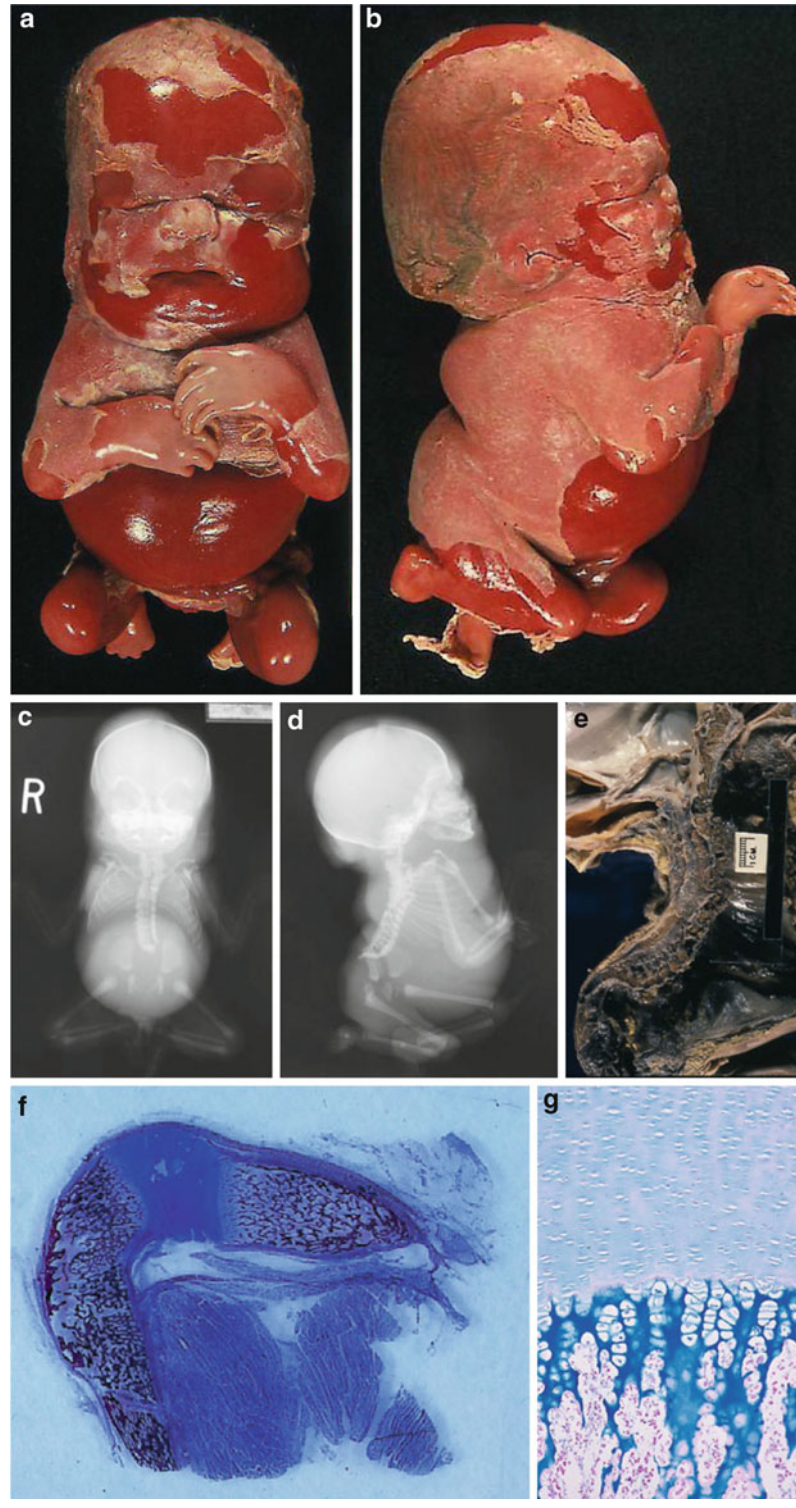

Fig. 1 The macerated 32-week stillborn (**a**, **b**) with Chen syndrome showing multiple pterygia involving the neck, axillae, antecubital, crural, popliteal, and interphalangeal areas, hygroma coli, and facial anomalies (hypertelorism, antimongoloid slant of the palpebral fissures, a shortened nose, depressed nasal bridge and tip of the nose, a long philtrum, a receding chin, and apparently low-set and malformed ears). Contractures of the fingers were present with ulnar deviation of the hands. Polyhydramnios and fetal hydrops were noted by ultrasonography at 30 weeks of gestation. Autopsy showed hypoplastic lungs and heart and a large left diaphragmatic hernia (containing intestine, pancreas, and part of the stomach and ascites). Radiographs (**c**, **d**) and postmortem section (**e**) revealed a large cystic hygroma, hypoplastic vertebral bodies, fusion of the posterior elements extended from the cervical into the midthoracic spine, angulated cervicothoracic junction, and undermodeled long bones. Representative section of the elbow (**f**) showed fusion of epiphyseal cartilages of the distal humerus and proximal ulna resulting in bending of the proximal portion of the ulna and a deficient joint space. The resting cartilage (**g**) was distinctly demarcated from the physeal growth plate, which showed slightly retarded but normally arranged chondrocytic column

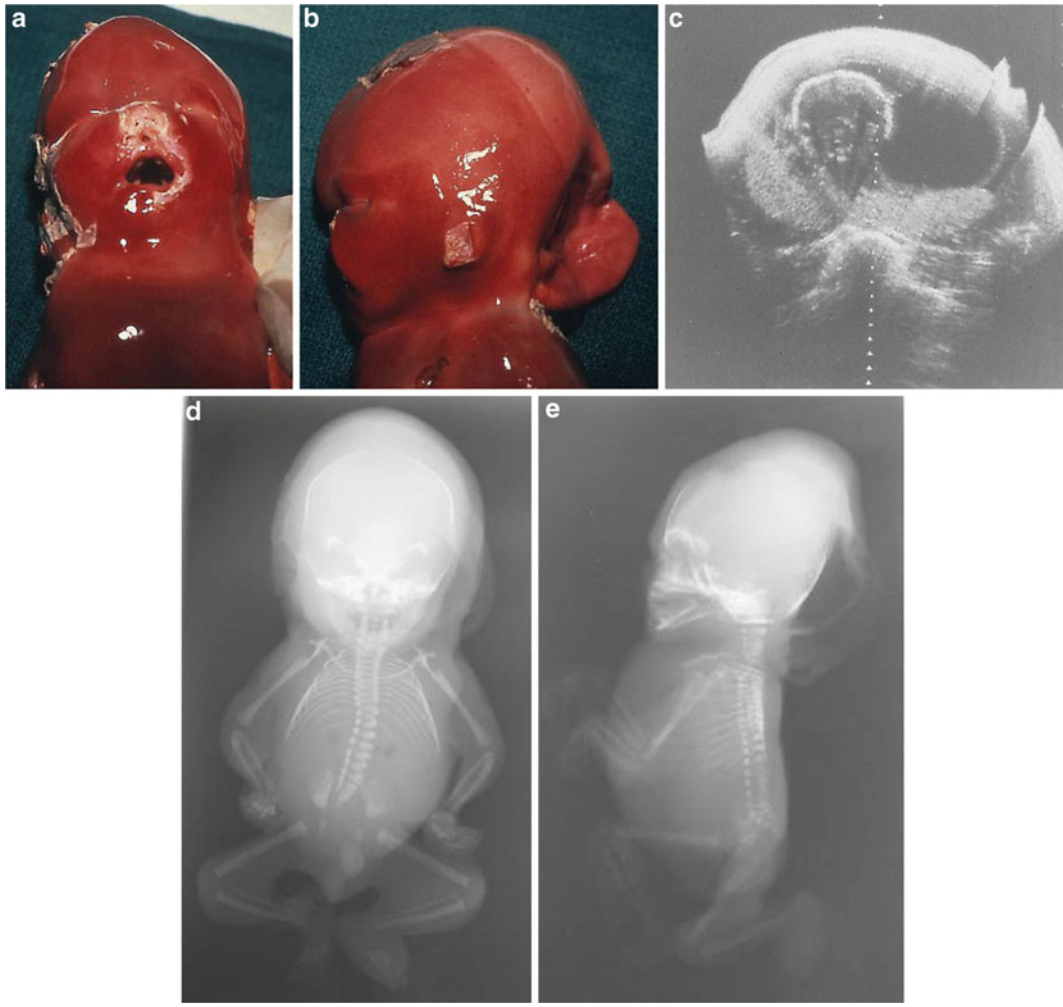

Fig. 2 A malformed macerated 28-week fetus (**a**, **b**) with Chen syndrome showing impressive skin webbing at the neck, axillae, antecubital, crural, and popliteal areas, and abnormal facies (markedly flattened nasal bridge with anteverted and hypoplastic nasal alae, low-set ears, and a small mouth with cleft soft palate). In addition, there were contractures of the hands and fingers and rocker bottom feet. The prenatal ultrasound at 25 weeks of gestation (**c**) showed a large cystic hygroma at the back of the head. Radiographs (**d**, **e**) revealed massive edema of the scalp contiguous with the neck pterygia, hypoplastic vertebral bodies, multiple fusions of the posterior elements of the cervical and lumbosacral spine bodies, and incipient fusion of the radius and ulna bilaterally. Post mortem study revealed markedly hypoplastic lungs and heart

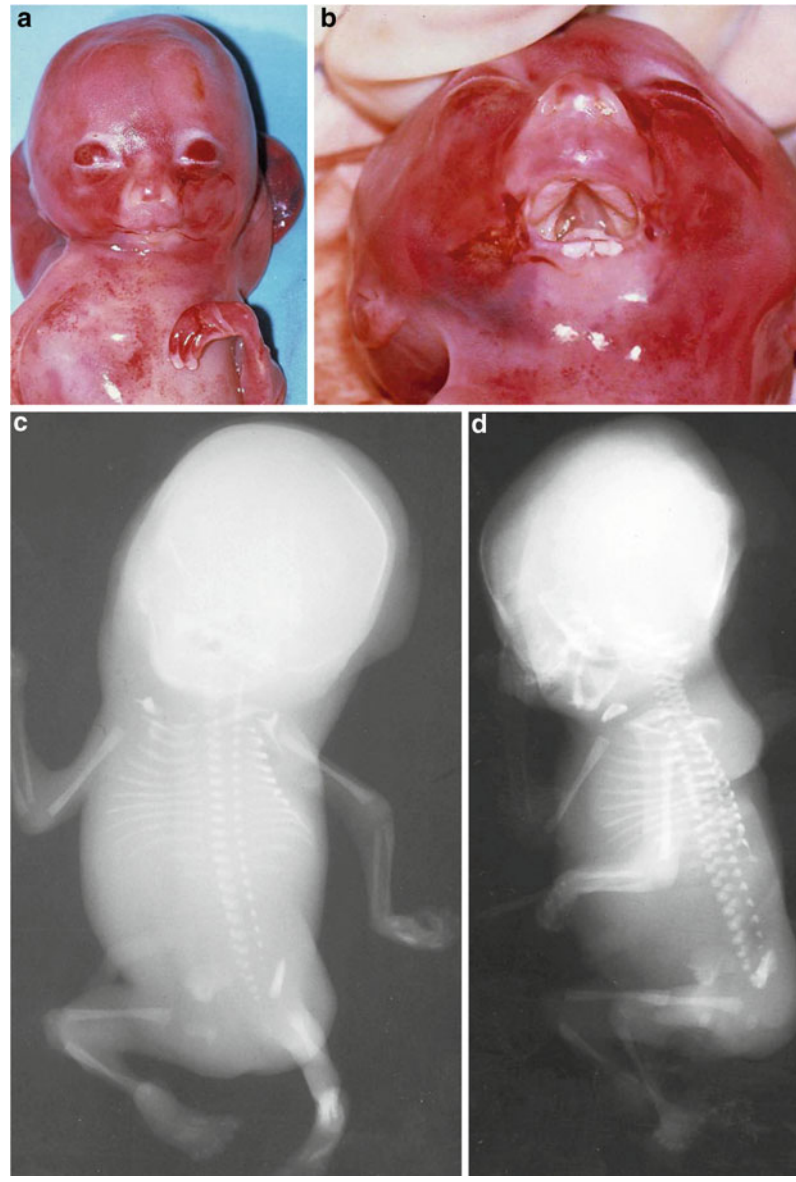

Fig. 3 A 19-week fetus with Chen syndrome (**a**, **b**) showing a large cystic hygroma, detected by prenatal ultrasonography, multiple pterygia involving neck, axillae, elbows, fingers, and knees with contractures, illustrated by radiographs (**c**, **d**). Distinctive facial features include hypertelorism, flat nasal bridge, cleft palate, and micrognathia. Postmortem study revealed hypoplastic lungs and heart, fusion of cartilage of the elbow joints, and hypoplastic cervical vertebral bodies with posterior elements beginning to come together but were not yet fused

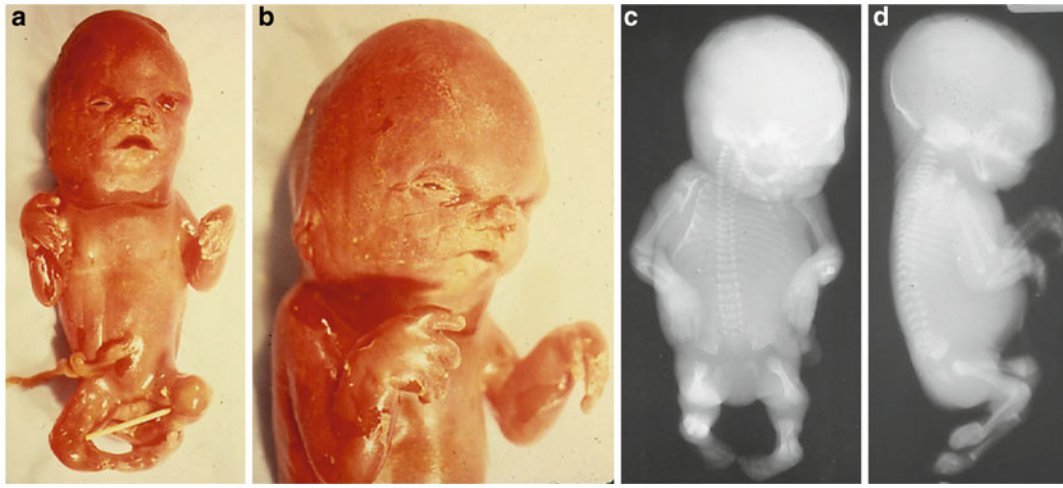

Fig. 4 A fetus with lethal multiple pterygium (**a**, **b**) syndrome showing multiple pterygia involving neck, axilla, elbows, and knees associated with multiple contractures illustrated by radiographs (**c**, **d**). There were hypertelorism, small nose, and micrognathia

Fig. 5 (**a**, **b**) A stillbirth with lethal multiple pterygium syndrome showing flexion of all four limbs with multiple pterygia involving neck, axillae, elbows, and knees; short neck; and cystic hygroma colli. There were antimongoloid slant of the palpebral fissures, hypertelorism, flat nasal bridge, micrognathia, and high-arched palate. The upper extremities were held in extreme flexion with ulnar deviation of both hands and camptodactyly. The lower limbs were rotated externally and flexed in a crossed position with bilateral calcaneus deformities of the feet. Postmortem findings include multiloculated cystic hygroma, hypoplastic lungs, and kyphoscoliosis

Loeys-Dietz Syndrome

Contents

Loeys-Dietz syndrome (LDS), a newly recognized connective tissue disorder, shares overlapping features with Marfan syndrome (MFS) and the vascular type of Ehlers-Danlos syndrome (EDS), including aortic root dilatation and skin abnormalities (Aalberts et al. 2008).

Synonyms and Related Disorders

Loeys-Dietz aortic aneurysm syndrome (Dietz et al. 2005); Marfan syndrome-related disorders; TGFBR1-related Loeys-Dietz syndrome; TGFBR2-related Loeys-Dietz syndrome

Genetics/Basic Defects

1. An autosomal dominantly inherited disorder of connective tissue.
2. Caused by heterozygous mutations in the gene encoding type I or II transforming growth factor beta (TGF-β) receptor.
3. An altered signaling of the TGF-β cytokine family.
    1. Plays an important role in cell proliferation and differentiation, apoptosis and extracellular matrix formation, underlining both LDS and MFS.
    2. Causes disarrayed elastic fibers and loss of elastin content in the aortic media, predisposing to dilatation and dissection of the aortic wall.
    3. Disruption of the normal TGF-β signaling takes place at the level of the TGF-β receptors. Mutations in either the TGF-β receptor 1 or 2 genes (Loeys et al. 2006; LeMaire et al. 2007; Mizuguchi and Matsumoto 2007; Drera et al. 2008) have been identified in one third and two thirds of LDS patients, respectively. However, in MFS an abnormal fibrillin protein causes an increased activity of TGF-β, leading to the typical phenotypic characteristics of the MFS.
4. Mutations in the *TGFBR* gene may be associated with greater phenotypic heterogeneity than previously reported (Akutsu et al. 2007).
5. Patients with a *TGFBR1* or *TGFBR2* mutation showed extensive clinical overlap between patients with MFS type 1, MFS type 2, and

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_149

LDS type 2A and 2B (Singh et al. 2006; Stheneur et al. 2008; Söylen et al. 2009).

6. Increased transforming growth factor-β (*TGF-β*) activity plays a crucial role in the pathogenesis of MFS and related disorders, such as Loeys-Dietz syndrome (LDS), which is caused by mutation in TGF-β signaling-related genes (Takeda et al. 2016).
7. LDS classification (MacCarrick et al. 2014).
    1. LDS 1 (thoracic aortic aneurysm and dissection) (*TGFBR1*)
    2. LDS 2 1 (thoracic aortic aneurysm and dissection; Marfan syndrome type 2) (*TGFBR2*)
    3. LDS 3 (aneurysms-osteoarthritis syndrome) (*SMAD3*)
    4. LDS 4 (aneurysm, aortic and cerebral, with arterial tortuosity and skeletal manifestations) (*TGFB2*)
8. Marfan syndrome-related disorders and mutated genes (Pearson et al. 2008; Verstraeten et al. 2016).
    1. Marfan syndrome: *FBN1*, *TGFBR*1, *TGFBR2*
    2. LDS: *FBN1*, *TGFBR*1, *TGFBR2*, *SMAD3*, *TGFB2*, *TGFB3*, *SMAD2*
    3. MASS (*M*itral valve, *A*orta, *S*kin and *S*keletal) phenotype: *FBN1*
    4. Neonatal Marfan syndrome: *FBN1*
    5. Familial thoracic aortic: aneurysms and dissections: *FBN1*, *TGFBR1*, *TGFBR2*
    6. Isolated ectopia lentis: *FBN*1
    7. Shprintzen-Goldberg craniosynostosis syndrome: *FBN1*, *TGFBR2*
    8. Autosomal dominant Weill-Marchesani syndrome: *FBN1*
    9. Loeys-Dietz syndrome (Loeys et al. 2006): *TGFBR1*, *TGFBR2*

Clinical Features

1. A wide range of intra- and interfamilial variability involving cutaneous, skeletal (Sousa et al. 2011), and cardiovascular systems (Loeys et al. 2005)
2. Clinical types (Aalberts et al. 2008)
    1. Type I (about 75% of cases): recognized by craniofacial characteristics (hypertelorism, bifid uvula, or cleft palate).
    2. Type II (about 25% of cases): absence of facial characteristics (However, certain common facial features have been recently observed in type II patients.).
    3. Generalized arteriopathy: the most salient feature in LDS whether in type I or type II.
    4. Aortic root aneurysms are present in 98% of LDS patients (Augoustides et al. 2009).
    5. Dural ectasia has recently been observed in LDS patients (Sheikhzadeh et al. 2014).
    6. Both types with interfamilial and intrafamilial phenotypic variability.
3. LDS type I
    1. Overlapping features with MFS
        1. Aortic root dilatation/aneurysm
        2. Arachnodactyly (long slender fingers)
        3. Dolichostenomelia (thin body habitus and long extremities)
        4. Pectus deformity
        5. Joint laxity
    2. Typical characteristics
        1. Aortic root aneurysm (98%)
        2. Aneurysms of other vessels (52%)
        3. Generalized arterial tortuosity (84%)
    3. Typical and easily recognizable facial characteristics
        1. Ocular hypertelorism (increased distance between the pupils) (90%)
        2. Cleft palate or bifid uvula (90%)
        3. Other facial features
            1. Blue sclera (40%)
            2. Malar hypoplasia (60%)
            3. Exotropia
            4. Proptosis
            5. Retrognathia (50%)
    4. Musculoskeletal manifestations
        1. Craniosynostosis (premature closure of cranial sutures) (48%)
            1. Premature fusion of the sagittal suture (resulting in dolichocephaly) most commonly involved
            2. Coronal suture synostosis (resulting in brachycephaly)
            3. Metopic suture synostosis (resulting in trigonocephaly)

2. Dolichostenomelia (18%)
3. Cervical spine instability
4. Pectus deformity (68%)
5. Arachnodactyly (70%)
6. Scoliosis (50%)
7. Joint laxity (68%)
8. Talipes equinovarus (45%)
9. Camptodactyly (38%)

5. Cutaneous manifestations
   1. Velvety skin (28%)
   2. Translucent skin (32%)
6. Congenital heart defects
   1. Patent ductus arteriosus (35%)
   2. Atrial septal defect (22%)
   3. Bicuspid aortic valve
   4. Bicuspid pulmonary valve
   5. Mitral valve prolapse
7. Developmental delay (15%)
8. Absence of ectopia lentis (lens subluxation) (0%) and other ocular manifestations seen in MFS

4. LDS type II
   1. Aortic root aneurysm with dissection (100%)
   2. Other aortic aneurysm (73%)
   3. Arterial tortuosity (67%)
   4. Overlapping features with the vascular type of EDS
      1. Skin abnormalities
         1. Easy bruising (67%)
         2. Translucent skin (64%)
         3. Velvety skin (83%)
         4. Skin hyperextensibility (20%)
         5. Atrophic scars (50%)
      2. Joint laxity (100%)
      3. Rupture of visceral organs
         1. Vascular rupture during pregnancy (50%)
         2. Uterine rupture (33%)
         3. Splenic or bowel rupture (25%)
      4. Uterine hemorrhage (17%)
      5. Inguinal hernia (36%)
   5. Facial features observed in most patients, although not exclusive to LDS II (Adès 2008)
      1. Dolichocephaly
      2. A tall broad forehead
      3. Frontal bossing
      4. A high anterior hairline
      5. Hypoplastic supraorbital margins
      6. A "jowly" appearance (particularly in the first 3 years of life)
      7. Translucent and redundant facial skin (often most pronounced in the periorbital region)
      8. Prominent upper central incisors in late childhood/adulthood
      9. An open-mouthed myopathic face
      10. The adult faces appeared prematurely aged
5. Cardiovascular involvement
   1. Type I
      1. Mean craniofacial-severity-index score (scores range from 0 to 11 with higher scores indicating more severe abnormalities): 4.8 years
      2. Mean age at first major event: 24.5 years
      3. Age at death: 22.6 years (0.5–45.0)
      4. Cause of death: thoracic aortic dissection (19%), abdominal aortic dissection (5%), subclavian artery dissection (0%), and cerebral bleeding (3%)
      5. Age at first cardiovascular surgery 16.9 years (1.2–46.0)
      6. Distribution of aneurysms: ascending aorta (84%), transverse aorta (5%), descending thoracic aorta (6%), abdominal aorta (8%), thoracic arterial branches (27%), head or neck arterial branches (11%), and abdominal arterial branches (3%)
   2. Type II
      1. Mean craniofacial-severity-index score: 0.8 year
      2. Mean age at first major event: 29.8 years
      3. Age at death: 31.8 years (18.0–47.0)
      4. Cause of death: thoracic aortic dissection (23%), abdominal aortic dissection (12%), subclavian artery dissection (4%), and cerebral bleeding (0%)
      5. Age at first cardiovascular surgery: 26.9 years (14.0–38.0)
      6. Distribution of aneurysms: ascending aorta (85%), transverse aorta (23%), descending thoracic aorta (19%), abdominal aorta (15%), thoracic arterial

branches (8%), head or neck arterial branches (8%), and abdominal arterial branches (15%)

6. Differential diagnosis (Kalra et al. 2011)
   1. Vascular type of Ehlers-Danlos syndrome (please see the chapter on "► Ehlers-Danlos Syndrome").
   2. Marfan syndrome (please see the chapter on "► Marfan Syndrome").
   3. Shprintzen-Goldberg syndrome (Marfanoid craniosynostosis syndrome).
      1. Phenotypes overlapping with some LDS patients with mutations in TGFBR1 or TGFBR2.
      2. Not associated with cleft palate, arterial tortuosity or risk of aneurysm, or dissection other than at the aortic root.
      3. Most affected individuals have no vascular pathology.
      4. Sequencing of TGFBR1 and TGFBR2 in five individuals with classic SGS identified no mutations (data not shown). Nevertheless, given the extent of phenotypic overlap between SGS, MFS, and selected individuals with mutations in either TGFBR1 or TGFBR2, the pathogenesis of SGS probably also relates to alteration in TGF-β signaling.
   4. Familial thoracic aortic aneurysm and dissections.
      1. Cardinal features: progressive dilation of the ascending aorta and thoracic aortic dissections
      2. Unlike LDS, cardiovascular abnormalities are typically the only manifestations of disease.
   5. Congenital contractural arachnodactyly (CCA).
      1. LDS and CCA share many features, including not only arachnodactyly but also camptodactyly, club foot, scoliosis, and aortic dilation that may progress over time
      2. Whereas aortic tortuosity/aneurysms are typically widespread in patients with LDS, dilation is restricted to the aorta in CCA and is not present in all individuals; moreover, no dissections have so far been reported in CCA patients
   6. Arterial tortuosity syndrome, a rare autosomal-recessive disorder with a clinical phenotype of aortic/arterial tortuosity, skeletal and cutaneous involvement, may closely resemble LDS.
   7. Children who present with diffuse hypotonia, joint laxity, and/or joint contractures and in whom a diagnosis of arthrogryposis, Larsen syndrome, or Beal syndrome is being entertained should undergo thorough genetic evaluation to rule out a *TGFBR1* or *TGFBR2* mutation.
   8. Larsen syndrome or Beals syndrome: presenting as joint contractures and joint hypermobility in the neonatal period (Yetman et al. 2007).

Diagnostic Investigations

1. Diagnosis of LDS.
   1. Based on characteristic clinical findings in the proband and family members
   2. Craniofacial examination for evidence of bifid uvula, cleft palate, and craniosynostosis
   3. Ophthalmologic examination by an ophthalmologist with expertise in connective tissue disorders
      1. Slit-lamp examination through a maximally dilated pupil for exclusion of lens subluxation or luxation
      2. Careful refraction and visual correction, especially in young children at risk for amblyopia
      3. Specific assessment for retinal detachment and blue sclerae
   4. Magnetic resonance angiography (MRA) or CT scan with 3D reconstruction from head to pelvis: to identify arterial aneurysms and arterial tortuosity throughout the arterial tree
   5. Radiographs to detect skeletal manifestations (e.g., severe scoliosis, cervical spine instability) that may require attention by an orthopedist

6. Multidetector CT angiography (Johnson et al. 2007)
    1. Enlargement of aortic root
    2. Marked tortuous carotid arteries/vertebral artery
7. Molecular genetic testing of *TGFBR1* and *TGFBR2*, the only two genes known to be associated with LDS, available on a clinical basis

2. Genetic testing of relatives at risk.
    1. To clarify genetic status of family members at risk if the causal *TGFBR1* or *TGFBR2* mutation is known in the proband
    2. To evaluate relatives at risk for signs of LDS, including echocardiography and extensive vascular imaging if the mutation is not known in the proband
3. Next generation sequencing approach for thoracic aortic aneurysm genetic testing overcomes the intrinsic hurdles of consecutive Sanger sequencing of all candidate genes and presents a powerful tool for the elaboration of clinical phenotypes assigned to different genes (Proost et al. 2015).

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. If a parent of the proband is affected: the risk to the sibs is 50%
        2. If parents are clinically unaffected: the risk to the sibs of a proband appears to be low but greater than that of the general population because of reported rare cases of somatic (Watanabe et al. 2008) and germline mosaicism
    2. Patient's offspring
        1. A 50% chance of inheriting the mutation and the disorder.
        2. Since the penetrance of disease-causing *TGFBR1* and *TGFBR2* mutations is reported to be near 100%, offspring who inherit a mutant allele from a parent will have LDS, although the severity cannot be predicted.
2. Prenatal diagnosis (Loeys and Dietz 2013)
    1. Ultrasonography
        1. Ultrasound examination in the first two trimesters: not sensitive in detecting manifestations of LDS although prenatal occurrence of aortic dilatation has been described
        2. Aortic root aneurysm identified in a fetus of 19 week of gestation (Viassolo et al. 2006)
    2. Molecular genetic testing
        1. Prenatal diagnosis for pregnancies at increased risk for LDS is possible by analysis of DNA extracted from fetal cells obtained by amniocentesis usually performed at approximately 15–18 weeks' gestation or chorionic villus sampling (CVS) at approximately 10–12 weeks' gestation.
        2. The disease-causing allele of an affected family member must be identified or linkage established in the family before prenatal testing can be performed.
        3. Linkage analysis should be used with caution unless *TGFBR1* or *TGFBR2* marker alleles can be shown to cosegregate with disease in a large family.
        4. Preimplantation genetic diagnosis: available for families in which the disease-causing mutations have been identified.
3. Management
    1. Careful follow-up and aggressive surgical treatment mandatory because of the following reasons:
        1. Aortic dissection and rupture in LDS tend to occur at a young age versus MFS.
        2. Vascular pathology can be seen throughout the entire arterial tree.
    2. Echocardiographic assessment of the aortic root diameter and its growth
    3. MR angiography from head to pelvis to discover other possible aneurysms
    4. Surgical fixation of cervical spine instability to prevent spinal cord damage
    5. Standard treatment of clubfeet and severe pes planus

6. Standard management of cleft palate and craniosynostosis, preferably by a craniofacial team
7. High risk of pregnancy following aortic root replacement in Loeys-Dietz syndrome: high risk of dissection (Braverman et al. 2016)
8. Prevention of secondary complications: consider subacute bacterial endocarditis prophylaxis in those undergoing dental work or other procedures expected to contaminate the bloodstream with bacteria
9. Initiate β-blockade therapy to reduce further aortic root dilatation or alternatively treat with angiotensin II receptor antagonist
10. Indications for surgical intervention in Loeys-Dietz syndrome (aggressive thoracic aortic aneurysm disease) (Williams et al. 2007)
    1. Adults
        1. Aortic root >4.0 cm or expanding rapidly (>0.5 cm/year)
        2. Descending thoracic aorta >5.0 cm or expanding rapidly (>0.5 cm/year)
        3. Abdominal aorta >4.0 cm or expanding rapidly (>0.5 cm/year)
        4. Rapid expansion of peripheral aneurysms
    2. Children
        1. Severe craniofacial features: aortic root z-score >3.0 or expanding rapidly (>0.5 cm/year), or mild craniofacial features: aortic root z-score >4.0 or expanding rapidly (>0.5 cm/year).
        2. Effort should be made to delay surgery until the annulus reaches 1.8 cm, allowing placement of a valve-sparing graft of sufficient size to accommodate growth.
        3. Large size or rapid expansion of the descending aorta or other vessels.
11. Situations and agents to avoid
    1. Contact sports
    2. Competitive sports
    3. Isometric exercise
    4. Agents that stimulate the cardiovascular system including routine use of decongestants
    5. Activities that cause joint injury or pain

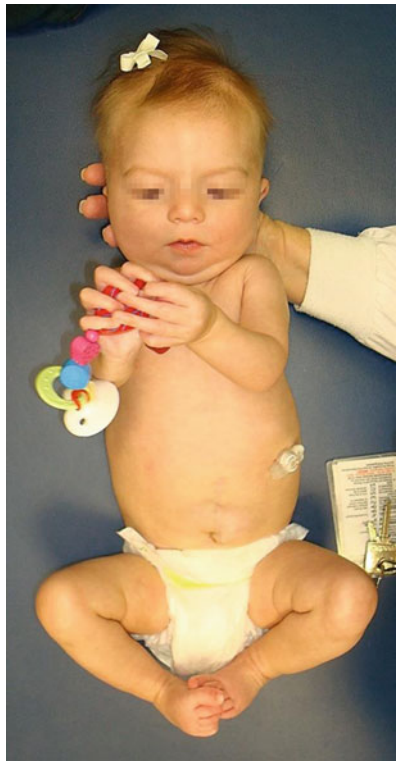

Fig. 1 A 5-month-old infant girl with molecularly confirmed Loeys-Dietz syndrome with *TGFBR1* exon 4 mutation c.722C > T (Ser241Leu). She was evaluated initially for possible neonatal Marfan syndrome because of very long fingers and toes. At 3 weeks of age, she was diagnosed to have intestinal malrotation which was surgically repaired and a Nissen fundoplication was performed. She had seizures since birth (eyes rolling up, occasional twitching, and head pulling back for a very short period). MRI of the brain showed bilateral caudal thalamic groove cyst. At 3 months of age, she was noted to be abnormally pale and was found to have bleeding due to a ruptured wandering spleen in the pelvis which was surgically removed. She had a surgical incision hernia at the site of the first surgery in addition to her original inguinal hernia. Multiple echocardiograms showed no aortic root dilatation but the patient was put on β-blocker for aortic root dilatation prevention. Family history was noncontributory. Note the ocular hypertelorism, dolichostenomelia, and arachnodactyly

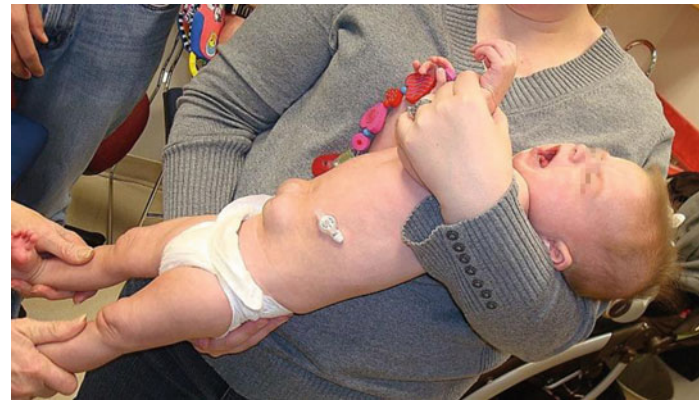

Fig. 2 Note the large incisional umbilical hernia

Fig. 3 Note the marked hypotonia and long and slender extremities

Fig. 4 Note the long toes

Lowe Syndrome

Contents

Lowe syndrome, also known as oculocerebrorenal syndrome, is a rare X-linked recessive disorder. It was initially recognized in 1952 by Lowe and colleagues who described the triad of congenital cataracts, mental retardation, and generalized aminoaciduria (Lowe et al. 1952). In 1954, a renal Fanconi syndrome was recognized as being associated with the syndrome (Bickel and Thursby-Pelham 1954) and in 1965, an X-linked recessive pattern of inheritance was determined (Richards et al. 1965). Its prevalence is estimated to be several cases per 100,000 males.

Synonyms and Related Disorders

Dent-2 disease; Oculocerebrorenal syndrome

Genetics/Basic Defects

1. Inheritance:
   1. X-linked recessive disorder predominantly affecting males, although several affected females have been reported (Abbassi et al. 1968)
   2. New mutations in 31.6% of affected males
   3. Germ line mosaicism in 4.5%
2. The gene involved (*OCRL1*):
   1. Map locus: Xq26.1, based on:
      1. Balanced X-autosome translocations with a break point in band Xq25–Xq26 in two unrelated female patients (Attree et al. 1992)
      2. Linkage analysis with RLFP in families with multiple affected individuals (Silver et al. 1987; Reilly et al. 1988, 1990)
   2. Mapped in 1977 (Nussbaum et al. 1997)
   3. Cloned in 1992
   4. Encoding *OCRL1*, a 105-kD enzyme with phosphatidylinositol 4,5-bisphosphate 5-phosphatase (PtdIns-4,5-P_2) activity localized to the Golgi complex:
      1. Loss or reduction of the enzyme demonstrated in affected males
      2. Carrier status of OCRL in females not readily determined by assays of the enzyme due to the X-linked nature of *OCRL1* and random X inactivation

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_150

3. Mutations of *OCRL1* gene responsible for Lowe syndrome (Lin et al. 1997; Satre et al. 1999):
   1. Nonsense mutations and deletions causing frameshifts and premature termination
   2. Deletions (Peverall et al. 2000)
   3. Missense mutations in domains conserved among all the known PtdIns(4,5)P_2 5-phosphatases
   4. Germ line mosaicism (Satre et al. 1999)
4. An exonic deletion of *OCRL1* gene affecting the catalytic 5-phosphatase domain is related to a severe phenotype in Lowe syndrome (Peces et al. 2013).
5. Carrier females with typical lens opacities (Gardner and Brown 1976; Reilly et al. 1988).
6. Affected females as a result of:
   1. Unfavorable lyonization
   2. Turner syndrome
   3. X-autosome translocation through the relevant gene
7. Dent-2 disease (a mild variant of Lowe syndrome (Bökenkamp et al. 2009)):
   1. Dent disease:
      1. An X-linked tubulopathy characterized by low-molecular-weight proteinuria, hypercalciuria, and nephrolithiasis/nephrocalcinosis (1)
      2. In more than half the patients, Dent disease is caused by mutations affecting the voltage-gated chloride channel and chloride/proton antiporter (ClC-5).
   2. Dent-2 disease:
      1. In approximately 15% of patients with a Dent phenotype, mutations in the oculocerebrorenal syndrome of Lowe gene (*OCRL*) encoding a phosphatidylinositol 4,5-bisphosphate 5-phosphatase has been found (Hoopes et al. 2005; Utsch et al. 2006; Sekine et al. 2007; Cho et al. 2008).
      2. These patients are classified as having "Dent-2 disease" to distinguish them from most patients with an *OCRL* mutation who have the more severe oculocerebrorenal syndrome of Lowe phenotype (Charnas et al. 1991) which is characterized by a proximal tubulopathy (Bökenhauser et al. 2008; Kleta 2008), congenital cataract, severe mental retardation, and behavioral disturbances.

Clinical Features

1. Variable age of onset and severity of clinical manifestations
2. Eye abnormalities (Ginsberg et al. 1981; Charnas and Gahl 1991; Lavin and McKeown 1993; Al-Uzri 2014):
   1. Congenital cataracts (the hallmark of the disease):
      1. Developed prenatally
      2. Always present prior to birth
   2. Congenital glaucoma with or without buphthalmos (50–60%)
   3. Microphthalmos
   4. Nystagmus
   5. Decreased visual acuity (blindness)
   6. Corneal scarring and keloid formation:
      1. Develops spontaneously without trauma
      2. Onset usually after age 5
      3. Causes significant visual impairment
3. Renal abnormalities:
   1. Fanconi syndrome of renal tubules (the cardinal features):
      1. Bicarbonaturia
      2. Proximal tubular acidosis
      3. Generalized aminoaciduria
      4. Hyperphosphaturia leading to osteomalacia, renal rickets, and pathologic fractures
      5. Hypercalciuria
      6. Proteinuria
      7. Glycosuria (not a feature of the renal tubular dysfunction)
      8. Impairment in urine concentration (polyuria)
      9. Carnitine wasting
   2. Variable age of onset and severity of the tubular dysfunction:
      1. Failure to thrive.
      2. Recurrent infections.
      3. Metabolic collapse.

