
    6. Fetal MR imaging can show abnormalities in the fetal brain after CMV infection, even when US results are normal. The early detection of some brain

abnormalities, such as microencephaly and cortical anomalies, may substantially influence the prognosis of fetal infection.

7. Neonatal auditory screening (Hicks et al. 1993)
8. Evidence of infection with CMV
    1. Fourfold rise in anti-CMV IgG titers.
    2. Seroconversion from negative to positive.
    3. Sensitivity of the CMV-IgM assays (50–90%). The IgM titers may not become positive during acute infection.
9. Viral isolation
    1. The most sensitive method to diagnose CMV infection
    2. Culture of CMV from virtually all body fluids, including saliva and urine of the newborn, semen, and cervicovaginal secretions
    3. Detection of CMV within the first 3 weeks of life: considered proof of congenital CMV infection
10. Identification of CMV-DNA through PCR on amniotic fluid (best sensitivity and 100% specificity) (Lazzarotto et al. 2000; Liesnard et al. 2000)
11. Newborn screening for congenital cytomegalovirus infection (Bale 2010)
    1. Universal screening methods by using polymerase chain reaction (PCR) analysis of newborn dried blood spots (Boppana et al. 2010).
    2. Cytomegalovirus infection.
        1. Accounts for as much or more disability over the past 50 years than was associated with congenital rubella syndrome
        2. Represents the most common nongenetic cause of permanent hearing loss among children in the USA
    3. The most effective strategy for reducing CMV-induced sensorineural hearing loss, as well as for eliminating CMV-associated neurodevelopmental disability, will not be universal screening but prevention of congenital CMV infection (Pass et al. 2009).

Genetic Counseling

1. Recurrence risk
    1. Preconceptional immunity to CMV provides substantial protection against intrauterine transmission and severe fetal infection.
    2. Presence of maternal humoral antibody: conferring no fetal protection in subsequent reinfection or reactivation.
2. Prenatal diagnosis
    1. Prenatal ultrasonography.
        1. Intrauterine growth retardation
        2. Microcephaly
        3. Ventriculomegaly
        4. Periventricular calcifications
        5. Intrahepatic calcifications
        6. Nonimmune hydrops
        7. Fetal ascites
        8. Pericardial effusion
        9. Hepatosplenomegaly
        10. Echogenic bowel
        11. Cardiomegaly
        12. Oligohydramnios
        13. Placentomegaly
    2. Prenatal diagnosis of congenital CMV infection by combined detection of CMV-DNA and CMV-IgM in fetal blood or by combined testing of AF and fetal blood for CMV-DNA and IgM antibodies (sensitivity of 100%) (Enders et al. 2001) or isolating the virus from amniotic fluid (Plosa et al. 2012).
    3. Prenatal diagnosis: established by serological tests in umbilical cord blood and confirmed by detection of viral DNA in fetal blood and tissues from the postmortem specimen after termination of pregnancy (Beksaç et al. 2001).
    4. Negative results of CMV culture or PCR in the amniotic fluid cannot formally exclude intrauterine infection (Bodéus et al. 1999).
    5. Prenatal diagnosis of CMV infection remains a "long-standing problem still seeking a solution" as long as no assistance (treatment or prevention) can be offered to the pregnant women.

6. Amniotic fluid peptidome analysis: effectively predict the severity of congenital CMV infection (Desveaux et al. 2016).

3. Management
   1. Prevention.
      1. Complicated because both primary and secondary maternal infections give rise to disease in the offspring and absence of characteristic symptoms in CMV-infected mothers excludes clinical recognition of at-risk pregnancies
      2. Routine screening of pregnant patients for CMV status: not currently recommended because no effective antiviral therapy is available during gestation and also there is no means to predict the outcome in an infected fetus
      3. Risk to CMV infection for women in high-risk environments (day-care centers, nurseries, elementary schools, or health-care facilities)
      4. Strict hygiene practices for seronegative women to reduce the risk for the infection
   2. Prospects of intervention (Cheeran et al. 2009).
      1. Antiviral drugs (Ganciclovir, Valganciclovir, Foscarnet, Cidofovir, CMV immune globulin) are available for treatment of congenital CMV infection (Plosa et al. 2012), and there is evidence that therapy ameliorates the severity of one of the CNS complications of infection, sensorineural hearing loss. Long-term neurodevelopmental follow-up studies should further clarify the value of antiviral therapy in congenitally infected infants.
      2. Uncontrolled studies of therapy in utero with CMV immune globulin have suggested an impact on neuropathogenesis, and controlled trials should be conducted with pregnant women.
      3. CMV vaccines (Pass et al. 2009; Bale 2010) may hold the greatest promise in reducing the neurodevelopmental consequences of congenital infection, although the immune correlates of protection of the fetus remain incompletely defined.
      3. Recent progress in developing novel antiviral drugs and vaccines suggests the possibility that the diverse effects of HCMV may soon become controllable at the individual and population level, respectively (Griffiths et al. 2015).

Congenital Generalized Lipodystrophy

Contents

Congenital generalized lipodystrophy (CGL), also called Berardinelli-Seip syndrome (BSCL) (Berardinelli 1954; Seip 1959; Seip and Tryqstad 1963, 1996), is an extremely rare genetic disorder characterized by extreme paucity of adipose tissue from birth, extreme insulin resistance, hypertriglyceridemia, hepatic steatosis, and early onset of diabetes (Agarwal et al. 2002). Its prevalence is estimated to be 1 in 200,000 (Portugal) to 1 in 12 million people (USA) (Mandal et al. 2006).

Synonyms and Related Disorders

Barraquer-Simons syndrome; Berardinelli-Seip congenital lipodystrophy; Dunnigan syndrome; Köbberling syndrome; Lawrence syndrome

Genetics/Basic Defects

1. Inheritance: autosomal recessive (Garg 2004)
2. Existence of two loci in a gene for congenital generalized lipodystrophy (CGL) (Berardinelli-Seip congenital lipodystrophy) (Heathcote et al. 2002; Magré et al. 2003)
    1. Berardinelli-Seip congenital lipodystrophy 1 (BSCL1)
        1. Identification of the aberrant gene, 1-acylglycerol-3-phosphate *O*-acyltransferase 2 (*AGPAT*2), in patients from several pedigrees in which the lipodystrophy was linked to chromosome 9q34
        2. Several homozygous or compound heterozygous mutations in the *AGPAT*2 gene identified in affected patients
        3. *AGPAT*2 (1-acylglycerol-3-phosphate *O*-acyltransferase 2) (Agarwal et al. 2004)
            1. Encodes the enzyme AGPAT2 that is responsible for the production of an important intermediate in the synthesis of triglycerides or fat (Agarwal and Garg 2003)
            2. Mutations of *AGPAT*2: which may cause CGL by inhibiting the fat synthesis and storage in adipocytes (fat cells)
    2. Berardinelli-Seip congenital lipodystrophy 2 (BSCL2)
        1. Identification of another disease locus (*BSCL*2) which is mapped to chromosome 11q13 (Magré et al. 2001)
        2. Identification of mutations of *BSCL*2 gene in all families linked to 11q13
        3. *BSCL*2 (*Seipin*) gene

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_51

    1. Highly expressive in the brain and testis
    2. Encodes a protein whose function remains unknown
  3. Berardinelli-Seip congenital lipodystrophy X (BSCLX): specific genetic locus that has not been identified (Van Maldergem et al. 2002)
3. Causes of CGL (Garg 2011; Cortés and Fernández-Galilea 2015)
  1. CGL-1: caused by mutations in *AGPAT*2
  2. CGL-2: caused by mutations in *BSCL*2
  3. CGL-3: caused by mutations in *CAV*1, encoding Caveolin 1, which is the main protein component of plasma membrane caveolae and a fatty acid (FA)-binding protein relevant for FA uptake
  4. CGL-4: caused by mutations in *PTRF*, encoding RNA polymerase I and transcript release factor, which enables the dissociation of paused ternary polymerase I transcription complexes from the 3′ end of pre-rRNA transcripts
4. Several other genes that are responsible for different types of inherited lipodystrophies
  1. Lamin A/C (*LMNA*) gene in familial partial lipodystrophy Dunnigan variety (autosomal dominant familial partial lipodystrophy) mapped to 1q21-22
  2. *PPAR-γ* (peroxisome proliferator-activated receptor-γ) gene in autosomal dominant familial partial lipodystrophy
5. The genetic heterogeneity (Rajab et al. 2002) also accompanied by phenotypic heterogeneity (Agarwal et al. 2003; Simha and Garg 2003)
6. Proposed pathogenesis: genetic defect resulting in poor growth and development of metabolically active adipose tissue with preservation of mechanical disposition of the adipose tissue (Garg et al. 1999; Premkumar et al. 2002)

Clinical Features

1. Classification of primary lipodystrophies (Cortés and Fernández-Galilea 2015)
  1. Genetic lipodystrophy
    1. Generalized (Berardinelli-Seip syndrome)
      1. Severe generalized lipoatrophy
      2. Acanthosis nigricans
      3. Hyperphagia
      4. Hyperlipidemia
      5. Hyperinsulinemia
      6. Diabetes mellitus
      7. Hypoleptinemia
    2. Familial partial lipodystrophy
      1. Type 1 (Köbberling syndrome): deficiency of subcutaneous fat in limbs and gluteal regions
      2. Type 2 (Dunnigan syndrome): reduced AT in extremities; lipohypertrophy in trunk, neck, supraclavicular fossa, and face; diabetes mellitus; and hypertriglyceridemia
      3. Types 3, 4, and 5: diabetes mellitus and dyslipidemia
  2. Acquired lipodystrophy
    1. Generalized (Lawrence syndrome)
      1. General lack of adipose tissue
      2. Insulin resistance
      3. Diabetes mellitus
      4. Dyslipidemia
      5. Hepatic steatosis
    2. Partial (Barraquer-Simons syndrome)
      1. Asymmetrical loss of subcutaneous adipose tissue
      2. Mild metabolic disorders
2. BSCL1 (Garg 2000, 2004; Kobashi et al. 2007)
  1. Prevalent in African-Americans
  2. Less severe
  3. Usually comes to clinical attention in the second or third decade of life
  4. Demonstrates marked lack of metabolically active adipose tissue in subcutaneous tissues, muscles, bone marrow, and intra-abdominal and intrathoracic regions
  5. Normal intelligence
3. BSCL2
  1. Slightly more common than BSCL1 worldwide
  2. More severe
  3. Onset in the neonatal period or early

4. Demonstrates marked lack of metabolically active adipose tissue in subcutaneous tissues, muscles, bone marrow, and intra-abdominal and intrathoracic regions
5. In addition, characterized by a paucity of adipose tissue from anatomical areas in which it serves a mechanical function such as the palms, soles, orbits, scalp, and periarticular regions (Simha and Garg 2003)

4. BSCLX (Van Maldergem et al. 2002)
   1. A very rare type
   2. Tends to be severely affected
   3. Comes to clinical attention in early infancy
5. Extreme paucity (near complete absence) of adipose tissue from birth, resulting in a generalized muscular appearance (an essential diagnostic criterion)
6. Characteristic features during early childhood
   1. Accelerated linear growth
   2. Voracious appetite
   3. Increased basal metabolic rate (hypermetabolism)
   4. Advanced bone age
7. Acanthosis nigricans (dark velvety pigmentation of the skin)
   1. Common occurrence
   2. Usually appears by age 8
   3. May be widespread, involving the neck, axillae, groin, and trunk
   4. Can eventually cause skin tag formation
   5. Associated with diabetes (Reed et al. 1965)
8. Umbilical hernia: common
9. Hepatosplenomegaly
   1. Almost universal presence of hepatomegaly from fatty liver, ultimately leading to cirrhosis
   2. Splenomegaly common
10. Acromegaloid appearance
    1. Enlarged hands and feet
    2. Prominent mandible
11. Premature thelarche and adrenarche
12. Affected women (Garg et al. 1999)
    1. Virilization (clitoromegaly and hirsutism)
    2. Oligo-amenorrhea
    3. Polycystic ovaries (Huseman et al. 1979) in postpubertal female patients
    4. Successful pregnancy rare
13. Affected males with normal reproductive potential.
14. Multiple focal lytic lesions in the appendicular bones in postpubertal patients.
15. Severe fasting and postprandial hyperinsulinemia and marked hypertriglyceridemia resulting in chylomicronemia, eruptive xanthomas, acute pancreatitis, and predisposing to premature atherosclerosis
16. Abnormal glucose intolerance and diabetes mellitus that develop during puberty or early adolescence. Diabetic nephropathy and nephropathy that may develop during adulthood
17. Rare hypertrophic cardiomyopathy (Rheuban et al. 1986)
18. Mental retardation in a few patients
19. Clinical diagnosis criteria (Van Maldergem 2012): three major criteria or two major criteria plus two or more minor criteria that make a diagnosis of BSCL very likely
    1. Major criteria
       1. Lipoatrophy affecting the trunk, limbs, and face
          1. Generalized lipodystrophy: apparent at birth
          2. In some individuals, the face which may be normal at birth with lipoatrophy becoming apparent during the first months of life
          3. Lipoatrophy that gives an athletic appearance, especially because skeletal muscle hypertrophy is also present
       2. Acromegaloid features
          1. Gigantism
          2. Muscular hypertrophy
          3. Advanced bone age
          4. Prognathism
          5. Prominent orbital ridges
          6. Enlarged hands and feet
          7. Clitoromegaly
          8. Enlarged external genitalia in the male

3. Hepatomegaly
    1. Secondary to fatty liver early on
    2. Progresses to cirrhosis late in the disease course
4. Elevated serum concentration of triglycerides
    1. Serum concentration of triglycerides that can be elevated up to 80 g/L
    2. Sometimes associated with hypercholesterolemia
5. Insulin resistance
    1. Elevated serum concentrations of insulin and C-peptide that may occur starting in the first years of life
    2. Overt clinical diabetes mellitus that usually develops during the second decade
    3. Its early clinical expression that is acanthosis nigricans of the groin, neck, and axillae, which may have, in some cases, a verrucous appearance

2. Minor criteria
    1. Hypertrophic cardiomyopathy: may be present in infancy or develop later in life
    2. Psychomotor retardation: mild (IQ: 50–70) and moderate (IQ: 35–50)
        1. Mild-to-moderate intellectual impairment observed in approximately 80 % of individuals with mutations in *BSCL*2
        2. Intellectual impairment observed in only 10 % of individuals with mutations in *AGPAT*2
    3. Hirsutism
        1. Manifests with low frontal and posterior hairline
        2. Apparently independent of hormonal stimulation
    4. Precocious puberty in females: in a series of 75 individuals with BSCL, three females that underwent puberty before age 7 years (Van Maldergem et al. 2002)
    5. Bone cysts
        1. Occur in 8–20 % of affected individuals and have a polycystic appearance in X-rays
        2. Located in the epiphyseal and metaphyseal regions of the long bones: often diagnosed during the second decade
        3. Are mostly observed in individuals with mutations in *AGPAT*2
    6. Phlebomegaly: prominence of the veins of the lower and upper limbs observed, in part because of the lack of subcutaneous fat

20. Differential diagnosis with other genetic lipodystrophies (Agarwal and Garg 2006; Garg 2011)
    1. Other autosomal recessive lipodystrophies
        1. Lipodystrophy associated with mandibuloacral dysplasia: characterized by hypoplasia of the mandible and clavicles and by acro-osteolysis (resorption of terminal phalanges) and other features (Simha and Garg 2002)
            1. Partial lipodystrophy (type A pattern): *LMNA* (lamin A/C) mutations (Shackleton et al. 2000)
            2. Generalized lipodystrophy (type B pattern): *ZMPSTE*24 (zinc metalloproteinase) mutations
            3. Other varieties
        2. Lipodystrophy associated with SHORT (*s*hort stature, *h*yperextensibility of joints and/or inguinal hernia, *o*cular depression, *R*ieger anomaly, and teething delay) syndrome: characterized by defects in multiple organs and loss of adipose tissue
        3. Lipodystrophy associated with neonatal progeroid syndrome (Wiedemann-Rautenstrauch syndrome) (Pivnick et al. 2000)
    2. Autosomal dominant lipodystrophies
        1. Familial partial lipodystrophy (FPL): characterized by variable symmetrical loss of body fat with or without disappearance of fat from the arms, chest, abdomen, and hips, but with retention

of distal adipose depots (Senior and Gellis 1964). The diagnosis made easily in women but difficult in men because even many normal men appear muscular. The diagnosis that can be suspected in nonobese patients with early onset of diabetes and hypertriglyceridemia, particularly if they have marked loss of fat from the extremities and hips
    1. Dunnigan variety (FPLD): LMNA (lamin A/C) mutations (Cao and Hegele 2000)
    2. FPL associated with *PPARG* (peroxisome proliferator-activated receptor-γ) mutations
    3. FPL associated with AKT2 (v-AKT murine thymoma oncogene homolog 2) mutations
    4. Other varieties
2. Lipodystrophy associated with SHORT syndrome
3. Lipodystrophy associated with Hutchinson-Gilford progeria syndrome
    1. Progressive and generalized loss of body fat during childhood resulting in severe lipodystrophy with increasing age
    2. Most patients having a de novo synonymous heterozygous Gly608Gly mutation in the *LMNA* gene of paternal origin (Eriksson et al. 2003; De Sandre-Giovannoli et al. 2003)
4. Puberty-onset generalized lipodystrophy due to *LMNA* mutations
    1. Puberty-onset of generalized lipodystrophy
    2. Diabetes
    3. Progeroid features
    4. Reported to have novel missense mutations in *LMNA* (Caux et al. 2003)

Diagnostic Investigations

1. Clinical laboratory workup
    1. Marked insulin resistance
    2. Severe hyperinsulinemia
    3. Nonketotic insulin-resistant diabetes mellitus
    4. Hypertriglyceridemia with low serum high-density lipoprotein (HDL) and cholesterol concentration
    5. Chylomicronemia
    6. Markedly low plasma leptin levels
2. Skeletal imaging (Fleckenstein et al. 1992; Westvik 1996)
    1. Radiographs
        1. Show numerous focal lesions within the long bones
        2. Advanced skeletal age
        3. A sclerotic skeleton: a major feature in childhood, later turning into osteolytic lesions or more distinct sclerotic patches in adolescence or early adulthood
    2. MRI
        1. Abnormal entire marrow space of the long bones
        2. Characterized, at least in part, by the absence of marrow fat
        3. Prolonged T1 and T2 times and marked gadolinium enhancement: observed in radiographically normal-appearing long one
        4. Radiographically lytic lesions: occasionally demonstrated fluid-fluid levels on MRI and enhanced peripherally after gadolinium infusion
    3. Appendicular skeleton of patients with CGL that is diffusely abnormal and predisposed to focal osteolysis and cyst formation
3. Ultrasonography and computerized tomography (Westvik 1996)
    1. Hepatosplenomegaly with fatty infiltration
    2. Lack of subcutaneous and intra-abdominal fat: easily confirmed with computerized tomography
    3. Pneumoencephalography: dilated brain ventricles and basal cisterns
4. MRI (confirmatory) and necropsy (Garg 1992; Garg et al. 1999)

1. An extreme paucity of subcutaneous and intermuscular fat
    1. Intra-abdominal sites (omental, mesenteric, and retroperitoneal areas)
    2. Thoracic cavity (retrosternal, epicardial, and superior mediastinal areas)
    3. Bone marrow
    4. Parathyroid glands
2. In contrast, a peculiar distribution of normal amounts of adipose tissue over whole body
    1. Orbits
    2. Crista galli
    3. Palms
    4. Soles
    5. Scalp
    6. Perineum
    7. Vulva
    8. Epidural area
    9. Pericalyceal regions of the kidney
    10. Periarticular regions (knee, hip, shoulder, elbow, wrist, and ankle joints)
    11. Some fat localizing in breasts, tongue, and buccal region
5. Skeletal radiography: multiple focal lytic lesions appearing in appendicular skeletons after puberty
6. Echocardiography to detect hypertrophic cardiomyopathy
7. Light and electron microscopy (Afifi et al. 1976)
    1. Variation in fiber size
    2. Ringbenden (circular myofibrils wrapped around the longitudinal myofibrils)
    3. Various degrees of fiber degeneration and fragmentation
    4. Accumulation of glycogen and aggregation of mitochondria
    5. Streaming of Z line
    6. Myofilamentous inclusions and dilatation of sarcoplasmic reticulum profiles
8. Molecular genetic analysis of mutations in *BSCL2* (*Seipin*) gene and *AGPAT2* gene
9. Exome sequencing: as a powerful diagnostic tool in Mendelian disorders that may complement missing clinical information and accelerate clinical diagnosis, such as CGL (Schuster et al. 2014)

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: 25 %
    2. Patient's offspring: not increased unless the spouse is a carrier or affected
2. Prenatal diagnosis (Van Maldergem 2012)
    1. Possible for pregnancy at risk for BSCL caused by *BSCL2* of *AGPAT2* mutations by analysis of fetal cell DNA obtained from amniocentesis or CVS, provided both disease-causing alleles of an affected family member must be identified previously
    2. Preimplantation genetic diagnosis (PGD) that may be available for families in which the disease-causing mutations have been identified
3. Management (Agarwal and Garg 2006; Patni and Garg 2015)
    1. Cosmetic management
        1. Facial reconstruction with free flaps, transposition of facial muscle, and silicone or other implants in the cheeks
        2. Liposuction or lipectomy for removal of excessive facial or neck fat
        3. Etretinate and fish oil that may improve acanthosis in some patients
    2. Diet
        1. Avoidance of weight gain to reduce the risk of developing diabetes and dyslipidemia
        2. Need sufficient energy to allow for growth and maturation in childhood
        3. Low-fat diet for extreme hypertriglyceridemia to minimize chylomicron formation
        4. Reduction in saturated fat and cholesterol intake to reduce LDL or non-HDL cholesterol levels that reduces atherosclerosis risk
    3. Hypoglycemic drugs
        1. Require rigorous glycemic control by oral hypoglycemic drugs and/or insulin therapy
        2. Require large dose of insulin to control hyperglycemia and prevent long-term

complications of diabetes, such as nephropathy, retinopathy, neuropathy, and possibly atherosclerosis

4. Lipid-lowering drugs
    1. Fibrates and, if needed, n-3 polyunsaturated fatty acids
    2. Avoid estrogens for oral contraception or postmenopausal hormone replacement therapy in women because it can accentuate hypertriglyceridemia
5. Adipocytes hormone leptin-replacement therapy that has shown a marked reduction in the blood glucose and lipids and reverse hepatic steatosis, allowing discontinuation of several medications (Oral et al. 2002; Petersen et al. 2002; Savage and O'Rahilly 2002; Cortés and Fernández-Galilea 2015)
6. Elucidation of the pathways underlying genetic lipodystrophies expected to help in developing innovative therapeutic strategies for treating diabetes, hyperlipidemia, hepatic steatosis, and other metabolic complications

Congenital Hemihyperplasia

Contents

In 1822, Meckel (1822) first described congenital hemihypertrophy. Hemihypertrophy, also called hemihyperplasia, is defined as asymmetric body overgrowth of one or more body parts. The overgrowth may involve an entire half of the body, a single limb, and one side of the face or combinations thereof. There may be accompanying asymmetric visceromegaly. Hemihyperplasia can be isolated or can occur as part of a syndrome. It is frequently not possible to determine if the enlargement is due to an increase in the size of cells (hypertrophy) or to an increase in the number of cells of normal size (hyperplasia) (Ballock et al. 1997).

Synonyms and Related Disorders

Beckwith-Wiedemann syndrome; Congenital hemihypertrophy; Congenital infiltrating lipomatosis of the face; Isolated hemihyperplasia/hemihypertrophy; Klippel-Trenaunay-Weber syndrome; McCune-Albright syndrome; Neurofibromatosis I; Overgrowth syndromes; Proteus syndrome; Russell-Silver syndrome

Genetics/Basic Defects

1. The asymmetric overgrowth, traditionally termed "hemihypertrophy," is more accurately referred to as hemihyperplasia, since the pathologic growth process involves an abnormal proliferation of cells (hemihyperplasia), rather than an increase in the size of existing cells (hemihypertrophy).
2. Isolated hemihyperplasia (IHH)
    1. Usually isolated: estimated prevalence as 1 in 13,200 to 1 in 86,000 live births
    2. Familial occurrence (Burchfield and Escobar 1980; Stoll et al. 1993; Heilstedt and Bacino 2004)
    3. *LIT1* and *H19* methylation defects in isolated hemihyperplasia (29.6%) (Martin et al. 2005)
3. Part of well-defined syndrome
    1. Beckwith-Wiedemann syndrome
    2. Proteus syndrome
    3. Russell-Silver syndrome
    4. Neurofibromatosis type I (NF I)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_52

5. Klippel-Trénaunay-Weber syndrome
6. McCune-Albright syndrome

Clinical Features

1. Clinical characteristics of isolated hemihyperplasia
    1. Birth incidence: 1:86,000 live births
    2. Females outnumber males two to one.
    3. Increased birth weight (mean 3.8 kg).
    4. Diagnosis by exclusion.
    5. Variable degree of asymmetry (mild cases are easily overlooked).
    6. Asymmetry becoming more pronounced or less noticeable with age with predominance of right-sided overgrowth.
    7. Involves a discrepancy in both length and circumference of the affected limb in comparison to the contralateral side.
    8. Observation of the enlargement of one kidney, adrenal, testis, or ovary with medullary sponge kidney, often an attendant finding.
    9. Nervous system accompaniments include unilateral peripheral nerve enlargement, sciatica, and hemimegalencephaly with frequent mental retardation.
    10. Facial involvement may be present (cheek, lip, nasal, external ear, palpebral fissure, tongue, maxillary, mandibular, palatal, and/or tooth asymmetry).
    11. Natural history of IHH varies markedly.
        1. Average life span.
        2. Prognoses for long-term survival may be modified by serious associated anomalies.
        3. Leg length discrepancy may lead to pelvic tilt and scoliosis.
        4. Renal function may be impaired by medullary sponge kidney.
    12. Predisposition to neoplasia (cancer) in isolated hemihyperplasia (Furukawa and Shinohara 1981; Geormaneanu et al. 1983; Viljoen et al. 1984; Clericuzio and Martin 2009; Craiglow et al. 2014) well known
        1. An overall incidence of intra-abdominal embryonal malignancies (5.9%)
        2. Embryonal neoplasms: similar to those noted in other overgrowth disorders
            1. Wilms tumor: hemihypertrophy occurs in approximately 3% of Wilms tumor cases.
            2. Adrenal cell carcinomas.
            3. Hepatoblastoma.
            4. Leiomyosarcoma.
2. Three types of hemihyperplasia/hemihypertrophy (Lee et al. 2013)
    1. Total: involves an entire half of the body
    2. Regional: involves an anatomical territory such as a limb
    3. Crossed: if opposite parts of the body are overgrown (e.g., left arm and right leg)
3. Malformation syndromes associated with hemihyperplasia (Hoyme et al. 1998; Cohen 1989)
    1. Beckwith-Wiedemann syndrome
        1. Omphalocele
        2. Hypoglycemia
        3. Generalized overgrowth
        4. Macroglossia
        5. Visceromegaly
        6. Earlobe pits and creases
        7. Predisposition to neoplasia
        8. Inheritance: heterogeneous (autosomal dominant, autosomal recessive, dup 11)
    2. Neurofibromatosis
        1. Café au lait spots
        2. Hypopigmented patches
        3. Axillary freckling
        4. Neurofibromas
        5. Iris Lisch nodules
        6. Macrocephaly
        7. Scoliosis
        8. Hypertension

9. CNS tumors
10. Inheritance (autosomal dominant)

3. Klippel-Trénaunay-Weber syndrome:
    1. Hemangiomata
    2. Lymphatic anomalies
    3. Poly-/syndactyly
    4. Oligodactyly
    5. Macrocephaly
    6. Glaucoma
    7. Cataracts
    8. Inheritance (unknown, sporadic)
4. Proteus syndrome
    1. Lipomata
    2. Hemangiomata
    3. Macrocephaly
    4. Scoliosis
    5. Macrodactyly
    6. Gyriform changes on soles of feet
    7. Inheritance (unknown, sporadic)
5. McCune-Albright syndrome
    1. Fibrous dysplasia of bones
    2. Irregular hyperpigmentation
    3. Precocious puberty
    4. Hyperthyroidism
    5. Hyperparathyroidism
    6. Other endocrinopathies
    7. Inheritance (unknown, sporadic, female predominance)
6. Epidermal nevus
    1. Epidermal nevi
    2. Pigmentary changes
    3. Mental deficiency
    4. Seizures
    5. CNS malformations
    6. Kyphoscoliosis
    7. Potential for malignancy
    8. Inheritance (heterogenous, usually sporadic but autosomal dominant and recessive inheritance described)
7. Triploid/diploid mixoploidy
    1. Large placenta with hydatidiform changes
    2. Incomplete calvarial ossification
    3. Microretrognathia
    4. Microphthalmia
    5. Colobomata
    6. Cataracts
    7. Irregular skin pigmentation
    8. Syndactyly
    9. Chromosomal diploid/triploid mosaicism (may be found only in fibroblasts)
8. Langer-Giedion syndrome
    1. Multiple exostoses
    2. Unusual facies with bulbous nose
    3. Long simple philtrum
    4. Microcephaly
    5. Loose skin in infancy
    6. Sparse scalp hair
    7. Deafness
    8. Inheritance (heterogenous, chromosome anomaly del(8)(q23q24), autosomal dominant)
9. Multiple exostoses
    1. Juxtaepiphyseal exostoses
    2. Forearm bowing
    3. Short stature
    4. Malignant transformation (sarcoma) in adulthood
    5. Inheritance (autosomal dominant)
10. Maffucci syndrome
    1. Enchondromata
    2. Hemangiomata (especially phlebectasia)
    3. Bowing of long bones
    4. Chondrosarcoma
    5. Inheritance (unknown, sporadic)
11. Osteochondromatosis (Ollier disease)
    1. Bilateral, asymmetric enchondromata
    2. Fractures
    3. Chondrosarcoma
    4. Inheritance (unknown, sporadic)
12. Trisomy 18 mosaicism
13. Translocation 7p;13q
14. Constitutional uniparental disomy (UPD) for chromosome 11p15
    1. Not common in patients with idiopathic hemihyperplasia (Bliek et al. 2008)
    2. Can result from various genomic changes including molecular

alterations of 11p15 (paternal UPD) and alterations of methylation at two imprinting centers at 11p15: IC1 (H19) and IC2 (*KCNQ1OT1*) (Shuman et al. 2006)

15. Hemihyperplasia/multiple lipomatosis syndrome (Boybeyi et al. 2010; Craiglow et al. 2014)
    1. Asymmetric nonprogressive overgrowth
    2. Multiple lipomas
    3. Superficial vascular malformations
16. *PIK3CA*-related overgrowth spectrum with overlapping clinical features (Keppler-Noreuil et al. 2015)
    1. Hemihyperplasia
    2. Overgrowth
    3. Vascular anomalies
    4. Skin abnormalities
    5. Tumors
    6. Scoliosis
    7. Others

4. Extent of involvement
    1. Range from enlargement of a single digit to an entire half of the body
    2. Segmental, unilateral, or crossed (affecting different anatomic areas on either side of the body)
    3. System involvement
        1. A single system
            1. Muscular
            2. Vascular
            3. Skeletal
            4. Nervous
        2. Combination of all systems
    4. Total hemihypertrophy
        1. Right side more affected than the left.
        2. Males appear to be affected more frequently.
    5. Associated anomalies found in about 50% of affected individuals
    6. Onset and course of asymmetry
        1. Almost always evident at birth
        2. May be accentuated at puberty
        3. Appears to be constant once developed
5. Facial involvement
    1. Involvement of the face only
    2. Unilateral facial enlargement accompanied by enlargement of the complete half of the body
    3. Variable degree of involvement
6. Skin and skin appendages
    1. Involved side
        1. Thicker with increased function of the sebaceous and sweat glands
        2. Pigmentation as well as early development of varicose veins or a medusa-like plexus of veins in the lower abdomen and groin area
        3. Supernumerary nipples as well as an enlarged breast
        4. Thicker and coarser hair
        5. Abnormal nail growth
    2. Either involved or contralateral side: telangiectasia and increased numbers of nevi
7. Skeletal system
    1. Unilaterally enlarged bones
    2. Other lesions
        1. Macrodactyly
        2. Polydactyly
        3. Syndactyly
        4. Lobster claw deformity
        5. Scoliosis
        6. Tilting of the pelvis
        7. Clubfoot
8. Central nervous system
    1. Mental retardation in 15–20% of affected individuals
    2. Sciatica probably resulting from pelvic tilt
    3. Dilatation of the anterior basal cisterna
    4. Dilatation of the pupil on the affected side
9. Genitourinary system
    1. The kidney and adrenal: most frequently enlarged on the involved side
    2. Other anomalies
        1. Hypospadias
        2. Cryptorchidism
        3. Elevated level of urinary gonadotropin and short stature
        4. Adrenogenital syndrome
        5. Embryonal tumors

6. Wilms tumor
7. Adrenal cortical carcinoma

10. Enlarged oral lesions on the involved side
    1. Enlarged and thickened tongue
    2. Oral soft and hard tissues such as lips, uvula, maxilla, mandible, tongue, alveolar process, and some teeth

Diagnostic Investigations

1. Serum alpha-fetoprotein measurement every 3 months until 4 years (Clericuzio and Martin 2009)
2. Radiographic studies of hemihypertrophy
3. Abdominal ultrasound for visceromegaly (tumor) (Ballock et al. 1997)
4. Brain MRI for hemihyperplasia
5. Chromosome analysis, UPD analysis, or gene mutation studies depending on the types of the malformation syndromes

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. Isolated case: a low recurrence risk.
        2. Familial case: recurrence risk depends on mode of transmission:
            1. Autosomal dominant: a low recurrence risk if parents are normal
            2. Autosomal recessive: a 25% risk
            3. Imprinting mechanism such as in Beckwith-Wiedemann syndrome
    2. Patient's offspring
        1. Isolated case: a low recurrence risk.
        2. Autosomal dominant: a 50% risk.
        3. Autosomal recessive: recurrence risk does not increase unless the spouse is a carrier or affected.
2. Prenatal diagnosis
    1. Prenatal ultrasound/radiography for fetal hemihyperplasia
    2. Chromosome analysis from amniocentesis or CVS for triploidy or mixoploidy
3. Management
    1. Screening abdominal ultrasounds every 3–6 months to monitor Wilms tumor development in patients with idiopathic hemihypertrophy
    2. Orthopedic management for hemihypertrophy
    3. Management for neoplasm

Congenital Hydrocephalus

Contents

Congenital hydrocephalus is one of the most common CNS congenital anomalies. The incidence of congenital hydrocephalus is estimated as 3 per 1,000 live births. Hydrocephalus is defined as an increase in the cerebral spinal fluid (CSF) volume within the ventricular system independent of the actual head circumference.

Synonyms and Related Disorders

Infantile hydrocephalus; Neonatal hydrocephalus; Non-syndromic autosomal recessive hydrocephalus; Pediatric hydrocephalus; X-linked hydrocephalus with aqueduct stenosis

Genetics/Basic Defects

1. Physiology of CSF production and absorption
    1. Production of CSF: by the choroid plexus of lateral ventricles
    2. Pathway of CSF flow
        1. From lateral ventricles to the third ventricle through the foramen of Monro
        2. From the third ventricle to the fourth ventricle through the aqueduct of Sylvius
        3. Out of the ventricular system: from the fourth ventricle to spinal subarachnoid spaces through the foramen of Magendie or to the basal cisterns through two lateral foramina of Luschka
    3. Site of CSF resorption into the venous system: primarily through the superior sagittal sinus via arachnoid granulations
2. Pathophysiologic consequences of hydrocephalus (Del Bigio 2001b)
    1. Hydrocephalus-induced damage is dependent on:
        1. The rate and magnitude of ventricular dilatation
        2. The proximity to the ventricle
        3. The developmental stage at which the disturbance occurs
    2. Developmental processes, including myelin production, can be impaired.
    3. The potential for reversal of damage by shunting diminishes as the duration and severity of hydrocephalus increase.
3. Types and causes of hydrocephalus (Aronyk 1993)
    1. Overproduction of CSF: usually caused by choroid plexus tumors (very rare)
    2. Noncommunicating hydrocephalus

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_53

1. Mechanical obstruction within the ventricular system causing impaired CSF absorption
    1. Foramen of Monro
    2. Aqueduct of Sylvius
    3. The fourth ventricle and its outlet channels
2. Causes
    1. Tumors
    2. Cysts
    3. Inflammatory scarring
    4. Intraventricular hemorrhage
    5. Rarely genetic disorders

3. Communicating hydrocephalus:
    1. Obstruction distally at the arachnoid granulations causing impaired absorption into bloodstream
    2. Causes
        1. Meningitis
        2. Trauma
        3. Intraventricular hemorrhage

4. Causes of pediatric hydrocephalus (Kahle et al. 2015)
    1. Acquired hydrocephalus
        1. Inflammatory
            1. Subarachnoid hemorrhage or infection: arachnoid scar (dysfunctional subarachnoid space)
            2. Intraventricular hemorrhage or infection: ependymal scar (ventricular obstruction)
        2. Neoplasm
            1. Parenchymal brain tumor: mass effect (ventricular obstruction)
            2. Spinal cord tumor: altered CSF composition (dysfunctional subarachnoid space)
            3. Disseminated tumor: tumors with meningeal infiltration – e.g., primitive neuroectodermal tumor (dysfunctional subarachnoid space)
            4. Choroid plexus tumor: altered CSF composition (dysfunctional subarachnoid space)
            5. Choroid plexus tumor: mass effect (ventricular obstruction)
            6. Choroid plexus tumor or hyperplasia: altered choroid plexus function (CSF overproduction – or hyperdynamic intraventricular pulsations)
        3. Vascular
            1. Vascular malformation: ventricular obstruction, e.g., vein of Galen malformation; venous hypertension, e.g., arteriovenous malformation (ventricular obstruction, decreased venous compliance – or decreased CSF absorption)
            2. Disordered cerebral venous function: extrinsic venous obstruction, e.g., skeletal dysplasias; intrinsic venous obstruction, e.g., venous sinus thrombosis; and idiopathic venous dysfunction, e.g., congenital idiopathic hydrocephalus (decreased venous compliance – or decreased CSF absorption)
    2. Congenital or developmental hydrocephalus
        1. Congenital aqueduct stenosis: third ventricle outlet obstruction (ventricular obstruction)
        2. Neural tube defects – e.g., myelomeningocele and Chiari II malformation: third or fourth ventricle outlet obstruction; altered venous compliance; arachnoid or ependymal scar (variable)
        3. Posterior fossa malformations: fourth ventricle outlet obstruction – e.g., Dandy-Walker complex; Chiari I malformation (ventricular obstruction)
        4. Developmental cysts: mass effect (ventricular obstruction)
        5. Congenital foramen of Monro atresia: lateral ventricle outlet obstruction (ventricular obstruction)

5. Etiology of congenital hydrocephalus (Schrander-Stumpel and Fryns 1998; Pattisapu 2001)
    1. Tumors blocking CSF pathway
        1. Benign tumors such as choroid plexus papilloma (Rickert and Paulus 2001)
        2. Malignant tumors
    2. CNS malformations/syndromes
        1. Congenital atresia of the foramina of Monro, Magendie, or Luschka

2. Dandy-Walker syndrome
    1. Atresia of the foramina of the fourth ventricle
    2. Dilation of the fourth ventricle
    3. Extreme dolichocephaly
    4. Sac formation at the caudal end of the cerebellum filling the posterior cranial fossa
3. Aqueductal stenosis
4. X-linked hydrocephalus, Bickers-Adams syndrome characterized by
    1. Stenosis of the aqueduct of Sylvius
    2. Severe mental retardation
    3. An adduction-flexion deformity of the thumb
5. Chiari II malformation
6. Cerebellar agenesis
7. Neural tube defects
    1. Meningomyelocele
    2. Encephalocele
8. Other Mendelian conditions with congenital hydrocephalus
    1. Walker-Warburg syndrome
    2. Hydrolethalus syndrome
    3. Meckel syndrome
    4. Smith-Lemli-Opitz syndrome

3. Chromosome abnormalities
    1. Trisomy 13
    2. Trisomy 18
    3. Trisomy 9 and 9p (mosaic)
    4. Triploidy
    5. Other aneuploidies
4. Skeletal dysplasias
    1. Achondroplasia
    2. Craniosynostosis syndromes such as Crouzon syndrome or Apert syndrome
    3. Fanconi anemia
    4. Hurler and Hunter syndromes
5. Infections
    1. Congenital CMV infection
    2. Congenital toxoplasmosis
    3. Congenital rubella infections
    4. Congenital syphilis
    5. Meningitis
    6. Ventriculitis
    7. Abscess
6. Vascular malformation
7. In utero intraventricular hemorrhage
8. Birth trauma
9. Destructive lesions
    1. Hydranencephaly
    2. Porencephaly
    3. Perinatal leukomalacia

6. Genetic abnormalities associated with pediatric hydrocephalus (Kahle et al. 2015)
    1. X-linked hydrocephalus with aqueduct stenosis (Online Mendelian Inheritance in Man (OMIM) identifier 307000): *L1CAM*
    2. Non-syndromic autosomal recessive hydrocephalus (HYC, OMIM 236600 [HYC1], OMIM 615219 [HYC2]): *CCDC88C* and *MPDZ*
    3. Fried-type syndromic mental retardation (OMIM 304340): *AP1S2*
    4. Walker-Warburg syndrome (multiple subtypes): *POMT1*, *POMT2*, *POMGNT1*, and others
    5. Neural tube defects (folate-sensitive [OMIM 601634] and folate-insensitive [OMIM 182940] forms)
        1. Multiple susceptibility genes involved in planar-cell polarity – e.g., *FUZ*, *VANGL1/2*, *CCL2*, and others
        2. Folate-sensitive neural tube defects associated with genes in folate synthesis pathway (*MTR*, *MTRR*, *MTHFR*, *MTHFD*)
    6. Primary ciliary dyskinesia and other ciliopathies (including the many heterogeneous subtypes of Meckel-Gruber syndrome and Joubert syndrome): multiple genes involved in cilia structure, function, and regulation – e.g., *CC2D2A*, *TMEM67*, *MKS1*, and others
    7. RAS-opathies – e.g., neurofibromatosis type 1, Noonan's syndrome, Costello's syndrome, and cardio-facio-cutaneous syndrome
        1. NF1
        2. Ras-Raf-MEK-ERK pathway genes – e.g., *KRAS*, *BRAF*, *PTPN11*, and others
    8. VACTERL-H (association of vertebral, anal, cardiac, tracheoesophageal, renal, and limb anomalies plus hydrocephalus) (OMIM 276950): *PTEN*
    9. X-linked VACTERL-H (OMIM 300515): *FANCB*

7. Familial (X-linked) aqueductal stenosis (HSAS, hydrocephalus-stenosis of the aqueduct of Sylvius sequence)
    1. X-linked recessive inheritance.
    2. Linked to chromosome Xq28.
    3. Mutations in *L1-CAM* (Weller and Gärtner 2001; Sztriha et al. 2002), the major gene for X-linked hydrocephalus (accounting for 7–27% of all male cases).
    4. *L1-CAM*, a neuronal surface glycoprotein, has been implicated in neuronal migration and axon fasciculation.
8. Traits known to be due to allelic mutations of *L1-CAM*
    1. HSAS
    2. MASA (Jouet et al. 1994)
        1. *M*ental retardation
        2. *A*phasia
        3. *S*huffling gait
        4. *A*dducted thumbs
    3. SP1 (complicated spastic paraparesis, type 1)
    4. MR-CT (mental retardation-clasped thumbs)
    5. ACC-DCC (agenesis or dysgenesis of the corpus callosum)
9. Pathogenesis of hydrocephalus-induced brain dysfunction, complex
    1. Chronic ischemia in white matter related to changes in intracranial pressure and in the vasculature
    2. Physical damage to periventricular axons with disconnection of neurons
    3. Alterations in the extracellular chemical environment of neurons

Clinical Features

1. Children <2 years
    1. Relatively benign course because infants can expand their cranium
    2. Early signs
        1. Increased head circumference (macrocephaly)
        2. Full anterior fontanelle
        3. Split cranial sutures
        4. Prominent scalp veins
        5. Poor feeding
        6. Vomiting
        7. Irritability
        8. Reduced activity
        9. Delay or loss of developmental milestones
        10. Hypertonia
        11. Hyperreflexia
    3. Late signs
        1. Lethargy
        2. Sixth cranial nerve palsy
        3. Limitation of upgaze resulting in a chronic downward deviation of the eyes (sunsetting sign)
2. Children >2 years
    1. Symptoms and signs more related to increased intracranial pressure due to inability of the cranium to expand sufficiently to offset the mounting volume of CSF
    2. Headaches
    3. Nausea
    4. Vomiting
    5. Lethargy
    6. Loss of milestones
    7. School performance and behavioral change
    8. Sunsetting of the eyes
    9. Sixth cranial nerve palsy
    10. Papilledema
3. Natural history of untreated childhood hydrocephalus: poor.
4. Handicaps resulting directly from hydrocephalus include the following (Vinchon et al. 2012)
    1. Impaired mobility and ambulation (e.g., cerebral palsy)
    2. Impaired cognition (mental delay, behavior)
    3. Sensory deficits (vision, hearing)
    4. Endocrine dysfunction (growth, puberty, weight balance, fertility)
    5. Epilepsy
    6. Depression
    7. Pain (chronic headache)
5. Most common clinical features of progressive hydrocephalus in the non-shunted group (Kirpatrick et al. 1989)
    1. Symptoms
        1. Asymptomatic (49%)
        2. Headache or irritability (33%)
        3. Vomiting (16%)

2. Signs
    1. Inappropriately increasing occipitofrontal circumference (76%)
    2. Tense anterior fontanelle (65%)
    3. Splayed sutures (39%)
    4. Scalp vein distension (33%)
    5. Sunsetting or loss of upward gaze (22%)
    6. Neck retraction or rigidity (14%)
6. Most common clinical features of progressive hydrocephalus in the shunted group (Kirpatrick et al. 1989)
    1. Symptoms
        1. Vomiting (48%)
        2. Drowsiness or lethargy (46%)
        3. Headache (46%)
        4. Behavioral change (including irritability) (38%)
        5. Anorexia (18%)
    2. Signs
        1. No clinical signs (25%)
        2. Decreased conscious level (18%)
        3. Acute strabismus (18%)
        4. Neck retraction (11%)
        5. Distended retinal veins (11%)
7. X-linked neurological syndromes
    1. HSAS (*h*ydrocephalus-*s*tenosis of the *a*queduct of *S*ylvius sequence)
        1. Hydrocephalus
        2. Macrocephaly
        3. Adducted thumbs
        4. Spasticity
        5. Agenesis of the corpus callosum
        6. Mental retardation
    2. MASA syndrome
        1. *M*ental retardation
        2. *A*phasia
        3. *S*huffling gait
        4. *A*dducted thumbs
        5. Hydrocephalus

Diagnostic Investigations

1. Fundoscopic examination
    1. Bilateral papilledema secondary to high intracranial pressure
    2. Normal finding in some cases of acute hydrocephalus
2. Lumbar puncture for measuring intracranial pressure
    1. Avoid if an increase in intracranial pressure is suspected due to obstruction since relief of pressure may cause herniation of the brainstem.
    2. Perform only after imaging studies rule out an obstruction.
3. TORCH titers on the infant and mother if intrauterine infection is suspected.
4. Chromosome analysis in cases of associated multiple congenital anomalies.
5. Cranial sonography (provided anterior fontanelle is still open)
    1. Ventriculomegaly
    2. Intraventricular hemorrhage
6. CT scans (Barkovich and Edwards 1992)
    1. Ventriculomegaly
    2. Cerebral edema
    3. Mass lesions
        1. Colloid cyst of the third ventricle
        2. Thalamic tumor
        3. Pontine tumor
7. MRI (Barkovich and Edwards 1992; Bradley 2001)
    1. Ventriculomegaly.
    2. Mass lesions.
    3. Associated brain anomalies
        1. Agenesis of the corpus callosum
        2. Chiari malformations
        3. Disorders of neuronal migration
        4. Vascular malformations
    4. More sensitive than CT
        1. For detecting interstitial edema (transependymal flow of cerebrospinal fluid [CSF])
        2. For detecting hyperdynamic CSF flow seen with shunt-responsive normal-pressure hydrocephalus (NPH)
        3. The presence of deep white matter ischemia that may contribute to the cause of the idiopathic form of NPH
    5. Phase-contrast MRI (PC-MRI) and/or 3D-Space methods (Kartal and Algin 2014)
        1. Relatively simple for evaluating true CSF flow and determining the obstruction level.

2. Provide additional physiological information.
3. Three-dimensional sampling perfection with application-optimized contrasts using different flip angle evolution (3D-SPACE) technique seems to be the most efficient and rapid for evaluating hydrocephalus, ETV and the shunt catheter.

6. PC-MRI, 3D-heavily-T2W, and/or contrast material-enhanced MR cisternography (CE-MRC) images may prevent false-negative or false-positive results (Kartal and Algin 2014).

8. Molecular genetic diagnosis to identify *L1CAM* mutations, identified in 22.4% (15/67) of sporadic cases of clinically or prenatally suspected L1 disease (Senat et al. 2001).

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Sporadic: low (4%)
      2. Multifactorial trait (e.g., neural tube defect or in female infants with congenital hydrocephalus due to stenosis of the aqueduct of Sylvius): low recurrence risk (4%) for subsequent sibling (Váradi et al. 1988), 10% risk if there are two affected siblings
      3. Autosomal recessive traits (e.g., Dandy-Walker syndrome): 25% affected, 50% carriers, and 25% normal
      4. X-linked hydrocephalus: 50% of brothers are affected and 50% of sisters are carriers if the mother is a carrier, negligible in males with "sporadic" hydrocephalus representing a new X-linked mutation
   2. Patient's offspring
      1. Sporadic: low (4%).
      2. Multifactorial trait: 3–4.5% recurrence risk.
      3. Autosomal recessive traits: not increased unless the spouse is a carrier or affected.
      4. X-linked hydrocephalus: all daughters will be carriers in case of an affected father.
2. Prenatal diagnosis (Habib 1981)
   1. Ultrasonography
      1. Etiologic heterogeneity of fetal hydrocephalus diagnosed by ultrasound (Harrod et al. 1984)
      2. Fetal ventriculomegaly
      3. Additional CNS malformations
      4. Extracerebral malformations
   2. Sonographic findings in HSAS (Senat et al. 2001) or MASA syndromes (Pomili et al. 2000)
      1. Male fetus
      2. Hydrocephalus
      3. Hypoplasia or agenesis of the corpus callosum
      4. Bilateral adducted thumbs
   3. The specific sonographic appearance of fetal isolated aqueductal stenosis (Emery et al. 2015)
      1. Symmetric severe CNS ventriculomegaly
      2. Thinning of the brain parenchyma, both anteriorly and posteriorly
      3. A dangling choroid plexus
      4. A dilated third ventricle
      5. A preserved posterior fossa
   4. Amniocentesis
      1. Alpha-fetoprotein and cholinesterase determination from amniotic fluid for neural tube defects
      2. Chromosome analysis for suspected chromosomal disorder
   5. Molecular genetic diagnosis
      1. DNA diagnosis often requested in families with "isolated" hydrocephalus case due to high rate of de novo mutations, small family size, and the improved sensitivity of prenatal ultrasound scanning
      2. Molecular diagnosis of prenatally suspected L1 spectrum disorders (Finckh and Gal 2000; Senat

et al. 2001), even in cases without positive family history

3. Management (Kanev and Park 1993; Del Bigio 2001a; Hamid and Newfield 2001; Kestle 2003)
    1. Folic acid intake before and during the first trimester reduces the incidence of neural tube defects, thereby the incidence of hydrocephalus.
    2. Poor intellectual outcome (Futagi et al. 2002), significantly correlated with the following:
        1. An early onset
        2. A high lateral ventricular width/hemispheral width ratio at diagnosis of hydrocephalus
    3. Different types of shunt surgeries, depending on the location of the proximal and distal shunt catheters (Toma 2015)
        1. Insufficient evidence to demonstrate an advantage for one shunt hardware design over another in the treatment of pediatric hydrocephalus (Baird et al. 2014).
        2. Ventriculoperitoneal (VP) shunting devices with pressure-controlled valves under the scalp close to the burr hole: the most common type.
        3. Ventriculopleural shunt: the distal catheter is placed within the pleural cavity.
        4. Ventriculoatrial shunt: the distal catheter is placed at the right atrium through the internal jugular vein.
        5. Lumboperitoneal shunts: a proximal catheter in the lumbar theca and distal catheter in the peritoneal cavity. These are only used in communicating hydrocephalus, commonly in pseudotumor cerebri.
        6. Examples of less common types of shunt
            1. Syringopleural shunt (draining spinal cord syrinx into the pleural cavity)
            2. Lumbopleural shunt (lumbar theca to the pleural cavity)
        7. It does not completely reverse the pathologic alterations in the brain, and, unfortunately, treatment by shunting is associated with frequent complications.
    4. Major complication associated with shunt treatment, 81% of children with shunts suffer at least one and usually several malfunctions necessitating hospitalization
        1. Shunt obstruction
        2. Valve malfunction
        3. Disconnection
        4. Hematoma
        5. Overdrainage
        6. Outgrown shunt
        7. Shunt fracture
        8. Shunt-related infections, most often caused by *Staphylococcus aureus*, with unexplained fever or frank meningitis
        9. Signs of increased intracranial pressure with headache, lethargy, and vomiting
        10. Abdominal complications
            1. Peritonitis
            2. Perforation of an abdominal organ
            3. Peritoneal cysts
            4. Development of hydroceles in boys
        11. Seizures
        12. Allergic reaction to material
    5. A trial of in utero ventriculoamniotic shunt for treating congenital hydrocephalus (Al-Anazi et al. 2008).
    6. Fetal ventriculoamniotic shunting for isolated AS (Emery et al. 2015)
        1. Mechanical shunting was attempted in the 1980s but was abandoned because of the inability to accurately identify suitable candidates.
        2. Advances in prenatal diagnosis and fetal therapy in the intervening decades may allow for the identification of a patient population amenable to in utero intervention, namely, fetuses with isolated AS diagnosed in the midtrimester.

3. Proposing an evidence-based reassessment of ventriculoamniotic shunting through the North American Fetal Therapy Network (NAFTNet).

Congenital Hypothyroidism

Contents

All forms of congenital hypothyroidism occur in 1 in 4,000 live births worldwide. The dysgenetic form affects twice as many females as males. It is the most prevalent congenital endocrine disease. The incidence is approximately 1 in 32,000 in Blacks and 1 in 2,000 in Hispanics.

Synonyms and Related Disorders

Ectopic thyroid gland; Thyroid agenesis; Thyroid dysgenesis; Thyroid hypoplasia; Thyrotropin resistance

Genetics/Basic Defects

1. Inheritance (Ambrugger et al. 2001)
    1. Thyroid dysgenesis (Fisher 1997)
        1. The most frequent cause of congenital hypothyroidism (85% of cases)
        2. Morphological classification
            1. Ectopic thyroid gland: the most frequent malformation, observed most frequently at the base of the tongue
            2. Athyreosis (absence of any detectable thyroid tissue)
            3. Hypoplasia (partially absent thyroid)
        3. Sporadic in most cases
        4. Genetic factors contributing to the development of thyroid dysgenesis in 2% of cases with a positive familial history (Castanet et al. 2001)
        5. Molecular defects clarified only in few cases of thyroid dysgenesis (Grüters et al. 2002)
            1. TSH receptor gene (thyroid hypoplasia, "apparent athyreosis") (Abramowicz et al. 1997b)
            2. Transcription factors: thyroid-specific transcription factor-1 (TTF-1) (hypothyroidism, chorea, choreoathetosis, respiratory distress), TTF-2 (thyroid hypoplasia, cleft palate, choanal atresia, curly hair, developmental delay) (Clifton-Blight et al. 1998), PAX-8 (thyroid hypoplasia, ectopy)
            3. NKX2A (athyreosis, hypoplasia, normally developed gland, choreoathetosis, pulmonary problems, mental retardation, pituitary abnormalities)
    2. Autosomal recessive defects of thyroid hormone biosynthesis with identification of the

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_54

following candidate genes for congenital hypothyroidism
1. A homozygous mutation of the *betaTSH* gene (Biebermann et al. 1999)
2. Thyroid peroxidase (*TPO*) gene
    1. A hemoprotein responsible for tyrosine iodination and coupling
    2. Intriguing role of *TPO* mutations in the development of thyroid tumor
3. Sodium-iodide symporter (*NIS*) gene
4. Thyroglobulin (*TG*) gene
5. Pendrin (*PDS*) gene (Pendred syndrome) (Coyle et al. 1998)
6. Thyroid oxidase 2 (*THOX2*) gene (Moreno et al. 2002; Pfarr et al. 2006)
7. Inactivating mutation of the thyrotropin receptor causing profound hypoplasia of the thyroid gland (Abramowicz et al. 1997a)
8. Mutations in the gene encoding thyroid transcription factor-1 (*TTF-1*) are not a frequent cause of congenital hypothyroidism with thyroid dysgenesis (Abramowicz et al. 1997b)

3. Autosomal dominant transmission of congenital hypoplasia due to loss-of-function mutation of *PAX-8* (Macchia et al. 1998; Vilain et al. 2001)

2. Etiology of primary (permanent) hypothyroidism (thyroidal congenital hypothyroidism) (Macchia et al. 1999; Macchia 2000; De Vijlder 2003; Jain et al. 2008; Rastogi and LaFranchi 2010)
    1. Thyroid dysgenesis (aplasia, hypoplasia, hemiagenesis, or ectopia) (85% of cases with congenital hypothyroidism)
        1. Hypothyroidism due to a developmental anomaly
        2. Associated mutations (these account for only 2% of thyroid dysgenesis cases; 98% unknown)
            1. *TTF-2*
            2. *NKX2.1*
            3. *NKX2.5*
            4. *PAX-9*
    2. Thyroid dyshormonogenesis (hypothyroidism due to impaired hormone production) (10–20%)
        1. Sodium-iodide symporter defect
        2. Thyroid peroxidase defects
            1. Hydrogen peroxide generation defects (*DUOX2*, *DUOXA2* gene mutations)
            2. Pendrin defect (Pendred syndrome)
            3. Thyroglobulin defect
            4. Iodotyrosine deiodinase defect (*DEHAL1*, *SECISBP2* gene mutations)
    3. Resistance to TSH binding or signaling
        1. TSH receptor defect
        2. G-protein mutation: pseudohypoparathyroidism type 1a
3. Etiology of central (hypothalamic-pituitary) hypothyroidism (secondary hypothyroidism) (Rastogi and LaFranchi 2010)
    1. Isolated TSH deficiency (TSH β subunit gene mutation)
    2. Thyrotropin-releasing hormone deficiency
    3. Isolated, pituitary stalk interruption syndrome (PSIS), hypothalamic lesion, e.g., hamartoma
    4. Thyrotropin-releasing hormone resistance
    5. TRH receptor gene mutation
    6. Hypothyroidism due to deficient transcription factors involved in pituitary development or function
    7. *HESX1, LHX3, LHX4, PIT1, PROP1* gene mutations
4. Etiology of peripheral hypothyroidism (Rastogi and LaFranchi 2010)
    1. Resistance to thyroid hormone
    2. Thyroid receptor β mutation
    3. Abnormalities of thyroid hormone transport
    4. Allan-Herndon-Dudley syndrome (monocarboxylate transporter 8 [*MCT8*] gene mutation)
5. Etiology of syndromic hypothyroidism (Rastogi and LaFranchi 2010)
    1. Pendred syndrome (hypothyroidism, deafness, goiter): Pendrin mutation

2. Bamforth-Lazarus syndrome (hypothyroidism, cleft palate, spiky hair): *TTF-2* mutation
3. Ectodermal dysplasia (hypohidrotic, hypothyroidism, ciliary dyskinesia)
4. Hypothyroidism (dysmorphism, postaxial polydactyly, intellectual deficit)
5. Kocher-Deber-Semilange syndrome (muscular pseudohypertrophy, hypothyroidism)
6. Benign chorea (hypothyroidism)
7. Choreoathetosis (hypothyroidism – neonatal respiratory distress): *NKX2.1*/*TTF-1* mutation
8. Obesity, colitis (hypothyroidism, cardiac hypertrophy, developmental delay)

6. Etiology of transient form of primary congenital hypothyroidism (Moreno et al. 2002; Jain et al. 2008; Rastogi and LaFranchi 2010)
   1. Occurs in 5–10% of infants detected by newborn screening
   2. Represents about 5% of cases with congenital hypothyroidism
   3. Etiology
      1. Maternal thyrotropin binding inhibitory immunoglobulins (Schwingshandl et al. 1993)
      2. Exposure to goitrogens (iodides or antithyroid drugs)
      3. Transient hypothyroidism of prematurity
      4. Sick euthyroid syndrome
      5. Exposure to excess iodine in the perinatal period
         1. Use of iodinated disinfectants
         2. Use of contrast agents
      6. Heterozygous mutations of *THOX2* or *DUOXA2*
      7. Congenital hepatic hemangioma/hemangioendothelioma
7. Down syndrome: congenital hypothyroidism occurs approximately 28 times more common among infants with Down syndrome than in the general population with an incidence of 1% detected by newborn screening
8. Pathogenesis of mental retardation in congenital hypothyroidism: due to the central role of thyroid hormones in brain development, which takes place during fetal life and early postnatal life up to the second or third year of age (DeLange 1997)

Clinical Features

1. Coarse facies and growth failure in infants: suspect congenital hypothyroidism or acquired (autoimmune) hypothyroidism (Beltroy et al. 2003)
2. Severe dysgenetic and athyreotic hypothyroidism (Smith et al. 1975; Brown 2015)
   1. Early symptoms
      1. Poor feeding
      2. Constipation
      3. Growth failure
      4. Hoarse cry
   2. Signs and symptoms in infants and toddlers
      1. Delayed linear growth
      2. Hypotonia
      3. Decreased activity
      4. Lethargy
      5. Prolonged jaundice
      6. Bradycardia
      7. Hypothermia
      8. Cold to touch
      9. Pallor
      10. Dry/puffy/thick skin
      11. Sparse hair
      12. Characteristic craniofacial appearance
          1. Coarse facial feature
          2. Puffy eyes
          3. Myxedematous facies
          4. Large fontanelles
          5. A broad, flat nose
          6. Pseudohypertelorism
          7. Large, protruding tongue (macroglossia)
      13. Delayed tooth eruption
      14. Occasional cardiomegaly
      15. Protuberant abdomen with umbilical hernia
      16. Constipation

17. Poor nail growth
18. Delayed return of the deep tendon reflexes
19. Irreversible growth failure and mental retardation

Diagnostic Investigations

1. Newborn screening (American Academy of Pediatrics AAP Section on Endocrinology and Committee on Genetics and American Thyroid Association Committee on Public Health 1993): ideally universal screening at 3–4 days of age should be done for detecting CH. Abnormal values on screening (T4 < 6.5 ug/dL, TSH > 20mu/L) should be confirmed by a venous sample (using age-appropriate cutoffs) before initiating treatment.
    1. Successful identification of infants with congenital hypothyroidism
    2. Enables early diagnosis and treatment of infants and prevention of mental retardation in the majority of children (>90%) with congenital hypothyroidism if therapy is commenced within the first 2 weeks of life, making neonate screening for this disorder the most successful population-based screening test in pediatrics (Grüters and Krude 2012)
    3. Newborn screening measures either TSH or T_4 in neonatal blood placed on filter paper
    4. Confirmation with a serum sample if the filter paper result is abnormal
        1. Primary congenital hypothyroidism
            1. Low serum T_4 levels
            2. Elevated serum TSH
        2. Hypopituitary hypothyroidism
            1. Low total T_4 levels
            2. Low or normal TSH
        3. Thyroxine-binding globulin (TBG) deficiency
            1. Low total T_4 but normal serum-free T_4 levels
            2. Normal TSH
    5. Screening programs for congenital hypothyroidism in premature newborns (Kugelman et al. 2009)
        1. Sick premature infants may display transient hypothyroxinemia secondary to immaturity of the hypothalamic-pituitary axis.
        2. Therefore, early screening programs of such infants may be misleading.
        3. Recommendations.
            1. Screening programs should report thyroid-stimulating hormone (TSH) as well as thyroxin (T4) levels in premature infants, which will allow the treating physicians to be aware of possible abnormality that needs to be followed.
            2. Sick premature infants and other populations at risk should undergo a full serum thyroid function evaluation including free T4 and TSH beyond the screening program at discharge or at 30 days of age, whichever comes first.
            3. Physicians should use their clinical judgment and experience even in the face of normal newborn thyroid screening test and reevaluate for hypothyroidism when there is a clinical suspicion.
    6. Pendred syndrome (Banghova et al. 2008)
        1. An autosomal recessive disorder characterized by sensorineural hearing loss and thyroid dyshormonogenesis
        2. Caused by mutations in the *PDS*/*SLC26A4* gene
        3. Present from birth
        4. Can be diagnosed by newborn screening
2. Diagnostic studies for evaluation of congenital hypothyroidism (Jain et al. 2008; Agrawal et al. 2015).
    1. Laboratory diagnosis
        1. Thyroid function tests
            1. Elevated serum TSH
            2. Low serum T_4 levels
        2. Determine antithyroglobulin and antithyroid peroxidase antibodies if indicated

3. Determine thyroxine-binding globulin (TBG) levels for suspected TBG deficiency
4. ^{123}I uptake
5. Serum thyroglobulin levels
    1. Reflects thyroid mass
    2. Generally elevated with increased thyroid activity
    3. Elevated thyroglobulin levels with radionuclide scan finding of absent uptake: suggest presence of thyroid gland and the neonate may have a TSH receptor inactivating mutation trapping defect or maternal thyroid receptor blocking antibodies (TRB-ab) rather than aplasia
6. Urinary iodine estimation
    1. 24 h urinary iodine excretion approximates daily iodine excretion.
    2. The normal range in neonates approximately 50–100 mg/24 h.
    3. Measurement of urinary iodine may confirm iodine deficiency or excess.