4. Severe hypokalemia or hypocalcemia requiring replacement therapy in a minority of patients. This is probably a part of preterminal exacerbation of tubular dysfunction.
5. Slowly progressive renal failure may occur in the second to fourth decade of life.

4. CNS (prominently involved organ) and behavioral abnormalities:
   1. Cardinal features:
      1. Neonatal/infantile hypotonia
      2. Delay in motor milestones
      3. Cognitive impairment
      4. Areflexia by 1 year of age
   2. Mental retardation (common but not cardinal feature)
   3. Seizures
   4. Neuropathologic and neuroimaging abnormalities
   5. Stereotypic behaviors (Kenworthy and Charnas 1995; Al-Uzri 2014):
      1. Temper tantrum (Lowe tantrum)
      2. Aggression
      3. Irritability
      4. Stubbornness
      5. Rigidity of thought
      6. Self-injury
      7. Repetitive nonpurposeful movements
5. Musculoskeletal abnormalities (Holtgrewe and Kalen 1986):
   1. Secondary consequences of hypotonia, renal tubular acidosis, and/or hypophosphatemia:
      1. Short stature
      2. Joint hypermobility
      3. Dislocated hips
      4. Genu valgum
      5. Scoliosis
      6. Kyphosis
      7. Platyspondylia
      8. Fractures
   2. Primary abnormality of excessive connective tissue growth:
      1. Nontender joint swelling
      2. Subcutaneous nodules
6. Typical facies:
   1. Frontal bossing
   2. Characteristic deep-set eyes
   3. Inattentiveness
7. Other features:
   1. Increased hemorrhagic risk (Lane et al. 2010)
   2. Cryptorchidism
8. Natural history:
   1. Succumb to either severe renal insufficiency and dehydration or infection
   2. Survival to adulthood if metabolic abnormalities are adequately treated
9. Manifestation in the carriers:
   1. Lens involvement:
      1. Micropunctate cataracts clustered in a radial wedge pattern
      2. Occasional dense posterior cortical cataract
   2. Sensitivity of carrier detection by slit-lamp examination (>90%), due to random inactivation of Lowe syndrome allele in the proportion of cells in the lens of female carriers
   3. Germ line or somatic mosaicism documented
   4. Positive family history of early cataracts in mother, maternal female relatives, and institutionalized maternal uncles

Diagnostic Investigations

1. Blood chemistry:
   1. Blood gas for metabolic acidosis
   2. Electrolyte disturbances (likely absent in neonates and young infants)
2. Urine:
   1. Aminoaciduria
   2. Hyperphosphaturia
   3. Low-molecular-weight (LMV) proteinuria: characterized by the excretion of proteins such as retinal-binding protein and *N*-acetyl glucosaminidase seen in:
      1. Lowe syndrome: LMW proteinuria can be seen early in life even in the absence of clinically significant aminoaciduria or other renal tubular abnormalities (Laube et al. 2004).

2. The allelic disorder Dent disease.
3. Many other diseases associated with the Fanconi syndrome.
4. Glycosuria
5. Low urine osmolality
6. Elevated 24 h volume

3. Serum enzyme values:
   1. Elevated CK
   2. Elevated SGOT
   3. Elevated LDH
   4. Elevated α2-globulin
4. Measurement of inositol polyphosphate 5-phosphatase OCRL1 activity in cultured skin fibroblasts (Lewis et al. 2008):
   1. Males: to confirm the diagnosis in affected males (Suchy et al. 1995; Zhang et al. 1995):
      1. Affected males have less than 10% normal activity of the enzyme.
      2. Such testing is abnormal in more than 99% of affected males.
   2. Carrier females. The activity is not accurate for carrier detection because of lyonization (random X chromosome inactivation), which results in a wide range of "normal" activity in females (Lin et al. 1999).
5. Karyotype. Translocations between an autosome and an X chromosome with a break point through the OCRL locus (Xq26.1) have been observed (Hodgson et al. 1986; Mueller et al. 1991).
6. Radiography:
   1. Rickets/osteoporosis
   2. Pathological fractures
   3. Frontal bossing
   4. Kyphoscoliosis
   5. Cervical spine anomalies
   6. Platyspondyly
   7. Hip subluxations/dislocation
7. Neuroimaging:
   1. Cranial MRI:
      1. Mild ventriculomegaly (33%)
      2. Multiple tiny periventricular cysts (no clinical significance)
      3. Two patterns of brain lesions (Ono et al. 1996; de Carvalho-Neto et al. 2009):
         1. Hyperintensities on T2-weighted images
         2. Periventricular cystic lesions (Demmer et al. 1992)
   2. MR spectroscopy (Sener 2004; Allmendinger et al. 2014):
      1. Shows an elevation at 3.56 ppm, likely corresponding to elevated levels of myo-inositol. This suggests the abnormal parenchymal signal is due to gliosis, given that myoinositol is a glial marker.
      2. The MR spectra also showed normal choline and *N*-acetyl aspartate (NAA) peaks, which also suggests gliosis, as demyelination typically produces an elevated choline and reduced NAA peak.
   3. Neuropathologic examination of the brain:
      1. Normal in some cases
      2. Diffuse or focal myelin pallor without myelin breakdown
      3. Ventriculomegaly
      4. Mild cerebral abnormalities
      5. Isolated cases of subependymal cysts
      6. Mesencephalic porencephaly
      7. Postencephalitic changes
      8. Blunted and foreshortened frontal lobes
      9. Acute pontine necrosis
      10. Cerebellar hypoplasia
      11. Aberrant neuronal migration
      12. Multiple tiny cysts without inflammatory changes
8. Affected male patients:
   1. Biochemical assay of reduced activity (<10%) of PtdIns (4,5)P_2 5-phosphatase in cultured fibroblasts to confirm diagnosis of patients with OCRL. Peripheral blood cannot be tested since the enzyme is not present in lymphocytes.
   2. Molecular analysis to detect mutations in the *OCRL* gene in about 95% of affected males:
      1. Sequence analysis
      2. Fluorescence in situ hybridization analysis (FISH), with cosmid probes that span the entire *OCRL1* gene
9. Carrier females:
   1. Karyotyping to rule out X-autosome translocation with a break point through the *OCRL* locus
   2. Carrier detection:

1. Biochemical assay of reduced activity of PtdIns (4,5)P_2 5-phosphatase in cultured fibroblasts is not suitable for determining OCRL carrier status, since random X inactivation could result in a wide range of enzyme activity that may overlap with the normal range.
2. An obligatory carrier based on evaluation of the family pedigree.
3. Slit-lamp examination (Gardner and Brown 1976; Roschinger et al. 2000) for numerous punctate opacities, especially in prepubertal females, is a better method and it has a low false-negative rate.
4. By direct detection of mutations when the mutation is previously identified (in about 95% of carrier females).
5. By mutation scanning of high-risk females by denaturing high-performance liquid chromatography (DHPLC) when:
    1. The affected male is not available.
    2. The diagnosis has been confirmed by enzyme analysis.
6. By linked markers when the mutation is unknown.

Genetic Counseling

1. Recurrence risk:
    1. Patient's sib:
        1. A 25% risk of having an affected boy and a 25% risk of having a carrier daughter if the mother is a carrier (Loi 2006)
        2. A low but finite recurrence risk (estimated to be about 1.5%) in case of a new mutation due to possibility of nonpenetrance or gonadal mosaicism in the mother
    2. Patient's offspring: affected males not known to reproduce
2. Prenatal diagnosis available for pregnancies at risk:
    1. Determine fetal gender by amniocentesis or CVS
    2. Biochemical assay for deficiency of PtdIns (4,5)P_2 5-phosphatase from cultured amniotic fluid cells (Suchy et al. 1998) or cultured CVS if the fetal karyotype shows 46, XY (not suitable for determining OCRL carrier status for females)
    3. Molecular analysis (Gazit et al. 1990):
        1. By direct detection of mutations when the *OCRL* disease-causing mutation in the family is known
        2. By linked markers in informative families when the mutation is unknown (Wadellius et al. 1989)
    4. Offer prenatal diagnosis by enzymatic analysis (Suchy et al. 1998) to every mother of a son with Lowe syndrome because of the relatively high rate (4.5%) of germ line mosaicism, even with the following situations:
        1. Negative family history
        2. Negative dilated slit-lamp examination
        3. DNA testing showing that the mother is not a carrier
3. Management:
    1. Ocular management:
        1. Cataract extraction to avoid amblyopia
        2. Refraction for aphakia
        3. Control of glaucoma
        4. Removal of corneal keloids: often with recurrence and enlargement of the lesions
    2. Speech and physical therapy for developmental delay
    3. Medications:
        1. Anticonvulsants
        2. Behavior-modifying medications if needed
    4. Replacement/supplementation (Charnas et al. 1991):
        1. Phosphate and sodium-potassium citrate for renal tubular acidosis (urinary bicarbonate, water, and phosphate losses) and bone disease (rickets)
        2. L-carnitine
        3. Vitamin D supplements as indicated
    5. Anesthetic risks (Saricaoğlu et al. 2004):
        1. Chronic metabolic acidosis
        2. Existing hypokalemia, a risk for serious cardiac arrhythmia

3. A risk of glaucoma
4. Hypophosphatemic rickets causing fragility of bone structures:
    1. Requires attention while positioning
    2. Difficulty in maintaining the airway due to craniofacial abnormalities and abnormal teeth structure

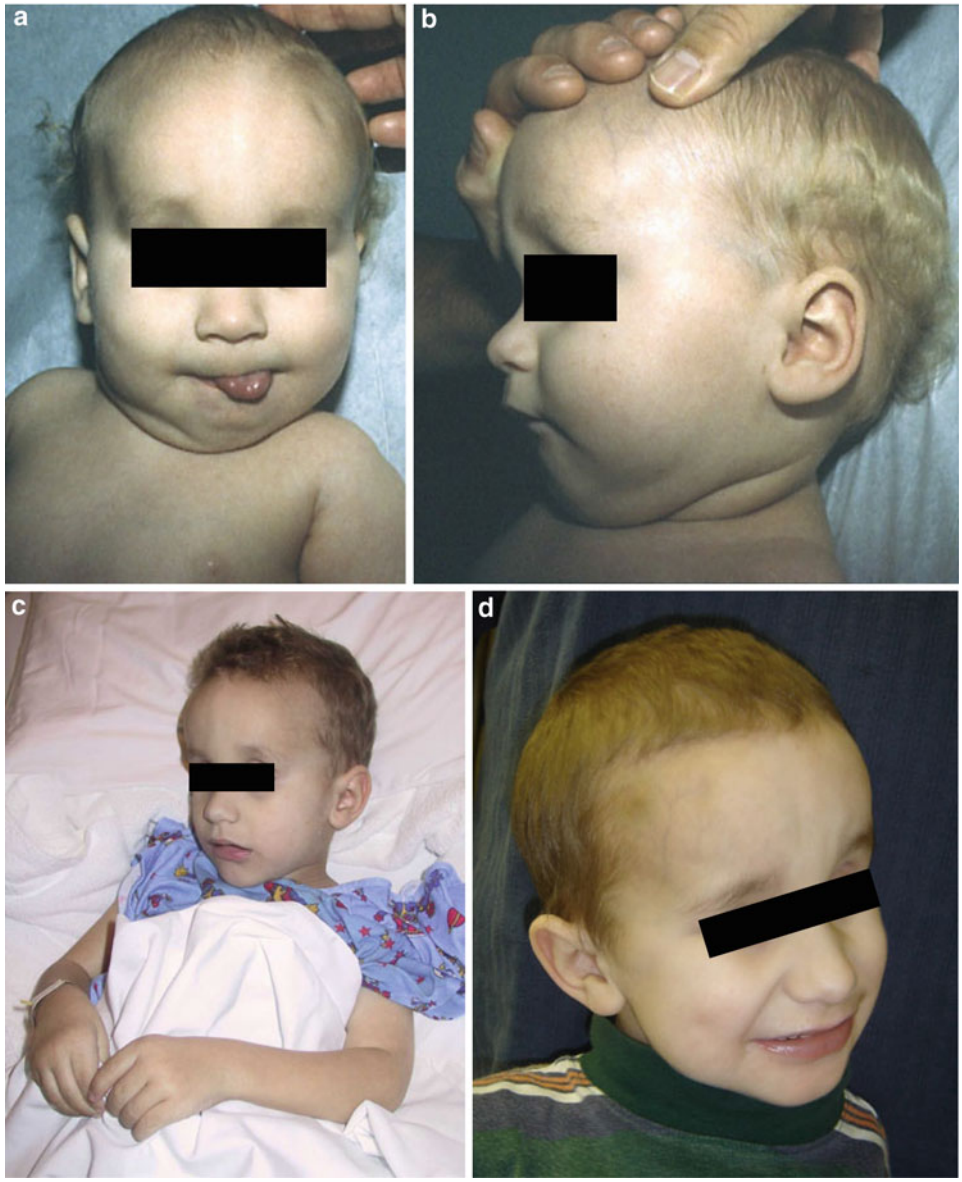

Fig. 1 (**a**–**d**) One-and-half-year-old boy with Lowe syndrome showing frontal bossing and deep-set eyes. He had a history of profound hypotonia, failure to thrive, cataracts, glaucoma, seizures, and generalized aminoaciduria. The diagnosis was confirmed by assay of markedly deficient phosphatidylinositol bisphosphate phosphatase activity in the cultured fibroblasts (0.05, control: 2–5 mmol/min/mg protein). The recent photos were taken at 6 and 9 years of age

Fig. 2 (**a**, **b**) A 10-year-old boy with Lowe syndrome showing short stature and visual impairment. The diagnosis was confirmed by assay of markedly deficient phosphatidylinositol bisphosphate phosphatase activity (0.05 with normal control of 2–5 nmol/min/mg protein) in the cultured fibroblasts

Fig. 3 This 12-year-old Hispanic boy from Panama was admitted for evaluation of global developmental delay and multiple congenital anomalies. He had a history of hypotonia, bilateral congenital cataracts which was repaired, seizures, and bony deformities. Blood chemistry showed CK [314 U/L (39-308)], LDH [452 U/L (87-241)]. AST [66 U/L (15-37)], PTH intact [91.7 pg/mL (12.4-76.8)], phosphorus [3.4 mg/dL (4.5-5.5)], and alpha-2-macroglobulin [316 mg/dL (131-293)]. Urine amino acids quantitative showed severe generalized aminoaciduria. Urinalysis showed high phosphorus (>90) and high protein (205). The clinical and laboratory findings are compatible with Lowe syndrome

Lymphangiomas and Lymphangiomatosis

Contents

Lymphangiomas are histologically benign but may have life-threatening potential with increasing size and encroachment of adjacent vital structures. Lymphangiomatosis is an extremely rare pathological condition where multiple lymphangiomas are present and may affect the visceral organs (lung, liver, and spleen), soft tissues, subcutaneous tissues, skin, and bones (long bones, pelvis, skull, vertebrae).

Synonyms and Related Disorders

Cystic hygroma; Generalized lymphangiomatosis; Gorham disease (Gorham-Stout syndrome, vanishing bone disease, massive osteolysis)

Genetics/Basic Defects

1. Lymphangiomas
    1. Basic pathological process of lymphangiomas (Whimster 1976; Stringel 1993)
        1. Large, multiloculated cisterns extend deep into the dermis and laterally beyond the obvious clinical lesions.
        2. Deep lymphangiomas show no evidence of communication with the adjacent normal lymphatics.
        3. The cause of failure of these primitive lymph sacs to connect to the rest of the lymphatic system is unknown.
    2. Relatively common benign proliferations of the lymphatic vessels, with abnormal connections to the lymphatic system representing 5-6% of childhood masses (Bhatti et al. 1985)
    3. Commonly occur in the area of primitive lymph sacs, such as the neck (where lymphangioma is referred to as "cystic hygroma") or the axilla (Grossman and Yousem 2003)
2. Lymphangiomatosis
    1. Heterogeneous disorders.
    2. Characterized by generalized or multifocal proliferation of lymphatic vessels that are lined by endothelia in osseous or extraosseous tissues (Faul et al. 2000).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_263

3. The majority of lesions occur in the thoracic (chest and mediastinum) (Faul et al. 2000) and neck region (Mirra 1989).
4. Histologically benign but infiltrates widely.

Clinical Features

1. Lymphangiomas
   1. Anatomic locations (Anderson and Kennedy 1992)
      1. Neck (75%)
      2. Axillary region (20%)
      3. Retroperitoneum and abdominal viscera (2%)
      4. Limbs and bones (2%)
      5. Cervicomediastinum (1%)
   2. Usually solitary
   3. May accompany other congenital syndromes, such as trisomies 13, 18, and 21, Turner syndrome, and Noonan syndrome (Ozturk and Yousem 2007)
   4. Asymptomatic unless pressing on adjacent structures with swelling and/or pain
2. Lymphangiomatosis
   1. Symptoms: depend on location and extent of involvement
   2. Can be devastating due to multi-organ involvement and/or osteolysis
   3. Generalized lymphangiomatosis (Yang and Goo 2006)
      1. Frequently involves the bones, mediastinum, spleen, liver, lungs, neck, and pleura.
      2. Asymptomatic in many patients.
      3. Respiratory difficulty due to pleural involvement.
      4. Pathologic fracture due to osteolytic lesions.
      5. Rarely lymphangiomatosis may involve the larynx causing obstruction of the airway tract.
   4. Diffuse intrapulmonary lymphangiomatosis, coined to describe lymphangiomatosis limited to the lungs and thoracic cavity with bilateral and diffuse involvement (Tazelaar et al. 1993; Satria et al. 2011)
      1. Nonspecific symptoms
         1. Wheezing
         2. Cough
         3. Chest tightness
         4. Shortness of breath
         5. Chest pain
         6. Dyspnea
      2. Other manifestations (Faul et al. 2000; Alvarez et al. 2004; Radhakrishnan and Rockson 2008)
         1. Cervical lymphangioma
         2. Pericardial effusions
         3. Chyloptysis
         4. Hemoptysis
         5. Protein-wasting enteropathy
         6. Lymphedema
         7. Splenic lesions
         8. Mediastinal compression
         9. Lymphangiomatosis with lytic bone lesions (also known as Gorham-Stout disease) (Gorham & Stout 1955; Nikolaou et al. 2014)
      3. Primary cause of death
         1. Respiratory failure
         2. Infections
         3. Accumulation of chylous fluid
   5. Renal lymphangiomatosis (benign cystic lymphangioma or renal lymphangiectasia) (Celebi et al. 2012)
      1. Does not usually impair kidney function but may lead to mechanical complications because of local compression effects (Chen et al. 2009)
      2. Rare signs and symptoms
         1. Flank pain
         2. Hematuria
         3. Proteinuria and ascites, due to lymphatic drainage through the urine (chyluria) and do not represent renal disease (Cheng et al. 2006)
         4. Hypertension

Diagnostic Investigations

1. Diagnostic challenge: Information from following scan types is useful in deriving the diagnosis. Imaging recommendation is

usually ultrasound and MRI. Bone scan and CT are not too much helpful and with radiation.

1. Plain film radiography: depends on disease extent
    1. Massive chylothorax
    2. Pulmonary infiltrates
    3. Splenomegaly
    4. Translucent bone lesions characterized by progressive dissolution of part or all of one or more adjacent bones
2. Magnetic resonance imaging of diffuse lymphangiomatosis (Maki et al. 1999; Ozturk and Yousem 2007)
3. Lymphoscintigraphy: provides direct evidence of the abnormal lymphatic flows associated with lymphangiomatosis (Beveridge et al. 2010)
4. Computed tomography (Raman et al. 2009)
    1. Thoracic lymphangiomatosis (Yekeler et al. 2005)
        1. Diffuse, bilateral, symmetric, and interlobular septal and peribronchovascular thickening.
        2. Usually spare alveolar spaces.
        3. Lymphatic proliferation diffusely infiltrates the mediastinum and thickens the visceral and parietal pleura.
    2. Extrathoracic lymphangiomatosis (Alvarez et al. 2004)
        1. Lytic bone lesions
        2. Splenomegaly
        3. Splenic lesions
        4. Disseminated intravascular coagulation or other coagulopathy
6. Bone scanning
7. Renal ultrasonography, CT, and MRI for renal lymphangiomatosis: detect multiple cystic-tubular structures that do not involve the parenchyma (Chen et al. 2009)

2. Histology and immunohistochemistry analysis (Ramani and Shah 1993).
    1. Characterized by multifocal proliferation of lymphatic vessels that are lined by cytologically benign endothelia.
    2. Endothelial cells lining the majority of the proliferating lymphatics showed intense immunostaining with FVIII-Rag and CD31 and focal immunoreactivity with UEA-1 in a minority of the lymphatics.
3. Pulmonary function tests for pulmonary lymphangiomatosis.

Genetic Counseling

1. Recurrence risk: apparently not significantly increased
2. Prenatal diagnosis and treatment
    1. Plain ultrasonography (Axt-Fliedner et al. 2002)
        1. Congenital lymphangiomas
            1. Most commonly noted in the neck, axilla, and anterolateral thorax
            2. May be detected antenatally as early as 8–10 weeks of gestation
            3. May be associated with skin edema, hydrops fetalis, and polyhydramnios
            4. Overall prognosis: poor with a mortality rate ranging from 50% to 100% (Pijpers et al. 1988), particularly for lesions identified in the nuchal region owing to frequent association with chromosomal anomalies
        2. Prenatal ultrasound features
            1. Present as multicystic, multiseptated structures varying in size and form (Chervenak et al. 1983; Benacerraf and Frigoletto 1987; Katz et al. 1992).
            2. Variable thickness with no solid components.
            3. Prenatal diagnosis of fetal lymphangiomatosis should be followed by targeted ultrasound and serial ultrasound scans.
    2. 3D ultrasounds: show better for extension and calculate the volume
    3. Droppler ultrasounds: to assess blood flow to exclude other vascular malformations
    4. Fetal MRI: provides essential information about the diagnosis and the anatomy of giant fetal neck masses and adjacent airways (Hubbard et al. 1998; Cozzi et al. 2010)
    5. Ex utero intrapartum treatment (EXIT): to secure fetal airway in cases of giant cervical lymphangioma complicated by fetal upper

airway obstruction (Liechty and Crombleholme 1999; Ogamo et al. 2005)
6. Elective cesarean section: avoids complications due to the exposed fetal mass during vaginal delivery
7. Parental counseling (Rasidaki et al. 2005)
    1. Prognosis depends on the location and extent of the lesion.
    2. There may be an association with chromosomal or other abnormalities.
    3. Neonatal outcome of large fetal lymphangioma is generally poor.
    4. Axillary or chest wall lymphangiomas may not carry a marked risk for aneuploidy or untoward pregnancy outcome.
    5. Fetal karyotyping may be indicated.
    6. There may be a much more optimistic prognosis with noncervical lymphangiomas.

3. Management (Blei 2011)
    1. General principle
        1. Dictated by the nature of symptoms, anatomic location, and associated problems
        2. Require concomitant or sequential therapy
    2. Systemic therapy
        1. Bisphosphonates and vitamin D: results ranging from stabilization to lack of response (Hammer et al. 2005; Lehmann et al. 2009; Heyd et al. 2011; Venkatramani et al. 2011)
        2. Direct intralesional instillation of bisphosphonate (Sun et al. 2011)
        3. Interferon alpha: successful in some cases (Venkatramani et al. 2011)
        4. Adjunctive therapy with interferon alpha-2b, low anticoagulant, low molecular weight heparin, radiotherapy, and surgery (Brodszki et al. 2011)
        5. Tyrosine kinase inhibitors: bevacizumab or propranolol (Grunewald et al. 2010; Ozeki et al. 2011)
        6. A clinical trial investigating the safety and efficacy of sirolimus for complex vascular anomalies including lymphangiomatosis and Gorham syndrome currently underway
    3. Surgery
        1. Sclerotherapy with bleomycin, doxycycline, OK-432, and other agents (Aoki et al. 1996; Guvenc et al. 2005): variable results
        2. Orthopedic surgery including bone grafts and reconstruction, arthroplasty, fracture management, and allograft-resurfacing composite (Paley et al. 2005; Burgess et al. 2006; Browne et al. 2011; Ruggieri et al. 2011; Tan et al. 2011)
        3. Total lymphectomy of mediastinum, ligation of all lymphatic vessels on the diaphragm and the thoracic inlet, and bilateral pleurectomy in cases of thoracic lymphangiomatosis (Steinacher et al. 2009)
        4. Lung and liver transplantation for lymphangiomatosis (Tepetes et al. 1995; Miller et al. 1988; Ra et al. 2007; Kinnier et al. 2008; Ooi et al. 2011): variable results
    4. Radiation therapy
        1. To prevent disease progression
        2. Result in stable or improved disease in 80% of a series of 8cases and in 77.3% of 44 previously published cases (Heyd et al. 2011)

Fig. 1 (**a**, **b**) This young boy had lymphangiomatosis, characterized by massive swellings of the left shoulder, anterior and lateral thorax, upper arm, and hand at birth. The boy had extensive surgeries to excise the lesions. The left hand was amputated

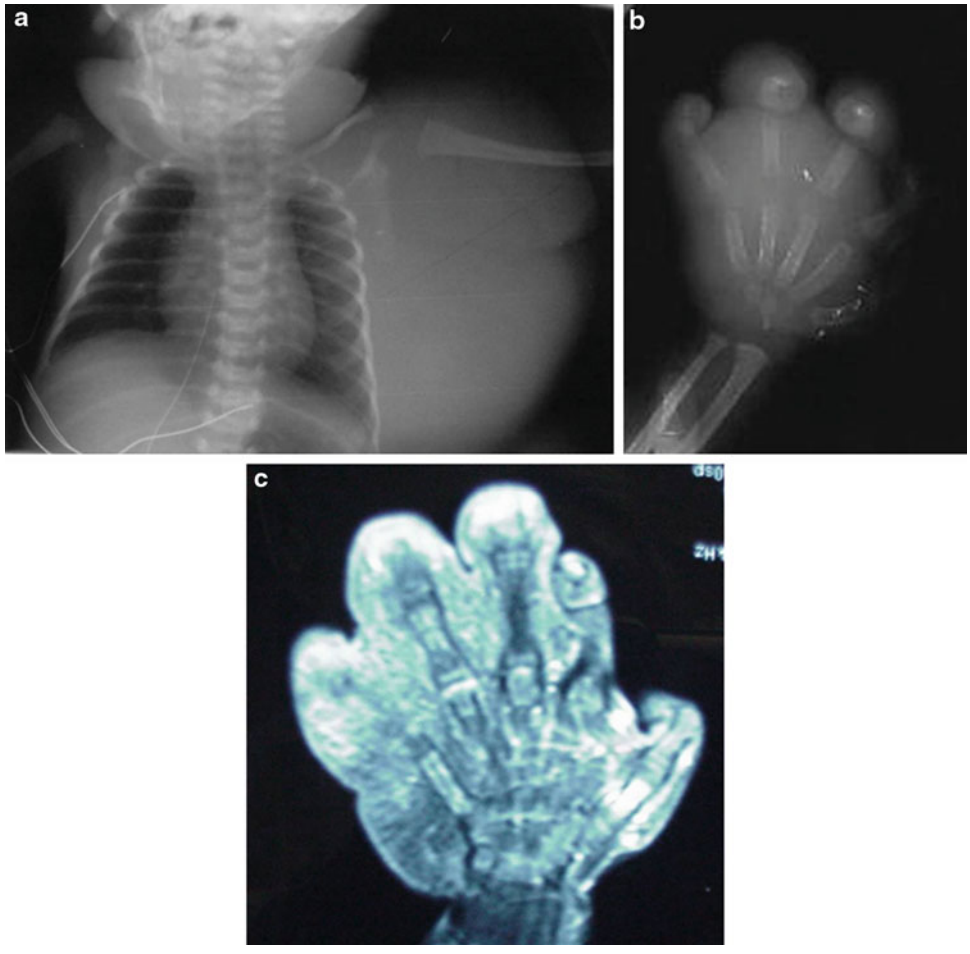

Fig. 2 (**a**–**c**) Radiography of the chest showed a huge lobulated soft tissue mass over the shoulder, proximal humerus, and left chest wall (**a**). Radiography (**b**) and MR image (**c**) of the left hand showed diffuse enlarged soft tissue with infiltrative process in the subcutaneous region. No focal abnormality was seen in the visualized bones

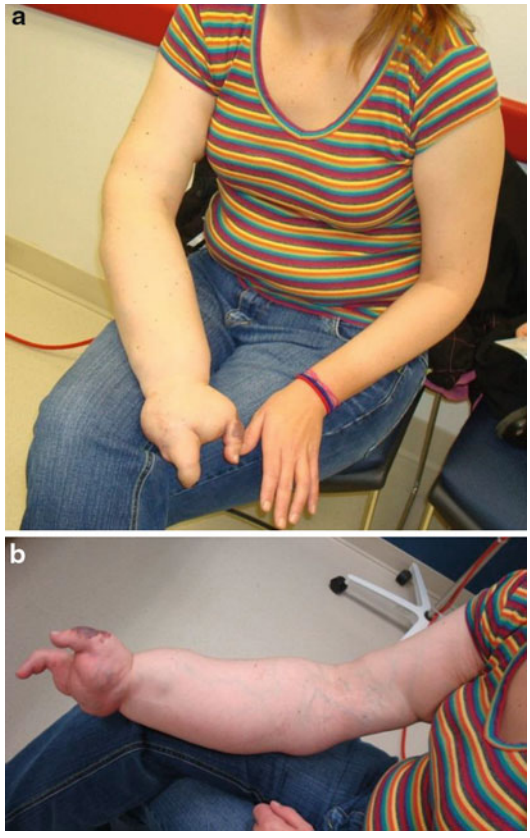

Fig. 3 (**a**, **b**) This mother with lymphangiomatosis was seen because her daughter has Poland syndrome with hypoplastic left upper arm. The mother had lymphangiomatosis involving her whole right upper extremities (**a**, **b**). She had three fingers excised and a hemangioma on the right thumb; her lymphangiomatosis also involved the breast (mastectomy), spleen, and adrenal gland

Fig. 4 (**a**, **b**) This neonate presented with lymphangioma having an enlarged left buttock (**a**). The plain radiography showed soft tissue density in the left buttock. There was no focal bone abnormality (**b**)

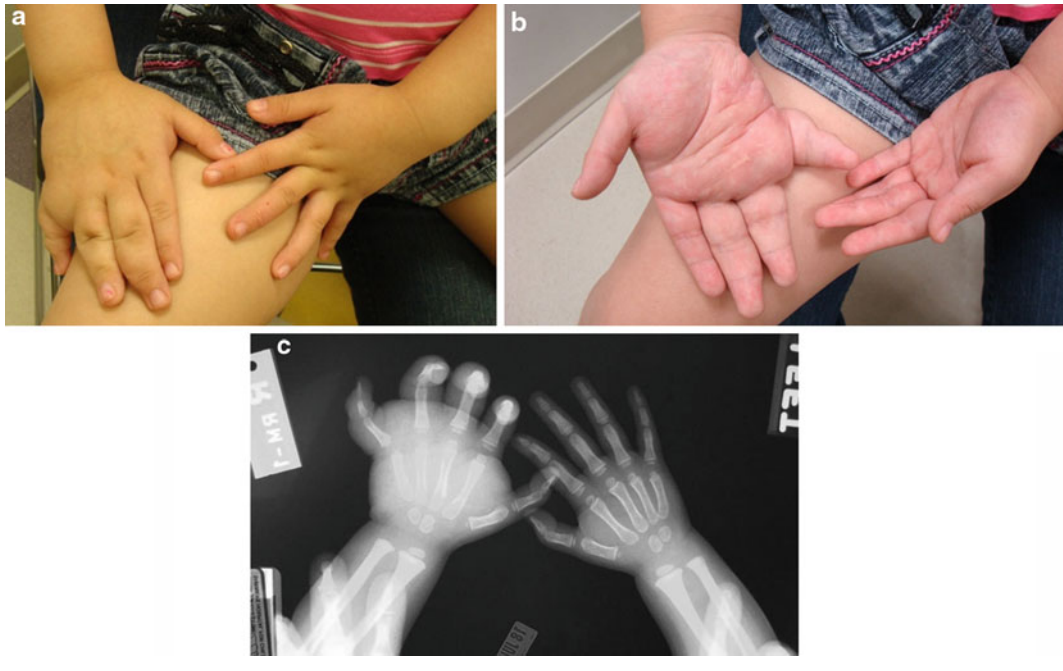

Fig. 5 (**a**–**c**) This 4-year-old boy was evaluated for soft tissue swelling of the right hand and fingers. At 10 months of age, he was operated for recurrent lymphangioma in the right hand with extensive involvement of the right hand and palmar and dorsal with severe perineural and peri-arterial scarring

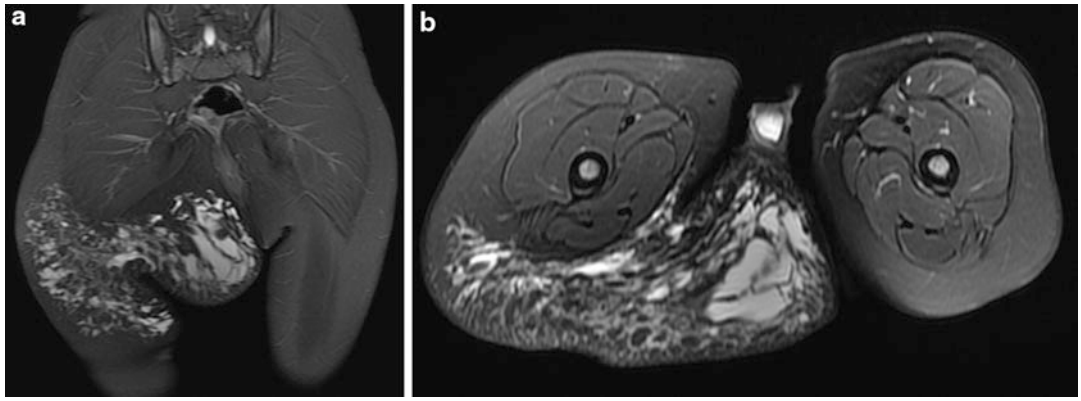

Fig. 6 (**a**, **b**) This patient was a 2-year 3-month-old male who presented for evaluation of his swollen right buttock. The parents noticed discrepancy in the size of buttocks after birth. The mother felt that the right buttock had been enlarging. There was no drainage, discolorations, or tenderness noticed. MRI (**a**, **b**) showed a large infiltrating complex mass lesion in the subcutaneous fat right of the right buttock. It was comprised of T2-weighted hyperintense collections with septations and minimal enhancement. The gluteal and thigh musculature were not involved (Courtesy of Dr. Grace Guo)

Fig. 7 (**a**, **b**) The patient was a 7-month-old girl with a history of left leg hemihypertrophy. MRI showed a large infiltrative lesion in the subcutaneous fat of the left thigh with high T2 signal abnormality (**a**) and minimal enhancement of septations (**b**). Abnormal signal did not involve the musculature. The bone marrow was normal in appearance (Courtesy of Dr. Grace Guo)

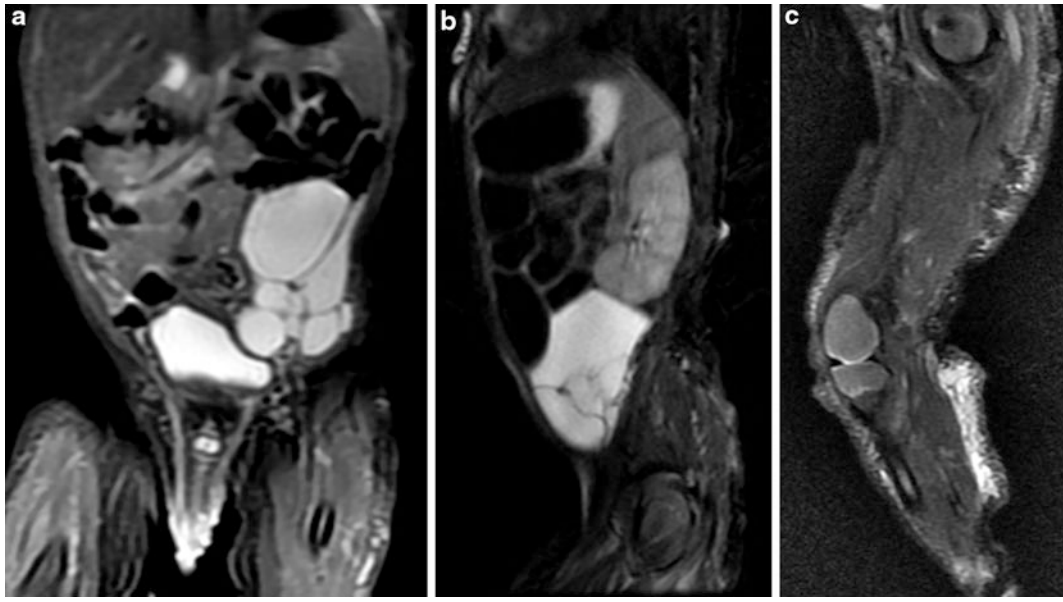

Fig. 8 (**a**–**c**) This one-week-old boy was seen because of superficial venous capillary malformations of the left lower extremity. Prenatal ultrasound showed maternal hydramnios and an abdominal cyst. On examination, the diameter of the left lower extremity was larger than the right lower extremity. There was an extensive vascular malformation of the left lower extremity extending onto the lower portion of the trunk, gluteal region, and thigh. The majority of visible portion appeared to be capillary malformation with the purple color. The clinical diagnosis of Klippel-Trenaunay-Weber syndrome with intra-abdominal lymphatic malformation and superficial venous capillary malformations of the left lower extremity was made. MRI showed a multicystic lesion in the left lower quadrant and the pelvis with displacement of the adjacent bowel loops and bladder (**a**, **b**), compatible with lymphatic malformation. There was also soft tissue abnormality that extends posterior to the left gluteal muscles and extends along the posterior lateral aspect of the thigh (**c**) with flow voids and enhancement. MRI shows two large veins laterally extending from the dorsal and ventral aspects of the hindfoot through the leg and thigh which drain into a large vein entering the pelvis to join with the left iliac vein (not shown). Correlating with clinic findings, the lesions are compatible with venous capillary malformations (Courtesy of Dr. Grace Guo)

Macrodactyly

Contents

Macrodactyly is a rare congenital anomaly resulting in overgrowth of all the mesenchymal elements of the digit including phalanges, tendons, nerves, and vessels. Currently, the term macrodystrophia lipomatosa refers to a form of progressive macrodactyly with osseous involvement associated with diffuse overgrowth of adipose tissue (Yaghmai et al. 1976; Baruchin et al. 1988; Viola et al. 1991).