2. Imaging studies
    1. Radiography for bone age
    2. Thyroid ultrasonography
        1. Considered as the best noninvasive method for the anatomical assessment of the thyroid gland
        2. Can detect thyroid aplasia or ectopic thyroid glands
3. Radionuclide scan (thyroid scintigraphy) using ^{99m}Tc or ^{123}I (DeLange 1997; Jain et al. 2008)
    1. To demonstrate the presence of ectopic thyroid tissue or thyroid aplasia (Kreisner et al. 2003)
    2. Iodide transport defect
        1. Low or absent uptake of ^{123}I
        2. Response to therapeutic doses of potassium iodide
    3. Defective organification of iodide
        1. Rapid uptake of ^{123}I
        2. Marked decrease in thyroid radioactivity when perchlorate or thiocyanate is administered 2 h after administering radioiodine
        3. Occasional sensorineural hearing loss (Pendred syndrome)
    4. Iodotyrosine-coupling defect
        1. Rapid uptake of ^{123}I
        2. No discharge by perchlorate
        3. Very high thyroid gland content of monoiodotyrosine (MIT) and diiodotyrosine (DIT)
        4. Virtually undetectable T_4 and T_3
        5. Adequately iodinated thyroglobulin
    5. Defects in thyroglobulin gene expression and thyroglobulin secretion
        1. Elevated uptake of ^{123}I
        2. No discharge by perchlorate
        3. Abnormal serum iodoproteins
        4. Elevated protein-bound/T_4 iodine ratio
        5. Low or borderline serum thyroglobulin
    6. Iodotyrosine deiodinase defect
        1. Rapid uptake and turnover of ^{123}I
        2. Elevated serum and urinary iodotyrosines (MIT, DIT)
        3. Response to iodine supplementation
    4. Suspected autoimmune thyroid disease: maternal and neonatal serum TBII measurement (not routinely available)
    5. Suspected iodine exposure or deficiency: urinary iodine measurement
    6. Ancillary test to determine severity of fetal hypothyroidism: radiograph of knee for skeletal maturation
3. Intelligence quotient (IQ) measurement for testing neuropsychological progress and outcome
4. Molecular genetic diagnosis (Grüters and Krude 2012)
    1. Mutations causing thyroid dysgenesis
        1. Due to the low frequency of mutations in patients with thyroid dysgenesis, genetic testing should be initiated only in those patients with either a suggestive clinical manifestation (*FOXE1*, *NKX2-1*, and *NKX2-5* gene mutations).
        2. Or with a familial occurrence of thyroid dysgenesis (*PAX8* and *TSHR* gene mutations).

2. Mutations causing thyroid dyshormonogenesis
    1. *TPO* and *TG*: the partial or complete loss of activity of the enzyme thyroid peroxidase (PO) or thyroglobulin (encoded by the *TG* gene) leads to severe hypothyroidism with a large goiter.
    2. *SLC26A4* gene: encodes pendrin, a protein expressed in follicular cells and in cells of the inner ear that transports iodine into the thyroid follicle.
    3. *DUOX*: defects in the H_2O_2-generating oxidase system (DUOX2, DUOX2a).
    4. *GNAS* mutations can cause central and primary congenital hypothyroidism.

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. Sporadic cases: low recurrence risk
        2. Autosomal recessive inheritance: 25%
        3. Autosomal dominant inheritance: low recurrence risk unless a parent is affected
    2. Patient's offspring
        1. Sporadic cases: low recurrence risk
        2. Autosomal recessive inheritance: low recurrence risk unless the spouse carries the recessive gene
        3. Autosomal dominant inheritance: 50%
2. Prenatal diagnosis (Agrawal et al. 2002)
    1. Ultrasonography and percutaneous fetal blood sampling (Noia et al. 1992; Abuhamad et al. 1995)
        1. Detection of fetal goiter (the second trimester)
            1. Presence of two echogenic masses in the fetal neck
            2. A rare yet potentially dangerous condition
            3. A large goiter may cause hyperextension of the neck of the fetus caused by a large goiter, resulting in malpresentation and complicating labor and delivery
            4. Possibility of compressing the trachea and asphyxiating the neonate after birth
        2. Fetal blood sample (28 weeks)
            1. Elevated TSH
            2. Low T4
            3. A repeat cordocentesis at 35 weeks showed normalization of fetal thyroid function
    2. Amniocentesis
        1. Determination of TSH concentration (markedly elevated TSH level) in amniotic fluid in the second trimester for the offspring of a couple both known to have an iodide (iodothyronine synthesis) enzymatic organification defect
        2. Affected fetus with markedly increased TSH level in the amniotic fluid sample for the trimester
    3. Molecular genetic diagnosis possible by sequencing of select exons on fetal DNA for previously identified mutations in a research laboratory
3. Management
    1. Sodium L-thyroxine
        1. The treatment of choice.
        2. Early therapy (within 14 days) with appropriate doses of thyroxine (about 10 μg/kg/day) will prevent any brain damage even in case of evidence of fetal hypothyroidism, since thyroxine of maternal origin will reach and protect the fetus (DeLange 1997).
        3. Avoid overtreatment to prevent the following adverse effects (LaFranchi 1999):
            1. Premature cranial suture fusion
            2. Acceleration of growth and skeletal maturation
            3. Problems with temperament and behavior
    2. X-linked dominant thyroxine-binding globulin deficiency (causing a low total T4 but normal free T4): no need for thyroid hormone replacement
    3. Intrauterine treatment of fetus with a large goiter (Perelman et al. 1990; Davidson

et al. 1991; Noia et al. 1992; Abuhamad et al. 1995; Agrawal et al. 2002)
   1. Indicated because of the morbidity associated with compression of the trachea and mechanical interferences during delivery.
   2. Intra-amniotic injections of T_3/thyroxine present the least invasive approach to fetal treatment.
      1. Rapid decrease in the fetal goiter size
      2. Normalization of fetal thyroid function
4. Intrauterine treatment of fetus affected with iodide organification defect with synthroid (Hirsch et al. 1990)
5. Intrauterine treatment of dyshormonogenetic fetal goiter due to defective thyroglobulin synthesis (Medeiros-Neto et al. 1997)

Congenital Infiltrating Lipomatosis of the Face

Contents

In 1983, Slavin et al. described a new entity termed "congenital infiltrating lipomatosis of the face" (CIL-F). It differs from the other lipomatosis in its exclusive facial location, its effects on adjacent structures, its congenital nature, and its precise histologic characteristics (Bouletreau et al. 2000).

Synonyms and Related Disorders

Facial infiltrating lipomatosis; *PIK3CA*-related overgrowth spectrum; *PIK3CA*-related segmental overgrowth

Genetics/Basic Defects

1. Etiology (Shenoy et al. 2015)
    1. Hamartomatous origin (Slavin et al. 1983).
    2. Aberrant differentiation in situ of mesenchymal cells into lipoblasts (Chen et al. 2002).
    3. Cytomegalovirus (CMV) infection (Donati et al. 1990; Patel and Gondalino 1991).
    4. Recently, patients with facial infiltrating lipomatosis, characterized by hemifacial soft tissue and skeletal overgrowth, precocious dental development, macrodontia, hemimacroglossia, and mucosal neuromas, were diagnosed with *PIK3CA*-activating mutations (Maclellan et al. 2014). The strategy used to identify somatic mutations in patients with facial infiltrating lipomatosis is applicable to other somatic mosaic disorders that have allelic heterogeneity.
2. Pathogenesis
    1. Unclear (Singh et al. 2011)
    2. Current theories
        1. Mutation in the PIK3CA gene, leading to lipomatous change through trauma, chronic irradiation, muscular metaplasia, degenerative processes with fatty transformation, influence of hormones on multipotential cells, and alteration in chromosome 12 (Mahadevappa et al. 2012; Sahai et al. 2013).
        2. CIL-F is at one end of a spectrum of overgrowth syndromes including Proteus syndrome, supporting the role of somatic mosaicism and sporadic occurrence with no age or sex predilection (Padwa and Mulliken 2001).
        3. Possibly due to sporadic, spontaneous somatic mutation involving local increase in tissue growth factor (Tadisina et al. 2015).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_282

Clinical Features

1. Onset: typically presents itself at birth or in early childhood
2. Unilateral swelling of the cheek with ill-defined borders
3. Progressive increase in the size of the swelling with a prominent soft tissue enlargement infiltrating muscle and soft tissues, making excision difficult and recurrence likely
4. Commonly ipsilateral macroglossia and macrodontia, in addition to enlargement of underlying bone (MacMillan et al. 1990), which can lead to a bite deformity (Bouletreau et al. 2000)
5. May involve the underlying bony structures of the temporomandibular joint, coronoid process, and zygomatic bone causing bony ankylosis and trismus (Keramidas et al. 2012)
6. Tooth abnormalities: common (Sun et al. 2013)
    1. Accelerated tooth formation
    2. Premature eruption
    3. Root malformations
7. Bony asymmetry becoming more prominent with age
8. A completely benign lesion with no evidence of malignant transformation
9. The rest of the clinical examination: normal with no trunk or limb anomalies
10. Differential diagnosis (Kim et al. 2010)
    1. Hemifacial hyperplasia
        1. Hemifacial and hemitongue enlargement: common
        2. Presence of mucosal neuromas and infiltration of soft tissue by mature adipocytes: not common
    2. Lymphangioma
        1. Diffuse neck swelling
        2. Histopathological analysis: typical lymphatic channels
    3. Lipoblastoma, lipoblastomatosis, or liposarcoma (Langhans et al. 2015)
        1. More localized soft tissue enlargements of the neck.
        2. Histopathological analysis: undifferentiated or immature adipocytes.
        3. Cytogenetic analyses identified a characteristic rearrangement of the long arm on chromosome 8 (8q11–8q13) occurring in nearly 90% of the lipoblastomas (Bruyeer et al. 2012; Coffin and Alaggio 2012).
        4. Cytogenetic analyses demonstrate a distinctive translocation t(12;16)(q13;p11) and a FUS-DDIT3 gene fusion in 95% of myxoid liposarcomas (Miller et al. 1997; Hicks et al. 2001; Kåbjörn Gustafsson et al. 2014).
    4. MEN2B, Cowden syndrome, and Bannayan–Riley–Ruvalcaba syndrome
        1. Presence of mucosal neuromas
        2. Testing positive for *RET* or *PTN* mutations
    5. Infiltrating angiolipoma or facial angioma: lack skeletal findings and mucosal neuromas
    6. Lipomatosis in Proteus syndrome: involve areas outside of the head and neck
    7. Encephalocraniocutaneous lipomatosis (also called Haberland syndrome) (Rizzo et al. 1993; Kocak et al. 2015)
        1. Unilateral skin lesions such as lipoma, connective tissue nevi, and alopecia
        2. Ipsilateral ophthalmological and cerebral malformation with or without psychomotor and mental retardation and early-onset seizure
    8. Nasopalpebral lipoma–coloboma syndrome
        1. Extremely rare, predominantly autosomal dominant disorder characterized by nasopalpebral lipomatous growth, accompanying eyelid colobomas, telecanthus, and maxillary hypoplasia (Babu et al. 2011).
        2. This is the second of two syndromes where lipomatous growth is isolated to the face.

9. *PIK3CA*-related segmental overgrowth: caused by heterozygous (usually somatic mosaic) *PIK3CA* mutations of (Mirzaa et al. 2013)
    1. Megalencephaly–capillary malformation syndrome
    2. Hemimegalencephaly
    3. Segmental body overgrowth
        1. Congenital *l*ipomatous asymmetric overgrowth of the trunk, lymphatic, capillary, venous, and combined-type vascular malformations, epidermal nevi, skeletal and spinal anomalies (CLOVES) syndrome
        2. Fibroadipose hyperplasia
10. *PIK3CA*-related overgrowth spectrum (Keppler-Noreuil et al. 2014)
    1. Absence of the term "segmental" because there are patients having the *PIK3CA* somatic mutation who present with bilateral and systemic involvement
    2. Inclusion of the term "spectrum" to emphasize that there are different but related phenotypes rather than one specific phenotype

Diagnostic Investigations

1. CT: typically showing a nonencapsulated diffusely infiltrating low-attenuation mass that usually measures between −65 H and −125 H (Hounsfield unit) in addition to bony changes (Malik et al. 2004)
2. MRI
    1. Probably the most helpful study
    2. Showing diffuse fatty infiltration and increased thickness of subcutaneous fat on the affected side
    3. A bright signal on both T1- and T2-weighted spin echo sequences with fatty extension into adjacent soft tissue (Ha et al. 1994)
3. Histopathological findings
    1. Important in obtaining the correct diagnosis.
    2. Infiltration of normal tissue by mature adipocytes versus undifferentiated or immature adipocytes in lipoblastomatosis (Shear 1967) and liposarcoma (Sauk 1971).
    3. Areas of normal tissue involved include submucosa, dermis, skeletal muscle, and parotid, submandibular, and minor salivary glands.
    4. An increased number of small vessels and mucosal neuromas are also seen.
4. Molecular study
    1. Patients were found to be negative to genetic testings: While FIL is thought to be caused by a somatic mutation involving local increase in tissue growth factors, molecular studies can be useful to rule out other disorders.
    2. Testing for *RET* mutation (MEN2B) and *PTEN* mutation (Cowden syndrome and Bannayan–Riley–Ruvalcaba syndrome) is recommended (Padwa and Mulliken 2001; Kim et al. 2010).

Genetic Counseling

1. Recurrence risk (Mirzaa et al. 2013)
    1. Patient's sib: the risk to sibs of a proband with somatic mosaicism for a mutation in *PIK3CA* would be expected to be the same as in the general population.
    2. Patient's offspring: no instances of vertical transmission of this disorder.
2. Prenatal diagnosis: usually not indicated for family members since CIL-F is not inherited
3. Management (Tadisina et al. 2015)
    1. Nonsurgical management
        1. Anti-angiogenic agents/anti-inflammatory therapy
        2. Chemotherapy with imatinib (Tracy et al. 2013) (in conjunction with excision)
    2. Surgical management
        1. Partial excision (complete excision not possible due to diffuse nature)
        2. Reconstruction of craniofacial deformity

Fig. 1 (**a**–**d**) This 6-year-old boy was seen for segmental overgrowth of his left face consistent with congenital infiltrating lipomatosis of the face. Considerable disfigurement and enlargement of the soft tissues around the left side of his face were noted (**a**–**c**). He had decreased movement of the gingiva, particularly on the left side and inside his mouth. A small nevus spilus was present on the left flank (**d**). Other physical features were normal. He was delivered at 32 weeks gestation with birth weight of 5 lb 5 oz and an obvious left side facial overgrowth. He met all of his developmental milestones at the appropriate age. He had received multiple debulking surgeries since birth. He has history of stable bicuspid valve, obstructive sleep apnea, and vision changes in the left eye (Courtesy of Dr. Jennifer Woerner and Dr. Ghali Ghali)

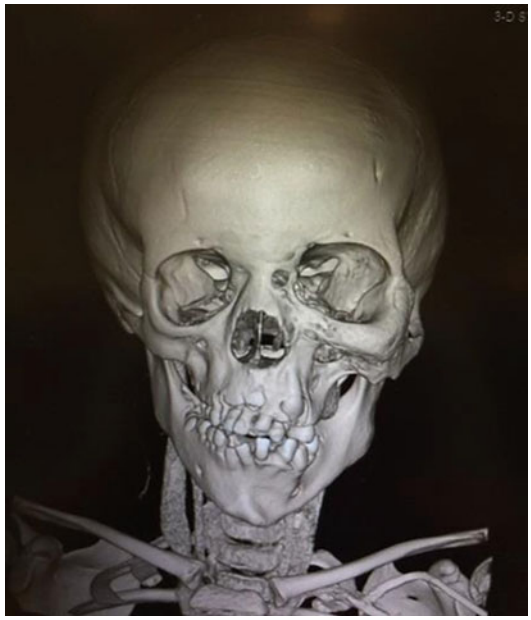

Fig. 2 3D reconstructed CT of his face, head, and neck showed hypertrophy of the left maxilla, left zygomatic arch, and left mandible. The left orbital cavity was distorted. There was a predominantly fatty lesion over the left side of his face, enhancing soft tissue and fatty infiltration into the left tongue and the floor of the mouth region. The CT of the neck also showed mild subcutaneous fat hypertrophy over the left side of the neck

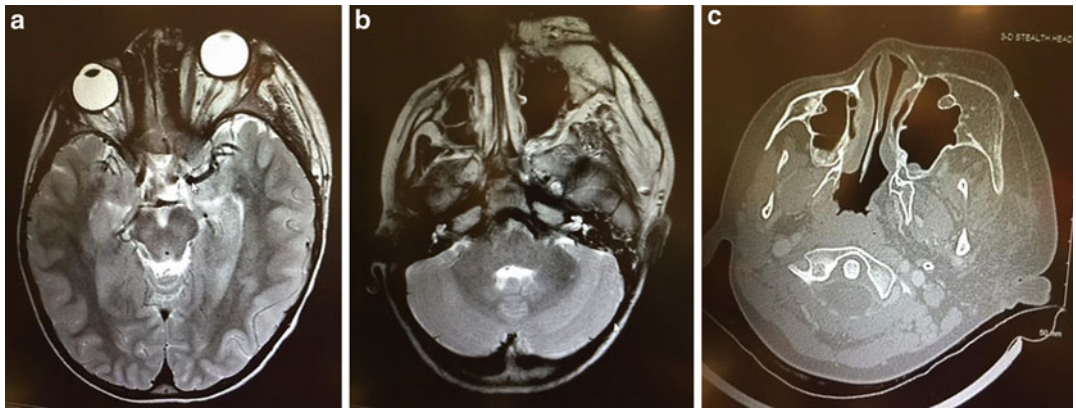

Fig. 3 (**a**–**c**) MRI of the brain and orbits showed extensive fatty tissue infiltration in the left side of the face with involvement of the orbit, infraorbital fissure, and inferior portion of the left cavernous sinus. There was proptosis involving the left orbit. There was thickening of the left medial rectus muscle compared to the right side. The brain parenchyma and ventricular system appeared unremarkable

Congenital Muscular Dystrophy

Contents

Congenital muscular dystrophy (CMD) refers to a group of genetic disorders in which weakness and an abnormal muscle biopsy are present at birth.

Synonyms and Related Disorders

Merosin-negative CMD; Merosin-positive CMD (rigid spine disease, Ullrich disease, pure CMD); Merosin-positive CMD with mental retardation and neuronal migration defects (Fukuyama CMD, muscle-eye-brain disease, Walker-Warburg syndrome)

Genetics/Basic Defects

1. Inheritance.
    1. Genetic heterogeneity
    2. Most are autosomal recessive (Muntoni and Voit 2004)
    3. Autosomal dominant (Leyten et al. 1986)
2. Caused by genetic defects in proteins of the sarcolemmal membrane or its supporting structures. The proteins may also be expressed in the central nervous system, and many forms of CMD are associated with structural brain and eye anomalies.
3. Classification of CMD (Guicheney et al. 1997; Topaloglu et al. 1990; Voit 1998; Cardamone et al. 2008; Mercuri and Muntoni 2012; Sparks et al. 2012; Iannaccone and Castro 2013; Bonnemann et al. 2014).
    1. Extracellular matrix protein
        1. Merosin (lamin-α2) (*LAMA2*): merosin-deficient CMD (MDC1A) (Helbling-Leclerc et al. 1995; Allamand and Guicheney 2002; Kang et al. 2015)
            1. Autosomal recessive merosinopathy
            2. Demyelinating neuropathy
            3. White matter signal changes on brain MRI
        2. Collagen VI (*COL6A1*, *COL6A2*, *COL6A3*) (Kang et al. 2015): Ullrich CMD, Bethlem CMD
            1. Proximal contractures
            2. Distal hyperextensibility
            3. Sandpaper rash
        3. Integrin α7 (*ITGA7*) deficiency (Lopate 2015)
            1. Described only in a few children
            2. Hypotonia in infancy with delayed motor milestones
            3. One patient with mental retardation

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_55

4. Another patient with contractures and respiratory failure
5. One patient required noninvasive ventilation at age 8 and became wheelchair bound at age 12

2. Sarcolemmal protein (Plectin, *PLEC1*): CMD with epidermolysis bullosa (Lopate 2015)
    1. Blistering skin rash from birth
    2. Nail dystrophy
    3. Scalp alopecia
    4. Progressive proximal muscle weakness, often leading to wheelchair bound by the second decade and may correlate with residual plectin function
    5. Myasthenic syndrome: may respond to pyridostigmine
        1. Ptosis
        2. Ophthalmoplegia
        3. Facial weakness
    6. Other systemic features
        1. Growth retardation
        2. Anemia
        3. Laryngeal webs
        4. Tooth decay
        5. Pyloric atresia
        6. Infantile respiratory insufficiency
        7. Cardiomyopathy.
3. Glycosyltransferases: autosomal recessive dystroglycanopathies (Kang et al. 2015)
    1. Fukuyama CMD (Toda et al. 1993, 2000; Kondo-Iida et al. 1999), Walker-Warburg syndrome
        1. *FKTN* (Fukutin)
        2. Eye and structural brain anomalies
        3. Seizures
        4. Mental retardation
        5. Absent α-dystroglycan on muscle immunocytochemistry
    2. Muscle-eye-disease: can be caused by the following mutations (Lopate 2015):
        1. *POMT1*
        2. *POMT2*
        3. *POMGnT1*
        4. *FKRP*
        5. *LARGE*
    3. Protein O-mannose β-1,2-N-acetylglucosaminyltransferase 1 (POMGnT1): muscle-eye-brain disease
        1. Eye and structural brain anomalies
        2. Absent α-dystroglycan on muscle immunocytochemistry
    4. Protein *O*-mannosyltransferase 1 (*POMT1*): Walker-Warburg syndrome, limb-girdle muscular dystrophy, type 2 K
        1. Eye and structural brain anomalies
        2. Seizures
        3. Mental retardation
        4. Absent α-dystroglycan on muscle immunocytochemistry
    5. Protein *O*-mannosyltransferase 2 (*POMT2*)
        1. Walker-Warburg syndrome: hydrocephalus
        2. Muscle-eye-brain disease: severe structural brain anomalies, absent α-dystroglycan on muscle immunocytochemistry
    6. Unknown protein: congenital muscular dystrophy type 1B (muscle hypertrophy, early respiratory failure)
    7. Fukutin-related protein (*FKRP*) (Brockington et al. 2001a, b): limb-girdle muscular dystrophy type 21, congenital muscular dystrophy type 1C, Fukuyama congenital muscular dystrophy, muscle-eye-brain disease, Walker-Warburg syndrome
        1. Duchenne phenocopy
        2. Cardiomyopathy
        3. Absent α-dystroglycan on muscle immunocytochemistry
    8. LARGE congenital muscular dystrophy: congenital muscular dystrophy type 1D
        1. Severe mental retardation
        2. White matter signal changes on brain MRI
    9. SIL1 (*SIL1*): Marinesco-Sjögren syndrome
        1. Cerebellar ataxia
        2. Congenital cataracts

4. Endoplasmic reticulum protein
    1. Rigid spine muscular dystrophy (Schara et al. 2008)
        1. Caused by mutations in *SEPN1* (selenoprotein N, 1) and *FHL1* (four-and-a-half LIM domain 1) (Kang et al. 2015)
        2. Extends the phenotypic spectrum of *ACTA1* myopathies to include congenital muscular dystrophy associated with rigid spine (O'Grady et al. 2015)
        3. Thin habitus
        4. Spinal rigidity
    2. Multicore myopathy: early respiratory failure
    3. Congenital fiber-type disproportion
    4. Myofibrillar myopathy
5. Nuclear envelope protein (Lamin A/C, *LMNA*): variable phenotype
    1. Emery-Dreifuss MD
    2. Limb-girdle muscular dystrophy type 1B
    3. Congenital muscular dystrophy
    4. Dilated cardiomyopathy
    5. Charcot-Marie-Tooth disease (CMT) type 2B1
6. RYR1 (ryanodine receptor 1)-related myopathy (Bharucha-Goebel et al. 2013)
    1. Autosomal recessive
    2. CMD presentation: dropped head syndrome, axial and scapuloperoneal involvement, absent or early loss of ambulation
    3. Milder presentations fuse with early-onset Emery-Dreifuss muscular dystrophy
7. CHKB-related CMD (Kobayashi et al. 1996; Nishino et al. 1998; Mitsuhashi et al. 2011; Bonnemann et al. 2014)
    1. Autosomal recessive
    2. Congenital weakness
    3. Cognitive impairment
    4. Pruritus
    5. Giant mitochondria in biopsy
8. PTRF-related PCGLP4 with CMD (Bonnemann et al. 2014)
    1. Autosomal recessive
    2. Congenital onset generalized progressive lipodystrophy
    3. Later rippling muscle

Clinical Features

1. Typical features
    1. Present in the first year of life.
        1. Hypotonia and weakness
        2. Respiratory insufficiency
        3. Bulbar dysfunction
        4. Arthrogryposis
    2. Hypertrophy of the tongue and limb muscles, scoliosis, and contractures may develop with age.
    3. Weakness is static or slowly progressive.
2. Merosin-negative CMD
    1. Demonstrating clinical homogeneity
        1. Severe hypotonia
        2. Multiple contractures
        3. Delayed developmental milestones
        4. Normal mentation
        5. Variable degrees of central hypomyelination seen on neuroimaging
    2. Patients with complete merosin deficiency
        1. Typically presenting as floppy infants
        2. May or may not require ventilatory assistance
        3. Most patients stabilize and able to continue developing without mechanical ventilation
        4. Feeding difficulty leading to recurrent aspiration and poor nutrition in some patients
        5. The best motor milestone achieved: standing with support
        6. Unable to ambulate
        7. Cognitive development
            1. Generally normal
            2. Mental retardation in patients with brain anomalies
        8. Epilepsy

3. Patients with partial merosin deficiency
    1. Wide clinical spectrum
        1. Marked hypotonia at birth, contractures, and severely delayed motor milestones
        2. Limb-girdle muscular dystrophy-like presentation in the teen
        3. An adult-onset proximal limb-girdle weakness with elevated CK concentration
    2. White matter abnormalities by MRI in all patients with documented merosin gene mutations
3. Merosin-positive CMD
    1. Rigid spine disease (Flanigan et al. 2000)
        1. Infantile hypotonia, with prominent neck muscle weakness and poor head control in the early years of life
        2. Initial improvement in muscle strength which parallels development, followed by stabilization or only minimal decrease in muscle strength, with marked loss of muscle bulk
        3. Contractures of the spine, resulting in rigidity in flexion and, to a lesser extent, contractures of limb joints
        4. Skeletal abnormalities, particularly scoliosis, which appear by age 5 years and may progress to require surgical intervention
        5. Early respiratory insufficiency, with onset before adolescence, often requiring nocturnal ventilatory support
        6. Normal intellectual function
        7. Essentially normal cardiac function
    2. Ullrich disease (Lopate 2015)
        1. Proximal joint contractures
        2. Distal joint laxity
        3. Delayed motor milestones
            1. Ability to walk in some cases
            2. Wheelchair dependent in majority of cases
        4. Normal intelligence
    3. Classic or "pure" CMD (Kobayashi et al. 1996; Leyten et al. 1996)
        1. Onset at birth or during the first year of life
        2. Respiratory difficult in early infancy
        3. Hypotonia and generalized muscular weakness
        4. Multiple joint contractures evident in the first year of life
        5. Clinical course nonprogressive or slowly progressive
        6. Normal or subnormal mental development (in any case IQ $>$ 50)
        7. CT/MRI: cerebral atrophy (24%) and areas of white matter lucency (11%)
    4. Other merosin-positive CMD
4. Merosin-positive CMD with mental retardation and neuronal migration defects
    1. Fukuyama CMD (Fukuyama et al. 1981; Fukuyama and Ohsawa 1984; Yoshioka and Kuroki 1994)
        1. An autosomal recessive disorder.
        2. Prevalent in Japan.
        3. Early onset (before 9 months).
        4. Muscle weakness.
        5. Accompanied by joint contractures.
        6. Hypotonia/hypokinesia.
        7. Small fraction of patients acquire the capacity to walk unassisted (Kondo-Iida et al. 1997).
        8. Severe mental retardation.
        9. Epilepsy.
        10. Eye anomalies (Chijiiwa et al. 1983).
            1. Entropion of lower lids
            2. Pathological myopia with astigmatism
            3. Congenital nystagmus
            4. Cortical blindness
            5. Optic nerve pallor/atrophy
            6. Irregular grayish subretinal mottling
            7. Choreoretinal degeneration
        11. Brain anomalies (cobblestone lissencephaly; type 2 lissencephaly).
            1. Micropolygyria
            2. Pachygyria
            3. White matter lucency
            4. Minor cerebellar alterations (cortical dysplasia)
    2. Muscle-eye-brain disease (Santavuori et al. 1977; Sparks et al. 2012)
        1. An autosomal recessive disorder

2. Mimics Walker-Warburg syndrome but overall changes tend to be much milder
3. Present as a floppy infant with suspected blindness
4. Severe mental retardation
5. Extensive neuronal migration disorder
    1. Pachygyria and polymicrogyria
    2. Brainstem hypoplasia
    3. Cerebellar dysgenesis
    4. Hydrocephalus
6. Muscle involvement: typical features of muscular dystrophy with ongoing de- and regeneration
7. Brain anomalies
    1. Frontoparietal pachygyria
    2. Polymicrogyria
    3. Vermis hypoplasia
    4. Cerebellum cyst/dysplasia
8. Normal expression of laminin α2

3. Walker-Warburg syndrome (Sparks et al. 2012)
    1. An autosomal recessive disorder
    2. Type II lissencephaly (Cormand et al. 2001)
        1. Micropolygyric "cobblestone" cortex
        2. Extensive white matter abnormalities
        3. Hydrocephaly with enlarged ventricles
        4. Brainstem hypoplasia
        5. Hypoplasia of the cerebellum, particularly the cerebellar vermis
    3. Ocular dysgenesis
        1. Megacornea
        2. Buphthalmos
        3. Corneal clouding
        4. Cataracts
        5. Abnormal vitreous
        6. Retinal hypopigmentation
        7. Hypoplasia of the optic nerve
        8. Clinically blind
    4. Muscular dystrophy
        1. Variable in severity: ranges from myopathy with increased variation of fiber size to severe, end-stage muscular dystrophy
        2. Well-preserved expression of laminin α2
    5. Brain anomalies
        1. Cobblestone lissencephaly
        2. Severe cerebellum hypoplasia
    6. Complete lack of psychomotor development (severe mental retardation) for those who survive for some years
5. Lethal congenital muscular dystrophy with arthrogryposis multiplex congenita (Sombekke et al. 1994)
    1. Maternal polyhydramnios.
    2. Arthrogryposis multiplex congenita.
    3. Severe muscle wasting.
    4. Lung hypoplasia.
    5. Hydrops.
    6. The muscle biopsies showed fibrosis, variation in fiber size, and extensive fat replacement compatible with muscular dystrophy.

Diagnostic Investigations

1. Serum creatine kinase (CPK) levels (Lopate 2015).
    1. Normal to mildly elevated (≤5 times normal): Ullrich congenital muscular dystrophy, rigid spine with muscular dystrophy (deficiency of selenoprotein N), and integrin-α7 deficiency
    2. Usually more than 1000: congenital muscular dystrophy with familial junctional epidermolysis bullosa
    3. Mildly to markedly elevated (2–150 times normal) in most patients with congenital muscular dystrophy due to abnormal glycosylation or with laminin-α2 mutations
2. Nerve conduction studies (NCV) may show demyelinating neuropathy in merosin-deficient CMD (Quijano-Roy et al. 2004).
3. Electromyography/NCV testing: useful to rule out a peripheral neuropathy associated particularly in LAMA2-related CMD (Quijano-Roy et al. 2004).

4. Muscle biopsy shows typical dystrophic changes (degeneration and regeneration of muscle fibers and proliferation of fatty and connective tissue).
5. Immunocytochemistry enables analysis of merosin, α-dystroglycan, collagen VI, and other muscle proteins (Jones and North 2003; Muntoni and Voit 2004; Bertini et al. 2011).
6. Muscle MRI.
    1. Particularly useful when suspecting a *COL6*-, *SEPN1*-, or *LMNA*-related CMD, showing specific or preferential involvement of certain muscle groups for each condition.
    2. In *COL6*-related disorders, the muscle MRI shows a characteristic pattern with diffuse fatty infiltration within thigh muscles taking the form of a rim of hypodensity at the periphery of muscles, particularly in vasti muscles, with a relative sparing of the central part and with relative sparing of the sartorius, gracilis, and adductor longus muscles.
    3. Particularly in the mild phenotypes of Bethlem myopathy, MRI shows a systematic fatty infiltration in the rectus femoris muscle and specifically takes the form of a central hypodensity described as a "central shadow sign."
    4. In selenoproteinopathies, selective involvement of sartorius and adductor longus muscles but sparing of the gracilis muscle is highly suggestive of the diagnosis.
7. Cerebral magnetic resonance imaging (MRI) may show abnormalities of neuronal migration and white matter signal.
    1. Pachygyria (with normal cognitive function)
    2. Cerebellar hypoplasia (with normal cognitive function but delay of speech development)
    3. Cerebellar cysts (in connection with pure CMD)
    4. Diffuse and symmetrical increase in signal in the white matter of the cerebral hemispheres (merosin-deficient CMD) (Caro et al. 1999)
    5. Large lissencephalic changes
    6. Hydrocephalus
8. Cardinal brain MRI findings of Fukuyama CMD (Aida 1998).
    1. Abnormalities of cerebral cortices, including cerebral polymicrogyria with preferential involvement of the frontal lobe and temporo-occipital pachygyria or type I1 lissencephaly
    2. Cerebellar polymicrogyria with parenchymal cysts
9. Molecular genetic analyses.
    1. Fukuyama CMD: sequencing of entire coding region or select exons of *FCMD* gene
    2. Muscle-eye-brain disease: sequencing of entire coding region or select exons or targeted mutation analysis of *POMGnT1* gene
    3. Walker-Warburg syndrome: sequencing of entire coding region or select exons or mutation scanning of *POMT1* gene
    4. Successful application of targeted sequencing in conjunction with next-generation sequencing to screen for mutations in hundreds of exons in a genetically heterogeneous human disorder, such as congenital muscular dystrophy (Valencia et al. 2012)

Genetic Counseling

1. Recurrence risk (Sparks et al. 2012).
    1. Patient's sib
        1. Autosomal recessive: a 25% recurrence risk
        2. Autosomal dominant (Ullrich congenital muscular dystrophy): a low recurrence risk but greater than that of the general population if both parents are clinically unaffected or if the disease-causing mutation found in the proband cannot be detected in the DNA of either parent, because of the possibility of germline mosaicism
    2. Patient's offspring:
        1. Autosomal recessive
            1. Many individuals not living long enough to reproduce.

2. All offspring are carriers.
3. Recurrence risk to offspring probably less than 1%.

2. Autosomal dominant: a 50% risk

2. Prenatal diagnosis.
   1. Possible for pregnancies at 25% risk for complete merosin deficiency, provided complete merosin deficiency has been documented in the muscle of the proband.
      1. The diagnostic testing must be done on a sample of direct and flesh-frozen chorionic villi obtained at about 10–12 weeks of gestation by immunostaining.
      2. Using molecular testing for mutations that have been previously identified in the proband by CVS or amniocentesis.
   2. Complete merosin deficiency (Guicheney et al. 1997, 1998): concerning families with a CMD child having complete merosin deficiency, microsatellite analysis can be used for prenatal diagnosis with or without a direct assessment of the laminin α2 chain in fetal chorionic villous biopsies.
   3. Partial merosin deficiency (Guicheney et al. 1997, 1998).
      1. Heterogeneous
      2. Important to detect laminin α2 chain gene defects in order to perform prenatal diagnoses by direct mutation analysis
   4. A combination of immunocytochemistry and linkage analysis can be used for the prenatal diagnosis of merosin-deficient CMD. The results are easy to interpret in families with total absence of the protein, while caution is required when dealing with families where partial expression occurs (Naom et al. 1997).
   5. Since laminin α2 chain is expressed in placental trophoblasts, the demonstration of its deficiency in chorionic villi is a useful aid to prenatal diagnosis of laminin-deficient CMD (Nass et al. 1999).
   6. Prenatal diagnosis by DNA mutation analysis is available for pregnancies at increased risk of Fukuyama MD (Kondo et al. 1996; Takai et al. 1998), muscle-eye-brain disease, Walker-Warburg MD, congenital muscular dystrophy type 1C and 1D, and congenital muscular dystrophy with early spine rigidity by analysis of fetal DNA, obtained by amniocentesis or CVS, provided both disease-causing alleles of an affected family member have been identified.
3. Preimplantation genetic diagnosis (PGD) may be an option for some families in which the disease-causing mutations have been identified in an affected family member (Sparks et al. 2012).
4. Management (Sparks et al. 2012).
   1. No definitive treatment available
   2. General approaches
      1. Weight control to avoid obesity
      2. Physical therapy and stretching exercises
         1. To promote mobility
         2. To prevent contractures
      3. Using mechanical devices to help ambulation and mobility
      4. Surgical interventions for scoliosis and foot deformity
      5. Medications for seizure control
      6. Respiratory aids as needed
      7. Social and emotional support

Congenital Radioulnar Synostosis

Contents

Although congenital proximal radioulnar synostosis is an uncommon malformation of the upper extremity, first described by Sandifort in 1973 (Simmons et al. 1983), congenital radioulnar synostosis (RUS) is the most common congenital functional disorder of the elbow joint (Siemianowicz et al. 2010). In most cases, RUS is an isolated defect involving only one limb. However, bilateral RUS is usually familial and affects males more than females (Figs. 1–3).

Synonyms and Related Disorders

Proximal radioulnar synostosis

Genetics/Basic Defects

1. Etiology (Rizzo et al. 1997; Elliott et al. 2010; Wurapa 2012)
    1. Isolated or congenital radioulnar synostosis types I and II (Davenport et al. 1924)
    2. Familial cases: inherited as autosomal dominant trait (Hansen and Andersen 1970; Spritz 1978; Rizzo et al. 1997)
    3. Association of RUS and chromosome anomalies: well known (Rizzo et al. 1997; Kidszun et al. 2012)
        1. X chromosome anomalies: polysomy X in both male and female patients with supernumerary X chromosomes (49,XXXXY, 49,XXXXX, 48, XXXX, 48,XXXY, 48,XXYY, 47, XXY)
        2. Y chromosome anomalies (De Smet and Fryns 2008; Syed and Quinton 2008)
        3. Other chromosome anomalies:
            1. Del(10)(pter-p13)
            2. Del(11)(q23)
            3. Del(13)(q22-qter)
            4. Dup(12)(q24-qter)
            5. Dup(14)(q23-qter)
            6. Partial trisomy 11q
            7. Trisomy 8 mosaicism
            8. Trisomy 18p
    4. Association of RUS with various syndromes
        1. Apert syndrome
        2. Arthrogryposis
        3. Berant syndrome (radioulnar synostosis and craniosynostosis)
        4. Carpenter syndrome

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_269

5. Cenani-Lenz syndactyly: a form of syndactyly resembling that of Apert syndrome but with additional features such as severe shortening of the ulna and radius with fusion, fusion of the metacarpals, "disorganization" of phalangeal development, and less severely affected feet (Cenani and Lenz 1967)
6. De Lange syndrome
7. Der Kaloustian syndrome (radioulnar synostosis, short stature, retinal changes)
8. Fetal alcohol syndrome (Froster and Baird 1992)
9. Fetal thalidomide syndrome (Smithells and Newman 1992)
10. Fetal vitamin A syndrome (Rizzo et al. 1991)
11. Holt-Oram syndrome
12. Jorgenson syndrome (blepharophimosis and radioulnar synostosis)
13. Mandibular dysostoses
14. Michels syndrome (clefting, ocular anomalies, radioulnar synostosis)
15. Multiple dysostosis
16. Nail-patella syndrome
17. Noonan syndrome
18. Poland syndrome
19. Williams syndrome
20. Others

5. Developmental gene(s) responsible has not been identified in isolated RUS (Elliott et al. 2010)
    1. Mutations in the homeobox A11 (*HOXA11*) gene resulting in autosomal dominant RUS with megakaryocytic thrombocytopenia in two pedigrees have been reported (Thompson and Nguyen 2000)
    2. The HOX genes: critical developmental genes in limb development
    3. Not all patients with the gene mutation demonstrated marrow failure

2. Developmental basis of proximal radioulnar synostosis (Elliott et al. 2010)
    1. The upper limb bud arises from the body wall at approximately 26 days of development (after conception)
    2. The elbow is first discernible at 35 days: presence of three connected cartilaginous anlagen which will eventually develop into the humerus, radius, and ulna
    3. Soon afterward, longitudinal segmentation produces separation of the distal radius and ulna. However, briefly, their proximal ends are united and share a common perichondrium (Lewis 1901)
    4. Abnormal genetic or environmental factors operating at this time in development could interrupt subsequent proximal radioulnar joint morphogenesis (Mital 1976)
    5. Such interference would allow for later ossification of the entire proximal cartilaginous model and produce complete bony synostosis. If joint development continued before the developmental arrest occurred, this could lead to a smaller area of coalition and the presence of a rudimentary radial head (Simmons et al. 1983)
    6. These two scenarios also represent related primary anomalies of radioulnar differentiation/segmentation. The final specific defect of this spectrum is influenced by subtle differences in developmental timing

Clinical Features

1. 2 types of radioulnar synostosis (Wilkie 1914; Bauer and Jonsson 1988)
    1. Type 1
        1. Proximal smooth fusion of 2–6 cm between the radius and ulna
        2. Absent radial head
        3. Resulting in a limitation of pronation and supination of the forearm
    2. Type 2
        1. A fusion just distal to the proximal radial epiphysis

   2. Association with congenital dislocation of the radial head
   3. Resulting in a limitation of pronation and supination of the forearm and a restriction of extension at the elbow
2. Pain
   1. Not always associated with radioulnar synostosis
   2. Occurrence of pain: usually thought to be due to progressive, symptomatic radial head subluxation (Sachar et al. 1994)

Diagnostic Investigations

1. Radiographic types (Cleary and Omer 1985)
   1. Type I (19%): fibrous synostosis with a reduced normal-appearing radial head
   2. Type II (8%): visible bony synostosis with a reduced radial head
   3. Type III (56%): visible bony synostosis with a hypoplastic and posteriorly dislocated radial head
   4. Type IV (17%): short bony synostosis with an anteriorly dislocated mushroom-shaped radial head
2. CT scans recommended especially in cases in which plain radiographs show no osseous fusion (Karatosun et al. 2004)
3. MRI: demonstrates soft tissue anatomy better

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Sporadic: probably not increased
      2. Autosomal dominant inheritance: not increased unless a parent is affected
   2. Patient's offspring
      1. Sporadic: probably not increased
      2. Autosomal dominant inheritance: 50%
2. Prenatal diagnosis of bilateral radioulnar synostosis by ultrasonography in a fetus of 49, XXXXY female at the second trimester of gestation (Martini et al. 1993)
3. Management
   1. Patients with congenital radioulnar synostosis in nearly neutral rotation could perform activities of daily living with the aid of compensatory movements of the shoulder and elbow (Kasten et al. 2009).
   2. Surgical intervention (Mostert and Tulp 2002):
      1. Usually not recommended, except in bilateral cases or in hyperpronation
      2. Optimal age for surgery difficult to define
         1. 4–5 years of age in cases of hyperpronated hand
         2. 12 years of age in the case of bilateral synostosis
   3. Derotational osteotomy at the shafts of the radius and ulna for congenital radioulnar synostosis (Murase et al. 2003).
   4. Surgical treatment with radial head excision yielded resolution of pain and restoration of elbow flexion (VanHeest et al. 2013).

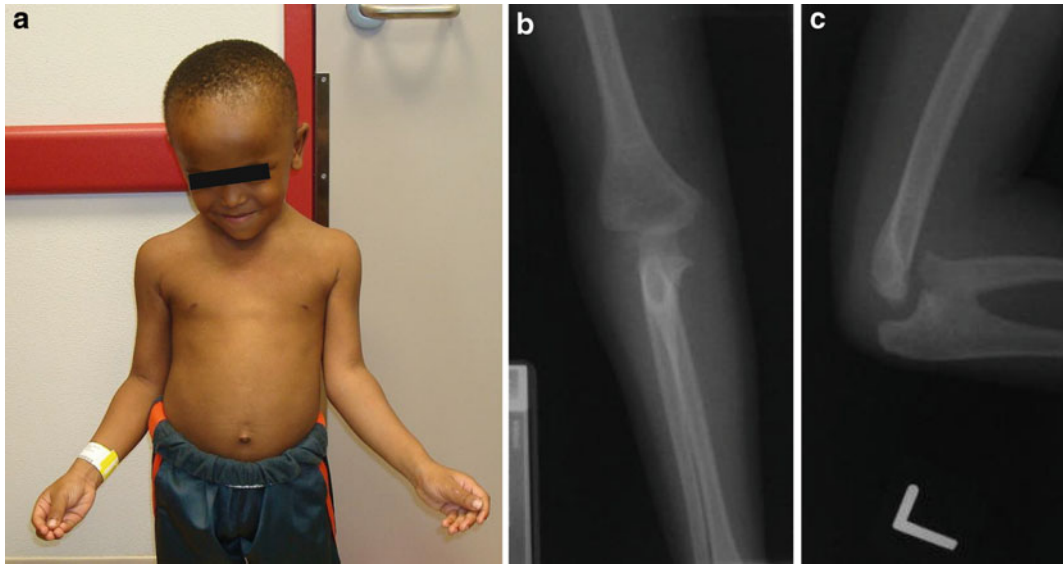

Fig. 1 (**a**–**c**) This 3½-year-old boy was evaluated for familial bilateral proximal radioulnar synostosis (shown by radiograph) (**b**, **c**). He had a large head, frontal bossing, and depressed nasal bridge is and unable to supinate both wrists (**a**)

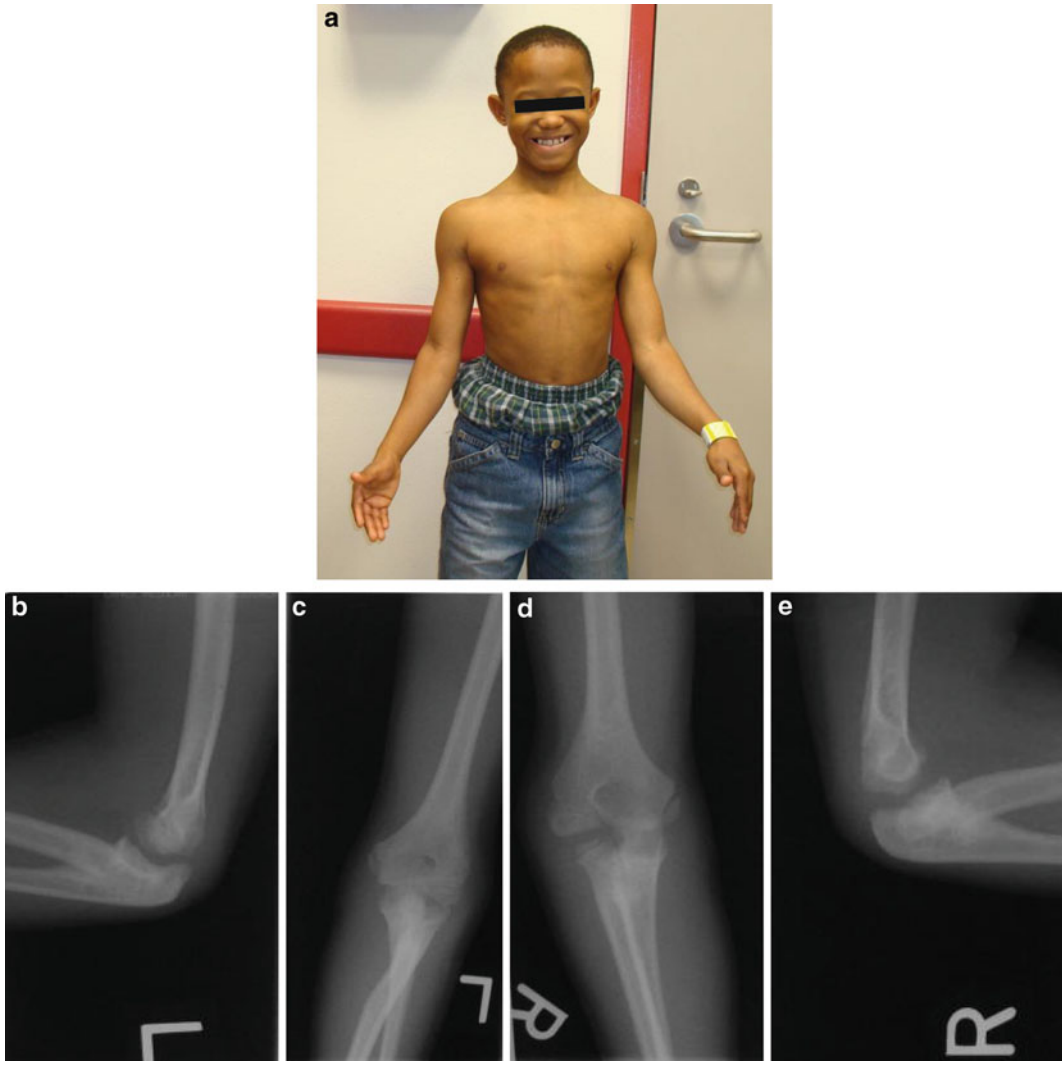

Fig. 2 (**a**–**e**) The 10-year-old brother also had bilateral proximal radioulnar synostosis, shown by radiographs (**b**–**e**) with similar clinical features (**a**)

Fig. 3 (**a**–**c**) This young boy was evaluated because of bilateral cubitus valgus (**a**). He could not extend his forearms fully and supinate his wrists. Radiographs showed bilateral proximal radioulnar synostosis (**b**, **c**)

Congenital Toxoplasmosis

Contents

Acute infection in a pregnant woman with a parasite, *Toxoplasma gondii*, can have serious consequences on the fetus, ranging from fetal loss to severe neurologic or ocular lesions. In other cases, infected newborns are asymptomatic at birth but are at risk for developing retinal diseases during childhood or adolescence on *Toxoplasma* reactivation (Wallon et al. 2004). In the United States, the incidence of congenital toxoplasmosis is estimated to be 1 in 1,000 to 1 in 10,000 births, and approximately 400–4,000 cases of congenital toxoplasmosis occur each year.

Synonyms and Related Disorders

Toxoplasma gondii infection in pregnancy

Genetics/Basic Defects

1. *Toxoplasma gondii* (Beasley and Egerman 1998; Black and Boothroyd 2000; Jones et al. 2003)
    1. A protozoan parasite
    2. The causative agent of toxoplasmosis, a common infection throughout the world with estimated one billion people infected worldwide
    3. Life cycle: exists in three forms
        1. The oocysts, or soil form
        2. The tachyzoite, or active infectious form
        3. The tissue cyst, or latent form
2. Hosts
    1. Cats
        1. The primary host
        2. Maintain the intestinal-epithelial sexual cycle of *Toxoplasma* development with the production of oocysts
    2. All other animals (humans, birds, rodents, and domestic animals)
        1. The intermediate or secondary hosts
        2. Have an extraintestinal asexual cycle with resultant parasitemia and the production of tissue cysts
3. Routes by which *Toxoplasma* is transmitted to humans
    1. Principal routes:

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_56

1. Acquired: risk factors for contracting toxoplasmosis (Kaye 2011; Maenz et al. 2014; Robert-Gangneux 2014)
    1. Cats in the home or stray cats in or around the home
    2. Any job or activity that requires contact with dirt, soil, or other material that could contain cat feces
    3. Ingestion of raw or inadequately cooked infected meat (beef, pork, or lamb), raw eggs, or unpasteurized milk
    4. Drinking untreated water
    5. Ingestion of unwashed fruit or vegetables
    6. Not washing hands thoroughly after handling raw meat or gardening
    7. Ingestion of oocysts, an environmentally resistant form of the organism that cats pass in their feces and human exposure to cat litter or contaminated soil (from gardening or unwashed fruits or vegetables)
2. Congenital: transplacental infection of unborn fetus by the newly infected mother

2. Rare routes:
    1. Blood and blood product transfusion
    2. Organ transplant
    3. Laboratory accident
3. No evidence of direct human-to-human transmission other than from mother to fetus

4. Seventy percent of the obstetric population with negative antibodies: at risk for transmission to the fetus.
5. Congenital toxoplasmosis usually occurs as a result of primary maternal infection.
6. Maternal-fetal transmission rate depends on gestational age at the time of maternal infection:
    1. Less than 5% before fifth week of gestation
    2. Twenty-five percent in the first trimester
    3. Seventy-five percent in the third trimester
    4. Greater than 90% in the last few weeks of pregnancy
7. Severity of the fetal infection inversely related to gestational age: the earlier infections being the most severe.
8. Untreated maternal infections: About 50% of cases transmit to the fetus.
9. An immunocompetent woman previously infected is considered immune and will not transmit *T. gondii* to her offspring. *Toxoplasma* infection leads to lifelong immunity with the presence of *T. gondii*-specific IgG antibodies. Acute toxoplasmosis in the adult is often asymptomatic and usually does not result in complications.
10. Reactivation can occur in immunocompromised pregnant woman (i.e., HIV) leading to parasitemia and fetal infection.

Clinical Features

1. Unpredictable manifestations in the fetus and in the newborn
2. Maternal infections
    1. Generally asymptomatic in immunocompetent mothers
    2. Subtle symptoms in about 15–20% of infected mothers
        1. Cervical lymphadenopathy: the most common clinical manifestation
        2. Fatigue
        3. Flu-like symptoms
    3. In immunocompromised mothers
        1. Chorioretinitis
        2. Encephalitis
        3. Pneumonitis
        4. Myocarditis
    4. Maternal infections early in pregnancy
        1. Less likely to be transmitted to the fetus than infections later in pregnancy
        2. More likely to be severe than later infections
3. Fetal infections
    1. Usually resulting from a primary maternal infection with risk of developing congenital abnormalities. Reactivation of *T gondii* in an immunocompromised patient can render the fetus susceptible to infection.

2. Infectivity: The incidence and severity of the fetal infection depend on the gestational age at the time of the maternal infection. The later the gestation, the higher the infectivity. However, the postnatal sequelae are severer when infection occurs early in gestation.

4. Natural history of congenital toxoplasmosis (Hall 1992)
   1. Free of symptoms at birth in vast majority of cases with congenital infection (70–90% of cases) (Bollani et al. 2013)
   2. About 15% of the infected children with signs or symptoms at birth or neonatal period
      1. Maculopapular rash
      2. Generalized lymphadenopathy
      3. Hepatosplenomegaly
      4. Jaundice
      5. Thrombocytopenia
      6. Consequences of intrauterine meningoencephalitis
         1. CSF abnormalities
         2. Hydrocephalus
         3. Microcephaly
         4. Chorioretinitis
         5. Seizures
      7. Signs of the "classic triad" (hydrocephalus, intracranial calcifications, and chorioretinitis) without systemic signs of disease
   3. Sequelae during childhood or early adult life in 50–90% of cases
      1. Learning disability
      2. Visual impairment
      3. Chorioretinitis: the most frequent congenital manifestation and is progressive in >80% of patients by 20 years of age
      4. Mental retardation
      5. Hearing loss
   4. Ocular lesions: the most frequent manifestations of congenital toxoplasmosis (Metz 2001; Hovakimyan and Cunningham 2002; Melamed et al. 2010)
      1. Chorioretinal scars: a clinical hallmark of ocular toxoplasmosis (79%)
      2. Strabismus (33%)
      3. Nystagmus (27%)
      4. Microphthalmia (13%)
      5. Phthisis (4%)
      6. Microcornea (19%)
      7. Cataract (10%)
      8. Active vitritis (11%)
      9. Active retinitis (11%)
      10. Optic atrophy (20%)
   5. Severely affected congenital infection
      1. Die in utero
      2. Die within a few days of life

Diagnostic Investigations

1. Serological testing (Beasley and Egerman 1998; Lynfield and Eaton 1995)
   1. IgM anti-*Toxoplasma* antibodies
      1. Produced 1–2 weeks after an infection
      2. Levels detectable for years after the acute infection
   2. IgM elevations (Alford et al. 1974)
   3. IgG anti-*Toxoplasma* antibodies
      1. Levels peak approximately 2 months after the initial infection
      2. Remain positive for life
   4. IgA anti-*Toxoplasma* antibodies
      1. Parallels IgM production
      2. Peak levels occur approximately 2 months after the initial infection and then rapidly decline
   5. IgE anti-*Toxoplasma* antibodies
      1. Detected early after an acute infection
      2. Usually present for 4–8 months
      3. May provide useful information regarding the timing of an acute infection
   6. *Toxoplasma gondii* recombinant antigens as tools for serodiagnosis of human toxoplasmosis (Holec-Gasior 2013)
2. Detection of antibodies to toxoplasmosis in the neonatal period (Naessens et al. 1999)
   1. Specific *T. gondii* IgM antibody
      1. A positive IgM antibody in the newborn: diagnostic of congenital toxoplasmosis
      2. A negative IgM antibody in the newborn does not exclude the diagnosis and may be due to the following reasons:

1. Lack of production of IgM
2. Waning of the IgM response by the time of birth
3. Insensitivity of the assay

3. A positive IgM antibody in the mother
   1. Associated with recent maternal infection
   2. Would support the diagnosis of congenital toxoplasmosis

2. Specific *T. gondii* IgA antibody: more sensitive test than IgM antibodies
3. Neonatal screening with IgM or IgA antibodies fails to detect majority of children with congenital toxoplasmosis when the maternal infection occurred before the 20 week of pregnancy

3. Definitive postnatal diagnosis of congenital toxoplasmosis
   1. Detection of parasites in material collected from the newborn (blood, cerebrospinal fluid, or other clinical material) by inoculation into mice or tissue culture
   2. Detection of persisting specific IgG antibodies at the age of 1 year
   3. Reappearance of specific IgG antibodies in the child after cessation of postnatal antibiotic therapy
   4. Diffuse cerebral calcifications and hydrocephalus detected by radiography, ultrasonography, CT scan, or MRI of the brain
4. Other diagnostic evaluation of the infants
   1. Physical examination
   2. Dilated retinal examination
   3. Examination of the cerebrospinal fluid
      1. Protein
      2. Glucose
      3. Cell count
      4. Antibody determination
   4. Audiologic screen
   5. Examination of the placenta
      1. Evidence of infection, although the gross appearance may not parallel the severity of fetal disease
      2. Inoculation of the placental tissue into mice or tissue culture to attempt isolation of the parasite
      3. The feasibility of placental analysis, in terms of sample recovery and rapid *T. gondii* detection by PCR, makes it a useful diagnostic tool for early monitoring and treatment of neonates at risk for congenital infection (Robert-Gangneux et al. 2010)
   6. Diminution or resolution of intracranial calcifications was an unexpected and remarkable finding in infants with treated, congenital toxoplasmosis, consonant with their improved neurologic functioning (Patel et al. 1996)

Genetic Counseling

1. Recurrence risk: women with previous infection not at risk for delivering a fetus with congenital toxoplasmosis unless immunosuppressed
2. Prenatal diagnosis (Daffos et al. 1988; Hezard et al. 1997)
   1. Seroconversion during pregnancy
      1. Absence of specific *Toxoplasma gondii* IgG antibodies in the first serum sample obtained during gestation
      2. Detection of specific IgG and IgM antibodies in the follow-up sample at a later prenatal visit or at birth
   2. Suggestive but not diagnostic signs by prenatal ultrasonography (Beasley and Egerman 1998)
      1. Ventriculomegaly: the most common sonographic finding in utero
      2. Intracranial calcifications
      3. Hydrops
      4. Microcephaly
      5. Choroid plexus cysts
      6. Growth retardation
      7. Hepatomegaly
      8. Splenomegaly
      9. Ascites
      10. A thickened placenta
   3. Prenatal diagnosis of acute infection in the fetus
      1. Amniocentesis or cordocentesis (Fricker-Hidalgo et al. 1997; Foulon et al. 1999a; Antsaklis et al. 2002)

1. Detection of parasites in amniotic fluid or in fetal blood by inoculation into tissue culture or mice
2. Detection of anti-*Toxoplasma gondii* IgM, IgA, and IgE antibodies in the fetal blood. The diagnosis of fetal *T. gondii* infection before 22 weeks using cordocentesis is not possible because fetal IgM or IgA may not be produced before 22 weeks' gestation
3. Detection of *T. gondii* DNA (B1 gene) by gene amplification in amniotic fluid: the best diagnostic tools for the detection of vertical transmission in pregnancies with seroconversion during pregnancy and more accurate and faster diagnosis of congenital toxoplasmosis (Hohlfeld et al. 1994)

2. Chorionic villus sampling not helpful because it will show placental but not fetal infection

3. Management
   1. Prevention of *Toxoplasma* infection
      1. Cook meat to a safe temperature to kill *Toxoplasma*.
      2. Peel or thoroughly wash fruits and vegetables before eating.
      3. Clean cooking surfaces and utensils after they have contacted raw meat, poultry, seafood, or unwashed fruits or vegetables.
      4. Avoid changing cat litter during pregnancy or use gloves and wash hands thoroughly.
      5. Do not feed raw or undercooked meat to cats and keep cats inside to prevent acquisition of *Toxoplasma* by eating infected prey.
      6. Avoid risk factors for *T. gondii* infection including careful adherence to simple hygienic measures during pregnancy (decrease *Toxoplasma* infection by 60%).
   2. Treat *Toxoplasma* infection with spiramycin, pyrimethamine, sulfonamides, and folinic acid (Hohlfeld et al. 1989; Roizen et al. 1995).
      1. Reduce sequelae of congenital infection by treating the mother as soon as possible after the serologic screening program identifies the infection (Foulon et al. 1999b).
      2. Treat infected neonates: The sooner the treatment, the better the outcome.
   3. Newborn screening for *Toxoplasma*-specific IgG and IgM allows the identification and treatment of subclinical cases so that the sequelae of infection with toxoplasmosis may be prevented or attenuated (Guerina et al. 1994).