Synonyms and Related Disorders

Congenital localized gigantism; Digital gigantism; Lipofibromatous hamartoma of nerve or type I macrodactyly; Macrodystrophia lipomatosa; Proteus syndrome

Genetics/Basic Defects

1. Exact etiology: unknown
2. Possible mechanisms (Inglis 1950)
    1. Abnormal nerve supply
    2. Abnormal blood supply
    3. Abnormal humoral mechanism
3. Molecular genetics of isolated congenital macrodactyly
    1. Caused by somatic activation of the PI3K/AKT cell-signaling pathway
    2. Genetically and biochemically related to other overgrowth syndromes (Rios et al. 2013)
4. Macrodactyly of the hand (Flatt 1994; Cerrato et al. 2013)
    1. Nonhereditary, rare, congenital overgrowth disorder
    2. Accounts for 0.9% of upper extremity congenital anomalies
    3. Unlike neoplastic lesions, digital enlargement involves all tissue types and maintains general patterns of growth and anatomic relationships within the affected portion of the hand
    4. Hypertrophy and tortuosity of the digital nerve: a striking features in macrodactyly of the hand
5. Macrodactyly of the foot (Hendrix et al. 2000)
    1. Relatively rare congenital deformity
    2. An incidence of 1 in 18,000 (Kowtharapu et al. 2009)
    3. An enlarged digit or digits, including the phalanges, tendons, nerves, blood vessels, subcutaneous fat, nails, and skin

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_278

4. Absence of hypertrophy and tortuosity of the digital nerve (Syed et al. 2005)

Clinical Features

1. Onset: recognized at birth or neonatal period.
2. No sex predilection.
3. Usually involve unilateral but bilateral involvement has been reported (Aydos et al. 2003).
4. Affects one or more digits and rarely one entire extremity (Bansal and Harmit 1989).
5. Favored sites: second to third digits corresponding to the median nerve and medial plantar nerve in upper and lower limbs, respectively (Sone et al. 2000).
6. Least likely affected site: fifth digit.
7. Lower extremity more commonly involved than the upper extremity.
8. Abnormal growth usually ceases at puberty.
9. Patients often present for cosmetic reasons.
10. Secondary osteoarthritis may ensue in the involved joints in adolescence or early adulthood causing mechanical problems.
11. Psychological distress can be severe and school-aged ridicule is likely because macrodactyly of the fingers may be difficult to conceal (Ghavami 2007).
12. McKusick's classification of macrodactyly (Tentamy and McKusick 1978).
    1. An isolated anomaly
        1. True type
        2. Pseudo type: digit is enlarged because of soft tissue involvement without bony enlargement
    2. A part of a syndrome, i.e.,
        1. Congenital partial gigantism
        2. Proteus syndrome
        3. Neurofibromatosis
        4. Ollier disease
        5. Maffucci syndrome
        6. Klippel-Trenaunay-Weber syndrome
        7. Trevor's disease
        8. Congenital lymphedema
13. Other classifications of true macrocephaly.
    1. Respect to the course of growth (Barsky 1967)
        1. Progressive macrodactyly: the affected enlarged digits grow disproportionally faster than the rest of the limb; more common than the static macrodactyly
        2. Static macrodactyly: affected enlarged digits grow proportionally to the rest of the limb
    2. Hyperostotic type (Kelikian 1974)
        1. Continued growth of bone elements with osteocartilaginous plaques around the joint
        2. Cartilaginous component of the periarticular deposits predominates in the early stage
        3. Cartilage gradually replaced by bone
        4. Eventually joint motion is mechanically blocked
    3. Four types of macrodactyly (Upton 2005)
        1. Type I: macrodactyly with lipofibromatosis of a nerve, either of a static or progressive subtype
        2. Type II: macrodactyly associated with neurofibromatosis
        3. Type III: associated hyperostosis
        4. Type IV: associated hemihypertrophy
14. Differential diagnosis (Singla et al. 2008)
    1. Proteus syndrome
        1. Hallmark: random or mosaic distribution of its manifestations throughout the body
        2. Hemihypertrophy
        3. Associated abnormalities
            1. Partial gigantism of hands or feet.
            2. Cerebriform connective tissue nevi (McCuaig et al. 2012).
            3. Calvarial changes: hyperostotic lesions.
            4. Pulmonary cysts.
            5. Pigmented nevi.
            6. Intra-abdominal lipomas.
            7. Vascular malformations.
            8. Some consider macrodactyly to be a localized form of Proteus syndrome.

2. Klippel-Trenaunay-Weber syndrome (please see the chapter of "▶ Klippel-Trenaunay Syndrome")
   1. Port-wine stains
   2. Excess growth of bones and soft tissue and varicose vein
3. Lymphangiomatosis (please see the chapter)
   1. Diffuse swelling.
   2. Pitting edema.
   3. Osseous growth not observed.
   4. Long TR/TE sequences show high-signal intensity lesion with low-signal-intensity septations of variable thickness.
4. Hemangiomatosis (please see the chapter)
   1. A bruit may be palpable.
   2. Osseous growth not observed.
   3. Long TR/TE sequences show high-signal intensity lesion with internal flow voids and vigorous enhancement.
5. Fibrolipomatous hamartoma of nerve
   1. Mature fat infiltrating the neural sheath.
   2. Majority of the lesions occurring in the median nerve.
   3. Macrodactyly is present in 30–66% of cases (Cavallaro et al. 1993).
   4. MRI features: speckled appearance correlating with its histologically known architecture, i.e., neural fascicles separated by fat and connective tissue.
6. Neurofibromatosis (please see the chapter)
   1. Cutaneous lesions.
   2. Marked hyperintensity on T2W images.

Diagnostic Investigations

1. Imaging (Ho et al. 2007; Singla et al. 2008; Upadhyay et al. 2011)
   1. Plain radiography
      1. Hypertrophy of soft tissue and bone
      2. Translucencies in the soft tissue due to increased adipose tissue
      3. Phalanges
         1. Elongated, broad, and splayed, especially the distal phalanx, sometimes giving rise to a mushroomlike appearance
         2. Secondary osteoarthritic changes-like joint space narrowing, subchondral cysts, and osteophytes often develop in adolescence or early adulthood (Silverman and Enzinger 1985)
   2. CT scan: to demonstrate the proliferation of fat along the nerve territory (Curry et al. 1988; Brodwater et al. 2000)
   3. MRI (Soler et al. 1997; Wang et al. 1997; Sone et al. 2000; Pandey 2007)
      1. Shows abundant adipose tissues in the involved areas.
      2. This fat has the same signal intensity as the normal subcutaneous fat.
         1. High signal on T1W
         2. Intermediate signal on T2W
         3. Low signal on fat-suppressed sequences
      3. Contrary to lipoma, the abnormal fat in this disorder is not encapsulated.
      4. Linear hypointense bands may be noted within this redundant adipose tissue representing fibrous strands (low-signal-intensity linear strands on T1W images).
      5. Fatty infiltration of the involved muscles; as well as, the bony overgrowth and cortical thickening of the enlarged bones can be well demonstrated.
2. Pathology
   1. Hallmark: increased amount of adipose tissue embedded within a fine mesh of fibrous tissue.
   2. An excess fat deposition within the nerve sheath, bone marrow, periosteum, muscles, and subcutaneous tissues.
   3. Neural enlargement may be observed, which is caused by infiltration of the nerve sheath by the adipose tissue, and there is no increase in the number of axons.
   4. The median nerve in the upper extremity and the planter nerves of the lower extremity are most commonly affected (Goldman and Kaye 1977).

Genetic Counseling

1. Recurrence risk: a sporadic occurrence; recurrence risk apparently not significantly increased
2. Prenatal diagnosis
    1. Ultrasonography detected an isolated macrodactyly in a fetus at 24 weeks of gestation (Yuksel et al. 2009).
    2. Molecular genetic analysis: not reported.
3. Management
    1. Surgeries (Cerrato et al. 2013)
        1. Soft tissue debulking (surgical removal of adipose or soft tissue).
        2. Osteotomy for volume reduction or partial amputation (surgical removal of bone either longitudinally, transversely, or both).
        3. Closing wedge osteotomy.
        4. Epiphysiodesis.
        5. Digit transfer.
        6. Toe transfer.
        7. Full ray amputation.
    2. Treatment of macrodactyly of the lower extremity (Hendrix et al. 2000)
        1. Goals
            1. To obtain a pain-free and functional foot that can fit appropriately and comfortably into a shoe approximately the same size as the contralateral normal foot.
            2. Clinical results: difficult to achieve and necessitate multiple procedures.
        2. Ablation procedures: standard treatment in the past
        3. Phalangeal resection
        4. Syndactylization
        5. Phalangeal amputation
        6. Shortening of the digit, with and without tissue debulking
        7. Osteotomy for bony deformities
        8. Epiphysiodesis in children: Although longitudinal growth is arrested, appositional growth continues and multiple surgical procedures are necessary before correction is obtained.
        9. Amputation especially in progressive types of macrodactyly
        10. Radical resection with tissue debulking remains the most definitive method of treatment (Tsuge 1967; Kalen et al. 1988)

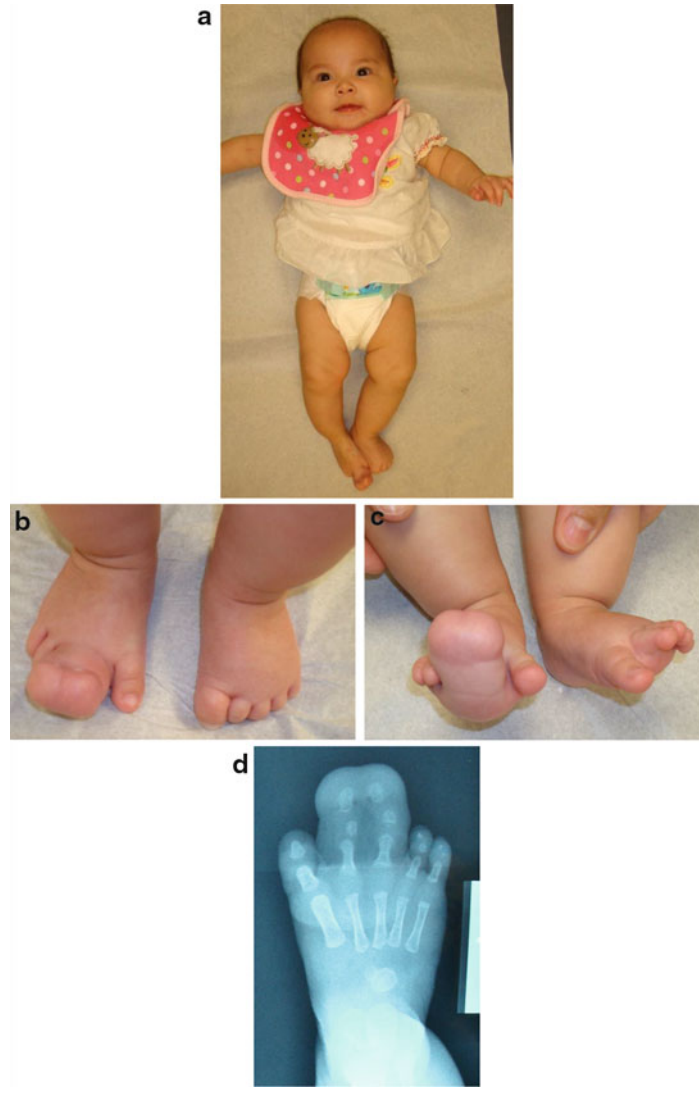

Fig. 1 (**a**–**d**) This 5-month-old female infant was seen for her macrodactyly of the right toes (**a**). Dorsal (**b**) and plantar (**c**) photographs showing macrodactyly of the second and third toes of the affected right foot with complete cutaneous syndactyly. AP radiograph (**d**) showed overgrowth of the bones and soft tissues with complete fusion of the soft tissues along the second and third toes. She also has situs inversus abdominus

Fig. 2 The infant was born with macrodactyly of the right forefoot including the right first toe through third toe with syndactyly between second and third toes. This picture was taken at approximately 7 months of age. At 9 month of age, resection of the first, second, and third ray was performed with debulking of tumorous tissue of the right foot. MRI showed extensive infiltration of the right foot by primarily fatty density tissue extending from the plantar aspect between the toes to the dorsal aspect of the right foot and extending posteriorly and medially into the ankle. This fatty density tissue has soft tissue interspersed within it in swirls. These findings most likely represent fibromatosis

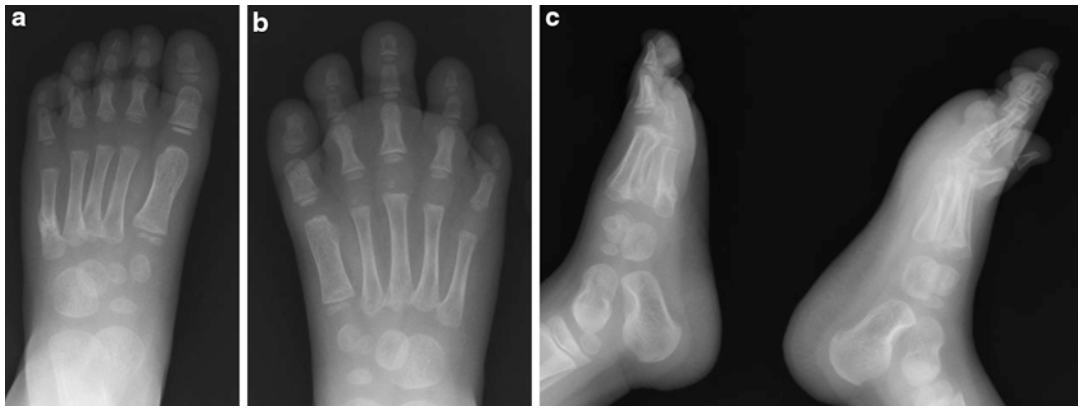

Fig. 3 This 2-year-old girl was seen for overgrowth of her right foot. Radiographs of bilateral feet showed asymmetry of the feet with overgrowth of bony structures as well as soft tissues on the right compared with the left (healing fracture was present in the left fifth metatarsal, otherwise normal left foot). It predominantly affects the right second, third, and fourth digits. In addition, the lateral cuneiform and cuboid are larger on the right than on the left. The upper and lower extremities are otherwise normal (Courtesy of Dr. Grace Guo)

Marfan Syndrome

Contents

Marfan syndrome (MFS) is an inherited connective tissue disorder, noteworthy for its worldwide distribution, relatively high prevalence, clinical variability, and pleiotropic manifestations involving primarily the ocular, skeletal, and cardiovascular systems, some of which are life threatening. Its estimated frequency is 2–3 per 10,000 individuals.

Genetics/Basic Defects

1. Inheritance.
   1. Autosomal dominant.
   2. New mutation in about 25–30% of the cases.
   3. About 70–75% of individuals diagnosed with Marfan syndrome have an affected parent.
2. Caused by a wide variety of mutations in the fibrillin-1 (*FBN1*) gene located on chromosome 15q21.1 (Dietz et al. 1991a, b; Giampietro et al. 2002).
3. Molecular defects in the fibrillin gene are responsible for the impaired structural integrity of the skeletal, ocular, and cardiovascular systems (Dietz and Pyeritz 1995).
4. Almost all mutations are specific (unique) to a particular individual or family (Robinson and Godfrey 2000).
5. *FBN1* mutation is helpful diagnostically only if it has been previously found in the person who independently meets the criteria for Marfan syndrome.
6. Criteria for causal *FBN1* mutation (Loeys et al. 2010).
   1. Mutation previously shown to segregate in Marfan family
   2. De novo (with proven paternity and absence of disease in parents) mutation (one of the five following categories)
   3. Nonsense mutation
   4. In frame and out of frame deletion/insertion
   5. Splice site mutations affecting canonical splice sequence or shown to alter splicing on mRNA/cDNA level
   6. Missense affecting/creating cysteine residues
   7. Missense affecting conserved residues of the EGF consensus sequence ((D/N)X(D/N)(E/Q)Xm(D/N)Xn(Y/F) with m and n representing variable number of residues: D aspartic acid, N asparagine, E glutamic acid, Q glutamine, Y tyrosine, F phenylalanine)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_151

8. Linkage of haplotype for n ≥ 6 meioses to the FBN1 locus
7. A compound heterozygous Marfan patient with two defective fibrillin alleles resulting in a lethal phenotype (Kartunnen et al. 1994).
8. No obvious correlation between location of mutation and phenotypic severity (except an apparent clustering of mutations associated with the most severe form of Marfan syndrome, i.e., neonatal Marfan syndrome).
9. Pathophysiological consequence of the elastic fiber degeneration: reduced distensibility in response to the pulse pressure wave or increased stiffness (Dean 2002).
10. Intrafamilial and interfamilial variability of clinical expression.
11. Fibrillin-1 mutations also observed in related disorders of connective tissue (type I fibrillinopathies) (Aoyama et al. 1995; Pyeritz 1996; Robinson and Godfrey 2000; Dietz 2009; Loeys et al. 2010).
    1. Autosomal dominant ectopia lentis (bilateral ectopia lentis without the typical skeletal and cardiovascular manifestations of the Marfan syndrome)
    2. Shprintzen-Goldberg syndrome
        1. Unclear inheritance pattern
        2. Marfanoid habitus
        3. Craniosynostosis
        4. Mental retardation
        5. Rarely aortic root dilatation
        6. Mitral valve prolapse
        7. Majority of cases are not caused by *FBN1* mutations
    3. Autosomal dominant Weill-Marchesani syndrome
        1. Ectopia lentis
        2. Short stature
    4. Familial ectopic lentis
        1. An autosomal dominant condition
        2. Bilateral ectopia lentis
        3. Scoliosis in some cases
        4. No cardiovascular manifestations
    5. Familial aortic aneurysm
        1. Ascending aortic aneurysm and dissection
        2. No ectopia lentis
        3. No specific skeletal findings
    6. MASS phenotype
        1. An autosomal dominant condition
        2. Acronym MASS stands for:
            1. *M*itral valve prolapse
            2. *A*ortic root dilation without dissection
            3. *S*keletal abnormalities
            4. *S*kin abnormalities
    7. Mitral valve prolapse syndrome
        1. An autosomal dominant condition
        2. Mitral valve prolapse
        3. Associated with subtle skeletal features that are reminiscent of the Marfan syndrome
    8. New variant of Marfan syndrome
        1. Skeletal features of Marfan syndrome
        2. Joint contractures
        3. Knee joint effusions
        4. Ectopia lentis
        5. No cardiovascular manifestations
    9. Marfan-like (marfanoid) skeletal abnormalities
        1. Tall stature
        2. Scoliosis
        3. Pectus excavatum
        4. Arachnodactyly
12. Other disorders overlap with Marfan syndrome (Dietz 2009; Loeys et al. 2010).
    1. Loeys-Dietz syndrome: please see the chapter on "▶ Loeys-Dietz Syndrome"
        1. An autosomal dominant condition.
        2. Shares many features of Marfan syndrome but ectopia lentis is absent.
        3. Unique features.
            1. Craniofacial involvement (bifid uvula/cleft palate, hypertelorism, craniosynostosis)
            2. Skin: soft, velvety, and translucent
            3. Easy bruising
            4. Generalized arterial tortuosity and aneurysms
            5. Dissection throughout the arterial trees
        4. Other features.
            1. Clubfoot
            2. Cervical spine instability
        5. Caused by mutations in either the *TGFBR1* or *TGFBR2* gene (Loeys et al. 2005, 2006).

6. Loeys-Dietz syndrome types 1 and 2: designate those with and without severe craniofacial involvement, respectively (Loeys et al. 2006).

2. Other related disorders due to defects in components of the TGFβ pathway (Cook et al. 2015)
   1. Shprintzen-Goldberg syndrome
   2. Aneurysm-osteoarthritis syndrome
   3. Syndromic thoracic aortic aneurysms
3. Congenital contractural arachnodactyly
   1. Caused by fibrillin-2 (*FBN2*) mutations (highly homologous to BBN1, mapped to chromosome 5q23-31)
   2. Characteristic features
      1. Marfanoid habitus
      2. Arachnodactyly
      3. Camptodactyly
      4. Crumpled ears
      5. Mild contractures of the elbows, knees, and hips
      6. Mild muscle hypoplasia especially of the calf muscles
4. Ehlers-Danlos syndrome: please see the chapter on "► Ehlers-Danlos Syndrome"
5. Homocystinuria
   1. An autosomal recessive condition
   2. Caused by cystathionine β-synthase deficiency resulting from mutations in the *CBS* gene
   3. Characteristic clinical features
      1. Variable mental retardation.
      2. Ectopia lentis and/or severe myopia.
      3. Skeletal abnormalities (including excessive height and limb length).
      4. Excessive overlap with Marfan syndrome (a long and lean body habitus, pectus deformity, scoliosis, mitral valve prolapse, highly arched palate, hernia, and ectopia lentis).
      5. A tendency for intravascular thrombosis and thromboembolic events: Thromboembolic events can be life threatening. Approximately half of affected individuals are responsive to pharmacologic doses of vitamin B6, highlighting the need to consider this diagnosis.
6. Stickler syndrome: please see the chapter on "► Stickler Syndrome"
7. Fragile X syndrome: please see the chapter on "► Fragile X Syndrome"

Clinical Features

Ghent criteria: For the diagnosis of Marfan syndrome in the first (index) case in a family, major criteria must be found in at least two different organ systems and minor criteria in a third body system. If a fibrillin-1 mutation is identified, a major criterion in one system and involvement of another system are required. In a relative of an individual with confirmed Marfan syndrome, a major criterion in one body system and involvement of another system are all that are needed for the diagnosis (de Paepe et al. 1996; Pyeritz 2000).

1. Skeletal system (requires at least two majors or one major plus two minors): Affected patients are usually tall and thin with respect to the family profile. Limbs are disproportionately long compared with the trunk (dolichostenomelia). Arachnodactyly is a very common feature.
   1. Major criteria (requires at least four manifestations)
      1. Pectus carinatum.
      2. Pectus excavatum requiring surgery.
      3. Reduced upper-to-lower body segment ratio (<0.85 in Caucasians and <0.78 in African descents) or arm span-to-height ratio greater than 1.05. Arms and legs may be unusually long in proportion to the torso.
      4. Positive wrist (Walker-Murdoch) and thumb (Steinberg) signs for arachnodactyly. Two simple maneuvers may help demonstrate arachnodactyly. First, the thumb sign is positive if the thumb, when completely opposed within the clenched hand, projects beyond the ulnar border. Secondly, the

wrist sign is positive if the distal phalanges of the first and fifth digits of one hand overlap when wrapped around the opposite wrist.
5. Scoliosis $\geq$20 or spondylolisthesis. More than 60% of patients have scoliosis. Progression is more likely with curvature greater than 20° in growing patients.
6. Reduced extension of the elbows ($<$170°).
7. Medial displacement of the medial malleolus, resulting in pes planus.
8. Protrusio acetabuli (intrapelvic protrusion of the acetabulum; abnormally deep acetabulum with accelerated erosion) of any degree (ascertained by pelvic radiograph). Prevalence is about 50%.

2. Minor criteria
1. Pectus excavatum of moderate severity
2. Joint hypermobility
3. High arched palate with dental crowding
4. Typical face
1. Dolichocephaly
2. Malar hypoplasia
3. Enophthamos
4. Retrognathia
5. Down-slanting palpebral fissures

2. Ocular system (requires one major or at least two minors).
1. Major criterion: ectopia lentis (usually superior temporal dislocation, almost always bilateral, occurs in up to 80% of affected individuals). This may present at birth or develop during childhood or adolescence.
2. Minor criteria
1. Abnormally flat cornea (measured by keratometry)
2. Increased axial length of the globe (measured by ultrasound)
3. Hypoplastic iris or hypoplastic ciliary muscle causing decreased miosis

3. Cardiovascular system (requires one major or one minor): the most serious problems associated with Marfan syndrome.
1. Major criteria
1. Dilatation of the ascending aorta with or without aortic regurgitation and involving at least the sinuses of Valsalva. The prevalence of aortic dilatation in Marfan syndrome is 70–80%. It presents at an early age and tends to be more common in men than women.
2. Dissection involving the ascending aorta.

2. Minor criteria
1. Mitral valve prolapse with or without mitral valve regurgitation. The prevalence of mitral valve prolapse is 55–69%.
2. Dilatation of main proximal pulmonary artery in the absence of valvular or peripheral pulmonic stenosis or any other obvious cause, below the age of 40 years.
3. Calcification of mitral annulus in patients less than 40 years of age.
4. Dilatation or dissection of abdominal or descending thoracic aorta in patients less than 50 years of age.

4. Pulmonary system (requires one minor).
1. Major criterion: none
2. Minor criteria
1. Spontaneous pneumothorax: occurs in about 5% of patients
2. Apical blebs (on chest radiography)

5. Skin and integument (requires one minor).
1. Major criterion: none
2. Minor criteria
1. Striae atrophicae (stretch marks) not associated with marked weight changes, pregnancy, or repetitive stress. Stretch marks are usually found on the shoulder, mid back, and thighs.
2. Recurrent or incisional hernia

6. Dura (requires the major criterion).
1. Major criterion: lumbosacral ectasia (ballooning or widening of the dural sac) by CT or MRI. Fewer than 20% of patients experience serious dural

ectasia. Dural ectasia is thought to be caused by CSF pulsations against weakened dura.
2. Minor criteria: none.

7. Family history (requires one major).
   1. Major criteria
      1. Having a parent, child, or sibling who meets the diagnostic criteria independently
      2. Presence of a mutation in *FBN1* known to cause the MFS
      3. Presence of a haplotype around *FBN1*, inherited by descent, known to be associated with unequivocally diagnosed MFS in the family
   2. Minor criterion: none
8. Other features not in the Ghent criteria.
   1. Ocular features
      1. Myopia (most common ocular feature)
      2. At increased risk for retinal detachment, glaucoma, and early cataract formation
   2. Skeletal system
      1. Bone overgrowth
      2. Disproportionately long extremities for the size of the trunk (dolichostenomelia)
      3. Overgrowth of the ribs pushing the sternum in (pectus excavatum) or out (pectus carinatum)
      4. Mild, severe, or progressive scoliosis
9. Natural history: age-related nature of some clinical manifestations and variable phenotypic expression.
   1. At birth, early in life, and childhood
      1. Dolichostenomelia
      2. Arachnodactyly
      3. Manifestations of other organ systems usually not present at birth, making the diagnosis during neonatal period difficult in the absence of family history
      4. Asthenic habitus
      5. Lens dislocation or lens subluxations (a hallmark feature) commonly diagnosed during the first year of life (not present at birth)
   2. Childhood and puberty
      1. Skeletal manifestations apparent during childhood
      2. Pectus deformities and scoliosis worsen during puberty
      3. Upper normal or larger than normal aortic root size in early childhood
      4. Rapidly increasing magnitude of dilatation during puberty
   3. Adulthood
      1. Lumbosacral dural ectasia manifesting as progressive dilatation of the dura with consequent erosion of vertebral bone during adulthood
      2. Aortic disease as the major cause of cardiovascular morbidity and reduced life expectancy (initial life expectancy: 32 ± 16 years)
      3. Increased life expectancy attributes to successive elective and emergent aortic surgery and to the use of β-adrenergic receptor antagonists for the prevention of the progression of aortic root dilatation (current life expectancy: 41 ± 18 years)
10. Revised Ghent nosology for the Marfan syndrome (Loeys et al. 2010).
    1. Established by an international expert panel.
    2. Puts more weight on the cardiovascular manifestations in which aortic root aneurysm and ectopia lentis are the cardinal clinical features.
       1. In the absence of any family history, the presence of aortic root aneurysm and ectopic lentis is sufficient for the unequivocal diagnosis of MFS.
       2. In the absence of either of aortic aneurysm or ectopic lentis, the presence of a bona fide *FBN1* mutation or a combination of systemic manifestations is required. The following new scoring system has been designed for systemic features: The score of ≥ 7 indicates systemic involvement (maximum total of 20 points).
          1. Wrist and thumb sign: 3 (wrist or thumb sign: 1)

2. Pectus carinatum deformity: 2 (pectus excavatum or chest asymmetry: 1)
3. Hindfoot deformity: 2 (plain pes planus: 1)
4. Pneumothorax: 2
5. Dural ectasia: 2
6. Protrusio acetabuli: 2
7. Reduced US/LS and increased arm/height and no severe scoliosis: 1
8. Scoliosis or thoracolumbar kyphosis: 1
9. Reduced elbow extension: 1
10. Facial features (3/5): 1 (dolichocephaly, enophthalmos, downslanting palpebral fissures, malar hypoplasia, retrognathia)
11. Skin striae: 1
12. Myopia >3 diopters: 1
13. Mitral valve prolapse (all types): 1

3. In this revised nosology, *FBN1* testing, although not mandatory, has greater weight in the diagnostic assessment.
4. Special considerations are given to the diagnosis of MFS in children and alternative diagnoses in adults.
5. These new guidelines may delay a definitive diagnosis of MFS but will decrease the risk of premature or misdiagnosis and facilitate worldwide discussion of risk and follow-up/management guidelines.

11. Neonatal Marfan syndrome.
    1. Diagnosed early in life because of striking and severe clinical manifestations (Gross et al. 1989)
        1. Two symptoms that are uncommon in severe Marfan syndrome presenting at birth but very common in neonatal Marfan syndrome (Hannekam 2005)
            1. Congenital pulmonary emphysema
            2. Mitral or tricuspid insufficiency (multivalvular involvement)
        2. Congestive heart failure
        3. Joint contractures
        4. Death usually within the first year of life
    2. Characteristic aged facial appearance
        1. Deep-set eyes
        2. Down-slanted palpebral fissures
        3. Crumpled ears
        4. High arched palate
    3. Striking arachnodactyly of the fingers and toes
    4. Pectus deformities
    5. Scoliosis
    6. Flexion contractures
    7. Pes planus
    8. Aortic root dilatation
    9. Ectopia lentis
    10. A cluster of mutations in exons 24–27 as well as in exons 31–32

Diagnostic Investigations

1. Annual physical examination including blood pressure measurement
2. Slit-lamp examination for lens dislocation
3. Electrocardiogram for symptomatic palpitations, syncope or near-syncope, and conduction disturbance
4. Echocardiography (Geva et al. 1987) and targeted imaging studies to carefully monitor the cardiovascular status
    1. Cross-sectional echocardiography for detecting aortic root dilatation
    2. Standard echocardiography for assessing mitral valve prolapse, left ventricular size and function, left atrial size, and tricuspid valve function
    3. Transesophageal echocardiography for visualizing the distal ascending and descending aorta and assessing prosthetic valves
    4. Doppler echocardiography for detecting and assessing the severity of aortic and mitral regurgitation
5. Radiography
    1. Chest X-ray for apical blebs, enlargement of cardiac silhouette, and detecting dissecting aneurysm of aorta
    2. Pelvic X-ray for additional diagnostic criteria of protrusio acetabuli
    3. Feet X-ray for medial displacement of the medial malleolus, responsible for pes planus

6. Computed tomography (CT) and magnetic resonance imaging (MRI)
    1. MRI: best choice for assessing chronic dissection of any region of the aorta
    2. CT or MRI of the lumbosacral spine for detecting dural ectasia
7. Cardiovscular MR (CMR) imaging (or CT) of the entire aorta (Dommand and Mohiaddin 2013)
    1. CMR: free from ionizing radiation; well visualization of aneurysm formation, dissection, and previous surgery; unsurpassed at characterizing vascular and myocardial tissue
    2. Advise every 5 years if normal aortic dimensions beyond root
    3. Advise at least annually if aneurysm formation beyond root
8. Avoid coronary angiography due to increased dissection risk (Dommand and Mohiaddin 2013)
9. Aortograph: still considered by many to be the gold standard for diagnosing acute aortic dissection although sensitivity is not 100% and there are associated risks
10. Molecular analysis of *FBN1* mutations by sequence analysis, mutation scanning, deletion analysis, or linkage analysis (may be used to determine if an individual has inherited an FBN1 allele that is associated with Marfan syndrome in family members)
    1. *FBN1* mutation screening not only confirms the diagnosis but also facilitates determination of prognosis and timely management (Loeys et al. 2001; Halliday et al. 2002; Chen 2014)
    2. Mutations detected nearly always specific to each family
    3. *FBN1* mutations observed in 20–80% of patients depending upon the clinical selection of patients and the mutation detection method used
        1. Mutation scanning
        2. Targeted mutation analysis
        3. Sequencing of entire coding region
    4. Genotype-phenotype correlations (Pyeritz 2000; Loeys et al. 2001)
        1. Little correlation observed in several hundred mutations reported to date
        2. Severe MFS detected in infancy (inappropriately termed neonatal MFS) usually caused by point mutations or small deletions in frame in the epidermal growth factor (ECF)-like motifs in the middle third of the fibrillin-1 protein
        3. Less severe phenotype, verging on the MASS phenotype, usually caused by chain-terminating mutations resulting in essence in null mutants
        4. Marked variability among individuals with the same mutation
    5. *FBN1* mutations of various types reported
        1. Classic Marfan syndrome
        2. Nonclassical Marfan related phenotypes
    6. Molecular diagnosis practical in the following two situations (Pyeritz 2000)
        1. Information about a known *FBN1* mutation in a person with MFS applied to relatives
        2. Linkage analysis using sufficient intragenic and tightly linked polymorphisms to MFS families with several available and willing relatives
11. Histology of the aorta
    1. Elastic fiber fragmentation and disarray
    2. Paucity of smooth muscle cells
    3. Deposition of collagen and the mucopolysaccharide between the cells of the media

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. Recurrence risk: small if neither parent is affected
        2. Gonadal mosaicism reported as the cause of multiple affected offspring being born to unaffected parents
        3. Fifty percent if one parent is affected
    2. Patient's offspring
        1. Fifty percent if the spouse is normal

2. "Homozygous" MFS reported in case of an affected spouse
3. "Compound heterozygosity" at the *FBN1* locus confirmed at the molecular level; the affected child had a severe phenotype leading to early death

2. Prenatal diagnosis
   1. Ultrasonography insensitive in the first two trimesters for detecting a fetus with MFS
   2. Presumptive prenatal diagnosis of fetal Marfan syndrome by fetal echocardiography at 34 weeks of gestation (Lopes et al. 1995)
      1. Cardiomegaly
      2. Pericardial effusion
      3. Prolapse of the tricuspid and mitral valves with mitral and tricuspid regurgitation
      4. Dilatation of Valsalva with typical "clover-lead" appearance
      5. Aortic and pulmonary regurgitation
   3. Main clinical cardiovascular features for the prenatal diagnosis of Marfan syndrome (Lopes et al. 2006)
      1. Cardiomegaly
      2. Dilated great vessels
      3. Dysplastic atrioventricular valves with tricuspid regurgitation and aneurysms of the pulmonary artery and/or sinus of Valsalva
   4. Prenatal diagnosis of Marfan syndrome can be confirmed in affected families by gene identification using chorionic villus sampling (Godfrey et al. 1993; Rantamaki et al. 1995).
      1. Only if the family's mutation is known in an affected parent
      2. Neonatal Marfan syndrome, mostly sporadic, appears to be more severe than those in familiar forms (Gross et al. 1989). Inability to predict exons 24–32 mutation to be associated with "classic, atypically severe or neonatal" Marfan syndrome (Tieck et al. 2001)
      3. Presence of sufficient affected family members available for genetic linkage analysis if linkage with markers in and around the *FBN1* locus can be established
   5. Preimplantation diagnosis accomplished but complicated by the potential for selective PCR amplification of the normal allele as with all autosomal dominant conditions (Eldadah et al. 1995; Kilpatrick et al. 1996; Blaszczyk et al. 1998; Sermon et al. 1999)
3. Management (Pyeritz and McKusick 1979; Nienaber and Von Kodolitsch 1999; Castellano et al. 2014)
   1. Address patients' perceptions of Marfan syndrome and its associated pain, fatigue, and depressive symptoms to enhance patient adaptation.
   2. Stress benefits of medication use (β-blockers or calcium-channel blockers to retard aortic root dilatation and dissection) and restriction of physical activities (to delay the onset of a severe cardiovascular event and prevent other syndrome-related problems such as lens dislocation).
      1. β-Blockers
         1. Should be considered in all Marfan patients, particularly in the younger age group
         2. Not suitable for patients with asthma, cardiac failure, or bradyarrhythmias
      2. Other treatments aimed at reducing the ejection impulse
         1. Calcium antagonists
         2. Angiotensin converting enzyme (ACE) inhibitors
   3. Lifestyle changes
      1. Avoid competitive and collision/contact sports which are potentially dangerous due to underlying aortic weakness and dilatation, valvular insufficiency, ocular abnormalities, and skeletal problems (Braverman 1998)
      2. Avoid blows to the head such as boxing and high diving.
      3. Protect against blows to the globe (racquet sports) with cushioned spectacles.

4. Avoid activities involving isometric work to prevent excessive elevations of systolic blood pressure and sudden death.
    1. Weight lifting
    2. Climbing steep inclines
    3. Gymnastics
    4. Water skiing
    5. Pull-ups
5. Avoid rapid decompression associated with quick ascents in elevators, scuba diving, and flying in unpressurized aircraft to protect against pneumothorax.
6. Favor noncompetitive, isokinetic activity performed at a nonstrenous aerobic pace.
    1. Golfing
    2. Walking
    3. Fishing

4. Surgical intervention recommended for affected individuals with significantly dilated or dissected aortic roots or aortic aneurysm (Baumgartner et al. 1999)
5. Management of scoliosis (Sponseller et al. 1997)
    1. Bracing
    2. Physical therapy
    3. Surgery for severe scoliosis
6. Pectus repair
    1. Repair of pectus excavatum to improve respiratory mechanics: should be delayed until midadolescence to lessen the chance of recurrence
    2. Repair of pectus carinatum performed mainly for cosmetic purpose
7. Pneumothorax
    1. Chest tube: an appropriate initial therapy
    2. Bleb resection and pleurodesis recommended after one recurrence
8. Ocular management (Koenig and Mieler 1996)
    1. Removal of dislocated lens (pars plana lensectomy and vitrectomy), only in the following few instances, due to an increased risk of retinal detachment related to lens extraction
        1. Dislocation of a lens in the anterior chamber, especially when it touches the corneal endothelium
        2. Significant lens opacity
        3. Evidence of lens-induced uveitis and glaucoma
        4. Inadequate visual acuity that is not correctable by refraction and iris manipulation
        5. Imminent complete luxation of the lens
    2. Lasers to restore a detached retina
9. Pregnancy in women with MFS (Curry et al. 2014)
    1. Preconceptional counseling of maternal risks during pregnancy and risk of transmitting the condition to offspring.
    2. A significantly increased risk of cardiovascular complications during pregnancy.
        1. Particularly risk of dissecting aortic aneurysm
        2. Increase in aortic root diameter
        3. Worsening mitral or aortic regurgitation, as seen in echocardiography
        4. Myocardial infarction
        5. Pulmonary edema
        6. Arrhythmia
        7. Endocarditis
        8. Cardiac death
        9. Aortic surgery within 6 months of delivery
    3. Obstetric complications.
        1. Antepartum hemorrhage
        2. Pregnancy-induced hypertension
        3. Pre-eclampsia
        4. Eclampsia
        5. Gestational diabetes
        6. Preterm labor/rupture of membranes
        7. Postpartum hemorrhage
        8. Thromboembolism
    4. Fetal/neonatal complications.
        1. Preterm birth
        2. Respiratory distress syndrome
        3. Intraventricular hemorrhage
        4. Fetal demise

5. Perinatal/neonatal mortality
5. Need for close surveillance during pregnancy.
6. Avoid pregnancy if echocardiography suggests a high risk of life-threatening cardiovascular compromise. Pregnancy bears a 1% risk of fatal complication; the risk rises with increasing aortic root diameter.
7. β-Blockers recommended in pregnant women to prevent aortic dilatation.
8. Cesarean section should be offered at 38 weeks gestation if aortic root diameter is greater than 4.5 cm (Child 1997).
9. Favorable outcomes in a tertiary referral center (Allyn et al. 2013).
    1. Pre- or early pregnancy evaluation
    2. Early β-blocker therapy
    3. Serial echocardiographic assessments
    4. Multidisciplinary planning of mode of delivery
    5. Avoidance of hemodynamic stress on the aortic root with appropriate analgesia/anesthesia technique
10. More extensive screening for Marfan syndrome and a search for additional risk factors are desirable because of high fatality rate in Marfan syndrome aortic root dissection (Groenink et al. 1999).
11. Genetic counseling that addresses patients' perception of Marfan syndrome and its associated pain, fatigue, and depressive symptoms may enhance patient adaptation to the condition (Peters et al. 2001a).
12. Genetic counseling should address beliefs about medication use and physical activity restrictions, as perception of these health behaviors may have a significant impact on how adults with Marfan syndrome adhere to these recommendations and cope with their condition (Peters et al. 2001b).
13. Dramatic increase in life expectancy (Silverman et al. 1995).
    1. Median (50%) cumulative probability of survival in 1993 was 72 years compared with 48 years in 1972.
    2. Overall improvement in population life expectancy.
    3. Benefits arising from cardiovascular surgery.
    4. Greater proportion of milder cases due to increased frequency of diagnosis.
    5. Medical therapy including β-blockers.