Conjoined Twins

Contents

Conjoined twins are incompletely separated monozygotic twins. They have long fascinated both medical profession and lay public. Such events are rare and occur in 1/50,000–1/100,000 births and 1 in 400 sets of monozygotic twins. Over 60% succumb in utero or are stillborn (Spitz 2005). It is a complication of monochorionic twinning at 13–15 days after conception.

Synonyms and Related Disorders

Cephalopagus; Craniopagus; Dicephalus; Diprosopus; Epigastrius; Fetus in fetu; Ischiopagus; Omphalopagus; Pygopagus; Rachipagus; Thoracopagus

Genetics/Basic Defects

1. Conjoined twins
    1. Rare variants of monozygotic, monochorionic twins
    2. Two theories of conjoined twin formation
        1. Resulting from the secondary union of two originally separate monovular embryonic disks
        2. Resulting from an incomplete separation of the inner cell mass at around 13–15 days of gestation of the monovular twins
    3. Twins conjoining at any site from the cranium downward to the sacrococcygeal region
    4. Approximately 60% stillborn
    5. Female predominance (Edmonds & Layde 1982): approximately 3:1 female-to-male ratio
2. Embryologic classification of conjoined twins (Zimmermann 1967; Benirschke et al. 1978; Spencer 1996; Spencer 2000a, b; McHugh et al. 2006; Winkler et al. 2008): Greek word "pagus" added to denote fixing to union site
    1. Ventral union (87%)
        1. Rostral (48%)
            1. Cephalopagus (11%): fusion from top of the head to umbilicus; each twin having two arms and legs; separate lower abdomen and pelvis
            2. Thoracopagus (20–40 %): position face to face, with fused thoraces and with a shared heart or single interatrial vessel
            3. Omphalopagus (18–33 %): similar fusion to thoracopagus

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_57

without shared heart or interatrial vessel
2. Caudal (11%) (ischiopagus): a large, conjoined pelvis, more commonly joined end to end; can be face to face with a conjoined abdomen; always shared external genitalia and anus

2. Dorsal union (13%)
1. Craniopagus (5%): joined by any portion of the skull except the face and foramen magnum, shared cranium, meninges, and, occasionally, the brain
2. Rachipagus (2%): dorsal fusion above the sacrum
3. Pygopagus (6%): fused sacrococcygeal and perineal regions, typically with shared anus but separate rectums; shared spinal cord

3. Lateral union (28%): parapagus (side-to-side connection with shared pelvis and variable cephalad sharing), defined as follows:
1. Dithoracic parapagus (separate thoraces and heads)
2. Dicephalic parapagus (separate head with fused thoraces)
3. Diprosopus parapagus (two faces on the same side of a single head)

3. Anatomic classifications of conjoined twins, based on how the body axes of the twins are mutually oriented in the embryonic disk
1. Notochordal axes facing each other
1. Ventro-ventral
1. Thoracopagus
2. Xiphopagus
3. Omphalopagus
2. Cranial ventro-ventral (cephalothoracopagus)
3. Caudal ventro-ventral (ischiopagus)
4. Cranial end to end (craniopagus)
5. Caudal end to end (pygopagus)

2. Notochordal axes facing side by side
1. Dicephalus
2. Diprosopus

4. Anatomic classifications of conjoined twins, based on how the subsequent events of migration, growth, and body folding result in different types of conjoined twins
1. Dipygus
2. Fetus in fetu
1. A fetiform mass located within a basically normal fetus (Spencer 2001)
2. Inclusion of a monozygotic diamniotic twin within the bearer being the best explanation

5. Duplicitas symmetros (symmetrical conjoined twins resulting from incomplete fission of the uniovum) (Gilbert-Barness et al. 2003)
1. Terata katadidyma (twins joined at the lower part of the body and double above)
1. Dicephalus (twins with two separate heads and necks side by side with one body; lateral conjugation)
2. Diprosopus (twins with two faces side by side, one head, and one body)
3. Ischiopagus (twins joined by the inferior margins of the coccyx and sacrum with two completely separate spinal columns; caudal conjugation)
4. Pygopagus (twins joined by posterior surfaces of the coccyx and sacrum, back to back; posterior conjugation)
5. Craniothoracopagus
6. Ileothoracopagus

2. Terata anadidyma (twins joined at the upper part of the body and double below)
1. Craniopagus (twins joined at the top of cranial vaults; cephalic conjugation)
2. Dipygus (twins with one head, one thorax, one abdomen, and double pelvis with or without two sets of external genitalia and up to four legs; lateral conjugation)
3. Syncephalus (twins joined by the face; the faces turning laterally)

3. Terata anakatadidyma (twins joined by the midportion of the body)
1. Omphalopagus (twins joined from the umbilicus to xiphoid cartilage; anterior conjugation)
2. Xiphopagus (twins joined at xiphoid process)

3. Rachipagus (twins joined by the vertebral column; back to back)
4. Thoracopagus (twins joined at the chest wall; anterior conjugation)

6. Duplicatas asymmetros (asymmetrical conjoined twins resulting from unequal and incomplete fission of the uniovum and unequal placental circulation to twins)
   1. Cephalic conjugation
      1. Craniopagus parasiticus
      2. Janus parasiticus
      3. Epignathus heteropagus
   2. Anterior conjugation
      1. Thoracopagus parasiticus
      2. Epigastrius
   3. Posterior conjugation
      1. Ischiopagus parasiticus
      2. Pygopagus parasiticus
      3. Sacral parasiticus (Chou et al. 2001)

Clinical Features

1. Thoracopagus twins
   1. Represents 40% of conjoined twins
   2. Conjoined at the thoracic region
   3. Face to face
   4. Associated congenital heart defects
      1. Present in 75% of cases
      2. Presence of varying degree of pericardial sac fusion
      3. A conjoined heart with two ventricles and a varying number of atria (most frequent abnormality)
      4. Ventricular septal defect in virtually all patients
2. Omphalopagus twins (fused umbilical region)/xiphopagus twins (fused xiphoid process of the sternum) (Harper et al. 1980; Wilcox et al. 1998)
   1. Constitutes one third of all types of conjoined twins
   2. The most readily separable conjoined twins since their union perhaps involving only the skin and portions of the liver, occasionally including portions of the sternum
   3. Most omphalopagus twins joined by a skin bridge that contains the liver and bowel
   4. Conjoined liver in 81%
   5. Conjoined sternal cartilage in 26%
   6. Conjoined diaphragm in 17%
   7. Conjoined genitourinary tract in 3%
   8. Malformations of the abdominal wall (usually omphalocele) in at least one of the twins in 33%
   9. Congenital heart defects in at least one of the twins in 25%
      1. Ventricular septal defects
      2. Tetralogy of Fallot
   10. Concordant congenital heart defects in only 1 out of 9 sets of twins
3. Pygopagus twins
   1. Constitutes 19% of conjoined twins
   2. Conjoined at sacrum (buttocks and lower spine)
   3. Most commonly back to back (face away from each other)
   4. May share part of the sacral spinal canal
   5. May share common rectum and anus
   6. Often with fused genitalia
4. Ischiopagus twins
   1. Constitutes 6% of conjoined twins
   2. Conjoined back to back at the coccyx
   3. Often with a common large pelvic ring formed by the union of the two pelvic girdles
   4. May have four legs (ischiopagus tetrapus)
   5. May have three legs (ischiopagus tripus)
   6. Frequently share the lower gastrointestinal tract
      1. The intestines joined at the terminal ileum
      2. Emptying into a single colon
   7. May have a single bladder and urethra
   8. Displaced anus
   9. Common vaginal anomalies
   10. Common rectovaginal communications
5. Craniopagus twins (fused at the cranial vault) (2%)
   1. Classification according to the area of junction
      1. Frontal craniopagus

2. Parietal craniopagus (most common)
3. Temporal craniopagus
4. Occipital craniopagus

2. Classification based on surgical and prognostic purposes
    1. Partial type (brains separated by the bone or dura with each brain having separate leptomeninges)
    2. Complete type (presence of cerebral connection)

6. Rachipagus twins (fused upper spinal column; back to back)
7. Pygodidymus twins (fused cephalothoracic region; duplicate pelvi and lower extremities)
8. Pygopagus twins/pygomelus twins (joined back to back at the sacrum; additional limb or limbs at or near the buttock)
9. Iniopagus twins/craniopagus occipitalis twins (fused head, at parasitic occipital region)
10. Epicomus twins/craniopagus parasiticus twins (smaller, parasitic twin joined to larger autosite at occiput)
11. Monocephalus twins (single head with two bodies)
12. Diprosopus twins (single body with two faces)
13. Dicephalus twins (symmetric body with two heads)
14. Dipygus parasiticus twins (the head and thorax completely merged; the pelvis and lower extremities duplicated)
15. Cephalopagus conjoined twins
    1. The rarest type of conjoined twins
    2. Fused from the top of the head to the umbilicus
    3. Presence of two faces on the opposite sides of the head with one face usually being rudimentary
    4. Separation of the lower abdomen
    5. With four arms and four legs
    6. Prognosis dismal dependent on the following factors
        1. Presence of associated anomalies
        2. Degree of fusion of the intracranial, intrathoracic, and/or intra-abdominal structures
        3. Extent of venous connections
16. Epigastric heteropagus twins (Petit et al. 2001)
    1. A rare type of conjoined twinning
    2. Resulting from an ischemic atrophy of one fetus at an early stage of gestation
    3. The pelvis and lower limbs of the ischemic fetus (incomplete parasitic twin; heteropagus) attached to the epigastrium of the well-developed fetus (the autosite)
17. Fetus in fetu
    1. The parasites embodied in the autosite, usually within cranial, thoracic, and abdominal cavities during the developmental process of the asymmetrical conjoined twins
    2. Most likely arise from inclusion of a monochorionic, diamniotic, monozygotic twin within the bearer due to anastomoses of vitelline circulation (Nastanski and Downey 2001)
18. Prognosis
    1. A high mortality rate.
        1. Nearly 40% are stillborn.
        2. One third die within 24 h of birth.
        3. No prospect of survival when complex cardiac union is present.
    2. Causes of death
        1. Severely abnormal conjoined heart
        2. Pulmonary hypoplasia due to distortion of fused thoracic cages
19. Examples of historically famous conjoined twins (Guttmacher 1967; Sills et al. 2001; Gilbert-Barness et al. 2003; Spitz 2005)
    1. So-called Biddenden Maids (1100–1134) in England
        1. Probably pygopagus twins
        2. Their famous image imprinted on the "cakes"
        3. Walks with their arms around each other
        4. Lived together for 34 years and died within 6 h
    2. Chang and Eng Bunker (1811–1874) from Bangkok and settled in the USA ("Siamese twins")

1. Born on a riverboat in Siam
2. Joined at the xiphisternum by a short bank that stretched so they were eventually able to stand side by side
3. Taken by Hunter, a traveling Scottish merchant, to the USA where they were exhibited by the showman
4. Later married to twin sisters
5. Fathered 22 children
6. Lived together for 63 years and one dying shortly from other twin

3. Blažek sisters (1878–1922) from Bohemia
   1. Two heads
   2. Four arms
   3. Four legs
   4. Partially fused torso
   5. Combined reproductive organs
   6. Delivered an infant through a single vagina but the gestation occurring in the uterus of one of the twins

Diagnostic Investigations

1. Prenatal echocardiography
   1. Presence and extent of cardiac conjunction
   2. Associated cardiac defects
2. Prenatal radiography
3. Prenatal ultrasonography (including transvaginal and three-dimensional sonography) (Maymon et al. 1998), (the surface-rendered image of the conjoined twin and its demonstration on an axially rotating cine loop facilitates explanation of the precise nature of the abnormalities, especially in the case of cephalothoracopagus conjoining)
4. CAT scan and MRI of the abdomen and the chest
   1. Anatomy of the heart
   2. Anatomy of the livers
   3. Anatomy of the genitourinary systems
   4. CT scan allows prospective diagnosis of fetus in fetu (Awashi et al. 2001)
5. Gastrointestinal contrast studies to demonstrate the presence and level of conjunction of the intestinal tract
6. Ventrally fused conjoined twins (Gore et al. 1982)
   1. Prenatal radiography/ultrasonography
      1. Fetal body parts on the same level
      2. Constant relative fetal position
      3. Fetal extremities in unusual proximity
      4. Face-to-face fetal position
      5. Bibreech, less commonly bicephalic presentation
      6. Hyperextension of one or both cervical spines
   2. Prenatal ultrasonography
      1. Nonseparable continuous external skin contour
      2. Single heart sound by Doppler
      3. Solitary large liver and heart
      4. Multiple shared omenta
      5. Solitary umbilical cord with >3 vessels
7. Cephalothoracopagus (Chen et al. 1997; Kuroda et al. 2000)
   1. Prenatal radiographic criteria
      1. Both fetal heads at the same level
      2. Backward fusion of the cervical spines
      3. A narrow space between lower cervical and upper thoracic spines
      4. No change in fetal relative positions after maternal movement
   2. Prenatal sonographic criteria
      1. Fusion of the skulls, face, thorax, and upper abdomen
      2. Fetal body parts at the same level
      3. Constant relative fetal motion
      4. Fetal extremities in unusual positions
      5. Breech position
      6. Hyperextension of both cervical spines
      7. Nonseparable external skin contour
      8. A solitary umbilical cord with multiple vessels
      9. Polyhydramnios
      10. Two actively beating hearts
      11. Two sets of pelvi, limbs, and spine

Genetic Counseling

1. Recurrence risk
    1. Patients sib: not higher according to family study
    2. Patient's offspring: report of delivery of a healthy male infant to the pygopagus Blažek sisters
2. Prenatal diagnosis: imaging techniques utilized in prenatal diagnosis of conjoined twins (Baken et al. 2013)
    1. Conventional 2D ultrasound: sufficient in most cases
    2. 3D ultrasound and Doppler ultrasound: to gain extra and more precise information in an efficient way
    3. Computed tomography (CT) scan
    4. Magnetic resonance imaging (MRI)
    5. 3D virtual embryoscopy: provide additional diagnostic information in evaluating complex anatomical structures, especially when depth perception is needed; may contribute to earlier, more appropriate counseling and management
3. Management
    1. Early prenatal diagnosis: highly desirable, given the extremely poor prognosis of some types of conjoined twins (Benirschke 1998)
    2. Psychological and prognosis counseling
    3. Accurate preoperative investigation
    4. A team approach
    5. Previous experience
    6. Meticulous operative and postoperative management
    7. Substantial mortality rate related to the underlying conditions
    8. High likelihood of success if major associated anomalies are absent
    9. Options of obstetrical management
        1. Continuing the vaginal delivery and delivering the twins intact
        2. Delivering the twins vaginally after intrauterine separation or a destructive procedure
        3. Cesarean section and delivering the twins intact
        4. Cesarean section and delivering the twins after intrauterine separation or destruction
    10. Anesthetic management for separating operations (Keats et al. 1967)
        1. Extensive cross circulation
            1. Through a liver bridge
            2. Common cerebral venous sinus
        2. Mechanical problems
            1. One anesthetist required for each infant
            2. A third anesthetist to look after intravenous infusions and monitor
            3. A fourth anesthetist to look after massive blood loss, circulatory collapse, or other catastrophic occurrence
        3. Anticipating complex congenital heart defects that was not diagnosed preoperatively
    11. Four separate time frames of management (Spitz & Kiely 2002; Spitz 2005)
        1. Prenatal
            1. Define the anatomy of the union once the diagnosis of conjoined twins is suspected.
            2. Termination can be considered in the event of complex cardiac fusion in thoracopagus twins or extensive cerebral fusion in craniopagus twins: required detailed echocardiography and accurate ultrasonography complemented as necessary with MRI scanning.
            3. Obtain informed decision as to either terminate or proceed with the pregnancy.
            4. Delivery by Cesarean section at 36–38 weeks of gestation (Rudolph et al. 1967).
        2. Nonoperative treatment
            1. In the presence of complex cardiac fusion

2. Where a severe unacceptable deformity would follow separation

3. Emergency separation
    1. When one twin is dead or dying, threatening the survival of the remaining twin
    2. Presence of a life-threatening correctable congenital abnormality (e.g., intestinal atresia, malrotation with or without volvulus, ruptured omphalocele, or anorectal agenesis)
    3. Emergency separation carrying a significantly higher mortality rate compared with elective procedures
4. Elective separation
    1. Normally takes place between 2 and 4 months
    2. Allows time to stabilize, thrive, and carry out detailed investigation to define the nature and the extent of union, and detailed planning of the operative procedure with all members of the operating team
    3. Survival rate: approaches 80%

12. Bioethics of separating conjoined twins (Lee et al. 2011)
    1. Informed consent: is it ethical to impose a surgical procedure of unknown risk, where the goal is to improve quality of life of children who cannot provide informed consent and who may potentially not want the separation?
    2. Medical need is classically determined by the following criteria: likelihood of benefitting the patient, urgency of need, change in quality of life, and duration of benefit.
    3. To achieve an optimal physician-patient relationship, the health-care provider should be an advocate for his or her patient.

Fig. 1 A stillbirth with dicephalic conjoined twins

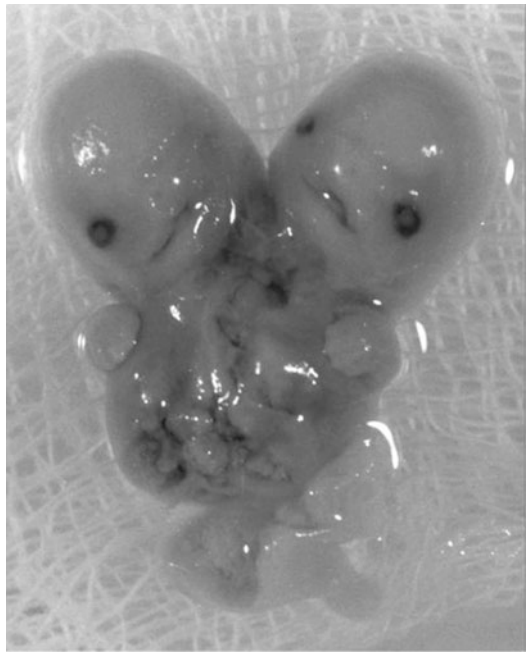

Fig. 2 A set of dicephalic conjoined twin embryos at 6–7 weeks of gestation

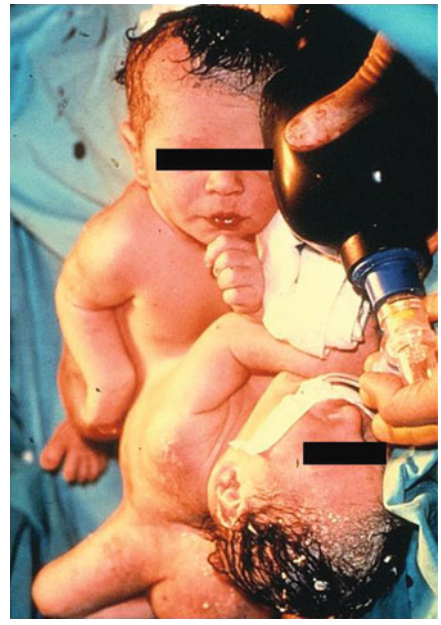

Fig. 3 The conjoined twins are joined at the level of abdomen from umbilicus to the xiphoid cartilage (xiphoomphalopagus). This type of conjoined twins is the one most amenable to successful surgical correction because the incidence of complex anatomical anomalies is low. Left twin was successfully separated from the right twin who succumbed shortly after surgery to multiple congenital anomalies including exstrophy of the cloaca, left Bochdalek hernia, hypoplastic kidney, hypoplastic lungs, imperforate anus, and a large sacral meningomyelocele

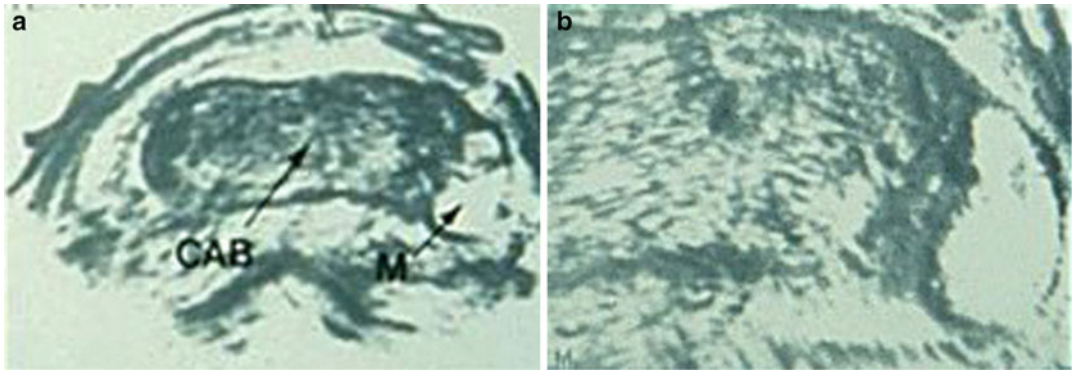

Fig. 4 Prenatal ultrasound (**a**) detected the above conjoined twins with a shared liver (CAB) and separate hearts, stomach, pelvis, and extremities. One fetus was noted to have a meningomyelocele (M). The magnified view (**b**) shows part of the shared liver and meningomyelocele

Fig. 5 These twins are thoraco-omphalopagus, connected at the thorax and upper abdomen. The heart showed complex anomalies with a common atrium and a single ventricle. Therefore, separation of the twins was not attempted

Fig. 6 The radiograph of the twins in Fig. 3 showing the connection at the thorax and the upper abdomen

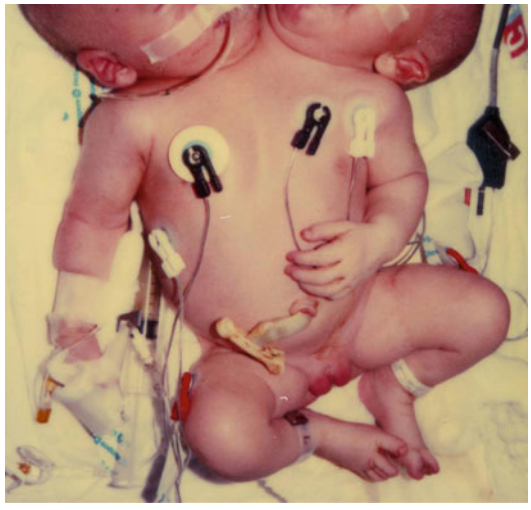

Fig. 7 Dicephalic conjoined twins. Two separate heads, two separate necks, and only one body are evident. The twins shared a common pericardium with complex cardiac anomalies, a common aorta at the level of iliac arteries, a common small intestine and other GI tract distally, a common bladder and urethra drained from a single kidney from each twin, and single normal female genitalia with normally placed fallopian tubes and ovaries. Surgical separation of the twins was deemed impossible and was not attempted

Fig. 8 Prenatal ultrasound study showed lateral view of the dicephalic twins with two heads side by side, one trunk with two overlapping vertebral columns, and two *upper* extremities

Fig. 9 Prenatal ultrasound study showed two separate vertebral columns

Fig. 10 Prenatal radiographic study showed dicephalic twins with two separate heads and two separate vertebral columns

Fig. 11 The postnatal radiograph of the above conjoined twins showing separate heads, separate vertebrae, and separate *upper* GI tract. There is one pericardium sac and a fused liver

Corpus Callosum Agenesis/Dysgenesis

Contents

The corpus callosum is an interhemispheric structure that permits the integration of motor, sensory, and cognitive performance between the two cerebral hemispheres. Agenesis/dysgenesis of the corpus callosum is one among the most common brain developmental malformations with a wide spectrum of associated clinical and pathologic abnormalities. The prevalence and clinical significance are uncertain. It is estimated to be 0.3–0.7% in the general population and 2–3% in the developmentally disabled (Jeret et al. 1985).

Synonyms and Related Disorders

Agenesis of corpus callosum; Dysgenesis of corpus callosum

Genetics/Basic Defects

1. Markedly heterogeneous etiology of agenesis/dysgenesis of the corpus callosum (Vergani et al. 1994; Dobyns 1996; Palmer and Mowat 2014; Al-Hashim et al. 2015)
    1. Sporadic in most cases
    2. Environmental factors
        1. Antenatal alcohol exposure: associated with microcephaly, a general reduction in white matter
        2. Volume and hypoplasia of the corpus callosum (most severe in the splenium) as well as partial and complete agenesis of corpus callosum
        3. Maternal antenatal infections: e.g., cytomegalovirus, toxoplasmosis, rubella, and influenza
        4. Maternal phenylketonuria: rare, especially since neonatal screening introduced in many countries since 1960s
        5. Maternal diabetes
        6. Vascular/hypoxic insults: rare
    3. A multifactorial trait
    4. As a part of autosomal dominant syndrome
        1. Agenesis/dysgenesis of the corpus callosum
        2. Apert syndrome
        3. Basal cell nevus syndrome
        4. Miller-Dieker syndrome

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_58

5. Rubinstein-Taybi syndrome
6. Tuberous sclerosis

5. As a part of autosomal recessive syndrome
    1. Agenesis/dysgenesis of the corpus callosum
    2. Agenesis/dysgenesis of the corpus callosum with thrombocytopenia
    3. Acrocallosal syndrome
    4. Andermann syndrome (Casaubon et al. 1996)
        1. Agenesis/dysgenesis of the corpus callosum with peripheral neuropathy
        2. Mapping of the gene to a 5-cM region in chromosome 15q13-15
    5. Cerebro-oculo-facio-skeletal (COFS) syndrome
    6. Cogan syndrome (ocular motor apraxia)
    7. Craniotelencephalic dysplasia
    8. Dincsoy syndrome
        1. Multiple midline malformations
        2. Limb abnormalities
        3. Hypopituitarism
    9. Fukuyama congenital muscular dystrophy
    10. Hydrolethalis syndrome
    11. Joubert syndrome (cerebellar vermis agenesis)
    12. Leprechaunism
    13. Lissencephaly syndrome
    14. Lowry-Wood syndrome
        1. Epiphyseal dysplasia
        2. Microcephaly
        3. Nystagmus
    15. Meckel-Gruber syndrome
    16. Microcephalic osteodysplastic primordial dwarfism type I/III
    17. Neu-Laxova syndrome
    18. Opitz G syndrome
    19. Peters plus syndrome
        1. Peters anomaly
        2. Short-limb dwarfism
    20. Shapiro syndrome: a rare condition of spontaneous periodic hypothermia, corpus callosum agenesis, and hyperhidrosis which can occur at any age (Tambasco et al. 2014)
    21. Smith-Lemli-Opitz syndrome
    22. Toriello-Carey syndrome
        1. Agenesis/dysgenesis of the corpus callosum
        2. Facial anomalies
        3. Robin sequence
    23. Vici syndrome
        1. Agenesis/dysgenesis of the corpus callosum
        2. Immunodeficiency
        3. Cleft lip/palate
        4. Cataract
        5. Hypopigmentation
    24. Walker-Warburg syndrome
        1. Hydrocephalus
        2. Agyria
        3. Retinal dysplasia
    25. Warburg micro syndrome
        1. Microcephaly
        2. Microphthalmia
        3. Cerebral malformations
        4. Other anomalies
    26. Hypoplastic corpus callosum, microcephaly, severe mental retardation, preauricular skin tag, camptodactyly, growth retardation, and recurrent bronchopneumonia (Da-Silva et al. 1988)
6. As a part of X-linked syndrome
    1. Agenesis/dysgenesis of the corpus callosum
    2. Agenesis/dysgenesis of the corpus callosum with Hirschsprung disease
    3. Agenesis/dysgenesis of the corpus callosum with hypohidrotic ectodermal dysplasia
    4. Aicardi syndrome (retinovertebral anomalies in females)
    5. ATR-X syndrome (X-linked alpha thalassemia mental retardation syndrome)
    6. Craniofrontonasal syndrome
    7. Curatolo syndrome
        1. Agenesis/dysgenesis of the corpus callosum
        2. Chorioretinal abnormality
    8. FG (Opitz-Kaveggia) syndrome
        1. Mental retardation
        2. Large head
        3. Imperforate anus

4. Congenital hypotonia
5. Partial agenesis/dysgenesis of the corpus callosum

9. HSAS syndrome (*h*ydrocephalus due to congenital *s*tenosis of *a*queduct of *S*ylvius)
10. Lenz dysplasia
    1. Microphthalmia/anophthalmia
    2. Associated anomalies
11. Lujan-Fryns syndrome
    1. X-linked mental retardation
    2. Marfanoid habitus
12. MASA syndrome
    1. *M*ental retardation
    2. *A*phasia
    3. *S*huffling gait
    4. *A*dducted thumbs
13. MLS syndrome
    1. *M*icrophthalmia
    2. *L*inear *s*kin defects
14. Opitz G syndrome
15. Oral-facial-digital syndrome I
16. Proud syndrome
    1. X-linked syndrome
    2. Seizures
    3. Acquired micrencephaly
    4. Agenesis/dysgenesis of the corpus callosum
17. XLIS syndrome (X-linked lissencephaly)

7. As a part of unknown-genesis syndrome
    1. Calloso-genital dysplasia
    2. Delleman (oculocerebrocutaneous) syndrome
    3. Frontonasal dysplasia
    4. Opitz C trigonocephaly syndrome
    5. Sebaceous nevus syndrome
8. As a part of metabolic disorders
    1. Adenylosuccinase deficiency
    2. Adipsic hypernatremia
    3. β-Hydroxyisobutyryl coenzyme A deacyclase deficiency
    4. Desmosterolosis
    5. Fumarase deficiency
    6. Glutaric aciduria type II
    7. Histidinemia
    8. Hurler syndrome
    9. Leigh syndrome
    10. Menkes syndrome
    11. Neonatal adrenoleukodystrophy
    12. Nonketotic hyperglycinemia
    13. Pyruvate dehydrogenase deficiency
    14. Smith-Lemli-Opitz syndrome
    15. Zellweger syndrome
9. Associated chromosome abnormalities (Serur et al. 1988)
    1. Trisomy 18
    2. Trisomy 13
    3. Trisomy 8 mosaicism
    4. Trisomy 21
    5. Trisomy 22
    6. Other trisomies
    7. Deletions
    8. Translocations
    9. Duplications
    10. Variable rearrangements and submicroscopic copy number variants
10. Agenesis of the corpus callosum with interhemispheric cyst: a heterogeneous group of disorders that have in common callosal agenesis and extraparenchymal cysts, both of which are among the commonest CNS malformations (Barkovich et al. 2001)
11. Incidental finding in normal individuals (isolated dysgenesis of the corpus callosum)

2. Embryogenesis of the corpus callosum
    1. Development of the corpus callosum
        1. A late event in cerebral ontogenesis
        2. Taking place between 12 and 18 weeks of gestation
    2. An important brain commissure connecting the cerebral hemispheres (Achiron and Achiron 2001)
    3. Essential for efficient cognitive function (Achiron and Achiron 2001)
    4. Failure of development of the commissural fibers connecting the cerebral hemispheres produces dysgenesis or agenesis of the corpus callosum
    5. Diagnosis of agenesis: a challenge even for expert sonologists, particularly prior to 20 weeks of gestation

3. Types of agenesis
   1. Complete agenesis: commonly regarded as a malformation deriving from faulty embryogenesis
   2. Type I agenesis
      1. Not associated with other disorders
      2. Usually absent or associated with mild neurologic manifestations
   3. Type II agenesis
      1. Associated with other migrational, genetic, and chromosomal disorders
      2. Usually associated with severe neurologic manifestations
   4. Partial agenesis
      1. Referred to as dysgenesis
      2. Either a true malformation or a disruptive event occurring at any time during pregnancy
      3. Missing caudad portion (splenium and body) to varying degrees
4. Agenesis/dysgenesis of the corpus callosum (Da-Silva 1988)
   1. Without other associated brain anomalies
   2. Frequently associated with other brain anomalies
      1. Defects of septum pellucidum and fornix
      2. Hydrocephalus
      3. Dandy-Walker malformation
      4. Interhemispheric cyst
      5. Holoprosencephaly
      6. Porencephaly
      7. Polymicrogyria
      8. Macrogyria
      9. Cortical heterotopia and atrophy
      10. Lipoma
      11. Encephalocele
      12. Hypoplasia of cerebellum
   3. Frequently associated other anatomical anomalies
      1. Congenital heart defects
      2. Costovertebral defects
      3. Gastrointestinal anomalies
      4. Genitourinary anomalies

Clinical Features

1. Craniofacial abnormalities
   1. Microcephaly
   2. Macrocephaly
2. Developmental anomalies
   1. Nonspecific mental retardation
   2. Developmental delay
   3. Learning disabilities
   4. Behavioral disorder
   5. Mental retardation
   6. Failure to thrive
3. Infantile spasms/seizures (Lacey 1985)
4. Signs and symptoms related to type I and type II agenesis
   1. Type I
      1. Variable intelligence: normal to mild or moderate mental retardation
      2. Seizure disorder
      3. Impaired visual, motor, and/or bimanual coordination
      4. Mild impairment of crossed tactile localization and skills requiring matching of visual patterns
   2. Type II
      1. Mental retardation
      2. Seizures
      3. Hydrocephaly
      4. Microcephaly
      5. Hemiparesis
      6. Diplegia
      7. Spasticity
      8. Failure to thrive

Diagnostic Investigations

1. Psychometric tests (Finlay et al. 2000)
   1. Difficulties in motor coordination
   2. Difficulties in interhemispheric transfer of tactile information
   3. Difficulties in some areas of memory
   4. A marked difference in verbal IQ and performance IQ in children
2. EEG for seizure activities

3. CT and/or ultrasound of the brain (Gupta and Lilford 1995)
    1. Absence of the corpus callosum
    2. Absence of septum pellucidum
    3. Increased separation of the lateral ventricles
    4. Marked separation of the slit-like anterior horns of the lateral ventricles and dilatation of the occipital horns creating the typical "rabbit's ear" or "tear drop" appearance
    5. Upward displacement of the third ventricle
    6. Evidence of other migration disorders
4. Coronal radiographs showing a pathognomonic bat-wing ventricular pattern
5. Karyotyping for underlying chromosomal disorder
6. Metabolic studies for underlying inborn error of metabolism
7. Exome sequencing: Exome sequencing identifies recessive *CDK5RAP2* variants in patients with isolated agenesis of corpus callosum (Jouan et al. 2015)

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: depending on the etiology and the mode of inheritance
        1. Isolated agenesis/dysgenesis of the corpus callosum
            1. Recurrence risk: 2–3% if no family history (Palmer and Mowat 2014)
            2. In isolated cases of ACC, long-term neurodevelopmental outcome is expected to be normal in approximately 75% of cases, meaning that continuation of pregnancy can be preferred (Pilu et al. 1993; Özyüncü et al. 2014)
        2. Environmental factor: recurrence risk not increased by avoiding the environmental factor
        3. Autosomal recessive inheritance: 25% of siblings affected, 50% siblings carriers, and 25% of siblings normal
        4. Autosomal dominant inheritance: recurrence risk not increased unless a parent is affected in which case the recurrence risk is 50%
        5. X-linked recessive inheritance
            1. Carrier mother (50% of brothers affected, 50% of sisters carriers)
            2. Affected father (all brothers normal, all sisters carriers)
        6. X-linked dominant inheritance
            1. Affected mother (50% of brothers and sisters affected)
            2. Affected father (all brothers normal, all sisters affected)
        7. Chromosomal disorder: recurrence risk increased, especially if a parent carries a balanced translocation
    2. Patient's offspring
        1. Environmental factor: recurrence risk not increased by avoiding the environmental factor
        2. Autosomal recessive inheritance: recurrence risk not increased unless the spouse is also a carrier, in which case the recurrence risk is 50%
        3. Autosomal dominant inheritance: 50%
        4. X-linked recessive inheritance
            1. Carrier female (50% of sons affected, 50% of daughters carriers)
            2. Affected male (all sons normal, all daughters carriers)
        5. X-linked dominant inheritance
            1. Affected female (50% of sons and daughters affected)
            2. Affected male (all sons normal, all daughters affected)
        6. Chromosomal disorder: recurrence risk increased, especially if a parent carries a balanced translocation
2. Prenatal diagnosis
    1. Ultrasonography (Pilu et al. 1993; D'Ercole et al. 1998)
        1. Prenatal detection of the agenesis of the corpus callosum usually not possible

before 22 weeks of gestation (Bennett et al. 1996)
2. Direct demonstration of the absence or partial absence of the corpus callosum
3. Failure to visualize the cavum septum pellucidum
4. Separated lateral ventricles
5. Upward displacement of third ventricle
6. Increased interhemispheric fissure
7. Radial disposition of the sulci on the internal aspects of the hemispheres
8. Third ventricle lying between widely separated lateral ventricles due to absent corpus callosum
9. Lateral ventricles more parallel to the midline than usual
10. A cyst arising from the superior aspect of the third ventricle communicating with the lateral ventricles
11. Vertical orientation of the gyri with agenesis instead of normal horizontal alignment
12. Colpocephaly (locally dilated occipital horns of the lateral ventricle) forming an appearance on axial views similar to bulls' horns
13. Absence of pericallosal artery
14. Up to 50% of cases with other associated anatomic defects
15. Variable developmental outcome on prenatal detection of an isolated agenesis of the corpus callosum

2. MRI (D'Ercole et al. 1998)
   1. Allows more detailed visualization of the fetal brain than ultrasonography
   2. Constitutes a useful additional procedure after ultrasonographic diagnosis or suspicion of corpus callosum agenesis
3. Amniocentesis recommended for karyotyping as there is 10–20% risk of aneuploidy associated with the agenesis of the corpus callosum
4. Cytogenetic findings (Alby et al. 2016)
   1. CNVp (copy number variation considered as pathogenic) detected by karyotype
      1. Duplication 1pter/deletion 1qter
      2. Interstitial del(1q44)
      3. Del(4p) (9 Mb)/dup(8p) (7 Mb)
      4. Del(6q) (4 Mb)
      5. Dup(7q) (55 Mb)
      6. Monosomy 7q36.3 (1.4 Mb)/Trisomy 8p23.3 (0.8 Mb)
      7. Isochromosome 9p10
      8. Trisomy 18
      9. Mosaicism ring 21/monosomy 21
   2. CNVp visible on karyotype and detected by CGH
      1. Del(3q) (15 Mb)
      2. Dup(8p8q) (98 Mb)
      3. Dup(8p8q) (45 Mb)
   3. CNVp not visible on karyotype and detected by FISH: Del(17p)
   4. CNVp not visible on karyotype and detected by CGH
      1. Del(14q) (2 Mb)
      2. Del(17q) (500 Kb)
      3. Dup(19p) (7 Mb)
      4. Dup(21q) (7 Mb)
      5. Mosaicism monosomy X
   5. VOUS (variant of unknown significance) not visible on karyotype and detected by CGH
      1. Del(10q) (2 Mb)
      2. Del(11p13.3) (384 Kb)
5. Molecular genetic diagnosis (Alby et al. 2016)
   1. Opitz syndrome: *MID1* mutation
   2. Zellweger syndrome: *PEX1* mutation
   3. PDH deficiency
   4. Tubulopathy: *TUBA1A* and *TUBB3* mutations
   5. Lissencephaly type 1: *PAFAH1B1* mutation
   6. Lissencephaly type 2: *POMT2*, *B3GALNT2*, and *ISPD* mutations
   7. Porencephaly type 2: *COL4A2* mutation
   8. Bicker-Adams syndrome: *LICAM* mutation
   9. Smith-Lemli-Opitz syndrome: *DHCR7* mutation
   10. Oral-facial-digital syndrome: *OFD1* mutation
   11. CHARGE syndrome: *CHD7* mutation
   12. Microcephaly 5: *ASPM* mutation

6. Prenatal counseling for ultrasonically diagnosed fetal agenesis of the corpus callosum remains very difficult, as giving precise information on outcome is impossible (Moutard et al. 2003). The following observation, however, may be of help in prenatal counseling: (Gupta and Lilford 1995)
    1. Isolated agenesis/dysgenesis of the corpus callosum (in the absence of other sonographically detectable anomalies) carrying apparent excellent prognosis
        1. 85% chance of a normal developmental outcome
        2. 15% risk of handicap
    2. Agenesis/dysgenesis of the corpus callosum with other associated anomalies: poor outcome
3. Management
    1. Identification of actual deficits resulting from the absence of such a major structure (corpus callosum): clearly an issue
    2. Multidisciplinary team approach to intervention programs
    3. Anticonvulsants for seizures
    4. Management based on the underlying etiology

Craniometaphyseal Dysplasia

Contents

In 1954, Jackson et al. (1954) coined the term "craniometaphyseal dysplasia" for a hereditary bone disease with metaphyseal widening of the tubular bones and bony overgrowth of the facial and skull bones (leonteasis ossea).

Genetics/Basic Defects

1. Genetic heterogeneity (Beighton 1995)
    1. Autosomal dominant form [also called CMD, Jackson type (CMDJ)]:
        1. Variability of expression within a large family (Beighton et al. 1979; Carnevale et al. 1983)
        2. CMDJ locus mapped to 5p15.2-p14.1 (Nürnberg et al. 1997; Chandler et al. 2001) within a region harboring the human homolog (*ANKH*) of the mouse progressive ankylosis (*ank*) gene
        3. Mutations in ANKH have been associated in craniometaphyseal dysplasia in some families (Nürnberg et al. 2001; Reichenberger et al. 2001)
        4. ANKH mutations that cause CMD most likely entail a loss of function (Kornak et al. 2010) or a loss of ANKH protein expression and activity in the plasma membrane as a result of aberrant intracellular protein trafficking (Zajac et al. 2010)
    2. Autosomal dominant form cosegregating with chondrocalcinosis
        1. Mutations in ANKH have been associated with familial chondrocalcinosis (OCAL2) in some families (Pendleton et al. 2002; Williams et al. 2003)
        2. A family was reported with an *ANKH* mutations in which these conditions cosegregated in some affected family members (Baynam et al. 2009)
    3. Autosomal recessive form
        1. Rare
        2. Ill-defined
        3. Probably heterogeneous
        4. Often difficult to diagnose with precision
        5. Autosomal recessive CMD locus mapped to 6q21-22 (Iughetti et al. 2000)
        6. A report of a female patient with CMD phenotype, born from healthy first degree cousins and displaying homozygosity for polymorphic markers at the 6q21-22 locus, further support the existence of an autosomal recessive CMD, expanding its clinical spectrum to a more severe phenotype (Prontera et al. 2011)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_59

2. Basic defects
    1. Autosomal dominant form: caused by mutations in the human homolog of the mouse progressive ankylosis gene (*ANKH*) (Reichenberger et al. 2001)
    2. Autosomal recessive form (Beighton 1995)
        1. May involve dysfunctional osteoclasts because reported metabolic responses of affected children to therapy with calcitonin and calcitriol
        2. Osteoclast-like cells derived from the bone marrow shown to lack expression of the osteoclast vacuolar proton pump (Yamamoto et al. 1993)

Clinical Features

1. Autosomal dominant form
    1. General features
        1. Good general health
        2. Normal intelligence
        3. Normal stature
    2. Bony overgrowth of the facial bone resulting in the typical facies:
        1. Frontal bossing
        2. Hypertelorism
        3. Paranasal bossing (30% of cases in childhood)
            1. May be present during infancy
            2. Tends to regress with age
            3. Virtually absent by adolescence and early adulthood
            4. May be associated with some degree of nasal obstruction and frequent mouth breathing
        4. Mild to moderate mandibular prognathism
        5. An open mouth secondary to bony encroachment of the nasal passages
        6. Malalignment of the teeth
        7. Grotesque hyperostosis of the facial bones
        8. Decreased facial movement
    3. Bony overgrowth of the cranial foramina resulting in the following features:
        1. Cranial nerve paralysis
            2. Nystagmus
            3. Optic atrophy
            4. Facial palsy (30% of cases)
                1. Common but variable
                2. May be unilateral or bilateral
                3. May occur at any age
                4. The involvement often fluctuant in early childhood
                5. May be permanent in adulthood
            5. Deafness (50% of cases)
                1. Due to compromised auditory nerve and inner ear by bone overgrowth
                2. May be unilateral or bilateral
                3. Often "mixed" in type due to chronic otitis media and upper respiratory tract infection secondary to minor anatomical abnormalities of the airway and sinuses
                4. Usually partial and rarely profound
            6. Less commonly reported conditions (Kietzer and Paparella 1969)
                1. Compression of the cerebellar tonsils and medulla secondary to a narrowed foramen magnum
                2. Obstruction of Eustachian tube
                3. Obstruction of nasolacrimal duct
                4. Obstruction of nasal passages
                5. Raised intracranial pressure: rare instances of a potentially lethal rise in intracranial pressure due to hyperostosis of the calvarium
    4. Abnormal modeling of the metaphyses of the long bones
        1. Metaphyseal widening of the long and short tubular bones
        2. Thin cortical layer
        3. Coarse trabeculations
    5. Clinical and radiographic features improved in later childhood in the dominant form
2. Autosomal recessive form
    1. Similar to, but more severe than, those seen in the dominant form
    2. An increasing severity with age
    3. Progressive overgrowth and craniofacial deformity
        1. Very severe facial distortion
        2. A thick bony wedge over the bridge of the nose

3. Dystopia canthorum
4. Ocular hypertelorism
5. Enlarged malar prominences and mandible (marked prognathism)
6. Wide alveolar ridge
7. Narrowed nasal passages leading to mouth breathing
8. Dental abnormalities
9. Blindness
10. Facial palsy
11. Deafness

4. Cerebellomedullary compression in recessive craniometaphyseal dysplasia (Boltshauser et al. 1996)
5. Abnormal modeling of the metaphyses of the long bones
   1. Gradual, club-shaped widening of the metaphyses
   2. Thin cortex and undermineralized medullary bone

3. Differential diagnosis (Cole and Cohen 1988; Reichenberger and Chen 2015)
   1. Pyle disease (metaphyseal dysplasia) (Gorlin et al. 1970)
      1. Frequently confused with craniometaphyseal dysplasia. In Pyle disease, metaphyseal flaring occurs but there is minimal involvement of the skull
      2. Autosomal recessive inheritance
   2. Craniodiaphyseal dysplasia (Cole and Cohen 1988)
      1. Most severe thickening, distortion, and enlargement of the craniofacial region
      2. Characterized by diaphyseal endostosis
      3. Does not exhibit metaphyseal flaring
      4. Inheritance likely autosomal recessive
   3. Frontometaphyseal dysplasia (Cooper 1974)
      1. A pronounced bony supraorbital ridge
      2. Hirsutism
      3. Long-bone alterations
      4. Conductive deafness
   4. Camurati-Engelmann disease (progressive diaphyseal dysplasia) (Cooper 1974)
      1. Presence of excess subperiosteal bone in the diaphyses of the long bone
      2. Normal metaphyses
      3. Rare craniofacial involvement
   5. van Buchem disease (hyperostosis corticalis generalisata) (Cooper 1974)
      1. *SOST*-related sclerosing bone dysplasias: including van Buchem disease and sclerosteosis
      2. Autosomal recessive disorder
      3. Caused by pathogenic variants in *SOST*, the gene encoding sclerostin, the bone morphogenetic protein (BMP) antagonist
      4. Dense and thickened craniofacial skeleton
      5. Generalized cortical thickening of the long bones mainly due to endosteal bone apposition
   6. Osteopathia striata with cranial sclerosis
      1. Characteristic findings: longitudinal striations of sclerotic long bones in combination with osteosclerosis of cranial and facial bones
      2. Inheritance is X-linked dominant, with likely genetic heterogeneity
      3. Caused by pathogenic variants in *AMER1* (Jenkins et al. 2009)

Diagnostic Investigations

1. Normal serum calcium, phosphorous, and alkaline phosphatase
2. Radiographic features (Beighton 1995)
   1. Autosomal dominant form: age-related radiographic features
      1. Characteristic hyperostosis and sclerosis of the skull
      2. Paranasal bony bossing, most evident in early childhood
      3. May be present with prognathism and asymmetry
      4. Characteristic nonsclerotic widening of the metaphyses of the tubular bones: a major radiographic feature
         1. Most obvious at the lower end of the femur
         2. An “Erlenmeyer flask” configuration in childhood
         3. A “club” shape in adulthood

5. A "ground glass" pattern of the alveolar bone in some areas with an associated loss of the lamina dura around some of the teeth (Bricker et al. 1983)

2. Autosomal recessive form: severe radiographic manifestations (Penchaszadeh et al. 1980)
   1. Increasing severity with age
   2. Sclerosis and hyperostosis of the calvarium, the base of the skull, and the facial bones and mandible
   3. Increased bone deposition on the walls of the paranasal sinuses
   4. Underpneumatization of mastoid cells
   5. Gradual, club-shaped widening of the metaphyses
   6. Thin cortex and undermineralized medullary bone

3. Gross pathological features (Kietzer and Paparella 1969)
   1. Thickened "ivory-hard" facial and cranial bones
   2. Narrow cranial foramina
   3. Narrowing of the nasal chambers and posterior choanae (Cheung et al. 1997)
4. Histological features (Kietzer and Paparella 1969)
   1. Compact laminar cortical bone with dilated Haversian canals containing osteoblasts
   2. No osteoclasts identified in the periosteal or endosteal layers
   3. An increased amount of ground substance and excessive formation of subperiosteal and subendosteal bone
5. Molecular genetic analysis for human ankylosis gene (*ANKH*): Sequence analysis detects mutations in about 90% of individuals meeting the diagnostic criteria for CMD (Reichenberger and Chen 2015)

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Autosomal dominant form: 50% risk if one parent is affected, otherwise risk not increased
      2. Autosomal recessive form: 25%
   2. Patient's offspring
      1. Autosomal dominant form: 50%
      2. Autosomal recessive form: not increased unless the spouse is also a carrier in which case there is 50% recurrence risk
   3. Possibility of the presence of a parental mosaicism in an *ANKH* mutation who had no apparent clinical or radiological features of CMD. Parental mosaicism may account for some apparently sporadic or new cases of CMD and has important implications in the genetic counseling of families affected by CMD (Kato et al. 2013)
2. Prenatal diagnosis and preimplantation genetic diagnosis for pregnancies at risk may be available through laboratories offering custom prenatal testing if the disease-causing mutations in the family is known (Reichenberger and Chen 2015)
3. Management
   1. Medical treatment attempted with the following two hormones
      1. Calcitonin: increases bone turnover and secondary hyperparathyroidism (Fanconi et al. 1988)
      2. Calcitriol (Key et al. 1988)
         1. Stimulates resorption of bone by promoting osteoclast formation
         2. Partial resolution of facial nerve paralysis, increased size of the cranial nerve foramina, and demineralization of the cranial base during treatment of one patient with high doses of calcitriol
   2. Hearing aids for hearing loss
   3. Most patients with CMD need orthodontic treatment (Chen et al. 2014)
   4. Psychological support for facial disfigurement
   5. Bony turbinoplasties along the whole length of the inferior turbinate may be required for nasal obstruction (Twigg et al. 2015).
   6. Surgical treatment with mixed results (Day et al. 1997)
      1. Resection of dysplastic bone arduous because it is highly mineralized with a consistency like thick ivory

2. Craniofacial reduction performed with some difficulty
3. Optic canal decompression for progressive visual loss
4. Facial nerve decompression
5. Middle ear exploration and implantation of total ossicular replacement prosthesis for conductive hearing loss
6. Foramen magnum decompression for cervicomedullary encroachment

Cri-Du-Chat Syndrome

Contents

Cri du chat syndrome is a chromosome 5p deletion syndrome first described by Lejeune et al. in 1963. The name of the syndrome refers to the most characteristic clinical feature, a high-pitched crying similar to the mewing of a cat, which usually disappears in the first years of life. The incidence is estimated to be approximately 1 in 15,000 (Higurashi et al. 1990) to 1 in 50,000 births (Niebuhr 1978). The prevalence among mentally retarded individuals is approximately 1.5 in 1,000.

Synonyms and Related Disorders

Cat cry syndrome; Chromosome 5p deletion syndrome

Genetics/Basic Defects

1. Cause:
   1. Caused by deletion of short arm of chromosome 5: The size of the deletion ranges from the entire short arm to the region 5p15 (Overhauser et al. 1994) and a deletion size ranging from 5 to 40 Mb (Simmons et al. 1995):
      1. De novo deletion (80%): paternally derived deletions in 80% of cases (Overhauser et al. 1990)
      2. Familial rearrangement (12%)
      3. Mosaicism (3%) (Perfumo et al. 2000)
      4. Rings (2.4%)
      5. De novo translocation (3%)
   2. A high-resolution physical and transcription map generated a 3.5-Mb region of 5p15.2 that is associated with the cri du chat syndrome region (Church et al. 1997).
   3. Mutations in the dynein axonemal heavy chain 5 gene (*DNAH5*) cause outer dynein arm ciliary defects and account for approximately 30% of cases of primary ciliary dyskinesia (Hornef et al. 2006). This gene resides in the same chromosome 5p region affected in cri du chat syndrome (Shapiro et al. 2014).
2. Genotype-phenotype correlation (Gersh et al. 1997; Mainardi et al. 2001):
   1. Deletion of 5p15.3 results in a catlike cry and speech delay (Gersh et al. 1995; Church et al. 1995).
   2. Deletion of 5p15.2 results in the distinct facial features associated with the syndrome as well as the severe mental and developmental delay.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_60

3. Progressive severity of clinical manifestation and psychomotor retardation related to the larger size of the deletion (Wilkins et al. 1983).
4. Analysis of seven patients with interstitial deletions and one with a small terminal deletion confirmed the existence of two critical regions:
    1. One for dysmorphism and mental retardation in p15.2
    2. Another for the cat cry in p15.3
3. Hemizygosity of δ-catenin (*CTNND2*, mapped to 5p15.2), reported to be associated with severe mental retardation in cri du chat syndrome (Medina et al. 2000).
4. Deletion of the *telomerase reverse transcriptase* (h *TERT*) gene (mapped at 5p15.33) and haploinsufficiency of telomere maintenance is probably a genetic element contributing to the phenotypic changes in cri du chat syndrome (Zhang et al. 2003).

Clinical Features

1. Characteristic mewing cry (Niebuhr 1978):
    1. A high-pitched monochromatic cry with subtle dysmorphism and neonatal complications: commonly observed in infants with this syndrome
    2. Observed in many infants with cri du chat syndrome
    3. Not associated with other aneuploidies
    4. Usually considered diagnostic
    5. Loss of the characteristic cry by age 2 years in one third of children
2. Clinical findings during infancy (Mainardi 2006; Chen 2015):
    1. Low birth weight
    2. Hypotonia
    3. Microcephaly
    4. Poor sucking/swallowing difficulties
    5. Need for incubator care
    6. Respiratory distress
    7. Jaundice
    8. Pneumonia
    9. Dehydration
    10. Failure to thrive/growth retardation
    11. Early ear infections
    12. Severe cognitive, speech, and motor delays
    13. Facial features:
        1. Round face with full cheek
        2. Hypertelorism
        3. Epicanthal folds
        4. Down-slanting palpebral fissures
        5. Strabismus
        6. Flat nasal bridge
        7. Down-turned mouth
        8. Micrognathia
        9. Low-set ears
    14. Cardiac defects:
        1. VSD
        2. ASD
        3. PDA
        4. Tetralogy of Fallot
    15. Short fingers
    16. Single palmar creases
    17. Less frequent features:
        1. Cleft lip and palate
        2. Preauricular tags and fistulas
        3. Thymic dysplasia
        4. Gut malrotation
        5. Megacolon
        6. Inguinal hernia
        7. Dislocated hips
        8. Cryptorchidism
        9. Hypospadias
        10. Rare renal malformations:
            1. Horseshoe kidneys
            2. Renal ectopia or agenesis
            3. Hydronephrosis
        11. Clinodactyly of the fifth fingers
        12. Talipes equinovarus
        13. Pes planus
        14. Syndactyly of the second and third fingers and toes
        15. Oligosyndactyly
        16. Hyperextensible joints
3. Clinical findings in childhood (Chen 2015):
    1. Severe mental retardation
    2. Developmental delay
    3. Microcephaly
    4. Hypertonicity
    5. Premature graying of the hair
    6. Small, narrow, and often asymmetric face

7. Dropped jaw
8. Open-mouth expression secondary to facial laxity
9. Short philtrum
10. Malocclusion of the teeth
11. Scoliosis
12. Short third–fifth metacarpals
13. Chronic medical problems:
    1. Upper respiratory tract infections
    2. Otitis media
    3. Severe constipation
    4. Hyperactivity

4. Clinical findings in late childhood and adolescence (Niebuhr 1971; Chen 2015):
    1. Coarsening of facial features
    2. Prominent supraorbital ridges
    3. Deep-set eyes
    4. Hypoplastic nasal bridge
    5. Affected females reaching puberty and developing secondary sex characteristics and menstruate at the usual time (Martinez et al. 1993)
    6. Small testis and normal spermatogenesis in males
    7. Changing phenotype in older patients (Van Buggenhout et al. 2000)
5. Dermatoglyphics:
    1. Transverse flexion creases
    2. Distal axial triradius
    3. Increased whorls and arches on digits
6. Behavioral profile (Cornish and Pigram 1996; Dykens and Clark 1997; Collins and Cornish 2002):
    1. Hyperactivity
    2. Aggression
    3. Tantrums
    4. Stereotypic and self-injurious behavior
    5. Repetitive movements
    6. Hypersensitivity to sound
    7. Clumsiness
    8. Obsessive attachments to objects
    9. Able to communicate needs and interact socially with others
    10. Autistic-like features and social withdrawal: more characteristic of individuals who have a 5p deletion as the result of an unbalanced segregation of a parental translocation
7. Prognosis (Wilkins et al. 1980):
    1. The ability of many children to develop some language and motor skills
    2. The ability of these children to attain developmental and social skills observed in 5–6-year-old children, although their linguistic abilities are seldom as advanced
    3. Older, home-reared children:
        1. Usually ambulatory
        2. Able to communicate verbally or through gestural sign language
        3. Independent in self-care skills

Diagnostic Investigations

1. Conventional cytogenetic studies once the suspected diagnosis is established. The size of the 5p deletion may vary from the entire short arm to only 5p15. A small deletion of 5p may be missed by a conventional cytogenetic technique.
2. High-resolution cytogenetic studies are required for a smaller 5p deletion.
3. Molecular cytogenetic studies using fluorescent in situ hybridization (FISH) (Marinescu et al. 1999; Dangare et al. 2012):
    1. Allow the diagnosis to be made in the patients with very small deletions.
    2. Use genetic markers that have been precisely localized to the area of interest.
    3. The absence of a fluorescent signal from either the maternal or paternal chromosome 5p regions: indicative of monosomy for that chromosomal region.
4. Comparative genomic hybridization (CGH) especially the CGH method based on DNA microarray and quantitative PCR (Mainardi et al. 2001; Rodriguez-Caballero et al. 2010).
5. Skeletal radiographs:
    1. Microcephaly
    2. Retromicrognathia
    3. Cranial base malformations:
        1. Reduced cranial base angle
        2. Malformed sella turcica and clivus
    4. Disproportionately short third, fourth, and fifth metacarpals and disproportionately

long second, third, fourth, and fifth proximal phalanges (frequent) (Fenger and Niebuhr 1978)
6. Echocardiography to rule out structural cardiac malformations.
7. MRI of the brain (Kjaer and Niebuhr 1999; Nandhagopal and Udayakumar 2014):
    1. Atrophic brainstem, middle cerebellar peduncles, and cerebellar white matter
    2. Possible hypoplasia of cerebellar vermis with enlargement of the cisterna magna and fourth ventricle
    3. Pontine hypoplasia (Mainardi 2006; Ninchoji and Takanashi 2010)
    4. Callosal agenesis
8. Swallowing study for feeding difficulty.
9. Comprehensive evaluation for receptive and expressive language (Cornish and Munir 1998): Most children have better receptive language than expressive language.
10. Developmental testing and referral to early intervention and appropriate school placement.

Genetic Counseling

1. Recurrence risk:
    1. Patient's sib:
        1. Recurrence risk for a de novo case is 1% or less (possibility of gonadal mosaicism in one of the parents cannot be ruled out).
        2. Rare recurrences in chromosomally normal parents: most likely the result of gonadal mosaicism for the 5p deletion in one of the parents.
        3. The risk is substantially high if a parent is a balanced carrier of a structural rearrangement. Risk should be assessed based on the type of structural rearrangement and its pattern of segregation.
    2. Patient's offspring: Female patients are fertile and can deliver viable affected offspring, with an estimated recurrence risk of 50% (Martinez et al. 1993).
2. Prenatal diagnosis:
    1. Abnormal maternal serum testing: high hCG level (Fankhauser et al. 1998)
    2. Ultrasonography (Aoki et al. 1999; Chen et al. 2013):
        1. Hypoplastic cerebellum
        2. Ventricular septal defect
        3. Overriding aorta
        4. Cystic lesion within the nuchal skin edema
        5. Hypospadias
    3. Amniocentesis, CVS, and PUBS for chromosome analysis to detect 5p deletion (Tullu et al. 1998)
    4. aCGH characterization using uncultured amniocytes (Chen et al. 2013)
3. Fluorescent in situ hybridization-based preimplantation genetic diagnosis (Ye et al. 2011)
4. Management:
    1. Supportive care: No treatment exists for the underlying disorder.
    2. Family stress and sibling reactions (ignored and misunderstood) (Hodapp et al. 1997).
    3. Appropriate treatment for chronic medical problems:
        1. Upper respiratory tract infections
        2. Otitis media
        3. Severe constipation
    4. Using the relatively good receptive skills to encourage language and communicative development rather than relying on traditional verbal methods (Cornish and Munir 1998).
    5. Early intervention programs:
        1. Physical therapy
        2. Occupational therapy
        3. Speech therapy
    6. Introduction to sign language, an effective means of developing communication skills (>50% of children are able to use sign language to communicate) (Cornish and Munir 1998).
    7. Behavior modification programs to successfully manage hyperactivity, short attention span, low threshold for frustration, and self-stimulatory behaviors (e.g., head-banging, hand-waving).

8. Surgical interventions:
    1. Correction of congenital heart defects if indicated
    2. Medical problems involving minor malformations such as strabismus and clubfoot
    3. Gastrostomy in infancy to protect airway of patients with major feeding difficulties
    4. Orchiopexy for undescended testes
    5. Issues important to anesthetic plan (Brislin et al. 1995):
        1. Anatomical abnormalities of the airway
        2. Congenital heart disease
        3. Hypotonia
        4. Mental retardation
        5. Temperature maintenance

Fig. 1 (**a**, **b**) Two infants with cri du chat syndrome. Note a round face with full cheeks, hypertelorism, epicanthal folds, and apparently low-set ears

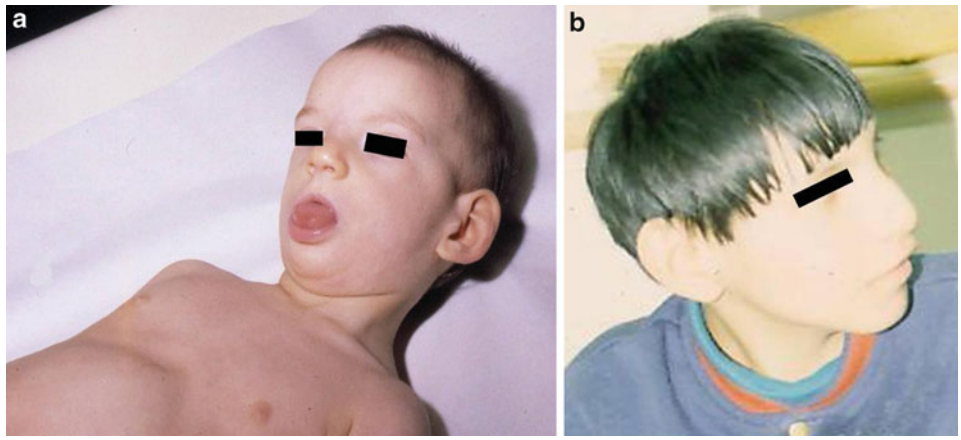

Fig. 2 (**a**, **b**) Cri du chat syndrome in an older child and a teenager showing a long and narrow face

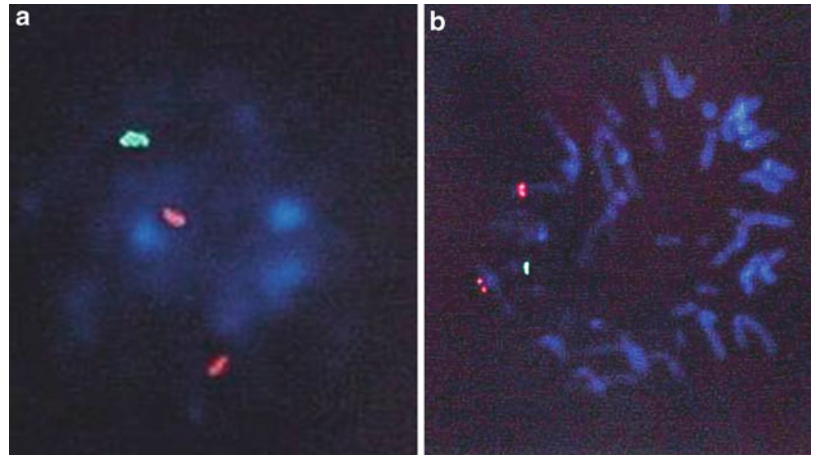

Fig. 3 (**a**, **b**) FISH of an interphase cell and a metaphase spread with two *orange* signals (LSI Spectrum *Orange*, D5S721) and one *green* signal (LSI Spectrum *Green*, D5S23 chromosome 5p15.2-specific probe) indicating deletion of 5p15.2

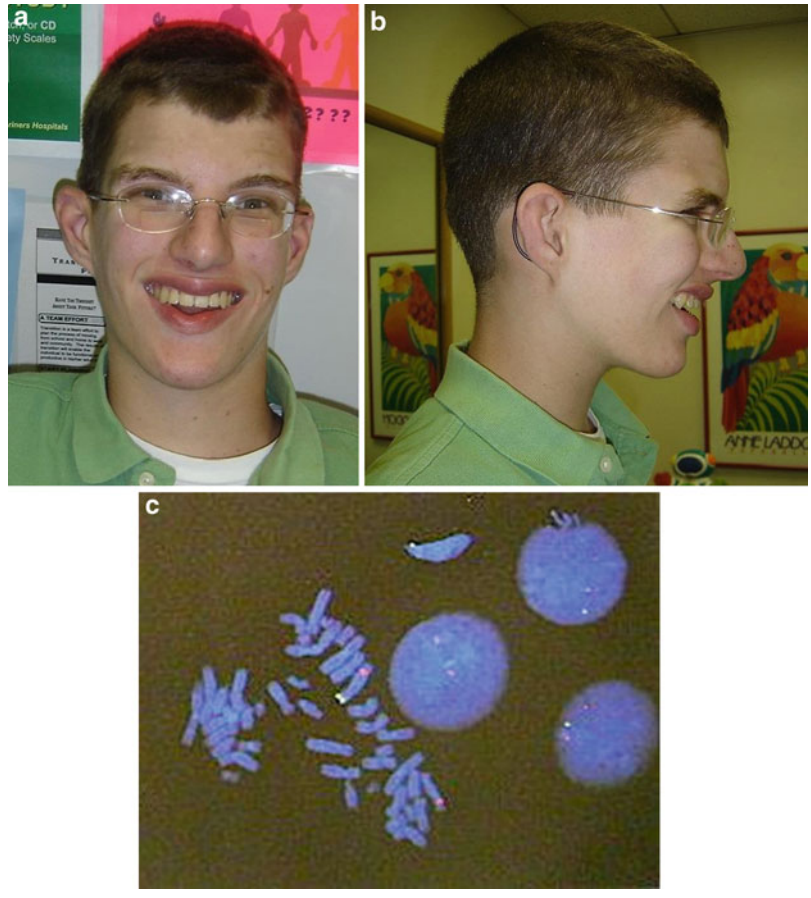

Fig. 4 (**a**–**c**) The 16-year-old boy was evaluated for developmental delay. He was noted to have unusual cry during early infancy, poor muscle control, and unable to hold his head up until 6 months of age. FISH using a locus specific for 5p11.2 cri du chat syndrome region showed 5p11.2 deletion (illustrated by a metaphase chromosome spread and interphase cells)

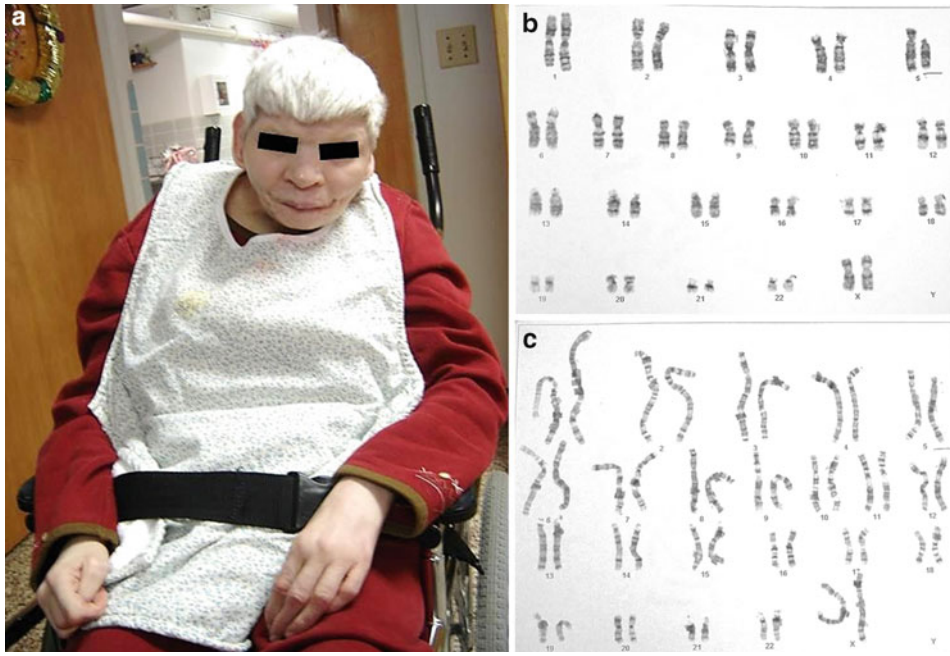

Fig. 5 (**a**–**c**) A blond-haired 60-year-old female with cri du chat syndrome, showing microcephaly with severe mental retardation. The karyotypes showed deletion of most of the short arm of a chromosome 4

Crouzon Syndrome

Contents

In *1912*, Crouzon described the hereditary syndrome of craniofacial dysostosis in a mother and son (Crouzon 1912). He described the triad of calvarial deformities, facial anomalies, and exophthalmos. Crouzon syndrome is characterized by premature closure of calvarial and cranial base sutures as well as those of the orbit and maxillary complex (craniosynostosis). Other clinical features include hypertelorism, exophthalmos, strabismus, beaked nose, short upper lip, hypoplastic maxilla, and relative mandibular prognathism. Prevalence is 1 per 60,000 (approximately 16.5 per 1,000,000) live births (Cohen and Kreiborg 1992). Crouzon syndrome makes up approximately 4.8% of all cases of craniosynostosis.

Synonyms and Related Disorders

Craniofacial dysostosis type I; Crouzon craniofacial dysostosis; Crouzon syndrome with acanthosis nigricans (Crouzonodermoskeletal syndrome)

Genetics/Basic Defects

1. Inheritance
   1. An autosomal dominant disorder with
      1. Complete penetrance
      2. Variable expressivity
   2. Sporadic in 50% of patients resulting from new mutations
   3. Paternal origin of FGFR2 mutation in sporadic cases of Crouzon syndrome (Glaser et al. 2000)
2. Cause
   1. Mutations in the fibroblast growth factor receptor-2 (*FGFR2*) gene which is mapped to 10q25-q26 (Preston et al. 1994; Reardon et al. 1994).
   2. Mutations reported in the third immunoglobulin-like domain (Oldridge et al. 1995; Meyers et al. 1996).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_61

3. Different mutations detected in both exon IIIa and exon IIIc. Most of these mutations are missense, although several different mutations leading to alternative splicing have been recognized (Meyers et al. 1996).
4. Crouzon syndrome exhibits locus heterogeneity with causal mutations in *FGFR2* (Crouzon syndrome) and *FGFR3* (Crouzon syndrome with acanthosis nigricans) in different affected individuals (Chen 2015).
5. Crouzon syndrome with acanthosis nigricans (Crouzonodermoskeletal syndrome).
    1. Described as a separate entity from Crouzon syndrome (Cohen 1999)
    2. Caused by the GAG to GCG transversion mutation in the *FGFR3* gene, leading to Ala391Glu substitution (Meyers et al. 1995; Wilkes et al. 1996)
6. Germinal mosaicism: two affected brothers born to unrelated parents (Rollnick et al. 1988).

3. Pathophysiology
    1. Premature synostosis of the coronal, sagittal, and occasional lambdoidal sutures.
        1. Begins in the first year of life
        2. Completed by the second or third year
    2. Degree of deformity and disability determined by the order and rate of suture fusion.
    3. After fusion of a suture.
        1. Growth perpendicular to that suture becoming restricted
        2. Fused bones acting as a single bony structure.
    4. Compensatory growth occurring at the remaining open sutures to allow continued brain growth.
    5. Multiple sutural synostoses often extend to premature fusion of the skull base sutures causing the following effects:
        1. Midfacial hypoplasia
        2. Shallow orbit
        3. A foreshortened nasal dorsum
        4. Maxillary hypoplasia
        5. Occasional upper airway obstruction

Clinical Features

1. History
    1. The presence of mildly affected individuals in the family.
    2. Craniofacial abnormalities often present at birth and may progress with time.
    3. Decreased mental function in approximately 12% of the patients.
    4. Headaches (29%) and failing vision due to elevated intracranial pressure.
    5. Visual disturbance results from corneal injury due to exposed conjunctivitis and keratitis.
    6. Conductive deafness common due to ear canal stenosis or atresia.
    7. Causes of upper airway obstruction.
        1. Septal deviation
        2. Mid-nasal abnormalities
        3. Choanal abnormalities
        4. Nasopharyngeal narrowing
    8. Meniere disease.
    9. Seizures (12%).
2. The skull and face
    1. Craniosynostosis
        1. Onset: commonly seen during the first year
        2. Usually completing by the second or third year
        3. Coronal suture most commonly involved
        4. Acrocephaly
        5. Brachycephaly
        6. Turricephaly
        7. Oxycephaly
        8. Flat occiput
        9. A high prominent forehead with or without frontal bossing
        10. Ridging of the skull usually palpable
    2. A cloverleaf skull
        1. Rare
        2. Occurring in most severely affected individuals
        3. Flattened sphenoid bone
        4. Shallow orbits
        5. Hydrocephalus (progressive in 30%)
        6. Midface (maxillary) hypoplasia

3. Eyes (Chen 2015)
    1. Exophthalmos (proptosis) (100%) secondary to shallow orbits resulting in frequent exposure conjunctivitis or keratitis
    2. Ocular hypertelorism (100%)
    3. Divergent strabismus
    4. Rare occurrence
        1. Nystagmus
        2. Iris coloboma
        3. Aniridia
        4. Anisocoria
        5. Microcornea
        6. Megalocornea
        7. Cataract
        8. Ectopia lentis
        9. Blue sclera
        10. Glaucoma
        11. Luxation of the eye globes
        12. Blindness from optic atrophy
4. The nose
    1. Beaked appearance (parrot-like nose)
    2. Compressed nasal passage
    3. Choanal atresia or stenosis
    4. Deviated nasal septum
5. The mouth
    1. Mandibular prognathism
    2. Overcrowding of upper teeth
    3. Malocclusions
    4. V-shaped maxillary dental arch
    5. Narrow, high, or cleft palate and bifid uvula
    6. Oligodontia
    7. Macrodontia
    8. Peg-shaped
    9. Widely spaced teeth
6. Ears
    1. Narrow or absent ear canals
    2. Deformed middle ears
    3. Mild-to-moderate hearing losses
7. Other skeletal manifestations
    1. Cervical fusion (18%), C2–C3 and C5–C6 (Anderson et al. 1997a)
    2. Block fusions involving multiple vertebrae
    3. Subluxation of the radial heads
    4. Ankylosis of the elbows
8. Acanthosis nigricans (5%) (Di Rocco et al. 2011)
    1. Crouzon syndrome with acanthosis nigricans: a clinically and genetically distinct entity
    2. Associated with a craniofacial phenotype to anomalies of the skin and long bones
    3. Can be detected by genetic testing due to a specific mutation in *FGFR3* gene
    4. Cutaneous features of acanthosis nigricans (Mir et al. 2013)
        1. Velvety, light-brown to black darkened, thickened skin with accentuated markings that occur in areas including the face, neck, axillae, groin, and breasts
        2. Hypopigmented scars
        3. Other cutaneous findings: sacral pits associated with pink plaques, verrucae vulgaris, molluscum contagiosum, and seborrheic dermatitis
    5. Usual age of onset: first decade (80%)
    6. Only one case reported at birth (Koizumi et al. 1992), some will be patent only in the infancy or early childhood
    7. Typical presentation (Arnaud-Lopez et al. 2007; Sharda et al. 2010)
        1. Crouzonoid facies
        2. Acanthosis nigricans with atypical distribution
        3. Choanal atresia
        4. Hydrocephalus
        5. An abnormal posterior fossa with a hypoplastic foramen magnum and cerebellar tonsillar herniation
        6. Oral abnormalities
        7. Melanocytic nevi
        8. Less frequent findings: vertebral abnormalities and deafness
    8. Associated to several disorders including endocrinopathies mostly associated to hyperinsulinism, FGFR3-related skeletal dysplasias (such as SADDAN), and autoimmune disorders
9. CNS
    1. Chronic tonsillar herniation (approximately 73%). Of these, 47% have progressive hydrocephalus (Cinalli et al. 1995).
    2. Syringomyelia.
    3. Mental retardation (3%).

10. Cardiopulmonary abnormalities (Beck et al. 2002)
    1. Absent pulmonary valve syndrome
    2. Tracheobronchomalacia

Diagnostic Investigations

1. Skull radiographs (Kreiborg 1981; Chen 2015)
    1. Synostosis: The coronal, sagittal, lambdoidal, and metopic sutures may be involved.
    2. Craniofacial deformities.
    3. Digital markings of the skull.
    4. Basilar kyphosis.
    5. Widening of the hypophyseal fossa.
    6. Small paranasal sinuses.
    7. Maxillary hypoplasia with shallow orbits.
2. Cervical radiographs (Anderson et al. 1997a)
    1. Butterfly vertebrae
    2. Fusions of the vertebral bodies and the posterior elements
        1. Cervical fusions in approximately 18% of patients.
        2. C2–C3 and C5–C6 affected equally.
        3. Block fusions may involve multiple vertebrae.
3. Limb radiographs
    1. Metacarpophalangeal analysis
    2. Subluxation of the radial head
    3. Carpal fusion (Anderson 1997b)
4. 3D computed tomography (CT) scan (Nørgaard et al. 2012)
    1. Brachycephalic skull with protrusion of the forehead and flattened occiput
    2. Prematurely fused sutures
    3. A thin skull with extremely increased digital markings
    4. Depressed nasal root
    5. Short orbital roofs
    6. Ocular hypertelorism
    7. Hypoplastic maxilla
    8. Decreased choanal height with constricted nasopharyngeal airway
    9. Comparative 3D reconstruction analysis of the calvaria and cranial bases to precisely define the pathologic anatomy and to permit specific operative planning
5. Magnetic resonance imaging (MRI): used to demonstrate occasional corpus callosum agenesis and optic atrophy
6. Molecular analysis
    1. *FGFR2* mutations in more than 50% of patients (*FGFR2* mutations also observed in Apert syndrome, Pfeiffer syndrome, and Jackson-Weiss syndrome).
    2. *FGFR3* ala391-to-glu mutation in all patients with associated acanthosis nigricans: Finding of acanthosis nigricans in a young child with Crouzon syndrome should prompt testing for the Ala391Gln substitution in *FGFR3* before testing for *FGFR2* mutations (Sharda et al. 2010).

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: not increased unless a parent is affected or with germinal mosaicism (Navarrete et al. 1991)
    2. Patient's offspring: 50%
2. Prenatal diagnosis
    1. Prenatal ultrasonography
        1. Exophthalmos (Menashe et al. 1989)
        2. Ocular hypertelorism (Leo et al. 1991)
    2. 2D, 3D prenatal ultrasonography diagnosis of Crouzon syndrome with acanthosis nigricans (Nørgaard et al. 2012)
        1. Brachycephaly
        2. Hypertelorism
        3. Ocular proptosis
        4. A beaked nose
    3. Identification of the disease-causing *FGFR2* mutation using:
        1. CVS in the first trimester (Schwartz et al. 1996)
        2. Amniocentesis in the second trimester
        3. Preimplantation genetic diagnosis (Harper et al. 2002)
3. Management (Helman et al. 2014)
    1. Medical care

1. No specific medical therapy available
2. Nasal continuous positive airway pressure device to relieve airway obstruction
3. Management of speech
4. Evaluation of hearing deficits and obstructive sleep apnea
5. A combination of orthopedic and orthodontic treatment: effective for improving the appearance and occlusion of patients with mild Crouzon syndrome without surgery (Maspero et al. 2014)

2. Surgical care (David and Sheen 1990)
   1. Stage reconstruction to coincide with facial growth patterns, visceral function, and psychosocial development.
   2. Suture release: early craniectomy with frontal bone advancement most often indicated to prevent or treat increased intracranial pressure because newborns with Crouzon syndrome develop multiple suture synostosis and fused synchondrosis.
   3. Fronto-orbital and midfacial advancements to help in the cosmetic reconstruction of facial dysmorphisms.
   4. A new technique, craniofacial disjunction, followed by gradual bone distraction (Ilizarov procedure) has been reported to produce complete correction of exophthalmos and improvement in the functional and esthetic aspects of the middle third of the face without the need for bone graft in patients aged 6–11 years.
   5. Shunting procedures for hydrocephalus.
   6. Tracheostomy for airway compromise.
   7. Myringotomy to drain middle ear secretions secondary to distorted nasopharynx.
   8. Orthodontic management.

Fig. 1 (**a**–**d**) Two children with Crouzon syndrome showing proptosis secondary to shallow obits and hypertelorism

Fig. 2 A neonate with Crouzon syndrome showing typical craniofacial features with tracheostomy in place for the respiratory problem

Fig. 3 (**a**, **b**) A father and a daughter with Crouzon syndrome showing characteristic craniofacial features

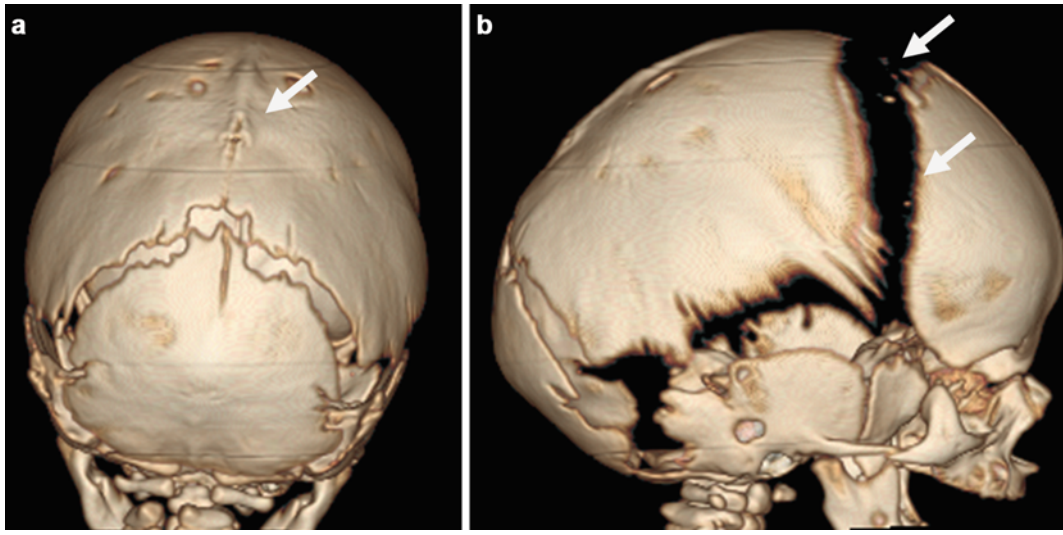

Fig. 4 (**a**, **b**) A 7-day-old boy was evaluated for Crouzon syndrome. CT scan showed complete sagittal synostosis (*arrow*) with consequent scaphocephaly (**a**). Partial fusion of the inferior aspect of the metopic suture was noted. The remainder of the sutures (*arrows*) is widened (**b**) (Courtesy of Dr. Grace Guo)

Cutaneous Vasculitis

Contents

Vasculitis, inflammation of the vessel wall, can result in mural destruction with hemorrhage, aneurysm formation, and infarction, or intimal-medial hyperplasia and subsequent stenosis leading to tissue ischemia and infarction. The skin, in part due to its large vascular bed, exposure to cold temperatures, and frequent presence of stasis, is involved in many distinct as well as unnamed vasculitic syndromes that vary from localized and self-limited to generalized and life-threatening with multi-organ disease. Cutaneous vasculitis comprises a wide spectrum of overlapping primary and secondary disease entities that are characterized by predominant skin involvement and varying degrees of systemic manifestations (Carlson et al. 2005).

Synonyms and Related Disorders

Cutaneous leukocytoclastic angiitis/vasculitis; Cutaneous small vessel vasculitis; Hypersensitivity angiitis/vasculitis; Leukocytoclastic vasculitis; Necrotizing vasculitis

Genetics/Basic Defects

1. Etiology:
    1. A primary process: no known cause or association
    2. A secondary process:
        1. Drug ingestion
        2. Infection
        3. Local factors such as trauma
        4. Systemic disease such as rheumatoid arthritis
2. Factors associated with vasculitis (Carlson et al. 2005):
    1. Gene polymorphisms:
        1. Major histocompatibility complex (MHC)
        2. Intercellular adhesion molecule 1 (ICAM1)
        3. Interleukin 1 receptor antagonist (IL1RA)
        4. Endothelial nitric oxide synthetase (eNOS)
    2. Chronic infections:
        1. Bacteria:
            1. *Neisseria* species
            2. *Staphylococcus aureus*

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_256

3. *Streptococcus* species
4. *Mycobacterium* species

2. *Rickettsia*: Rocky Mountain spotted fever
3. Virus:
   1. Hepatitis viruses A, B, and C
   2. *Hantavirus*
   3. *Herpesviridae*
   4. Parvovirus B19
   5. Human immunodeficiency virus
4. Fungus
5. Protozoa: malaria
6. Helminthic infections:
   1. Gnathostomiasis
   2. Schistosomiasis

3. Drugs:
   1. Insulin
   2. Antibiotics (penicillin, sulfonamides, chloramphenicol, streptomycin)
   3. Anticonvulsants (hydantoin)
   4. Diuretics (thiazides, furosemide)
   5. Analgesics (aminosalicylic acid, phenylbutazone)
   6. Phenothiazine
   7. Vitamins
   8. Quinine
   9. Streptokinase
   10. Tamoxifen
   11. Oral contraceptives
   12. Serum (sickness)
   13. Propylthiouracil
   14. Potassium iodide
   15. Granulocyte colony-stimulating factor (GCSF)
   16. Leukotriene inhibitors (montelukast)
   17. Interferons (IFN-γ/α)
   18. Nicotine patches
   19. TNF inhibitors
4. Vaccines:
   1. Anti-influenza
   2. Anthrax
   3. Hepatitis B
5. Chemicals, environmental agents, and external factors:
   1. Insecticides
   2. Petroleum products
   3. Particulate silica (quartz, granite, sandstone, and grain dust)
   4. Solvents
   5. Farm work
   6. Drug abuse (cocaine)
   7. Radiocontrast media
   8. Protein A column pheresis
   9. Arthropod assaults
   10. Prolonged exercise
   11. Coronary artery bypass surgery
   12. Coral ulcers
6. Allergy:
   1. Food allergens (milk proteins, gluten)
   2. Drug allergy
   3. Atopy
   4. Hyposensitization antigen
7. Connective tissue diseases:
   1. Systemic lupus erythematosus
   2. Rheumatoid arthritis
   3. Sjogren syndrome
   4. Mixed connective tissue disease
   5. Scleroderma
   6. Dermatomyositis/myositis
   7. Relapsing polychondritis
   8. Ankylosing spondylitis
   9. Primary biliary cirrhosis
   10. Adult Still disease
8. Other systemic inflammatory diseases:
   1. Behcet disease
   2. Sarcoidosis
   3. Inflammatory bowel disease
9. Chronic disease:
   1. Cryoglobulinemia
   2. Hyperglobulinemic states
   3. Cystic fibrosis
   4. Bowel-bypass syndrome
   5. Alpha-1 antitrypsin deficiency
   6. St. Jude aortic valve replacement
   7. Diabetes mellitus
   8. Chronic hepatitis (viral, alcoholic)
   9. Endocarditis
   10. Wiskott-Aldrich syndrome
   11. Hemolytic anemia
10. Immunodeficiency states:
    1. Primary combined immunodeficiency
    2. Acquired immunodeficiency syndrome (AIDS)
11. Cancer, lymphoproliferative disorders:
    1. Hodgkin disease
    2. Mycosis fungoides

3. Chronic lymphocytic leukemia
4. B- and T-cell lymphomas
5. Myeloma
6. Adult T-cell lymphoma/leukemia
7. Waldenstrom macroglobulinemia
8. Angioimmunoblastic lymphadenopathy
9. Hairy cell leukemia

12. Cancer, solid tumors/carcinomas:
    1. Lung, colon, renal, breast, prostate, head, and neck squamous cell carcinoma
    2. Nasopharyngeal carcinoma
    3. Barrett esophagus

Clinical Features

1. Physical signs of cutaneous vasculitis affecting the skin with varying intensity, depth, and distribution (Carlson et al. 2005):
    1. Urticaria
    2. Purpura
    3. Purpuric papules
    4. Infiltrated erythema
    5. Ulcer
    6. Infarct
    7. Livedo reticularis
    8. Nodules
2. Clinical assessment for extracutaneous (systemic) vasculitis (Carlson et al. 2005):
    1. Systemic (generalized) disease:
        1. Malaise
        2. Myalgia
        3. Arthralgia/arthritis
        4. Headache
        5. Fever
        6. Weight loss
    2. Mucous membranes and eyes:
        1. Oral or genital ulcers
        2. Proptosis
        3. Conjunctivitis
        4. Episcleritis
        5. Visual disturbances
        6. Uveitis
        7. Retinal exudates/hemorrhages
    3. Ear, nose, and throat disease:
        1. Nasal obstruction
        2. Bloody nasal discharge
        3. Crusting
        4. Sinus involvement
        5. New deafness
        6. Hoarseness/stridor
        7. Subglottic stenosis
    4. Respiratory disease:
        1. Persistent cough
        2. Dyspnea
        3. Wheeze
        4. Hemoptysis
        5. Pulmonary
        6. Hemorrhage
        7. Nodules
        8. Cavities
        9. Infiltrates
        10. Pleurisy/pleural effusion
        11. Respiratory failure
    5. Genitourinary disease:
        1. Hypertension >95 mg Hg diastolic
        2. Proteinuria >0.2 g/24 h
        3. Hematuria >10 red blood cells/ml
        4. Renal impairment/failure
        5. Rise in creatinine >30% or fall in creatinine clearance >25%
    6. Neurologic disease:
        1. Organic confusion/dementia
        2. Seizures (not hypertensive)
        3. Stroke
        4. Cord lesion
        5. Sensory peripheral neuropathy
        6. Cranial nerve palsy
        7. Motor mononeuritis multiplex
    7. Gastrointestinal disease:
        1. Severe abdominal pain
        2. Bloody diarrhea
        3. Intestinal perforation/infarction
        4. Acute pancreatitis
3. A constellation of morphologic signs overlapping with another clinical entity preventing confident clinical diagnosis (Guillevin et al. 1996; Sorensen et al. 2000).
4. Names of vasculitides adopted by the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis (CHCC1994): the goals were to reach consensus on names of the

most common forms of vasculitis and to construct a specific definition for each (Jennette et al. 1994). For American College of Rheumatology (ACR) criteria, please refer to Carlson et al. (2005).

1. Large vessel vasculitis:
    1. Giant cell (temporal) arteritis:
        1. Granulomatous arteritis of the aorta and its major branches, with a predilection for the extracranial branches of the carotid artery
        2. Often involves the temporal artery
        3. Usually occurs in patients older than 50 and often associated with polymyalgia rheumatica
    2. Takayasu arteritis:
        1. Granulomatous inflammation of the aorta and its major branches
        2. Usually occurs in patients younger than 50
2. Medium-sized vessel vasculitis:
    1. Polyarteritis nodosa: necrotizing inflammation of medium-sized or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules
    2. Kawasaki disease:
        1. Arteritis involving large, medium-sized, and small arteries and associated with mucocutaneous lymph node syndrome.
        2. Coronary arteries are often involved.
        3. Aorta and veins may be involved.
        4. Usually occurs in children.
3. Small vessel vasculitis:
    1. Wegener granulomatosis:
        1. Granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small- to medium-sized vessels (e.g., capillaries, venules, arterioles, and arteries).
        2. Necrotizing glomerulonephritis is common.
    2. Churg-Strauss syndrome: eosinophil-rich and granulomatous inflammation involving the respiratory tract, and necrotizing vasculitis affecting small- to medium-sized vessels, and associated with asthma and eosinophilia
    3. Microscopic polyangiitis:
        1. Necrotizing vasculitis, with few or no immune deposits, affecting small vessels (capillaries, venules, and arterioles).
        2. Necrotizing arteritis involving small- and medium-sized vessels may be present.
        3. Necrotizing glomerulonephritis: very common.
        4. Pulmonary capillaritis often occurs.
    4. Henoch-Schonlein purpura:
        1. Vasculitis, with IgA-dominant immune deposits, affecting small vessels (capillaries, venules, and arterioles)
        2. Typically involves the skin, gut, and glomeruli and is associated with arthralgias or arthritis
    5. Cryoglobulinemic vasculitis (essential):
        1. Vasculitis, with cryoglobulin immune deposits, affecting small vessels (i.e., capillaries, venules, or arterioles), and associated with cryoglobulins in the serum.
        2. The skin and glomeruli are often involved.
    6. Cutaneous leukocytoclastic vasculitis: isolated cutaneous leukocytoclastic angiitis without systemic vasculitis or glomerulonephritis
5. Because of our understanding of vasculitis, another (Revised) International Chapel Hill Consensus Conference on the Nomenclature of Vasculitides (CHCC2012) was convened to improve CHCC1994 nomenclature, change names and definitions as appropriate, and add important categories of vasculitis that were not included in CHCC1994 (Jennette et al. 2013). Names for vasculitides adopted by CHCC2012 are:
    1. Large vessel vasculitis:
        1. Takayasu arteritis
        2. Giant cell arteritis
    2. Medium vessel vasculitis:
        1. Polyarteritis nodosa
        2. Kawasaki disease

3. Small vessel vasculitis (SVV):
   1. Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis:
      1. Microscopic polyangiitis
      2. Granulomatosis with polyangiitis (Wegener)
      3. Eosinophilic granulomatosis with polyangiitis (Churg-Strauss)
   2. Immune complex SVV:
      1. Anti-glomerular basement membrane disease
      2. Cryoglobulinemic vasculitis
      3. IgA vasculitis (Henoch-Schonlein)
      4. Hypocomplementemic urticarial vasculitis
4. Variable vessel vasculitis:
   1. Behcet disease
   2. Cogan syndrome
5. Single-organ vasculitis:
   1. Cutis leukocytoclastic angiitis
   2. Cutaneous arteritis
   3. Primary central nervous system vasculitis
   4. Isolated aortitis
   5. Others
6. Vasculitis associated with systemic disease:
   1. Lupus vasculitis
   2. Rheumatoid vasculitis
   3. Sarcoid vasculitis
   4. Others
7. Vasculitis associated with probable etiology:
   1. Hepatitis C virus-associated cryoglobulinemic vasculitis
   2. Hepatitis B virus-associated vasculitis
   3. Syphilis-associated aortitis
   4. Drug-associated immune complex vasculitis
   5. Drug-associated ANCA-associated vasculitis
   6. Cancer-associated vasculitis
   7. Others

6. Prognosis:
   1. Cutaneous vasculitis should be considered a cutaneous disease with potential to progress to life-threatening systemic disorder (Figs. 1–3) as a minority of these patients will have internal organ involvement and a few of these patients will die of vasculitis.
   2. Mean mortality: 4%.

Diagnostic Investigations

1. Skin biopsy for routine histologic examination, direct immunofluorescence, and tissue culture and sensitivity:
   1. Acute signs: fibrinoid necrosis.
   2. Chronic signs: endarteritis obliterans.
   3. Past signs: acellular scar of healed arteritis.
   4. Presence of extravascular findings such as patterned fibrosis or collagenolytic granulomas.
   5. Most biopsies of cutaneous vasculitis will exhibit a small vessel neutrophilic vasculitis (leukocytoclastic vasculitis) that is associated with immune complexes on direct immunofluorescence examination or, less commonly, antineutrophil cytoplasmic antibodies by indirect immunofluorescence testing (Carlson and Chen 2007).
2. Laboratory studies (Carlson et al. 2005):
   1. Routine blood tests for full blood count, erythrocyte sedimentation rate, aminotransferases, alkaline phosphatase, albumin, bilirubin, creatinine, blood urea nitrogen, serum electrolytes, and urine analysis
   2. Tests for antineutrophil cytoplasmic antibodies (ANCA), antinuclear antibodies (ANA), rheumatoid factor, antidouble-stranded DNA, cryoglobulins, precipitins (Ro, La, RNP, Sm), and complement studies (CH50, C3, C4)
   3. Thrombophilia tests for anticardiolipin antibody, lupus anticoagulant (activated partial thromboplastin time, Russell viper venom test), thrombin time, prothrombin time, antigenic and functional antithrombin III, protein C, protein S, factor V Leiden mutation, and serum homocysteine levels
   4. Paraproteinemia screens including serum protein electrophoresis, serum protein immunofixation, serum immunoglobulins, and random urine protein immunofixation

5. Viral serologic screens for human immunodeficiency virus and hepatitis B and C
6. ECG

3. Radiology:
   1. Chest X-ray.
   2. Skeletal survey (Fig. 4).
      1. Bone age: may be retarded.
      2. Joints: contractures.
      3. Tubular bones: infarcts.
      4. Subcutaneous tissue: calcifications may be present.
      5. Fractures of tubular bones and spines.

Genetic Counseling

1. Recurrence risk: depends on underlying etiology
2. Prenatal diagnosis: not reported to date
3. Management (Carlson et al. 2005; Chen and Carlson 2008):
   1. By and large empiric in nature and defined by the principal of do no harm.
   2. The foremost reason to treat: to comfort the patient.
   3. In most instances, cutaneous vasculitis represents a self-limited condition and will be relieved by leg elevation, avoidance of standing, and therapy with NSAIDs.
   4. For mild recurrent or persistent disease, colchicine and dapsone are first-choice agents.
   5. Severe cutaneous disease requires treatment with systemic corticosteroids or more potent immunosuppression (azathioprine, methotrexate, and cyclophosphamide).
   6. A combination of corticosteroids and cyclophosphamide is required therapy for systemic vasculitis, which is associated with a high risk of permanent organ damage or death.
   7. In cases of refractory vasculitis, plasmapheresis and intravenous immunoglobulin are viable considerations.
   8. The new biologic therapies that act via cytokine blockade or lymphocyte depletion, such as the tumor necrosis factor-α inhibitor infliximab (Booth et al. 2004) and the anti-B-cell antibody rituximab, respectively, are showing benefit in certain settings such as connective tissue disease (CTD) and antineutrophil cytoplasmic antibodies (ANCA)-associated vasculitis.
   9. Goal of treatment for more severe vasculitis: to prevent extensive ulceration and infarction (permanent damage of the skin and other tissues).
   10. Treatment of small vessel neutrophilic vasculitis: follow a therapeutic ladder from safe and cheap (e.g., support hose and antihistamines) for nonulcerative, purpuric lesions to expensive and dangerous (e.g., daily pulses of cyclophosphamide) for severe systemic disease with ulcers and infarcts (Sais et al. 1998; Lotti et al. 1998; Garcia-Porrua et al. 2001).
   11. In cases not associated with systemic involvement or neuropathy, conservative treatment usually leads to good results.
   12. If an associated disorder can be identified, management of this disorder may result in abatement or clearing of the vasculitis. For example, hepatitis C-induced mixed cryoglobulinemia treated with IFN-α and antiviral medication (ribavirin) leads to decreased liver inflammation and resolution of the hepatitis C-associated vasculitis.
   13. Suppression of inflammation due to systemic inflammatory disorders such as CTD may reduce both acute and long-term vascular damage (Raza et al. 2000).
   14. Basic instructions on self-care, including diminishing factors known to exacerbate vasculitis such as excessive stress or heat or cold exposure (in vasculitis caused by cryoglobulins).
   15. The bottom line in caring for patients with cutaneous vasculitis is to tailor treatment to disease severity (Willcocks et al. 2003).

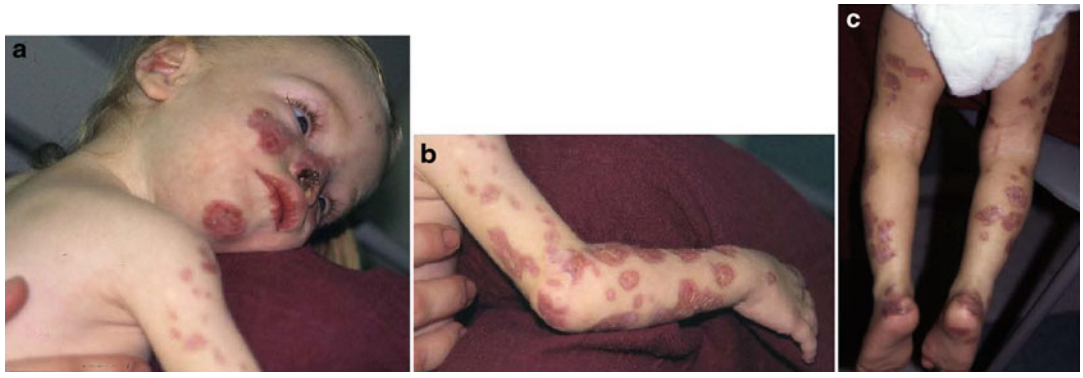

Fig. 1 (**a**–**c**) A 6-year-old Caucasian female was seen for leukocytoclastic vasculitis of unknown etiology, possibly due to autoimmune etiology. She was born 2 weeks early with birth weight of 5 lb 14 oz. She appeared developing normally until around 2 months of age when she was noticed to have small *red dots* on her soles, associated with fever. The rash started as small papules and then ulcerated, spreading to the body and face and leaving extensive scarring. She was also noted to have failure to thrive, growth retardation, developmental delay, and aspiration pneumonia. Throughout the course of her history, the patient has seen rheumatologists, allergists, immunologists, infectious disease experts, dermatologists, and geneticists. Antibiotics, steroids, and methotrexate were tried without success. The biopsy was performed around 3 months of age and was interpreted to be leukocytoclastic vasculitis. A second biopsy around 1 year of age was interpreted to be lupus erythematosus. She had bilateral cataracts and severe growth retardation (severe short stature). She auto-amputated her nasal cartilage and right fifth digit and had multiple contractures at the elbows, knees, ankles, and wrists. She also had chronic hypertension, limb spasticity, chronic infections, and chronic osteomyelitis of multiple joints

Fig. 2 (**a**, **b**) Patient at 7 years of age

Fig. 3 Patient at 12 years of age. Her height was 34½ in. (height age of approximately 2 years and 3 months). Her weight was 22 lb (weight age of approximately 2 years of age). She had extensive skin lesions affecting mostly the nose, face, cheeks, mouth, ears, and upper and lower extremities. Her trunk, chest, and abdomen were mostly spared. The cartilage portion (nose tip) of her nose was gone. The skin lesions were dry and irregularly shaped with healed ulcerations (*reddened color*). She was admitted to NIH under the undiagnosed diseases program protocol at 17 years of age with chief complaints of leukocytoclastic vasculitis, lupus profundus, bilateral cataracts, multiple joint contractures, hypertension, and severe growth retardation, Raynaud phenomenon with auto-amputation, spasticity, chronic elevated CRP, and wounds with a history of *Pseudomonas* infection with sensitivity to amikacin and gentamicin. She was diagnosed to have a rheumatologic process involving either a vasculitis or vasculopathy with a destructive panniculitis, severe ichthyosis with autoimmune process of unclear etiology, poor wound healing, primordial dwarfism, chronic osteomyelitis versus primary bone disease of unclear etiology, severe generalized osteopenia, multiple contractures, intellectual disability, iron-deficiency anemia, vitamin D toxicity, left renal stones, and vitamin A and zinc deficiencies. This patient may represent a unique syndrome (Collaboration with Dr. Vidya Raman)

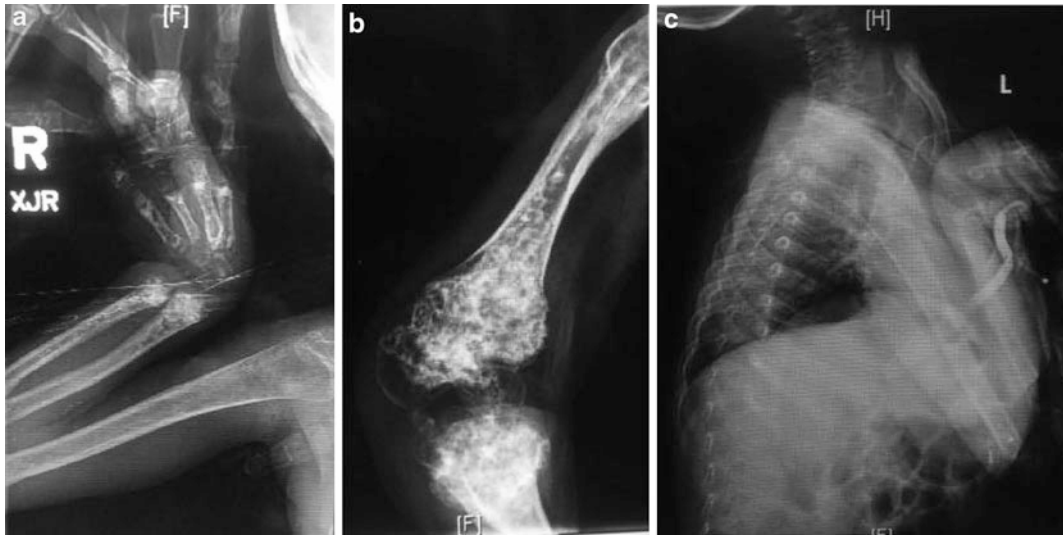

Fig. 4 (**a**–**c**) The radiographs at 18 years of age showed widespread blastic lesions (bone marrow calcifications) involving the dia-metaphyseal portions of the distal radius and ulna as well as the metacarpals and phalanges. There were also subcutaneous calcifications in her forearms and elbows. The extremities appeared to be held in a flexion contracture. There was widespread disuse osteoporosis with multiple chronic-appearing compression fractures throughout the thoracic and lumbar spine. Appearance is consistent with widespread chronic-appearing bony infarcts

Cutis Marmorata Telangiectatica Congenita

Contents

In 1922, Van Lohuizen (Van Lohuizen 1922) first described cutis marmorata telangiectatica congenita (CMTC) as a pattern of reticulate erythema and telangiectasia, skin atrophy, and/or ulceration.

Synonyms and Related Disorders

Adams-Oliver syndrome; CMTC phakomatosis pigmentovascularis; Macrocephaly-CMTC syndrome

Genetics/Basic Defects

1. Pathogenesis
    1. Unknown
    2. Most cases are sporadic
2. Hypothesis
    1. Environmental factors
    2. Multifactorial cause
    3. A nerve conduction defect (Bormann et al. 2001)
    4. A lethal gene surviving by mosaicism suggested by segmental distribution often with a sharp midline separation (Rogers and Poyzer 1982)
    5. Autosomal dominant inheritance with low or variable penetrance
        1. An affected parent showing more limited involvement than his offspring (Kurczynski 1982)
        2. Two siblings with one having CMTC alone and the other showing associated anomalies (hypertension and acrocyanosis) (Andreev and Pramatarov 1979)

Clinical Features

1. Onset (Garzon and Schweiger 2004):
    1. Congenital: common
    2. Later onset (Way et al. 1974)
2. Reticulated vascular pattern
    1. Finely reticular or coarse pattern: will not resolve completely with warming of the skin
    2. Broad streaks of discolored skin in a "train-track-like" pattern
    3. Relatively fixed and discernable at rest
    4. Pallor of the skin between the vascular network pattern: often reported (Ben-Amitai et al. 2000)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_62

5. Often accompanied by:
    1. Phlebectasia (prominent veins)
    2. Telangiectasias
    3. Cutaneous and subcutaneous tissue atrophy: may manifest as hypoplasia of the affected limb (an inconsistent feature) (South and Jacobs 1978)
    4. Ulceration of the affected skin, particularly involving the skin overlying the elbows and knees (Picascia and Esterly 1989)
    5. Hyperkeratosis
6. The presence of atrophy and ulceration helps to differentiate CMTC from physiologic cutis marmorata
7. Localized lesions
    1. Most commonly affecting the trunk and extremities
    2. Sharp segmental pattern: easy to differentiate from physiologic cutis marmorata
8. Generalized lesions
    1. Often unilateral
    2. May involve face but mucosal involvement uncommon (Ben-Amitai et al. 2000)
    3. Do not occur on the entire body surface (Devillers et al. 1999)

3. Associated anomalies (27–80%) (Picascia and Esterly 1989; Devillers et al. 1999; Gerritsen et al. 2000)
    1. Relatively high associated defects
        1. May represent true associations or coincidental
        2. May represent a bias toward reporting cases with more severe anomalies
        3. Inconsistency among authors regarding diagnostic criteria
    2. Asymmetry
        1. Limb asymmetry (hyperplasia or hypoplasia of a limb)
            1. The most common associated anomaly
            2. Cutaneous atrophy may be noted concomitantly with asymmetry
        2. Facial asymmetry may occur
    3. Skeletal defects
        1. Syndactyly
        2. Tendonitis stenosans
        3. Hip dysplasia
        4. Clubfoot
        5. Scoliosis
        6. Macrocephaly
        7. Skull asymmetry
        8. Scaphoid scapula
        9. Micrognathia
        10. Generalized osteoporosis
        11. Consider Adams-Oliver syndrome and macrocephaly-CMTC if limb defects are present
4. Other vascular anomalies:
    1. May occur distant to the area of CMTC or within the same affected area (Picascia and Esterly 1989)
    2. Capillary malformations (port-wine stains): the most commonly associated vascular birthmark occurring in 20% of patient (Ben-Amitai et al. 2000)
    3. Sturge-Weber syndrome (Petrozzi et al. 1970)
    4. Hemangiomas of infancy
    5. Multiple angiokeratomas
5. Ocular anomalies:
    1. Glaucoma
    2. Infrequent anomalies:
        1. Persistent arterial hyaloidia (an embryonic vessel that typically regresses)
        2. Granular retinal pigmentation
        3. Small optic disks
        4. Optic nerve atrophy
6. Macrocephaly-CMTC syndrome (Moore et al. 1997; Robertson et al. 2000; Lapunzina et al. 2004; Katugampola et al. 2008):
    1. Macrocephaly and cutis marmorata: diagnostic features
    2. Hypotonia
    3. Psychomotor retardation
    4. Seizures
    5. Hydrocephaly
    6. Cerebral atrophy
    7. Agenesis of the corpus callosum
    8. Dilated ventricles
    9. Hemangioma of the lip and philtrum
    10. Syndactyly of the second and third toes

11. Segmental overgrowth
12. Connective tissue abnormalities: features similar to Ehlers-Danlos syndrome

7. Other cutaneous anomalies (may be coincidental) (Ben-Amitai et al. 2000):
   1. Congenital melanocytic nevi
   2. Café au lait macules
   3. Mongolian spots
8. Other systemic anomalies (uncommon):
   1. Hypothyroidism
   2. Cardiac defects
   3. Genitourinary tract anomalies (Del Guidice and Nydorf 1986; Ben-Amitai et al. 2001; Sills et al. 2002; Fujita et al. 2003):
      1. Hypospadias
      2. Renal cysts
      3. Duplication of the renal collecting system
      4. Rectovaginal and ureterovaginal fistulae
      5. Absent clitoris
      6. Imperforate anus
      7. Unilateral ovarian agenesis
      8. Septate uterus
      9. Premature gonadal failure associated with de novo balance translocation affecting chromosomes 8 and 9

4. Suggested diagnostic criteria for cutis marmorata telangiectatica congenita (Kienast and Hoeger 2009): The presence of all three major criteria and two minor criteria is sufficient for diagnosis:
   1. Major criteria
      1. Congenital reticulate (marmorated) erythema (27%)
      2. The absence of venectasia (27%)
      3. Unresponsiveness to local warming (27%)
   2. Minor criteria
      1. Fading of erythema within 2 years (18%)
      2. Telangiectasia (5%)
      3. Port-wine stain outside the area affected by CMTC (2%)
      4. Ulceration (2%)
      5. Atrophy (2%)
5. Differential diagnosis
   1. Cutis marmorata (physiologic)
   2. Cutis marmorata (associated with genetic syndrome)
      1. Cornelia de Lange syndrome
      2. Down syndrome
      3. Homocystinuria
      4. Divry and Van Bogaert syndrome
         1. A rare disorder
         2. Corticomeningeal angiomatosis
         3. Visual field defects
         4. Seizures
         5. "Marble" skin
   3. Reticulated capillary malformations
      1. A diffuse, generalized form of a "livedoid" capillary malformation involving the entire skin
      2. Not associated with atrophy, ulceration, or limb hypoplasia
      3. Associated with a significant risk of associated visceral vascular anomalies (eye, brain, kidneys, and heart) and requires evaluation and follow-up (Enjolras and Garzon 2001)
   4. Bockenheimer syndrome (diffuse phlebectasia):
      1. A very rare disorder
      2. Onset in infancy
      3. Characterized by progressive venous varicosity
   5. Neonatal lupus erythematosus
   6. CMTC "syndrome"
      1. Macrocephaly-CMTC syndrome
      2. Adams-Oliver syndrome
      3. CMTC phakomatosis pigmentovascularis

Diagnostic Investigations

1. Physical evaluation (Garzon and Schweiger 2004)
   1. Reticulated vascular pattern
   2. Limb length and girth
   3. Limb defects
   4. Scalp defects
   5. Head circumference
   6. Other associated anomalies
   7. Facial lesions
2. Ophthalmologic evaluation

3. Brain MRI in macrocephaly-CMTC (Akcar et al. 2004; Giuliano et al. 2004; Garavelli et al. 2005)
    1. Megalencephaly
    2. Asymmetry of the cerebral hemispheres
    3. Abnormally increased signal of white matter
    4. Chiari type I malformation
    5. Bilateral prominent lateral ventricles
    6. Generalized cortical dysplasia
    7. Cavum septi pellucidum cyst
    8. Calvarial hemangioma.

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. Sporadic cases: a low recurrence risk
        2. A 50% risk if one of the parents is affected
    2. Patient's offspring: a 50% risk in autosomal dominant transmission, otherwise a low recurrence risk
2. Prenatal diagnosis: not reported
3. Management
    1. Careful physical examination to assess for other congenital anomalies
    2. Measurement of limb length and girth at the time of evaluation
    3. Baseline and follow-up ophthalmologic examinations should be performed when the vascular lesions affect the periocular skin
    4. Local supportive care including application of hydrocolloid dressings for ulcerations

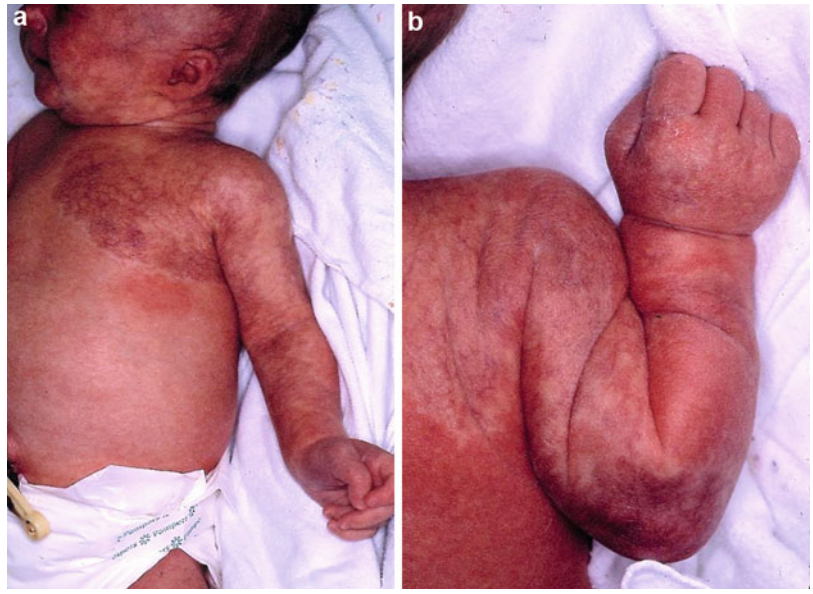

Fig. 1 (**a**, **b**) A 2-month-old infant with cutis marmorata telangiectatica congenita showing a reticular vascular pattern which was present from birth

Fig. 2 (**a**, **b**) The same infant at 14 months of age

Fig. 3 (**a**, **b**) The same patient at 26 months of age showing development of a large diffuse vascular lesion extending from the whole *left* anterior chest to the *left* neck

Fig. 4 (**a**–**c**) A 3-month-old infant boy with cutis marmorata telangiectatica congenita. Cutaneous vascular lesions consist of a 4 × 4 × 2 cm soft vascular lesion of the upper posterior back and diffuse *bluish* vascular lesions on the front chest, shoulders, arms, trunk, buttock, and legs. The right leg is larger than the left

Fig. 5 Another infant with a reticular vascular pattern on the *right* leg

Fig. 6 (**a**–**f**) A child with cutis marmorata telangiectatica congenita at different ages (newborn, 4 months, and 4 years of age)

Cystic Fibrosis

Contents

Cystic fibrosis (CF) is the most common Caucasian lethal genetic disorder (with gene frequency of 1 in 25) in the USA, where 4–5% of population have at least one CF allele. CF affects approximately 1 in 2,500 live births among Caucasians, 1 in 17,000 among African-Americans, and 1 in 90,000 among Asians (Ruzal-Shapiro 1998).

Synonyms and Related Disorders

CFTR-related disorders; Congenital absence of vas deferens; Mucoviscidosis

Genetics/Basic Defects

1. Inheritance
    1. Autosomal recessive
    2. CF gene mapped to chromosome 7q31.2
2. Molecular defect (Moskowitz et al. 2008)
    1. Caused by a single gene defect on chromosome 7 that encodes a cAMP-regulated chloride channel (Davis et al. 1996) known as the cystic fibrosis transmembrane conductance regulator (CFTR)
        1. CFTR usually resides in the apical membrane of epithelial cells lining the airway, biliary tree, intestines, vas deferens, sweat ducts, and pancreatic ducts.
        2. Insufficient fluid secretion secondary to inability of CFTR to transport chloride ion at the above sites causes higher viscidity of the protein portions of the secretions and obstructing the ducts, leading to plugging and dysfunction at the organ level.
        3. CFTR also regulates the activity of other proteins that conduct ions and affects intracellular regulatory processes at the cellular level.
    2. Presence of close to 1,500 different disease-causing mutations of the *CFTR* gene (Ruzal-Shapiro 1998; O'Sullivan and Freedman 2009)
        1. Presence of a striking difference in the distribution of CFTR mutations in different populations (Cystic Fibrosis Genetic Analysis consortium 1994)
        2. Deletion mutations including delta F508 which, observed in over 70% of

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_63

patients with CF, have a deletion of three contiguous base pairs resulting in the loss of a single amino acid, phenylalanine at codon 508
3. Missense mutation (single base pair exchange within a normal length CFTR protein)
4. Nonsense mutations (exchange of a single base pair resulting in premature termination of the protein)
5. Frameshift mutations (the deletions or insertion of a single base pair)

3. Classification of CFTR mutations (Culling and Ogle 2010)
   1. Class I mutations
      1. Introduce a stop codon prematurely
      2. Produce either an unstable mRNA with no detectable protein being made or an unstable protein that is rapidly degraded or has no functional capability
      3. No CFTR protein in the cell membrane
      4. For example, G542X, 394delTT, 1717-1 G → A
   2. Class II mutations
      1. Block the processing of the protein due to aberrant folding and subsequent degradation when recognized as abnormal by cellular "quality control" mechanisms
      2. No CFTR protein at the apical cell membrane
      3. For example, N1303K, ΔF508, 3905insT
   3. Class III mutations:
      1. Produce a CFTR protein that does not function as a chloride channel due to a block in regulation, despite being fully processed and correctly located.
      2. Within this class there are mutations that have very little function (G551D), those where ATP is less potent at stimulating activity (S1255P) and those with reduced absolute activity (G551S, G1244E, and G1349D).
   4. Class IV mutations
      1. Produce a fully processed and correctly located CFTR protein
      2. However, the conductance and/or gating properties of the channel have been altered by mutations in the membrane spanning domains
      3. Extent to which conduction is affected varies between mutations
      4. For example, R117H, R347P
   5. Class V mutations
      1. Result in a reduction in the synthesis of CFTR protein
      2. Include promoter mutations, the promotion of alternative splicing, and inefficient protein maturation
      3. For example, A455E, 2789 + 5G → A, IVS8-5 T
   6. Class VI mutations
      1. Presence of functional but unstable CFTR protein at the apical membrane
      2. Decreased stability on CFTR protein
      3. For example, Q1412X, 4326delTC, 4279insA
4. Genotype-phenotype correlations (Zielenski and Tsui 1995; Kerem and Kerem 1996a, 1996b; Ruzal-Shapiro 1998)
   1. CF phenotype: highly variable and hundreds of different genotypes are responsible for the varied clinical presentations of the disease (Fiel 1998).
   2. Patients with homozygous delta F508 typically have respiratory distress and malabsorption.
   3. A CF mutation associated with mild lung disease: Patients with the *A455E* mutation have a better prognosis than patients who are homozygous for the delta F508 mutation (Gan et al. 1995).

4. A good correlation between CFTR genotype and one of the clinical variables – pancreatic function status.
5. Documentation of CFTR mutations in patients with atypical CF disease presentations, including congenital absence of vas deferens and several pulmonary diseases.
6. Patients with less severe variations of the disease or typical CF with borderline normal sweat tests may have other haplotypes.