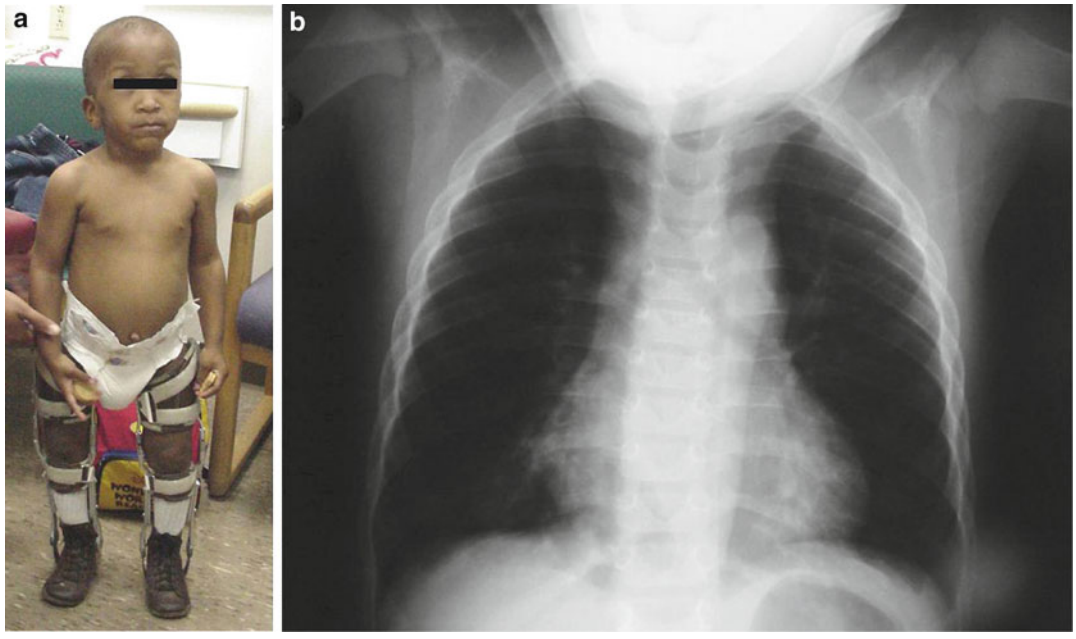

Fig. 1 (**a**, **b**) A boy with severe Marfan syndrome showing arachnodactyly, joint contractures, and aortic root dilatation, illustrated by the chest radiography

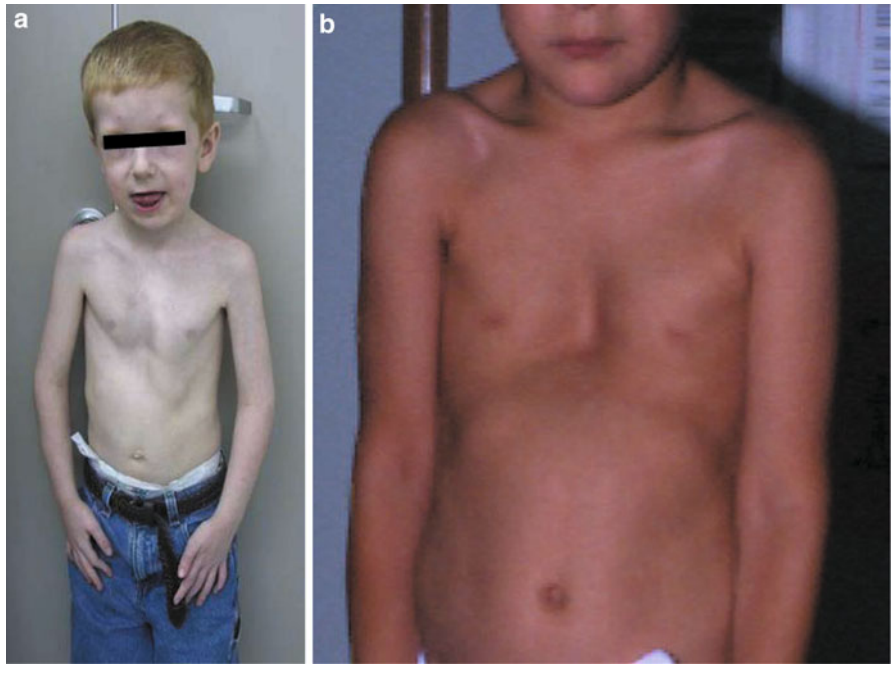

Fig. 2 (**a**, **b**) Two children with Marfan syndrome showing pectus and arachnodactyly. The first patient had dural ectasia detected by MRI. The second patient had aortic root dilatation and mitral valve prolapse

Fig. 3 A 4-year-old girl with Marfan syndrome showing pectus excavatum and the operation scar from surgical correction of marked aortic dilatation. She also has hyperextensible joints and scoliosis

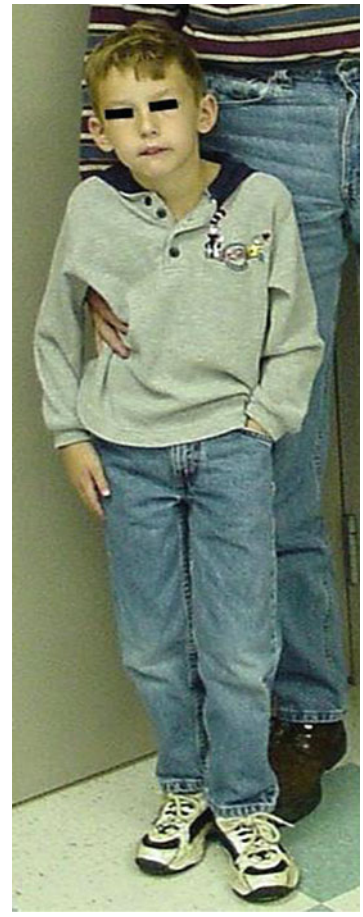

Fig. 4 A 5-year-old boy with Marfan syndrome showing tall and slender body habitus. He was noted to have mitral valve prolapse and aortic root dilatation at age 2. In addition, he has bilateral lens dislocations and scoliosis

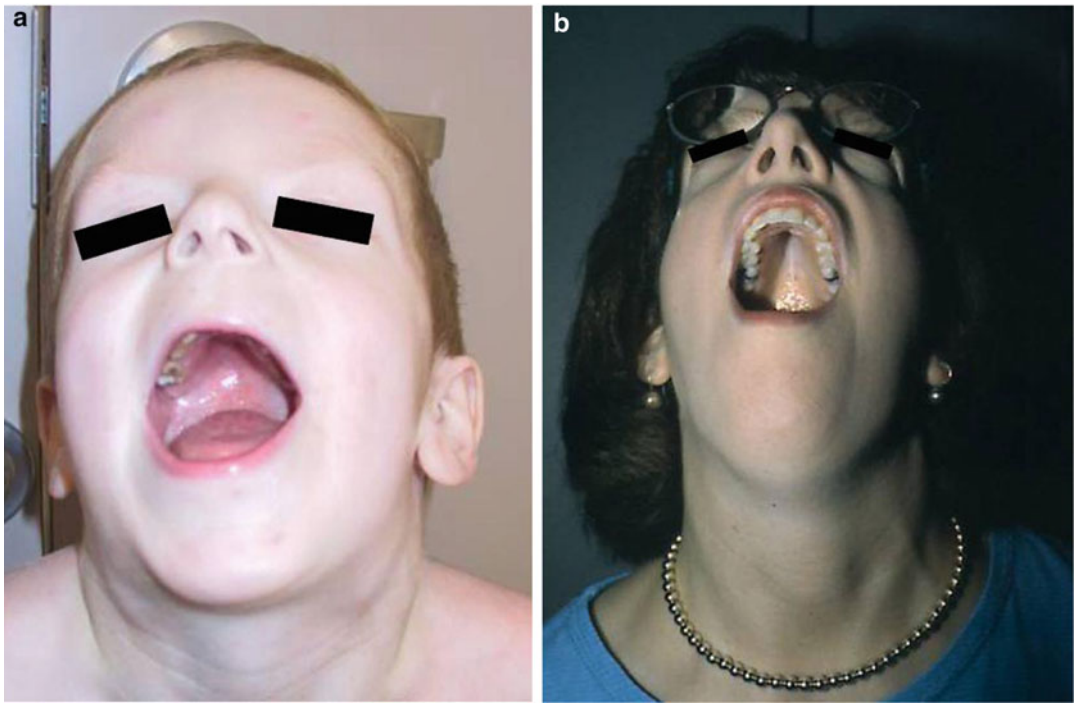

Fig. 5 (**a**, **b**) A child and an adult with Marfan syndrome showing high arched palate

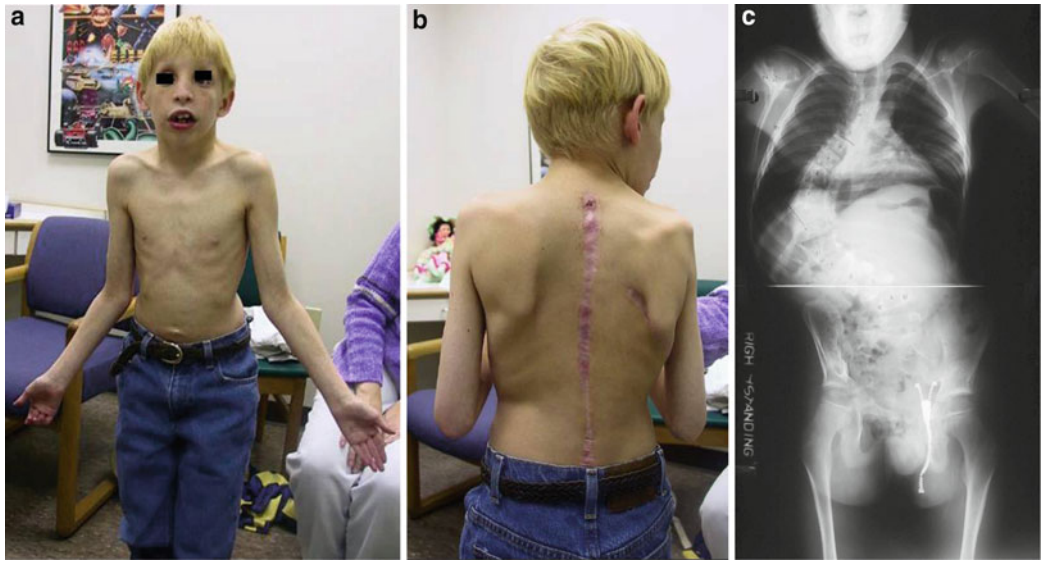

Fig. 6 (**a**–**c**) A child with Marfan syndrome showing cubitus valgus, arachnodactyly, and postsurgical spinal fusion for severe scoliosis (Illustrated by radiograph)

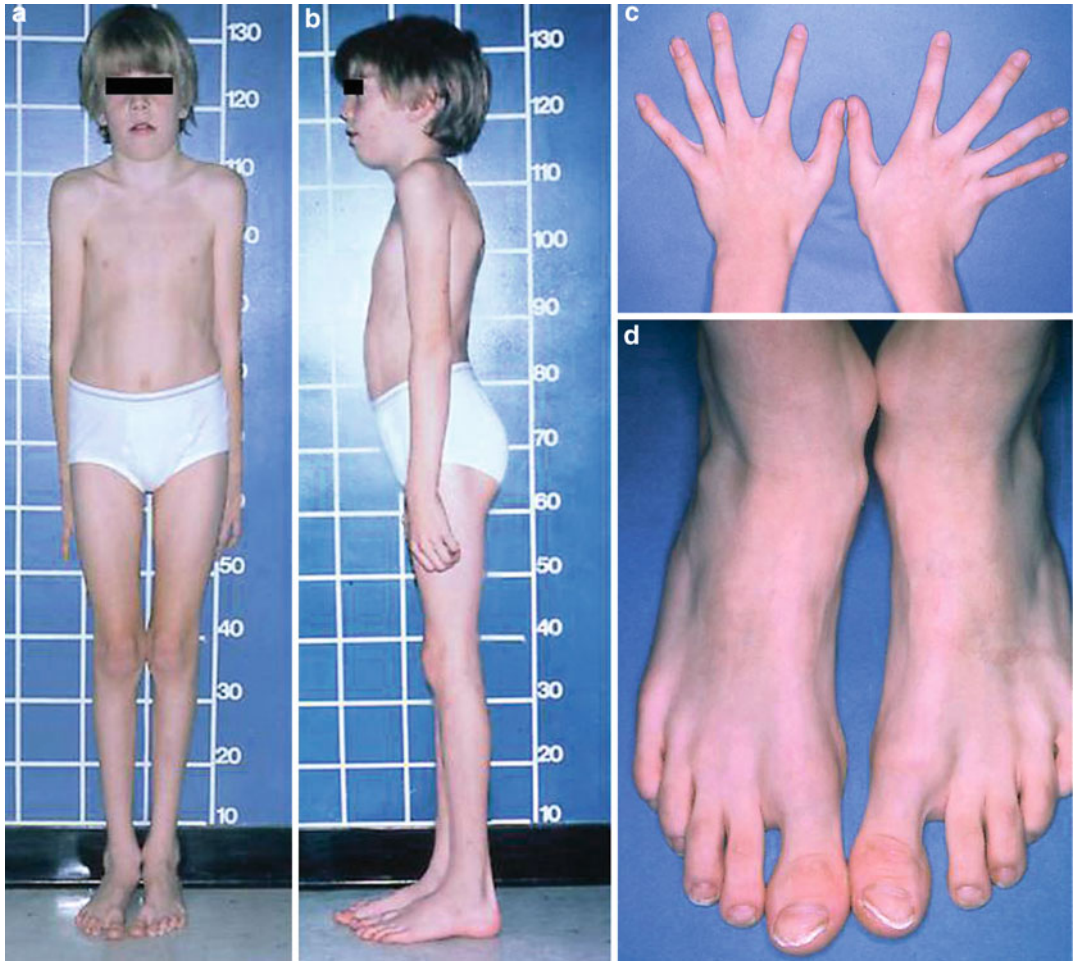

Fig. 7 (**a**–**d**) A boy with Marfan syndrome showing a slender/tall habitus and arachnodactyly

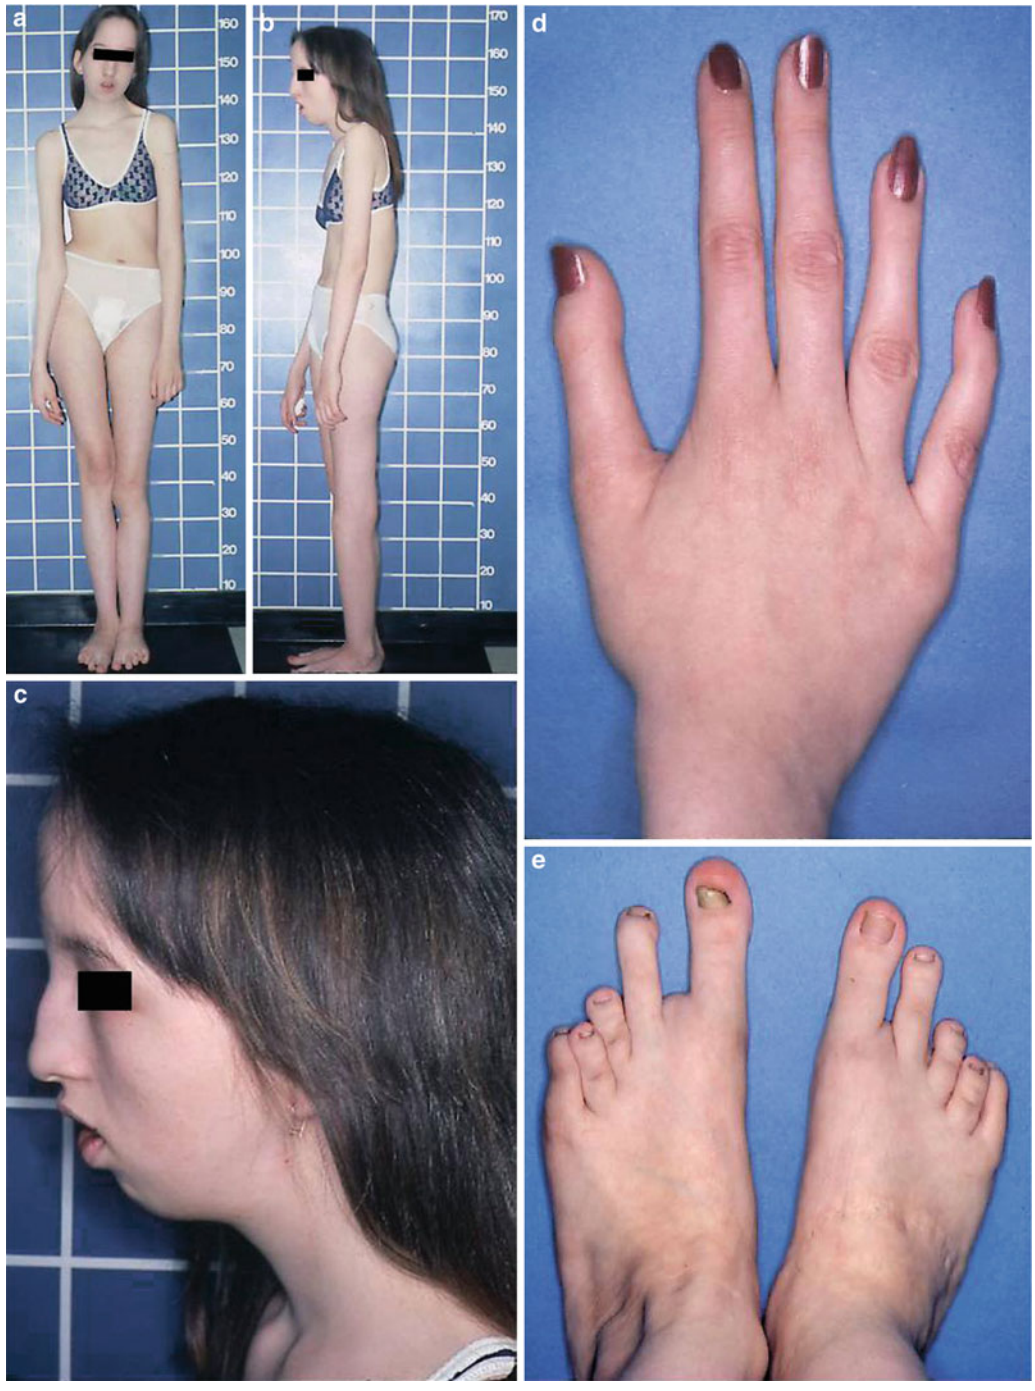

Fig. 8 (**a**–**e**) A girl with Marfan syndrome showing a slender/tall habitus, typical facies, arachnodactyly, and toe anomalies

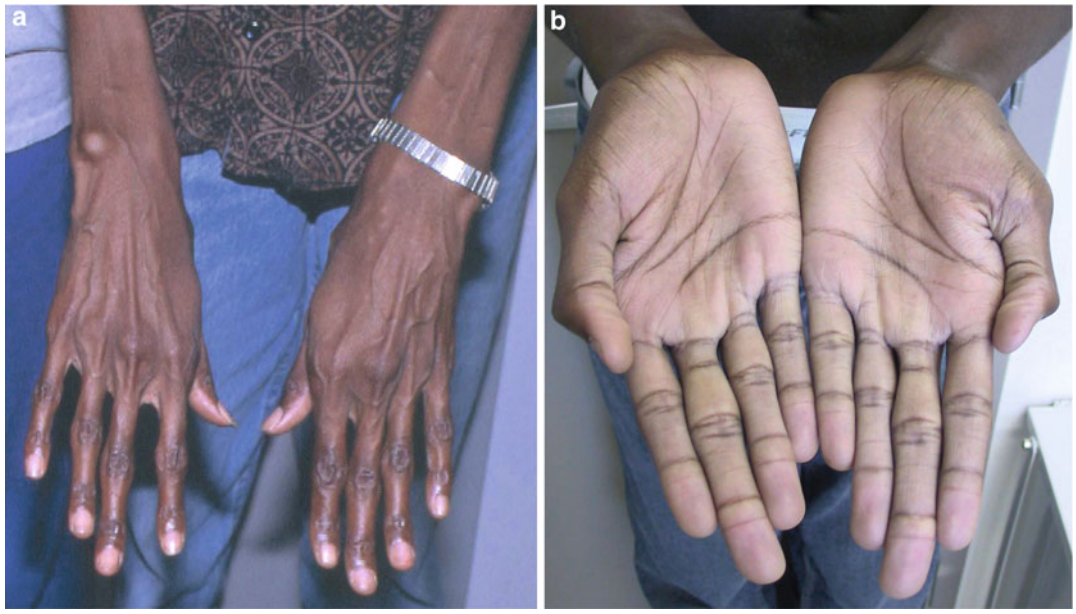

Fig. 9 (**a**, **b**) Arachnodactyly in two adult patients with Marfan syndrome

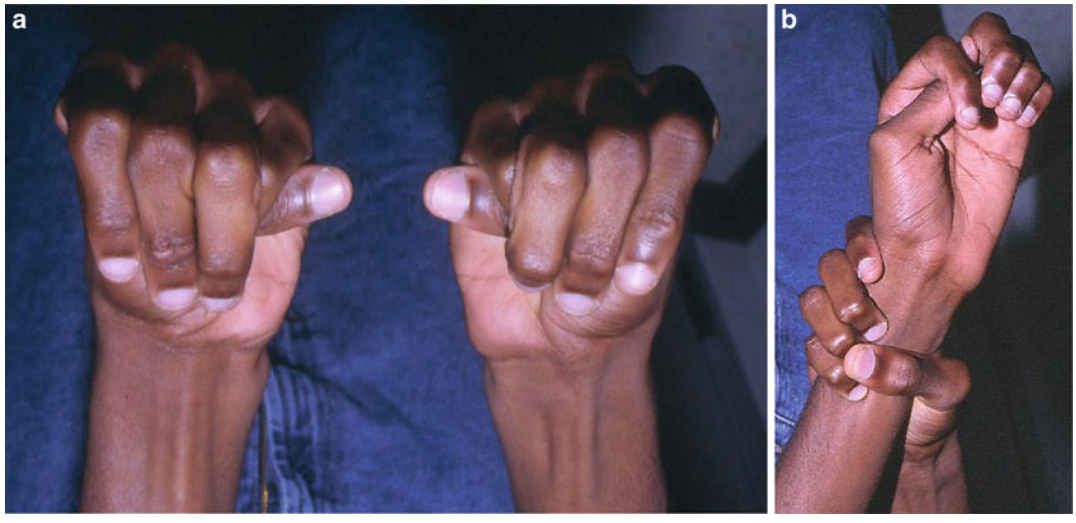

Fig. 10 (**a**, **b**) Thumb and wrist signs

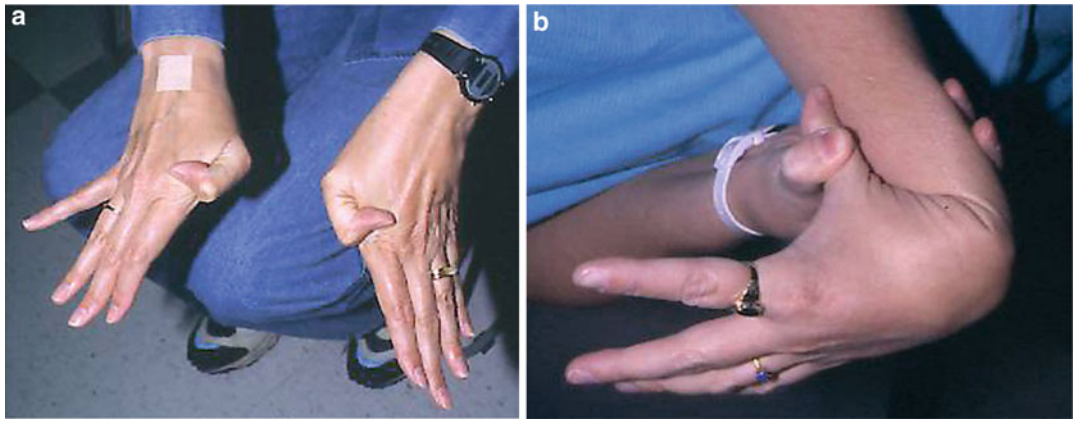

Fig. 11 (**a**, **b**) Hypermobile joints in two patients with Marfan syndrome

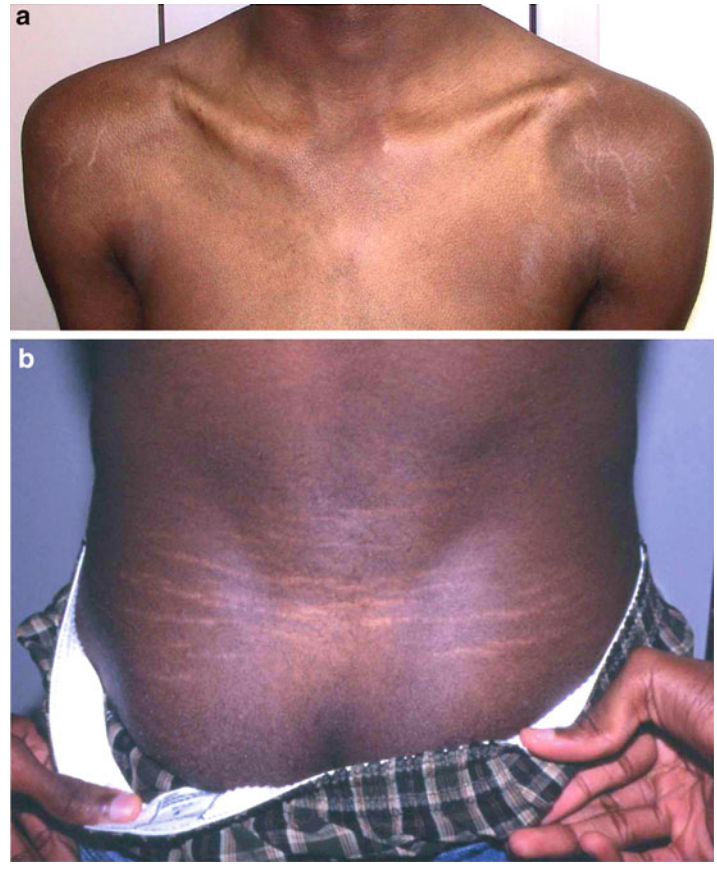
Fig. 12 (**a**, **b**) Stretch marks in the shoulders in one patient and in the buttock region in other patient with Marfan syndrome



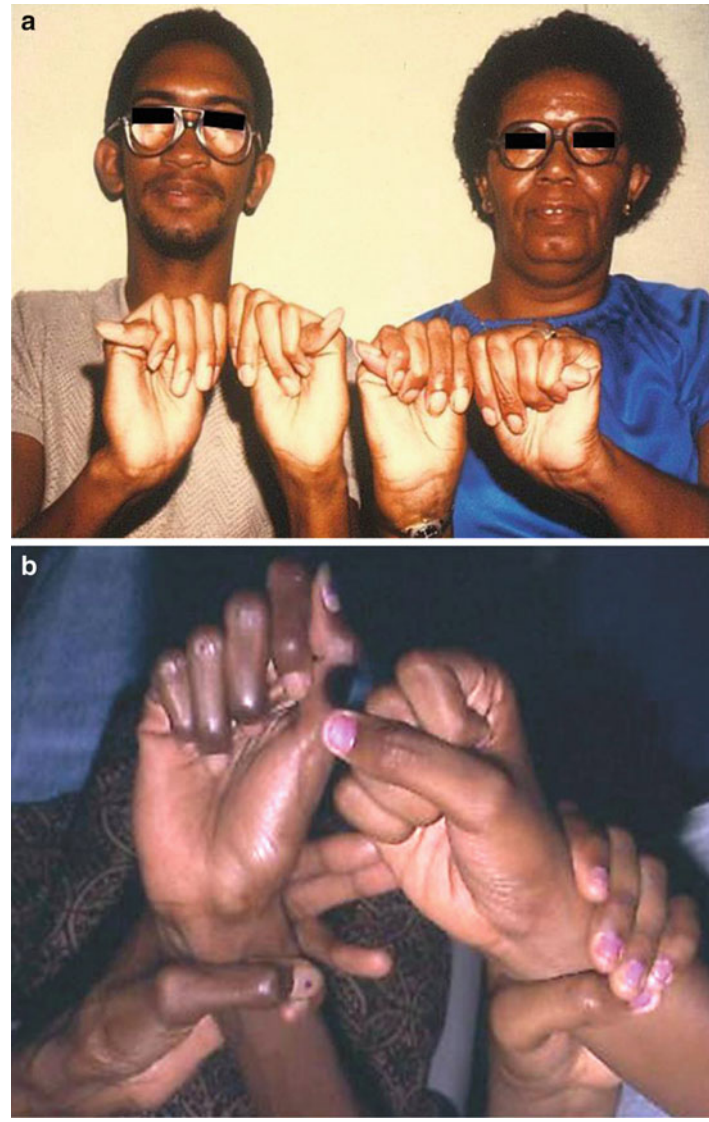


Fig. 13 (**a**, **b**) Familial Marfan syndrome in a mother and a son showing extreme myopia (lens dislocation) and thumb and wrist signs

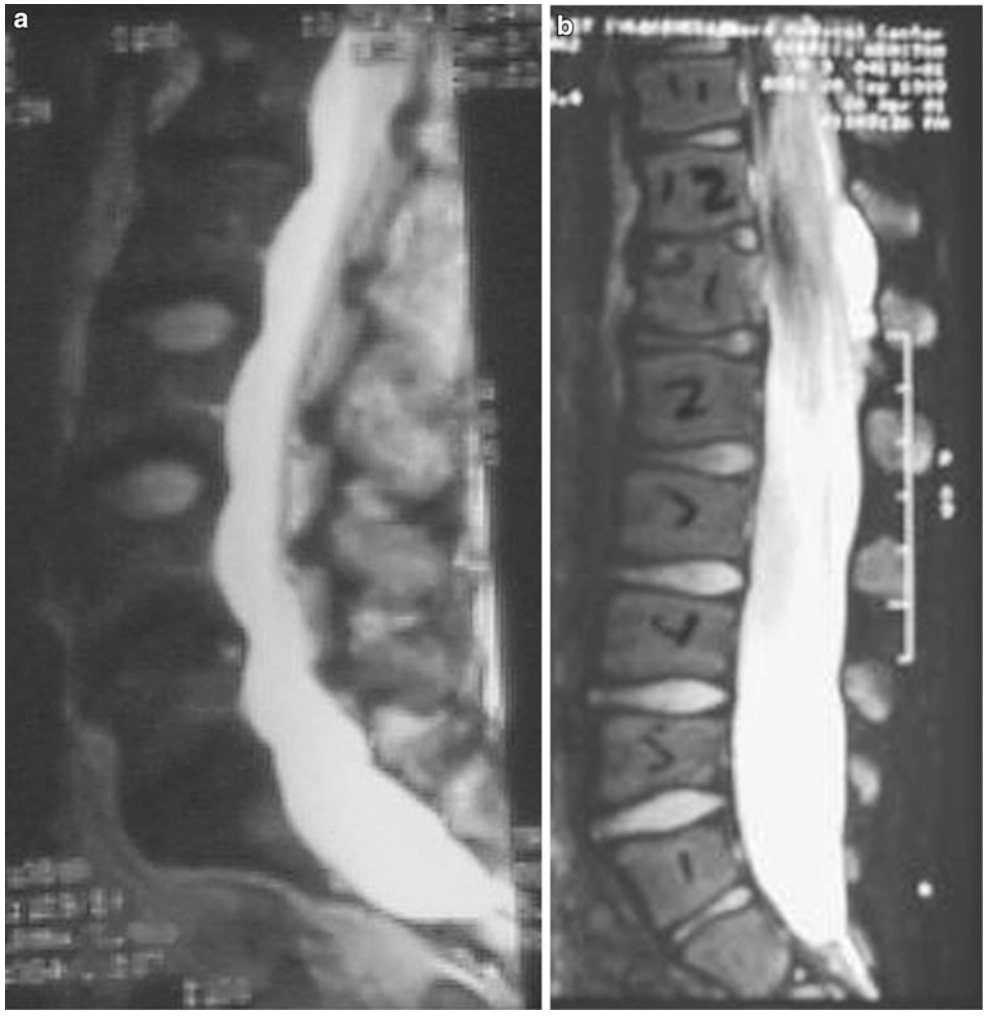

Fig. 14 (**a**, **b**) MRI of the lumbosacral spine in two patients showing dural ectasia

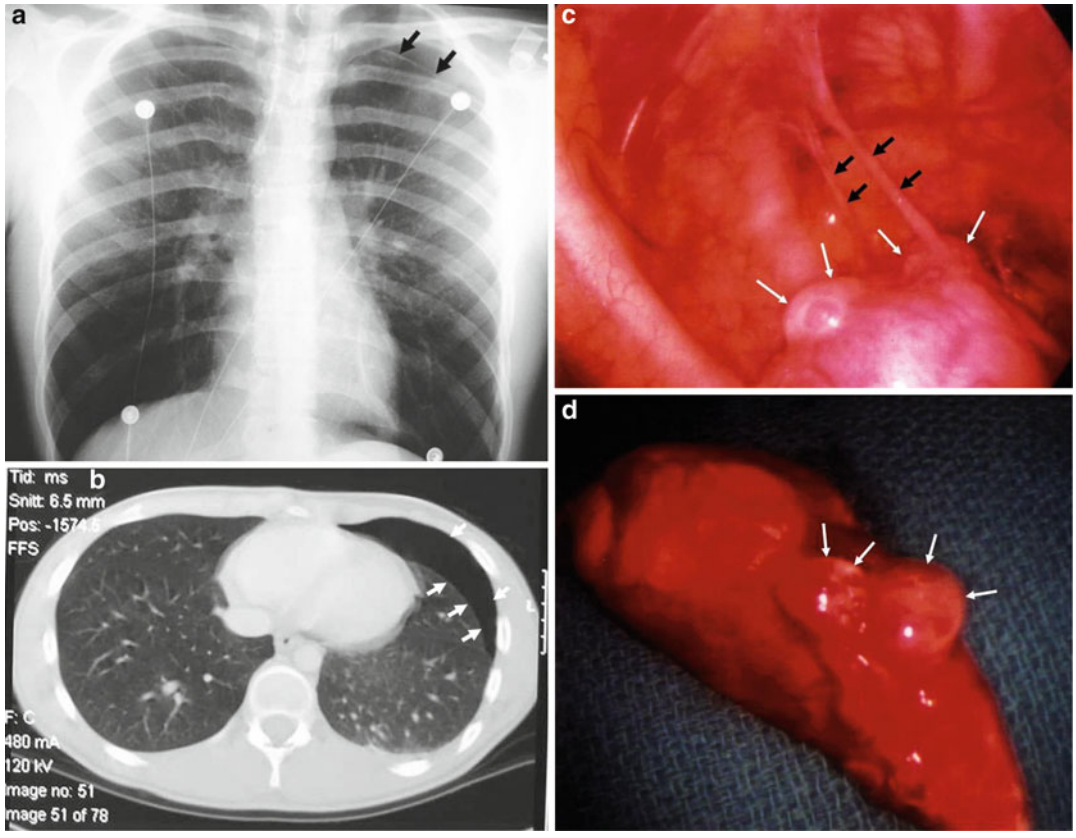

Fig. 15 (**a**–**d**) A 20-year-old male with Marfan syndrome with repeat spontaneous pneumothorax from ruptures of apical blebs. The chest X-ray shows collapsed left lung with pleural line (*arrows*). The CT of the chest shows pneumothorax on the right lung (*arrows*). Thoracoscope image from the right lung shows two bands representing the old adhesions due to previously ruptured apical blebs (*black arrows*) and two intact blebs (*white arrows*). The wedge biopsy specimen of the right apex shows two emphysematous blebs (*white arrows*) which were demonstrated in the previous figure

Fig. 16 (**a, b**) This premature baby girl (**a, b**) was born at 30 4/7 weeks gestation via cesarean section due to pregnancy-induced hypertension and omphalocele. Craniofacial features were characterized by trigonocephaly, anti-mongoloid slant of the palpebral fissures, cleft palate, and crumpled low-set ears. The neck was short. Fingers and toes were long. Echocardiograms showed a large patent ductus arteriosus and obstructive right ventricular muscle bundle at 70 %. Due to family history of her mother with Marfan syndrome and baby's clinical features of cardiac anomalies and long fingers and toes, *FBN1* gene test for neonatal Marfan syndrome and full gene sequence of *FBN1* were performed (Mayo Clinical Laboratories). A pathogenic variant was not detected in exons 24–32 of *FBN1*gene which has been reported in individual with neonatal Marfan syndrome to harbor mutations in exons 24–32 of the *FBN1* gene. However, one copy of the following mutations was detected in *FBN1*: exon 2, nucleotide c.240dupT, and amino acid p.Ile81Tyrfs*48.This pathogenic FBN1 variant is consistent with Marfan syndrome. In addition, chromosome microarray analysis identified a complex 9p rearrangement, resulting in a terminal deletion from 9p24.3 to 9p22.2, spanning approximately 17.5 megabases. FISH studies using a 9p subtelomere probe (Abbott Molecular) and a probe within the duplicated interval (CTD-2054C7) confirmed the deletion and are consistent with an inverted duplication. Similar complex 9p rearrangements have been reported in patients with developmental delay, intellectual disability, trigonocephaly, facial dysmorphism, hypotonia, and additional phenotypic features (Recalcati et al. 2012; Di Bartolo et al. 2012) (Courtesy of Dr. Lea Bonifacio)

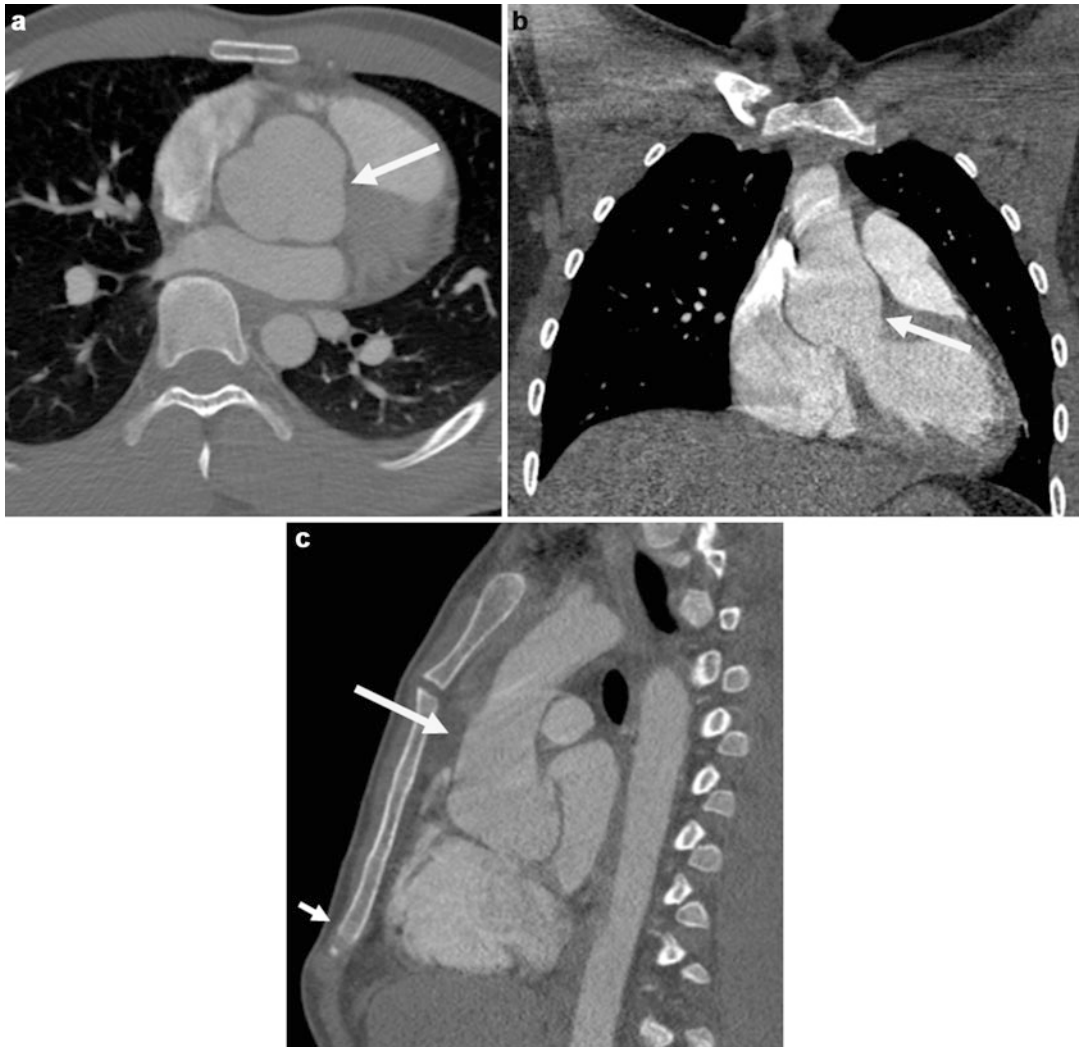

Fig. 17 (**a**–**c**) A 17-year-old male was evaluated because of a history of Marfan syndrome with complaints of headache and tearing back pain. He was noted to have pectus carinatum since birth. Since 12 years of age, he was noted to have flat feet and hyperextensible joints. He wore glasses and was told that he did not have lens dislocation (no ophthalmologic record was available). Previous echocardiogram (not shown) confirmed a markedly dilated aortic root of 3.8 cm (a Z-score of approximately +5.5). There was clover-leafing, also suggesting dilated aortic root. There was mild ascending aorta dilation and trivial mitral valve prolapse. Chest radiographs (not shown) showed a good expansion of left aortic arch and a prominent aortic knob. CT images (**a–c**) showed moderate dilation of the aortic root (*large arrows*) which measured 4.8 × 5 cm in AP and transverse dimensions. No evidence of aortic dissection or pulmonary embolism was noted. Sagittal image (**c**) showed mild pectus carinatum (*small arrow*). He was diagnosed with Marfan Syndrome at 12 years of age. His diagnosis was based on aortic root dilation, skeletal features, and FBN1 mutation (C.2695GG insertion resulting in a frameshift mutation and abnormal mRNA processing). He is now status post valve sparing aortic root replacement. (Courtesy of Dr. Grace Guo)

McCune-Albright Syndrome

Contents

McCune in 1936 described a 9-year-old female with precocious puberty, hyperpigmentation of the skin, and hyperthyroidism (McCune and Bruch 1936). In 1937, Albright published a case series of five females with bone disease, areas of hyperpigmentation, and precocious puberty (Albright et al. 1937). McCune-Albright syndrome (MAS) consists of polyostotic fibrous dysplasia, precocious puberty, café au lait spots, and other endocrinopathies secondary to hyperactivity of various endocrine glands. It is a rare disease with an estimated prevalence between 1/100,000 and 1/1,000,000.