Clinical Features

1. Criteria for the diagnosis of CF (Rosenstein and Cutting 1998)
    1. One or more characteristic phenotypic features:
        1. Or a history of CF in a sibling
        2. Or a positive newborn screening test result
    2. And an increased sweat chloride concentration by pilocarpine iontophoresis on two or more occasions:
        1. Or identification of two CF mutations
        2. Or demonstration of abnormal nasal epithelial ion transport
2. Signs and symptoms of cystic fibrosis (Davies et al. 2007; O'Sullivan and Freedman 2009)
    1. General (any age)
        1. Family history of cystic fibrosis
        2. Salty-tasting skin
        3. Clubbing fingers and toes
        4. Cough with sputum production
        5. Mucoid *Pseudomonas aeruginosa* isolated from airway secretions
        6. Hypochloremic metabolic alkalosis
    2. Prenatal
        1. Echogenic bowel on ultrasound
        2. Perforated meconium ileus
    3. Neonatal
        1. Meconium ileus
        2. Protracted jaundice
        3. Abdominal or scrotal calcifications
        4. Intestinal atresia
    4. Infancy
        1. Persistent infiltrates on chest radiographs
        2. Failure to thrive
        3. Anasarca or hypoproteinemia
        4. Chronic diarrhea
        5. Abdominal distention
        6. Cholestasis
        7. *Staphylococcus aureus* pneumonia
        8. Idiopathic intracranial hypertension (vitamin A deficiency)
        9. Hemolytic anemia (vitamin E deficiency causes anemia by increasing fragility and reducing lifespan of red blood cells)
    5. Childhood
        1. Chronic pansinusitis or nasal polyposis
        2. Steatorrhea
        3. Rectal prolapse
        4. Distal intestinal obstruction syndrome or intussusceptions
        5. Idiopathic recurrent or chronic pancreatitis
        6. Liver disease
    6. Adolescence and adulthood
        1. Allergic bronchopulmonary aspergillosis
        2. Chronic pansinusitis or nasal polyposis
        3. Bronchiectasis
        4. Hemoptysis
        5. Idiopathic recurrent pancreatitis
        6. Portal hypertension
        7. Delayed puberty
        8. Azoospermia (male infertility) secondary to congenital bilateral absence of the vas deferens
        9. Malabsorption
        10. Liver disease
        11. Dehydration and electrolyte disturbance (pseudo-Barter syndrome)
3. Classic clinical triad
    1. Exocrine pancreatic insufficiency

2. Chronic obstructive pulmonary disease
3. Elevation of sodium and chloride concentration in sweat

4. Chronic sinopulmonary disease
   1. Varying widely in age of onset and rate of progression
   2. Clinical course
      1. Newborn with CF with histologically normal respiratory systems
      2. First few months of age
         1. Epithelial chloride channel defect, leading to abnormal respiratory secretions, bronchopulmonary infections, and airway obstruction
         2. Clinical manifestations including cough, wheezing, retractions, and tachypnea
   3. Persistent endobronchial infection and inflammation with typical CF pathogens (Ruzal-Shapiro 1998)
      1. *Staphylococcus aureus*
         1. Responsible for the majority of lung disease when CF was first described
         2. Commonly isolated in the first year of life from the sputum of patients with CF
         3. Typically controlled by antibiotic therapy
         4. Currently only 10% of adult patients with CF are chronically colonized by the pathogen.
      2. Mucoid and nonmucoid *Pseudomonas aeruginosa*
         1. The most prevalent of the pathogens in CF, causing chronic infection in up to 90% of adults and 80% of children
         2. Initial colonization with nonmucoid forms
         3. Subsequent conversion to mucoid variants
      3. *Hemophilus influenzae*
         1. Commonly seen in babies
         2. Rarely encountered in the adults
      4. Other pulmonary pathogens
         1. *Burkholderia cepacia*
         2. Aspergillus
         3. Mycobacteria
         4. Respiratory viruses
   4. Upper airway disease
      1. Opacified or maldeveloped sinuses
      2. Nasal polyps (up to 26% of patients)
      3. Sinusitis
         1. Facial pain
         2. Swelling
         3. Tenderness
         4. Air-fluid levels on radiograph
   5. Pulmonary exacerbations
      1. Persistent cough and sputum production
      2. Increased dyspnea
      3. Reduction in pulmonary function
      4. Increased hemoptysis: a life-threatening complication but fatal hemoptysis is rare
      5. Digital clubbing
      6. Changes in chest radiographic findings
      7. Bronchiolitis
      8. Increased rales or rhonchi
      9. Decreased air exchange
      10. Increased use of accessory muscles of respiration
      11. Spontaneous pneumothorax (5–8%), a life-threatening complication
      12. Obstructive airway disease, leading to respiratory insufficiency associated with bronchiectasis
5. Gastrointestinal abnormalities (Shalon and Adelson 1996; Haller et al. 2014)
   1. Intestine
      1. Meconium ileus at birth
         1. An obstruction of the distal ileum or proximal colon with thickened, viscous meconium in 15–20% of CF patients developed in utero in the second trimester
         2. Virtually diagnostic of CF
      2. Meconium peritonitis (rupture of the intestine secondary to complete obstruction)
      3. Meconium plug syndrome in the newborn infants, a more benign

condition characterized by blockage of the colon
4. Distal intestinal obstruction syndrome later in childhood, adolescence, or adulthood (10%), presenting as crampy abdominal pain, usually with decreased stooling
5. Rectal prolapse occurring in less than 1% of patients but may be the presenting symptom, particularly in infants
6. Occasional intussusception
7. Disorders of motility
    1. Gastroesophageal reflux (GER)
    2. Gastroparesis: previously described as a common phenomenon in the group of lung-transplanted patients and may be associated with the increased incidence of GER and its pulmonary complications
8. Disorders related to intestinal dysbiosis, infection, and inflammation
    1. Small bowel bacterial overgrowth
    2. Colonic dysbiosis
    3. *Clostridium difficile* infection
    4. Intestinal inflammation and associated gastrointestinal disorders
9. Disorders of intestinal obstruction
    1. Meconium ileus
    2. Constipation
    3. Intussusception
    4. Appendicitis
10. Gastrointestinal cancer

2. Pancreas
    1. Pancreatic exocrine insufficiency
        1. Failure of the pancreas to produce sufficient digestive enzymes to allow breakdown and absorption of fats and protein
        2. Obstruction of the pancreatic duct in utero with resultant progressive loss of exocrine pancreatic acini and their function
        3. A hallmark of the disease, occurring in 90% of patients by 1 year of age
        4. Leads to frequent, bulky, foul-smelling, oily stools
        5. Steatorrhea (presence of excessive undigested fat in the stool)
        6. Failure to thrive is common in the patients with CF
    2. Recurrent pancreatitis in few patients
    3. CF-related diabetes mellitus (Nathan et al. 2010)
        1. Affect approximately one third of all CF patients
        2. Rare before 10 years of age
        3. Resulting from a loss of functional pancreatic β cells and a state of relative insulin deficiency
        4. Oral glucose tolerance test as a screening tool
        5. HbA1c, an accepted diagnostic test for diabetes in the general population (International Expert Committee 2009), cannot be used as screening tool because levels are often falsely low (Holl et al. 2000).
3. Liver
    1. Prolonged obstructive jaundice in a few affected infants, presumably secondary to obstruction of extrahepatic bile ducts by thick bile along with intrahepatic bile stasis
    2. Chronic hepatic disease manifested by clinical or histologic evidence of focal biliary cirrhosis or multilobular cirrhosis

6. Genitourinary manifestations (Ruzal-Shapiro 1998)
    1. Congenital bilateral absence of the vas deferens in most males
        1. Leading to azoospermia
        2. A significant cause of infertility
    2. Infertility common in women
        1. Due to increased amounts of thick mucus in the cervical canal
        2. An increased incidence of amenorrhea
        3. Occasional patients carrying pregnancies to term without significant respiratory deterioration

7. Skeletal manifestations (Ruzal-Shapiro 1998)
    1. Hypertrophic pulmonary osteoarthropathy
        1. Rarely seen in children with CF
        2. Increasing frequency with increasing age and severity of disease
    2. Triad of skeletal manifestations
        1. Clubbing of fingers and toes
        2. Arthritis
        3. Periosteal new bone formation
8. Nutritional abnormalities
    1. Failure to thrive, a common manifestation during infancy and beyond
    2. Poor appetite
    3. Weight loss
    4. Fatigue
    5. Prone to heat prostration
    6. Hypoproteinemia with or without edema, anemia, and deficient fat-soluble vitamins A, D, E, and K
    7. Peripheral neuropathy secondary to deficient vitamin E
    8. Delayed puberty largely due to nutritional factors
    9. Potentially lethal protein-energy malnutrition in some infants
    10. Development of some degree of malabsorption by 4 years of age in roughly 85% of patients
9. Salt losing syndromes
    1. Acute salt depletion
    2. Chronic hypochloremic or hyponatremic alkalosis
    3. Excessive salt loss in the sweat potentially fatal for patients exposed to moderate heat or during prolonged hot weather
10. Prognosis
    1. Respiratory failure: the leading cause of death in CF and occurs eventually in nearly all patients
    2. Current median survival: approximately 35 years in the USA
    3. Current data suggesting a lifespan exceeding 50 years for those diagnosed and treated early

Diagnostic Investigations

1. Newborn screening (Farrell and Mischler 1992; Pollitt 1998; Farrell 2000; Farrell and Farrell 2003)
    1. Potential benefits
        1. Reductions in mortality (patients dying with undiagnosed CF estimated at 5%)
        2. Improved nutrition
        3. Informed reproductive decisions
        4. Creation of the opportunity for early pulmonary intervention before irreversible lung disease develops
    2. Measuring blood immunoreactive trypsinogen in dried blood spots (Hammond et al. 1991)
        1. Elevated levels in most CF infants (85–90% sensitive)
        2. Associated with a relatively large number of false-positive results
        3. Diagnosis must be confirmed by sweat tests or genotyping (CF multimutational analysis)
    3. Use DNA-based testing on dried blood spots by CFTR multimutational analysis
2. Population screening (Grody 1999)
    1. Target population to be offered testing (the entire population vs. high-risk ethnic groups)
    2. Size and nature of the mutation test panel (universal vs. ethnic specific)
    3. Inclusion or exclusion of CFTR variants that do not cause classical CF
    4. Optimal testing technology
    5. Appropriate standards for laboratory quality assurance
    6. Development of sufficient educational materials
    7. Genetic counseling resources for test delivery
    8. Reporting and interpretation
3. Sweat test (Bye et al. 1994; LeGrys 1996; LeGrys et al. 2007)
    1. The traditional method (gold standard) of CF diagnosis

2. Remains the most readily available and clinically useful way of making the diagnosis of CF, provided it is done according to strict guidelines with pilocarpine iontophoresis and a quantitative determination of chloride concentration (LeGrys et al. 2007)
3. Reliably identifies the vast majority of patients with CF who have multiorgan involvement including the lungs and pancreas
4. Using pilocarpine iontophoresis technique to produce sweat for chloride analysis
5. Sweat chloride concentrations
    1. >60 mEq/L, observed in:
        1. CF patients with clinical manifestation of chronic pulmonary disease and/or pancreatic insufficiency
        2. CF patients with positive family history
        3. Untreated Addison disease
        4. Ectodermal dysplasia
        5. Certain types of glycogen storage diseases
        6. Untreated hypothyroidism
        7. A few normal adults
    2. <60 mEq/L, observed in:
        1. Very few patients with CF (fewer than 1% of CF patients when they are well)
        2. CF patients with malnutrition and edema

4. Indications for sweat testing (Davis 2001)
    1. Meconium ileus or peritonitis (neonate)
    2. Jaundice (infancy)
    3. Hypochloremic alkalosis (infancy)
    4. Heat prostration (infancy or adulthood in males)
    5. Failure to thrive (infancy to childhood)
    6. Rectal prolapse (childhood)
    7. Nasal polyposis (childhood to adulthood)
    8. Panopacification of sinuses or pansinusitis (childhood)
    9. Pancreatitis (late childhood to early adulthood)
    10. Unexplained cirrhosis (childhood to adolescence)
    11. Gallstones (late childhood to early adulthood)
    12. Congenital bilateral absence of the vas deferens or azoospermia (any age but more obvious in adults)
    13. Recurrent or persistent pneumonia (any age)
    14. Staphylococcal pneumonia (any age but especially infants)
    15. Mucoid *Pseudomonas* in lung (any age)
    16. Bronchiectasis (any age)
    17. Positive family history in siblings or first cousins (any age)
5. Causes of false-positive or false-negative sweat test results (O'Sullivan and Freedman 2009)
    1. False-positive result
        1. Atopic dermatitis (eczema)
        2. Malnutrition
        3. Congenital adrenal hyperplasia
        4. Mauriac syndrome
        5. Fucosidosis
        6. Ectodermal dysplasia
        7. Klinefelter syndrome
        8. Nephrogenic diabetes insipidus
        9. Adrenal insufficiency
        10. Hypothyroidism
        11. Autonomic dysfunction
        12. Environmental deprivation
        13. Munchausen syndrome by proxy
    2. False-negative result
        1. Dilution of sample
        2. Malnutrition
        3. Peripheral edema
        4. Low sweat rate (quantity not sufficient)
        5. Hypoproteinemia
        6. Dehydration
        7. CFTR mutations with preserved sweat duct function (e.g., 3,849 + 10 kb C → T; Arg117His-7 T)

6. Other clinical laboratory tests
    1. Prolonged prothrombin time secondary to deficient vitamin K
    2. Shortened red blood cell survival time secondary to deficient vitamin E
    3. Hypochloremic alkalosis secondary to high salt loss
    4. Isolation of organisms from the respiratory tract
        1. *Pseudomonas aeruginosa*
        2. *Burkholderia cepacia*
        3. *Staphylococcus aureus*
    5. Oxygen saturation
7. Radiographic findings
    1. Chest X-ray
        1. Earliest finding: hyperinflation often with right upper lobe mucus retention
        2. Progression to widespread bronchial dilatation, cysts, linear shadows, and infiltrates
    2. Sinuses X-ray: nearly universal presence of pansinusitis
    3. Abdominal X-ray
        1. Uncomplicated meconium ileus: multiple loops of dilated small bowel
        2. Meconium peritonitis
            1. Calcifications within the abdominal cavity or even within the scrotum
            2. Resulting from an in utero perforation or complicated meconium ileus associated with volvulus
    4. Skeletal X-ray
        1. Arthritis
        2. Periostitis in the diaphysis of the tubular bones
8. CT scan, especially high-resolution CT scan (Ruzal-Shapiro 1998)
    1. Readily identify air trapping in the expiratory phase
    2. Mosaic perfusion, a secondary sign of small airway abnormality
    3. Centilobular nodule characterized by a cluster of ill-defined nodules corresponding to branching terminal airways filled with secretions
    4. Classic findings of CF of progressive bronchiectasis involving the large airways
        1. Thick parallel bronchial walls seen as linear shadows or tram-line tracts
        2. Ring shadows representing dilated thick-walled bronchi
        3. Multiple nodular densities representing mucus plugging
9. Pulmonary function test
10. Molecular testing
    1. More than 1,000 different mutations described to date
    2. ΔF508 mutation (deletion of a phenylalanine residue at position 508 in the 1,480 amino acid protein)
        1. Present in about 70% of CF alleles in the USA
        2. Homozygous ΔF508 mutation in about 50% of American CF patients
    3. Higher frequencies of certain mutations in different ethnic groups
        1. A455E mutation in Dutch CF patients
        2. W1282X mutation in Ashkenazi Jewish CF patients
    4. Presence of two alleles with CF causing mutations confirms the diagnosis
    5. Conventional commercial genotyping testing for about 80 specific mutations in CFTR (including ΔF508 mutation) identifies about 95% of all CF alleles
11. Carrier testing: available for family members of known patients (Wilson et al. 2002) or for couples without a family history
12. In general, a diagnosis of cystic fibrosis can be made in a patient with clinical features of the disease if the concentration of chloride in sweat is greater than 60 mmol/L or if it is in the intermediate range (30–59 mmol/L for infants less than 6 months of age, 40–59 mmol/L for older individuals), and two disease-causing CFTR mutations are identified (Farrell et al. 2008)

Genetic Counseling

1. Recurrence risk
    1. Both parents carrying at least one abnormal copy of the CF gene
    2. Patient's siblings
        1. 25 % with CF disease
        2. 50 % with CF carrier
    3. Patient's offspring: low recurrence risk unless the spouse is affected or a carrier of CF mutation
2. Prenatal diagnosis (Rosenstein 1998)
    1. Prenatal screening programs: ensuring more good than harm, the ultimate objective and duty (Farrell and Fost 2002)
    2. Ultrasonography
        1. Bowel abnormalities in the fetus (Corteville et al. 1996)
            1. Dilated bowel with hyperechoic bowel (33% with cystic fibrosis) (Estroff et al. 1992): outcome (no bowel obstruction, meconium ileus, malrotation, jejunal obstruction/atresia, choledochal cyst)
            2. Ascites: most commonly associated with hydrops of diverse causes
            3. Cystic abdominal masses: outcome (gastrointestinal duplications, meconium pseudocyst, ovarian cyst, choledochal cyst, omental cyst, and biliary atresia)
            4. Fetal bowel anomalies by ultrasonography: indicate a risk of severe cystic fibrosis and justify careful *CFTR* molecular analysis (Muller et al. 2002)
        2. Hyperechogenic fetal bowel suggestive of intestinal obstruction: perform carrier testing for CF gene mutations in the parents
            1. Diagnosis of CF highly likely in the fetus if both parents are carriers of a CF mutation
            2. Confirmed CF diagnosis by direct mutation analysis of amniotic fluid cells
        3. Meconium peritonitis secondary to small bowel perforation in utero
            1. Associated with CF in only 7% of cases
            2. Presence of abdominal calcification usually associated with causes of meconium peritonitis other than CF
            3. Absence of abdominal calcifications favors the diagnosis of CF, to be confirmed by parental CF carrier testing and mutation analysis of fetal cells in at-risk couples
    3. Molecular genetic analysis
        1. Prenatal diagnosis accomplished in most families with an affected member by mutation analysis from fetal cells obtained from CVS (10 weeks) or amniocentesis (15–18 weeks)
        2. Preimplantation genetic diagnosis to screen embryos before implantation, an alternative for at-risk couples
            1. A cleavage stage biopsy of embryo on day 2 or 3 after in vitro fertili-zation
            2. Removal of one or two cells for genetic analysis by nested polymerase chain reaction and heteroduplex formation
            3. Transfer of normal or carrier embryos to establish pregnancy
            4. Followed by CVS or amniocentesis to confirm the original diagnosis
    4. Postnatal sweat testing mandatory in all cases in which the diagnosis of CF has been made or excluded on the basis of prenatal DNA analysis
3. Management (Davis et al. 1996; Orenstein et al. 2002)
    1. Antibiotic treatment of acute respiratory infections and exacerbations of chronic endobronchial infections
        1. Purpose
            1. To improve pulmonary function
            2. To improve exercise tolerance
            3. To improve quality of life

2. Short-term oral ciprofloxacin for mild exacerbations by pseudomonas agent with caution in the younger pediatric age patients
3. Intravenous antibiotics, a mainstay of treatment of acute exacerbations of pulmonary disease
    1. Aminoglycoside (usually tobramycin) and β-lactam antibiotics
    2. Implanted central lines or peripheral vein catheters to maintain IV access
4. Aerosol (inhaled) antibiotics such as tobramycin
5. Other aerosol antibiotics such as colistin

2. Airway clearance and exercise (Marshall and Samuelson 1998)
    1. Percussion and postural drainage in an attempt to keep the airways free of infected and obstructive secretions
    2. Positive expiratory pressure (PEP) devices to promote mucous clearance by preventing airway closure and increase collateral ventilation
    3. ThAIRapy Vest, a chest wall compression and oscillation system comprising a fitted vest coupled to a pneumatic compressor
    4. Flutter valve vibrating devices
    5. Directed exhalation techniques
3. Sodium cromolyn (Intal™) or nedocromil (Tilade™) beneficial in some patients
4. Use of inhaled (aerosolized) bronchodilators such as β-adrenergics
5. Use of inhaled alpha dornase (DNase) (Pulmozyme™) to reduce sputum viscosity by cleaving extracellular neutrophil-derived DNA and brings about sustained improvement in pulmonary function in many patients with CF
6. Avoid cough depressants
7. Oxygen therapy if indicated
8. Anti-inflammatory therapies
    1. Glucocorticoids: useful in selected patients
    2. Ibuprofen
9. Nutritional support to prevent malnutrition
    1. Provide pancreatic enzyme supplements and vitamins to correct malabsorption
    2. Provide normal or high-fat diets with essential fatty acids necessary for growth and development
    3. Provide fat-soluble vitamin supplements
10. Management of gastrointestinal obstructive complications
    1. Gastrografin enema for treatment of fecal impaction with distal intestinal obstruction syndrome
    2. Surgery for intussusception if indicated
    3. Surgery necessary to correct obstruction due to meconium ileus in most newborns
11. Management of biliary tract disease
    1. Treatment of severe focal or multilobular biliary cirrhosis, portal hypertension, and hypersplenism
        1. Sclerosing of esophageal varices
        2. Hepatic shunt procedures
        3. Liver transplantation
    2. Cholecystectomy for gallstones
    3. Urodeoxycholic acid for selected cases of liver dysfunction
12. Management of CF-related diabetes mellitus
    1. Dietary management
    2. Insulin often required
    3. Complementary diabetes pharmaceutical agents: no current place in management of CF-related diabetes (Nathan et al. 2010)
13. Management of pneumothorax
    1. Chest tube drainage
    2. Followed by simple surgical oversewing of blebs if the initial air leak does not resolve

3. Followed by definitive pleural ablation if necessary

14. Management of hemoptysis
    1. Reassurance in most cases
    2. Additional vitamin K
    3. Discontinue drugs that may interfere clotting
    4. Bronchial artery embolization by interventional radiologic techniques in unusual cases
15. Management of respiratory failure
    1. Oxygen administration
    2. Tracheal intubation and mechanical ventilation in terminally ill patients on the lung transplant waiting list
    3. Lung transplantation (Yankaskas and Mallory 1998): now an accepted therapy in patients with end-stage lung disease (Rosenblatt 2009)
        1. Acceptable survival rate
        2. Good quality of life
        3. Overall survival, however, still lags behind other solid-organ transplants
        4. Despite the higher incidence of diabetes mellitus, poor nutrition, and colonization with both multiresistant and panresistant Gram-negative organisms, the patients with CF clearly benefit from lung transplantation
    4. Heart-lung and lung transplantation successfully applied to patients with end-stage CF patients (Zuckerman and Kotloff 1998)
16. Management goals in CF (Martiniano et al. 2014)
    1. Nutritional
        1. Maintain normal growth patterns in children: goal weight for length $\geq$50th percentile for infants $<$2-year old; goal BMI $\geq$50th percentile for children $\geq$2-year old
        2. Maintain normal blood levels of fat-soluble vitamins
        3. Prevent hyponatremia and hypochloremia
    2. Lung health
        1. Minimize lung damage caused by infection, mucus plugging, and inflammation
        2. Maintain lung function (age $\geq$6 year)
        3. Prevent onset of new lung infections
        4. Detect and treat chronic lung infections
        5. Prevent and treat pulmonary exacerbations
    3. Comorbidities: detect and treat complications of CF including:
        1. CF liver disease
        2. CF-related diabetes
        3. Nasal polyposis
        4. Gastrointestinal complications
        5. Allergic bronchopulmonary aspergillosis
        6. CF-related osteoporosis
        7. Depression
        8. Anxiety
17. Cystic fibrosis in pregnancy (Whitty 2010)
    1. Women with cystic fibrosis (CF): now living to childbearing age and many have successful pregnancies
    2. Improvement of fertility and pregnancy outcome:
        1. Preconception care with optimization of pulmonary function
        2. Eradication of pulmonary infection
        3. Improved nutritional status
        4. Improved diabetes
    3. Women with CF with poor pulmonary function and nutrition, and less than ideal body weight: more likely to suffer adverse outcomes
    4. Women with CF with pulmonary hypertension, cor pulmonale, and forced expiratory volume $<$50% predicted: adversely affect mild and moderate lung disease due to cystic fibrosis and should avoid pregnancy (Edenborough et al. 2000)

5. Women with lung transplants can have successful pregnancy, but the risk of organ rejection and death are high

18. Fertility in men with cystic fibrosis (Smith 2010)
    1. Men with CF, now surviving longer, may wish to be fertile and want to have children regardless of the disease severity (Sawyer et al. 2005)
    2. Obstructive azoospermia in men with CF are due to (Kaplan et al. 1968; Holsclaw et al. 1971):
        1. Congenital bilateral absence of the vas deferens, or
        2. Atrophy or complete absence of the epididymis or seminal vesicles
    3. Sperm capable of fertilizing mature oocytes by intracytoplasmic sperm injection in vitro can be extracted from the majority of men with cystic fibrosis
    4. Sperm may be retrieved either by aspiration from the caput of the epididymis or directly from the testis or other alternative procedures
19. Recently, a first-in-class disease-modifying CF treatment was approved in the USA and Europe for patients with a specific mutation in their *CFTR* gene. The clinical development of this small molecule CFTR modulator (ivacaftor) serves as a promising example of how personalized therapies can transform the therapeutic landscape (Elborn 2013)
20. The UK CF Gene Therapy Multidose trial, along with continuing work on viral vectors, will shape the role of this exciting therapy as a potential treatment for all CF patients in the years ahead (Armstrong et al. 2014; Davies et al. 2014)

Fig. 1 This 5-month-old infant has history of failure to thrive, foul-smelling stools, and excessive spitting. The patient is positive for two copies of the ΔF508 mutation

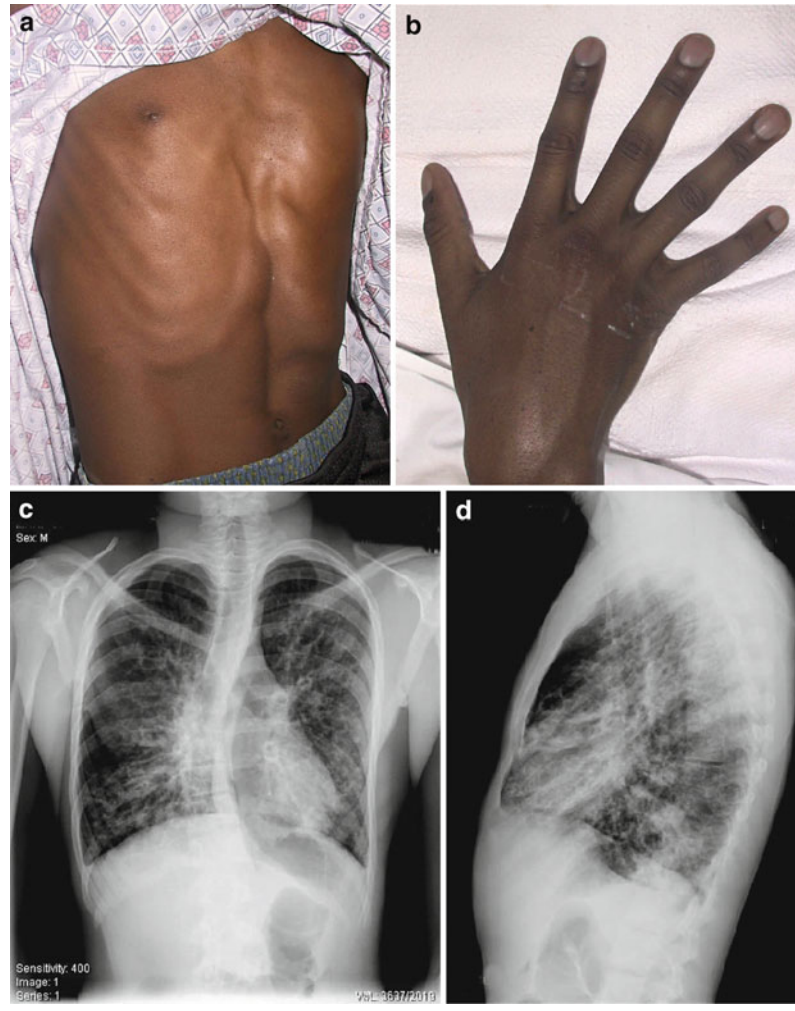

Fig. 2 (**a-d**) A 16-year-old boy with cystic fibrosis showing an emaciated chest (**a**), club fingers (**b**), and a honeycomb-like chest with air trapping illustrated by chest radiographs (**c**, **d**)

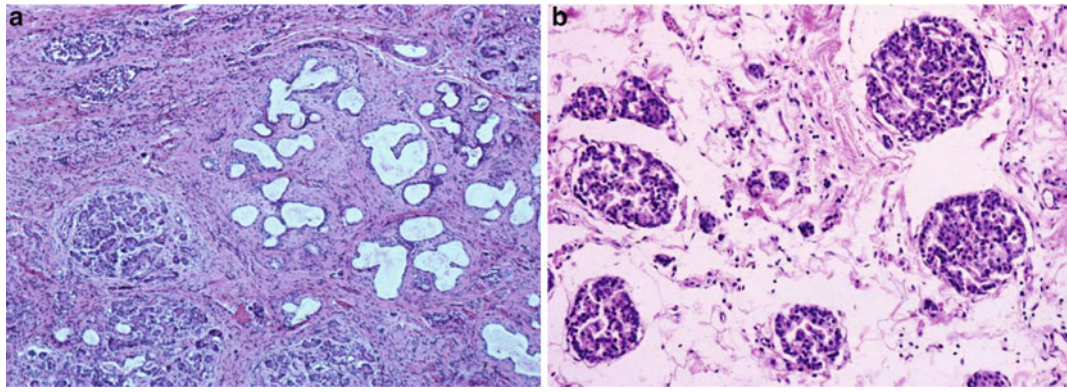

Fig. 3 (**a**, **b**) Photomicrograph of the pancreas of a 16-year-old male who died of bronchiectasis and bronchopneumonia. In the left photomicrograph (**a**), the exocrine glands (acini) are mostly absent. Irregularly dilated exocrine ductules are lined by flattened atrophic epithelium. Many unaffected islets of Langerhans are present at left lower corner. In the right photomicrograph with higher magnification (**b**) there are many islets of Langerhans but normal exocrine glands and ductules are absent

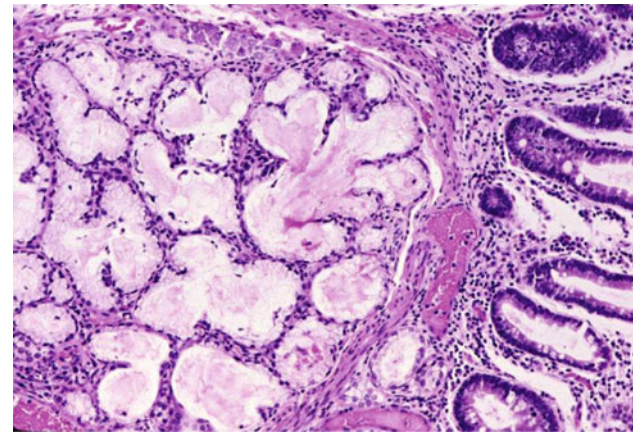

Fig. 4 Photomicrograph of the duodenum of the same patient. The Brunner's glands in the submucosa are distended by inspissated secretion. Three mucosal crypts are also slightly dilated

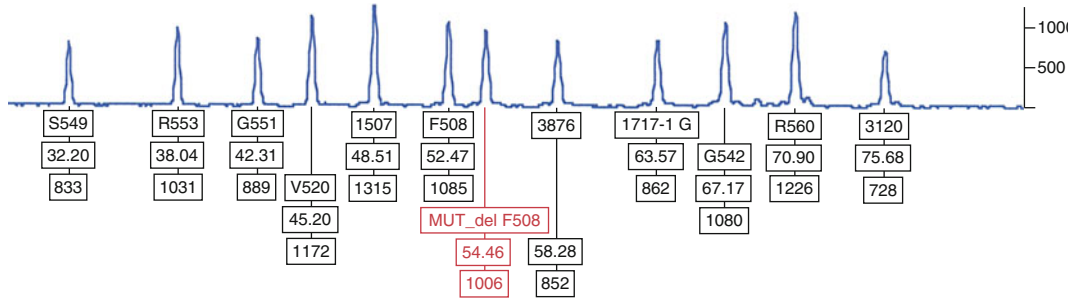

Fig. 5 Fragment size separation of CFTR mutations using capillary gel electrophoresis (ABI 310 genetic analyzer, Applied Biosystems). A mutation in ΔF508 is noted in *red*

Dandy–Walker Malformation

Contents

In 1954, Benda (Benda 1954) introduced the term Dandy–Walker syndrome to indicate the association of (1) ventriculomegaly of variable degree, (2) a large cisterna magna, and (3) a defect in the cerebellar vermis through which the cyst communicates with the fourth ventricle. Currently, the following findings are included in the Dandy–Walker syndrome or malformation: (4) cystic dilatation of the fourth ventricle, (5) dysgenesis of the cerebellar vermis, and (6) a high position of the tentorium. The Dandy–Walker malformation has a prevalence of about 1 in 30,000 live births and is found in 4–12% of infantile hydrocephalus.

Genetics/Basic Defects

1. Heterogeneous etiology (Murray et al. 1985)
    1. Isolated
    2. A part of a Mendelian disorder
    3. A part of a chromosome disorder (Nyberg et al. 1991; Liao et al. 2012)
        1. Trisomy 18
        2. Triploidy (69,XXX)
        3. Trisomy 13
        4. Trisomy 21
        5. Trisomy 9
        6. Turner syndrome
        7. Duplication 3q
        8. Deletion 3q25.1–25.33
        9. Deletion 13q
        10. Duplication 1q
        11. Duplication 1q
    4. Chromosome abnormalities and genetic loci associated with DWM in humans and animal models (Correa et al. 2011)
        1. Deletion of 3p2 (*ZIC1*, *ZIC4*)
        2. Deletion or duplication of 6p25.3 (*FOXC1*)
        3. Tetrasomy 9p
        4. Deletion of 13q
        5. Deletion of 2q36.1 (*PAX3*)
        6. Deletion and duplication of 7p21.3 (*NDUFA4*, *PHF14*) (Liao et al. 2012)
    5. Potential high incidence of subtelomeric anomalies in isolated DWM, especially 6p deletion (Guibaud et al. 2012)
    6. Environmental factors
2. Uncertain significance of the Dandy–Walker variant and mega-cisterna magna

Clinical Features

1. Maternal polyhydramnios/oligohydramnios
2. Fetal anomalies

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_64

1. Echogenic bowel
2. Effusions/hydrops
3. Single umbilical artery
4. Growth restriction
5. Abundant nuchal folds
6. Cystic hygroma

3. Dandy–Walker complex (Harwood-Nash and Fitz 1976): a triad of malformation
   1. Cystic dilatation of the fourth ventricle
   2. Complete or partial agenesis of the cerebellar vermis
   3. An enlarged posterior fossa with displacement of the tentorium and torcular and lateral sinus
4. Dandy–Walker variant (Harwood-Nash and Fitz 1976): cerebellar dysgenesis without enlargement of the posterior fossa and with variable hypoplasia of the cerebellar vermis
5. Associated intracranial anomalies (70% of cases) (Incesu 2015)
   1. An enlarged posterior fossa
   2. Ventriculomegaly
   3. Atresia of the foramina of Magendie and Luschka
   4. Midline anomalies
      1. Agenesis of the corpus callosum (17%) (Sawaya and McLaurin 1981)
      2. Holoprosencephaly
      3. Occipital meningocele and encephalocele
   5. Porencephalic cyst
   6. Migrational disorder
   7. Gyral abnormalities
   8. Microcephaly
6. Non-CNS-associated malformations
   1. Facial clefting
   2. Cardiovascular defects
   3. Diaphragmatic hernia
   4. Omphalocele
   5. Polycystic kidneys
   6. Spinal defects
   7. Limb defects
      1. Polydactyly
      2. Syndactyly
7. Common presenting signs and symptoms
   1. Macrocrania
   2. Bulging fontanel
   3. Upward gaze palsy
   4. Hypertelorism
   5. Strabismus
   6. Hypotonia
   7. Headache and vomiting
   8. Seizures
   9. Hemiparesis
   10. Facial palsy
   11. Palpebral ptosis
   12. Pyramidal signs
   13. Cerebellar dysfunction
   14. Motor dysfunction
   15. Mental retardation: subnormal intelligence reported in 40–70% of cases
8. Incidental asymptomatic Dandy–Walker syndrome (DWS) (Jha et al. 2012)
   1. Presentation at extremes of age signifies that slow degenerative changes in communicating channels between fourth ventricular cyst and surrounding basal cisterns may cause asymptomatic DWS to manifest.
   2. Cases having good communication between these structures can remain asymptomatic throughout their life.
9. Concurrent psychosis and Dandy–Walker complex of all four subtypes: might help further illuminate the role that the cerebellum plays in the etiology of schizophrenia or bipolar disorder (Gan et al. 2012)
10. Prognosis
    1. Grim but not uniformly fatal
    2. Prognosis and intellectual outcome: mostly depend on the presence of associated malformations, the degree of vermian malformation, and the adequate control of hydrocephalus (Spennato et al. 2011)
    3. Worst prognosis when there are associated anomalies and chromosome abnormalities (Kölble et al. 2000)
    4. Better chance of normal outcome for isolated Dandy–Walker variant (Maria et al. 1987)
    5. Dandy–Walker malformation (DWM) with an isolated and partially agenetic vermis (Klein et al. 2003): compatible with a normal life

6. DWM with a severely abnormally lobulated vermis and associated brain malformation (Klein et al. 2003): always accompanied by mental retardation

11. Classification of posterior fossa malformations (Shekdar 2011)
    1. Large posterior fossa
        1. Classic Dandy–Walker malformation
        2. Blake's pouch cyst (an inferior protrusion of the fourth ventricle, which results from a finger-like expansion of the posterior membranous area)
        3. Mega-cisterna magna
        4. Posterior fossa arachnoid cyst
    2. Normal or small posterior fossa
        1. Dandy–Walker variant
        2. Joubert syndrome (an autosomal-recessive syndrome characterized by hyperapneic/apneic spells, hypotonia, ataxia, abnormal ocular movements, and psychomotor delay; found in association with posterior fossa abnormality characterized by vermian hypoplasia and abnormal ponto-mesencephalic junction, which results in the classic "molar tooth" sign on imaging) (please see the chapter on "▶ Joubert Syndrome")
        3. Tecto-cerebellar dysgraphia
        4. Rhombencephalosynapsis
        5. Neocerebellar hypoplasias
        6. Cerebellar atrophy

Diagnostic Investigations

1. Sonography (Estroff et al. 1992; Ecker et al. 2000)
    1. Sonographic diagnosis of classic Dandy–Walker malformation: straightforward from mid-gestation
    2. Detection of Dandy–Walker malformation as early as 11 weeks using vaginal sonography (Achiron and Achiron 1991)
    3. In the transcerebellar view
        1. An enlarged cisterna magna connected to the area of the fourth ventricle through a defect in the cerebellar vermis
        2. Presence of borderline-to-overt ventriculomegaly
        3. Frequent association of other neural and extra-neural malformation
2. CT and MRI of the brain
    1. Large median posterior fossa cyst widely communicating with the fourth ventricle
    2. Cystic enlargement of the fourth ventricle
    3. Cerebellar vermis dysgenesis
    4. An upwardly displaced tentorium
    5. Hydrocephalus
    6. Atresia of the foramina of Magendie and Luschka
    7. Frequently associated CNS anomalies
        1. Agenesis of corpus callosum
        2. Occipital encephalocele
        3. Porencephalic cyst
        4. Holoprosencephaly
        5. Others
3. PET/CT appearance of Dandy–Walker syndrome: an ametabolic large cyst in the posterior fossa and hypoplasia of cerebellar vermis (Infante et al. 2016)
4. For prenatal purpose, subtelomeric analysis associated with investigation of *ZIC1–ZIC4* gene deletion in patients with normal karyotype was proposed, because of a potential high incidence of subtelomeric anomalies, especially 6p deletion, in apparently isolated DWM (Guibaud et al. 2012)

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: a low recurrence risk in the order of 1–5% unless the Dandy–Walker malformation is a part of a Mendelian disorder or associated with chromosome anomaly.
    2. Patient's offspring: not surviving to reproductive age because of severe neurologic deficits associated with major malformations.
2. Prenatal diagnosis
    1. Ultrasonography for detecting unique previously described CNS malformations

2. First-trimester sonographic findings associated with a Dandy–Walker malformation and inferior vermian hypoplasia: evaluation of the fourth ventricle–cisterna magna complex by measuring the intracranial translucency or brain stem-to-occipital bone diameter may identify some cases with structural malformations (Bornstein et al. 2013)
3. MRI of the fetal DWM (Bernardo et al. 2015)
    1. Dorsal rotation of the vermis with enlarged fourth ventricle
    2. Widening of the tegmento-vermian angle
    3. Flat fastigium
    4. The "tail" sign: dysmorphic appearance of the posterior lobe of the vermis, which presents a thick and elongated nodulus with the appearance of a "tail"
4. Prenatal amniocentesis for fetal karyotyping
5. Array-based comparative genomic hybridization: three fetuses with a de novo adjacent microdeletion/duplication region mapping to chromosome 7p21.3 and suggesting that the critical region associated with DWM may be limited to the 7p21.3 region (Liao et al. 2012)

3. Management (Alexiou et al. 2010)
    1. Ventriculoperitoneal shunt
    2. Cyst-peritoneal shunt: avoids the risk of an entrapped fourth ventricle and is presently the best surgical procedure (Hirsch et al. 1984)
    3. Ventriculocystoperitoneal shunt (Kumar et al. 2001)
    4. Posterior fossa craniectomy with cyst fenestration (Almeida et al. 1990)

Fig. 1 (**a**–**c**) Eight-month-old patient with Dandy–Walker malformation associated with multiple congenital anomalies including facial dysmorphism, skin tags (pseudotails) on the cheek, and limb anomalies

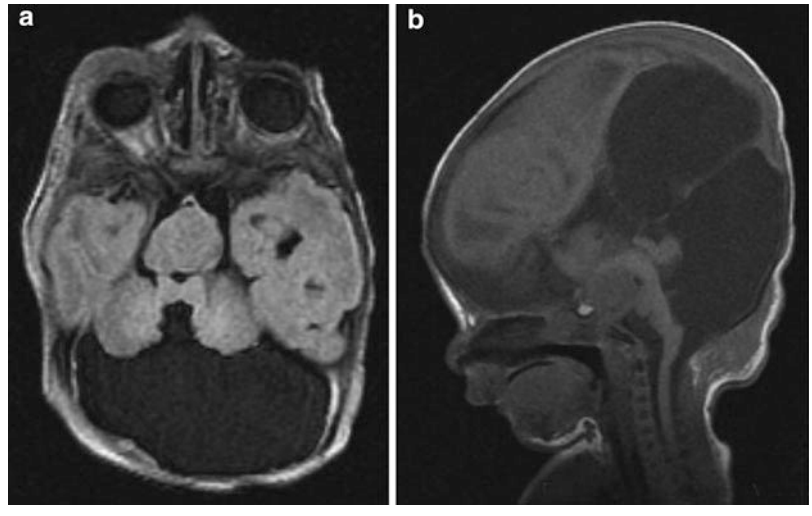

Fig. 2 (**a**, **b**) MRI of the brain of the patient in Fig. 1 shows Dandy–Walker malformation with a large posterior fossa cyst which communicates with dilated fourth ventricle. In addition, this patient also has agenesis of corpus callosum, hydrocephalus, and vermis dysgenesis

De Lange Syndrome

Contents

In 1933, Cornelia de Lange reported two nonfamilial infant girls with severe mental retardation and multiple abnormalities of the skull, face, and extremities (De Lange 1933). Earlier in 1916, Brachmann had described a child with similar features (Brachmann 1916). The syndrome is also called Brachmann-de Lange syndrome or Cornelia de Lange syndrome. The prevalence is estimated to be 1 in 10,000 births (Opitz 1985).

Synonyms and Related Disorders

Brachmann-de Lange syndrome; NIPBL-related Cornelia de Lange syndrome; SMC1A-related Cornelia de Lange syndrome; Typus degenerativus amstelodamensis

Genetics/Basic Defects

1. A heterogeneous clinical entity.
    1. Sporadic in vast majority of cases (99%) (Russell et al. 2001; Tekin et al. 2015)
    2. Striking concordance in MZ twins
    3. Rare familial occurrences (Beratis et al. 1971)
        1. Autosomal dominant inheritance
        2. Autosomal recessive inheritance: unlikely
2. Inconsistent chromosome abnormalities occasionally associated with de Lange phenotype (Kousseff et al. 1994). In addition, the following significant cytogenetic findings were reported:
    1. Deletions of chromosome 5p13 where Cornelia de Lange syndrome gene (*NIPBL*) has been reported in two cases (Taylor and Josifek 1981; Hulinsky et al. 2005).
    2. An increased rate of precocious sister chromatic separation has been reported in affected individuals (Kaur et al. 2005).
3. Combined mutations in *NIPBL*, *SMC1A*, and *SMC3*: identified in nearly 60% of patients with a confident clinical diagnosis of de Lange syndrome (Dorsett and Krantz

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_65

2009; Boyle et al. 2014). Mutations in five genes (*NIPBL*, *SMC1A*, *SMC3*, *RAD21*, and *HDAC8*), all regulators or structural components of cohesin, have been identified (Mannini et al. 2013).

1. *Nipped-B-like* (*NIPBL*) gene on chromosome 5p13 (Krantz et al. 2004)
    1. At least 50% of cases are caused by loss-of-function mutations of *NIPBL* gene.
    2. Required for binding of the cohesion complex that mediates sister chromatid cohesion to chromosome (Dorsett 2007).
2. *SMC1A* gene
    1. X-linked (on Xp11.22).
    2. Encodes the SMC1 subunit of mitotic cohesion.
    3. Missense or small in-frame deletion was noted in approximately 5% of individuals with clinical diagnosis of de Lange syndrome.
3. *SMC3* gene
    1. On chromosome 10q25.
    2. Mutation is heteroallelic with a wild-type allele.
4. *HDAC8* gene (on Xq13.1)
5. *RAD21* gene (on 8q24.11)

4. De Lange syndrome, thus, considered to be a cohesinopathy, along with Roberts syndrome/SC phocomelia (Tekin 2015)
5. Genotype-phenotype correlations
    1. More severe *NIPBL* mutations (such as deletions or truncations) usually cause more severe clinical manifestations than missense mutations.
    2. Missense mutations in *NIPBL* are associated with mild phenotypic features.
    3. Mutations in SMC1A and SMC3 are associated with a milder phenotype with absence of limb defects and other structural anomalies.
    4. In the mildest forms, affected individuals generally have mild to moderate mental retardation and, at least at a young age, typical facial characteristics.

Clinical Features

1. Marked clinical variability (Pashayan 1969; Greenberg and Robinson 1989; Van Allen et al. 1993; Opitz 1994; Chrzanowska 2014)
2. General history
    1. Prenatal and/or postnatal growth deficiency
    2. Prematurity
    3. Diminished sucking and swallowing ability
    4. Low-pitched cry (74%) in the newborn period and in the early infancy but may disappear in the late infancy
    5. Global developmental delay
    6. Initial hypertonicity
    7. Recurrent respiratory tract infections
    8. Gastroesophageal reflux
    9. Failure to thrive
3. Growth
    1. Prenatal onset growth retardation (Jackson et al. 1993)
    2. Short stature
4. Skin
    1. Hypertrichosis (hirsutism) (78%): often with hairy whorls over the shoulders, lower back, and extremities
    2. Cutis marmorata (60%)
    3. Periorbital "cyanosis"
5. Characteristic craniofacial appearance (Boyle et al. 2014)
    1. Microcephaly (98%)
    2. Brachycephaly
    3. Hairy (low hairline) forehead
    4. Masklike (grim, devoid of expression) facies
    5. Hypertelorism
    6. Antimongoloid slant of palpebral fissures
    7. Synophrys (prominent bushy, confluent eyebrows joining at the nose) (99%)
    8. Long and curly eyelashes (99%)
    9. Depressed nasal bridge (83%)
    10. Small nose
    11. Anteverted nares (88%)
    12. Micrognathia (84%)
    13. Long bulging, prominent philtrum (94%)
    14. Thin upper lip (94%)
    15. Central depression below the lower lip

16. Down-turned corners of the mouth (94%)
17. Late eruption of teeth
18. Widely spaced teeth (86%)
19. High-arched palate (86%)
20. Low set, malformed, and hairy ears (70%)
21. Low posterior hairline (92%)
22. Short neck (66%)

6. Eye abnormalities (57%)
    1. Strabismus
    2. Nystagmus (37%)
    3. Myopia (60%)
    4. Ptosis (45%)
    5. Microcornea
    6. Astigmatism
    7. Optic atrophy
    8. Coloboma of the optic nerve
    9. Eccentric pupils
    10. Microphthalmia
    11. Blue sclerae
7. Limb abnormalities
    1. Upper extremities
        1. Micromelia (shortened limbs) (93%)
        2. Ectrodactyly/oligodactyly/phocomelia (27%)
        3. Clinodactyly of the fifth fingers (74%)
        4. Small hands
        5. Proximally placed thumbs
        6. Camptodactyly
        7. Webbings of fingers
        8. Brachydactyly
        9. Flexion contractures of the elbows common (64%)
        10. Restriction of supination and pronation
        11. Subluxation or dislocation of the radial head
    2. Lower extremities
        1. Small feet
        2. Cutaneous syndactyly of the second and third toes (86%)
        3. Tight Achilles tendon (equinus deformity)
        4. Pes planus
        5. Valgus heel
        6. Flexion contractures of the knees
8. CNS anomalies
    1. Variable mental retardation to near-normal intellect
    2. Seizures (23%)
    3. Abnormal speech development (Goodban 1993)
    4. Hearing deficits (60–100%)
    5. Hypoplasia of the vermis
    6. Hypertonia/hypotonia
9. Behavior disorder (Berney et al. 1999)
    1. Sleep disturbance (55%)
    2. Aggression (49%)
    3. Self-destructive tendencies (44%)
    4. Hyperactivity (40%)
    5. Low-pitched growling sound rather than cry
    6. Infrequent facial expressions of emotion
    7. Severe language delay
    8. Autistic-like behavior
    9. Repetitive stereotypic movement
    10. Eliciting pleasurable responses by vestibular stimulation or vigorous movement
10. Other anomalies
    1. Small hypoplastic nipples (55%)
    2. Small hypoplastic umbilicus (53%)
    3. Cardiovascular anomalies (15–20%)
        1. Ventricular septal defect
        2. Atrial septal defect
        3. Patent ductus arteriosus
        4. Aortic valve anomaly
        5. Hypoplasia of the aorta
        6. Persistent left superior vena cava
        7. Pulmonary stenosis
        8. Endocardial cushion defect
        9. Tetralogy of Fallot
    4. Gastrointestinal anomalies
        1. Inguinal hernia
        2. Hiatus hernia
        3. Congenital diaphragmatic hernia
        4. Gut duplication
        5. Malrotation of colon
        6. Pyloric stenosis
    5. Genitourinary anomalies
        1. Hypoplastic, dysplastic, or cystic kidneys
        2. Hypoplastic external genitalia, cryptorchidism or hypospadias in males
        3. Small labia majora, bicornuate or septate uterus in females

6. Otolaryngological presentations (Hamilton et al. 2014)
   1. Stridor/noisy breathing
   2. Laryngomalacia
7. Abnormal dermatoglyphics
   1. Transverse palmar creases (51%)
   2. Increased atd angle
   3. Hypoplastic finger ridge patterns

Diagnostic Investigations

1. Radiography (Braddock et al. 1993)
   1. Skull
      1. Microcephaly: frequent
      2. Brachycephaly: frequent
      3. Trigonocephaly with orbital hypotelorism
      4. Parietal foramina
      5. Micrognathia
      6. High-arched palate
      7. Cleft palate
   2. Spine
      1. Kyphoscoliosis
      2. Platyspondyly
      3. Scheuermann disease
      4. Spina bifida
      5. Square vertebrae
      6. Coxa valga
   3. Chest
      1. Aspiration pneumonia: frequent
      2. Thin ribs
      3. Short clavicles
      4. Short hypoplastic sternum with reduced number of ossification centers
      5. Abnormal sternal angle
      6. Cervical ribs
      7. Hypoplasia of the first rib
      8. Chronic pneumonia
      9. Bronchiolitis
   4. Congenital heart diseases
   5. Gastrointestinal tract
      1. Swallowing dysfunction: frequent
      2. Bowel rotation anomalies with bands: frequent
      3. Hiatal hernia
      4. Hypertrophic pyloric stenosis
      5. Duodenal stenosis
      6. Colon duplication
      7. Inguinal hernia
      8. Umbilical hernia
   6. Genitourinary tract
      1. Incomplete rotation of the kidneys
      2. Renal duplication
      3. Polycystic kidneys
      4. Chronic pyelonephritis
      5. Abnormal renal function with poor visualization on excretory urography
      6. Vesicoureteral reflux
      7. Divided uterine canal with septate vagina
   7. Limbs
      1. Micromelia: frequent
      2. Short humerus and/or forearm bones: frequent
      3. Elongated humeral neck (similar to femoral neck): frequent
      4. Subluxation or dislocation of malformed radius (Joubin et al. 1982) and/or ulna at elbow with fixation in flexion
      5. Absent or hypoplastic ulna: frequent
      6. Retarded bone maturation with abnormal sequence of appearance of ossification centers: frequent
      7. Absent carpals, metacarpals, and fingers (ectrodactyly/oligodactyly): frequent
      8. Short, broad metacarpals, particularly one and five: frequent
      9. Hypoplastic phalanges particularly middle fifth (curved) and middle second fingers: frequent
      10. Cutaneous syndactyly of second and third toes or other toes and fingers: frequent
      11. Cutis valgus
      12. Absent or hypoplastic radius
      13. Lunate and triquetral fusion
      14. Aplastic or hypoplastic ulnar styloid
      15. Double distal phalanges of thumbs and/or great toes
      16. Congenital dislocated hips
      17. Aseptic necrosis of femoral head
      18. Broad ischial bones
      19. Large obturator foramina

20. Short broad femoral necks
21. Absent tibia with deformed fibula
22. Fusion of phalanges of the fifth toe
23. Rocker-bottom foot
24. Metatarsus adductus
25. Planovalgus foot
26. Talipes equinovarus
27. Shortening of the femur and/or leg bones
28. Wide gap between first and second toes
29. Osteoporosis

2. Endocrinologic studies in patients with severe growth retardation
3. Echocardiography for evaluation of congenital heart defects
4. Abdominal ultrasonography for GU anomalies
5. EEG for seizures
6. Neuroimaging (Whitehead et al. 2015)
   1. Skull base dysplasia with coronal clival cleft
   2. Cerebral and brainstem volume loss
   3. Gyral simplification
   4. Membranous labyrinth dysplasia
   5. Anterior segment and optic pathway hypoplasia
   6. Basilar artery fenestration
   7. Absent massa intermedia
   8. Spinal anomalies
7. High-resolution chromosome analysis for associated chromosome anomaly
8. Mutation scanning and sequence analysis (Deardorff et al. 2011)
   1. Mutation scanning of *NIPBL* gene detected mutations in approximately 50% of 179 individuals from three studies (Borck et al. 2004; Gillis et al. 2004; Tonkin et al. 2004).
      1. Frameshift mutations
      2. Nonsense mutations
      3. Splice-site mutation
      4. Missense mutations
   2. Study by Musio et al. (2006).
      1. A *NIPBL* mutation was identified in 44% (24/54) of probands.
      2. A *SMC1A* mutation was detected in 4% (2/54) of probands.
9. Combination of massively multiplex PCR technology and next-generation sequencing was used to screen the coding sequences of the five known causative Cornelia de Lange syndrome genes in 163 individuals with Cornelia de Lange syndrome and Cornelia de Lange syndrome-like phenotypes (Ansari et al. 2014).
   1. As expected, intragenic mutations in *NIPBL* were, by far, the most common identifiable cause.
   2. 3/46 *NIPBL*, 1/5 *SMC1A*, and 1/5 *SMC3* mutations were found to be mosaic.

Genetic Counseling

1. Recurrence risk (Deardorff et al. 2011)
   1. Patient's sib
      1. Autosomal dominant inheritance
         1. An empiric risk of about 1–4%.
         2. Possibility of recurrence in siblings exists since gonadal mosaicism cases have been demonstrated (Niu et al. 2006).
      2. X-linked recessive inheritance
         1. The risk to sibs depends on the carrier status of the mother.
         2. If the mother of the proband has a disease-causing mutation, the chance of transmitting it in each pregnancy is 50%. Male sibs who inherit the mutation will be affected; female sibs who inherit the mutation will be carriers and will usually not be affected.
         3. If the disease-causing mutation cannot be detected in the DNA of the mother of the only affected male in the family, the risk to sibs is low but greater than that of the general population because of the possibility of germline mosaicism.
   2. Patient's offspring
      1. Autosomal dominant inheritance.
         1. A 50% risk.
         2. While most familial recurrences are the result of germline mosaicism in a phenotypically normal parent, rare cases of

a mildly affected individual having affected children have been reported.
2. X-linked recessive inheritance: Males with X-linked de Lange syndrome will pass the disease-causing mutation to all of their daughters and none of their sons.

2. Prenatal diagnosis
   1. Ultrasonography (2-D and 3-D) (Ackerman and Gilbert-Barnes 1997; Sepulveda et al. 2009; Ghazle et al. 2011; Clark et al. 2012).
      1. Intrauterine growth retardation
      2. Characteristic facies
         1. Long eyelashes (Spaggiari et al. 2013)
         2. A small bulging nose
         3. Hypoplastic nasal bone
         4. A depressed nasal bridge
         5. Anteverted nostrils
         6. A long philtrum
         7. A protruding and overhanging upper lip
         8. Micrognathia
      3. Limb defects
         1. Micromelia
         2. Monodactyly
         3. Ulnar agenesis
      4. Diaphragmatic hernia (Marino et al. 2002)
   2. Molecular genetic diagnosis: Prenatal diagnosis is possible by demonstrating *NIPBL* mutation by DNA analysis of fetal cells obtained from amniocentesis or CVS or products of conception (Dempsey et al. 2014).
3. Management
   1. Adequate caloric intake
   2. Treat gastroesophageal reflux with thickened feeds in an upright position and pharmacotherapy
   3. Fitting of hearing aids and early consistent training for hearing-impaired children
   4. Early intervention and special education programs for psychomotor delay
   5. Behavioral modification
   6. Correction of refractory errors with glasses
   7. Anticonvulsants for seizures
   8. Surgical repairs
      1. Fundoplication and gastrostomy feedings necessary in patients with severe esophagitis and progressive failure to thrive despite conservative intervention
      2. Diaphragmatic hernia
      3. Cardiac defect
      4. Severe skeletal deformities
      5. Renal malformations
      6. Ptosis obstructing the visual axis
      7. Orchiopexy

Fig. 1 (**a**–**h**) Three neonates with de Lange syndrome showing characteristic facies, oligodactyly, hirsutism, and ambiguous genitalia in one

Fig. 2 (**a**, **b**) Another neonate with de Lange syndrome showing similar phenotype (characteristic facies, oligodactyly, and severe hirsutism)

Fig. 3 (**a**–**d**) A 12-year-old boy with de Lange syndrome showing characteristic facies and reduction malformation with ectrodactyly/oligodactyly of the right arm and partial syndactyly of second to third fingers with transverse palmar crease of the left hand

Fig. 4 (**a**–**d**) Four patients with classic de Lange syndrome of different ages showing typical facial appearance (synophrys, coarse eyebrows, long curly eyelashes, depressed nasal bridge with anteverted nares, long thin upper lip, down-turned angles of the mouth, and widely spaced teeth) and ectrodactyly/oligodactyly in the first two cases

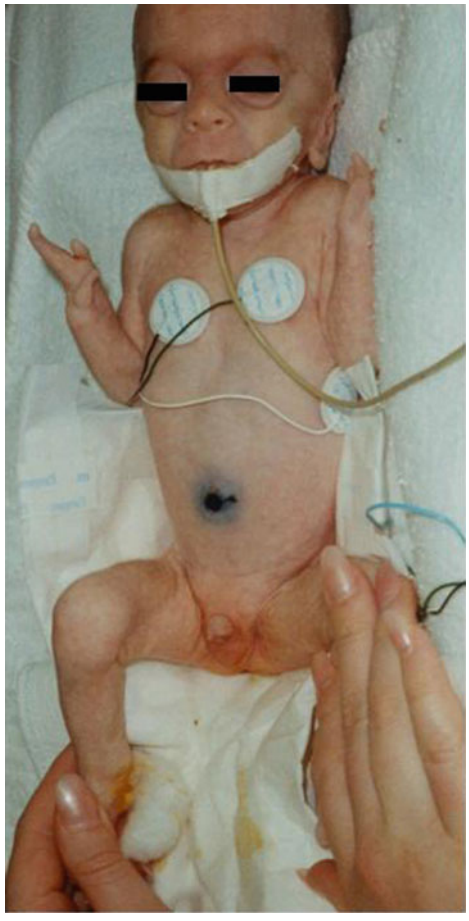

Fig. 5 A 46, XX male with de Lange phenotype

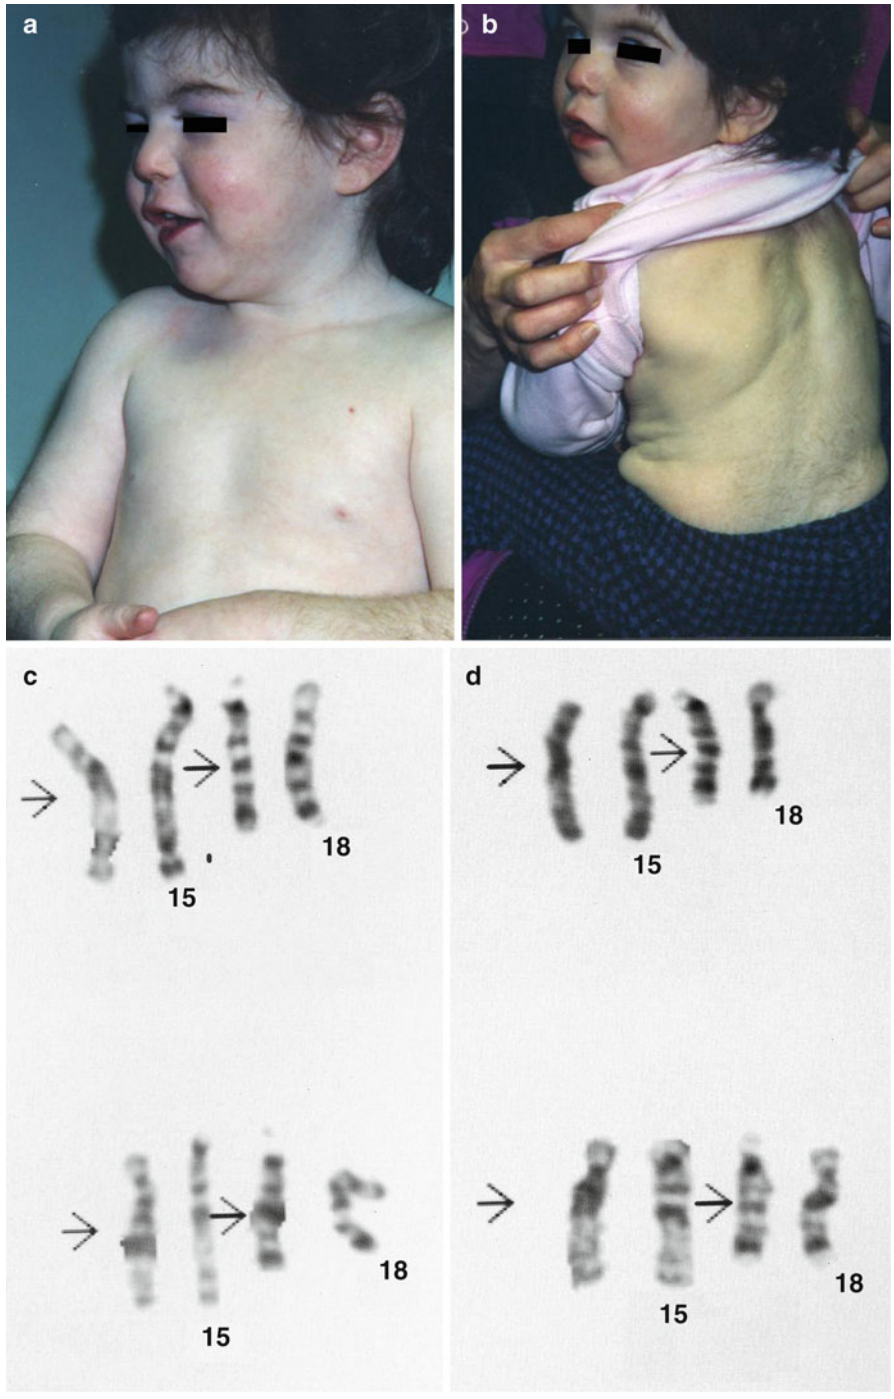

Fig. 6 (**a**–**d**) A child with t(15q;18q) showing de Lange phenotype

Fig. 7 (**a**, **b**) Two adults with de Lange syndrome showing hirsutism and mental retardation

Fig. 8 This 3-year-old boy had a history of failure to thrive, gastroesophageal reflux, hiatal hernia, short stature, bilateral hydroceles, recurrent otitis media, ptosis of the left eye, strabismus, blocked tear ducts, cryptorchidism, and seizures. On examination, he has typical facies of de Lange syndrome. DNA sequence analysis of the *SMC1A* gene in this patient demonstrated a base pair change, c.1877G>A, which results in an arginine to histidine change at amino acid position 626, p.Arg626His. This is a nonconservative amino acid change that affects an evolutionarily conserved amino acid residue in a known functional domain of the SMC1A protein. While this particular sequence change does not appear to have been previously described in other patients with Cornelia de Lange syndrome, it is similar to other pathogenic sequence changes described in the *SMC1A* gene and occurs in the same area of the gene where other missense sequence changes have been described. This sequence change is the likely cause of this patient's disease phenotype (Courtesy of Dr. Susonne Ursin)

Del(18p) Syndrome

Contents

De Grouchy in 1963 (De Grouchy et al. 1963) reported the syndrome, the first example of a partial monosomy compatible with life. The incidence is approximately 1 in 50,000 live-born infants (Turleau 2008).

Synonyms and Related Disorders

18p- syndrome; Monosomy 18p syndrome

Genetics/Basic Defects

1. Monosomy 18p syndrome (Turleau 2008)
   1. Refers to a chromosomal disorder, resulting from the deletion of all or part of the short arm of chromosome 18
   2. One of the most frequent autosomal terminal deletion syndromes
2. Types of 18p deletion
   1. Monosomies of the entire short arm as well as partial monosomies 18p have been reported (Schaub et al. 2002).
   2. De novo deletions in most cases (about two-thirds).
   3. Consequences of an unbalanced whole arm translocation: usually occurring between the long arm of an acrocentric chromosome and the long arm of the chromosome 18 and resulting in a karyotype with 45 chromosomes (Wang et al. 1997).
   4. Consequences of malsegregation of a balanced parental translocation with a variable breakpoint on 18p and are accompanied by a partial trisomy for another chromosome.
   5. Cryptic subtelomeric deletions or translocations: evidenced using subtelomeric screening (Horsley et al. 1998; Babovic-Vuksanovic et al. 2004).
   6. Mosaicism or association with another aneuploidy.
   7. Ring 18 chromosome (Stankiewicz et al. 2001) or after recombination in a pericentric inversion leading to a 18p monosomy associated with a 18q trisomy (Leonard et al. 2000).
   8. Familial transmission of 18p- from one of the parents to the child reported in at least eight cases, all of them maternally inherited (Uchida et al. 1965; Velagaleti et al. 1996;

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_66

Tonk and Krishna 1997; Rigola et al. 2001; Tsukahara et al. 2001; Maranda et al. 2006; Portnoi et al. 2007; Misceo et al. 2009).
    1. 18p- may be in a homogeneous or a mosaic state in the parent.
    2. Intrafamilial clinical variability.
3. The most distal segment of 18p contains the critical region of HPE4 (Overhauser et al. 1995).
    1. Mutations in the *TGIF* gene located on 18p11.3 have been shown to cause holoprosencephaly (Gripp et al. 2000).
    2. Hemizygosity of HPE4 does not automatically confer the phenotype of HPE, since only 10–15 % of patients have features consistent with HPE, confirming that multiple genetic and environmental factors intervene in HPE spectrum phenotypes.

Clinical Features

1. Marked phenotype variability (Sebold et al. 2015)
    1. Neonatal complications
        1. The most common findings (jaundice, respiratory difficulties, and feeding problems)
        2. Additional findings (meconium staining, bradycardia, tachypnea, hypoglycemia, urosepsis, nuchal cord, and abdominal swelling of unknown etiology)
    2. Cardiac abnormalities: tetralogy of Fallot, VSD, ASD, pulmonary stenosis, mild aortic valve abnormality, trivial tricuspid regurgitation, and patent foramen ovale
    3. Neurologic abnormalities: seizures, hypotonia, and MRI abnormalities
    4. Orthopedic abnormalities: kyphoscoliosis, pectus excavatum, congenital hip dysplasia, sacral dysgenesis, elbow valgus deformity, genu recurvatum/valgus, pes planus/vagus, and toe syndactyly
    5. Gastrointestinal abnormalities: chronic constipation, hernias (hiatal, inguinal, umbilical), diastasis recti, and a proximally placed anus
    6. Genitourinary abnormalities: cryptorchidism and hydrocele
    7. Hearing loss: chronic otitis media
    8. Ophthalmologic abnormalities: strabismus, ptosis, refractive errors, astigmatism, myopia, hyperopia, congenital cataracts, nystagmus, iris coloboma, optic nerve hypoplasia, and transient cortical blindness
    9. Endocrinology: pituitary abnormalities (growth hormone deficiency, anterior pituitary hormone deficiency, ovary agenesis, Graves' disease, multinodular goiter, and precocious puberty)
    10. Dysmorphology: epicanthal folds, upslanting or downslanting palpebral fissures, a wide depressed nasal bridge, and a small nose
    11. Growth parameters: short stature and small head circumference
    12. Autoimmune disorders: Graves' disease, psoriasis, lupus, and immunodeficiency (IgA, IgG, IgM)
2. Very frequent clinical features (Turleau 2008)
    1. Mental retardation with variable severity
    2. Speech delay
    3. Short stature
    4. Hypotonia
3. Frequent clinical features
    1. Variable features of the holoprosencephaly (HPE) spectrum
    2. Ptosis
    3. Flat nasal bridge
    4. Wide mouth with short upper lip
    5. Small mandible
    6. Excessive caries
    7. Large, protruding ears
    8. Short, webbed neck
    9. Broad trunk
    10. Pectus excavatum
    11. Kyphoscoliosis
4. Rare clinical features
    1. Behavioral disorders
    2. Autoimmune diseases
    3. Alopecia
    4. Dystonia
5. Genotype-phenotype correlation: a correlation between the extent of the deleted region and the mental development (Wester et al. 2006)

Diagnostic Investigations

1. Cytogenetic analysis including subtelomeric FISH
    1. Patient: to detect absence of all or part of the short arm of one chromosome 18
    2. Parent: to determine if either parent is a balanced translocation carrier or has the unbalanced 18p deletion
2. MRI of the brain (Sebold et al. 2015)
    1. Normal
    2. Delayed myelination
    3. Septo-optic dysplasia
    4. Lobar holoprosencephaly
    5. Ventriculomegaly
    6. White matter abnormalities
    7. A CSF cystic area in the occipital horn as well as a "large pituitary"
    8. Areas of increased signal
3. Molecular analysis (Sebold et al. 2015)
    1. Array-based comparative genomic hybridization (CGH)
    2. Parental origin of the abnormal chromosome: using PCR-based polymorphic microsatellites

Genetic Counseling

1. Recurrence risk (Turleau 2008)
    1. Patient's sib
        1. A de novo case
            1. Not significantly increased above that of the general population.
            2. Caution: cryptic mosaicism may be present in one of the parents.
        2. Presence of a structural rearrangement in one of the parents (most frequently balanced translocation, followed by pericentric inversion)
            1. Recurrence risk depends on the type of rearrangement, in which chromosomes are involved, and on the size of the rearranged segments.
            2. A high recurrence risk of either a monosomy or a trisomy for 18p for some rearrangement.
        3. One of the parents with a 18p deletion.
            1. A 50 % risk if the parent has non-mosaic 18p deletion
            2. Lower than 50 % risk if the parent has mosaic 18p deletion
    2. Patient's offspring
        1. A 50 % risk if the patient has non-mosaic 18p deletion
        2. Lower than 50 % risk if the patient has mosaic 18p deletion
2. Prenatal diagnosis
    1. Cytogenetic analysis including FISH: can detect deletion 18p when a parent is heterozygous for a balanced rearrangement involving 18p or carrier of a 18p deletion, following detection of a holoprosencephaly-type defect at sonography, or after the birth of a first affected child
    2. Deletion 18p is rarely observed in first-trimester abortions suggesting that this imbalance is not selected against
3. Management
    1. No specific treatment available
    2. Early rehabilitative and education interventions, mainly speech therapy
    3. Physical therapy for hypotonia

Del(22q11.2) Syndrome

Contents

The 22q11.2 deletion syndrome is one of the most common multiple anomaly syndrome and the most common microdeletion syndrome. It is the most common syndrome associated with palatal clefts and congenital velopharyngeal dysfunction (Kirschner 2005) and the second most common cause of developmental delay accounting for about 2.4% of affected individuals. The occurrence is approximately 1 in 4,000 live births (Botto et al. 2003; Óskarsdóttir et al. 2005).

Synonyms and Related Disorders

22q11.2 Microdeletion Syndrome; CATCH-22 syndrome; Cayler cardiofacial syndrome associated with del(22q11.2); Congenital thymic hypoplasia associated with hypocalcemia; DiGeorge syndrome; Takao syndrome; Velocardiofacial syndrome (Shprintzen syndrome)

Historic overviews of the syndromes associated with 22q11.2 deletion (Driscoll 1994; Cuneo 2001; Emanuel et al. 2001; McDermid and Morrow 2002):

1. Congenital thymic hypoplasia associated with hypocalcemia
2. DiGeorge syndrome (DGS) (De la Chapelle et al. 1981)
    1. Congenital thymic hypoplasia
    2. Hypocalcemia
    3. T-cell dysfunction
    4. Typical facial anomalies
    5. Typical cardiac anomalies
3. Takao syndrome (conotruncal anomaly face syndrome) (Burn et al. 1993; Matsuoka et al. 1998)
    1. Conotruncal cardiac anomalies (Momma et al. 1996)
    2. Typical facial appearance
    3. Velopharyngeal insufficiency
    4. Learning disability
4. Velocardiofacial syndrome (VCFS) (Shprintzen syndrome) (Driscoll et al 1992; Goldberg et al. 1993; Motzkin et al. 1993; Carlson et al. 1997; Shprintzen 2000; Horenstein et al. 2014)
    1. Velopharyngeal abnormalities
    2. Cardiac abnormalities
    3. Facial abnormalities
    4. The birth incidence of 1/1,800–1/4,000, making VCFS the second most common cause of congenital heart disease after Down syndrome
5. DiGeorge syndrome speculatively linked to chromosome 22

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_67

6. Partial monosomy of chromosome 22
7. "CATCH-22 syndrome" (Hall 1993): not a preferred term (Burn 1999)
    1. *C*ardiac disease
    2. *A*bnormal facies
    3. *T*hymic hypoplasia
    4. *C*left palate
    5. *H*ypocalcemia
    6. Associated with a deletion in chromosome-*22*
8. Cayler cardiofacial syndrome associated with del(22q11.2) (Giannotti et al. 1994)
    1. Asymmetric crying facies
    2. Phenotypic spectrum expanded to include extracardiac anomalies
    3. Associated with del(22q11.2)
9. Some cases of autosomal dominant Opitz G/BBB syndrome (McDonald-McGinn et al. 1995)
    1. Hypertelorism
    2. Laryngotracheoesophageal cleft
    3. Cleft palate
    4. Swallowing difficulty
    5. Genitourinary defects
    6. Mental retardation
    7. Congenital heart defects

Genetics/Basic Defects

1. Inheritance (Thomas and Graham 1997)
    1. De novo deletions in the majority of cases (80–90%) (Yamagishi and Srivastava 2003)
    2. The deletion can be transmitted as an autosomal dominant trait
    3. Familial deletions identified in 7% of probands
    4. Deletions within chromosome 22q11: an important cause of familial heart defects (Wilson et al. 1992)
2. Cause: hemizygous deletion of 22q11.2
    1. Deletions inherited from an affected parent (<14%)
    2. Up to 89% of patients show a typical phenotype of DiGeorge syndrome.
    3. Occupy roughly 15% of the patients with congenital heart disease
    4. Microdeletions detected by fluorescence in situ hybridization (FISH) probes
3. Molecular/cytogenetic basis (Amati et al. 1999)
    1. DiGeorge critical region (300–600 kbp containing approximately 25–30 candidate genes) mapped to 22q11.2
    2. Candidate genes (Yamagishi 2002)
        1. Ubiquitin-fusion-degradation-1-like (*UFD1L*) gene located in the DiGeorge critical region, which is most consistently deleted in patients with DGS (88%) or VCFS (76%). A significant percentage of cardiac patients with conotruncal cardiac malformations have a 22q11.2 deletion.
        2. Mutation in *TBX1* gene (belongs to the T-box family of transcription factors) located in 22q11.2 region has been suggested as a rare cause of the syndrome (Yagi et al. 2003; Gao et al. 2013). *TBX1* haploinsufficiency is likely the major determinant of aortic arch defects in patients with 22q11.2 deletion syndrome.
4. Cardiac embryogenesis and branchial arch abnormalities
    1. Cardiac structures (derived from the cardiogenic cord in the embryonic mesoderm during very early embryogenesis)
    2. Conotruncus (outflow structures of the heart, derived from branchial arches IV and VI, which differentiate into aorta and pulmonary artery respectively). Malalignment of these structures and incomplete septation give rise to the following diverse congenital heart disease associated with DiGeorge syndrome (Wilson et al. 1991):
        1. Arch abnormalities (interrupted aortic arch, aortic coarctation) (Goldmuntz et al. 1993)
        2. Conotruncal abnormalities (truncus arteriosus, pulmonary artery atresia) (Johnson et al. 1995)
        3. Malalignment of the interventricular septum with the conotruncus (VSD, ASD, Tetralogy of Fallot, DORV)
        4. Valvular or myocardium abnormalities (unusual)

3. Branchial arches are also the embryological origin of the anterior facial structures, thyroid, thymus, and parathyroids. Their abnormalities are the phenotypic hallmark of the DiGeorge syndrome groups.

5. Heterogeneous etiology of congenital heart defects
    1. Deletion 22q11.2 (the second most common chromosomal cause of significant congenital heart disease)
    2. Aneuploidy (trisomy 21 remains the most common chromosomal cause of significant congenital heart disease) (Goodship et al. 1998)
    3. Single gene disorder (De Decker and Lawrenson 2001)
    4. Multifactorial trait
    5. Maternal disease such as diabetes mellitus
    6. Teratogen exposure

Clinical Features

1. Marked variability of phenotype (Ryan et al. 1997; Di Rocco et al. 1998; Akiba et al. 2000; McDonald-McGinn et al. 2001)
2. Intrafamilial phenotypic variability (Vergaelen et al. 2015)
3. Endocrine abnormalities: common in patients with a 22q11.2 deletion (Weinzimer 2001)
    1. Hypocalcemia (30%)
        1. Invariably due to hypoparathyroidism, documented by aplasia or hypoplasia of the parathyroid glands at surgery or autopsy.
        2. Symptoms of hypocalcemia most likely manifest in the neonatal period, because maternal calcium supply by fetal circulation is abruptly interrupted at birth and the calcium intake within the first few days of life is usually insufficient.
            1. Seizures
            2. Tremors
            3. Tetany
        3. Other signs of hypocalcemia.
            1. Paresthesias
            2. Muscle cramps
            3. Rigidity
    4. Prevalence of hypocalcemia by phenotypic characteristics.
        1. DiGeorge syndrome (69–72%)
        2. Velocardiofacial syndrome (13–22%)
        3. Conotruncal anomaly face syndrome (10%)
        4. 22q11.2 deletion (49–60%)
    5. Autoimmune enteropathies
    2. Growth disorders
        1. Growth hormone deficiency
        2. Short stature
    3. Thyroid disorders
        1. Congenital hypothyroidism
            1. Noted in 7% of patients with VCFS
            2. Noted in 5% of patients with DGS
        2. Hyperthyroidism due to Graves disease
4. Immunodeficiency (highly variable) (77%) (Sullivan et al. 1998)
    1. Primary T-cell dysfunction (decreased production of T cells caused by impaired formation of thymic tissue) (67%)
    2. Secondary T-cell functional defects (19%)
    3. Humoral immune deficits (23%)
    4. IgA deficiency (13%) (Smith et al. 1998)
    5. Associated autoimmune disease
        1. Polyarticular juvenile rheumatoid arthritis, a frequency 150 times that of the general population rate
        2. Autoimmune hemolytic anemia
        3. Idiopathic thrombocytopenic purpura
        4. Autoimmune enteropathies (celiac disease)
        5. Vitiligo
5. Cardiovascular malformations (75%, the most common structural anomaly)
    1. Conotruncal heart defects (Marino et al. 2001)
        1. Tetralogy of Fallot (the most common heart anomaly)
        2. Pulmonary atresia with ventricular septal defect
        3. Truncus arteriosus (25%)
        4. Interrupted aortic arch type B (30%)
        5. Atrial septal defect
    2. Right-sided, cervical, or double aortic arch/aberrant subclavian artery
    3. Pulmonary artery abnormalities
        1. Discontinuity of the pulmonary arteries
        2. Diffuse hypoplasia

3. Discrete stenosis
4. Defect of arborization
5. Major aortopulmonary collateral arteries

4. Infundibulum abnormalities
   1. Malaligned
   2. Hypoplastic
   3. Absent
5. Semilunar valve abnormalities
   1. Bicuspid
   2. Severely dysplastic
   3. Insufficient
   4. Stenotic

6. Craniofacial features
   1. Palate
      1. Velopharyngeal incompetence (27%)
      2. Submucous cleft palate (16%)
      3. Overt cleft palate (11%)
      4. Bifid uvula (5%)
      5. Cleft lip/palate (2%)
      6. Suspected velopharyngeal incompetence
      7. Normal
   2. Ears
      1. Low-set ears
      2. Over-folded helices
      3. Squared off helices
      4. Cupped, microtic, and protuberant ears
      5. Preauricular pits/tags
      6. Narrow canals
      7. Chronic otitis media
      8. Conductive hearing loss
   3. Nose
      1. Prominent nasal root
      2. Bulbous nasal tip
      3. Hypoplastic alae nasae
      4. Nasal dimple/bifid nasal tip
      5. Chronic sinusitis
   4. Throat
      1. Stridor caused by a vascular ring
      2. Laryngomalacia
      3. Laryngeal webs
   5. Eyes
      1. Tortuous retinal vessels (58%)
      2. Posterior embryotoxon (69%)
      3. Hooding of the upper and/or lower lid (47%)
      4. Ptosis (9%)
      5. Epicanthal folds (3%)
      6. Distichiasis (3%)
   7. Skeletal abnormalities
      1. Vertebral anomalies (19%)
         1. Coronal clefts
         2. Hemivertebrae
         3. Butterfly vertebrae
         4. Scoliosis
      2. Rib anomalies including supernumerary ribs (19%)
      3. Hypoplastic scapulae
      4. Upper limb anomalies including pre/postaxial polydactyly (6%)
      5. Lower limb anomalies (15%)
         1. Postaxial polydactyly
         2. Club foot
         3. Over-folded toes
         4. 2, 3 syndactyly
      6. Craniosynostosis
   8. Renal abnormalities (37%)
      1. Calculi
      2. Single kidney
      3. Small kidneys
      4. Echogenic kidney
      5. Horseshoe kidney
      6. Bladder wall thickening
      7. Multicystic dysplastic kidney
      8. Duplicated collecting system
      9. Renal tubular acidosis
   9. Neuromuscular development
      1. Developmental delays
      2. Hypotonia
      3. Feeding disorders
   10. CNS manifestations
      1. Mental retardation
      2. Seizures (with or without hypocalcemia)
      3. Asymmetric crying facies
      4. Ataxia
      5. Cerebellar hypoplasia
      6. Enlarged Sylvian fissures
      7. Pituitary abnormalities
      8. Polymicrogyria
      9. Mega cisterna magna
      10. Neural tube defects
   11. Neuropsychological manifestations (Woodin et al. 2001; Cancrini et al. 2014; Jonas et al. 2014)
      1. Attention deficit/hyperactivity disorder

2. Anxiety disorders (most commonly specific and social phobia)
3. Mood disorders
4. Autism spectrum disorders
5. Nonverbal learning disability
6. Speech and language deficits
7. Psychomotor developmental delay
8. Social/emotional concern
9. Psychiatric disorders

12. Adult phenotype (Cohen et al. 1999)
    1. Lower rates of congenital heart defects
    2. Higher rates of palate anomalies, learning disabilities/mental retardation, and psychiatric disorders
    3. B cell and immunoglobulin defects have been described and appear to be increased in the adult population (Derfalvi et al. 2016)

Diagnostic Investigations

1. Cytogenetic studies
    1. High-resolution chromosome analysis to detect del(22q11.2)
    2. Fluorescence in situ hybridization (FISH) for the chromosome region 22q11.2 to detect submicroscopic deletion (Kornfeld et al. 2000)
2. Parental cytogenetic studies are warranted in all families with an affected child in order to identify mildly affected parents, as well as to rule out low level mosaicism (McDonald-McGinn and Zackai 2008).
3. Genetic studies (Bawle 2015)
    1. Chromosome microarray analysis or array comparative genomic hybridization
    2. Fluorescent in situ hybridization
    3. Multiplex ligation-dependent probe amplification
    4. TBX1 gene studies (DiGeorge syndrome)
4. Echocardiography for cardiovascular anomalies
5. Chest X-ray
    1. Presence of a heart defect
    2. Absence of thymus shadow
6. Renal ultrasound examination at irregular intervals for the development of renal stones
7. MRI of the brain: detects high prevalence of brain abnormalities that are most likely neurodevelopmental and may partially explain the high prevalence of learning disability and psychiatric disorder (Van Amelsvoort et al. 2001)
    1. Cerebellar atrophy
    2. Agenesis of the corpus callosum
    3. White matter hyperintensities
    4. Cavum septum pellucidum
    5. Cerebral atrophy
    6. Widespread differences in white matter bilaterally
    7. Region-specific differences in gray matter in the left cerebellum, insula, and frontal and right temporal lobes
8. Blood calcium levels
9. Initial immunological investigations (Gennery 2012)
    1. Full blood count and differential leukocyte count
    2. Immunoglobulins (IgM, IgA, IgG,)
    3. Lymphocyte phenotyping (CD3, CD4, CD8, CD19, or CD20, CD16 or CD56)
    4. Lymphocyte proliferations to phytohemagglutinin if T lymphocyte counts low
    5. Postvaccination antibody responses to tetanus, and polysaccharide-protein conjugated *Haemophilus influenzae* type B capsular (Hib) and/or
    6. Pneumococcal antigens
    7. Beyond 2 years of age – assessment of polysaccharide antigen response
    8. Assessment of autoantibodies, if clinically indicated, including direct antiglobulin test and thyroid antibodies

Genetic Counseling

1. Recurrence risk (McDonald-McGinn et al. 2013)
    1. Patient's sib
        1. Low recurrence risk, provided parents are phenotypically normal and neither one is a carrier of del(22q11.2)
        2. A higher recurrence risk in case of a parent with germline mosaicism or

low-level somatic mosaicism for a microdeletion syndrome
3. A 50% recurrence risk if a parent is also found to have the 22q11.2 deletion syndrome
2. Patient's offspring: 50% affected

2. Prenatal diagnosis (Driscoll 2001)
1. Indications for prenatal testing for the 22q11.2 deletion
1. A previous child with a 22q11.2 deletion or DiGeorge/velocardiofacial syndrome
2. An affected parent with a 22q11.2 deletion
3. In utero detection of a fetus with a conotruncal cardiac defect (Boudjemline et al. 2002)
2. Prenatal ultrasonography and fetal echocardiography for a fetus at risk for the 22q11.2 deletion
1. Conotruncal cardiac defect with associated anomalies
2. Conotruncal cardiac defect without associated anomalies
3. Aplasia or hypoplasia of the fetal thymus in the presence of conotruncal cardiac anomalies: very specific for deletion 22q11.2 (Chaoui et al. 2002)
4. Cardiac lesions with the deletion
1. Interrupted aortic arch (50–80%)
2. Truncus arteriosus (35%)
3. Tetralogy of Fallot (15%)
4. Rare in double outlet right ventricle and transposition of the great vessels
5. Sensitivity of different sonographic features allowing discrimination of a subgroup likely to be associated with microdeletion 22q11.2
1. Nuchal translucency (12%) (Machlitt et al. 2002)
2. Polyhydramnios (20%)
3. IUGR (8%)
4. Extracardiac anomalies (36%)
3. Prenatal diagnosis of 22q11.2 deletion by amniocentesis or CVS
1. Fluorescence in situ hybridization (FISH) analysis with probes from the DiGeorge chromosomal region (DGCR)
2. Preimplantation genetic diagnosis by FISH reported in an at-risk mother with a 22q11.2 deletion
3. Occasional detection of an unbalanced translocation or an interstitial deletion of 22q11.2 by cytogenetic analysis
4. Molecular genetic analysis
1. Demonstrate failure to inherit a parental allele or hemizygosity in the deleted region
2. Restriction fragment length polymorphism (RFLP) analysis and quantitative hybridization
3. PCR assays using short tandem repeat polymorphisms (STRs) within the DGCR
4. Array comparative genomic hybridization characterization using uncultured amniocytes: has the advantage of detecting uncharacterized chromosomal deletions or genomic imbalance with haploinsufficiency of the genes responsible for conotruncal heart malformations and tetralogy of Fallot, as well as refining the 22q11.2 deletion breakpoints (Chen et al. 2013)
5. Limitations of prenatal testing for the 22q11.2 deletion
1. DGS/VCFS, a heterogeneous disorder in which 10–15% of patients do not have the deletion. Therefore, FISH analysis is of limited value in couples who have had a previously affected child without a deletion.
2. Atypical deletions of 22q11.2, unbalanced chromosomal translocations, deletions involving other chromosomes have not been detected by FISH using commercially available probes.
3. Consider other causes of congenital heart defects such as aneuploidy, single gene defects, maternal diseases such as diabetes, and exposure to teratogens.
4. Inability to predict accurately the phenotype prenatally.

4. Preimplantation genetic diagnosis: available for families in which the diagnosis of the 22q11.2 deletion syndrome has been established in an affected family member (Iwarsson et al. 1998)

3. Management (Sullivan 2008)
    1. Medical care
        1. Manage the feeding problems
            1. Modification of spoon placement when eating
            2. Treat gastroesophageal reflux with acid blockade, prokinetic agents, postural therapy, and medication to treat gastrointestinal dysmotility and to facilitate bowel evacuation
        2. Early intervention programs including speech therapy for developmental delay
        3. Management of psychiatric disorder
        4. Hypocalcemia
            1. Asymptomatic hypocalcemia: treat with oral calcium supplements
            2. Severe symptomatic hypocalcemia: treat with prompt administration of parenteral calcium
            3. Goal of treatment: maintain calcium in the low-normal range (8–9 mg/dL) to minimize hypercalcinuria
            4. Over supplementation of calcium leads to nephrocalcinosis
        5. Management of immunodeficiency
            1. Most patients have diminished T-cell numbers as a consequence of thymic hypoplasia.
            2. Most patients do not demonstrate a susceptibility to opportunistic infections.
            3. Risk of using live viral vaccines in infants seems to be low except for patients who have thymic aplasia and/or very low T-cell counts (McDonald-McGinn et al. 1999).
            4. Both the measles, mumps, rubella, and the varicella vaccine are found to be safe and efficacious in children who had the deletion and who had mild to moderate T-cell compromise (Junker and Driscoll 1995; Pierdominici et al. 2003).
            5. Management of thymic aplasia: A thymus transplant, fully matched peripheral blood transplant, or donor lymphocyte infusions are required.
        6. Thyroid hormone for hypothyroidism
        7. Growth hormone therapy in growth hormone–deficient children with a 22q11.2: associated with sustained improvements in height and growth velocity
        8. Guidelines focused on managing the neuropsychiatric, endocrine, cardiovascular, reproductive, psychosocial, genetic counseling, and other issues that are the focus of attention in adults with 22q11.2 deletion syndrome (practical strategies for the recognition, evaluation, surveillance, and management of the associated morbidities) (Fung et al. 2015)
    2. Surgical care
        1. Congenital heart diseases
            1. Palliative operation
            2. Corrective operation
        2. Velopharyngeal dysfunction
            1. Pharyngoplasty
            2. Plastic surgery of cleft lip/palate
        3. Surgery
            1. Gastrointestinal anomalies
            2. Renal anomalies
            3. Musculoskeletal anomalies

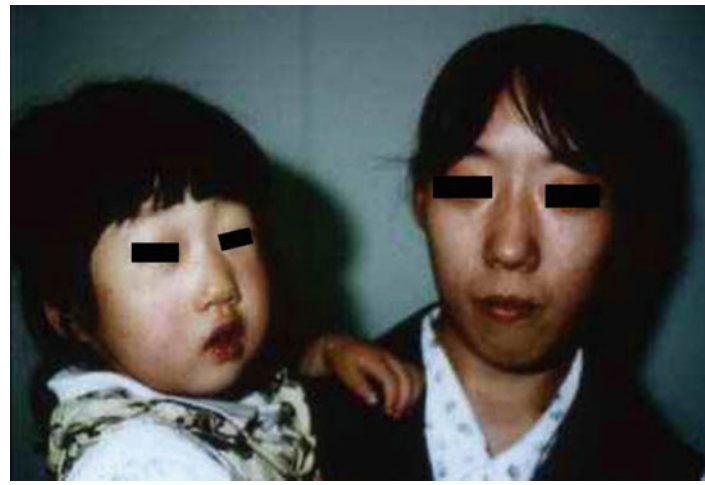

Fig. 6 A mother and daughter both have deletion 22q11.2

Del(Yq) Syndrome

Contents

In 1976, Tiepolo and Zuffardi (1976) first recognized the deletions of the long arm of the Y chromosome, large enough to be recognized by light microscopy, in six azoospermic men. Large structural rearrangements of the Y chromosome are known to be commonly associated with a 45, X/46,XY chromosomal mosaicism (Siffroi et al. 2000). Majority of Yq deletions are microdeletions and, therefore, require analysis by molecular means (Martin 2008).

Synonyms and Related Disorders

Chromosome Yq deletion syndrome

Genetics/Basic Defects

1. Role of Yq deletions in male infertility (Ma et al. 2000)
    1. Factors controlling human spermatogenesis: postulated to be located on the distal portion of the euchromatin segment of the long arm of the Y chromosome, Yq11 (Tiepolo and Zuffardi 1976).
    2. This spermatogenesis locus at Yq11.23, as demonstrated with high-resolution banding techniques, has since come to be known as the "azoospermia factor" or "AZF" (Bühler 1985).
    3. Further molecular investigations into genotype-phenotype correlation in azoospermic men led to the localization of the *AZF* locus to interval 6 of the Y chromosome (Vergnaud et al. 1986; Affara et al. 1986; Andersson et al. 1988).
    4. Microdeletions of the long arm of the Y chromosome.
        1. Represents the most frequent molecular genetic cause of severe male infertility (Ferlin et al. 2006; Krausz and Degl'Innocenti 2006)
        2. The first solid molecular evidence that failure of spermatogenesis may be caused by cytologically undetectable deletions on the Y chromosome: identification of two nonoverlapping microdeletions mapped to the distal region of intervals 5 and 6, carried by two azoospermic otherwise normal men (Ma et al. 1992)
        3. Further studies led to the proposal of the existence of three *AZF* subregions

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_68

termed *AZFa* (formerly JOLAR region), *AZFb*, and *AZFc* (formerly KLARD region), respectively (Vogt et al. 1996).
   1. Deletion of AZFa: associated with lack of germ cells or Sertoli cell-only syndrome.
   2. Deletion of *AZFb*: associated with spermatogenesis arrest.
   3. *AZFc* gene products: involved in the maturation process of postmeiotic germ cells (Vogt et al. 1996).
   4. The above hypothesis remains controversial and it is generally accepted that the completion of spermatogenesis requires multiple genes not only on the Y chromosome but elsewhere as well.
4. Recent description of another *AZF* subregion further complicated the issue: *AZFd*: localized between *AZFb* and *AZFc* (Kent-First et al. 1999).
5. The discovery of the two separate microdeletions on the Yq in infertile men subsequently led to the identification of four candidate gene families for *AZF*:
   1. RNA-binding motif (*RBM*), previously named Y-linked RNA recognition motif (*YRRM*) (Ma et al. 1993)
   2. Deleted in azoospermia (*DAZ*) (Reijo et al. 1995)
   3. *Drosophila* fat facets related Y (*DFFRY*) (Brown et al. 1998)
   4. *C*hromodomain Y (*CDY*) (Lahn and Page 1999)
5. Male infertility: most likely result from deletions and/or mutations of one or more of the myriad of genes necessary for spermatogenesis (Krausz et al. 2003)

2. 45,X cell line associated with large cytogenetically visible Yq deletions (Hwa et al. 2004; Cui et al. 2007)
   1. Structural aberrations of the Y chromosome, such as large cytogenetically visible deletions of the long arm, ring Y, *iso*- or isodicentric short arm, are unstable and usually lost during mitosis, leading to mosaic 45,X (Hsu 1994; Kirsch et al. 2000; Siffroi et al. 2000; Bertini et al. 2005).
   2. In the presence of a 45,X cell line, a fetus has a risk of being a phenotypic female with Turner syndrome manifestations or to have ambiguous external genitalia, whether the other cell line is Yp, Yq, Yp plus Yq, or even a free Y chromosome (Hsu 1994).
   3. Patients with Turner syndrome with a Y-derived marker have milder phenotypic abnormalities than those with an X-derived marker. In general, patients with a Y-derived marker are not as short as, and have fewer somatic abnormalities than, patients with an X-derived marker chromosome (Schwartz et al. 1997).

Clinical Features

1. Deletion/microdeletion of the long arm of the Y chromosome
   1. Men with deletions, in general, are infertile and therefore deletions are not transmitted to sons unless in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI) are performed.
   2. Associated with severe oligozoospermia.
2. Phenotype-genotype correlative analyses (Cram et al. 2000)
   1. Identified four subregions within AZF, called AZFa, b, d, and c
   2. Most deletions observed in infertile men occur in the AZFc region (Totonchi et al. 2012; Elfateh et al. 2014): associated with severe oligospermia or azoospermia and occasionally oligozoospermia
   3. Men with more extensive deletions in the AZFb region that extend into the AZFa region: commonly exhibit histologic phenotypes such as germ cell arrest or Sertoli cell-only syndrome and as a result are usually azoospermic
   4. Men with deletions localized exclusively to AZFd: present with mild oligozoospermia or even normal sperm counts

associated with abnormal sperm morphology (Kent-First et al. 1999)

3. Phenotypes of 45,X/46,X,del(Y)(q11) (Werner et al. 1985; Hwa et al. 2004)
    1. Phenotypic males (34.2%): small testes, short stature, small penis, hypospadias, azoospermia, Turner syndrome, and gonadoblastoma (Hsu 1994).
    2. Intersex (47.4%).
    3. Phenotypic females (18.4%).
    4. Only a few cases of mos45,X/46,X,del(Y) reported with normal male external genitalia (Bühler 1980; Hoshi et al. 1998).
    5. The deletions of Y chromosomes are associated with abnormalities of the external genitalia, secondary sexual characteristics, and/or gonadal function.
    6. These phenotypic differences are related not only to the presence or absence of the *SRY* gene on Yp but also to the proportion of 45,X line in gonadal tissue.
        1. A sufficient SRY transcript level is necessary to trigger testes formation: once testes differentiate, male endocrine function is responsible for the rest of the events involving male phenotypic sexual differentiation.
        2. When the 45,X line is predominant in gonadal tissue, the phenotype of Turner syndrome would appear.
4. A case of Y chromosome with terminal deletion associated with nondisjunction, leading to mosaicism of three cell lines, has been reported (Cui et al. 2007): an azoospermic male with complete masculinization associated with karyotype 45,X/46,X,del(Y)/ 47,X,del(Y),del(Y)

Diagnostic Investigations

1. Diagnostic investigations of all infertile men (Bhasin 2007)
    1. Several semen analyses
        1. Sperm count
        2. Sperm motility
        3. Sperm morphology
    2. Hormone measurements (testosterone, LH, and FSH levels) to help determine:
        1. Low testosterone and low or inappropriately normal LH and FSH: gonadotropin deficiency: hypogonadotropic hypogonadism (Gnoth et al. 2005)
        2. Low testosterone, elevated LH, and FSH: obtain karyotype: primary testicular failure
        3. Normal testosterone and LH, elevated FSH: spermatogenic failure, test for Yq microdeletion
        4. High testosterone, elevated LH: androgen resistance
        5. Normal testosterone, normal LH, and FSH (Templeton 2000)
            1. Majority of infertile men: have normal testosterone, LH, and FSH levels
            2. Azoospermia: rule out obstruction by postejaculatory urine and seminal fructose and screen for Yq microdeletions
            3. Oligo/asthenozoospermia: exclude antisperm antibodies
2. Genetic testing of infertile couples and the offspring: important, especially in couples who are being considered for ICSI
    1. All infertile men with nonobstructive azoospermia, severe oligozoospermia, or very small testes should be offered a karyotype (Simpson and Lamb 2001; Allen et al. 2006).
    2. Screen infertile men with azoospermia or severe oligozoospermia for Yq microdeletions (Cram et al. 2006; Ferlin et al. 2007).
    3. Azoospermic men with at least one absent vas deferens or with evidence of normal spermatogenesis should be tested for CFTR mutations (Anguiano et al. 1992).
    4. Consider CREM mutations in men with postmeiotic maturation arrest (Blendy et al. 1996; Peri et al. 1998; Weinbauer et al. 1998).
    5. Genetic testing is indicated in men in whom personal or family history suggests disorders that have a genetic basis such as hemoglobinopathies and myotonic dystrophy (Takeda and Ueda 1977; Kletzky et al. 1979; Marchini et al. 2000); these patients also need genetic counseling.

3. Yq microdeletions are detected by PCR-based mapping of several conserved molecular markers or genes located within and outside the AZF region; these tests are available from commercial laboratories. With the availability of precise Y chromosome maps, more specific molecular markers have been developed, and guidelines for standardized testing of Yq microdeletions have been published by the European Molecular Genetics Network (Simoni et al. 2004). A novel universal multiplex PCR improves detection of AZFc Y-chromosome microdeletions (Zheng et al. 2014).
4. Array comparative genomic hybridization approach: a reliable high-resolution alternative to multiplex polymerase chain reaction for the discovery of pathogenic chromosome Y microdeletions in male infertility (Osborne 2007; Yuen et al. 2014).
5. GENOSEARCHTM AZF Deletion kit for the detection of a panel of AZF deletions using Luminex xMAP arrays: provides a routine tool for the diagnosis of AZF deletions in male infertility in Japan and also be useful for the detection of atypical microdeletions (Iijima et al. 2014).

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. Father without Yq deletion: since most Yq microdeletions occur de novo, the recurrence risk to the male sibling is not significantly increased.
        2. Father with Yq deletion: Father's Yq deletion will be transmitted to the male sibling.
    2. Patient's offspring
        1. The genetic defects responsible for infertility in the parent may be transmitted to the offspring through ICSI: Yq deletions will be transmitted to male offspring (Page et al. 1999; Cram et al. 2000; Simpson and Lamb 2001; Ferlin et al. 2007).
        2. Children born through ICSI have increased risk of sex chromosome aneuploidy (45,X and 47,XXY embryos) (Palermo et al. 1999; Ferlin et al. 2007).
        3. Children born through ICSI to infertile couples may have a higher risk of being infertile or subfertile (Cram et al. 2006): may need counseling upon reaching adulthood and surveillance of their reproductive function.
2. Prenatal diagnosis
    1. Prenatal testing, including chorionic villous sampling, may be appropriate in some couples undergoing ICSI.
    2. A fetus with a prenatally diagnosed mosaic 45,X/46,X,del (Y)(q11.2) karyotype from amniotic fluid, in which the deletion was defined by polymorphic microsatellite markers analysis and multiplex STS-PCR.
3. Management (Krausz and Degl'Innocenti 2006; Bhasin 2007)
    1. Gonadotropin therapy: highly effective in gonadotropin-deficient men
    2. Intracytoplasmic sperm injection (ICSI): emerges as the treatment of choice for idiopathic male factor infertility
        1. Expensive
        2. Associated with the following higher risks compared to naturally conceived pregnancies:
            1. Multiple gestation
            2. Low birth weight
            3. Preterm delivery
            4. Perinatal complications
            5. Chromosome aneuploidy
    3. Men with Yq microdeletions considering ICSI should be offered:
        1. Karyotyping
        2. Yq microdeletion testing
        3. Genetic counseling
            1. Obligatory transmission of Yq deletion to male offspring
            2. The phenotype of son: varies substantially and the extent of spermatogenic failure cannot be predicted entirely due to different genetic background and the presence or absence of

environmental factors with potential toxicity to reproductive function
3. A significant proportion of spermatozoa from men with Y microdeletion are nullisomic for sex chromosomes (Siffroi et al. 2000; Jaruzelska et al. 2001), indicating a potential risk for the offspring to develop 45, X Turner syndrome and other phenotypic anomalies associated with sex chromosome mosaicism, including ambiguous genitalia.
4. Screening for Y chromosome microdeletions in patients bearing a mosaic 45,X/46,XY karyotype with sexual ambiguity and/or Turner stigmata has shown a relatively high incidence of AZFc deletions (33%) (Patsalis et al. 2002).
5. Yq microdeletions could be associated with an overall Y chromosomal instability leading to the formation of 45,X cell lines (Le Bourhis et al. 2000; Jaruzelska et al. 2001; Patsalis et al. 2005).
6. Despite this theoretical risk, the 36 babies (18 male and 18 female) born from fathers affected by Yq microdeletions are phenotypically normal (Krausz et al. 2003). This could be due to the reduced implantation rate and a likely higher risk of spontaneous abortions of embryos bearing a 45,X karyotype.
7. In order to avoid the transfer of embryos with sex chromosome mosaicism, preimplantation diagnosis could be offered to the couple. This analysis, together with the abortion rate, would provide a more realistic estimation about the real risks of 45, X/46,XY mosaicism and Turner syndrome.

4. The screening for Yq deletions: of additional clinical utility in azoospermic men in which the type of deletion may have prognostic value for testicular sperm retrieval
5. Testicular sperm extraction (TESE): not recommended for complete AZFa or AZFb deletions since the probability of the presence of mature sperm is virtually zero
6. Advice cryoconservation of sperm as a preventive therapy since it is a noninvasive procedure.
7. The development of assisted reproductive techniques (intracytoplasmic sperm injection and testicular sperm extraction) helps to bypass the natural barriers of fertilization, but it increases the concern about the transmission of genetic defects such as Y chromosome microdeletions (Suganthi et al. 2014).

Diabetic Embryopathy

Contents

Maternal diabetes adversely affects the fetus during pregnancy. The risk of developing congenital malformations has been well documented (Reece and Homko 2000; Correa et al. 2008). The frequency of congenital anomalies among insulin-dependent diabetic offspring is estimated at 3–6% of all infants at birth, representing a twofold to threefold increase, when compared with nondiabetics (Reece and Hobbins 1986).

Synonyms and Related Disorders

Infant of diabetic mother

Genetics/Basic Defects

1. Diabetes mellitus (Zhao and Reece 2013):
    1. Type 1 (insulin deficiency) or insulin-dependent diabetes: caused by autoimmune destruction of insulin-producing β cells in the pancreas
    2. Type 2 (insulin resistance) diabetes: caused by failure in insulin signaling to regulate cellular glucose uptake
    3. Pre-gestational diabetes: refers to diabetes mellitus, either type 1 or type 2, diagnosed in women before pregnancy
    4. Gestations diabetes: pregnant women with hyperglycemia detected after the onset of pregnancy, usually in the third trimester (24–28 weeks) (women who have a fasting plasma glucose $\geq$126 mg/dL and HbA_{1c} $\geq$ 6.5% are diagnosed as having gestational diabetes mellitus)
2. Gestations diabetes mellitus (GDM) (Gabbay-Benziv and Baschat 2015):
    1. Gestational diabetes can be regarded as one of the great obstetric syndromes where early placental development coupled with maternal predisposition initiates a chain of events that affects placental, maternal, and fetal development with lasting impacts on mother and child.
    2. The placentas of diabetic pregnancies are characterized by increased placental to fetal ratio and by histological findings such as villous fibrinoid necrosis, villous immaturity, chorangiosis, and ischemic changes.
    3. Placental changes depend on GDM onset at gestation. Structural placental changes are seen in early GDM while more functional changes are seen in late-onset GDM.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_69

4. GDM-associated fetal and neonatal adverse outcome may be associated with placental structural and functional changes.

3. Teratogenicity of maternal diabetes mellitus in human:
   1. Occurring during embryogenesis at the end of blastogenesis and organogenesis between the third and seventh weeks of gestation
   2. Leading to a spectrum of malformations known as diabetic embryopathy (Becerra et al. 1990)
4. Diabetic fetopathy:
   1. Occurs during fetal development (after the tenth week of gestation)
   2. Not associated with malformations
   3. Fetal hyperinsulinism: the cause of macrosomia and numerous other postnatal complications
5. Genotoxicity and diabetic embryopathy: impaired expression of developmental control genes as a cause of defective morphogenesis (Chang and Loeken 1999)
6. Potential pathogenetic mechanisms of diabetic embryopathy: most likely multifactorial (Reece et al. 1996b; Dhanasekaran et al. 1999; Chugh et al. 2003):
   1. Oxidant stress
   2. Perturbed biosynthesis of prostaglandins and DNA
   3. Altered expression of some of the morphogenetic regulatory molecules:
      1. Extracellular matrix (ECM) proteins
      2. Transcription factors
      3. Proto-oncogene

Clinical Features

1. General features of infants of diabetic mothers (Cowett and Schwartz 1982; Grix et al. 1982; Khoury et al. 1989; Kousseff 1999; Hay 2012; Moore 2014; Potter and Kicklighter 2016):
   1. Higher rate of congenital malformations
   2. Signs of diabetic fetopathy:
      1. Macrosomia (increase in adipose tissue and organomegaly) (Tyrala 1996):
         1. Classic appearance: a large, ruddy, puffy, fat, and often limp infant, with legs held in a flexed and abducted position
         2. The presence of prominent fat pads over the upper back and around the lower jaw to produce the image of a round cherubic face
         3. A predisposing factor for the occurrence of a variety of birth trauma-related injuries
      2. Birth trauma-related injuries due to difficult vaginal delivery secondary to shoulder dystocia:
         1. Cephalohematoma
         2. Subdural hemorrhage
         3. Clavicular fracture
         4. Cranial nerve palsies
         5. Brachial plexopathy (palsy)
      3. Hypoglycemia (hyperinsulinemia) (Agrawal et al. 2000)
      4. Polycythemia
      5. Hypomagnesemia
      6. Hyperbilirubinemias (jaundice)
      7. Hypocalcemia
      8. Cardiomyopathy (thickened interventricular septum)
      9. Renal vein thrombosis
   3. Other features:
      1. Large for gestational age
      2. Higher fetal death rate
      3. Fetal growth retardation in diabetic women with vasculopathy
      4. Higher risk of respiratory distress (hyaline membrane disease)
      5. Asphyxia
      6. Acidosis
      7. Apneic spells
      8. Sepsis
      9. Intracranial bleeding
      10. Neuromuscular excitability
      11. Single umbilical artery
      12. Small left colon syndrome
      13. Transient hematuria
      14. Abnormal vernix caseosa
      15. Hirsutism
2. Spectrum of diabetic embryopathy: Malformations vary in extent and severity:

1. CNS abnormalities (Reece and Hobbins 1986):
    1. Neural tube defects: a higher incidence of 19.5 per 1,000 in the diabetic gestation, compared with 1–2 per 1,000 in the general population
    2. Anencephaly:
        1. The most common anomaly affecting the CNS
        2. An incidence of 0.57% in the diabetic pregnancy, representing a threefold increase over the general population
    3. Holoprosencephaly
    4. Hydrocephalus
    5. Absent corpus callosum
    6. Arnold-Chiari anomaly
    7. Schizencephaly
    8. Microcephaly
    9. Macrocephaly
    10. Agenesis of olfactory tracts
    11. Intracranial lipoma
    12. Facial nerve palsy
    13. Calcified falx cerebri
    14. Bizarre undergrowth or overgrowth of the brain
    15. Postnatal developmental delay
2. Facial features (85%)
    1. Hemifacial microsomia (oculoauriculovertebral anomalies) (Ewart-Toland et al. 2000)
    2. Macrostomia/lateral facial cleft
    3. Cleft lip/palate
    4. Micrognathia
    5. Branchial cleft cyst (Johnson and Fineman 1982)
    6. Frontonasal dysplasia
    7. Choanal atresia
    8. Short nose
    9. Nasal milia
    10. Fat pad across nose
    11. Facial skin tags
3. Eye anomalies (48%):
    1. Lens opacity
    2. Cataracts
    3. Microophthalmia/optic nerve hypoplasia
    4. Colobomas of iris or chorioretina
    5. Anterior chamber dysgenesis
    6. Epibulbar dermoid/oculolipoma
    7. Laterally displaced inner canthi
    8. Tear duct obstruction
4. Ear anomalies (95%):
    1. Microtia
    2. Sensorineural/conductive hearing loss
    3. Preauricular tags
    4. Anotia
    5. Atretic ear canal
    6. Additional ear malformations
5. Cardiovascular anomalies:
    1. Complex transposition of the great vessels
    2. Single ventricle
    3. Hypoplastic left heart
    4. Tricuspid atresia
    5. Tetralogy of Fallot
    6. Ventricular septal defect
    7. Atrial septal defect
    8. Double outflow right ventricle
    9. Pulmonary atresia
    10. Coarctation of the aorta
    11. Subaortic stenosis
    12. Right aortic arch
    13. Tricuspid regurgitation
    14. Cleft mitral valve
    15. Symmetric hypertrophy of interventricular septum
    16. Hypertrophic cardiomyopathy
6. Gastrointestinal anomalies:
    1. Situs inversus
    2. Pyloric stenosis
    3. Duodenal atresia
    4. Small bowel atresias
    5. Small left colon (microcolon) syndrome
    6. Rectal atresia
    7. Anal atresia (imperforate anus)
    8. Meckel diverticulum
    9. Diaphragmatic hernia
    10. Omphalo-enteric cyst/fistula
7. Genitourinary anomalies (19%):
    1. Renal agenesis
    2. Cystic kidneys
    3. Ectopic kidney
    4. Hydronephrosis
    5. Ureteral duplication

6. Ureterocele
7. Ambiguous genitalia
8. Hypospadias
9. Micropenis
10. Cryptorchidism
11. Uterine agenesis
12. Hypoplastic vagina

8. Skeletal anomalies (52%):
    1. Hand anomalies (limb reduction defects):
        1. Radial clubbing
        2. Bifid thumbs
        3. Hypoplastic/absent thumb
        4. Radial hypoplasia
    2. Polysyndactyly.
    3. Contractures.
    4. Costovertebral anomalies:
        1. Fused cervical vertebrae
        2. Hemivertebrae
        3. Torticolis
        4. Bifid/fused ribs
    5. Hip dislocation.
    6. Femoral hypoplasia (Johnson et al. 1983).
    7. Caudal regression (sirenomelia) (Assemany et al. 1972): it is very rare, but it is one of the most unique and commonly associated lesion with maternal diabetes (occurring in 0.2–0.5% of infants of diabetic pregnancies, a 200-fold increase over the general population) (Reece and Hobbins 1986):
        1. Agenesis of sacrum and lumbar spine
        2. Hypoplasia of the lower extremities
        3. Phocomelia
    8. Craniosynostosis.
    9. Skin anomalies:
        1. Aplasia cutis
        2. Cutaneous vascular dysplasia
3. Maternal diabetes: an independent risk factor for major cardiovascular malformations with increased mortality of affected infants (Loffredo et al. 2001)
4. Exposure to hypoglycemia in utero may have long-term effects on offspring including neuropsychological defects (Ter Braak et al. 2002)

Diagnostic Investigations

1. Complete blood cell count to detect polycythemia
2. Serum or whole blood glucose concentration to detect neonatal hypoglycemia
3. Serum magnesium concentration (ionized or total levels) to detect hypomagnesemia
4. Serum calcium concentration to detect hypocalcemia
5. Serum bilirubin level (total and unconjugated) to detect hyperbilirubinemia
6. Arterial blood gas to assess oxygenation and ventilation with evidence of respiratory distress
7. Radiography for cardiopulmonary distress and skeletal and vertebral anomalies
8. Echocardiography for detecting cardiomyopathy and congenital heart defects
9. Renal ultrasonography for renal anomalies

Genetic Counseling

1. Risk of congenital malformation in infants of mothers with insulin-dependent diabetes (Hajianpour 1993):
    1. Relative risk (per 100 live births):
        1. Major malformations: 7.9
        2. Major CNS malformations: 15.5
        3. Cardiovascular malformations: 18.0
    2. Absolute risks (per 100 live births):
        1. Major malformations: 18.4
        2. Major CNS malformations: 5.3
        3. Major cardiovascular malformations: 8.5
2. Risk of congenital malformation in infants of mothers with gestational diabetes mellitus who required insulin during the third trimester of pregnancy (Hajianpour 1993):
    1. Relative risk: 20.6 times more likely to have major cardiovascular system defects than infants of nondiabetic mothers
    2. Absolute risk: 9.7%
3. Prenatal diagnosis:
    1. Determination of glycosylated hemoglobin (HbA_{1c}) of the diabetic mother during the first trimester (Miller et al. 1981). There is a

significantly higher incidence of major congenital anomalies in the offspring of diabetic women with elevated first trimester HbA_{1c} values (>8%) (Reece and Hobbins 1986).
2. Maternal serum alpha-fetoprotein determination for the presence of associated neural tube defect.
3. Prenatal ultrasonography (Diabetic forum) (Reece et al. 1996a):
    1. Estimation of gestational age
    2. Evaluation of congenital malformations:
        1. Cardiac anomalies
        2. Skeletal anomalies
        3. CNS anomalies
        4. Renal anomalies
        5. Other anomalies
    3. Evaluation of fetal growth:
        1. Macrosomia
        2. Intrauterine growth retardation
    4. Assessment of fetal status
    5. Maternal hydramnios
4. Fetal echocardiography for congenital heart defects

4. Management (Fischer 1961):
    1. Pre-pregnancy and antenatal care in women with preexisting diabetes (Visser and de Valk 2015):
        1. Pre-pregnancy:
            1. Folic acid, 3–5 mg per day
            2. Optimization of glucose control
            3. Retinal examination
            4. Examination of urine for (micro) albuminuria
            5. Blood pressure control and medication in case of hypertension
            6. Counseling regarding increased incidence of fetal morphological malformations and regarding increased risk of (severe) hypoglycemic events during the first trimester
        2. Pregnancy:
            1. Adequate glucose control throughout pregnancy
            2. Counseling as to optimal weight gain during pregnancy, based on the maternal body mass index (BMI)
            3. Ultrasound examination for fetal malformations at 12–14 weeks and around 20 weeks of gestation
            4. Fetal growth assessment (abdominal and head circumference) every 4 weeks from 20 weeks onward and every 2 weeks after 28 weeks. Assessment of the amount of amniotic fluid volume
            5. Assessment of the incidence of fetal movements (as observed by the mother)
            6. Determining the timing and mode of delivery based on gestational age, glucose control, and estimated fetal weight
    2. To reduce the rate of congenital malformations in offspring of mothers with diabetes mellitus (Reece and Hobbins 1986):
        1. Preconceptional care and counseling
        2. Pregnant glycemic control to provide endocrine milieu necessary for normal embryogenesis
    3. Plan of delivery:
        1. Deliver newborn infant of the diabetic mother between 35th and 37th weeks of gestation
        2. Anticipate Cesarean section with identification of the macrosomic fetus
    4. Management of respiratory distress
    5. Management of hypoglycemia, hypocalcemia, and hypomagnesemia
    6. Management of cardiomyopathy and heart failure
    7. Management of congenital anomalies

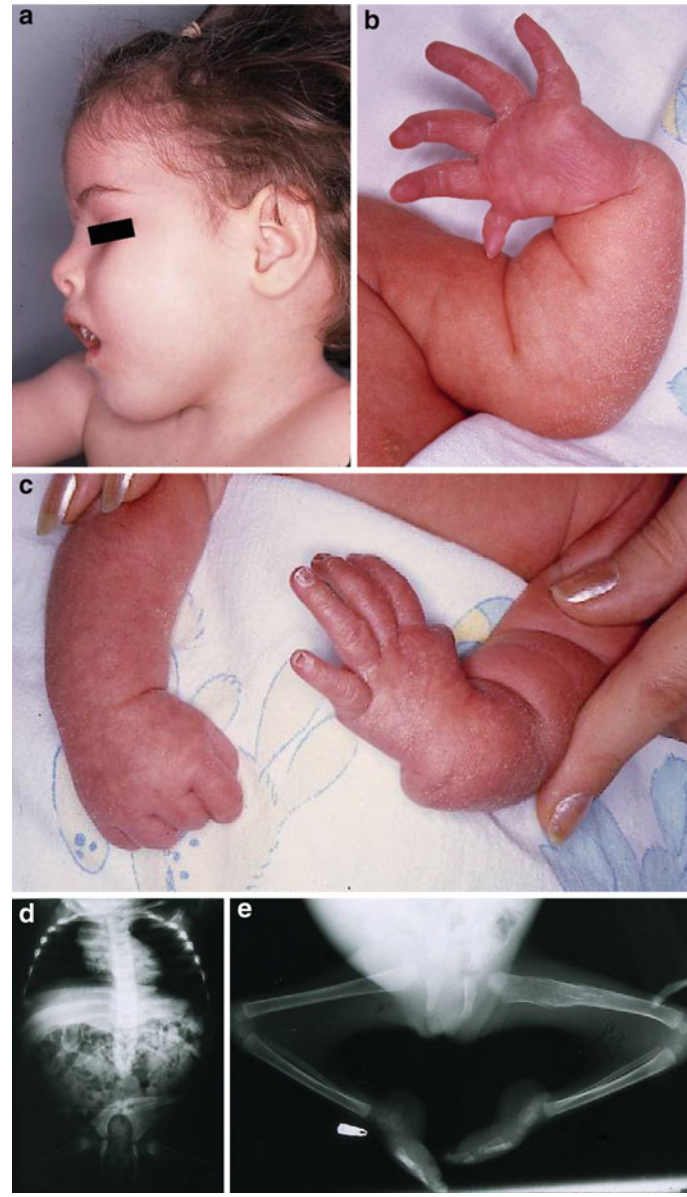

Fig. 1 (**a**–**e**) A girl, 2 years and 9 months old, with diabetic embryopathy showing left club hand with hypoplastic thumb and sacral agenesis with contractures of knees illustrated by radiographs

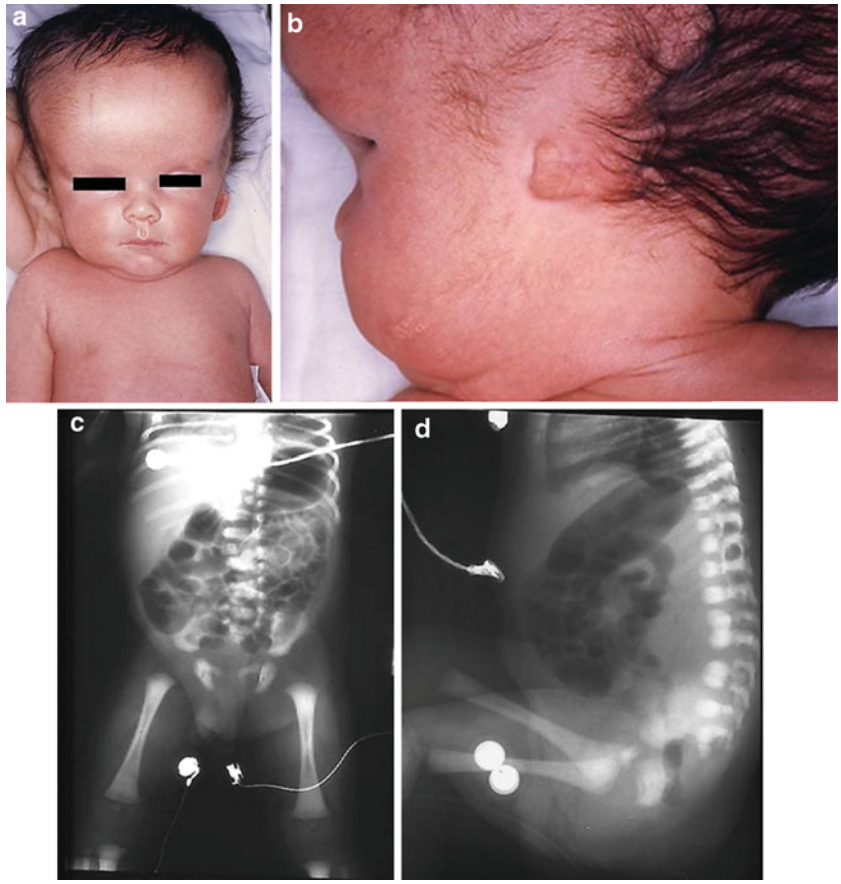

Fig. 2 (**a**–**d**) A newborn with diabetic embryopathy showing a large head due to hydrocephalus, depressed nasal bridge, short nose, micrognathia, microtia, right club hand, hemivertebrae, and caudal dysgenesis

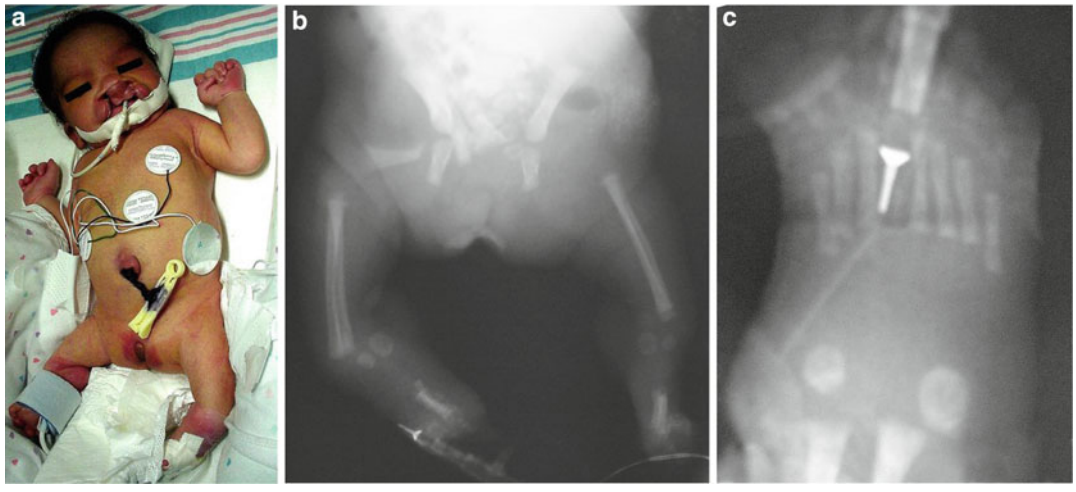

Fig. 3 (**a**–**c**) A newborn with diabetic embryopathy showing cleft lip/palate, caudal regression, femoral hypoplasia, and polydactyly

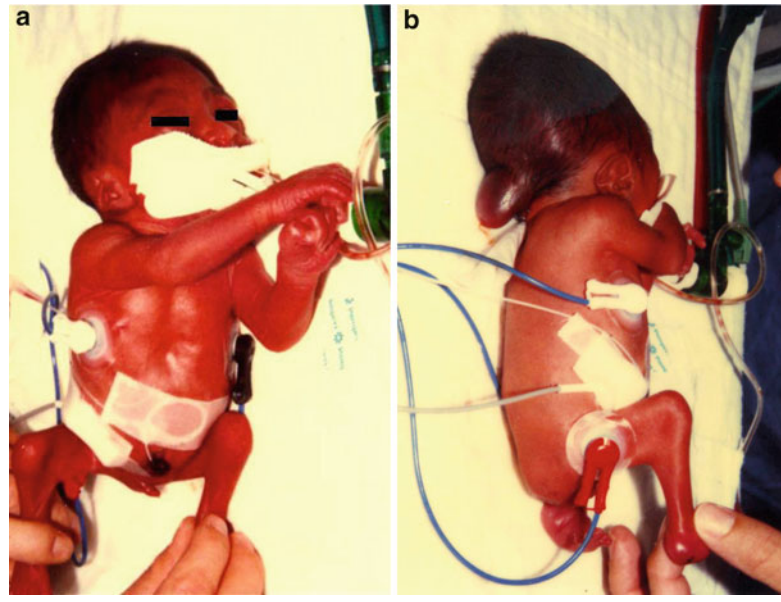

Fig. 4 (**a**, **b**) An infant born to the diabetic mother showing cystic hygroma with multiple contractures and multiple pterygia

Down Syndrome

Contents

In 1866, Down (1866) described clinical characteristics of the syndrome that now bears his name. In 1959, Lejeune et al. (1959) and Jacobs et al. (1959) independently determined that Down syndrome is caused by trisomy 21.