Synonyms and Related Disorders

Albright syndrome; Mazabraud syndrome; Polyostotic fibrous dysplasia

Genetics/Basic Defects

1. Inheritance
    1. A sporadic condition
    2. Lack of genetic transmission in this syndrome
2. Molecular basis (Akintoye et al. 2002)
    1. Caused by a noninherited postzygotic somatic mutations in the guanine nucleotide-binding protein alpha subunit (*GNAS1*) gene coding for the alpha subunit of the stimulatory G protein ($G_s\alpha$) (Spiegel 1997).
    2. Mutations in *GNAS1* result in the constitutive activation of adenyl cyclase, which stimulates the synthesis of cAMP from ATP within cells.
    3. Diseases resulting from constitutive Gsα activity (Turan and Bastepe 2015).
        1. McCune-Albright syndrome
        2. Endocrine and nonendocrine tumors
    4. G proteins.
        1. Central in cell originating pathway leads to the generation of intracellular second messenger, cAMP/protein kinase A signaling (Anitha et al. 2015).
        2. Involved in transmitting hormone signals intracellularly by coupling cell surface receptors to intracellular signaling cascades.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_152

3. Constitutively activated Gs protein stimulates autonomous cell proliferation in skin and bones and hormonal hypersecretion of gonads, hypophysis, thyroid, and adrenal glands.
4. Constitutive activation of these intracellular signaling cascades is caused by the specific mutations in the absence of hormone stimulation.

5. Vast majority of $G_s\alpha$ mutations.
   1. Point mutations at the Arg201 position: associated with severe endocrine and nonendocrine manifestations (Shenker et al. 1993).
   2. Most being Arg201His or Cys
6. Potential mechanism for the development of fibrous dysplasia as a result of $G_s\alpha$ mutation in cells of the osteogenic lineage (Riminucci et al. 1997).
7. An activating $G_s\alpha$ mutation is present in fibrous dysplasia of bone in MAS (Shenker et al. 1994).
8. The term *gsp* oncogene was assigned to these mutations due to their association with certain neoplasms.
9. Presence of somatic mosaicism is reflected by the identification of normal and mutated cells throughout the body (Tinschert et al. 1999).
10. Timing of mutations.
    1. Early in embryogenesis: widespread involvement of the tissue and is likely lethal (accounts for the lack of autosomal dominant transmission of this disorder)
    2. Late in embryogenesis: milder phenotype
    3. Very late in tissue development after differentiation into a specific cell line
       1. Development of a single adenoma
       2. $G_s\alpha$-activating mutations reported in isolated hyperfunctioning thyroid nodules and in somatotroph adenomas

Clinical Features

1. Clinical features (Lee et al. 1986; Boston 2010)
   1. Extremely variable among affected individuals
   2. Consistent with a postzygotic somatic mutational event resulting in a mosaic distribution of the mutation (Weinstein et al. 1991)
   3. Clinical triad (de Sanctis et al. 1999)
      1. Polyostotic fibrous dysplasia
      2. Patchy cutaneous pigmentation (café au lait)
      3. Gonadotropin-independent sexual precocity (Bareille et al. 1999)
2. Endocrine abnormalities (Benedict 1962)
   1. Precocious puberty
      1. The most common endocrine feature and a central hallmark of MAS.
      2. Resulting from gonadotropin-independent autonomous ovarian or testicular function.
      3. Far more commonly observed in girls than boys (>50% of affected girls, only 15% of affected boys).
      4. The signs of puberty (development of breasts, testes, and pubic and axillary hair, body odor, menstrual bleeding, and increased growth rate) may appear before the age of 8 years in girls and 9 1/2 years in boys.
      5. Affected girls.
         1. Breast development or vaginal bleeding as early as 4 months of age
         2. Premature development of secondary sex characteristics (Foster et al. 1986)
         3. Excessive estrogen production, independent of gonadotropin activities, with development of ovarian cysts, sexual precocity, increased growth velocity, and markedly advanced skeletal maturity
      6. Affected boys.
         1. Premature testicular enlargement
         2. Premature spermatogenesis
         3. Premature development of secondary sex characteristics
         4. Macroorchidism (Coutant et al. 2001)
   2. Hyperthyroidism (30%)
      1. The second most commonly associated endocrinopathy
      2. Typically occurring in later childhood but occasionally within the first year of life

3. Primarily due to multinodular toxic goiter
4. Clinical effects
    1. Severe failure to thrive in infants and young children
    2. Decreased attention span
    3. Osteoporosis
    4. Tachycardia

3. Acromegaly/gigantism
    1. Resulting from excess growth hormone secreted by somatotroph adenomas in the pituitary (Bhansali et al. 2003)
    2. Characteristic stigmata
        1. Coarsening of facial features, such as frontal bossing and prognathism
        2. Enlargement of hands and feet
        3. Arthritis
    3. Complications
        1. Glucose intolerance
        2. Hypertriglyceridemia
        3. Hypertension
        4. Mild myopathy
4. Cushing syndrome (Danon et al. 1975)
    1. Adrenocorticotropic hormone (ACTH) independent
    2. Caused by adrenal enlargement and excessive secretion of the adrenal hormone cortisol
    3. Described mostly in infants (Bareille et al. 1999) and children
    4. Clinical signs
        1. Cessation of growth
        2. Poor muscle tone
        3. Obesity of the face and trunk
        4. Weight gain
        5. Skin fragility
        6. Hypertension in infancy
        7. Death possible in long-term untreated hypercortisolism
5. Clinical manifestations related to activating Gsα mutations (Chapurlat and Orcel 2008)
    1. Fibrous dysplasia of bone
    2. Café au lait spots
    3. Endocrine tumors and hypersecretion
        1. Gonadotropin-independent precocious puberty
        2. Testicular tumors
        3. Thyroid nodules and hyperthyroidism
        4. Pituitary tumors (acromegaly, corticotroph adenoma, non-secreting tumors)
        5. Adrenal cortical hyperplasia
        6. Adrenal adenomas with hypercortisolism
        7. Hyperparathyroidism
        8. Isolated premature thelarche
    4. Intramuscular myxomas
    5. Cardiomyopathy, sudden death
    6. Cholestatic liver disease
    7. Thymic hyperplasia
    8. Myelofibrosis
    9. Gastointestinal polyps
3. Nonendocrine abnormalities
    1. Skin pigmentation (café au lait spots)
        1. Flat brown patches of pigmentation with irregular contour (coast of Maine) of varying size.
        2. Frequently evident at birth.
        3. Involved area may be extensive.
    2. Fibrous dysplasia (HD) (Singer 1997)
        1. The invariable component of the syndrome
        2. Bone lesions usually evident by age of 10 years, often presenting with a limp, leg pain, or fractures
        3. Polyostotic in nature
            1. Affecting any bones
            2. Most commonly involving the femur, tibia, pelvis, phalanges, ribs, and the base of the skull
        4. Size and extent of involvement: ranging from small asymptomatic areas to markedly disfiguring lesions resulting in limping deformities
            1. Leg length discrepancy
            2. Coxa vara
            3. Shepherd's crook deformity of the femur (a characteristic sign of the disease)
            4. Bowing of the tibia
            5. Harrison's groove
            6. Protrusio acetabuli
            7. Frequent pathologic fractures
            8. Impingement on vital nerves

5. Craniofacial form
    1. Involvement of mandible (Gurler et al. 1998)
    2. Involvement of orbital and periorbital bones resulting in hypertelorism, cranial asymmetry, facial deformity such as leontiasis ossea, visual impairment, exophthalmos, and blindness
    3. Involvement of the sphenoid wing and temporal bones resulting in vestibular dysfunction, tinnitus, and hearing loss
    4. Involvement of cribriform plate resulting in hyposmia or anosmia
6. Low risk of malignant degeneration (0.4%) (Gross and Montgomery 1967)
7. Sarcoma may develop after radiation of the fibrous dysplasia lesion (Harris et al. 1962)
8. Fibrous dysplasia associated with single or multiple intramuscular or juxtamuscular myxomas (Mazabraud syndrome) (Cabral et al. 1998)

3. Hypophosphatemia
    1. Resulting from decreased reabsorption of phosphate in the renal tubule
    2. Causing rickets and short stature
    3. Normal parathyroid hormone levels
4. Chronic liver disease
    1. Mild cases: mild elevation of hepatic transaminases
    2. Severe cases: neonatal jaundice and chronic cholestasis
5. Persistent tachycardia: rare sudden death presumably due to cardiac arrhythmias
6. Associated malignancies (rare)
    1. Osteosarcomas (most common)
    2. Chondrosarcomas
    3. Fibrosarcomas
    4. Liposarcomas
    5. Breast cancer
    6. Thyroid cancer

4. Differential diagnosis of polyostotic fibrous dysplasia (Muthusamy et al. 2014)
    1. Multiple enchondromatosis (Ollier disease and Maffucci syndrome)
    2. Multiple hereditary exostosis (diaphyseal aclasis)
    3. Paget disease of bone (osteitis deformans)
    4. Skeletal metastases

Diagnostic Investigations

1. Elevated estradiol levels and suppressed or undetectable gonadotropins: diagnostic of gonadotropin-independent precocious puberty (Boston 2010).
2. Suppressed or undetectable levels of LH and FSH after administration of luteinizing hormone-releasing hormone: consistent with the diagnosis.
3. Elevated liver enzymes or hyperbilirubinemia even after normalization of cortisol or thyroxine levels suggests presence of $G_s\alpha$ activating mutations in the liver.
4. Hypophosphatemia (rickets and osteomalacia) results from increased urinary phosphate excretion.
5. Elevated thyroxine levels and suppressed TSH levels: consistent with hyperthyroidism.
6. Generally suppressed ACTH levels despite elevated cortisol levels since the glucocorticoid secretion is ACTH independent.
7. Elevated cortisol levels after dexamethasone suppression test: suggestive of Cushing syndrome.
8. Elevated 24-h urine-free cortisol levels: suggestive of Cushing syndrome.
9. Elevated serum growth hormone and insulin-like growth factor 1 levels in individuals with somatotroph adenomas due to $G_s\alpha$ activating mutations.
10. Biopsy of fibrous dysplasia lesions: can confirm the diagnosis if doubt remains after review of the radiographs.
11. Histology.
    1. Fibrous dysplasia:
        1. Caused by hyperproliferation of preosteoblastic cells
        2. Replacement of normal bones by irregular masses of fibroblasts
    2. Ovarian cyst: generally large, unilateral, and follicular in nature

3. Thyroid nodules: ranging from multinodular hyperplasia to colloid goiter
4. Adrenal hyperplasia
5. Somatotroph adenoma
6. Liver: ranging from normal hepatocytes with some fatty infiltration to focal nodular hyperplasia with fibrosis and chronic cholestasis

12. Pelvic ultrasound to detect ovarian cysts.
13. Isotopic bone scan.
    1. The most sensitive tool for detecting the presence of fibrous dysplasia lesions
    2. To detect asymptomatic fibrous dysplasia sites
    3. Often useful, especially at the initial evaluation, for determining the extent of the disease and predicting functional outcome
14. Skeletal survey (Anand 2011).
    1. Plain radiographs (Dumitrescu and Collins 2008)
        1. Often sufficient to make the diagnosis of fibrous dysplasia.
        2. Plain radiographs, demonstrating the classic ground-glass appearance, are usually sufficient for the diagnosis of fibrous dysplasia in the axial and appendicular skeleton. (The axial skeleton is comprised of bones of the skull, hyoid bone, vertebra, sternum, and ribs; the appendicular skeleton includes the hip, pelvic bone, and the shoulder girdle (clavicle and scapula)).
    2. Advanced skeletal maturation
    3. Premature closure of growth plates resulting in short stature
    4. Polyostotic fibrous dysplasia
        1. Often unilateral
        2. More frequently involved sites
            1. Lower extremities: femur (91%), tibia (81%)
            2. Pelvis (78%)
            3. Skull and facial bones (50%)
            4. Ribs
            5. Upper extremities
            6. Spine
            7. Shoulder girdle
    5. Pathological fractures (up to 85%)
        1. X-rays are often unable to detect new, small microfractures.
        2. When new focal pain develops in a fibrous dysplasia lesion and no fracture is evident on plain radiograph, CT and/or MRI can be useful for detecting subtle fractures.
        3. The classic lesion of the proximal femur in FD, the shepherd's crook deformity, is common.
    6. Long and short tubular bones
        1. Lucent lesions in the diaphysis or metaphysis
            1. With endosteal scalloping
            2. With or without bone expansion
            3. Absence of periosteal reaction
            4. Usually smooth and relatively homogeneous matrix of the lucency, described as a ground-glass appearance
            5. Presence of irregular areas of sclerosis with or without calcification
            6. The ring sign (a lucent lesion with a thick sclerotic border)
        2. Extension of lesions into the epiphysis observed only after fusion
            1. Premature fusion of the ossification centers resulting in adult dwarfism
            2. Dysplastic bone undergoing calcification and endochondral bone formation
    7. Skull and facial bones
        1. Sclerotic skull base. Diffuse sclerosis of the base of the skull often involves the sphenoid, sella turcica, roof of the orbit, thickening of the occiput, and obliteration of the paranasal sinuses.
        2. Mixed radiolucent and radiopaque pattern of maxillary and mandibular bones.
            1. Displacement of the teeth
            2. Distortion of the nasal cavities
    8. Pelvis and ribs
        1. Common cystic lesions characterized by a diffuse ground-glass appearance and ring lesions
        2. Protrusio acetabuli

9. Spine
    1. Well-defined, expansile, and radiolucent lesions with multiple internal septa or striations involving the vertebral body and, occasionally, the pedicles and arches
    2. Kyphotic deformity
    3. Spinal cord compression
    4. Rare paraspinal soft tissue extension and vertebral collapse
10. Radiographic features suggestive of malignant degeneration
    1. A rapid increase in the size of the lesion
    2. A change from a previously mineralized bony lesion to a lytic lesion

15. Radiologic features of fibrous dysplasia (Bousson et al. 2014)
    1. Bones
        1. No bone exempt
        2. Ribs, tubular bones, pelvis, spine
            1. Most frequent benign lesion of the rib
            2. Frequent benign lesion of the proximal femur
        3. Skull base, sphenoid, ethmoid, and frontal and mandibular bones
    2. Distribution
        1. Infrequent solitary involvement of the ilium (affected concomitantly with femur)
        2. Infrequent solitary involvement of the phalanges
        3. Several fibrous dysplasia foci separated by normal osseous tissue within the same bone
        4. Unilateral or predominantly unilateral involvement of a limb; involvement of vertebra and rib in the same metamere
    3. Location in long bones
        1. Diaphysis, metaphysis (femoral neck). Epiphyses usually spared
        2. Central (intramedullary) rather than peripheral
    4. Shape and size
        1. Elongated lesion along the long axis of the bone
        2. Spindle-shaped enlargement of tubular bones and ribs
        3. Curvature of the long bones: humerus, femur. "Shepherd's crook" deformity
        4. Calvarial deformity. Exophthalmos
    5. Margin
        1. Sharp with a well-defined border of sclerotic bone
        2. Expansile: the shell is thick, thin, or very thin with small perforations. No expansion if the lesion is smaller than the internal diameter of the bone
    6. Matrix
        1. Variable aspect, depending on the degree of ossification of the fibrous stroma. All aspects from radio transparent to opaque
        2. Characteristic ground-glass appearance
        3. Pure osteoblastic patterns are rare
        4. Few internal trabeculations
        5. Islands of cartilage occur in 10%
        6. Doughnut-shaped aspect in the cranial vault
        7. Increased uptake by bone scan and FDG PET
    7. Mandatory signs
        1. No soft tissue mass
        2. No lamellar, spiculated, or triangular periosteal reaction
16. Bone scintigraphy: valuable in early detection of the bone lesions (Anitha et al. 2015).
17. CT scan.
    1. CT scan of the skull: the most useful test for diagnosis of craniofacial fibrous dysplasia
    2. CT scan of the abdomen to demonstrate bilateral enlargement of the adrenal glands in infantile Cushing syndrome
18. Whole-body MRI can be used for evaluation and follow-up of polyostotic fibrous dysplasia (Ferreira et al. 2010).
19. Mutation detection (Akintoye et al. 2002).
    1. Standard PCR-based amplification
    2. Followed by sequencing of the appropriate region of the *GNAS1* gene
    3. Targeted sequence analysis of exons 8 and 9 of the GNAS gene: to detect p.Arg201His and p.Arg201Cys (Boyce and Collins 2015)

Genetic Counseling

1. Recurrent risk.
    1. Patient's sib: not increased since MAS is due to a somatic mutation
    2. Patient's offspring: not increased since a germ line-activating mutation in the $G_s\alpha$ gene might be lethal
2. Prenatal diagnosis: As FD/MAS is mosaic and not inherited, prenatal testing is not indicated (Boyce and Collins 2015).
3. Management (Boston 2010).
    1. Precocious puberty
        1. Medical care
            1. Difficulty to treat precocious puberty.
            2. The biosynthetic forms of gonadotropin-releasing hormone such as deslorelin, histrelin, and Lupron which suppress LH and FSH are not effective in most girls with MAS.
            3. Provera, a progesterone-like hormone, for cessation of vaginal bleeding but not effective in slowing the rapid rates of growth and bone development and may have unwanted effects on adrenal functioning.
            4. Ketoconazole, aimed at interrupting adrenal steroid biosynthesis, for cessation of vaginal bleeding.
            5. Testolactone and fadrozole (aromatase inhibitors, to block the conversion of testosterone to estradiol, thus lowering circulating estrogen levels) for halting pubertal progression.
            6. A multicenter trial of tamoxifen (an estrogen agonist/antagonist) treatment of precocious puberty in girls, resulting in a reduction of vaginal bleeding and significant improvements in growth velocity and rate of skeletal maturation (Eugster et al. 2003)
        2. Surgical care: ovarian cystectomy or oophorectomy not typically warranted because of the likelihood of cyst recurrence in residual ovarian tissue
    2. Hyperthyroidism
        1. Medical care: propylthiouracil or methimazole, drugs which block thyroid hormone synthesis, for patients with excessively high thyroid hormone levels
        2. Surgical care: thyroidectomy or hemithyroidectomy for hyperthyroidism associated with a goiter
    3. Infantile Cushing syndrome
        1. Medical care
            1. Treat with drugs that block cortisol synthesis
            2. Adequate adrenal steroid (hydrocortisone, Florinef) replacement after bilateral adrenalectomy
        2. Surgical care: surgical removal of the affected adrenal glands
    4. Acromegaly/gigantism
        1. Medical care: treat with synthetic analogs of the hormone somatostatin to suppress growth hormone secretion (Bhansali et al. 2003)
        2. Surgical care: surgical removal of the area of the pituitary which is secreting the pituitary growth hormone
    5. Early detection and treatment of patients with excess growth hormone to prevent morbidity related to the craniofacial form of the fibrous dysplasia (50% of polyostotic form)
        1. Morbidity
            1. Hearing loss
            2. Blindness
        2. Therapy
            1. Cabergoline
            2. Long-acting octreotide therapy
    6. Hypophosphatemic rickets: treat with oral phosphates, supplement with vitamin D
    7. Fibrous dysplasia
        1. Medical care (Isaia et al. 2002)
            1. Monitor vision and hearing closely if lesions are located near or around the orbits.
            2. Avoid contact sports to minimize the risk of pathologic fractures.
            3. Bisphosphonates used to inhibit bone absorption by osteoclast activity

through apoptosis induction and protein prenylation inhibition.

4. Pamidronate, a second-generation aminobisphosphonate for reduction in bone pain and markers of bone turnover.

2. Surgical care: grafting, pinning, and casting to surgically correct fractures and deformities

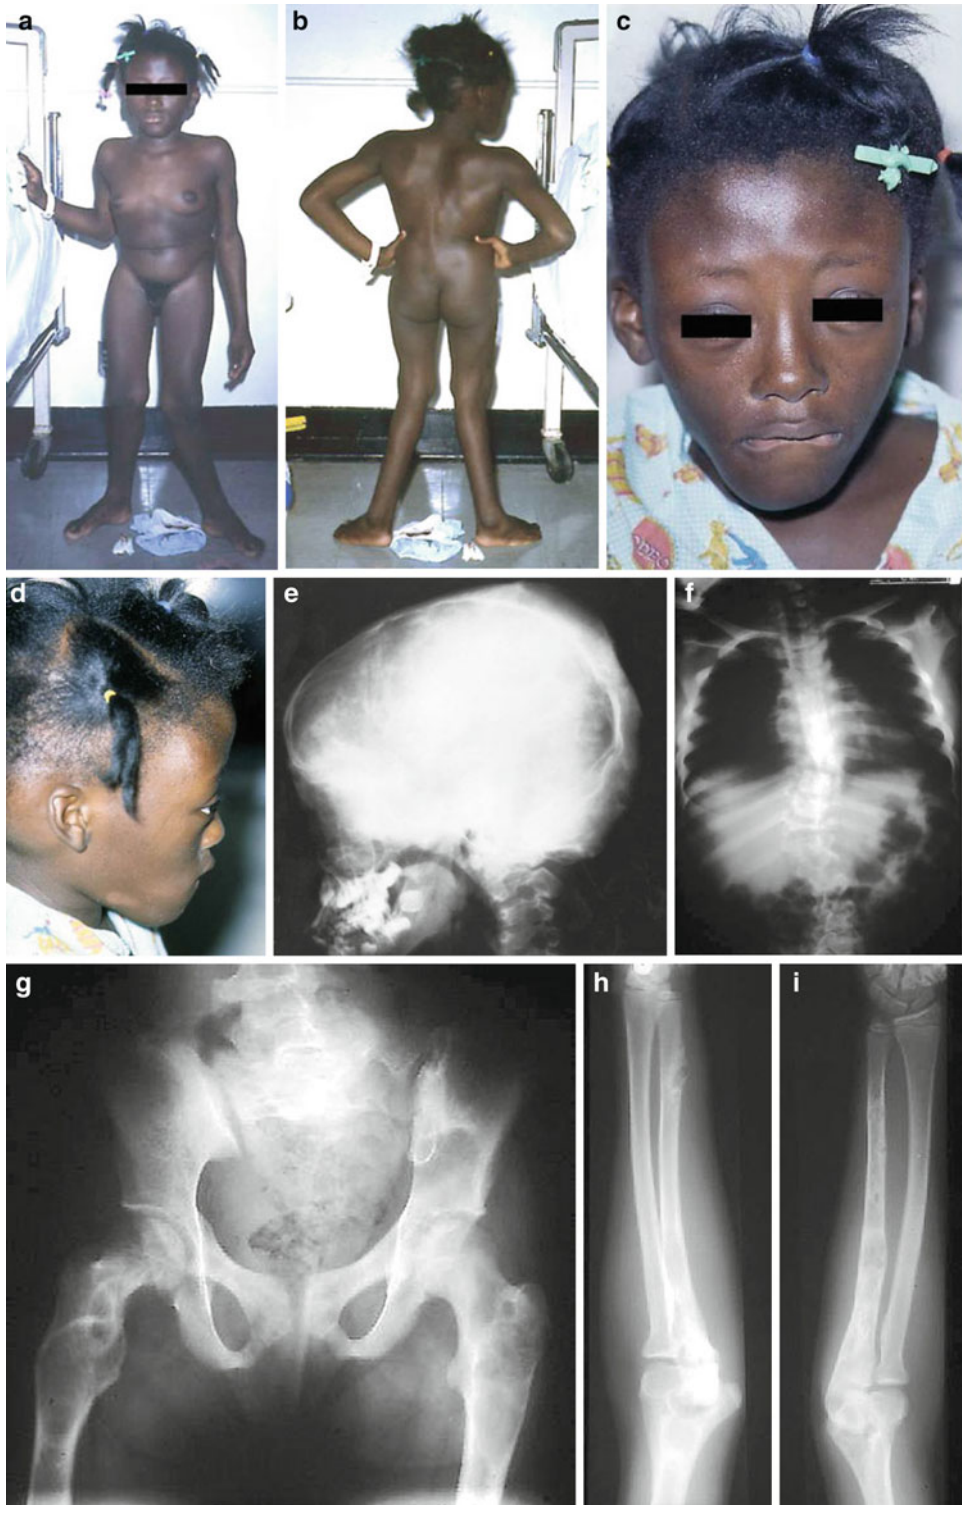

Fig. 1 (**a**–**i**) A girl with McCune-Albright syndrome showing precocious puberty, hyperpigmentation, and fibrous dysplasia affecting many bones shown by radiographs

Fig. 2 (**a**, **b**) A 3-year-old female with patchy cutaneous pigmentation (café au lait spots) mainly on her right lower extremity was seen for McCune-Albright syndrome. The radiographs of upper extremities showed both humeri with ground-glass opacities (only left upper extremity is shown here) (**a**). The proximal and mid-humeral shafts were expanded and the cortices were markedly thinned. There was a small area of cortical irregularity with overlying periosteal reaction best appreciated on the second view which suggested a remote fracture. The radiographs of both lower extremities (**b**) showed two intramedullary rods within the right femur and a single intramedullary variable rod within the left femur. Two pins were seen through the left femoral neck. There was extensive expansion of the intertrochanteric region on the left side and slight varus configuration on the right side with mild expansion of the intertrochanteric region. There was diffuse osteopenia. Ground-glass density was present in both tibiae and fibula bilaterally, consistent with patient's history of polyostotic fibrous dysplasia (Courtesy of Dr. Grace Guo)

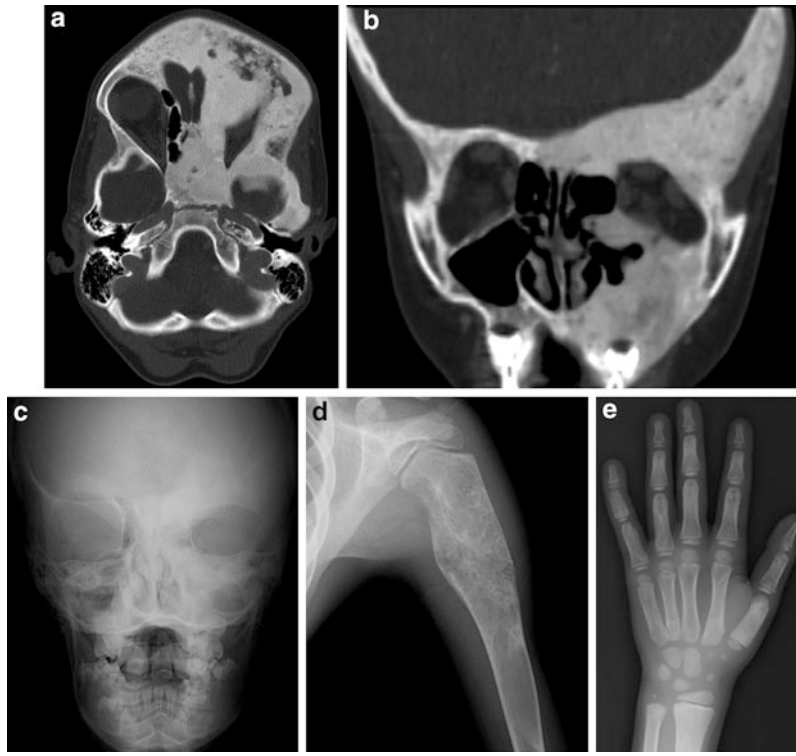

Fig. 3 (a-e) A boy has a diagnosis of McCune–Albright syndrome with polyostotic fibrous dysplasia and multiple cafe au lait spots with jagged borders and freckling. At age 6, head CT images (a, b) showed diffuse ground glass density, expansile bone lesion present in the high left parietal and left frontotemporal region. It involved the entire left the sphenoid bone, maxillary bone, superior bilateral nasal bones. It also extended into the anterior aspect of bilateral ethmoid sinuses as well as bilateral sphenoid sinuses. Posterior portion of the left orbital space was decreased due to surrounding bone lesion. At age 8, skeletal bone survey showed diffuse calvarial thickening in the left parietal bone. There was also marked thickening with ground glass density involving the left frontal bone and the skull base on the left. Involvement extended into the ethmoid sinuses (c). Expansile ground glass lesion involves the proximal half of the left humerus (d), and metacarpals and multiple phalanges (e) (Courtesy of Dr. Grace Guo)

Meckel-Gruber Syndrome

Contents

Meckel-Gruber syndrome (MKS) is a rare, lethal, and autosomal recessive disorder, characterized by occipital encephalocele, cystic dysplastic kidneys, and postaxial polydactyly. The incidence is estimated to be 1/13,250 (in USA) and 1/149,000 (in Great Britain) live births. The incidence in North African and Finnish populations is much higher at 1/3,500 and 1/9,000 (Salonen and Norio 1984), respectively. Meckel-Gruber syndrome is considered the most frequent syndromic cause of neural tube defects (Paetau et al. 1985; Morgan et al. 2002).

Synonyms and Related Disorders

Ciliopathies (Nephronophthisis, Jubert syndrome); Dysencephalia splanchnocystica; Gruber syndrome; Meckel syndrome

Genetics/Basic Defects

1. Inheritance: autosomal recessive (Hsia et al. 1971)
2. Genetic (locus) heterogeneity (Paavola et al. 1997; Morgan et al. 2002; Jayakar et al. 2011; Szymanska et al. 2012; Barisic et al. 2014)
    1. *MKS1* locus to 17q21-24 in Finnish kindreds (Paavola et al. 1995; Roume et al. 1997; Salonen and Paavola 1998)
    2. *MKS2* locus to 11q13 in North African-Middle Eastern cohorts (Roume et al. 1998)
    3. *MKS3* to 8q21.3-q22.1 in Indian subcontinent cohorts: *MKS3* mutation also causes Jubert syndrome (Baala et al. 2007)
    4. *MKS4* to 12q21.31-q21.33 in a Kosovar Albanian family with two affected male fetuses
    5. *MKS5* to 16q12.2
    6. *MKS6* to 4p15.3 in 11 Finnish families
    7. *MKS7* to 3q21 (*NPHP3* gene)
    8. *MKS8* to 12q24.31 (*TCTN2* gene)
    9. *MKS9* to 17p11.2 (*B9D1* gene)
    10. *MKS10* (*B9D2* gene)
    11. *MKS11* (TMEM231 gene)
    12. Known MKS loci account for the overwhelming majority of MKS cases but additional loci exist including MKS13

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_153

caused by TMEM107 mutation (Shaheen et al. 2015)
13. Report of the first MKS patients with TMEM231 mutations, combined with the recent identification of TMEM231 mutations in Joubert syndrome, confirms the designation of TMEM231 as a ciliopathy gene with variable phenotypic consequences (Shaheen et al. 2013)

3. The ciliopathies (Barker et al. 2014)
   1. Ciliopathies share many clinical features, with renal, retinal, and hepatic involvement frequently observed alongside skeletal malformations and central nervous system developmental defects. The most severe are lethal in the early gestation or neonatal periods (Adams et al. 2008).
   2. While many genes are associated with a single ciliopathy, mutation in others can give rise to a number of clinically different outcomes. For example, there is substantial overlap in the underlying genetic basis of the kidney disorder nephronophthisis (NPHP), the neurodevelopmental disorder Joubert syndrome (JBTS), and the lethal malformation disorder Meckel-Gruber syndrome (MKS) even though the clinical presentation of the three diseases varies considerably and genotype-phenotype correlations are frequently unclear (Coppieters et al. 2010).