Down syndrome is by far the most common, the best known chromosome disorder in humans and the most common cause of intellectual disability (Peterson and Mikkelsen 2000). Mental retardation, dysmorphic facial features, and other distinctive phenotypic traits characterize the syndrome. Frequency is estimated to be 1 in 800 live births. Approximately 6,000 children are born with Down syndrome annually in the USA (Canfield et al. 2006). Major reviews of pathogenesis, epidemiology, clinical aspects, cytogenetics/nondisjunction, hematology/immunology, neurology, and social aspects are available (American Journal of Medical Genetics 1990).

Synonyms and Related Disorders

Trisomy 21 Syndrome

Genetics/Basic Defects

1. Caused by an extra chromosome 21
    1. Affect almost every organ system
    2. Result in a wide spectrum of phenotypic consequences
        1. Life-threatening complications
        2. Significant alteration of life course (e.g., mental retardation)
        3. Dysmorphic physical features
        4. Decreased prenatal viability
        5. Increased prenatal and postnatal morbidity
2. Typical physical phenotype due to an extra copy of the proximal part of 21q22.3
    1. Mental retardation
    2. Characteristic facial features
    3. Hand anomalies
    4. Congenital heart defects
3. 21q22.1-q22.3 region containing the gene (s) responsible for the congenital heart disease observed in Down syndrome (Korenberg et al. 1992)
4. Down syndrome critical region (DSCR): the region from 21q22.1 to 21q22.3 (McCormick et al. 1989; Rahmani et al. 1989; Opitz and Gilbert-Barness 1990)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_70

5. DCR-1: a region with the largest number of associated features, including facial and hand phenotypes and mental retardation
6. Types of trisomy 21
    1. Full trisomy 21 (94%)
    2. Mosaicism (2.4%)
    3. Translocations (3.3%)
        1. De novo (75%)
        2. Familial translocation (25%)
    4. Isochromosome 21
7. Origin of nondisjunction: maternal nondisjunction in the first meiotic division (75%, most common)
8. Well-documented risk factor for maternal meiotic nondisjunction: advanced maternal age (Roitzen and Patterson 2003)
9. Down syndrome due to translocation occurs independent of maternal age and may be inherited from either parent (Tolmie 2002)
10. Majority of mosaic cases result from a trisomic zygote with mitotic loss of one chromosome 21

Clinical Features

1. Growth and development
    1. Short stature
    2. Hypotonia which improves with age
    3. Moderate-to-severe mental retardation with IQ range of 20–85 (mean IQ is approximately 50)
    4. Articulatory problems
    5. Sleep apnea occurring when inspiratory airflow from the upper airway to the lungs is impeded for 10 s or more, often resulting in hypoxemia or hypercarbia
    6. Seizure disorder (5–10%)
        1. Infantile spasms (most common type of seizures seen in infancy)
        2. Tonic-clonic seizures (most commonly seen in older patients)
    7. Visual and hearing impairments in addition to the presence of mental retardation further limiting the child's overall function and may prevent the child from participating in significant learning processes and obtaining appropriate language development and interpersonal skills
    8. Obesity during adolescence
    9. Premature aging
        1. Decrease in skin tone
        2. Early graying or loss of hair
        3. Hypogonadism
        4. Cataracts
        5. Hearing loss (Roitzen et al. 1993)
        6. Age-related increase in hypothyroidism
        7. Seizures
        8. Neoplasms
        9. Degenerative vascular disease
        10. Loss of adaptive abilities
        11. Increased risk of senile dementia of Alzheimer type (Zigman et al. 1996)
2. Behavior
    1. Natural spontaneity
    2. Genuine warmth
    3. Cheerfulness
    4. Gentleness
    5. Patience
    6. Tolerance
    7. Anxiety
    8. Stubbornness
3. Psychiatric disorders
    1. Prevalence among children (17.6%)
    2. Prevalence among adults (27.1%)
    3. Children and adolescents at a higher risk for
        1. Autism
        2. Attention deficit hyperactivity disorder
        3. Conduct disorder
        4. Obsessive-compulsive disorder
        5. Tourette syndrome
        6. Depressive disorder during the transition from adolescence to adulthood
4. Skull
    1. Brachycephaly
    2. Microcephaly
    3. Sloping forehead
    4. Vertical creases on the forehead when crying ("Woolley" sign, named after the late mentor, Dr. Woolley)
    5. Flat occiput
    6. Large fontanels with late closure

7. Patent metopic suture
8. Absence of frontal and sphenoid sinuses
9. Hypoplasia of the maxillary sinuses

5. Eyes
   1. Upslanting palpebral fissures
   2. Bilateral epicanthal folds
   3. Brushfield spots (speckled iris)
   4. Refractive errors (50%)
   5. Strabismus (44%)
   6. Nystagmus (20%)
   7. Blepharitis (33%)
   8. Conjunctivitis
   9. Tearing from stenotic nasolacrimal ducts
   10. Congenital cataracts (3%)
   11. Pseudopapilledema
   12. Spasm nutans
   13. Acquired lens opacity (30–60%)
   14. Keratoconus
6. Nose
   1. Hypoplastic nasal bone
   2. Flat nasal bridge
7. Mouth
   1. Open mouth
   2. Tendency of tongue protrusion
   3. Fissured and furrowed tongue
   4. Mouth breathing
   5. Drooling
   6. Chapped lower lip
   7. Angular cheilitis
8. Teeth
   1. Partial anodontia (50%)
   2. Tooth agenesis
   3. Malformed teeth
   4. Delayed eruption
   5. Microdontia (35–50%) in both the primary and secondary dentitions
   6. Hypoplastic and hypocalcified teeth
   7. Malocclusion
   8. Taurodontism (0.54–5.6%)
   9. Increased periodontal destruction
9. Ears
   1. Small.
   2. Overfolded helix.
   3. Chronic otitis media.
   4. Hearing loss common. Between 66% and 89% of children have hearing loss of greater than 15–20 dB in at least one ear by auditory brainstem response.
10. Neck
    1. Atlantoaxial instability (14%) resulting from laxity of transverse ligaments that ordinarily hold the odontoid process close to the anterior arch of the atlas
    2. Laxity causing backward displacement of the odontoid process, leading to spinal cord compression
11. Chest
    1. Narrow chest
    2. Decreased internipple distance (Chen et al. 1974)
12. Congenital heart defects
    1. Common (40–50%).
    2. Frequently seen in hospitalized Down syndrome patients (62%).
    3. Common cause of death in the first 2 years of life.
    4. Endocardial cushion defect/atrioventricular canal (43%, most common type): About 70% of all endocardial cushion defects are associated with Down syndrome.
    5. Ventricular septal defect (32%).
    6. Secundum atrial septal defect (10%).
    7. Tetralogy of Fallot (6%).
    8. Isolated patent ductus arteriosus (4%).
    9. Multiple cardiac defects (30%). The most common associated lesions are patent ductus arteriosus (16%) and pulmonic stenosis (9%).
13. Abdomen
    1. Diastasis recti
    2. Umbilical hernia
14. Gastrointestinal (12%)
    1. Duodenal atresia or stenosis
    2. Hirschsprung disease (less than 1%)
    3. TE fistula
    4. Meckel diverticulum
    5. Imperforate anus
    6. Omphalocele
15. Genitourinary
    1. Renal malformations
    2. Hypospadias
    3. Micropenis
    4. Cryptorchidism

16. Musculoskeletal anomalies (Arumugam et al. 2015).
    1. Atlantoaxial (and atlantooccipital) instability (American Academy of Pediatrics Committee on Sports Medicine and Fitness 1995)
        1. Occurring in approximately 15% of individuals (<21 years old).
        2. Mildest asymptomatic form.
        3. Severe symptomatic subluxation or dislocation at the atlantoaxial joint may injure the spinal cord (cervical myelopathy) (1–2%). Neurologic manifestations include:
            1. Easy fatigability
            2. Difficulties in walking
            3. Abnormal gait
            4. Neck pain
            5. Limited neck mobility
            6. Torticollis (head tilt)
            7. Incoordination and clumsiness
            8. Sensory deficits
            9. Spasticity
            10. Hyperreflexia
            11. Clonus
            12. Extensor-plantar reflex
            13. Other upper motor neuron and posterior column signs and symptoms
            14. Rarely progressing to paraplegia, hemiplegia, quadriplegia, or death
    2. Short and broad hands
    3. Brachydactyly
    4. Clinodactyly of the fifth fingers with a single flexion crease (20%)
    5. Hyperextensible finger joints
    6. Increased space between the great toe and the second toe
    7. Acetabular dysplasia leading to pain, difficulty in gait, and subluxation of the hip joint
    8. Acetabular retroversion: the most common cause of posterior subluxation/dislocation of the hip in patients with DS
    9. Dislocation/subluxation of the patella, deformities such as genu valgum, pes planus, metatarsus primus varus, all of which have been attributed to ligament laxity (Galli et al. 2014)
17. Endocrine
    1. Thyroid disease
        1. Primarily autoimmune disorder with a lifetime prevalence of 13–63%
        2. Congenital hypothyroidism: about 28 times more common among infants with Down syndrome than in the general population with an incidence of 1% detected by newborn screening
            1. 0.7% permanent congenital hypothyroidism
            2. 0.3% transient congenital hypothyroidism
        3. Hypothyroidism in 16–20% of young patients
    2. Diabetes
    3. Decreased fertility
        1. Almost invariably infertile in males
        2. Decreased fertility in females
18. Hematologic
    1. Neonatal leukemoid reactions (i.e., pseudoleukemia) are common. To distinguish this from true leukemia is frequently a diagnostic challenge.
    2. 10- to 15-fold increased risk of developing leukemia in children with Down syndrome. Approximately 1 in 150 patients develops leukemia.
    3. Uniquely predisposed to clonal disorders affecting the megakaryocyte lineage in children with Down syndrome.
        1. Transient myeloproliferative disorder (also known as transient leukemia)
            1. Resolves spontaneously in most cases
            2. Develops acute megakaryoblastic leukemia in up to 30% of cases
        2. Acute megakaryoblastic leukemia
    4. An increased risk of hepatitis B carrier status if previously institutionalized
19. Immunodeficiency: Patients have about 12-fold increased risk of developing infectious diseases, especially pneumonia, secondary to impaired cellular immunity.

20. Upper airway obstruction
    1. Causes
        1. Large tonsils and adenoids
        2. Lingual tonsils
        3. Choanal stenosis
        4. Glossoptosis
    2. Consequences
        1. Serous otitis media
        2. Alveolar hypoventilation
        3. Arterial hypoxemia
        4. Cerebral hypoxia
        5. Pulmonary artery hypertension
        6. Cor pulmonale
        7. Heart failure
21. Skin
    1. Cutis marmorata
    2. Thickened nuchal folds
    3. Xerosis
    4. Localized hyperkeratotic lesions
    5. Elastosis serpiginosa
    6. Alopecia areata (up to 10%)
    7. Vitiligo
    8. Folliculitis
    9. Abscess formation
    10. Recurrent skin infections
22. Dermatoglyphics
    1. Distal axial triradius in the palms
    2. Transverse palmar creases
    3. A single flexion crease in the fifth finger
    4. Ulnar loops (often 10) in the digital patterns
    5. A pattern present in hypothenar and interdigital III regions
23. Significant health problems observed in adults with Down syndrome (Van Allen et al. 1999).
    1. Untreated congenital heart anomalies (15.8%)
    2. Acquired cardiac disease (15.8%)
    3. Pulmonary hypertension (7.8%)
    4. Recurrent respiratory infections/aspiration leading to chronic pulmonary interstitial changes (30%)
    5. Presenile dementia/Alzheimer-type disease (42%)
    6. Adult-onset epilepsy (36.8%)
    7. Osteoarthritic degeneration of the spine (31.6%)
    8. Osteoporosis with resultant fractures of the long bones or vertebral bodies (55%)
    9. Untreated atlantooccipital instability (7.9%)
    10. Acquired sensory deficits
        1. Loss of vision due to early onset of adult cataracts (50%)
        2. Recurrent keratitis (21%)
        3. Keratoconus (15.8%)
        4. Significant hearing loss (25%)
    11. Behavioral problems (50%)
    12. Loss of cognitive abilities and onset of symptoms of Alzheimer disease (group 1: 5.5%; group 2: 75%)
24. Prognosis
    1. Life expectancy
        1. Approximately 75% of conceptuses die in embryonic or fetal stage
        2. Approximately 85% of infants survive up to 1 year
        3. About 50% can be expected to live beyond the age 50 years
    2. Mobility and mortality
        1. Children with DS are at increased risk of leukemia and testicular cancer (Roitzen and Patterson 2003)
        2. Presence of congenital heart disease (most significant factor that determines survival)
        3. Esophageal atresia with or without TE fistula, Hirschsprung disease, duodenal atresia, infection, and leukemia adding to mortality
        4. Higher mortality rate later in life secondary to premature aging
        5. Most common causes of mortality in Down syndrome (Arumugam et al. 2015)
            1. Respiratory diseases (pneumonia)
            2. Congenital heart diseases
            3. Circulatory disorders
            4. Dementia

3. Phenotype of mosaic individuals: depends on the frequency and distribution of trisomic cells, with typical Down syndrome as the worst phenotype

Diagnostic Investigations

1. Serum triple screen.
    1. Alpha-fetoprotein
    2. Unconjugated estriol
    3. Human chorionic gonadotrophin
2. Common techniques used for diagnosis of Down's syndrome (Asim et al. 2015).
    1. Cytogenetic analysis
        1. Clinical diagnosis should be confirmed with cytogenetic studies.
        2. Karyotyping is essential for determination of recurrence risk: free trisomy 21 (93–96%), Robertsonian translocation (2–5%), reciprocal translocation (<1%), isochromosome (<1%), mosaicism (2–4%).
        3. In translocation or isochromosome Down syndrome, karyotyping of the parents and other relatives is required for proper genetic counseling.
        4. Giemsa banding (G-banding): performed on fetal cells at metaphase stage on amniocytes (grown in vitro) or CVS.
    2. Interphase fluorescence in situ hybridization (FISH)
        1. Involves hybridization of selected chromosome specific DNA sequences that have been labeled with fluorescent dye to chromosome preparation that can be visualized under microscope
        2. Used for rapid diagnosis
        3. Successfully applied to both prenatal diagnosis and diagnosis in the newborn period
    3. Quantitative fluorescent-polymerase chain reaction (QF-PCR)
        1. Involves amplification and detection of short tandem repeat using fluorescently labeled primers
        2. Highly reliable and reproducible
        3. Easily detects maternal contamination
        4. Can give diagnosis within 24 h
    4. Paralogous sequence quantification (PSQ)
        1. A PCR based method for detection of targeted chromosome number abnormalities, based on the use of paralogous genes
        2. Can handle 30–40 samples in a day and report result in less than 48 h
    5. Multiplex probe ligation assay (MLPA)
        1. Based on hybridization and PCR method
        2. Very short time for diagnosis (2–4 days)
    6. Next generation sequencing (NGS)
        1. Clonally amplified DNA templates are sequenced in a massively parallel shot gun sequencing
        2. Current time for sample processing, sequencing, and data interpretation in experienced hands: 5–8 days
3. Extraction of fetal cells from maternal circulation: After fetal nucleated red blood cells have been sorted using different cell transferrin and glycophorin-A receptors on the cell surface, interphase FISH can determine chromosome constitution. Chromosome-specific probes for X, Y, 13, 18, and 21 permit diagnosis. The FISH finding should be confirmed by standard cytogenetic techniques.
4. Thyroid function tests (Hardy et al. 2004): TSH and T4 should be obtained at birth and annually thereafter.
5. Measurement of IgG.
    1. Used to identify deficiency of IgG subclasses 2 and 4
    2. A significant correlation between decreased IgG subclass 4 and bacterial infections
    3. Cellular immunity deficits documented in individuals with gingivitis and periodontal disease
6. Skeletal radiography.
    1. Craniofacial anomalies include
        1. Brachycephalic microcephaly
        2. Hypoplastic facial bones and sinuses

2. Cervical spine X-rays (lateral flexion and extension views).
3. Required to measure the atlantodens distance for excluding atlantoaxial instability at 3 years of age.
4. Used prior to anesthesia if there are signs suggesting spinal cord compression.
5. Reduced iliac and acetabular angles in the young infant.
6. Short hands with shortened digits and clinodactyly due to hypoplastic middle phalanx of the fifth finger.

7. Echocardiography (Al-Biltagi 2013): This test should be performed on all infants with Down syndrome for identification of congenital heart disease, regardless of findings on physical examination.
8. Auditory brainstem response (ABR), also known as brainstem auditory evoked response (BAER), to demonstrate hearing loss. Evaluation of ABR in 47 unselected children with Down syndrome, aged between 2 months and 3 1/2 years, demonstrated some degree of hearing loss in 66% of the children examined (28% unilateral, 38% bilateral).
9. Speech evaluation.
10. Pediatric vision screening for ophthalmologic disorders.
11. Modified Denver Developmental Screening Test chart for noninstitutionalized children for assessing the developmental milestones (Chen and Woolley 1978).
12. Growth charts available for children with Down syndrome (Cronk et al. 1988).

Genetic Counseling

1. Recurrence risk (Chen 2015)
   1. Patient's sib
      1. Nondisjunction type: about 1% for younger women and approximates the age-related risk for older women (Nussbaum et al. 2004)
      2. De novo Robertsonian translocation type: 2–3%
   2. Familial Robertsonian translocation type
      1. Theoretical recurrence risk for a Robertsonian carrier parent to have a live-born Down syndrome offspring: 1 in 3
      2. The actual risks to future offspring depend on parental sex:
         1. Mother with rob(Dq;21q): 10–11%
         2. Father with rob(Dq;21q): 2.4%
         3. Mother with rob(21q;22q): 14%
         4. Father with rob(21q;22q): 1–2%
   3. A carrier parent with a 21q21q translocation or isochromosome: a 100% recurrence risk
   4. Gonadal mosaicism postulated for having more than one trisomic child in the family with apparently normal parents
   5. Patient's offspring
      1. Affected individuals rarely reproduce
      2. Females with trisomy 21: About 15–30% are fertile and have a 50% risk of having an affected child
      3. Males with trisomy 21: no evidence of fathering a child
2. Prenatal screening
   1. Advanced maternal age.
      1. The first prenatal diagnosis of Down syndrome made in 1968
      2. Gradual introduction of screening women on the basis of advanced maternal age with amniocentesis into medical practice
   2. Maternal serum biochemical markers (Rose 1996).
      1. Low maternal serum alpha-fetoprotein (MSAFP) shown to be associated with Down syndrome in 1983.
      2. Later, elevated human chorionic gonadotropin (hCG) and low unconjugated estriol (uE3) found to be the additional markers for Down syndrome.
      3. By 1988, the three biochemical markers, together with maternal age, were accepted as a method of prenatal screening for Down syndrome in the general population.
      4. Estimated detection rate when ultrasound is used to estimate gestational

age: 20% when using only the MSAFP test, 59% using the double test (MSAFP and hCG), and 69% using the triple test (MSAFP, hCG, uE3). The false positive rate is 5%. Other factors for adjustment are maternal age and weight, insulin-dependent diabetes mellitus, multiple pregnancy, ethnic origin, previous Down syndrome pregnancy, and first or repeat test in a pregnancy. A positive screening test suggests only an increased risk for having a Down syndrome fetus and that definitive testing by amniocentesis with chromosome analysis is indicated.

3. First-trimester free beta-hCG and pregnancy-associated plasma protein A retrospective screening study (Krantz et al. 1996) achieved rates as high as those associated with MSAFP, hCG, or uE3 in the second trimester.
4. First-∪trimester screening for Down syndrome using nuchal translucency, maternal serum pregnancy-associated plasma protein A, free-β human chorionic gonadotrophin, placental growth factor, and α-fetoprotein (Huang et al. 2015).

3. Prenatal diagnosis (rose 1996)
   1. Ultrasonography.
      1. Nuchal fold thickening identifies 75% of Down syndrome fetuses
      2. Shortened humerus or femur length detects 31% of cases
      3. Cystic hygroma
      4. Duodenal atresia or stenosis (double-bubble sign)
      5. Echogenic intracardiac focus
         1. Endocardial cushion defect with atrial and ventricular septal defects
         2. Abnormal mitral and tricuspid valves
      6. Hyperechogenic bowel
      7. Renal pyelectasis
      8. Slightly shortened femora
      9. Wider lateral flare of the iliac bones
      10. Other subtle sonographic signs
      1. Short ears
      2. Hypoplasia of the middle phalanx of the 5th fingers (clinodactyly)
      3. Choroid plexus cyst
      4. Delayed fusion of the amnion and chorion
      5. Simian crease of the hand
      6. Separation of the great toe ("sandal gap foot")
   2. Amniocentesis, CVS, or fetal blood sampling.
      1. FISH analysis of interphase cells or metaphase spreads
      2. Chromosome analysis
   3. Extraction of fetal cells from maternal circulation: Noninvasive prenatal testing using cell-free fetal DNA has very high sensitivity and specificity for Down syndrome, with slightly lower sensitivity for Edwards and Patau syndrome. However, it is not 100% accurate and should not be used as a final diagnosis for positive cases (Taylor-Phillips et al. 2016).
   4. Preimplantation diagnosis.
4. Management (Pueschel 1990; Carey 1992; Roitzen and Patterson 2003; Baum et al. 2008)
   1. Health supervision for children with Down syndrome (American Academy of Pediatrics Committee on Genetics 2001)
   2. Medical care
      1. Early intervention programs (Hines and Bennett 1996)
         1. Physical therapy
         2. Occupational therapy
         3. Speech therapy
         4. Special education programs
      2. Eye evaluation and management (Miyazaki 2014)
         1. Visual acuity
         2. Refractive errors
         3. Strabismus
         4. Amblyopia
      3. Hearing evaluation and management
      4. Thyroid hormone for hypothyroidism
      5. Medical management of congenital heart defects
         1. Digitalis and diuretics usually required

    2. Subacute bacterial endocarditis prophylaxis
6. Prompt treatment of respiratory tract infections and otitis media
7. Pneumococcal and influenza vaccines for children with chronic cardiac and respiratory disease
8. Anticonvulsants for seizures
9. Provide pharmacologic agents, behavioral therapy, and psychotherapy for behavioral/psychiatric disorders
10. Treat skin disorders
    1. Weight reduction
    2. Proper hygiene
    3. Frequent baths
    4. Application of antibiotic ointment
    5. Systemic antibiotics therapy
11. Prevent dental caries and periodontal disease
    1. Appropriate dental hygiene
    2. Fluoride treatments
    3. Good dietary habits
    4. Restorative care
12. Prevention of obesity
13. Monitor celiac disease
14. Vigilance
    1. Arthritis
    2. Atlantoaxial subluxation
    3. Diabetes mellitus
    4. Leukemia
    5. Obstructive sleep apnea
    6. Seizures
15. Megadoses of vitamins and minerals supplemented with zinc and/or selenium: have not shown benefits in a number of well-controlled studies
16. Transition from childhood to adulthood: to live well-adjusted and happy adult lives (Pueschel 1996)

3. Surgical care
    1. Presence of Down syndrome alone does not adversely affect the outcome of surgery in the absence of pulmonary hypertension.
    2. Timely surgery of cardiac anomalies necessary to prevent serious complications.
    3. Prompt surgical repair of the following gastrointestinal anomalies:
        1. TE fistula
        2. Pyloric stenosis
        3. Duodenal atresia
        4. Annular pancreas
        5. Aganglionic megacolon
        6. Imperforate anus
    4. Adenotonsillectomies may be required for obstructive sleep apnea.
    5. Surgical intervention may be necessary to reduce the atlantoaxial subluxation and to stabilize the upper segment of the cervical spine if neurologic deficits are significant.
    6. Extract congenital cataracts, which occur in about 3% of children, soon after birth with subsequent correction with glasses or contact lenses to assure adequate vision.
    7. Anesthetic airway management (Lin 1998).
        1. Adequate evaluation of the airway and neurological status
        2. Cervical spine radiography (flexion and extension views) when any neurologic deficits suggest spinal cord compression
        3. Avoid hyperextension of the head during laryngoscopy and intubation
        4. Prescribe anticholinergics to control airway hypersecretion
        5. Aware of other airway complications (subglottic stenosis and obstructive apnea resulting from a relatively large tongue, enlarged adenoids, and midfacial hypoplasia)
4. Prenatal treatment of Down syndrome (Guedj et al. 2014)
    1. To date, only EGCG has shown promising results in improving learning/memory in young adults affected with Down syndrome. These results are being confirmed in a multicenter larger study.
    2. Adult therapies, even if they prove to be successful, will only partially improve brain development and cognition in Down syndrome due to the fact that

there is a permanent loss of neuronal progenitors during fetal life.

3. This reduction of neurogenesis and synaptogenesis can potentially be rescued by administering safe and effective molecules to pregnant women as soon as a diagnosis of trisomy 21 is made.

Duncan Syndrome

Contents

In 1975, Purtilo et al. (1975) reported the Duncan pedigree in which 6 of 18 males died of a lymphoproliferative disorder. The boys, aged between 2 and 19 years, exhibited a progressive combined variable immunodeficiency disease characterized by benign or malignant proliferation of lymphocytes, histiocytosis, and alterations in concentrations of serum immunoglobulins. This condition is now known as Duncan syndrome or X-linked lymphoproliferative syndrome (XLP) which is a rare T and NK cell immune deficiency which most frequently presents as fulminant infectious mononucleosis following infection with the Epstein-Barr virus (EBV) in most affected boys, leading to death in 50% of the cases.

Synonyms and Related Disorders

X-Linked Lymphoproliferative Disease

Genetics/Basic Defects

1. An X-linked recessive disorder.
2. The gene causing XLP, identified and described in 1998 (Coffey et al. 1998), was termed *SH2D1A* or SAP [signaling lymphocyte activation molecule (SLAM)-associated protein]. The gene encodes a protein which interacts with the SLAM (or CD150, a T-cell surface marker, and self-ligand) and several related receptors (Sayos et al. 1998; Morra et al. 2001; Latour and Veillette 2003).
3. In XLP patients who lack functional SAP, the SLAM family receptors may not signal properly. This property likely contributes to the phenotypes of XLP, including fulminant infectious mononucleosis, lymphoma, and hypogammaglobulinemia (Nichols et al. 2005).
4. Macro- and microdeletion observed in the *SH2D1A* gene of XLP patients or their established B-cell line (Sumegi et al. 2000).
5. XLP is known to be caused by mutation of either of two genes (Filipovich et al. 2013).
   1. *SH2D1A*, encoding SH2 domain protein-containing protein 1A/SLAM-associated protein (SAP); this disorder is sometimes referred to as XLP1.
   2. *XIAP* (also known as *BIRC4*), encoding baculoviral IAP repeat-containing protein

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_71

4 (X-linked inhibitor of apoptosis; XIAP); this disorder is sometimes referred to as XLP2.

6. The immune response of XLP patients against EBV:
    1. Not efficient for the control of EBV expansion (in contrary to the coordinated immune response to EBV seen in normal individuals).
    2. Exhibit a dysregulated response characterized by an excessive accumulation of activated CD8+ T cells, natural killer (NK) cells, and macrophages and by the inability to control acute EBV infection.

Clinical Features

1. Diverse phenotype in affected boys.
2. Fulminant infectious mononucleosis (FIM) with virus-associated hemophagocytic syndrome (VAHS) (Gaspar et al. 2002).
    1. The most common and most dramatic manifestation of XLP with the worst prognosis (over 90% mortality).
    2. Clinically well until EBV infection, leading to a dysregulated and exaggerated immune response with proliferation of cytotoxic T cells, EBV-infected B cells, and macrophages in tissues throughout the body.
    3. Clinically manifests as pronounced lymph-adenopathy and hepatosplenomegaly, resulting in extensive parenchymal damage with accompanying dysregulated cytokine release.
        1. Most prominent in the liver, causing fulminant hepatitis and hepatic necrosis (Sullivan and Woda 1989), and in the bone marrow, leading to profound marrow hypoplasia.
        2. Infiltration in other tissues.
            1. Spleen (white pulp necrosis).
            2. Brain (perivascular mononuclear cell infiltrates).
            3. Heart (mononuclear cell myocarditis).
            4. Kidney (mild interstitial nephritis).
            5. Postmortem hemophagocytosis observed in various tissue in 90% of XLP boys presenting with FIM.
3. Dysgammaglobulinemia (Gaspar et al. 2002).
    1. Extensive necrosis and lymphoid depletion throughout the lymphoreticular system that follows acute EBV infection.
    2. Abnormal immunoglobulin (Ig) production after EBV infection: ranging from decreased levels of IgG to panhypogammaglobulinemia.
    3. Humoral dysfunction may accompany cellular T and natural killer (NK) defects in more severe cases.
4. Malignant lymphoma (Harrington et al. 1987; Gaspar et al. 2002).
    1. Found in approximately one third of boys with XLP, with B-cell lymphoma being the most common lymphoproliferative disorder observed.
    2. Median age: 4–6 years.
    3. Extranodal lesions: approximately 75% in ileocecal region and a smaller number in central nervous system, liver, and kidneys.
    4. Almost all the lymphomas were of B-cell origin but tumors with a T-cell phenotype have also been described.
    5. Lymphomas can be histologically classified as:
        1. Burkitt's lymphomas (53% of all B-cell lymphomas).
        2. Immunoblastic lymphomas (12% of all cases).
        3. Small cleaved or mixed cell lymphomas (12%).
        4. Unclassifiable lymphomas (5% of all cases) (Harrington et al. 1987).
        5. Four cases of Hodgkin's disease were reported to the XLP registry.
    6. Features of lymphomas in XLP: similar to those seen in other primary immunodeficiencies.

1. Extranodal involvement.
2. High-grade histology.
3. Evidence of clonality.
4. Gene rearrangements.

7. Poor survival rate (35%).
8. Remission can often be achieved with the use of standard pediatric lymphoma chemotherapy protocols but there is a high rate of relapse or development of the other manifestations of XLP.

5. Other clinical manifestations (Gaspar et al. 2002).
   1. Aplastic anemia can arise as a complication of fulminant infectious mononucleosis (Purtilo et al. 1982) with hemophagocytosis, leading to marrow aplasia. However, 3% of all cases can present initially as aplastic anemia.
   2. Lymphoid vasculitis.
      1. Another uncommon but well-described complication of XLP.
      2. Histological features: arterial wall destruction with aneurismal dilatation.
   3. Accompanied by various degrees of hemophagocytic lymphohistiocytosis.
6. Phenotype is likely determined by a number of factors, including the SAP mutation, and environmental and infectious factors on a background of disease modifier genes, as seen in other primary immunodeficiencies.
7. XLP without EBV infection: at least 10% of cases of XLP are driven without EBV infection.
8. Posttransplant lymphoproliferative disorder (PTLD) (Ho et al. 1988; Boyle et al. 1997).
   1. Primary EBV infection after transplantation: the major risk factor for the development of PTLD.
   2. Estimated to occur in 2–5% of all transplant recipients.
   3. More common in children since many children are EBV-naive at the time of transplant.
   4. Frequency of EBV infection in pediatric liver recipients: 63%.
   5. 3 clinical types of lymphoproliferative syndrome.
      1. The first type: self-limited mononucleosis-like syndrome.
      2. The second type: begins similarly, but then progresses over the next 2 months to widespread lymphoproliferation in internal organs and death.
      3. The third type: an extranodal intestinal monoclonal B cell lymphoma, occurring late after primary infection.
   6. Mortality rates reported for children who develop PTLD: high and range from 36% to 69%.
9. Males with XIAP deficiency (XLP2) (Filipovich et al. 2013).
   1. Typically present with hemophagocytic lymphohistiocytosis (HLH) (often without EBV infection), recurrent episodes of HLH, splenomegaly, and gastrointestinal disease and may be better described as having an X-linked form of familial hemophagocytic lymphohistiocytosis rather than XLP (Marsh et al. 2010).
   2. To date, neither lymphoproliferative disease (Pachlopnik Schmid et al. 2011) nor common variable immunodeficiency (CVID) has been reported in males with XIAP deficiency (Salzer et al. 2008).
   3. Of note, some males with pathogenic variants in XIAP are asymptomatic and their long-term prognosis is not known.
10. Diagnostic criteria for XLP (Conley et al. 1999).
    1. Definitive: male patients with a mutation in SAP.
       1. Lymphoma/Hodgkin's disease.
       2. Fatal EBV infection.
       3. Immunodeficiency.
       4. Aplastic anemia or lymphohistiocytic disorder.
    2. Probable.
       1. Male patients experiencing lymphoma/Hodgkin's disease, immunodeficiency,

plastic anemia or lymphohistiocytic disorder, resulting in death, following acute EBV infection.
2. Maternal cousins, uncles, or nephews with a history of similar diagnoses, following acute EBV infection.
3. Possible: male patients with lymphoma/Hodgkin's disease, immunodeficiency, plastic anemia, or lymphohistiocytic disorder, resulting in death, following acute EBV infection.

Diagnostic Investigations

1. Identification of SAP as the defective gene in XLP now allows unambiguous diagnosis of the condition.
2. Screen all male patients with common variable immunodeficiency (CVID) since some patients previously labeled as having CVID have been shown to have mutations in the SAP gene.
3. Prior to an encounter with EBV: no uniform abnormalities are observed on laboratory testing of individuals with XLP. Some individuals may have:
   1. Decreased numbers of lymphocyte subsets including decreased T cells, B cells, and NK cells.
   2. Variably decreased NK cell function.
   3. Dysgammaglobulinemia, most frequently manifest by low serum concentration of IgG with elevated serum concentration of IgM and/or IgA.
4. Evidence of acute EBV infections supported by:
   1. Heterophil antibodies on monospot testing.
   2. EBV detection by polymerase chain reaction (PCR).
   3. Detection of EBV-specific IgM antibodies.
   4. Atypical lymphocytosis on peripheral blood smear.
5. Specific tests suggesting the diagnosis of XLP in males with severe EBV infections:
   1. Markedly elevated liver transaminases.
   2. Inverted CD4:CD8 ratio in peripheral blood.
   3. Liver biopsy consistent with widespread necrosis during severe EBV infection.
   4. Bone marrow biopsy with evidence of hemophagocytosis during severe EBV infection.
   5. Positive EBV viral capsid antigen (VCA) titer, but negative Epstein-Barr virus nuclear antigen (EBNA) titer.
6. Molecular genetic testing (Filipovich et al. 2013): clinically available.
   1. Sequence analysis and deletion/duplication analysis of *SH2D1A*.
      1. Sequence analysis of the entire coding region of *SH2D1A* and exon/intron boundaries identifies nucleotide substitutions, small deletions, small insertions, small insertions/deletions, and small inversions.
      2. PCR-based sequencing can detect about 97% of *SH2D1A* mutations in affected males who have two or more maternally related family members with an XLP phenotype and about 75% of mutations in obligate carrier females.
      3. Large deletions account for about 25% of mutations in families with XLP.
      4. Because males have one X chromosome, the absence of amplification of a region of a gene under stringent laboratory conditions implies that a large deletion or rearrangement is present, and because females have two X chromosomes, amplification of a region occurs even in the presence of a large deletion because of the contribution of the second X chromosome; thus, PCR-based sequencing does not accurately detect a large deletion.
   2. Sequence analysis and deletion/duplication analysis of *XIAP*.
7. Carrier detection of at-risk female relatives: available on a clinical basis when the mutation has been identified in the proband or family relative.
8. Postmortem PTLD histology (Collins et al. 2001).
   1. Lymphoma.
   2. Hyperplasia.

3. Combined lymphoma and hyperplasia.
4. EBER1 messenger RNA detected in B-cell PTLD.

Genetic Counseling

1. Recurrence risk (Filipovich et al. 2013).
    1. Patient's sib: The risk to sibs depends upon the carrier status of the mother.
        1. Mother is a carrier: The chance of transmitting the disease-causing mutation in each pregnancy is 50%.
        2. Male sibs who inherit the mutation will be affected.
        3. Female sibs who inherit the mutation will be carriers but asymptomatic and have no immunologic or biochemical markers of the disorder.
        4. Presence of germline mosaicism of the mother: Even if the disease-causing mutation has not been identified in DNA extracted from the mother's leukocytes, her offspring are still at increased risk.
    2. Patient's offspring.
        1. Affected males will likely live to reproduce in the near-future following bone marrow transplantation and that the chemotherapy regimen used prior to BMT will not render them infertile.
        2. Males will pass the disease-causing mutation to all of their daughters and none of their sons.
3. Prenatal diagnosis (Filipovich et al. 2013).
    1. Fetal karyotyping to determine male fetus (46,XY).
    2. DNA extracted from fetal cells by amniocentesis or CVS analyzed for known gene mutation (SH2DA1 or XIAP pathogenic variant).
3. Preimplantation genetic diagnosis (PGD) may be an option for some families in which the pathogenic variant has been identified (Filipovich et al. 2013).
4. Management (Gaspar et al. 2002; Seiter 2015).
    1. All identified males receive immunoglobulin replacement to prevent bacterial and viral infections.
    2. Allogeneic hematopoietic stem cell transplantation (HSCT): the only definitive cure for XLP and prevention of EBV and non-EBV complications at present.
    3. Treatment is difficult during the acute FIM phase of XLP, as demonstrated by the high mortality rate.
        1. Treatment using antivirals (acyclovir/ganciclovir/foscarnet), high-dose immunoglobulin, immunosuppressive agents, and IFN-a and IFN-c have been disappointing.
        2. The high rate of hemophagocytosis associated with XLP has led to the use of antihistiocytic regimes with etoposide such as HLH-94 (Henter et al. 1997), for the treatment of boys with XLP, shown to induce long-term remission or to stabilize the patient prior to allogeneic HSCT.
        3. Etoposide has also been included in the conditioning regime in combination with busulphan and cyclophosphamide for some patients.
    4. Regular immunoglobulin replacement to prevent recurrent infection and additional bacterial prophylaxis in patients developing hypogammaglobulinemia postviral infection. This may not prevent subsequent development of malignant lymphoma or aplastic anemia. Patients with lymphoma have been treated according to standard chemotherapy protocols but there is a high rate of relapse and patients may also develop other phenotypes of XLP.
    5. Anti-CD20 rituximab: Preemptive use of B-cell-directed therapy may reduce the morbidity and mortality of primary EBV infection in X-linked lymphoproliferative disease (XLP)-affected individuals (Milone et al. 2005).

6. Successful bone marrow transplantation in a boy with X-linked lymphoproliferative syndrome and acute severe infectious mononucleosis (Pracher et al. 1994).
7. Autologous lymphokine-activated killer cell infusion: effective for treatment of EBV+ organ transplant recipients (Nalesnik et al. 1997).
8. Allogeneic stem cell transplantation.
    1. Currently only cure for XLP (Gross et al. 1996).
    2. Should be recommended in both symptomatic and asymptomatic XLP patients (Lankester et al. 2005).
9. Prospect of gene therapy as a future treatment option with the identification of the XLP gene.
    1. Recent success of gene therapy for the treatment of human severe combined immunodeficiency (SCID)-X1 disease offers hope for other immunodeficient conditions (Cavazzana-Calvo et al. 2000).
    2. Gene therapy for XLP is attractive in that the cellular defects are primarily confined to T and NK cells, both of which are readily accessible and can be efficiently transduced.

Sumegi, J., Huang, D., Lanyi, A., et al. (2000). Correlation of mutations of the SH2D1A gene and Epstein-Barr virus infection with clinical phenotype and outcome in X-linked lymphoproliferative disease. *Blood, 96*, 3118–3125.

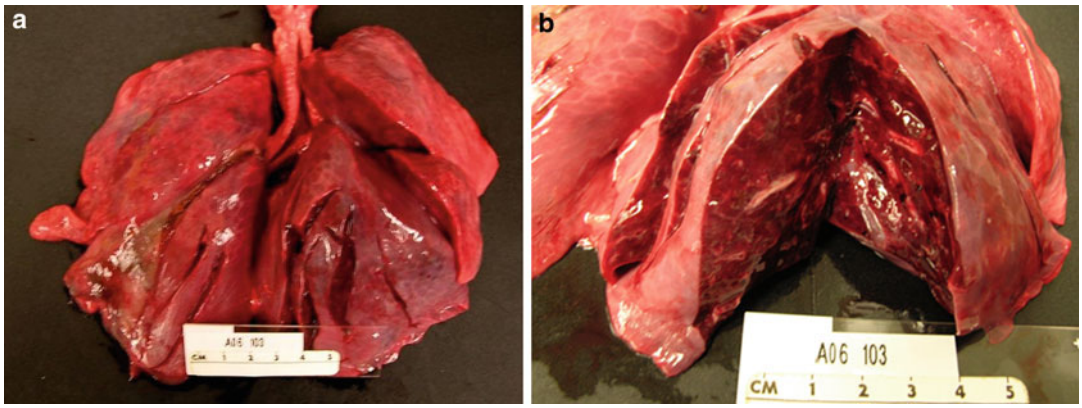

Fig. 1 (**a**, **b**) The deceased patient was a 4-year-old boy complained of fever, anemia, neutropenia, thrombocytopenia, and lymphadenopathy. He was noted to have cervical, axillary, and inguinal lymphadenopathy and hepatosplenomegaly. DNA analysis revealed a nonsense mutation, 172 C > T (Q56X), in the coding sequence of *SH12D1A* gene which confirmed the diagnosis of X-linked lymphoproliferative disease. A maternal first cousin is also affected with Duncan disease. On necropsy, both lungs appeared congested and the cut surface of both lungs was dark and airless with diffuse atelectasis

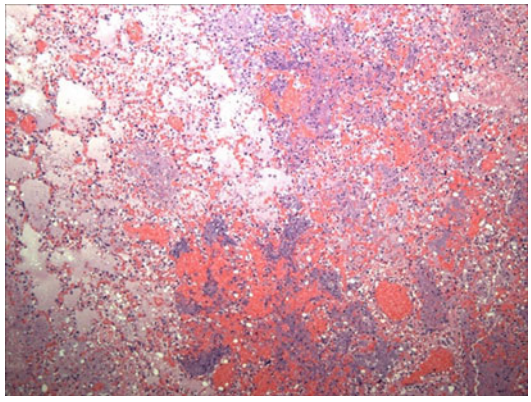

Fig. 2 Microscopic examination of the lungs showed congestion, hemorrhage, and edema with extensive gram-negative bacterial growth

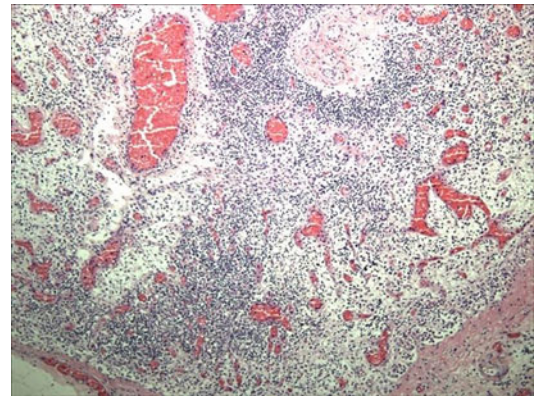

Fig. 3 The microscopic examination of the lymph nodes showed absence of germinal centers, depletion of the lymphocytes, sinus histiocytosis, and vascular congestion

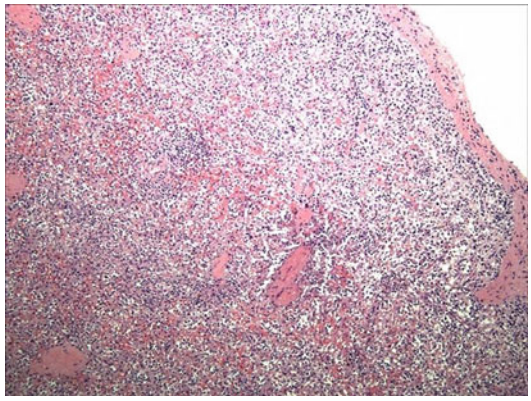

Fig. 4 Microscopic examination of the spleen showed lymphocyte depletion and rare megakaryocytes

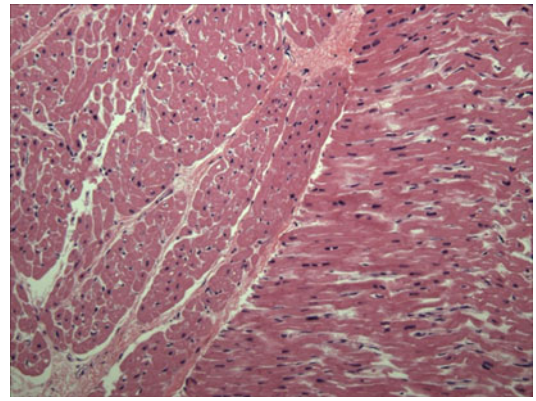

Fig. 6 Nuclei of heart muscles were enlarged, consistent with moderate hypertrophy

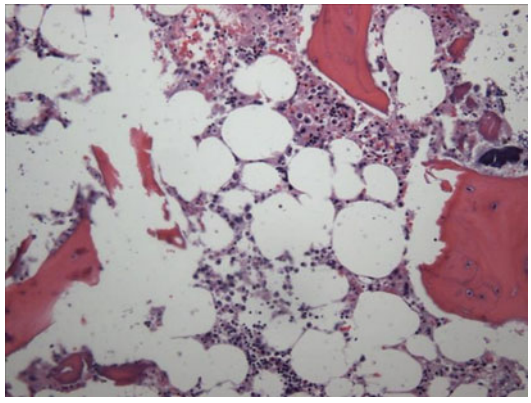

Fig. 5 Bone marrow was hypocellular with fat to cell ratio of 90:10 and very few mature lymphocytes

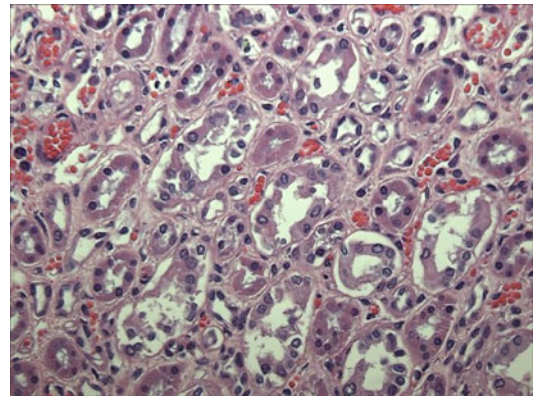

Fig. 7 Proximal tubules of the kidney were necrotic, consistent with ischemic changes

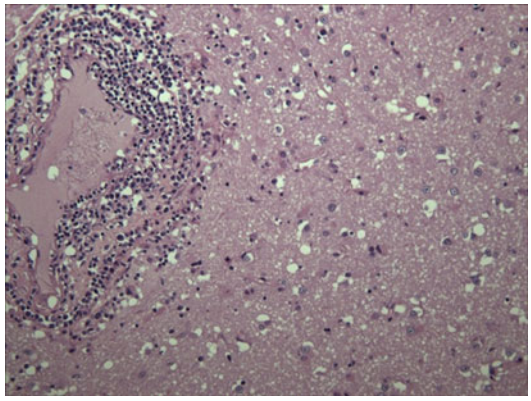

Fig. 8 The brain showed intense perivascular and mild patchy parenchymal infiltration with atypical reactive lymphocytes

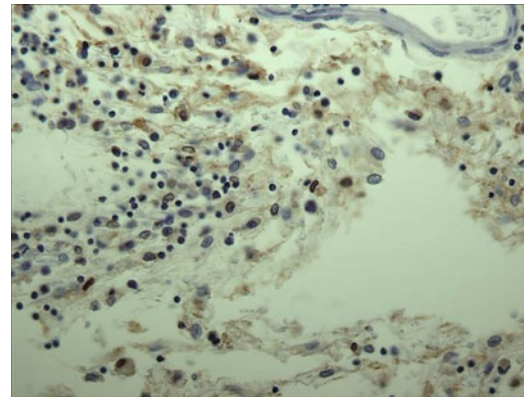

Fig. 10 Some cells in the infiltrate were positive for EB virus by FISH analysis

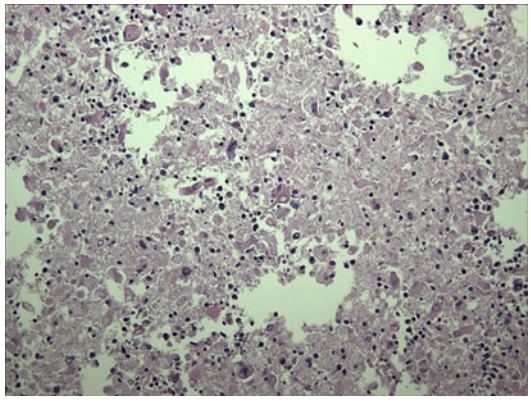

Fig. 9 The liquefied areas of the brain contained numerous foamy macrophages and the surrounding tissue contained numerous gemistocytes (active gliosis) in the RSFG, left corpus striatum, brain stem, and cerebellum

Dyschondrosteosis

Contents

Dyschondrosteosis is an autosomal dominant form of mesomelic dysplasia, first described by Leri and Weill in 1929. Langer mesomelic dysplasia, also called mesomelic dwarfism of the hypoplastic ulna, fibula, and mandible type (Langer 1967), is a more severe form (homozygous state) of Leri-Weill dyschondrosteosis.

Synonyms and Related Disorders

Langer mesomelic dysplasia; Leri-Weill syndrome (LWS)

Genetics/Basic Defects

1. Inheritance
    1. Dyschondrosteosis: autosomal dominant inheritance (Lichtenstein et al. 1980)
    2. Langer mesomelic dysplasia: pseudoautosomal dominant inheritance (Shears et al. 2002)
    3. The pseudoautosomal region 1 is a known recombination "hot spot" in male meiosis. Published genetic maps indicate high recombination frequency of ~40% for *SHOX* (short stature homeobox-containing) in male meiosis leading to pseudoautosomal inheritance. (Evers et al. 2011)
    4. Compound heterozygous deletions in pseudoautosomal region 1: reported in an infant with mild manifestations of Langer mesomelic dysplasia (Tsuchiya et al. 2014).
2. Molecular basis (Zinn et al. 2002)
    1. Caused by mutations and deletion of *SHOX* (short stature homeobox-containing) gene (Belin et al. 1998; Huber et al. 2001)
        1. The *SHOX* gene is mapped to Xp22.3 based on the observation of unbalanced translocation involving the pseudoautosomal region of the short arm of the X and Y chromosomes (PAR1) (Yp11.3) in dyschondrosteosis patients and of some degree of Madelung deformity in Turner syndrome patients (Guichet et al. 1997)
        2. The Xp22.3 region encompasses the pseudoautosomal *SHOX* gene, which encodes isoforms of a homeo-domain transcription factor expressed in developing human limbs

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_72

3. The gene in the Xp22.3 region escapes X-inactivation in females and participates in obligate recombination during male meiosis. Consequently, dyschondrosteosis segregates as an apparently "autosomal" dominant disorder
4. Duplications of cis-regulatory DNA elements can result in a SHOX-related phenotype (Bunyan et al. 2015)
5. 67% of mutations observed in patients with bilateral Madelung deformity (Flanagan et al. 2002)

2. In usual circumstances, *SHOX* is present in two identical copies (Binder and Rappold 2015)
   1. In females, one copy is present on each X chromosome
   2. In males, one copy is present on the X chromosome and one copy – sometimes called *SHOX(Y)* – is present on the Y chromosome
3. Haploinsufficiency of the *SHOX* gene implicated in the following disorders (Rao et al. 1997; Rappold et al. 2002; Binder 2011; Binder and Rappold 2015):
   1. Turner syndrome: *SHOX* is haploinsufficient in females with 45,X Turner syndrome, accounting for approximately 2/3 of the characteristic growth deficit
   2. Idiopathic short stature: Observation that a point mutation that cosegregates with idiopathic short stature suggests that *SHOX* haploinsufficiency may also cause growth failure in the patients with normal karyotype. *SHOX* mutations have been found in 2–3% of patients with idiopathic short stature
   3. Leri-Weill dyschondrosteosis (Palka et al. 2000) (including homozygous form of Langer mesomelic dysplasia)
   4. 45,X male: Loss of the *SHOX* gene associated with Leri-Weill dyschondrosteosis (Stuppia et al. 1999)
4. Identification of large-scale deletions or mutations in the *SHOX* gene in the majority of the cases
5. *SHOX* mutations: causative for mesomelic growth retardation, Madelung deformity in Leri-Weill dyschondrosteosis, and Langer mesomelic dysplasia (Barca-Tierno et al. 2012)
6. Leri-Weill syndrome as a part of contiguous gene syndrome with deletion of Xp22.3

3. Langer mesomelic dwarfism
   1. A homozygous state of dyschondrosteosis gene (Espiritu et al. 1975a, b; Fryns and Van den Berghe 1979; Kunze and Klemm 1980)
   2. Caused by deletion of both *SHOX* alleles (complete *SHOX* deficiency)
   3. Also associated with compound heterozygous mutations and deletions of the *SHOX* gene, mapped to the pseudoautosomal region 1 (PAR1) of the sex chromosomes Xp22.33 and Y11.32 or the downstream PAR1 where SHOX enhance elements are located
      1. A compound heterozygote with a deletion in the 3′ *SHOX* flanking region in one allele and the loss of the entire *SHOX* gene in the other has been described with a "mild" Langer mesomelic dysplasia phenotype (Fukami et al. 2005)
      2. Detection of two different deletions in a proband with clinical features of Langer mesomelic dysplasia in the pseudoautosomal 1 region (PAR1) of the X and Y chromosomes: a *SHOX* encompassing deletion inherited from his father and a downstream PAR1 deletion not including *SHOX* inherited from his mother (Campos-Barros et al. 2007)

Clinical Features

1. Dyschondrosteosis (LWS) (Carter and Currey 1974; Dawe et al. 1982)
   1. Phenotypic inter- and intrafamilial heterogeneity is a frequent finding in LWS (Schiller et al. 2000)
   2. Mesomelic dwarfism (disproportionate short stature) (Felman and Kirkpatrick 1970)

3. Phenotypic inter- and intrafamilial heterogeneity, a frequent finding
4. Much more common and less severe than Langer mesomelic dysplasia
5. Females more commonly and more severely affected (more severe Madelung deformity) than males (Ross et al. 2001)
6. Intelligence: normal
7. Limbs
    1. Mesomelia (disproportionate forelimb shortening)
        1. Shortened forearms
        2. Shortened forelegs
    2. A Madelung deformity of the forearms and wrists (Anton et al. 1938; Herdman et al. 1966; Felman and Kirkpatrick 1969; Beals and Lovrien 1976) secondary to bowing of the radius and dorsal subluxations of the distal ulna
    3. Reduced radiocarpal motion
    4. Limited elbow and wrist pronation and supernation
    5. Genu varum

2. Langer mesomelic dysplasia
    1. The homozygous form of Leri-Weill syndrome (Espiritu et al. 1975a, b)
    2. Severe disproportionate short stature with marked mesomelic and rhizomelic limb shortening
    3. Parents of some children with Langer mesomelic dysplasia have features of the more common dominantly inherited mesomelic skeletal dysplasia Leri-Weill dyschondrosteosis (Balci et al. 1999)
    4. Intelligence: normal
    5. Limb malformations
        1. Aplasia or severe hypoplasia of the ulna and fibula
        2. Thickened and curved radius and tibia
    6. Hypoplasia of the mandible
    7. A variable degree of Madelung deformity and mesomelic shortening in both parents
3. Prognosis
    1. Minimal disability from the Madelung deformities of the wrists
    2. Secondary arthrosis of the radiocarpal joint
    3. Osteoarthritis of the large joints
    4. Langer mesomelic dysplasia: much more severe phenotype than dyschondrosteosis
4. Skeletal dysplasias associated with Madelung deformity (Lamberti and Light 2014)
    1. Dyschondrosteosis: the most important skeletal dysplasia associated with Madelung deformity
    2. Multiple hereditary osteochondromatosis
    3. Ollier disease
    4. Achondroplasia
    5. Multiple epiphyseal dysplasias
    6. Mucopolysaccharidoses (e.g., Hurler and Morquio syndromes)

Diagnostic Investigations

1. Radiography (Langer 1965; Carter and Currey 1974)
    1. Mesomelic dysplasia
    2. Madelung deformity of the wrists
        1. Short forearm
        2. Bowed radius
        3. Bowed ulna
        4. Premature fusion of the ulnar half of the radial epiphysis
        5. A V-shaped deformity of the wrist with slanting at the distal radial contour and dorsal dislocation of the ulna
        6. Wedging of the carpal bones between the deformed radius and protruding ulna, resulting in a triangular configuration with the lunate at the apex
        7. Cubitus valgus
    3. Coxa valga
    4. Lateral subluxation of the patella
    5. Short tibia
    6. Exostosis of the proximal medial tibia
    7. Langer mesomelic dysplasia
        1. Aplasia or severe hypoplasia of the ulna and fibula
        2. Thickened and curved radius and tibia
2. Cytogenetic analysis (Binder and Rappold 2015)
    1. Rare patients with Leri-Weill dyschondrosteosis

1. A contiguous gene syndrome caused by deletion in distal Xp22.3 (Ballabio et al. 1989; Spranger et al. 1999)
2. An unbalanced X;Y translocation (Shears et al. 1998; Calabrese et al. 1999)
3. Complex sex chromosome abnormalities (Wei et al. 2001)

2. Submicroscopic deletions of SHOX causing the SHOX-related haploinsufficiency disorders: not usually detectable by G-banded karyotyping

3. Molecular genetic analysis (Schiller et al. 2000)
   1. *SHOX* deletions detected by FISH analysis using cosmid probe for *SHOX*
   2. Southern blot and SSCP analysis
   3. Long range PCR and sequencing
   4. MLPA for PAR1 deletions
   5. High-resolution melting (HRM), dHPLC, and/or DNA sequencing for point mutations, small deletions, and insertions of *SHOX*

Genetic Counseling

1. Recurrence risk
   1. Patient's sibs
      1. Leri-Weill dyschondrosteosis
         1. Neither parent is affected: not increased
         2. One parent is affected with Leri-Weill dyschondrosteosis: 50% affected with Leri-Weill dyschondrosteosis and 50% unaffected
         3. Two parents are affected with Leri-Weill dyschondrosteosis: 50% affected with Leri-Weill dyschondrosteosis, 25% affected with Langer mesomelic dysplasia, and 25% risk of having neither conditions
      2. Langer mesomelic dysplasia (both parents with Leri-Weill dyschondrosteosis): 50% affected with Leri-Weill dyschondrosteosis, 25% affected with Langer mesomelic dysplasia, and 25% unaffected
   2. Patient's offspring
      1. Leri-Weill dyschondrosteosis
         1. Spouse is normal: 50% affected and 50% unaffected
         2. Spouse is affected with Leri-Weill dyschondrosteosis: 50% affected with dyschondrosteosis, 25% affected with Langer mesomelic dysplasia, and 25% having neither condition
      2. Langer mesomelic dysplasia
         1. Spouse is normal: All children will be affected with Leri-Weill dyschondrosteosis
         2. Spouse is affected with Leri-Weill dyschondrosteosis: 50% affected with Langer mesomelic dysplasia and 50% affected with Leri-Weill dyschondrosteosis
   2. Prenatal diagnosis possible for at-risk families
      1. Prenatal ultrasonography of skeletal features compatible with mesomelic dwarfism
      2. Molecular analysis of previously identified disease-causing *SHOX* mutations in the proband or a parent from the fetal DNA obtained from amniocentesis or CVS
      3. Preimplantation genetic diagnosis may be available for families in which the disease-causing mutation has been identified
3. Management (Lamberti and Light 2014; Kozin and Zlotolow 2015)
   1. Medical therapy of Madelung deformity
      1. May be helpful in skeletally mature individuals with Madelung deformity who have mild-to-moderate short-term wrist pain
      2. Splints to relieve joint pain
      3. Decrease manual activity levels to manage symptoms without surgery
   2. Surgical therapy of Madelung deformity
      1. Primary goals: pain relief and cosmetic improvement of Madelung deformity

1. Minimal improvement of range of motion, especially in pronation and supination
2. Release of the Vickers ligament alone or in combination with an osteotomy
2. Radial dome osteotomy
3. Radioulnar length adjustment
4. Ulnar shortening osteotomy
3. Tibial osteotomy and lengthening combined with epiphysiodesis of the distal fibular epiphysis for the tibiofibular disproportion
4. Ongoing clinical trial with growth hormone therapy in patients with short stature due to *SHOX* mutations

Dysmelia

Contents

Dysmelia is a widely accepted term used to define a group of malformations in which there is hypoplasia, and partial or total aplasia of the tubular bones of the extremities, ranging from isolated peripheral hypoplasia to complete loss of the extremity. The condition is commonly known as limb deficiency or limb reduction defect. The prevalence rate for all types of limb deficiency is 0.69 per 1,000 (McGuirk et al. 2001).