Clinical Features

1. Phenotypic variability (Seller 1981; Farag et al. 1990; Wright et al. 1994)
2. Major clinical features (Alexiev et al. 2006)
   1. Clinical triad (Nyberg et al. 1990)
      1. Occipital encephalocele (85%)
         1. Extrusion of rhombic roof elements (cerebellar vermis, caudal third ventricle, distended fourth ventricle) through a widened posterior fontanelle
         2. Protruding CNS structures covered by a dural sac
         3. Medial occipital cortex occasionally included in the sac formed by the dilated caudal third ventricle
      2. Dysplastic cystic kidneys (100%)
         1. Result in oligohydramnios
         2. Lead to fetal pulmonary hypoplasia
      3. Postaxial polydactyly (55%)
   2. Microcephaly
   3. Oral clefts
      1. Cleft lip
      2. Cleft palate
   4. Liver fibrosis (Salonen 1984)
   5. Ambiguous genitalia
3. Other clinical features
   1. CNS abnormalities
      1. Absent olfactory lobe
      2. Absent pituitary gland (hypopituitarism)
      3. Hydrocephalus
      4. Dandy-Walker malformation
   2. Craniofacial features
      1. Sloping forehead
      2. Microphthalmia/anophthalmia
      3. Micrognathia
      4. Malformed tongue
      5. Abnormal ears
   3. Short neck
   4. Hypoplastic thyroid
   5. Congenital heart defect
   6. Gastrointestinal abnormalities
      1. Omphalocele
      2. Malrotated bowel
      3. Fibrotic or cystic liver
   7. Absent or small adrenals
   8. Accessory spleen
   9. Urinary tract anomalies
   10. Short limbs
   11. Abnormal palmar creases
   12. Club feet
   13. Syndactyly
4. Lethal outcome
   1. Abortions
   2. Stillborns
   3. Neonatal deaths
   4. Rare survivals till 2 years of age

Diagnostic Investigations

1. Ultrasonography
    1. CNS anomalies
    2. Cystic dysplastic kidneys
2. MRI of the brain for CNS anomalies
3. Echocardiography for congenital heart defect
4. Radiography (Seppänen and Herva 1983; Kjaer et al. 1999)
    1. Microcephaly with an occipital bone defect and encephalocele or hydrocephaly
    2. Malformations of the cranial base (basilar part of the occipital bone or the postsphenoid bone)
    3. Short upper extremities
    4. Bell-shaped thorax with abdominal distension
    5. Cleft vertebral bodies in the lumbar region of the spine
    6. Postaxial polydactyly in the hands and feet
5. Necropsy
    1. Renal anomalies
        1. Cystic dysplastic kidneys
        2. Hypoplastic kidneys/ureters/bladder
        3. Rectovesical fistula
    2. Triad of CNS malformations (Herman and Siegel 1996)
        1. Prosencephalic dysgenesis (Ahdab-Barmada and Claassen 1990)
            1. Agenesis of olfactory bulbs and tracts (arhinencephaly)
            2. Complete holoprosencephaly
            3. Hypoplasia of optic nerves and chiasm
            4. Microphthalmia
            5. Agenesis of the corpus callosum
            6. Fused thalami
            7. Hypoplasia of the third ventricle
            8. Small or absent pituitary gland
            9. Microcephaly
            10. Cleft/high arched palate
            11. Micrognathia
        2. Occipital encephalocele
            1. Displacement of rhombic roof elements including caudal third ventricle, cerebellar vermis, and fourth ventricle
            2. Extruded through an enlarged posterior fontanelle rather than through an occipital cranium bifidum
            3. Often associated with a variant of Dandy-Walker cyst with Chiari malformation
        3. Rhombic roof dysgenesis
            1. Absent brain stem tectum
            2. Agenesis/dysgenesis cerebellar vermis
            3. Elongated brain stem
            4. Aqueduct stenosis
    3. Histologic features of the CNS (Paetau et al. 1985)
        1. Polymicrogyria
        2. Heterotopias
        3. Characteristic neuroepithelial rosettes
    4. Hepatic dysgenesis (Blankenberg et al. 1987)
        1. Consistent features
        2. Arrested development of the intrahepatic biliary system
            1. Reactive biliary bile duct proliferation
            2. Bile duct dilatation
            3. Portal fibrovascular proliferation
    5. Lung hypoplasia
    6. Gastrointestinal anomalies
        1. Pancreatic cyst
        2. Malrotated bowel
        3. Anal atresia
    7. Genital anomalies
        1. Hypoplastic genitalia
        2. Bicornuate uterus
        3. Persistent urogenital sinus
6. Next-generation sequencing (Jones et al. 2014): detected mutations in *CC2D2A* (*MKS6*) (known to cause MKS and Joubert syndrome)

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: 25%

2. Patient's offspring: not surviving to reproductive age

2. Prenatal diagnosis
   1. Ultrasonography (Friedrich et al. 1979; Braithwaite and Economides 1995): diagnosis more difficult in the second trimester because of oligohydramnios secondary to poor renal output impairing visualization. However, 1st trimester diagnosis has been made (Jones et al. 2014).
      1. Occipital encephalocele
      2. Renal anomalies (large cystic kidneys, renal agenesis, renal hypoplasia, and ureteral duplication)
      3. Postaxial polydactyly
      4. Oligohydramnios
      5. Dandy-Walker malformation
      6. Cerebellar hypoplasia
   2. MRI, a valuable complement to ultrasonography in assessing fetal anomalies in the presence of severe oligohydramnios
   3. Elevated serum α-fetoprotein
   4. Amniocentesis
      1. Elevated amniotic fluid α-fetoprotein (Nevin et al. 1979; Johnson and Holzwarth 1984)
      2. Normal karyotype
   5. Preimplantation genetic diagnosis reported in a Chinese family with autosomal recessive Meckel-Gruber syndrome type 3 (MKS3) (Lu et al. 2013)

3. Management
   1. No specific treatment
   2. Supportive care for lethal cases
   3. Operative excision of a small encephalocele
   4. Ventriculoperitoneal shunt for hydrocephalus

Fig. 1 (**a**–**c**) A neonate with Meckel-Gruber syndrome showing a large occipital encephalocele, microcephaly, sloping forehead, micrognathia/retrognathia, low-set malformed ears, and short neck (**a**, **b**). The infant also had post-axial polydactylies. Necropsy showed unilateral renal dysgenesis. Contralateral renal cystic dysplasia was present (**c**)

Fig. 2 (**a**–**e**) Another neonate with Meckel-Gruber syndrome showing a large occipital encephalocele, microcephaly, sloping forehead, micrognathia/retrognathia, low-set malformed ears, short neck, (**a**) and post-axial polydactylies (**b**–**e**)

Megalencephalic Leukoencephalopathy with Subcortical Cysts

Contents

In 1995, van der Knaap et al. (1995) described a syndrome of cerebral leukoencephalopathy and megalencephaly with infantile onset in eight children, including two siblings. These children had normal or near-normal neurologic status despite evidence of severe white matter disease. The syndrome is currently termed megalencephalic leukoencephalopathy with subcortical cysts (MLC).

Synonyms and Related Disorders

Vacuolating megalencephalic leukoencephalopathy with subcortical cysts; Van der Knaap disease/leukoencephalopathy

Genetics/Basic Defects

1. A heterogeneous neurodegenerative leukodystrophy (Arnedo et al. 2014):
    1. About 75% of MLC patients have an autosomal recessive inheritance with mutations in the *MLC1* gene (MLC1) that encodes a putative membrane protein, expressed mainly in the brain at distal astrocyte junctions, nearby the cerebrospinal fluid–brain barrier and the glial limiting membrane.
    2. Only, recently, a second gene, *HEPACAM* (*GLIALCAM*, hepatic and glial cell adhesion molecule), was discovered through a combination of proteomics and genetic approaches and found to be responsible for the disease, confirming genetic heterogeneity, not only in terms of an additional gene but also in terms of inheritance.
    3. Patients with recessive mutations in *GLIALCAM* gene (MLC2A) presented a classical MLC phenotype, overlapping with the clinical presentation of *MLC1* gene-mutated patients.
    4. Patients with dominant mutations in the *GLIALCAM* gene (MLC2B) are always preceded by signs of MLC and, thereafter, are associated with various degrees of phenotypic expression, ranging from benign familial macrocephaly to macrocephaly–mental retardation with or without autism.
2. An autosomal recessive disorder suggested by parental consanguinity and affected siblings (Goutieres et al. 1996).
3. Caused by mutation in the *MLC1* gene which is expressed predominantly in astrocytes, located

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_154

on 22 qt13.33, encoding a putative membrane protein with eight predicted transmembrane domains (Leegwater et al. 2001).
4. Megalencephalic leukoencephalopathy with subcortical cysts protein-1 regulates epidermal growth factor receptor signaling in astrocytes (Lanciotti et al. 2016).
5. Genetically determined homozygous or compound heterozygous cases have been documented in almost all racial groups throughout the world and in both sexes equally.
6. Although the disease is considered rare, a higher frequency is observed in populations where consanguinity remains a common cultural practice:
    1. Indian Agarwal megalencephalic leukodystrophy with cysts is caused by a common MLC1 mutation (320insC) (Gorospe et al. 2004).
    2. Among the Agarwals of India, almost all documented cases test positive for a homozygous insertional mutation (135insC) owing to founder effect (Singhal et al. 2003).
    3. G59E mutation appears to be common among Libyan Jews (Ben-Zeev et al. 2002).
    4. S93L mutation appears to be somewhat among the Japanese (Saijo et al. 2003; Tsujino et al. 2003).
    5. MLC is relatively common in Iranian population, as expected for rare diseases with high inbreeding, with a surprisingly high frequency of novel mutations (Karimineja d et al. 2015).
    6. Autosomal recessive inheritance pattern and clinical variability of MLC in Egyptian patients (Mahmoud et al. 2014).
7. Marked clinical intrafamilial and interfamilial variability in mutation-proven cases and genetic heterogeneity (Blattner et al. 2003; Patrono et al. 2003).
8. A broad spectrum of pathogenetic mutations (missense, splice site, insertion, and deletions) identified in the *MLC1* gene, enlarging the spectrum of allelic variants without a straightforward genotype–phenotype correlation.

Clinical Features

1. Clinical findings of 122 patients reviewed by Riel-Romero et al. (2005):
    1. Clinical presentation:
        1. Accelerated head growth beginning in the first year of life, resulting in extreme macrocephaly (48%)
        2. Mild developmental delay (25%)
    2. Gradually increasing spasticity (pyramidal findings) (86%) and ataxia (78%)
    3. Seizures (66%) (Van der Knaap et al. 1995)
    4. Loss of ambulation (38%)
    5. Dysarthria (15%)
    6. Hypotonia (11%)
    7. Dysmetria (9%)
    8. Tremor (7%)
    9. Dystonia (5%)
    10. Dysphagia (5%)
    11. Choreoathetosis (3%)
2. Clinical course: although progressive in its nature, MLC is characterized by a relatively mild clinical course (discrepantly mild cognitive impairment) compared with the severity of the neuroradiological findings (Van der Knaap et al. 1995).
3. Differential diagnosis (Van der Knaap and Scheper 2011; Koç et al. 2015): infantile megalencephalic leukoencephalopathies (neurologic disorders characterized by progressive deterioration and severe impairment of neurological function resulting in marked disability and a shortened lifespan, leukodystrophic changes on neuroimaging, and megalencephaly):
    1. Alexander disease:
        1. A rare neurological disorder that follows a progressive and usually fatal course
        2. Does not share the relatively benign course of MLC
        3. The most common infantile form: characterized by loss of developmental milestones, inexorable psychomotor retardation, megalencephaly, spasticity, seizures, ataxia, hyperreflexia, and

pyramidal signs, with a lifespan of a few months to early childhood
4. Considered a leukodystrophy because myelin changes are invariably observed while sparing the axons
5. *GFAP* as the causative gene for Alexander disease
6. Magnetic resonance imaging (MRI) findings:
1. Abnormal enhancement of caudate nuclei, anterior columns of the fornices, and periventricular areas
2. Frequent hydrocephalus
3. Cavitations in the frontal deep white matter

2. Canavan disease:
1. Does not share the relatively benign course of MLC.
2. MRI findings: frequent involvement of the globus pallidus and thalami which are not involved in MLC.
3. The white matter may be cystic in Canavan disease, but the typical subcortical cysts seen in MLC are lacking.
4. *N*-Acetylaspartate is elevated in urine and blood.
5. Deficiency of the enzyme aspartoacylase can be demonstrated in cultured fibroblasts.

3. Glutaric aciduria I: the presence of biochemical abnormalities (glutaric acid, 3-OH-glutaric acid in the urine, glutarylcarnitine in the blood)
4. Laminin alpha-2 deficiency:
1. Most closely resembles that observed in MLC.
2. However, the typical subcortical cysts are generally lacking (van der Knaap et al. 1997). In addition, individuals with laminin alpha-2 deficiency have prominent weakness and hypotonia, not shared by individuals with MLC. The diagnosis can be confirmed with molecular genetic testing.

4. Other differential diagnosis (Van der Knaap and Scheper 2011):
1. Merosin-deficient congenital muscular dystrophy:
1. Typical subcortical cysts are generally lacking, although the white matter disease most clearly resembles that observed in MLC.
2. Prominent weakness and hypotonia in affected individuals, not shared by individuals with MLC.
3. Diagnosis: confirmed using muscle biopsy and staining for merosin.

2. Infantile GM gangliosidosis:
1. Infantile GM1 gangliosidosis:
1. MRI features in infantile GM1 gangliosidosis: very similar to those of GM2 gangliosidosis.
2. Demonstration of deficiency of beta-galactosidase activity in leukocytes or cultured fibroblasts confirms the diagnosis.

2. Infantile GM2 gangliosidosis:
1. MRI: characterized by prominent involvement of the basal ganglia and thalami in addition to the white matter abnormalities
2. Definitive diagnosis: established by assaying hexosaminidase A and B in serum, leukocytes, or cultured skin fibroblasts

Diagnostic Investigations

1. Brain imaging (CT, MRI) (Mejaski-Bosnjak et al. 1997):
1. Diffusely abnormal and swollen white matter of the cerebral hemispheres
2. The presence of subcortical cysts in the anterior temporal and frontoparietal region with preservation of gray matter structures

2. Brain MRI (Leegwater et al. 2002; Zukić et al. 2016):
1. "Swollen white matter" and diffuse supratentorial symmetrical white matter changes in the cerebral hemispheres, with relative sparing of central white matter structures, such as the corpus callosum, internal capsule, and the brain stem.

2. Subcortical cysts are almost always present in the anterior temporal region and are also frequently noted in the frontoparietal region.
3. The white matter swelling gradually decreases and cerebral atrophy may ensue.
4. The subcortical cysts may increase in size and number (Rajagopal et al. 2006).

3. Quantitative proton MRS (MR spectroscopy) (Brockmann et al. 2003):
   1. Underlines the MRI evidence of a white matter disorder without cortical involvement.
   2. Quantitative localized proton MR spectroscopy of white matter revealed marked reduction of *N*-acetylaspartate, creatine, and choline with normal values for myoinositol, consistent with axonal loss and astrocytic proliferation.
4. Technetium-99 m ethyl cysteinate dimer SPECT (Kiriyama et al. 2007):
   1. Hypoperfusion in the cerebral white matter (shown high signal intensity on magnetic resonance imaging (MRI) T2 images).
   2. Hypoperfusion found unexpectedly in the frontal cortices (corresponded clinically to a low score on the frontal assessment battery), which showed no abnormalities on MRI.
   3. Decreased GABA receptor density as suggested by ^{123}I-iomazenil SPECT provided further evidence of cortical neuron dysfunction.
   4. Findings suggest that SPECT can be used to noninvasively monitor in vivo cortical function in this disease.
5. Histopathology:
   1. Splitting of the outer most lamellae of the myelin sheaths consistent with an edematous process, with sparing of the axons
   2. Cavitating spongiform leukoencephalopathy with vacuoles in the outermost lamellae of myelin sheaths
   3. Intense fibrillary astrogliosis of subcortical white matter with well-preserved myelinated axons
   4. Normal cortical neuronal structure
6. Molecular genetic testing:
   1. *MLC1* gene mutation determination clinically available.
   2. Sequence analysis of *MLC1* gene mutations detects approximately 70% of cases whose MRI and clinical picture are consistent with the diagnosis of MLC, implying that at least one other gene may be responsible for the remaining 30% of cases.

Genetic Counseling

1. Recurrence risk for autosomal recessive inheritance:
   1. Patient's sib:
      1. Twenty-five percent chance of inheriting both mutation alleles and being affected
      2. Two thirds chance of being carriers in unaffected sibs
   2. Patient's offspring: recurrence risk not increased unless the spouse is a carrier, in which case 50% of offspring will be affected; otherwise, all offspring of the affected parent will be carriers who will be asymptomatic.
2. Prenatal diagnosis for pregnancies at increased risk and carrier testing for relatives at risk: possible if both *MLC1* disease-causing alleles have been identified in the family:
   1. Prenatal diagnosis of MLC in two families of Agarwal community in India in whom the affected children were positive for this common mutation (c.135 136insC) by restriction fragment length polymorphism using chorionic villi (CV) sample at 12 weeks of gestation (Shukla et al. 2008).
   2. After molecular confirmation of the disease, molecular prenatal diagnosis in the 11th week of pregnancy on DNA extracted from CVS: the fetus was heterozygous and also a carrier for the novel deletion in the *MLC1* gene (Shariati et al. 2015).
3. Management: largely supportive
   1. Antiepileptic drugs for seizure control
   2. Physical therapy to improve motor function
   3. Occupational therapy

4. Speech therapy as needed
5. Special education
6. Antibiotic treatment for infections
7. Attention to general care and nutritional requirements
8. Prevention of head trauma: protective helmet suggested

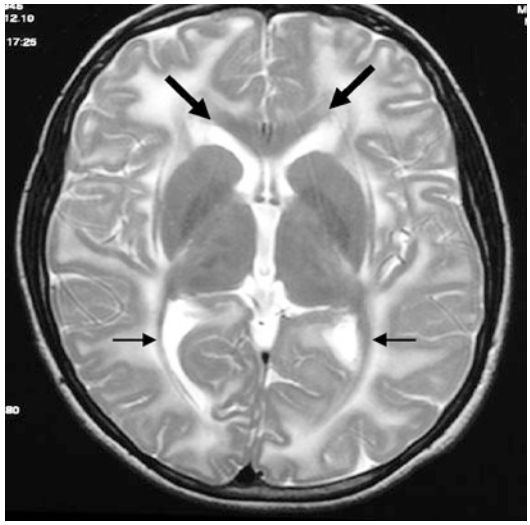

Fig. 1 A 15-year-old Caucasian female was evaluated for megalencephaly and possible leukodystrophy. Early developmental status was normal except for the presence of macrocephaly. She had a bicycle accident with trauma to her head, followed by a generalized tonic–clonic seizure 7 months later. At 15 years of age, she had striking macrocephaly (head circumference of 65 cm), receiving special education, and was found to have mild bilateral clonus axial T1-weighted scan that demonstrates hyperintensity throughout cerebral white matter with sparing of the genu of the corpus callosum (*large arrowheads*), middle portion of the internal capsule, and the geniculocalcarine tracts (*small arrows*). Sequence analysis of the *MLC1* gene revealed two novel mutations. One mutation was inherited from the mother and was characterized by the substitution of adenine for guanine at nucleotide position 366 in exon 3. This mutation resulted in a change in the corresponding amino acid from arginine to histidine at amino acid position 84 (R84H). The other mutation was inherited from her father; it is in the canonical splicing site following exon 5 (538 + 1 g → a) and is expected to cause the transcription of a variant messenger ribonucleic acid (RNA) that can be translated into an altered protein. A 12-year-old brother was noted to have macrocephaly, seizures, significant learning difficulty, behavioral problems, increasing difficulty in ambulation, hyperreflexia, spasticity with positive Babinski reflexes, sustained clonus, and difficulty with tandem gait. His MRI showed a markedly increased T2-weighted signal throughout the supratentorial white matter with cysts in both temporal lobes in a pattern virtually identical to his sister's. Sequencing of the MLC1 gene revealed the same mutations identical to his older sister (Courtesy of Dr. DMS Riel-Romero)

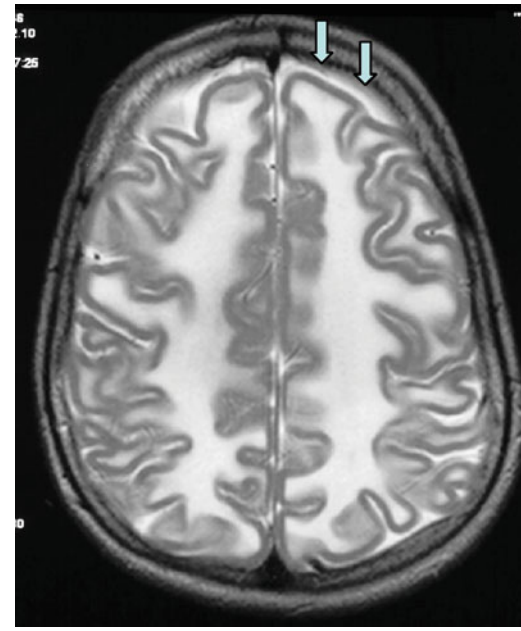

Fig. 2 Axial T-weighted scan at a more rostral level shows that the cortical U fibers are also hyperintense and therefore not spared (*arrows*)

Fig. 3 Anterior temporal regions show homogeneous white matter hyperintensity within the cysts, which expand and smooth the convolutions of the temporal poles – typical findings in megalencephalic leukoencephalopathy with subcortical cysts

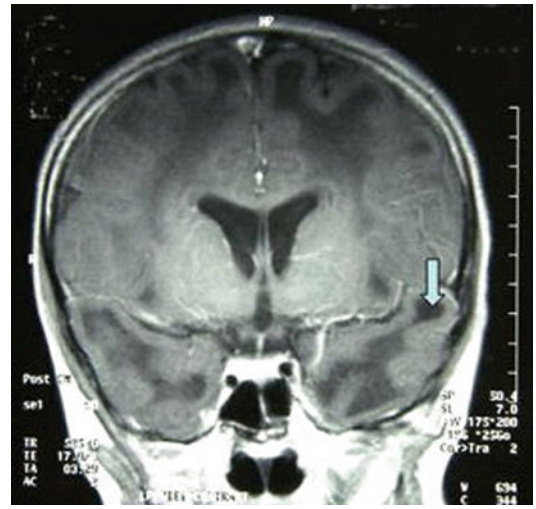

Fig. 4 Gadolinium-enhanced T-weighted coronal slice through the anterior temporal lobes demonstrates the absence of abnormal enhancement in the white matter or elsewhere and hypointensity within a subcortical cyst (*arrowhead*)

Menkes Disease

Contents

Menkes and colleagues described Menkes disease in 1962 that reported five male infants in a family affected with a distinctive syndrome of neurologic degeneration, peculiar hair, and failure to thrive. Menkes disease is also called "kinky or steely hair disease." The incidence of MK was originally estimated to be 1/35,000 (Danks et al. 1972), but more recent estimates have shown it to be a very rare disorder with 1/300,000 live-born babies affected (Tönnesen et al. 1991, 1992).

Synonyms and Related Disorders

ATP7A-related copper transport disorders; ATP-related distal motor neuropathy; Kinky hair disease (Menkes 1972); Occipital horn syndrome

Genetics/Basic Defects

1. Inheritance:
    1. An X-linked recessive disorder of copper metabolism (Tümor 1998):
        1. Recognized to segregate as an X-linked recessive trait (Menkes et al. 1962)
        2. Observation of two different cell populations (normal fibroblasts and mutant cells with increased copper accumulation) in cultured fibroblasts of female Menkes carriers, suggesting that the Menkes disease gene was subject to random X-inactivation and also confirming the X-linked recessive inheritance of the disease
    2. New mutations in one third of cases
2. Menkes gene mapped to chromosome Xq13.3:
    1. Physical evidence of the location of the Menkes disease gene (*ATP7A*, *MNK*) suggested by observation of a female patient with a de novo balanced X:2 translocation (X breakpoint at Xq13) and a male patient with X chromosome rearrangements with a breakpoint at Xq13.3 (Kodama and Murata 1999).
    2. The Xq13.3 breakpoint subsequently shown to be at the *MNK* locus by fluorescence in situ hybridization (FISH) analyses.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_155

3. MNK belongs to a large family of cation-transporting P-type ATPases.
4. Studies on a male patient with an intrachromosomal insertion, resulting in 46,Y,ins(X)(p11.4q13.3q21)mat, detected during a systematic screening of 180 unrelated MK patients, helped in the localization and cloning of the gene (Tommerup et al. 1993; Tümor et al. 1992).

3. Cause: Mutations in *ATP7A* gene (Gu et al. 2001), which encodes a transmembrane copper-transporting P-type adenosine triphosphatase (ATPase) protein, leading to deficiencies of copper absorption in intestinal absorption and in intracellular processing of copper in the central nervous system and connective tissues, whereby enzymes requiring copper as a cofactor no longer function properly.
4. The genes for two copper-transporting ATPases, ATP7A and ATP7B, are defective in the heritable disorders of copper imbalance, Menkes disease (MNK) and Wilson disease (WND), respectively (Menkes 1999; His and Cox 2004).
5. Mutation spectrum:
   1. Cytogenetic abnormalities (Tümor 1998):
      1. Visible cytogenetic abnormalities comprising about 1% of the underlying genetic defect in Menkes disease
      2. Four female patients reported to have balanced X-autosomal translocations (Abusaad et al. 1999):
         1. The first patient with a de novo t (X;2) (Kapur et al. 1987) with a breakpoint at Xq13.3 (Verga et al. 1991) provided the first convincing physical evidence of the location of the Menkes disease gene (MNK) and proved to be a starting point for the identification of the gene by three groups (Chelly et al. 1993; Mercer et al. 1993; Vulpe et al. 1993).
         2. The second female, with an X;1 translocation, reinforced the cytogenetic evidence that the Menkes gene is located at Xq13.3 (Beck et al. 1994).
      3. In both of these X;autosome translocation carriers, and in the third female with an X;21 reciprocal translocation [t(X;21)(q13.3;p11.1)] (Sugio et al. 1998), a de novo translocation disrupting the disease gene, the breakpoints were subsequently shown to be at the MNK locus by fluorescence in situ hybridization (FISH) analyses (Beck et al. 1994; Tümer et al. 1992).
      4. A girl with classic Menkes disease, carrying a de novo balanced translocation 46,X,t(X;13)(q13.3;q14.3), was reported (Abusaad et al. 1999). The translocation breakpoints at Xq13.3 and 13q14.3 coincide with the Menkes disease and Wilson disease loci, respectively.
   3. Other affected females with Menkes disease and variant phenotypes (Smpokou et al. 2015):
      1. 46,X,t(X;16)(q13.3;p11.2) (Sirleto et al. 2009).
      2. A 22-month-old girl: ATP7A gene analysis showed a heterozygous, frameshift mutation in exon 17 (c.3445delC), predicted to be pathogenic.
      3. A 4-year-old girl: ATP7A gene analysis showed a heterozygous deletion of exons 8–12, predicted to be pathogenic as well as 2 polymorphisms (c.2299G > C, IVS13-290A).
      4. A 7-year-old girl: ATP7A gene analysis showed the same two heterozygous polymorphisms (c.2299G > C, IVS13-29C > A) as in the 4-year-old patient but no pathogenic mutations or deletions detected.
   4. A male patient reported to have a unique rearrangement of the X chromosome where the long arm segment Xq13.3-q21.2 was inserted into the short arm

2. Gross deletion mutations (20%)
3. Point mutations (remaining genetic defects):
    1. Splice site (23%)
    2. Nonsense (20.7%)
    3. Missense (17.2%)
    4. Small insertions/deletions (39.1%)
    5. Partial gene deletions (Poulsen et al. 2002a, b):
        1. About 15% of the mutations causing Menkes disease are partial gene deletions.
        2. Only spanning of the deletion can be applied for carrier detection.
        3. In addition to spanning of the deletion on genomic DNA, carrier detection based on the use of a previously unrecognized polymorphism in intron 13 of ATP7A in combination with previously identified intragenic polymorphic markers, which can be used for carrier detection.
6. Genetic defect/pathogenesis:
    1. Failure of copper transport to the affected fetus resulting in copper deficiency in utero, compounded by impairment of copper absorption and ineffective copper transport into the central nervous system after birth
    2. Decreased copper transport across cellular compartments, particularly the gut
    3. Decreased availability of copper for cuproenzymes
    4. Dysfunction of numerous copper-dependent enzyme systems (decreased enzyme activities):
        1. Dopamine β-hydroxylase:
            1. Severe neurodegeneration
            2. Hypothermia
            3. Abnormalities in serum catecholamines
        2. Ascorbate oxidase: skeletal deformities
        3. Cytochrome c oxidase:
            1. Hypothermia
            2. Severe neurodegeneration
            3. Impaired myelination
            4. Muscle weakness
            5. Mitochondrial abnormalities
        4. Lysyl oxidase (decreased strength of collagen and elastin):
            1. Frayed/split internal elastic layer of arteries
            2. Bladder diverticula
            3. Loose skin and joints
        5. Monamide oxidase:
            1. Kinky hair
            2. Reduced pigmentation of hair and skin
            3. Severe neurodegeneration
        6. Tyrosinase:
            1. Depigmentation of hair
            2. Skin pallor
        7. Sulfhydryl oxidase: pili torti (Kodama and Murata 1999)
        8. Ceruloplasmin: decreased levels of circulating copper
        9. Copper–zinc superoxide dismutase:
            1. Failure of free radical detoxification, contributing to profound Purkinje cell loss
            2. Cytotoxic effects
    7. Loss of function of specific cuproenzymes resulting in the clinical features of Menkes disease:
        1. Abnormal hair and pigmentation
        2. Laxity of the skin
        3. Metaphyseal dysplasia
        4. Cerebellar degeneration
        5. Failure to thrive
    8. Favorably skewed X-inactivation accounts for neurological sparing in female carriers of Menkes disease (Desai et al. 2011)
    9. Allelic heterogeneity resulting in milder forms of the disease, occipital horn syndrome, also known as X-linked cutis laxa or Ehlers–Danlos syndrome type IX (Peltonen et al. 1983; Kaler 1998; Tümor 1998; Kodama et al. 1999):
        1. Clinical resemblances to Menkes disease with milder manifestations
        2. Biochemical resemblances to Menkes disease:
            1. Patients typically have between 20% and 35% residual copper transport function and far less severe neurodevelopmental abnormalities, even in the

absence of early diagnosis and treatment (Kaler et al. 1994).
2. Low serum copper and ceruloplasmin.
3. Increased copper accumulation and markedly low lysyl oxidase activity.
4. Impairment of *MNK* in patients with occipital horn syndrome (base pair substitution mutations affecting the normal mRNA splicing) giving a direct molecular evidence for the allelic relationship between the two diseases.

10. *ATP7A*-related distal motor neuropathy:
    1. Another allelic variant of Menkes disease.
    2. Caused by mutations in the copper-transporting P-type ATPase gene, *ATP7A*.
    3. Males with *ATP7A* mutations have even greater quantity of residual copper transport activity and manifest a late-onset syndrome restricted to progressive distal motor neuropathy, without overt signs of systemic copper deficiency (Kennerson et al. 2010).

Clinical Features

1. Phenotype: considerable variability in the severity of clinical expression encompassing the severe classical form (90–95% of patients) to the mild occipital horn syndrome.
2. Distinctive clinical features present by 3 months of age, often manifested by:
    1. Loss of early developmental milestones
    2. Poor weight gain (failure to thrive)
3. Neonatal hypothermia.
4. Neonatal hypoglycemia.
5. Hyperbilirubinemia.
6. Poor feeding.
7. Impaired weight gain (failure to thrive).
8. CNS abnormalities:
    1. Profound (truncal) hypotonia
    2. Abnormal head control
    3. Hyperactive reflexes
    4. Generalized seizures:
        1. Myoclonic
        2. Occasional tonic–clonic
    5. Developmental delay
    6. Severe mental retardation
9. Abnormal and characteristic hair, responsible for the synonyms of "kinky hair disease" or "steely hair disease" in the past (Bankier 1995):
    1. Depigmented, short, sparse, coarse, and twisted scalp hair: a striking and pathognomonic feature
    2. Fragile, frequently broken hair
    3. Twisted strands reminiscent of steel wool cleaning pads
    4. Eyebrows:
        1. Unusual appearance
        2. Scant
    5. White or gray hair lacking pigment secondary to absence of tyrosinase activity
10. Characteristic face:
    1. "Jowly," "pudgy," or "cherubic" face
    2. Sagging cheeks
    3. Large-appearing ears
    4. High-arched palate
    5. Delayed tooth eruption
11. Ocular abnormalities:
    1. Retinal hypopigmentation
    2. Retinal vessel tortuosity
    3. Macular dystrophy
    4. Congenital cataracts
    5. Partial optic nerve atrophy
    6. Decreased retinal ganglion cells
    7. Microcysts in the pigment epithelium of the iris
12. Connective tissue abnormalities (Menkes 1988) secondary to loss of lysyl oxidase activity:
    1. Loose skin (cutis laxa)
    2. Pectus excavatum
    3. Umbilical and/or inguinal hernias
    4. Diverticula of the bladder, uterus, and other organs
    5. Vascular complications including aortic aneurysms commonly present
    6. Tortuosity of the intracranial blood vessels by neuroimaging techniques
    7. Radiographic evidence:
        1. Wormian skull bones
        2. Osteoporosis

3. Metaphyseal dysplasia including anterior flaring and fracture of the ribs
4. Resembling scurvy

13. Progressive neurologic deterioration:
    1. Usually death by 3 years of age
    2. Rare survival beyond childhood in some children with profound neurologic deficits
    3. Long survival, especially with copper therapy, to teens and people in their twenties
14. Patients with milder or atypical manifestations than "classical" Menkes disease:
    1. Milder phenotype:
        1. Mild intellectual delay
        2. Ataxia
    2. Later onset of symptoms
    3. Less severe clinical course
    4. A longer life span
15. Clinical expression of Menkes disease in a girl with X;13 translocation (Abusaad et al. 1999):
    1. Onset: 4 months.
    2. Hypotonia.
    3. Delayed milestones.
    4. Seizures (Verrotti et al. 2014) are usually characterized by 3 stages:
        1. An early stage with focal clonic seizures and status epilepticus
        2. An intermediate stage with infantile spasms
        3. A late stage with multifocal, myoclonic, and tonic seizures
    5. Hair: dry, sparse, lusterless.
    6. Alopecia: pili torti.
    7. Dysmorphic facies:
        1. A high forehead and bitemporal narrowing
        2. Somewhat asymmetrical face with a prominent right ear, broad cheeks, downturned mouth corners, and sparse eyelashes and eyebrows
    8. Dry scaly skin.
    9. Hyperextensible joints.
    10. Tapering fingers.
    11. Puffy hands and feet.
    12. Decreased serum Cu.
    13. Decreased serum ceruloplasmin.
    14. Increased Cu uptake.
    15. Death at 3 years.
16. Occipital horn disease is a very mild allelic form of Menkes disease:
    1. A connective tissue disorder caused by a secondary deficiency of the cuproenzyme, lysyl oxidase.
    2. Milder phenotypic manifestations.
    3. Connective tissue abnormalities:
        1. Hyperelastic and easily bruisable skin
        2. Bladder diverticula
        3. Varicosities
        4. Hypermobile joints
    4. Skeletal abnormalities:
        1. Short broad clavicles
        2. Fused carpal bones
        3. Thoracic malformations
        4. Bony exostosis of the occiput (occipital horn) secondary to calcifications of the muscle at the insertion sites
    5. Occasional mild neurologic impairment.
    6. Any male infant with connective tissue abnormalities and mental retardation should be evaluated for the possibility of Menkes disease for biochemical evidence of defective copper transport because of somewhat atypical presentation of these milder phenotypes (Proud et al. 1996).

Diagnostic Investigations

1. Biochemical phenotype:
    1. Low levels of copper in the serum, liver, and brain resulting from impaired intestinal absorption (Kaler 2010).
    2. Low serum ceruloplasmin levels.
    3. Diagnosis of Menkes disease is confirmed by decreased serum copper and ceruloplasmin. Interpretation of these values is difficult in the first months of life. In such cases, the following analysis may be helpful in confirming the diagnosis:
        1. Copper accumulation in the placenta or chorionic villi
        2. Copper accumulation in the cultured skin fibroblasts
    4. Low activities of numerous copper-dependent enzymes (Kaler 2010):

1. Dopamine β-hydroxylase:
   1. Temperature instability
   2. Hypoglycemia
   3. Eyelid ptosis
   4. Pupillary constriction
2. Peptidylglycine α-amidating monooxygenase (reduced bioactivity of many neuroendocrine peptides)
3. Cytochrome c oxidase (impaired myelination, muscle weakness)
4. Copper–zinc superoxide dismutase (diminished protection against O_2 free radicals, possible motor neuron damage)
5. Tyrosinase (reduced pigmentation of hair and skin)
6. Diamine oxidase (reduced histamine degradation)
7. Lysyl oxidase (decreased strength of collagen and elastin)
8. Ceruloplasmin (decreased circulating copper levels)

5. Paradoxical accumulation of copper in certain tissues, such as the duodenum, kidney, spleen, pancreas, skeletal muscle, and placenta

2. Light microscopy of hair (Chang 2014):
   1. Pathognomonic pili torti (180° twisting of the hair shaft)
   2. Trichoclasis (transverse fracture of the hair shaft)
   3. Trichoptilosis (longitudinal splitting of the shaft)
   4. Trichorrhexis nodosa (small, beaded swelling with fractures at regular intervals)
   5. Monilethrix elliptica (swelling with intervening tapered constrictions)
3. MRI/MRA of the brain:
   1. White matter abnormalities reflecting impaired myelination
   2. Progressive degeneration of gray matter
   3. Cortical encephalomalacia
   4. Diffuse cerebral atrophy
   5. Cerebellar atrophy
   6. Ventriculomegaly
   7. Tortuosity (corkscrew appearance) of cerebral blood vessels
   8. Subdural hematoma (common in infants)
   9. Cerebrovascular accidents in older patients
4. Cerebral angiogram for tortuous winding vessels.
5. Variable electroencephalogram (normal, moderately to severely abnormal):
   1. Hypsarrhythmia after 5 months of age
   2. Low amplitude or absent evoked potentials
6. Echocardiography:
   1. Dysplastic coronary vessels
   2. Vascular complications including aortic aneurysms
7. Pelvic ultrasound to detect diverticula of the urinary bladder.
8. Renal ultrasound:
   1. Hydronephrosis
   2. Hydroureter
   3. Bladder diverticula
9. Radiography:
   1. Skull radiograph:
      1. Wormian bones in the lambdoidal and posterior sagittal sutures
      2. “Occipital horn”
   2. Metaphyseal spurring of long bones
   3. Diaphyseal periosteal reaction
   4. Anterior flaring or multiple fractures of ribs
   5. Scalloping of the posterior aspects of the vertebral bodies
   6. Osteoporosis seen after 6 months of age
10. Histologic examination of tortuous cerebral blood vessels:
    1. Thinning of the connective tissue
    2. Disruption of the elastic lamina
11. Ultrastructural cutaneous alterations of the elastic fibers (Martins et al. 1997): The reticular dermis showed marked changes in the elastic fibers with a paucity of the central amorphous component while retaining normal microfibrillary material.
12. Cytogenetic studies using traditional chromosome banding techniques verified by FISH using yeast artificial chromosomes spanning the gene:
    1. Mainly carried out in affected females for identification of possible X:autosome translocation at Xq13.3

2. Rare chromosome abnormality in male patients

13. Molecular diagnosis:
    1. Molecular diagnosis of Menkes disease: complicated by the heterogeneity at this locus.
    2. Almost all mutations detected in the Menkes disease gene are unique to an affected family.
    3. About 20% of these mutations involve rearrangements or partial gene deletions that can be identified by Southern blot analysis.
    4. Molecular diagnosis (superior to biochemical information) when the mutation in a given family is known, especially in cases of prenatal diagnosis.
    5. Carrier diagnosis is best done with mutation analysis and is readily accomplished when the specific mutation is known. In families where the mutation has not been identified, polymorphic markers and intragenic repeats have been used to facilitate carrier diagnosis.
14. Female carrier determination:
    1. Measurement of copper (^{64}Cu) accumulation in fibroblasts: difficult to interpret negative results because of random X-inactivation of one of the X chromosomes. Normal results do not completely exclude carrier status (Tümor 1998).
    2. Presence of pili torti in the hair: a positive clinical indicator, but its absence does not eliminate the possibility.
    3. Heterozygote detection by mutation detection in a given family with a known mutation (Kaler 2010):
        1. Allele-specific PCR
        2. Restriction enzyme analysis
        3. Heteroduplex analysis
        4. SSCP followed by DNA sequencing
        5. Southern blot analysis
    4. Linkage studies using intragenic polymorphic markers helpful in carrier detection, prenatal diagnosis, and genetic counseling where the mutation has not been identified (Tümor 1998).

Genetic Counseling

1. Recurrence risk:
    1. Patient's sib:
        1. Carrier mother: 50% of brothers affected, 50% of brothers normal; 50% of sisters carriers, 50% of sisters normal
        2. Noncarrier mother: instances of recurrence reported due to gonadal mosaicism
    2. Patient's offspring: not surviving to reproduction
2. Prenatal diagnosis:
    1. First trimester (Tonnesen et al. 1989):
        1. Measurement of total copper content in chorionic villus (CV) samples.
        2. Maternal deciduum contamination of a CV sample could cause a false-positive diagnosis.
        3. First trimester prenatal diagnosis by DNA analysis (Tümor et al. 1994)
    2. Second trimester: copper (^{64}Cu) accumulation and kinetic studies in cultured amniotic fluid cells (Gu et al. 2002) and chorionic villus cells (Tonnesen and Horn 1989).
    3. Nine female fetuses: identified as carriers on the basis of the tissue culture studies or raised placenta copper values (Horn 1981).
    4. Mutation detection in a given family with a known mutation (Das et al. 1995; Kaler and Tümer 1998).
    5. Almost every affected family shows a different alteration, ranging from cytogenetic abnormalities to single base pair changes (Tümer and Horn 1997). Thus, although the gene has been cloned, molecular testing for prenatal diagnosis is quite challenging, and confirmation by biochemical diagnosis is still required. DNA-based analysis is used in families where the mutation has been identified and for carrier detection where negative results are not reliable owing to random X chromosome inactivation.
3. Prenatal diagnosis/preimplantation genetic diagnosis may be an option for some families in which the pathogenic variant has been identified (Kaler 2015).

4. Management:
    1. No definitive therapeutic options currently available.
    2. Oral copper treatment: not effective.
    3. Early parenteral administrations of cupric acetate:
        1. Normalizes serum copper and ceruloplasmin levels but not CNS copper levels
        2. Improves seizure control
        3. Will not interrupt the progression of neurologic manifestations
    4. Early subcutaneous injections of copper–histidine with encouraging results (Kreuder et al. 1993; Sarkar et al. 1993; Sarkar 1997; Christodoulou et al. 1998; Gu et al. 2002; Tümer and Møller 2010; Tümer 2013):
        1. Normalizes serum copper, ceruloplasmin, dopamine, and norepinephrine levels after 3 months of treatment.
        2. May be able to cross the blood–brain barrier and thus disrupt the progression of neurological symptoms including decreased seizures.
        3. Prolong survival, especially if treatment started within 1 month of life.
        4. Does not prevent the connective tissue complications because lysyl oxidase may not incorporate copper–histidine well.
        5. Certain Menkes disease mutations that inhibit copper-induced trafficking of an otherwise functional copper transporter may be particularly responsive to copper replacement therapy (Kim et al. 2003).
        6. Importance of diagnosis with molecular analysis in the neonatal period so that early treatment with parenteral copper–histidine can be initiated (Costa et al. 2015).
    5. Prenatally initiated copper replacement is inadequate to correct Menkes disease caused by severe loss-of-function mutations and that postnatal ATP7A gene addition represents a rational approach in such circumstances (Haddad et al. 2012).

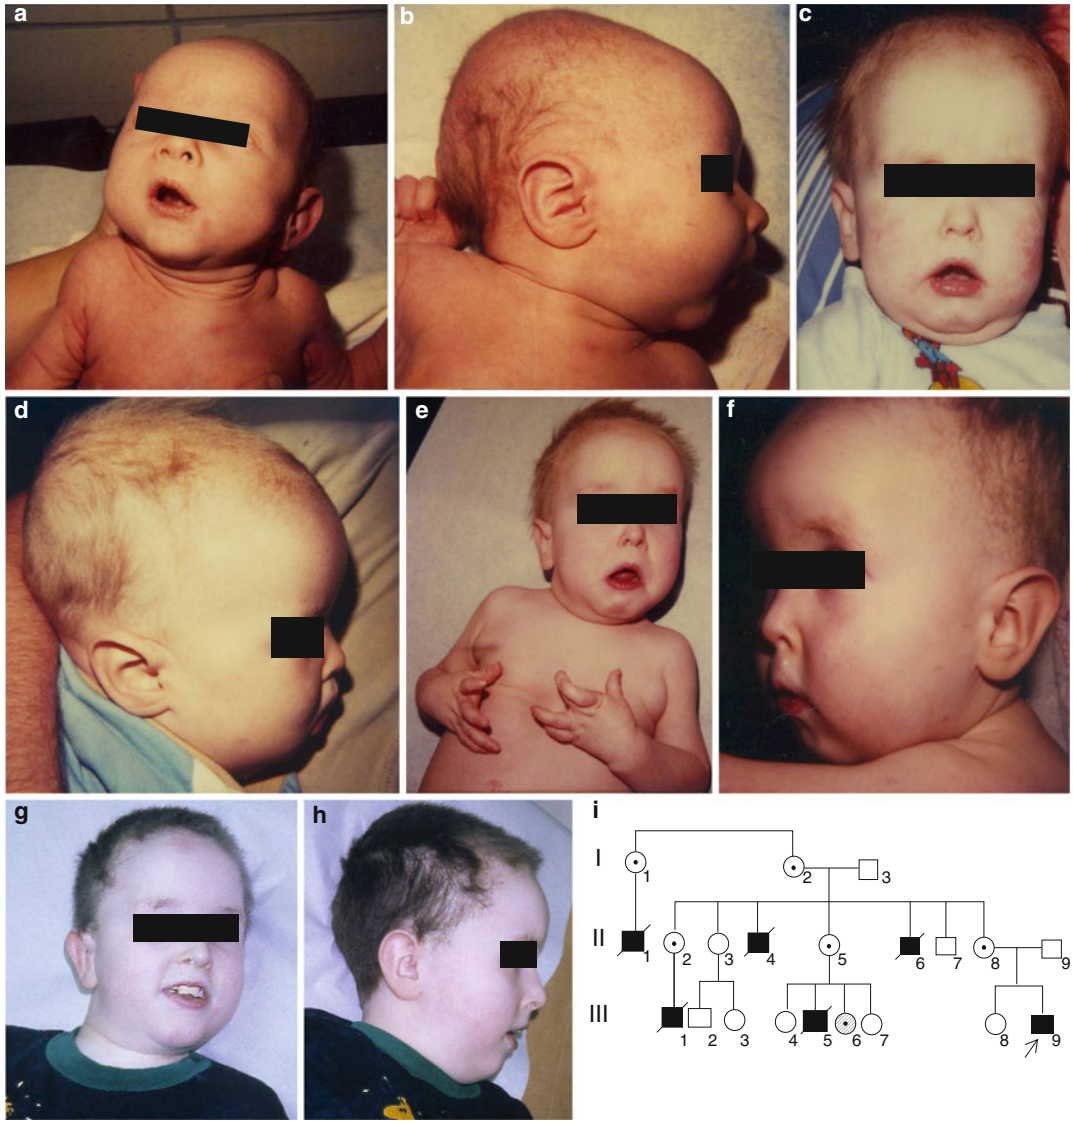

Fig. 1 (**a**–**i**) A boy with Menkes disease at 1 month (a, b), 9 months (c), 1 year (d), 27 months (e, f), and 9 years (g, h) showing sparse, coarse, twisted hair, sagging cheeks, large-appearing ears, and pectus excavatum. The boy was treated with cuprous sulfate and survived to his twenties. The pedigree is shown here illustrating X-linked recessive mode of inheritance

Fig. 2 (**a**–**b**) A cousin of the previous child with Menkes disease at 3 years of age showing coarse/twisting hair, sagging cheeks, and large-appearing ears

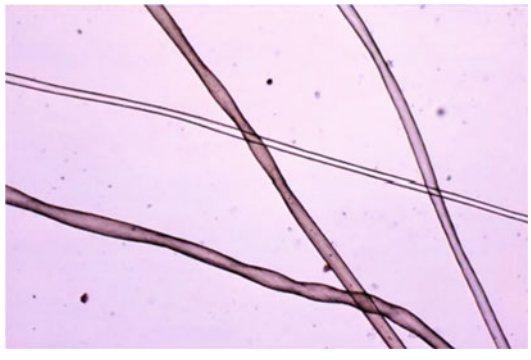

Fig. 3 Hairs showing pili torti (moderate variation in diameters; two hair shafts are twisted) in an 8-month-old male infant affected with Menkes disease

Metachromatic Leukodystrophy

Contents

Metachromatic leukodystrophy (MLD) is a lysosomal storage disease resulting from the deficient arylsulfatase A activity and the accumulation of sulfatides. The incidence among Caucasians is estimated to be about 1 in 40,000 births (Gustavson and Hagberg 1971). The name of MLD originated from the metachromatic staining of the stored substance in histological sections.

Synonyms and Related Disorders

Arylsulfatase A deficiency; Cerebroside sulfatase deficiency; Metachromatic leukoencephalopathy

Genetics/Basic Defects

1. Inheritance: autosomal recessive
2. Genetic heterogeneity (Kihara 1982)
3. Caused by deficiency of arylsulfatase A (ASA) activity:
    1. Resulting in accumulation of the enzyme substrate sulfatide (cerebroside sulfuric ester) in:
        1. Oligodendrocytes (Gieselmann et al. 1994a) and Schwann cells
        2. Visceral organs such as the kidneys (sulfatide excreted in high amounts in the urine)
    2. Leading to severe myelin breakdown:
        1. Resulting in demyelination of the white matter of the brain, spinal cord, and peripheral nerves
        2. Providing the pathophysiologic basis for the deterioration and eventual premature demise
4. Arylsulfatase (*ARSA*) gene:
    1. Mapped to 22q13.31
    2. MLD caused by *ARSA* mutations (Gieselmann 2008): more than 11 different mutations have been identified in the *ASA* gene (missense mutations are by far the most frequent type of defect found):
        1. Two most common mutations observed in Europe are (Berger et al. 1997) as follows:
            1. 459 + 1G > A
            2. A missense mutation causing a Pro426Leu substitution (accounts for about 25% of all alleles among European patients) (Polten et al. 1991)
        2. A missense mutation causing an Ile179Ser substitution (accounts for

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_156

about 12% of all defective alleles) (Berger et al. 1997).
   3. All other mutant alleles have only been found in a few or single patients (Schestag et al. 2002).
   4. Patients homozygous for alleles, which do not allow for the synthesis of functional ASA, always suffer from the severe form of the disease, whereas alleles allowing the expression of residual enzyme activity are associated with the later-onset juvenile or adult forms of metachromatic leukodystrophy (Gieselmann 2008).
3. ASA pseudodeficiency (ASA-PD) caused by *ARSA* mutation:
   1. Originally described in healthy individuals.
   2. Low ASA activity.
   3. Normal urinary sulfatide levels.
   4. The pseudodeficiency, in most cases, is caused by homozygosity for the arylsulfatase A pseudodeficiency (ASA-PD) allele (Polten et al. 1991).
   5. MLD mutations are also known to occur within this allele: 1–2% of PD alleles are estimated to have a disease-causing mutation (Rafi et al. 2003).
   6. Characterization of the mutations causing pseudodeficiency has allowed the detection of the pseudodeficiency allele in the DNA of probands and has thus improved the diagnosis and genetic counseling for metachromatic leukodystrophy (Gieselmann et al. 1994b).
4. Chromosomal deletion unmasking a recessive disease such as 22q13 deletion syndrome and metachromatic leukodystrophy (Bisgaard et al. 2009):
   1. One patient had a pathogenic mutation in the *ARSA* gene and succumbed to MLD.
   2. Another patient had a pseudoallele which did not lead to MLD.
5. Pathophysiology (Ikeda et al. 2010):
   1. Inability to degrade sulfated glycolipids, especially the galactosyl-3-sulfate ceramides, characterizes metachromatic leukodystrophy.
   2. A deficiency in the lysosomal enzyme sulfatide sulfatase (arylsulfatase A) is present in metachromatic leukodystrophy.
   3. Some patients with clinical metachromatic leukodystrophy have normal arylsulfatase A activity but lack an activator protein that is involved in sulfatide degradation.
   4. Both defects result in the accumulation of sulfatide compounds in neural and in nonneural tissue, such as the kidneys and gallbladder.
   5. These defects may result from a number of different mutations, and many new causative mutations have been identified (Anlar et al. 2006; von Figura et al. 2001).
5. Prosaposin (PSAP) gene including rare variants (Cesani et al. 2016):
   1. Codes for the activator protein saposin B.
   2. Mutation update, an extensive review of all the ARSA- and PSAP-causative variants published in the literature to date, accounts for a total of 200 ARSA and 10 PSAP allele types.

Clinical Features

1. Three main clinical forms based on the age of onset of the disease (Barth et al. 1994):
   1. Late-infantile form (50–60% of cases)
   2. Juvenile form (20–30% of cases)
   3. Adult form (15–20% of cases)
2. Late-infantile form (Clark et al. 1979):
   1. The most common form
   2. Onset of the disease: between the ages of 15 months and 2 years
   3. Clinical symptoms:
      1. Loss of acquired motor skills
      2. Flaccid weakness and hypotonia
      3. Ataxic gait with absent tendon reflexes
   4. Progression of the disease:
      1. Quadriplegia.
      2. Speech disturbances:
         1. Dysarthria
         2. Aphasia

3. Speech deterioration leading to loss of speech
3. Difficulty in feeding (dysphagia) with bulbar and pseudobulbar palsies.
4. Irritability.
5. Muscle wasting.
6. Peripheral neuropathy.
7. Ataxia.
8. Ophthalmic features:
   1. Nystagmus
   2. A cherry-red spot in the macula in some patients (Crumrine 2001)
   3. Optic atrophy leading to blindness
9. Epileptic seizures usually occur at advanced stages of the disease.
10. Mental deterioration progresses with the disease until the patients are no longer able to establish any contact with their surroundings.
11. Death generally occurs 1–7 years after onset.

3. Juvenile form (Haltia et al. 1980):
   1. Clinical symptoms usually develop between the ages of 4 and 12 years.
   2. Progression of the illness similar to that of the infantile form.
   3. Clinical characteristics:
      1. Loss of developmental milestones by the end of the first decade
      2. Gross motor:
         1. Incoordination
         2. Clumsiness
         3. Ataxia with progressive gait disturbance leading to loss of ambulation
         4. Progressive hypertonia with tremor, postural abnormalities, and/or leg scissoring
         5. Diminished deep tendon reflexes
      3. Speech and language:
         1. Slurred speech
         2. Speech deterioration
      4. Cognitive and behavioral changes:
         1. Abnormal and bizarre behavior
         2. Daydreaming
         3. Difficulty in following directions
         4. Emotional difficulties
         5. Intellectual decline
         6. Mental deterioration
      5. Ophthalmologic features: optic atrophy leading to blindness
      6. Other CNS manifestations:
         1. Pseudobulbar palsy.
         2. Epileptic seizures usually occur at advanced stages of the disease.
         3. Mental illness with features of psychosis, dementia, and emotional disorders in older children.
         4. Progressive neurological problems but less severe than in the late-infantile form.
   4. Prognosis:
      1. Fatal in majority of cases.
      2. Course of disease may last more than 20 years in a few cases.
4. Adult form (Baumann et al. 1991):
   1. Wide range of onset: from 19 to 46 years
   2. Very rare occurrence
   3. Slow progression of the disease
   4. Survival of 5–10 years common
   5. Cognitive and behavioral changes (the first symptoms in many cases):
      1. Personality changes:
         1. Anxiety
         2. Apathy
         3. Bewilderment
         4. Emotional instability
         5. Psychosis
      2. Poor school or job performance:
         1. Decreased mental alertness
         2. Defective visual-spatial discrimination
         3. Disorganized thinking
         4. Poor memory
   6. Mental deterioration:
      1. Often the first symptom
      2. Loss of professional abilities leading to total incapacity
      3. Progressive deterioration eventually leading to dementia
   7. Rare epileptic seizures
   8. Ophthalmologic features:
      1. Horizontal nystagmus
      2. Optic atrophy leading to blindness
   9. Final stages:
      1. Loss of speech
      2. Immobility
      3. Incontinence

5. Arylsulfatase pseudodeficiency:
   1. Low arylsulfatase activity in healthy individuals
   2. Allelic variant metachromatic leukodystrophy
6. Nonallelic variants of MLD (Fluharty 2008):
   1. Multiple sulfatase deficiency (Austin variant of MLD):
      1. Caused by a defect in processing of an active site cysteine to formylglycine (alanine-semialdehyde), a proenzyme activation step common to most sulfatases (Dierks et al. 2005; Zafeiriou et al. 2008).
      2. Findings suggesting a diagnosis of multiple sulfatase deficiency include:
         1. Reduced activity of other sulfatases including arylsulfatase B, arylsulfatase C, and iduronate sulfatase (the enzyme that is deficient in Hunter syndrome and heparan-N-sulfamidase in leukocytes or cultured cells)
         2. Presence of mucopolysaccharides (glycosaminoglycans) as well as sulfatides in the urine
      3. Although clinical variability of multiple sulfatase deficiency is great, features of both MLD and a mucopolysaccharidosis (MPS) may be present (Macaulay et al. 1998).
      4. More severe forms of multiple sulfatase deficiency resemble late-infantile MLD. In other cases, MPS-like features such as coarse facial features and skeletal abnormalities may be evident in infancy and early childhood, with MLD-like symptoms becoming evident in later childhood.
      5. Eventually, the disease course resembles MLD with demyelination dominating the clinical picture (von Figura et al. 2001). Ichthyosis, common to arylsulfatase C deficiency, is also often present.
      6. A defect in the formylglycine-generating enzyme (FGE) is causative (Dierks et al. 2005) and is responsible for the activation of most sulfatases, and a variable degree of arylsulfatase A deficiency occurs in many tissues in its absence.
   2. Sphingolipid activator protein B-deficient MLD (saposin B deficiency):
      1. A defect in the glycolipid-binding protein saposin B, which is needed to solubilize sulfatides before they can be hydrolyzed by arylsulfatase A, causes an MLD-like disorder.
      2. While a number of other glycolipid degradative processes are disrupted in saposin B deficiency, it is the failure in sulfatide catabolism that dominates the clinical picture.
      3. Age of onset is variable, with too few cases having been reported to delineate a typical clinical picture.
      4. An MLD-like clinical presentation, leukodystrophy on MRI, normal arylsulfatase A enzyme activity, and evidence of excess urinary sulfatide excretion and/or sulfatide storage suggest activator deficiency.
      5. Diagnosis depends on depressed sulfatide degradation by cultured cells, immunochemical assessment of saposin B levels, or sequence analysis of the gene encoding prosaposin (Sandhoff et al. 2001).

Diagnostic Investigations

1. Diagnosis suspected in individuals with progressive neurologic dysfunction and MRI evidence of a leukodystrophy.
2. Demonstration of decreased (<10% of normal controls) or absence ASA enzyme in the urine, leukocytes, or cultured skin fibroblasts (Gieselmann 1991; Gieselmann et al. 1991a):
   1. Low ASA activity also observed in:
      1. Individuals with multiple sulfatase deficiency
      2. Individuals with copies of pseudodeficiency (PD) allele

2. Low ASA activity is seen in individuals without MLD due to the high frequency of the common PD allele in the general population.
3. Differentiation of ASA pseudodeficiency from MLD:
    1. Inability to reliably distinguish MLD and ASA pseudodeficiency, based solely on enzyme activity determinations
    2. Cerebroside sulfate loading test:
        1. Exposure of the cells to radioactively labeled cerebroside sulfate, the natural substrate of arylsulfatase A.
        2. Cultured cells from pseudodeficient individuals will degrade this substrate at normal rates, whereas those from MLD patients do not.
        3. Disadvantages: require experienced investigator, noncommercially available substrate, and tissue culture facilities.
    3. PD allele mutations studies using allele specific amplification
3. Urinalysis showing metachromatic granules in the urine sediment.
4. Urine chemistry showing markedly increased sulfatide levels.
5. Sulfatide analysis by mass spectrometry for screening of metachromatic leukodystrophy in dried blood and urine samples (Spacil et al. 2016).
6. Ultra-performance liquid chromatography/tandem mass spectrometry for determination of sulfatides in dried blood spots from patients with metachromatic leukodystrophy: This method provides a fast and effective screening and monitoring tool for the diagnosis and treatment of MLD (Han et al. 2014).
7. Sulfatide loading of fibroblast cultures and subsequent measurement of hydrolysis of added substrate: The differences in hydrolysis of added sulfatide provide a functional test that separates late-infantile, juvenile, and adult forms (Krivit et al. 1995).
8. Absence of gallbladder function on a cholecystography (Crumrine 2001).
9. Screening for gallbladder abnormalities by ultrasound in order to prevent early death (van Rappard et al. 2016b):
    1. Gallbladder involvement is the rule rather than the exception in MLD.
    2. The high prevalence of hyperplastic polyps, a known precancerous condition, and one death from gallbladder carcinoma at a young age suggest that MLD predisposes to neoplastic gallbladder abnormalities.
10. Abnormal brain stem auditory, visual, and somatosensory evoked potentials.
11. Elevated CSF levels of protein and cytokines (Thibert et al. 2016).
12. Brain imaging shows progressive loss of white matter due to demyelination (Faerber et al. 1999):
    1. Symmetric diffuse high-intensity signal on proton density and T2-weighted images throughout the white matter consistent with demyelination
    2. Hypointense signal abnormalities in the white matter of the centrum semiovale with the following two distinct appearances (Liaw et al. 2015):
        1. A radiating pattern ("tigroid" appearance) of linear tubular structures or horizontal linear hypodensity indicative of spared perivascular white matter
        2. Areas of relatively normal-appearing white matter: a punctate appearance to the linear structures ("leopard skin" appearance) within the demyelinated centrum semiovale
    3. Cerebral atrophy with ventricular enlargement
13. Volumetric MRI data correlate to disease severity in metachromatic leukodystrophy (Tillema et al. 2015):
    1. Significant cerebral cortical gray matter volume (GMV) loss is already present in early stages of MLD.
    2. IQ correlates with cerebral white matter (WM) severity scores and lesion volume, but not with volumetric measures.
    3. In adult presentations, there is more pronounced global atrophy with GMV and

WM volume loss and accelerated cortical thinning, most prominently in the cingulate gyrus and frontal lobes.

14. Nerve conduction studies show decreased nerve conduction velocities and demyelinating polyneuropathy (Liaw et al. 2015).
15. Nerve biopsies show metachromasia of Schwann cells.
16. Molecular studies of ASA mutations (Fluharty 2008):
    1. Targeted mutation:
        1. *ARSA*-mild alleles
        2. *ARSA*-PD alleles
    2. Sequence analysis/mutation scanning
    3. Deletion/duplication analyses
17. Diagnosis of the presymptomatic siblings of the index case: Only combination of gene sequencing with thorough biochemical analysis allowed the correct diagnosis of the sibling, who was promptly directed to treatment (Lorioli et al. 2014).

Genetic Counseling

1. Recurrence risk:
    1. Patient's sib:
        1. Recurrence risk: 25%
        2. Younger siblings in the same family with an older sibling who is clinically affected by MLD (Krivit et al. 1995):
            1. Require appropriate and rapid evaluation.
            2. May be affected but clinically presymptomatic.
            3. Therapy with bone marrow transplantation in affected but asymptomatic sibling may be curative.
            4. Sibling with very low levels of white blood cell arylsulfatase A may not indicate the presence of disease because of the combination of the pseudodeficient gene with a metachromatic leukodystrophy gene.
    2. Patient's offspring:
        1. Do not survive into reproductive age in late-infantile and juvenile forms
        2. Not increased in adult form unless the spouse is a carrier
2. Carrier detection (Gieselmann 1991a, b):
    1. Individuals with about 50% of arylsulfatase A:
        1. Suspected to be carriers of an MLD allele and have genetic risk for MLD
        2. Likely to be carriers of a pseudodeficiency allele and have no genetic risk for MLD
    2. Enzyme activity determination: impossible to distinguish heterozygotes of a pseudodeficiency allele from heterozygous of an MLD allele
    3. Mutation detection of the pseudodeficiency allele in the DNA to facilitate the differential diagnosis of MLD and pseudodeficiency
3. Prenatal diagnosis for couples at risk:
    1. Demonstration of the absence of arylsulfatase A in cultured chorionic villi or amniocytes (van der Hagen et al. 1973; Eto et al. 1982).
    2. A combination of biochemical and molecular tests performed on chorionic villus samples or cultured amniotic fluid cells.
    3. Demonstration of the disease-causing mutation previously identified in the proband on fetal DNA obtained from amniocentesis or CVS.
    4. Preimplantation genetic diagnosis for at-risk pregnancies requires prior identification of the disease-causing mutations in the family.
4. Management:
    1. Primarily supportive:
        1. Currently, no available treatment can reverse the fatal outcome of the devastating MLD.
        2. Nasogastric or G-tube feeding for dysphagia of bulbar and pseudobulbar palsies
        3. Multidisciplinary approach
    2. Replacement of ASA might degrade the accumulated cerebroside sulfate and thereby be an effective treatment: both

intravenous and intrathecal infusion of ASA in a patient with the late-infantile form of metachromatic leukodystrophy (Greene et al. 1969).

3. Kidney transplantation from a deceased donor with MLD: The excellent clinical result after kidney allograft, and the ability to continue dialysis if acute rejection intervenes, suggests that renal transplantation from MLD patients is safe and effective (Sondheimer et al. 2014).
4. Bone marrow transplantation:
    1. For individuals who are presymptomatic or have only mild neurologic manifestations
    2. Significant risks associated with this procedure
    3. Highly dependent on the availability of adequately matched donors
    4. Long-term stabilization after bone marrow transplantation in juvenile metachromatic leukodystrophy (Kidd et al. 1998)
    5. Appears to slow the progression of the disease and improve the quality of life
    6. Bone marrow transplantation: an effective treatment of patients with lysosomal and peroxisomal storage diseases, including metachromatic leukodystrophy (Krivit et al. 1999)
    7. Successful treatment of metachromatic leukodystrophy using bone marrow transplantation of HoxB4 overexpressing cells in the mouse model (Miyake et al. 2010)
5. Developing treatment options for metachromatic leukodystrophy (Batzios and Zafeiriou 2012):
    1. Correction of ASA deficiency by a recombinant adenovirus that potentially could be used to transfer the gene to the brain, and gene therapy for MLD based on gene transfer of the ASA gene to mutant cells will be feasible because the overexpression of ASA in cells does not lead to profound deficiency of other sulfatases or result in a new phenotype (Ohashi et al. 1996).
    2. Hematopoietic stem cell transplantation (HSCT) (Solders et al. 2014; van Rappard et al. 2016a):
        1. In comparison with the untreated siblings, HSCT halted the progression of the disease in treated patients.
        2. Effectiveness is overshadowed by serious limitations.
        3. As the best moment for hematopoietic cell transplantation (HCT) is as early as possible and before clinical disease onset, it is of utmost importance to test all siblings of an index case, including older ones.
        4. For more advanced and late-infantile patients, results are discouraging.
        5. For the majority of patients evaluated, HCT was no longer an option neither did they qualify for treatment trials, emphasizing the need of earlier diagnosis and better treatment strategies.
    3. Umbilical cord blood transplantation: may be greatly beneficial even to late-infantile MLD patients or minimally symptomatic juvenile MLD (Martin et al. 2013), since it has important advantages, such as quick availability and low risk of morbidity and mortality in relation to HSCT.
    4. Mesenchymal stem cell (MSC) transplantation: Initial results show that MLD patients might benefit from this treatment option, since MSCs have significant advantages, such as great transdifferentiation capability, widespread distribution throughout the body, and easy accessibility.
    5. Intracerebral gene therapy with oligodendroglial, neural progenitor, embryonic, and microencapsulated recombinant cells represents add-on treatment options still on experimental level.

Fig. 1 A 28-month-old boy with late-infantile form metachromatic leukodystrophy showing extreme hypotonia. At about 15 months of age, he stopped talking and showed muscle weakness. MRI of the brain demonstrated demyelination. Arylsulfatase A activity was absent in the cultured fibroblasts. Urinary excretion of excess sulfatides confirmed the diagnosis of metachromatic leukodystrophy. DNA analysis shows no copies of the pseudodeficiency allele or the common late-infantile mutation. Mutation screening of the entire coding sequence of the arylsulfatase A gene revealed the mutation E253K which was inherited from the mother and the second mutation P192R which was inherited from the father. The E253K mutation has been described as a disease-causing mutation in the literature. The second mutation P192R most likely is a disease-causing mutation

Fig. 2 A 3-year-old girl presented with progressive muscle weakness in the lower limbs for 2–4 months. The low leukocyte arylsulfatase A at 0.4 (control: $\geq$2.5) was consistent with diagnosis of metachromatic leukodystrophy

Miller-Dieker Syndrome

Contents

In *1963*, Miller reported two siblings with a specific pattern of malformations in which lissencephaly was a key feature. Later in *1969*, Dieker et al. described a similar condition. Jones et al. in *1980* further characterized the phenotype and suggested the designation Miller-Dieker syndrome to distinguish it from other lissencephaly syndromes. At present, Miller-Dieker syndrome is known to be a contiguous gene disorder caused by haploinsufficiency of a gene or genes having a major role in the development of the brain and the face (Alvarado et al. 1993).

Synonyms and Related Disorders

Chromosome 17p13.3 deletion syndrome; Miller-Dieker lissencephaly syndrome

Genetics/Basic Defects

1. Genetics: a contiguous gene deletion syndrome involving chromosome 17p13.3 (Miny et al. 1993; Chitayat et al. 1997)
    1. Association of Miller-Dieker syndrome and del(17)(p13) (Stratton et al. 1984)
        1. First reported by Dobyns et al. in *1983*
        2. Deletions of the lissencephaly critical region in 17p13.3 including LIS1 (Ledbetter et al. 1992; Dobyns et al. 1993)
        3. Familial cases reported by Miller (1963) with affected members being carriers of an unbalanced rearrangement from t (15;17)(q26.1;p13.3)
        4. Family reported by Dieker et al. (1969) with affected members being carriers of an unbalanced rearrangement from t (12;17)(q24.31;p13.3)
    2. A microdeletion in a critical 350-kb region of chromosome 17p13.3 observed in familial and sporadic cases, detected by high-resolution banding
    3. Southern blot analysis of restriction fragment length polymorphism with several different DNA markers in 17p13.3 and later FISH analysis using different DNA probes of this segment
        1. Observed in >90% of patients with Miller-Dieker syndrome
        2. Observed in 38% of patients with isolated lissencephaly

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_157

2. Mutations and large deletions of the lissencephaly gene (*LIS1*)
   1. Deletions involving *LIS1*: more common than mutations
   2. *LIS1* deleted in Miller-Dieker syndrome
   3. *LIS1* mutations observed in patients with isolated lissencephaly sequence
      1. Missense mutations
      2. Nonsense mutations
      3. Small deletions or insertions
      4. Splice site mutations
      5. Partial deletions
   4. Phenotype-genotype correlations (Cardoso et al. 2002)
      1. Most severe LIS phenotypes observed in patients with large deletions of 17p13.3
      2. Milder phenotypes observed in patients with intragenic mutations
      3. Mildest phenotypes observed in patients with missense mutations
3. Classification of lissencephaly (Dobyns et al. 1984; Pilz and Quarrell 1996; Spalice et al. 2009)
   1. Lissencephaly type I (classical) (de Rijk-van Andel et al. 1990)
      1. Isolated lissencephaly sequence (Dobyns et al. 1992)
      2. Miller-Dieker syndrome
      3. Subcortical band heterotopia
      4. Nonclassified forms
   2. Lissencephaly type II (cobblestone)
      1. Walker-Warburg syndrome
      2. Fukuyama congenital muscular dystrophy
      3. Muscle-eye-brain disease
      4. Non-unclassified forms
   3. Rare forms
      1. Neu-Laxova syndrome
      2. Cerebrocerebellar syndrome
4. Cytogenetic mechanisms in Miller-Dieker syndrome (Dobyns et al. 1991)
   1. De novo abnormalities (44%)
      1. Deletion (terminal or interstitial) (36%)
      2. Dicentric translocation (4%)
      3. Ring chromosome (4%)
   2. Familial rearrangement (12%)
      1. Reciprocal translocation (8%)
      2. Pericentric inversions (4%)
   3. Normal karyotype (44%)
      1. Submicroscopic deletion (36%)
      2. No deletion detected (8%)
5. Molecular explanation for Miller-Dieker syndrome (Toyo-oka et al. 2003)
   1. Heterozygous deletions of 17p13.3 result in the human neuronal migration disorders.
      1. Isolated lissencephaly sequence
      2. More severe Miller-Dieker syndrome
   2. Mutations in *PAFAH1B1* (the gene encoding LIS1): responsible for isolated lissencephaly sequence and contributing to Miller-Dieker syndrome.
   3. The gene encoding 14-3-3ε (YWHAE), one of a family of ubiquitous phosphoserine/threonine-binding proteins: always deleted in individuals with Miller-Dieker syndrome, providing a molecular explanation for the differences in severity of human neuronal migration defects with 17p13.3 deletions.
   4. *CRK*: may be involved in the facial phenotype of the 17p13.3 microdeletion syndrome, and that CRK, and not YWHAE, seems to be involved in limb malformations (Østergaard et al. 2012).

Clinical Features

1. Prenatal and neonatal history
   1. Polyhydramnios
   2. Prenatal growth deficiency
   3. Neonatal resuscitation
   4. Neonatal jaundice
   5. Postnatal growth deficiency
2. CNS anomalies
   1. Type I (classical) lissencephaly: can occur either in association with the Miller-Dieker syndrome or as an isolated finding, termed “isolated lissencephaly sequence.”
      1. Agyria (absent gyration of the cerebral cortex)
      2. Pachygyria (unusually thick convolutions of the cerebral cortex)

2. Absent or hypoplastic corpus callosum
3. Cavum septi pellucidi
4. Midline calcification
5. Ventricular dilatation
6. Abnormal positioning of the olivary nuclei in the midbrain
7. Occasional mild cerebellar vermis hypoplasia
8. Microcephaly
9. Seizures usually by age 9 weeks
10. Cerebral palsy
11. Profound mental retardation

3. Craniofacial features
   1. High, prominent, and wrinkled forehead
   2. Bitemporal narrowing
   3. Furrowed brow
   4. Epicanthal folds
   5. Broad nasal bridge
   6. Short and pointed nose with anteverted nostrils
   7. Long prominent upper lip with thin upper vermilion border
   8. Micrognathia
   9. High-arched palate
   10. Low-set and malformed ears
4. Congenital heart defects
5. Omphalocele (Chitayat et al. 1997)
6. Hands and fingers
   1. Clinodactyly
   2. Camptodactyly
   3. Transverse palm crease
7. Sacral dimple
8. Cryptorchidism
9. Prognosis: often die within the first few months of life
10. Differential diagnosis
    1. Isolated lissencephaly sequence (Dobyns et al. 1984, 1992)
       1. Brain abnormalities
          1. Lissencephaly (type I)
          2. Numerous heterotopias
          3. Failure of opercularization
          4. Enlarged ventricles (usually colpocephaly)
          5. Probable hypoplasia of the corpus callosum
       2. Neurological abnormalities
          1. Profound mental retardation
          2. Decreased spontaneous activity
          3. Early hypotonia
          4. Subsequent hypertonia
          5. Poor feeding
          6. Seizures
       3. Craniofacial features
          1. Microcephaly
          2. Bitemporal hollowing
          3. Prominent occiput
          4. Micrognathia
       4. Occasional abnormalities
          1. Prenatal polyhydramnios, decreased fetal movement
          2. Postnatal: may require resuscitation at birth
          3. Neurological: infantile spasms
       5. Chromosome studies
          1. Normal chromosomes by conventional studies
          2. Submicroscopic deletions by FISH observed in increasing numbers
    2. Norman-Roberts syndrome (Dobyns et al. 1984)
       1. Probably an autosomal recessive disorder
       2. Brain abnormalities
          1. Lissencephaly (type I)
          2. Numerous heterotopias
          3. Failure of opercularization
          4. Slightly enlarged ventricles (probable colpocephaly)
          5. Probable hypoplasia of the corpus callosum
       3. Neurological abnormalities
          1. Profound mental retardation
          2. Decreased spontaneous activity
          3. Poor feeding
          4. Seizures
       4. Cranial abnormalities
          1. Microcephaly
          2. Bitemporal hollowing
          3. Slightly prominent occiput
          4. Low, sloping forehead
       5. Facial features
          1. Widely set eyes
          2. Broad, prominent nasal bridge
          3. Micrognathia
          4. Absence of upturned nares
          5. Normal eyes

6. Other features
    1. Clinodactyly
    2. Chordee
    3. Low birth weight
7. Normal chromosomes

3. Walker-Warburg syndrome (Dobyns et al. 1989)
    1. Most commonly seen in the United Kingdom
    2. An autosomal recessive disorder
    3. Type II lissencephaly
    4. Hydrocephalus
    5. Cerebellar malformation (vermian hypoplasia)
    6. Eye abnormalities
        1. Retinal dysplasia
        2. Microphthalmia
        3. Colobomata
        4. Cataracts
        5. Glaucoma
        6. Corneal clouding commonly due to Peters' anomaly
        7. Congenital muscular dystrophy in all patients
        8. Elevated CK
        9. Abnormal EMG
        10. Pathological changes on muscular histology
    7. Other abnormalities
        1. Cleft lip/palate
        2. Genital anomalies in males: cryptorchidism, small penis
        3. Occasional contractures
4. Muscle-eye-brain disease (Santavuori et al. 1989)
    1. Mainly reported in Finnish population
    2. An autosomal recessive disorder
    3. Type II lissencephaly
    4. Hydrocephalus
    5. Eye abnormalities
        1. Primarily myopia
        2. Occasional glaucoma, retinal dystrophy, and cataracts
    6. Congenital muscular dystrophy: a constant feature
    7. Elevated CK levels
    8. Hypotonia
    9. Feeding difficulties
    10. Severe mental retardation
    11. Seizures common
5. Fukuyama congenital muscular dystrophy (Fukuyama et al. 1981)
    1. Mainly reported in the Japanese population
    2. An autosomal recessive disorder
    3. Cobblestone lissencephaly (type II)
    4. Eye abnormalities
        1. Myopia
        2. Optic atrophy in some patients
    5. Muscular dystrophy in all patients
    6. CK levels ranging from 10 to 50 times normal
    7. Hypotonia
    8. Marked mental retardation

Diagnostic Investigations

1. Chromosome analysis to detect microdeletion at 17p13.3
    1. High-resolution analysis indicated for all patients with type I or atypical lissencephaly
    2. Molecular cytogenetic technology using FISH (Pilz et al. 1998) to detect a submicroscopic deletion when chromosome analysis is normal and Miller-Dieker syndrome is suspected based on clinical evaluation
    3. Parental studies in case of positive findings (van Zelderen-Bhola et al. 1997)
2. MRI of the newborn brain
    1. Smooth brain
    2. Bilateral primitive Sylvian fissure giving rise to a "figure 8" appearance of the brain
    3. Persistent fetal configuration of the posterior horns of the ventricular system (colpocephaly)
3. DNA mutation analysis of *LIS1* available clinically (Dobyns and Das 2009)
    1. Direct sequencing
    2. Deletion/duplication analysis to identify deletions/duplications not detectable by sequence analysis
    3. Array comparative genomic hybridization (aCGH)

4. Multiplex ligation-dependent probe amplification (MLPA) analysis

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: based on the specific cytogenetic mechanism involved
        1. Very low recurrence risk in most patients (80% of individuals with MDS) whose abnormalities occur de novo
        2. Very high recurrence risk in families (20% of individuals with MDS) where one parent is the carrier of a balanced chromosome rearrangement involving 17p13
        3. Proband with an intragenic mutation in *LIS1*: risk to sibs negligible if neither parent has mosaicism for the mutation present in the proband
    2. Patient's offspring: patients not surviving to reproductive age
    3. A high risk for abnormal phenotypes for an individual carrying a balanced translocation with a breakpoint in 17p13 ascertained because of a relative with Miller-Dieker syndrome or dup(17p)
        1. Approximately 26% risk in all recognized pregnancies
        2. Thirty-three percent risk in pregnancies which remain viable in the second trimester or after
        3. Frequency of spontaneous miscarriages and stillbirths not appearing to be unduly elevated in these families
2. Prenatal diagnosis (Chen et al. 2013)
    1. To date, at least 28 cases of chromosome 17p13.3 deletion syndrome with prenatal findings and diagnosis reported
    2. Ultrasonography for pregnancy at risk (Sultzman et al. 1991)
        1. Polyhydramnios
        2. IUGR
        3. Lissencephaly
        4. Microcephaly
        5. Ventriculomegaly
        6. Absence of corpus callosum
        7. Congenital heart defects
        8. Omphalocele
        9. Renal abnormalities
    3. Fetal MRI of the brain
    4. Prenatal diagnosis by amniocentesis or CVS
        1. Indications
            1. Carrier parents with balanced chromosome rearrangements involving 17p13 (Pollin et al. 1999)
            2. Probably parents of all Miller-Dieker syndrome patients because of the small possibility of gonadal mosaicism in apparently de novo cases
            3. Normal relatives of unknown karyotype
        2. Cytogenetic analysis
            1. High-resolution analysis of chromosome 17
            2. Molecular cytogenetic studies (FISH)
        3. Analysis of fetal DNA: aCGH
        4. Preimplantation genetic diagnosis: available for families in which the disease-causing mutation has been identified
3. Management
    1. Supportive care
    2. Early infant intervention
    3. Anticonvulsants for seizures

Prenatal and postnatal investigation of a case with Miller-Dieker syndrome due to a familial cryptic translocation t(17;20)(p13.3; q13.3) detected by fluorescence in situ hybridization. *Prenatal Diagnosis, 17*, 173–179.