Synonyms and Related Disorders

Amelia; Congenital limb deficiency/reduction; Ectromelia (ectrodactyly); Phocomelia; Thalidomide embryopathy

Genetics/Basic Defects

1. Causes: heterogeneous
   1. Known syndromes
      1. Holt-Oram syndrome (please see the chapter of "Holt-Oram Syndrome")
      2. Fanconi anemia (please see the chapter of "Fanconi Anemia")
      3. Split hand and foot malformation (SHFM) (Gurrieri and Everman 2013)
         1. This rare condition: affects 1 in 8,500–25,000 newborns
         2. Extremely complex because of its variability in clinical presentation, irregularities in its inheritance pattern, and the heterogeneity of molecular genetic alterations
         3. Caused by duplications in the 10q24.3 region (Vergult et al. 2013)
      4. Nonsyndromal SHFM caused by a 10q24 microduplication containing *FBXW4* gene
      5. Syndromal SHFM (occurs with extra-limb manifestations)
         1. EEC syndrome (most common) (please see the chapter "► Ectrodactyly-Ectodermal Dysplasia-Clefting (EEC) Syndrome")
         2. Limb-mammary syndrome
         3. ADULT (Acro-Dermato-Ungual-Lacrimal-Tooth) syndrome
         4. Rapp-Hodgkin syndrome
         5. AEC (ankyloblepharon-ectodermal dysplasia-clefting) syndrome (also called Hay-Wells syndrome), EEM syndrome
         6. Acro-cardio-facial syndrome

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_73

7. Karsch-Neugebauer syndrome
6. Thrombocytopenia-absent radius (TAR) syndrome (please see the chapter of "Thrombocytopenia-Absent Radius Syndrome")

2. Chromosome abnormalities
3. Teratogens
   1. Thalidomide (Tseng et al. 1996; Radomsky and Levine 2001)
      1. Probably the most potent primate teratogen known
      2. Between one in every two to one in every ten fetuses exposed at the critical development period were affected (Newman 1986)
      3. A hypnosedative drug, introduced and marketed as Contergan in Germany in the 1950s
      4. Promoted as a safe sedative and was found to be useful as an antiemetic during pregnancy, resulting in its widespread use throughout Europe in late 1960
      5. Has been used in the past few decades in a variety of dermatologic conditions (e.g., erythema nodosum leprosum, prurigo nodularis, actinic prurigo, discoid lupus erythematosus, aphthous stomatitis, Behcet syndrome, and graft-versus-host disease)
      6. Side effects: teratogenicity and peripheral neuropathy
      7. Producing a symmetrical pattern of deficiency (or polydactyly) on the preaxial side of both arms and legs
   2. Misoprostol (prostaglandin E1 analog)
      1. Asymmetrical digit loss
      2. Constriction rings
      3. Syndactyly
4. Fetal constraint/in utero limb compression (Graham et al. 1980; Graham 1986)
   1. Ectopic tubal gestation
   2. Uterine structural anomalies
   3. A large uterine fibroid
   4. Early amnion rupture
5. Vascular disruption
   1. Early chorionic villous sampling
      1. The risk for transverse deficiencies, especially of the central digits in the hand, is increased with chorionic villus sampling, particularly when performed before 10 weeks of gestation (Brumback et al. 2000; golden et al. 2003)
      2. Unilateral upper limb reduction (Boyd et al. 1990)
      3. Symmetrical digit loss
      4. Constriction rings
      5. Syndactyly
   2. Dilation and curettage
   3. Exposure to ergotamine
   4. Trauma to the abdomen and placenta
   5. Intrauterine thrombosis causing intrauterine vascular deficiency of the upper limb (Armstrong and Page 1997)
      1. Emboli from closure of ductus arteriosus, placenta, umbilical arteries
      2. Prematurity
      3. Maternal diabetes (venous thrombosis)
      4. Dehydration
      5. Polycythemia
      6. Protein C, S, and antithrombin III deficiencies
      7. Sepsis
      8. Congenital heart disease
      9. Musculoelastic ridge within a vessel
   6. Fetal vascular occlusive disease (Hoyme et al. 1982)
      1. Occlusion of the brachial artery secondary to embolization from the placental vascular thrombi
      2. A massive thrombus occluding the brachial artery secondary to hypovolemia and hypoperfusion associated with fetal blood loss during placental abruption
6. Vascular abnormalities such as cavernous hemangioma at the site of limb deficiency (Hall 1992)

7. A candidate gene for radial ray deficiencies: detected in the 7p22.1 deletion including the *RAC1* gene (Vergult et al. 2013)
8. Duplications of *BHLHA9*: associated with ectrodactyly and tibia hemimelia inherited in non-Mendelian fashion (Klopocki et al. 2012)
9. Unknown causes

2. The pattern of malformation in dysmelia (Henkel and Willert 1969)
   1. A diminution of skeletal material
   2. Disturbance of maturation of remaining skeletal elements
   3. Relationship of the malformed extremities to each other
3. A diminution of skeletal material: common to all malformations of dysmelia
   1. Reduction tendencies of individual bones: The reduction of the skeletal material of the individual bone follows a certain direction and sequence:
      1. Thumb: The reduction tendency of the thumb directs from proximal to distal
         1. Hypoplastic tubular bones of the thumb and the first metacarpal in the mildest cases
         2. Reduction of skeletal material beginning at the base of the first metacarpal in the more severe cases
         3. The shaft of the thumb becomes aplastic with increasing severity
         4. The last remnant of the first metacarpal is its head, followed by defective proximal phalanx.
         5. Preservation of the terminal phalanx until, in total aplasia, all bones of the thumb disappear
      2. Big toe and first metatarsal: the reduction tendency same as the thumb
      3. Radius and tibia: The reduction tendency directs from distal to proximal:
         1. Hypoplasia: the mildest degree of malformation of the radius or the tibia
         2. A defect seen in the distal part of the metaphysis with increasing severity, extending in a proximal direction with more severe deformities
         3. The head disappears last, before the radius or tibia becomes totally aplastic.
      4. Humerus and femur: The reduction tendency directs from proximal to distal:
         1. Hypoplastic: the mildest cases of the axial form of ectromelia.
         2. A defect of bone at the proximal end (just distal to the head of the humerus or in the region of the neck and the trochanter in the femur) in more pronounced cases.
         3. Distal epiphysis represents the last part of the humerus or the femur until it disappears in total aplasia.
   2. Reduction tendency of the limb as a whole:
      1. Upper limb
         1. Mild manifestations of the deformity restricted to the radial ray of the hand.
         2. With increasing severity, the radius becomes involved and only after the radius is either completely absent or its remnants have fused with ulna is the humerus affected.
      2. Lower limb
         1. Impairment of the tibia and the tibial ray in mild cases.
         2. The tibia need not be totally absent and its remnants need not be fused before the femur shows signs of reduction.
         3. The isolated malformations of the femur have been observed without impairment of the distal part of the limb.
      3. Coincidental impairment of the shoulder and pelvic girdles with the reduction of the limb mass
         1. The degree of the impairment dependents on the severity of the humeral or femoral defect.
         2. Most pronounced in phocomelia and amelia.

4. Reduction of the hand and fingers
    1. Strictly dependent on the severity of the defect of the skeleton of the arm.
    2. A decrease in the number of remaining fingers as the defect of the skeleton of the arm increases.
    3. Radial hypoplasia: All fingers may be present; their number is reduced to four or even three in the axial types and very often to one in phocomelia.
    4. The reduction of the hand starting at the thumb and progressing from the radial to the ulnar side, so that with increasing severity of the arm deficiency, the index, middle, and ring fingers are absent.
5. Reduction of foot in dysmelia
    1. Reduction progresses from the tibial to the fibular rays.
    2. Isolated malformations of the tibial ray: extremely rare in dysmelia.

3. The axis of malformation in dysmelia:
    1. Combination of the humerus, radius, and radial ray of the hand in an axis of malformation within the skeleton of the upper extremity, sparing the ulnar.
    2. Same combination seen in the lower extremity, where the axis is formed by the femur, the tibia, and the tibial ray of the foot, sparing the fibula.
    3. In the short axial types, the ulna or the fibula is the only long bone of the extremity that still exists.
4. Fusion of the adjacent bones:
    1. The skeletal elements undergoing fusion: always hypoplastic or partially aplastic.
    2. Fusion occurring in parallel bones (carpals, tarsals, metacarpals, metatarsals, radius, and ulna) or in bones arranged longitudinally (phalanges, humerus, and ulna).
    3. Tendency toward synostosis in the lower extremity appears to be limited to the bones of the foot.

4. Disturbance of maturation of remaining skeletal elements
    1. Retardation of cartilage ossification in bones not directly involved in the defect.
    2. Ossification centers far away from the part directly involved tend to ossify in a delayed manner.
5. Relationship of the malformed extremities to each other
    1. Bilateral and symmetrical in manifestation in most cases of amelia.
    2. Presence of lower limbs is observed in most patients with dysmelia of the upper extremity, even if the arms are phocomelic or amelic.

Clinical Features

1. Classification of dysmelia (Henkel and Willert 1969)
    1. Ectromelia:
        1. Definition: used to include those dysmelia in which the radius and the tibia with their peripheral rays and the humerus or the femur are involved.
        2. Classification (Henkel and Willert 1969): There is a need to subdivide into the distal, axial, and proximal forms of ectromelia because there are differences in manifestation and severity of skeletal abnormality and in some cases synostosis occurs as well as reduction.
            1. Distal form of ectromelia
            2. Axial form of ectromelia
            3. Proximal form of ectromelia
    2. Phocomelia:
        1. Definitions
            1. Used to include those dysmelia in which no remnants of long bones are seen between the limb girdle and the peripheral part (hands and foot)
            2. Used to describe the congenital anomaly in which a limb is represented by a flipper-like appendage
        2. Classification (Frantz and O'Rahilly 1961)

1. Type I: complete phocomelia (hand or digits attached directly to trunk)
2. Type II: proximal phocomelia (forearm bones between hand and trunk)
3. Type III: distal phocomelia (hand attached directly to humerus)

3. Unclassifiable limbs (Tytherleigh-Strong and Hooper 2003)
1. Type A: an abnormal humerus with an abnormal single forearm bone
2. Type B: an abnormal humerus with an abnormal radius and ulna
3. Type C: an abnormal humerus fused to a forearm bone or bones

3. Amelia: used to include the most severe degree of dysmelia in which there is total loss of an extremity

2. Distal form of ectromelia
1. Confined to the distal part of the extremity
2. Involving the radial ray of the hand and the radius only
1. Thumb type: the mildest degree of dysmelia, affecting the first ray of the hand only with the following two different manifestations:
1. Triphalangism of the thumb
2. Hypoplasia of the thumb
2. Radial type: sparing the ulnar
1. Hypoplasia of the radius
2. Hypoplasia of the radius with radioulnar synostosis
3. Partial aplasia of the radius
4. Partial aplasia of the radius with radioulnar synostosis
5. Total aplasia of the radius

3. Involving the tibial ray of the foot and the tibia only
1. Big toe type
1. Triphalangism of the big toe
2. Duplication of the big toe
2. Tibial type: sparing the fibula
1. Hypoplasia of the tibia
2. Partial aplasia of the tibia
3. Total aplasia of the tibia

3. Axial form of ectromelia
1. Involvement of the distal as well as the proximal part of the limb
1. Involving the radius, the radial ray of the hand, and the humerus
1. Sparing the ulnar
2. The malformed radius: hypoplastic, partly aplastic, or totally aplastic
3. The remnants of the radius in partial aplasia: regularly fused with the ulna, presenting as radioulnar synostosis
2. Involving the tibia, the tibial ray of the foot, and the femur
1. Sparing the fibula
2. The remnant of the tibia not showing tendency toward synostosis

2. Radial longitudinal/ray deficiency (RLD) (Bauer et al. 2013)
1. Most often bilateral, although the extent of involvement is usually asymmetric
2. Severity: ranges from mild thumb hypoplasia to complete absence of the radius, radial carpus, and thumb
3. Selected syndromes with radial ray deficiencies (Wilcox et al. 2015)
1. Thrombocytopenia absent radius syndrome
2. Holt-Oram syndrome
3. Vertebral defects, anal atresia, cardiac malformations, tracheoesophageal fistula, esophageal atresia, renal anomalies, and limb anomalies (VACTERL) association
4. Fanconi anemia
5. Radial ray deficiency, X-linked
6. Radial aplasia, X-linked
7. Radial ray hypoplasia with choanal atresia
8. Radial aplasia with cleft lip/palate
9. Radial hypoplasia, triphalangeal thumbs, hypospadias, and maxillary distema
10. Trisomy 18
11. Others

3. Ulnar longitudinal deficiency (Bauer et al. 2013)
1. Occurs far less often than RLD, at a rate of about 1 in 25,000 live births.
2. A sporadic, noninherited condition.

3. Unlike RLD, it is not associated with systemic conditions, but it has a strong association with other musculoskeletal conditions.
    1. Proximal femoral focal deficiency
    2. Postaxial lower extremity deficiency (fibular deficiency)
    3. Congenital scoliosis
    4. Hand and finger differences
    5. Upper limb involvement: most commonly unilateral
    6. Entire involved limb: usually hypoplastic.
    7. Elbow is abnormal or fused in most cases
4. Tibial hemimelia (please see the chapter of "Tibial Hemimelia")
5. Fibular hemimelia (please see the chapter of "Fibular Hemimelia")
6. The different degrees of reduction of the humerus or the femur leading to the upper and lower limb types:
    1. Upper limb type
        1. Long axial type of the arm: hypoplasia or partial aplasia of the humerus with partial aplasia of the radius and radioulnar synostosis or with total aplasia of the radius
        2. Intermediate axial type of the arm: subtotal aplasia of the humerus with partial aplasia of the radius and radioulnar synostosis or with total aplasia of the radius
        3. Short axial type of the arm: total aplasia of the humerus with partial aplasia of the radius and radioulnar synostosis or with total aplasia of the radius
    2. Lower limb type
        1. Long axial type of the leg: hypoplasia or partial aplasia of the femur with partial or total aplasia of the tibia
        2. Intermediate axial type of the leg: subtotal aplasia of the femur with partial or total aplasia of the tibia
        3. Short axial type of the leg: total aplasia of the femur with partial or total aplasia of the tibia
    3. Lower limb deficiency associated with other organ system defects (Le and Scott-Wyard 2015)
        1. Tibial deficiency: deafness, ectrodactyly or polydactyly of the hands, craniofacial abnormalities
        2. Femoral hypoplasia-unusual facies syndrome (please see the chapter of "Femoral Hypoplasia: Unusual Facies Syndrome"): bilateral femoral deficiency, facial abnormalities including micrognathia and cleft palate, hypoplasia or synostosis of the upper extremity, vertebral abnormalities, congenital heart disease, and polydactyly
        3. Roberts or SC phocomelia syndrome (please see the chapter of "Roberts Syndrome"): bilateral symmetric tetraphocomelia, thumb aplasia, syndactyly, elbow and knee flexion contractures, mental retardation, cleft lip/palate, micrognathia, hypotelorism, cryptorchidism, and cardiac defects
        4. Sacral agenesis: hemipelvectomy or hip disarticulation and is often associated with neurogenic bowel and bladder
4. Proximal form of ectromelia
    1. Can be found only in the lower limb
    2. No parallel defect in the upper limb
    3. Only involves the proximal part of the lower limb, the femur (proximal focal femoral deficiency) (Bedoya et al. 2015), which can display all different degrees of reduction, leading to the following subtypes:
        1. Long proximal type: hypoplasia of the femur, coxa vara or partial aplasia of the femur without impairment of the distal part of the limb
        2. Intermediate proximal type: subtotal aplasia of the femur without impairment of the distal part of the limb
        3. Short proximal type: total aplasia of the femur without impairment of the distal part of the limb

5. Phocomelia
    1. Absent humerus, radius, and ulna or femur, tibia, and fibula
    2. Remainder of the extremity
        1. Consisting of a malformed hand formed by one, two, or three ulnar finger rays and ulnar parts of the carpus or of a similarly affected foot
        2. Directly attached to a hypoplastic shoulder girdle or to a misshapen pelvis
6. Amelia
    1. The most severe form of dysmelia
    2. Total absence of the arm or the leg
    3. Shoulder girdles: hypoplastic in the absence of the arms
    4. Pelvis: deformed in a box-like shape in the absence of the legs
7. Selected syndromes with multiple limb deficiencies (Wilcox et al. 2015)
    1. Acheiropody: hypoplasia/aplasia of the radius, ulna, tibia, fibula, and distal humerus and aplasia of hands and feet
    2. Acromesomelic dysplasia, Hunter-Thompson type: hypoplastic ulna, tibia, fibula, small fingers and toes
    3. Amelia, autosomal recessive
        1. All limbs absent
        2. May have defects in other organs
    4. Anonychia-onchodystrophy with hypoplasia or absence of distal phalanges (Cooks syndrome)
        1. Triphalangeal thumb, hypoplasia/aplasia of distal phalanges
        2. Nail dysplasia or anonychia
    5. Aprosencephaly
        1. Oligodactyly, radiohumeral fusion
        2. Brain and craniofacial malformations
    6. Brachial amelia, cleft lip, holoprosencephaly
        1. Upper limb amelia, femoral, fibular hypoplasia, oligodactyly
        2. Cleft lip, holoprosencephaly, omphalocele, congenital heart disease
    7. CHARGE syndrome
        1. Can have a variety of limb deficiencies
        2. Ocular coloboma, congenital heart disease, choanal atresia, retarded growth and development, genital anomalies, ear anomalies, and deafness
    8. Faciocardiomelic dysplasia
        1. Radial, ulnar, tibial, fibular, digital hypoplasia
        2. Micrognathia, macroglossia, microstomia, congenital heart disease
    9. Grebe dysplasia: radial, ulnar, tibial, fibular hypoplasia, small fingers and toes, polydactyly
    10. Hanhart syndrome (hypoglossia-hypodactylia)
        1. Variable hypoplasia/aplasia of any segment
        2. Hypoglossia, hypoplastic mandible
    11. Laryngeal atresia, encephalocele, limb deformities
        1. Radial, ulnar, tibial hypoplasia, oligodactyly
        2. Laryngeal atresia, encephalocele, renal anomalies
    12. Mesomelic dysplasia, Kantaputra type: ulna > radial, fibula > tibia hypoplasia
    13. Mesomelic dysplasia, Langer type
        1. Radial, ulnar, fibula > tibia hypoplasia
        2. Micrognathia
    14. Microgastria-limb reduction defects association
        1. Hypoplasia of the upper limb
        2. Microgastria, hypoplastic lungs, genitourinary anomalies
    15. Nievergelt mesomelic dysplasia: hypoplasia of the radius, ulna, tibia, fibula
    16. Orofacial digital syndrome type 10
        1. Radial and fibular hypoplasia, oligodactyly, preaxial polydactyly
        2. Dysmorphic facies, oral frenula
    17. Roberts syndrome (SC phocomelia)
        1. Humeral, radial, ulnar, femoral, tibial, fibular hypoplasia/aplasia; upper extremities more severely affected than lower; may have tetraphocomelia, oligosyndactyly
        2. Cleft lip/palate, congenital heart disease, microcephaly, intellectual disability
    18. Rodriguez acrofacial dysostosis
        1. Radial, ulnar, humeral, fibular hypoplasia/aplasia to phocomelia, oligodactyly

2. Micrognathia, microtia, brain, cardiac, and lung malformations
19. Skeletal defects, genital hypoplasia, mental retardation
    1. Hypoplasia of all segments, hypoplastic clavicle and scapula, oligodactyly
    2. Genital hypoplasia, microcephaly, dysmorphic facies, intellectual disability
20. Tetramelic monodactyly: only 5th digit present
21. Tukel syndrome
    1. Postaxial oligosyndactyly,
    2. Opthalmoplegia

8. Differential diagnosis (Tseng et al. 1996; Radomsky and Levine 2001)
    1. Transverse limb defects
        1. Adam-Oliver syndrome
        2. Amniotic band sequence
        3. Oromandibular limb hypogenesis syndrome
        4. Poland anomaly
        5. Fetuses with homozygous α-thalassemia (Lam et al. 1997)
    2. Preaxial limb defects
        1. Chromosome syndromes
        2. Facio-radial syndromes (e.g., Nager syndrome)
        3. Hemato-radial syndromes
            1. Aase syndrome
            2. Fanconi anemia
            3. TAR syndrome
        4. Holt-Oram syndrome
        5. Poland anomaly
        6. Roberts syndrome
        7. VATER association
    3. Central limb defects
        1. EEC syndrome
        2. Poland anomaly
    4. Postaxial limb defects
        1. Cornelia de Lange syndrome
        2. Facio-ulnar syndromes (e.g., Miller syndrome)
        3. Femur-fibula-ulna complex
        4. Ulnar mammary syndrome
    5. Amniotic band syndrome and other mechanical and constraint problems
        1. Digital constrictions and amputations
        2. Transverse amputations of the distal and proximal limbs, with a normal limb above the amputation
        3. Amelia
    6. Vascular compression, disruption thrombosis, embolization
        1. Transverse amputations
        2. Postaxial and preaxial limb reduction defect
        3. Femoral hypoplasia
        4. Digital amputation or hypoplasia
        5. Poland anomaly
    7. Genetic diseases
        1. Bilateral and unilateral limb reduction defect of preaxial or postaxial type
        2. Ectrodactyly (Nair et al. 2011)
            1. An autosomal dominant ectodermal dysplasia presenting as bilateral congenital malformed hands and feet.
            2. Affects about 1 in 90,000 births with males and females equally as likely to be affected.
            3. Characterized by transverse terminal aphalangia or partial to total absence of the distal segments of fingers.
            4. May involve one or more digits or the full hand and even part of the upper arm. More severe manifestations are hemimelia or amelia.
            5. All these abnormalities are considered to represent various degrees of severity of the same anomaly and may be due to an intrauterine vascular occlusion or insufficiency.
            6. These different forms are connected with a different genetic mutation.
            7. Ectrodactyly type I, the most frequent form, has been found to be a mutation on chromosome 7 in a region that contains two homeobox genes, *DLX5* and *DLX6*.
            8. Usually, this is characterized as the split hand/foot deformity due to the absence of the third digit, with clefting into the proximal portion of the hand or foot and syndactyly of

remaining digits on each side of the cleft. The hand resembles a lobster claw.
3. Monodactyly
4. Limb reduction defects as features of many different genetic disorders, such as absent radius with absence/hypoplasia of the thumb

8. Cytogenetic abnormalities (e.g., del(13q) syndrome and trisomy 18 syndrome) (Christianson and Nelson 1984)
1. Severe limb hypoplasia
2. Polydactyly
3. Absent thumb
4. Absent radius
5. Other multiple congenital anomalies

9. Thalidomide embryopathy (Mongeau et al. 1966; Newman 1986; Brent and Holmes 1988; Radomsky and Levine 2001)
1. Deformities of the upper and lower extremities: grossly symmetric, although opposite limbs are often unequally affected to some degree
1. Phocomelia
2. Amelia
3. Bone hypoplasia
4. Absence of bones
5. Paraxial hemimelia
6. Transverse hemimelia
7. Dyscheiria
8. Dyspodia
2. Malformed external ears
1. Anotia
2. Micropinna
3. Small or absent auditory canals
3. Abnormalities of the eyes
1. Anophthalmia
2. Microphthalmos
3. Coloboma
4. Cataracts
4. Face
1. Hypoplastic nasal bridge
2. Choanal atresia
3. Facial palsy
5. CNS malformations
1. Facial nerve paralysis
2. Deafness
3. Marcus Gunn or jaw-winking phenomenon
4. Crocodile-tear syndrome
5. Seizure disorder
6. Respiratory tract anomalies
1. Laryngeal and tracheal abnormalities
2. Abnormal lobulation of the lungs
7. Cardiovascular anomalies
1. Capillary hemangioma, extending from dorsum of the nose to the philtrum in the midline
2. Congenital heart diseases (conotruncal defects)
8. Gastrointestinal anomalies
1. Upper intestinal atresia
2. Congenital absence of the gall bladder and the appendix
3. Anal stenosis
4. Inguinal hernias
9. Renal anomalies
1. Abnormal rotation of the kidney
2. Pelvic position of the kidneys
3. Horseshoe kidney
4. Hydronephrosis
5. Double ureter
10. Genital anomalies
1. Double vagina
2. Vaginal atresia
3. Rectovaginal fistula
4. Cryptorchidism
11. Other malformations
1. Aglossia
2. Teratoma at the sacral region
3. Fissure of the mandible
12. Mortality: 40% at or shortly after birth

10. Warfarin and diphenylhydantoin
1. Digital hypoplasia
1. Usually mild
2. Can be severe
2. Limb hypoplasia due to chronic exposure throughout gestation, usually very mild

11. Maternal diabetes
1. Femoral hypoplasia
2. Sacral agenesis

Diagnostic Investigations

1. Radiography (Cobben et al. 1994)
    1. Evaluate limb defects
    2. Evaluate nonlimb skeletal defects
2. Diagnostic protocol for preaxial defects
    1. Blood count including thrombocytes
    2. Hb F (electrophoresis)
    3. Urine sediment
    4. Renal sonography
    5. Echocardiography
    6. Chromosome analysis
    7. Audiologic evaluation
    8. Ophthalmologic evaluation

Genetic Counseling

1. Recurrence risk (Cobben et al. 1994)
    1. Patient's sib
        1. Genetic syndromes: depending on the inheritance pattern of the disorder
        2. Chromosome abnormalities: about 1% unless the parent carries a translocation
        3. Environmental factors: not increased unless the mother exposes to the teratogen during pregnancy
        4. Nonsyndromic nonfamilial reduction defects of one limb
            1. Transversal: <1%
            2. Postaxial: <1%
            3. Preaxial: low
            4. Central: low
        5. Nonsyndromic nonfamilial reduction defects of more than one limb
            1. Transversal: probably low
            2. Postaxial: probably low
            3. Preaxial: unknown
            4. Central: unknown
    2. Patient's offspring
        1. Genetic syndromes: depending on the inheritance pattern of the disorder
        2. Chromosome abnormalities: patients usually not surviving to reproduction
        3. Environmental factors: not increased unless patient exposes to the same teratogen during pregnancy
        4. Nonsyndromic nonfamilial reduction defects of one limb
            1. Transversal: <1%
            2. Postaxial: <1%
            3. Preaxial: probably low
            4. Central: probably low
        5. Nonsyndromic nonfamilial reduction defects of more than one limb
            1. Transversal: possibly low
            2. Postaxial: possibly low
            3. Preaxial: unknown
            4. Central: autosomal dominant
2. Prenatal diagnosis
    1. Transvaginal sonography: an important element in the evaluation of any first trimester limb deficiencies
    2. Second trimester ultrasonography to detect limb deficiencies and other associated anomalies (Rijhsinghani et al. 1995; Piper et al. 2015)
    3. Chromosome analysis from amniocentesis or CVS to rule out chromosome anomaly
3. Management
    1. Avoid using teratogenic agents during pregnancy
    2. Management of malformation of the upper extremities
        1. Bilateral upper extremity: amelia and/or phocomelia
            1. Good prosthetic fitting of children based primarily on relating prosthetic function to the functional needs of the patient to be fitted
            2. Satisfactory foot function, a prerequisite to the prosthetic habilitation of the severe bilateral upper limb problem in children
            3. Compensatory prehension patterns developed by the feet, helpful particularly in total toilet care and total dressing and undressing
            4. The combination of the 3 prime functional patterns (self-feeding, toilet care, and total dressing and undressing), plus the acquired secondary functional patterns (writing, control of light switches, ability to open and close doors, ability to

operate radio and television, card-playing, etc.) produces a gratifying level of rehabilitation (Aitken 1964)

2. Upper extremity: paraxial hemimelica
   1. Passive stretching
   2. Application of splints to stabilize the wrists
3. Bilateral transverse hemimelia: fit with standard prostheses with hooks as terminal devices
4. Prosthetic treatment of upper limb deficiency: casting and fitting techniques applicable to transverse forearm loss with myoelectric hand prostheses (Curran and Hambrey 1991)

3. Management of malformation of the lower extremities
   1. Lower extremity bilateral phocomelia (Lamb et al. 1970)
      1. Fit with a special bucket on a pair of short skis to develop balance
      2. Prostheses (McLaurin swivel walker for children) to help walking
   2. A transverse lower limb deficiency: fits with conventional prosthesis (Hirons et al. 1991)
4. Occupational therapy: exercise and other treatment of the upper extremities to increase strength and dexterity to prepare to operate prostheses
5. Prosthetic training of the children
6. Parents' contribution
   1. Observation of the child's training session
   2. Parent to learn to:
      1. Put on and remove prostheses
      2. Care and encourage use of the prostheses
      3. Cleanse the stump
7. Prosthetic devices
   1. Every effort to be made to develop a prosthesis that will compensate for the absence of functions and restore independence to the greatest possible degree
   2. Main objectives
      1. To assist the child to develop a normal body image
      2. To construct a prosthesis based on sound anatomical principles which has an adequate range of motion
      3. To fit the prosthesis early so that, at a few months of age, the child unconsciously accepts it as a part of his body
8. Psychosocial counseling
   1. To assist parents to cope with the situation
   2. To explain the plan of treatment to parents
   3. Overall success of a given family in accepting and adjusting to a congenital deformity: related to its educational level and the usual pattern of behavior of its members under stress

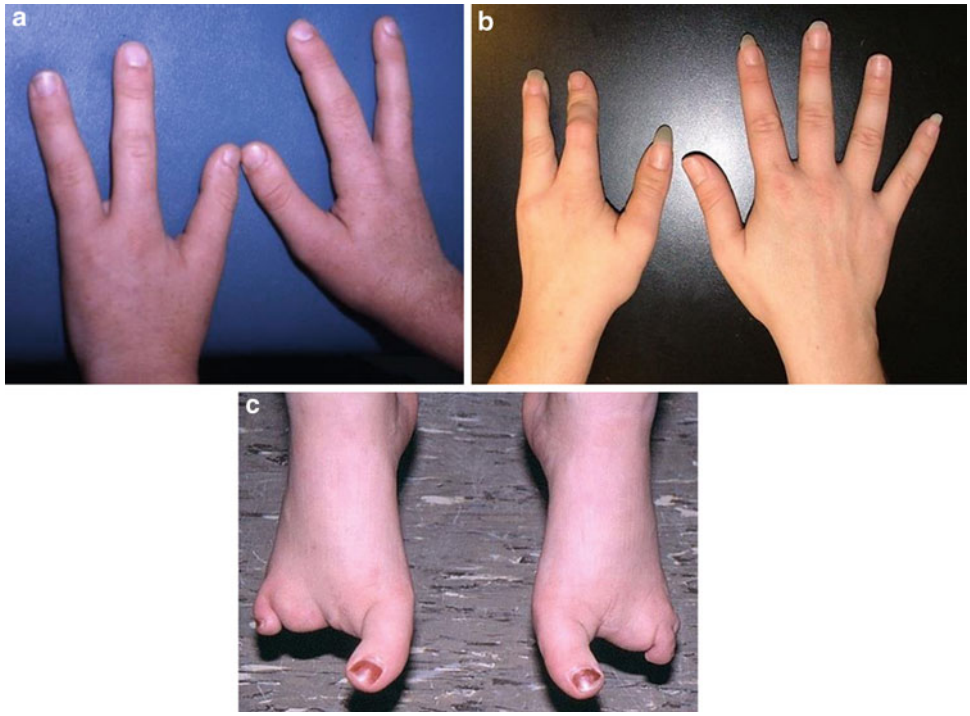

Fig. 1 Ectrodactyly of hands (**a**, **b**) and feet (**c**) in three patients showing symmetric and asymmetric anomalies

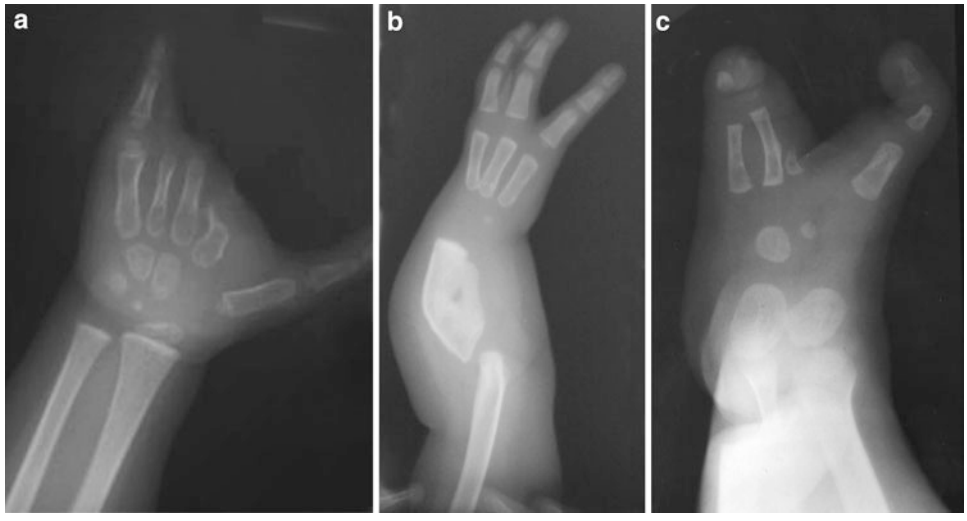

Fig. 2 Radiographs of ectrodactyly (two hands (**a**, **b**) and a foot (**c**)) in three patients showing different types of ectrodactyly

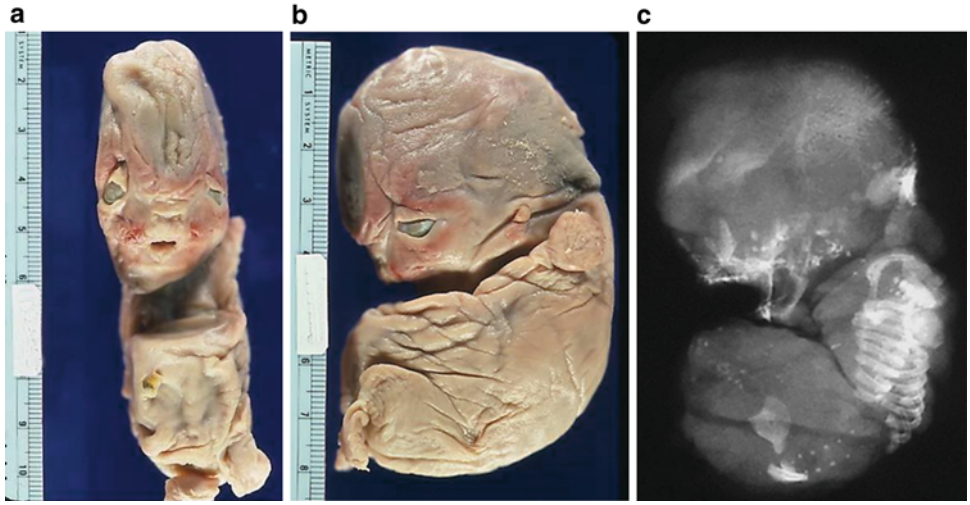

Fig. 3 An embryo with phocomelia showing deficient limbs (**a**, **b**), illustrated by radiograph (**c**)

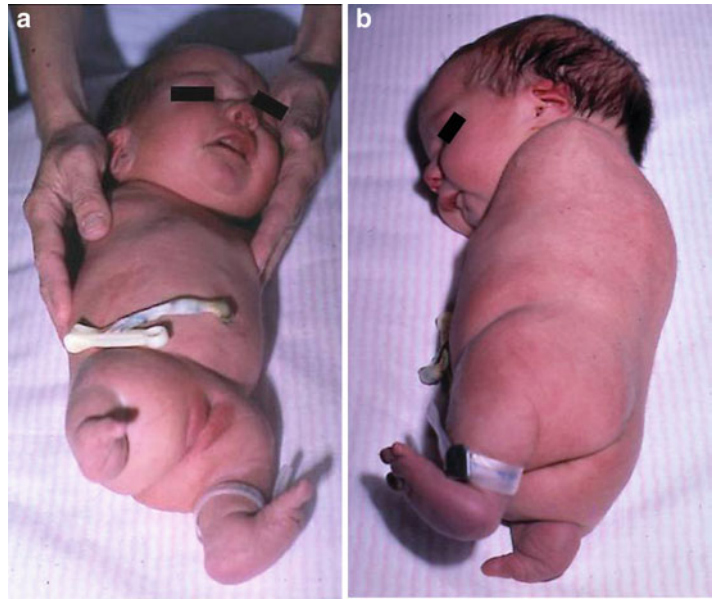

Fig. 4 (**a**, **b**) A neonate with amelia of the upper limbs and reduction malformations of the lower limbs

Fig. 5 A child with amelia showing complete absence of upper extremities

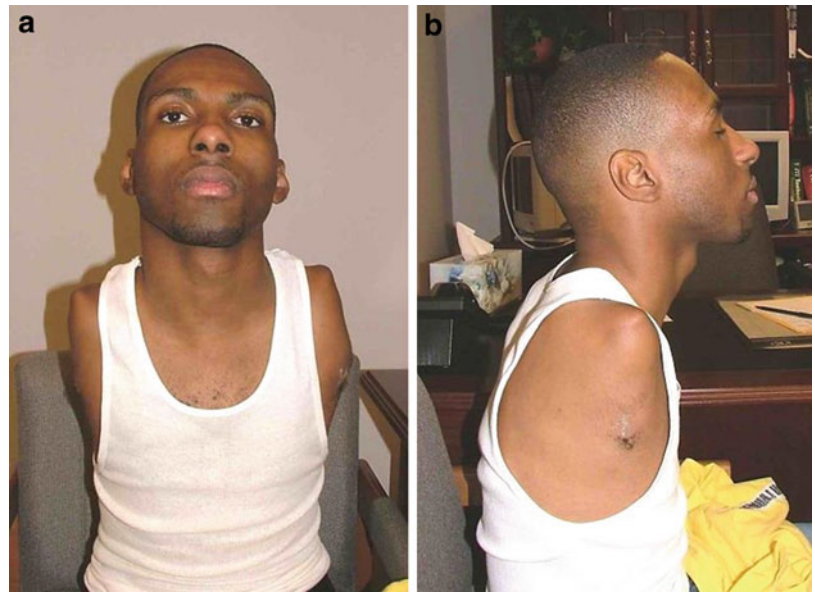

Fig. 6 (**a**, **b**) A patient with amelia of the upper extremities. He is intelligent, uses his chin and shoulder to write, and drives a car by using one foot to turn the driving wheel and one foot to pedal the accelerator and brake

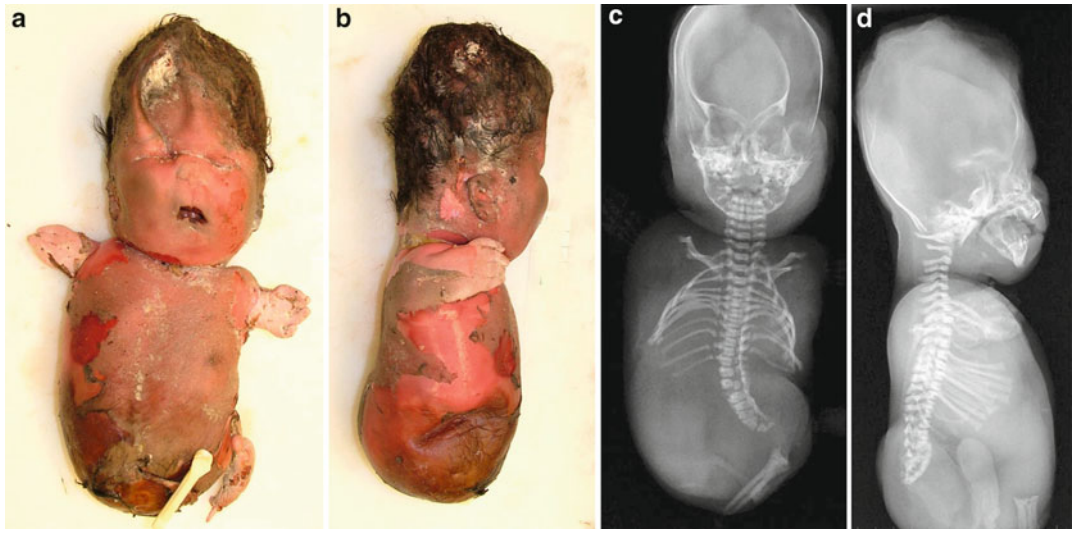

Fig. 7 (**a**–**d**) A macerated stillborn with phocomelia. Her upper extremities consist of hands attached to the shoulders with absence of the long bones. Her left lower extremity consists of a foot attached via thin twisted skin to the pelvic area with absence of the long bones. Right lower extremity was completely absent. There were severe dysplastic vertebrae, fusions of ribs, and absence of pelvic bones. In addition, the infant had blind vagina, absent right kidney, rudimentary left kidney, hypoplastic lungs, and microphthalmia

Fig. 8 (**a**–**g**) A girl and a lady with phocomelia showing flipper-like hands, illustrated by radiographs

Fig. 9 An infant with transverse reduction of the lower extremities

Fig. 10 An infant with unilateral transverse reduction of left upper extremities (intrauterine amputation), constriction ring of the left big toe, and syndactyly of the toes of both feet, secondary to amniotic band syndrome

Fig. 11 (**a**–**d**) An infant with reduction malformations of both upper and lower extremities

Fig. 12 (**a**–**e**) A neonate with del(13q) syndrome showing hypoplastic thumbs, syndactyly of toes, in addition to multiple congenital anomalies. The karyotype shows the deletion of 13q

Fig. 13 Radiograph of another neonate with del(13q) syndrome showing limb reduction anomalies of the upper extremities

Fig. 14 A neonate with trisomy 18 syndrome showing limb reduction defects of the upper extremities in addition to multiple congenital anomalies

Dysplasia Epiphysealis Hemimelica

Contents

Dysplasia epiphysealis hemimelica (DEH) is a rare osteocartilaginous overgrowth involving one or multiple epiphyses or ossification centers, usually in the lower extremity on one side of the body. In 1926, Mouchet and Belot (1926) described a condition called tarsomegaly, which Trevor, later in 1950 (Trevor 1950), called tarso-epiphyseal aclasis. As the tarsal bones are not the only bones involved, Fairbank in 1956 (Fairbank 1956) used the term dysplasia epiphysealis hemimelica. The term reflects the characteristic hemimelica involvement and typically affects either the medial or the lateral side of the epiphysis, with the medial side affected twice as frequently (Lang and Aztiuz 1997; Kuo et al. 1998; Araujo et al. 2006; Mann et al. 2010). The condition has been referred to as Trevor disease.

Synonyms and Related Disorders

Trevor disease

Genetics/Basic Defects

1. Inheritance
   1. Most cases: sporadic
   2. Autosomal dominant inheritance in rare familial DEH
      1. Epiphyseal osteochondromas with autosomal dominant inheritance and multiple parosteal bone proliferations (DEH) (Fahmy and Pandey 2008)
      2. Dominant carpotarsal osteochondromatosis (DEH)
      3. In a family with seven affected members (Maroteaux et al. 1993)
      4. A single family with seven members affected by different combinations of dysplasia epiphysealis hemimelica, intracapsular chondroma, extraskeletal osteochondroma, and typical osteochondroma (Hensinga et al. 1974)
   3. Male-to-female ratio, 3:1
2. Etiology and pathogenesis
   1. Etiology unknown (Grogan 2015)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_74

2. A congenital disorder becoming clinically evident in the course of the development of the epiphyses
3. Basic pathologic process: an abnormal proliferation of cartilage in an epiphysis, similar to osteochondroma

Clinical Features

1. Most frequent presentation: ages 2–14 years (birth to 63 years of age) (Gerscovich and Greenspan 1989)
2. Chief clinical signs
    1. Massive ossification of the hypertrophic cartilaginous areas, and the involved joints undergo rapid degenerative changes (arthrosis) (Bernard et al. 1984)
    2. Unilateral asymmetric bony hard swelling on the extremities: variable severity (Carlson and Wilkinson 1979; Wiedemann et al. 1981)
    3. Cartilage overgrowth: usually found to be limited to one extremity and to half of the affected epiphysis (Kettelkamp et al. 1966)
    4. Rare bilateral lesions reported (Merzoug et al. 2002)
    5. Angular deformity
    6. Usually on the inner or outer aspect of the knee and/or ankle
    7. Regional muscle wasting
    8. Occasional recurrent locking of the joint
    9. With or without pain
    10. With or without restriction of motion
    11. Slow progression
3. Apparent deformity
    1. Varus or valgus deformity depending on the site of involvement
    2. Genu valgum or varum depending on the site of involvement
    3. Flexion contracture
    4. Pes planus
    5. Pes equinus
4. Sites of involvement
    1. Lower extremities, more commonly affected than the upper extremities
        1. Four most common locations of involvement (Rosero et al. 2007)
            1. Talus-calcaneus (22%)
            2. Distal tibia-fibula (22%)
            3. Proximal tibia (11%)
        2. Proximal tibial epiphysis
        3. Tarsal navicular
        4. First cuneiform
        5. Middle and lateral cuneiforms
        6. Metatarsals
        7. Phalanges
    2. Upper extremities: very uncommon involvement (Azouz et al. 1984; Vanhoenacker et al. 1999; Takagi et al. 2000; Rosero et al. 2007)
        1. Carpal bones
            1. Scaphoid
            2. Lunate
            3. Capitate
            4. Hamate
            5. Trapezium
            6. Trapezoid
        2. Metacarpals
        3. Phalanges
        4. Proximal radius
        5. Proximal and distal ulna
        6. Proximal and distal humerus
        7. Glenoid cavity
        8. Coracoid process of the scapula
        9. Extremely rare DEH of the elbow presenting with a symptomatic ulnar nerve compression (Maalouf et al. 2011)
    3. Pelvis
        1. Acetabulum
        2. Pubic bone
        3. Iliac bone
5. Affected limb
    1. May be longer than the unaffected one due to:
        1. The enlargement of several ossification centers
        2. Increased diaphyseal length
    2. May be shorter due to focal early closure of the epiphyseal plate

6. Quiescent following epiphyseal plate fusion
7. Prognosis
    1. Relatively benign condition
    2. Complications do occur (Aydin 2014)
        1. Angular deformity may recur because of the epiphyseal disturbance (Keret et al. 1992)
        2. Loose bodies may be present in the joint: present with acute onset of symptoms such as locking and swelling of patients with DEH (Wheeldon and Altiok 2015)
        3. A fixed deformity may persist
        4. The limb lengths could be different
        5. May develop an early degenerative osteoarthritis due to the joint irregularity
    3. Malignant degeneration has not been reported
8. Classification based on degrees of involvement (Azouz et al. 1985)
    1. Localized form
        1. Usually affecting the bones of the hindfoot or ankle
        2. Also may affect an epiphysis
    2. Classical form
        1. Characteristic hemimelic distribution seen in more than one area in a single lower extremity (two-thirds of the reported cases), particularly:
            1. Talus
            2. Distal femoral epiphyses
            3. Distal tibial epiphyses
        2. Lesion localized to the ankle and foot, called Mouchet and Belot type
    3. Generalized or severe form
        1. Involving a whole lower extremity from the pelvis to the foot or ankle
        2. Involving femoral head, symphysis pubis, or triradiate cartilage of the acetabulum
9. Differential diagnosis with other osteocartilaginous lesions (Douira-Khomsi et al. 2011)
    1. Synovial chondromatosis
    2. Capsular or para-articular chondroma
    3. Myositis ossificans
    4. Tumoral calcinosis
    5. Particularly osteochondroma

Diagnostic Investigations

1. Radiography (Gerscovich and Greenspan 1989; Silverman 1989; Schmidt and Lomasney 1994)
    1. Skeletal survey to look for sites of involvement
    2. Earliest radiographic sign
        1. Appearance of secondary centers of ossification adjacent to an epiphysis
        2. Slow enlargement of these centers eventually merging with each other and then with the epiphysis
    3. Asymmetric hemimelic distribution of overgrowth of one side of epiphysis with irregular contour and ossification
        1. Generally only half or part (either the medial or lateral half) of an epiphysis or ossification center affected
        2. Rarely involving the entire epiphysis
    4. Overgrowth of adjacent bones
    5. Adjacent (probably secondary) metaphyseal and growth plate involvement
        1. Exhibiting widening and streak-like metaphysis (as in Ollier disease)
        2. Spur formation (as in osteochondroma)
    6. Mature lesions showing enlargement of one side of an epiphysis, simulating as osteochondromatous mass or enlargement of one side of an ossification center
    7. Epiphysis irregularly calcified and ossified
    8. Joints usually deformed
    9. Advanced bone age in unaffected epiphyses
    10. Less common findings
        1. Loose bodies in affected joints
        2. Osteochondral fractures
    11. Bilateral involvement extremely rare
2. CT of the lesions
    1. Improving diagnostic accuracy in the growing skeleton
    2. Demonstration of the anatomic relationship of the involved structures
    3. Visualization of the soft tissues, bones, and tumorous mass
    4. Evaluation of the condition of the articular surfaces

3. MRI imaging (Keret et al. 1992; Azouz 1996; Iwasawa et al. 1996; Peduto et al. 1999)
    1. To identify a definite plane of separation between the pathologic osteochondromatous mass and the normal epiphysis
    2. To accurately identify bony and cartilaginous structural abnormalities in multiple planes noninvasively without ionizing radiation
    3. To identify secondary changes in menisci, tendons, ligaments, and muscles
    4. Epiphyseal mass of the knee mostly showed the same signal intensity as normal cartilage but contained low-signal spots corresponding to calcified foci. The cartilaginous cap was depicted as a mottled area of high intensity on a T2-weighted image (Iwasawa et al. 1996)
4. Histopathology
    1. Osteocartilaginous exostosis (with cartilaginous cap) (Kettelkamp et al. 1966) arising from an epiphysis, apophysis, or round bone (Oates)
    2. Nests of cartilage cells showing active proliferation during growth of the lesions
    3. Diminishing amount and activity of the cartilage as the lesions mature
    4. Increased size of lesions in adults showing areas of actively proliferating cartilage
    5. Infrequently with an area of necrosis, presumably caused by inadequate nutrition
    6. Histological findings (Bahk et al. 2010)
        1. Identical to those of osteochondromas
        2. Presence of caps of disorganized hyaline cartilage
        3. Endochondral ossification of varying degrees underlying the caps

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: not increased unless in rare autosomal dominant familial cases
    2. Patient's offspring: not increased unless in rare autosomal dominant familial cases
2. Prenatal diagnosis has not been reported

3. Management
    1. Observation in asymptomatic cases; no cases of malignant transformation has been reported (Kuo et al. 1998)
    2. Dysplasia epiphysealis hemimelica with a painless intra-articular mass should not be excised unless the mass interferes with the joint motion (Luevitoonvechkij et al. 2012)
    3. Surgical excision of the mass or corrective osteotomy generally recommended for the following lesions:
        1. Causing disabling pain
        2. Interfering function
        3. Increasing deformity of the involved joint
    4. Simple excision indicated if the cartilaginous overgrowth is not in the weight-bearing articular surface
    5. Extraarticular osteotomy indicated for correction of varus/valgus deformities if the arthrogram shows the smooth joint surface
    6. Anticipate recurrence of the angular deformity after the corrective osteotomy if the growth plate at the affected joint is open and active

Fig. 1 (**a**–**i**) A 9-year-old boy with dysplasia epiphysealis hemimelica showing hard swellings on the inner sides of the knees and the ankle of the right lower extremities (**a**). The knee radiographs at 9 years of age (**b**, **c**) show the secondary ossification center merged with the medial side of the epiphyses of the distal femur and that of the proximal tibia. The radiographs of ankles at 4 (**d**, **e**), 5 (**f**, **g**), and 9 years (**h**, **i**) of age show irregularly calcified mass extending from medial malleolus of the distal tibia and involvement of the talus. The patient had bony protuberance of the right knee and right ankle without pain or restriction of motion. The age of onset was about 2 years

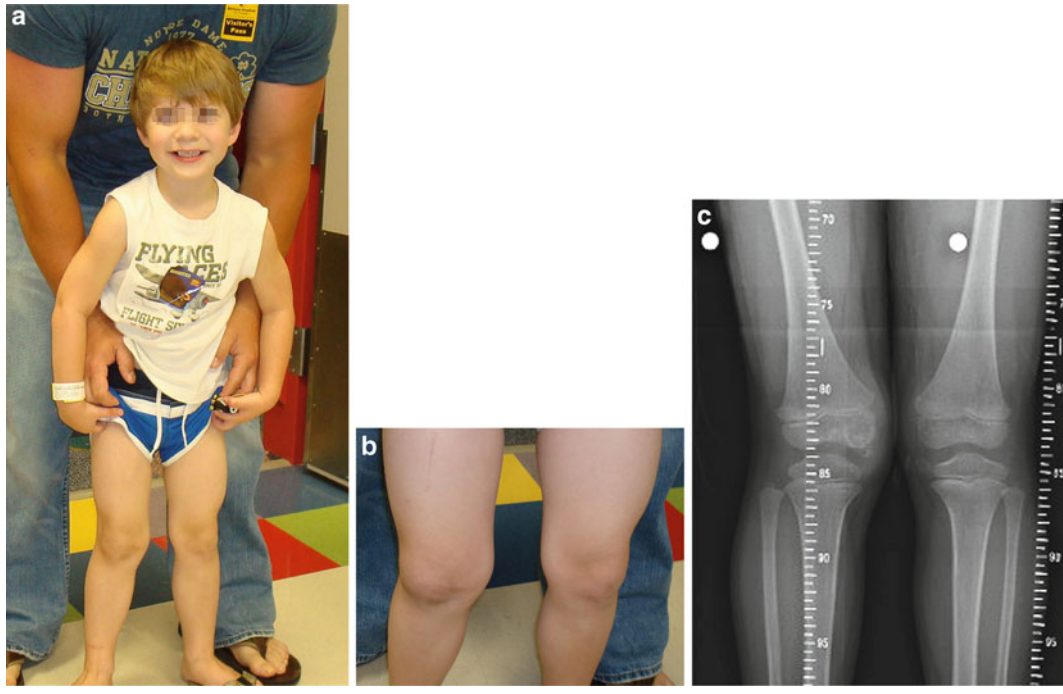

Fig. 2 (**a**–**c**). A 5-year-old boy (**a**) was seen because of swollen right knee with complaint of knee pain and limping. Note the swelling of the medial aspect of the right knee (**b**). The knee radiograph (**c**) shows second ossification center merged with the medial aspect of the epiphysis of the right distal femur

Dystonia

Contents

Dystonia is characterized by sustained, nonsuppressible contractions of agonist and antagonist muscles, resulting in twisting and repetitive movements that typically lead to abnormal postures (Fahn et al. 1998; Friedman and Standaert 2001; Brűggermann and Klein 2010).

Synonyms and Related Disorders

Dystonia (types 1–19); dystonia plus; heredodegenerative dystonia; paroxysmal dystonia; primary (idiopathic) dystonia; secondary dystonia

Genetics/Basic Defects

1. Genetically defined forms of the primary dystonias and dystonia-plus syndromes (Brűggermann and Klein 2010)
    1. Monogenic forms of dystonia have been assigned the acronym DYT according to the gene or gene locus involved
    2. This assortment of clinical rather than heterogeneous dystonias and dyskinesias is represented by a current list of 20 DYTs, in which monogenic forms of dystonia are included in chronological order based on the first appearance in the literature
    3. Although this listing of DYTs can serve as an orientation, it does not represent a logical classification in the strict sense of the word Rather, the monogenic forms can be pragmatically grouped as:
        1. Pure dystonias
            1. Part of the primary forms and thought to occur in the absence of neuropathologic changes
            2. Considered mainly to alter the function of neuronal basal ganglia circuits
        2. Dystonia-plus syndromes: characterized by additional neurologic manifestations, such as parkinsonism and myoclonus (Albanese et al. 2006)
        3. Paroxysmal dyskinesias: typically manifest episodically; dystonia usually is only one of several movement disorders present, and there are no interictal neurologic abnormalities

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_75

2. At least 25 different types of dystonia can be distinguished genetically as follows (Müller et al. 1998; Németh 2002; Bhidayasiri 2006; Brűggermann and Klein 2010; Morgante and Klein 2013; Lohmann and Klein 2013; Balint and Bhatia 2014; Klein et al. 2014; Skogseid 2014; Xiao et al. 2014):
    1. Dystonia type 1 (early-onset generalized primary torsion dystonia, Oppenheim dystonia)
        1. Autosomal dominant inheritance with reduced penetrance of about 30–40%
        2. Locus/gene: DYT1/*TOR1A* on chromosome 9q34 (Ozelius et al. 1989)
        3. Mutations
            1. GAG deletion in the *DYT1* gene resulting in loss of glutamic acid residues in the C-terminus of a novel ATP-binding protein, torsin A
            2. 18-base pair deletion resulting in loss of six amino acids (F323-Y328del) in a novel ATP-binding protein, torsin A
    2. Dystonia 2 (autosomal recessive torsion dystonia)
        1. Autosomal recessive inheritance
        2. Locus: *DYT2* (chromosome map unknown)
    3. Dystonia 3 (X-linked dystonia parkinsonism)
        1. X-linked recessive inheritance
        2. Locus/gene: *DYT3*/*TAF1* on chromosome Xq13.1
    4. Dystonia 4 (whispering dysphonia)
        1. Autosomal dominant inheritance
        2. Locus/gene: *DYT4*/*TUBB4A* on chromosome 19 (Hersheson et al. 2013; Lohmann et al. 2013)
    5. Dystonia 5 (dopa-responsive dystonia parkinsonism)
        1. Common autosomal dominant inheritance
            1. Locus/gene: *CYT5a*/*GCH1* (GTP cyclohydrolase 1) on chromosome 14q22.1-q22.2
            2. Caused by mutation in the *guanosine triphosphate cyclohydrolase I* gene, *GCH1*
        2. Rare autosomal recessive form (Segawa syndrome)
            1. Associated with mutations in the tyrosine hydroxylase gene, *TH*
            2. Locus/gene: *DYT5b*/*TH* on chromosome11p15.5
    6. Dystonia 6 (adolescent-onset torsion dystonia of mixed type)
        1. Autosomal dominant inheritance
        2. Locus/gene: *DYT6*/*THAP1* on chromosome 8p21-p22
    7. Dystonia 7 (adult-onset focal torsion dystonia)
        1. Autosomal dominant inheritance
        2. Locus: DYT7 on chromosome 18p
    8. Dystonia 8 (paroxysmal nonkinesigenic dyskinesia)
        1. Autosomal dominant inheritance
        2. Locus/gene: *DYT8*/*MR-1* on chromosome 2q33-q35
    9. Dystonia 9 (paroxysmal choreoathetosis with episodic ataxia and spasticity)
        1. Autosomal dominant inheritance
        2. Locus: *DYT9* on chromosome 1p21-p13.3
    10. Dystonia 10 (paroxysmal kinesigenic choreoathetosis)
        1. Locus/gene: *DYT10*/*PRRT2* on chromosome 16p11.2-q12.1
        2. Autosomal dominant inheritance
    11. Dystonia 11 (myoclonus-dystonia)
        1. Autosomal dominant inheritance
        2. Locus/gene: *DYST11*/*SGCE* on chromosome 7q21
        3. Caused by mutations in the ε-sarcoglycan gene in most families
    12. Dystonia 12 (rapid-onset dystonia parkinsonism)
        1. Autosomal dominant inheritance
        2. Locus/gene: *DYT12*/*ATP1A3* on chromosome 19q13
    13. Dystonia 13 (multifocal/segmental dystonia)
        1. Autosomal dominant inheritance
        2. Locus: *DYT13* on chromosome 1p36.13-36.32 (Valente et al. 2001)
    14. Dystonia 14: recently redefined as *DYT5*

15. Dystonia 15 (myoclonus-dystonia)
    1. Autosomal dominant inheritance
    2. Locus: *DYT15* on chromosome 18p11
16. Dystonia 16 (young-onset dystonia parkinsonism)
    1. Autosomal recessive inheritance
    2. Locus/gene: *DYT16*/*PRKRA* on chromosome 2p
17. Dystonia 17 (autosomal recessive primary torsion dystonia)
    1. Autosomal recessive inheritance
    2. Locus: *DYT17* on chromosome 20pq
18. Dystonia 18 (paroxysmal exertion-induced dyskinesia 2)
    1. Autosomal dominant inheritance
    2. Locus/gene: *DYT18*/*SLC2A1* on chromosome 1p
19. Dystonia 19 (episodic kinesigenic dyskinesia 2)
    1. Autosomal dominant inheritance
    2. Locus: *DYT19* on chromosome 16q
20. Dystonia 20 (paroxysmal nonkinesigenic dyskinesia 2)
    1. Autosomal dominant inheritance
    2. Locus: *DYT20* on chromosome 2q
21. Dystonia 21 (late-onset pure dystonia)
    1. Autosomal dominant inheritance
    2. Locus: *DYT21* on chromosome 2q14.3-q21.3
22. Dystonia 22 (undescribed form of dystonia)
23. Dystonia 23 (adult-onset cranial-cervical dystonia)
    1. Autosomal dominant inheritance
    2. Locus/gene: *DYT23*/*CIZ1* on chromosome 9q
24. Dystonia 24 (adult-onset cranial-cervical dystonia)
    1. Autosomal dominant inheritance
    2. Locus/gene: *DYT24*/*ANO3* on chromosome 11p
25. Dystonia 25 (adult-onset cranial-cervical dystonia)
    1. Autosomal dominant inheritance
    2. Locus/gene: *DYT25*/*GNAL* on chromosome 18p

3. Secondary dystonia (Schlaggar and Mink 2003)
    1. Association with a number of disorders
        1. Hepatolenticular degeneration (Wilson disease)
            1. Dystonia in over a third of the patients
            2. Associated with lesions in the putamen in 80% of cases
        2. Hallervorden-Spatz disease (pantothenate kinase-associated neurodegeneration)
        3. Huntington chorea
        4. Lesch-Nyhan disease
        5. Metachromatic leukodystrophy
        6. Methylmalonic acidemia
        7. Mitochondrial disorders
        8. Ceroid lipofuscinosis
        9. Gangliosidoses
        10. Glutaric aciduria
        11. Ataxia telangiectasia
        12. Niemann-Pick disease type C
        13. Early-onset parkinsonism
        14. Corticobasal degeneration
        15. Certain forms of spinocerebellar ataxia
            1. Spinocerebellar ataxia 3 (Machado-Joseph disease): The severity of the dystonic symptoms is related to the length of the trinucleotide repeat
            2. Spinocerebellar ataxia 17 (caused by mutations in the thymine-adenine-thymine-adenine binding protein: Dystonia may be the presenting sign of the disorder)
        16. Other inherited disorders (Cloud and Jinnah 2010)
    2. Other causes
        1. Psychogenic
        2. Vascular lesions such as carotid occlusive disease and hemorrhagic stroke
        3. Anoxic brain injury (cerebral anoxia/hypoxia): a well-known cause of secondary dystonia
        4. Acute disseminated encephalomyelitis
        5. Trauma
            1. Head trauma: Dystonia is among the most common movement disorders following severe head injury
            2. Peripheral trauma causing segmental dystonia.

6. Both acute and chronic use of dopamine blocking medications and other medications
    1. Haloperidol
    2. Resperidol
    3. Fluphenazine
    4. Thioridazine
    5. Chlorpromazine
    6. Metoclopramide
    7. Phenytoin
    8. Stonatrioran
7. Other acquired and sporadic causes (Cloud and Jinnah 2010)

4. Pathophysiology: a new interpretive hypothesis involving multiple levels of the nervous system
    1. Spinal cord: increased spinal motor neuron excitability in patients with generalized dystonia due to reduced presynaptic inhibition and compromised supraspinal inhibition systems
    2. Basal ganglia: disturbed pattern of basal ganglia output neurons
    3. Thalamus: disorganization of input–output properties and hyperactivity in thalamic neurons in two dystonic cynomolgus monkeys
    4. Somatosensory system: increased temporal discrimination thresholds for tactile stimuli
    5. Sensorimotor integration and motor cortical function
        1. Abnormal somatotopic arrangement of sensorimotor interaction
        2. Abnormal functioning of cortico-subcortical loops causing abnormalities of both intracortical inhibition and cortical excitability
5. Dystonia with unknown etiology

Clinical Features

1. Dystonia describes a symptom that may be part of many disorders with a variety of causes
    1. An abnormal sustained posture that is often writhing or twisting in quality
    2. Can be rapid or slow
    3. Often painful