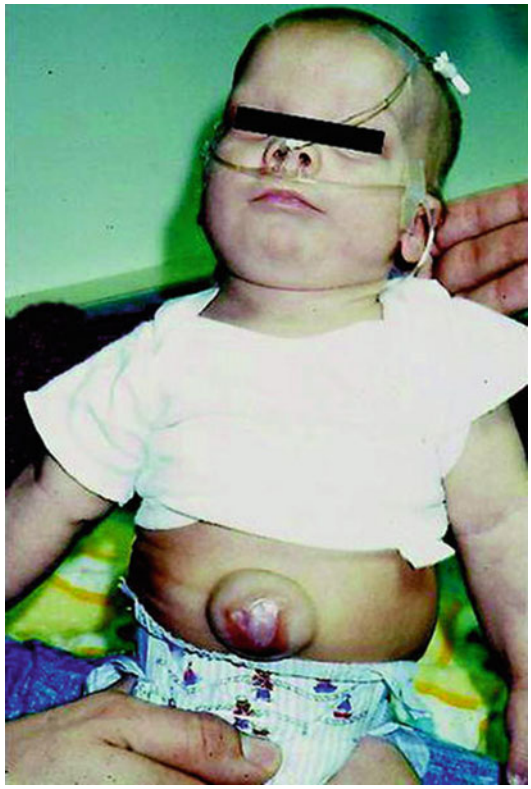

Fig. 1 A child with Miller-Dieker syndrome showing high forehead, frontal bossing, bilateral temporal narrowing, small nose with anteverted nares, prominent upper lip, micrognathia, and a surgically repaired omphalocele

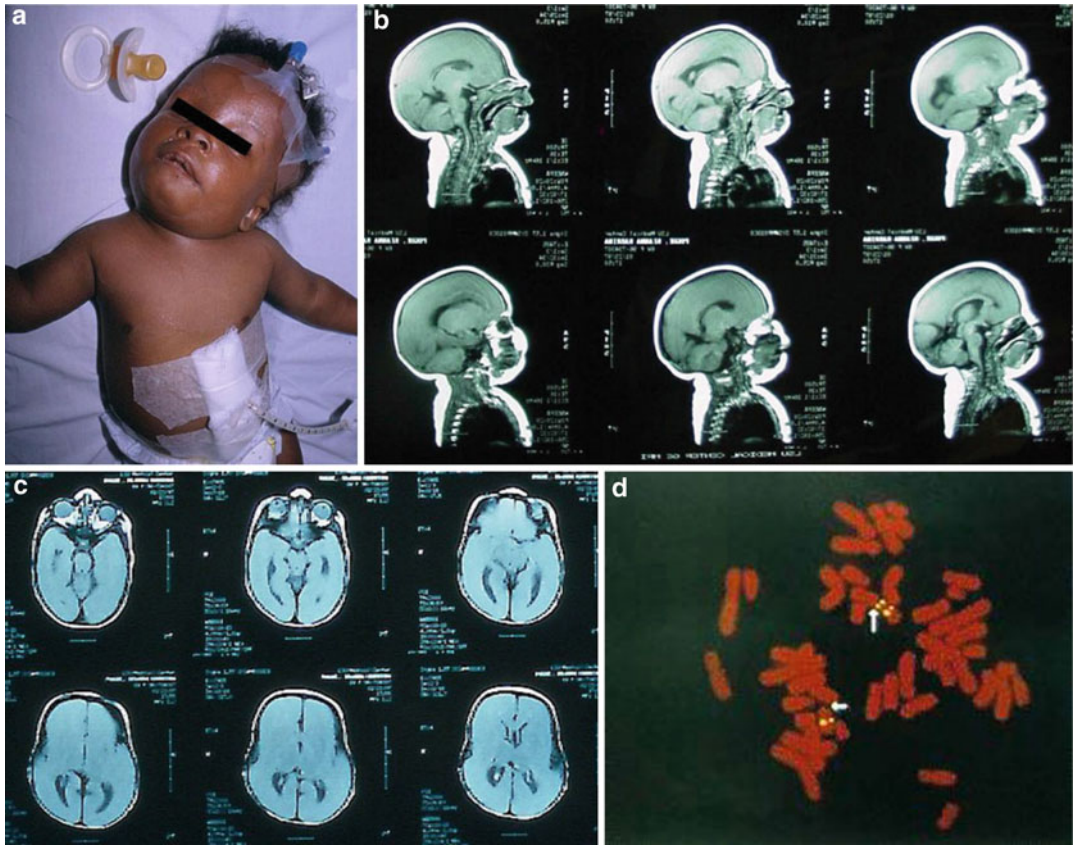

Fig. 2 (**a**–**d**) A child with Miller-Dieker syndrome showing characteristic facial traits like the previous child. The MRI of the brain showed diffuse and complete type I lissencephaly. FISH revealed one chromosome 17 lacked a signal at 17p13 indicating the presence of a deletion

Fig. 3 This 7-week-old baby boy was evaluated for symmetrical intrauterine growth retardation with lissencephaly, hypostasis, undescended testicles, camptodactyly of digits 3 and 4 bilaterally on the hands, and craniofacial dysmorphism consisting of hypertelorism, downslanting palpebral fissures, and retrognathia. CT of the brain without contrast showed pachygyria and figure-8-shaped lissencephaly, consistent with Miller-Dieker syndrome. MRI of the brain showed remarkable abnormality consistent of lack of cortical gyri. There is a smooth cortical surface with lack of cortical sulci and a layer of subcortical heterotopic gray matter (band heteropia), consistent with lissencephaly, pachygyria, heterotopic gray matter. These findings are most consistent with a Miller-Dieker syndrome

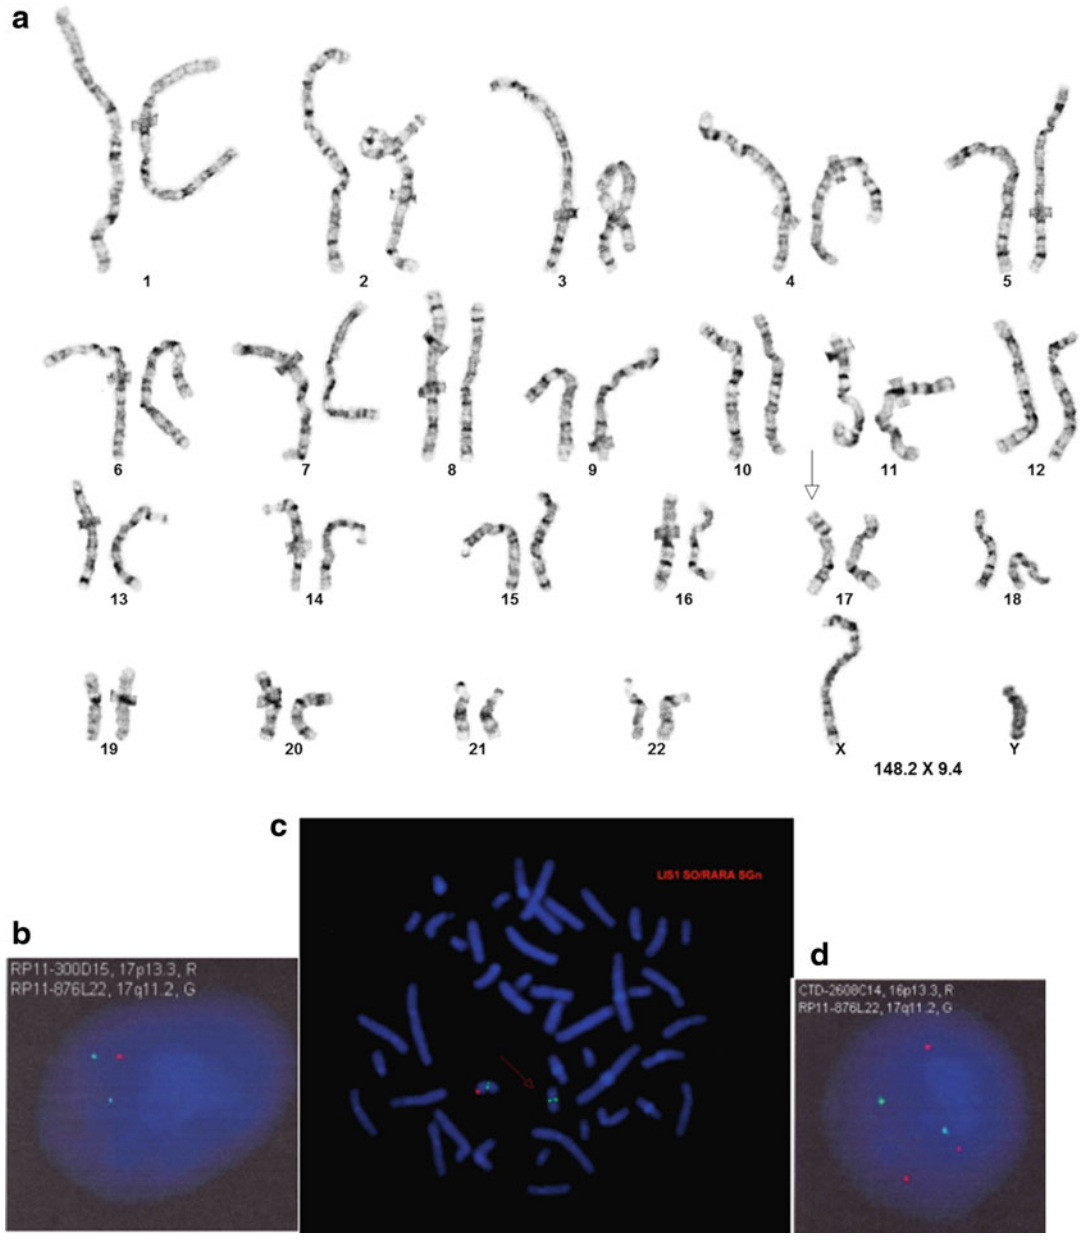

Fig. 4 (**a**–**d**) Results of high-resolution karyotype (**a**) (Courtesy of Dr. Leonard Prouty) and metaphase (**c**) and interphase (**b**, **d**) FISH analysis were consistent with cells exhibiting an unbalanced derivative chromosome 17, arising from the translocation of genetic material from the terminal short arm of chromosome 16 at band 16p13.3 to the terminal short arm of chromosome 17 at band 17p13.3 in all analyzed cells, resulting in a net gain of the terminal 16p arm and a net loss of the terminal 17p arm [ish der(17) t(16;17)(p13.3;p13.3)(CTD-2608C14+;RP11-300D15-)] (Courtesy of CombiMATRIX Diagnostics). The mother's metaphase and interphase FISH analysis exhibited an apparently balanced translocation between the terminal short arms of chromosomes 16 and 17 at bands 16p13.3 and 17p13.3 based on the unbalanced derivative chromosome seen in her offspring (Figures not shown)

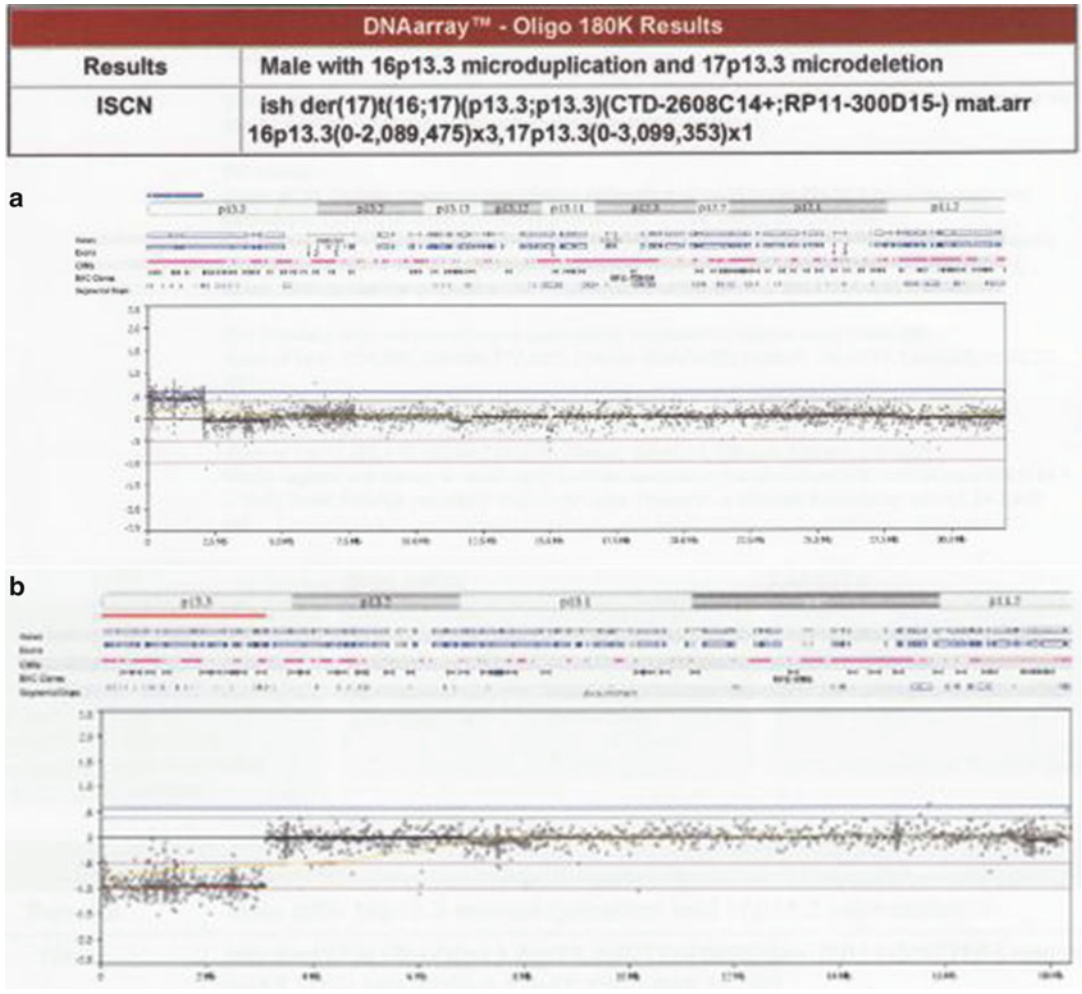

Fig. 5 (**a**, **b**) A chromosomal microarray was done and the baby found to have a 2.0 Mb microduplication of 16p13.3 (**a**) and a 3.0 Mb microdeletion of 17p13.3 (**b**) (Courtesy of CombiMATRIX Diagnostics). The deleted segment of 17p included the *LIS1* (PAFAH1B1) gene and is consistent with Miller-Dieker syndrome or lissencephaly/subcortical band heterotopia. The mother had FISH analysis results consistent with an apparently balanced translocation between the terminal short arms of chromosomes 16 and 17 at bands 16p13.3 and 17p13.3

Mitochondrial Leber Hereditary Optic Neuropathy

Contents

Mitochondrial diseases are a clinically heterogeneous group of disorders that arise as a result of dysfunction of the mitochondrial respiratory chain. They can be caused by mutation of genes encoded by either nuclear DNA or mitochondrial DNA (mtDNA) (Chinnery 2014). Mitochondrial disorders are a major cause of chronic human disease with an estimated prevalence of 1 in 10,000 in the United Kingdom, and 1 in 200 individuals is at-risk mutational carrier (Elliott et al. 2008; Schaefer et al. 2008). Ocular involvement, especially optic nerve dysfunction, is a prominent feature in this group of disorders, suggesting the underlying mitochondrial etiology. Leber hereditary optic neuropathy (LHON) and autosomal dominant optic atrophy (DOA) (Kjer-type optic atrophy) are the two most common inherited optic neuropathies, resulting from mitochondrial dysfunction.

In 1871, the German ophthalmologist Theodore Leber (1871) first described the distinctive clinical entity of LHON with a characteristic pattern of visual loss among members of four families, subsequently confirmed in pedigrees from different populations (Bell 1931; Imai and Moriwaki 1936; Lundsgaard 1944). These early studies highlighted the salient features of LHON, including the maternal transmission of the disease, the predilection of males to lose vision, and the almost exclusive involvement of the optic nerve.

Autosomal dominant optic atrophy is the most common primary hereditary optic neuropathy (Yoshida et al. 2006). It is characterized by optic nerve pallor and reduced visual acuity (Eliott et al. 1993; Votruba et al. 1998a, b). It was first described clinically by Batten (1896) and later by Kjer (1959) and typically presents in childhood with bilateral visual loss that is usually symmetrical, temporal optic nerve pallor, centrocecal visual field scotoma, and color vision deficit (Caldwell et al. 1971; Smith 1972; Hoyt 1980; Jaeger 1988).

Synonyms and Related Disorders

Autosomal dominant optic atrophy (DOA) (Kjer-type optic atrophy); Hereditary optic neuropathies; Leber hereditary optic neuropathy (LHON); Leber optic atrophy; Leber optic neuropathy

DOI 10.1007/978-1-4939-2401-1_158

Genetics/Basic Defects

1. LHON (Yu-Wai-Man et al. 2009):
    1. Caused by primary mitochondrial DNA (mtDNA) mutations affecting the respiratory chain complexes:
        1. Over 95% of LHON pedigrees are now known to harbor one of the three mitochondrial DNA (mtDNA) point mutations: m.3460G > A, m.11778G > A (a point mutation within the mitochondrial genome known to cause the first human disease, LHON) (Wallace et al. 1988; Newman et al. 1991), and m.14484T > C, which all involve genes encoding complex I subunits of the mitochondrial respiratory chain (Mackey et al. 1996).
        2. New MT-ND1 pathologic mutations for Leber hereditary optic neuropathy (Martinez-Romero et al. 2014): this mutation expands the spectrum of deleterious changes in mitochondrial DNA-encoded complex I polypeptides associated with this pathology and highlights the difficulties in assigning pathogenicity to new homoplasmic mutations that show incomplete penetrance in sporadic Leber hereditary optic neuropathy patients.
    2. Mitochondrial genetic factors:
        1. Homoplasmy: in most LHON pedigrees, the primary mutation is homoplasmic (every mtDNA molecule harbors the mutant allele, i.e., only one type of mtDNA exists within an individual).
        2. Heteroplasmy (both mutant and wild-type mtDNA coexist within an individual):
            1. Cells can contain anywhere between 100 and 10,000 mitochondria depending on their metabolic demands. With 2–10 mtDNA molecules in each mitochondrion, this results in a very high copy number per cell.
            2. Ten to fifteen percentage of LHON carriers are thought to be heteroplasmic (one mtDNA subpopulation carrying the wild-type allele) (Smith et al. 1993; Harding et al. 1995; Man et al. 2003).
            3. Available data suggest that heteroplasmy contributes to incomplete penetrance, with the risk of blindness being minimal if the mutational load is <60% (Chinnery et al. 2001).
        3. MtDNA haplogroups:
            1. MtDNA accumulates mutations about ten times faster than nuclear genome, resulting in a high degree of polymorphism (Brown et al. 1979).
            2. Because human mtDNA is strictly maternally inherited and does not recombine, polymorphisms have accumulated sequentially along radiating female lineages as women migrated out of Africa into the different continents about 150,000 years ago (Wallace et al. 1999).
            3. Reflecting its evolution, a number of stable polymorphic variants cluster together in specific combinations referred to as haplogroups, with individuals of European ancestry belonging to one of nine haplogroups: H, I, J, K, T, U, V, W, and X (Torroni et al. 1996; Hofmann et al. 1997).
            4. Comprehensive studies of almost 95% of a 328-living-member pedigree with LHON 11778/J haplogroup indicate the strong influence of environmental risk factors (Sadun et al. 2003).
            5. A recent meta-analysis of 159 - European LHON pedigrees indicated that the risk of visual loss for the three primary LHON mutations is influenced by the mtDNA background (Hudson et al. 2007).
    3. Nuclear genetic factors:
        1. The predominance of affected males in LHON cannot be explained by mitochondrial inheritance, and segregation

analysis suggests the existence of a recessive X-linked susceptibility gene acting in synergy with the mtDNA mutation to precipitate the optic neuropathy (Bu and Rotter 1991, 1992; Nakamura et al. 1993).
2. LHON has been suggested to involve both mitochondrial and X-chromosome-linked loci: a proportion of affected females are likely heterozygous at the X-linked locus and affected due to unfortunate X-chromosome inactivation (Bu and Rotter 1992).
3. Although the actual causative gene in this region of interest has not yet been identified, a high-risk haplotype (DXS8090-DXS1068) at Xp21 was defined which increased the risk of visual failure >35-fold for the m.11778G > A and m.14484 T > C mutations but not for m.3460G > A (Hudson et al. 2005).
4. The possibility of other autosomal nuclear modifier genes in LHON has not been excluded, and the genetic etiology of LHON might prove even more complex, with epistatic interaction of these multiple nuclear susceptibility loci and genetic heterogeneity.

4. Environmental factors:
   1. The existence of discordant monozygotic twins strongly suggests that environmental factors also contribute to penetrance.
   2. Anecdotal reports of nutritional deprivation, exposure to industrial toxins, antiretroviral drugs, psychological stress, or acute illness precipitating the onset of blindness in LHON (Mackey et al. 2003; Sanchez et al. 2006; Carelli et al. 2007).
   3. The role of environmental triggers in LHON remains largely unanswered, and more robust epidemiological data are needed, which will necessitate a multicenter collaborative effort in order to collect sufficient number of subjects for analysis.

2. DOA (Allen et al. 2015):
   1. Caused by mutations in the *OPA1* gene, a gene encoding for a dynamin-like mitochondrial GTPase, an inner mitochondrial membrane protein critical for mtDNA maintenance and oxidative phosphorylation, in the majority of DOA families.
   2. These mutations are maternally inherited and can have an asymmetric presentation.
   3. The mitochondrial DNA haplogroup appears to contribute to disease pathogenicity with haplogroup J of particular importance (Howell et al. 2003; Sadun et al. 2003).
   4. Rarely, mutations in OPA3 cause recessive optic atrophy that is commonly associated with cataracts and other neurological abnormalities (Ferré et al. 2009).
3. Pathology for both LHON and DOA: limited in the majority of cases to the retinal ganglion cells (RGCs), a highly specialized group of cells within the eye
4. Expanding phenotype associated with LHON and DOA: providing important insights into possible disease pathways leading to optic nerve degeneration and visual failure

Clinical Features

1. LHON (Yu-Wai-Man et al. 2009; Milea et al. 2010):
   1. Affected individuals are usually entirely asymptomatic – blurring and clouding of vision affecting the central visual field are usually the first symptoms of LHON (Piotrowska et al. 2015).
   2. Presymptomatic phase:
      1. Fundal abnormalities such as telangiectatic vessels around the optic disks and variable degrees of retinal nerve fiber layer edema:
         1. Documented in some asymptomatic carriers
         2. Can fluctuate with time
      2. Thickening of the temporal retinal nerve fiber layer found in a proportion of

unaffected carriers by using optical coherence tomography imaging: provides further evidence that the papillomacular bundle is particularly vulnerable in this disorder (Savini et al. 2005; Quiros et al. 2006)
3. Subtle impairment of optic nerve function in some individuals on detailed psychophysical testing (Sadun et al. 2006):
    1. Loss of color vision affecting mostly the red-green system
    2. Reduced contrast sensitivity
    3. Subnormal visual electrophysiological parameters
3. Acute phase:
    1. Experiencing blurring or clouding of vision in one eye
    2. Subacute presentation in the vast majority of an early age of onset (<20 years) with slow progression of the visual deficits and large optic nerve head surface area (Nikoskelainen et al. 1996; Barboni et al. 2006)
    3. Devastating, with the majority of patients showing no functional improvement and remaining as legally blind
4. Interval between involvement between both eyes (Ohden et al. 2016):
    1. The vision of the fellow eye may remain unaffected for months to years after initial presentation.
    2. Involvement of the fellow eye may occur at any time after initial presentation – even after decades of stable unilateral vision loss.
    3. With advancements in therapeutics for LHON, it is important to note that any delay in involvement of the fellow eye may represent the natural disease course, rather than an effect of therapy.
5. Associated features:
    1. Cardiac arrhythmias.
    2. Neurological abnormalities: rarely clinically significant, but a small number of LHON pedigrees have severe neurological deficits such as spastic dystonia, ataxia, and juvenile onset encephalopathy in addition to the optic neuropathy ("LHON plus" syndromes) (Bower et al. 1992; Nikoskelainen et al. 1994, 1995; Meire et al. 1995; Mashima et al. 1996)
        1. Postural tremor
        2. Peripheral neuropathy
        3. Nonspecific myopathy and movement disorders

2. DOA:
    1. Prevalence:
        1. A historical figure of 1 in 50,000 among Caucasians often quoted in the literature (Lyle 1990)
        2. Thought to be the most common inherited optic neuropathy in the Netherlands, with a population frequency of 1 in 12,000, a higher prevalence linked to a mutational founder event (Thiselton et al. 2001)
    2. Insidious onset of symptoms: 13–25% of patients with optic atrophy in premolecular case series were visually asymptomatic and were only identified through contact tracing via other affected family members (Kline and Glaser 1979; Hoyt 1980).
    3. Pronounced inter-/intrafamilial variability in the severity of visual symptoms:
        1. Makes genetic counseling difficult
        2. Visual decline: classically starts in the first two decades of life
        3. Visual acuity: ranges from 6/6 to the detection of hand movement only
        4. The rate of progression of visual loss: not easy to predict, with 19–50% of patients experiencing further, albeit slow, deterioration on long-term follow-up (Kjer 1959; Eliott et al. 1993; Votruba et al. 1998a, b; Puomila et al. 2005; Cohn et al. 2008).
    4. Pupil afferent deficits (Bremner et al. 2001):
        1. Pupil function appears less affected than visual function.
        2. The retinotectal fibers serving the pupil light reflex are less susceptible to damage from the *OPA1* genetic defect than the retinogeniculate fibers serving vision.

5. Better overall visual prognosis compared to LHON (Kjer et al. 1996; Votruba et al. 1998a, b; Cohn et al. 2007):
    1. A mean visual acuity of 6/24–6/36
    2. Results in significant visual impairment with about half of all affected individuals failing the driving standards and 13–46% registered as legally blind
6. Generalized dyschromatopsia: predominant color defect involving both the blue-yellow and red-green axes, with a minority of patients having pure tritanopia (<10%), which was once considered to be a pathognomonic feature of dominant optic atrophy (Berninger et al. 1991).
7. Central, centrocecal, and paracentral scotomas are the most common field abnormalities with sparing of the periphery, findings consistent with the primary involvement of the papillomacular bundle in this condition.
8. The optic disk pallor in DOA falls into two main categories (Kline and Glaser 1979; Hoyt 1980; Kjer 1959):
    1. Diffuse pallor involving the entire neuroretinal rim in about half of all cases
    2. A temporal wedge in the remainder of cases
9. Other common optic disk findings (Votruba et al. 1998a, b, 2003; Fournier et al. 2001):
    1. Saucerization (79%)
    2. Peripapillary atrophy (69%)
    3. A cup to disk ratio 0.5 (48%)
    4. A typical profile with bilateral symmetrical thinning around the optic disk, most pronounced in the temporal quadrant (circumpapillary retinal nerve fiber layer thickness using optical coherence tomography) (Ito et al. 2007; Kim and Hwang 2007)
10. Normal tension glaucoma: single nucleotide polymorphisms in intron 8 and exon 4 of the *OPA1* gene could increase the risk of normal (but not high) tension glaucoma in whites (Yu-Kai-Man et al. 2010b).
11. Extraocular findings: *OPA1* gene may be responsible for a continuum of phenotypes, ranging from mild visual loss to very variable, sometimes severe, multisystemic involvement of the disease (Amati-Bonneau et al. 2008; Hudson et al. 2008).
12. Optic atrophy associated with multiple sclerosis-like disease in a patient carrying a new missense *OPA1* mutation (p.S646L) in the highly conserved dynamin domain (Vemy et al. 2008), suggesting a relationship between mitochondrial dysfunction and the central nervous system defect.
13. Optic atrophy and deafness occurring in patients with a specific R445H mutation (Amati-Bonneau et al. 2005; Zeviani 2008) and other mutations.
14. Multisystemic disorders associated with optic atrophy 1 mutations (autosomal dominant optic atrophy "plus") (ADOA "plus syndrome"): an optic atrophy associated with early onset in childhood, followed by chronic progressive external ophthalmoplegia, ataxia, sensorineural deafness, sensorimotor neuropathy, and myopathy in adult life.

Diagnostic Investigations

1. LHON (Yu-Wai-Man et al. 2009):
    1. Tentative diagnosis of LHON usually be made on the following:
        1. Clinical grounds (especially if classical ophthalmological features are present).
        2. A clear maternal history is elicited.
    2. Ophthalmoscopic findings (Huoponen 2001):
        1. Presymptomatic stage:
            1. Peripapillary telangiectatic microangiopathy visible in the presymptomatic stage: the first sign of the disease (Nikoskelainen et al. 1982, 1983)

2. Increased hyperemia, swelling of the optic disk, and arteriolar dilation at the end of the presymptomatic stage
2. Acute stage:
   1. Visual loss.
   2. Severe hyperemia, arteriolar dilation, disk swelling, telangiectatic angiopathy, and a glistening, whitish, opaque nerve fiber layer: hallmarks of this stage of the disease.
   3. Decreased visual acuity and development of a relative centrocecal scotomas can be minimal or even absent.
3. End stage:
   1. Disappearance of microangiopathy
   2. Fading of retinal nerve fiber layer
   3. Large and absolute centrocecal scotoma

3. Molecular genetic testing on a blood DNA sample: remains the gold standard and will confirm that the patient harbors one of the three primary mtDNA LHON mutations, with implications for future genetic counseling:
   1. Targeted mutation analysis:
      1. Primary pathogenic LHON-causing mtDNA mutations
      2. Secondary LHON-causing mtDNA mutations
   2. Sequence analysis and mutation scanning
4. Biochemical findings associated with the primary mutations:
   1. Variable complex I defects: associated with all the primary mutations
   2. A defect in respiratory chain function in LHON: first demonstrated in platelet mitochondria from a family that was subsequently shown to harbor the ND1/3460 mutations (Parker et al. 1989)
   3. A marked reduction in the specific activity of complex I associated with the ND1/3460 mutation: further detected in lymphoblasts (Majander et al. 1991; Brown et al. 2000), leukocytes (Carelli et al. 1997), and fibroblasts (Cock et al. 1999)
   4. ND4/11778 mutation: less severe reduction in complex I function
   5. A reduction in respiration of NADH-linked substrates (Majander et al. 1991; Lodi et al. 2000)
   6. Alteration in the affinity of complex I for ubiquinone (Degli Esposti et al. 1994)
5. Electrophysiological studies, including pattern electroretinograms (PERGs) and visual evoked potentials (VEPs), if indicated, can be carried out to exclude retinal pathology and confirm optic nerve dysfunction (Sherman and Kleiner 1994).
6. An electrocardiogram is also recommended to exclude a preexcitation syndrome which has been documented in LHON, although such a finding is rare and does not require any intervention in the absence of cardiac symptoms (Nikoskelainen 1994; Riordan-Eva and Harding 1995).
7. Computed tomography (CT) and magnetic resonance imaging (MRI) scans are usually normal in LHON.

2. DOA (Votruba et al. 1998a, b; Delettre-Cribaillet et al. 2009):
   1. Clinical diagnosis: the majority of patients present in early to mid-childhood and the clinical diagnosis are generally reliable from 6 years of age and above, except in rare cases.
   2. Visual acuity.
   3. Color vision.
   4. Visual fields.
   5. Assessment of extraocular muscles.
   6. Hearing evaluation.
   7. Electrophysiology:
      1. Visual evoked potentials (VEPs): typically absent or delayed, indicating a conduction defect in the optic nerve
      2. Pattern electroretinogram (PERG): an abnormal N95:P50 ratio with reduction in the amplitude of the N95 waveform (Holder et al. 1998), supporting a ganglion cell origin for the optic atrophy since the N95 component of the PERG is thought to be specific for the retinal ganglion cell

8. Muscle biopsy and histoenzymology (La Morgia et al. 2014):
    1. As for LHON, DOA also may present a "plus" phenotype, which includes deafness, chronic external ophthalmoplegia, peripheral neuropathy, cerebellar atrophy, and mitochondrial myopathy (Amati-Bonneau et al. 2008; Yu-Wai-Man et al. 2010a).
    2. In these cases, muscle biopsy histology and histoenzymology may disclose the hallmarks of mitochondrial myopathy with cytochrome *c* oxidase negative fibers, whereas molecular analysis will reveal the pathological accumulation of multiple mtDNA deletions (Yu-Wai-Man et al. 2010a).
9. Molecular genetic testing available clinically:
    1. Sequence analysis of all exons of *OPA1*
    2. Target mutation analysis for the Danish founder mutation
    3. Sequence analysis of RNA RT-PCR amplification on *OPA1*
    4. Deletion/duplication analysis
3. Diffusion tensor imaging mapping of brain white matter (Manners et al. 2015):
    1. Patients with Leber hereditary optic neuropathy had preferential involvement of the optic and acoustic radiations, consistent with transsynaptic degeneration.
    2. Whereas patients with optic atrophy gene 1-autosomal dominant optic atrophy presented with widespread involvement suggestive of a multisystemic, possibly a congenital/developmental, disorder.

Genetic Counseling

1. Recurrence risk (Yu-Wai-Man and Chinnery 2013; Yu-Wai-Man et al. 2009):
    1. LHON:
        1. Not possible to predict accurately whether or when LHON carriers will become affected
        2. Two main predictive factors for visual failure:
            1. Gender: males, a 50% lifetime risk of blindness, and females, only 10% lifetime risk of blindness.
            2. Age: most patients experience visual loss in their late teens and 20s. The probability of becoming affected decreases with age, being minimal once past the age of 50 years.
        3. Once a primary LHON mutation has been identified in a proband, other maternally related family members can be offered molecular genetic testing to exclude the possibility of a de novo mutation, which is rare.
        4. Since LHON shows strict maternal inheritance, male carriers can be reassured that none of their children will inherit the mtDNA mutation, whereas female carriers will transmit the pathogenic mutation to all of their offspring.
        5. Since most mothers are homoplasmic, their children will only harbor the mutant species, but the situation is more complex for a heteroplasmic mother as she could transmit a higher or a lower level of the mutation to a particular offspring, which will impact on the latter's risk of visual failure.
        6. Given the variability associated with the clinical manifestation of LHON, finding evidence of the 11778 mutation in the older man gave his young relative the advantage of a rapid diagnosis, avoiding unnecessary diagnostic procedures and providing him a small window of opportunity to prepare for his visual disability (Malouf et al. 2016).
        7. Although the mutant level can be determined and there is evidence that a mutational threshold of $>60\%$ in blood is necessary for disease expression, genetic counseling for these unaffected heteroplasmic carriers remains difficult.

8. For similar reasons, the prenatal genetic testing of heteroplasmic women with amniocentesis or chorionic villus sampling (CVS) would be difficult to interpret.
9. Patient's sib:
    1. The recurrent risk depends on the genetic status of the mother.
    2. All sibs at risk of inheriting the mutation if the mother has the mtDNA mutation.
10. Patient's offspring:
    1. An affected or unaffected male with a primary LHON-causing mtDNA mutation cannot transmit the mutation to any of his offspring.
    2. An affected or unaffected female with a primary LHON-causing mtDNA mutation transmits the mutation to all of her offspring.
    3. An affected female with heteroplasmy may transmit a low level of mutant mtDNA to her offspring, confirming a low disease risk (Chinnery et al. 2001).
11. Other family members:
    1. The recurrence risk depends on the genetic status of the proband's mother.
    2. If the proband's mother has an mtDNA mutation, her sibs and mother are also at risk.

2. DOA (Votruba et al. 1998a, b; Yoshida et al. 2006; Delettre-Cribaillet et al. 2009):
    1. Despite DOA being an autosomal dominant Mendelian disorder with high penetrance (0.98) (Eiberg et al. 1994), genetic counseling for mutational carriers is difficult because of the pronounced inter- and intrafamilial heterogeneity and variability in the visual phenotype.
    2. A multidisciplinary approach to the diagnosis and management of these patients is helpful, involving both clinical ophthalmologists and geneticists, electrodiagnostic services, low vision specialists, and educational advisors.
3. An apparently sporadic person who presents with nonprogressive optic atrophy and normal neuroimaging:
    1. Important to examine all family members fully, as relatives may be only mildly affected.
    2. Establish a disease pedigree and the mode of transmission.
4. A person uncertain of his clinical status from a family known to be affected by dominant optic atrophy: needs to include color vision and electrophysiology in the full clinical assessment of the patient in order to be able to make a diagnosis.
5. Patient with the absence of a mutation: genetic counseling relies on conventional risk assessment.
6. With the availability of molecular testing for *OPA1* becoming more accessible, an increasing number of individuals with pathogenic mutations are being identified who are otherwise visually unaffected.
7. Patient with *OPA1* mutation:
    1. Genetic counseling is difficult since clinical manifestation of the same mutation within a family can be remarkably variable.
    2. Dramatic psychological impact on the person involved with awareness of one's susceptibility to the disease without an actual possibility of intervention.
8. The clinical features of the primary optic neuropathies are sufficiently similar that clinical examination cannot reliably differentiate individuals with dominantly inherited disease caused by mutations in *OPA1*, maternally inherited disease caused by mitochondrial DNA mutations, or recessively inherited disease in patients with *OPA3* mutations. By identifying the disease-causing mutation, genetic testing can accurately define the inheritance pattern and subsequent disease risk for family members (Allen

et al. 2015). In addition, genetic testing can measure mitochondrial heteroplasmy, which is an important feature of mitochondrial disease pathogenicity (Wallace and Chalkia 2013).

9. Patient's sib:
    1. Risk depends on the genetic status of the parents.
    2. A 50% risk if a parent is affected.
    3. Apparently low risk when the parents are found to be clinically unaffected on the basis of visual acuity study, color vision evaluation, fundus examination, VET, and PERG.
    4. Possibilities of germ line mosaicism in a parent or a de novo mutation in the proband exist if a disease-causing mutation cannot be detected in the DNA of either parent.
10. Patient's offspring: a 50% risk of inheriting the mutation.

2. Prenatal diagnosis and preimplantation genetic diagnosis (Yu-Wai-Man and Chinnery 2013): once the mtDNA LHON-causing variant in the mother has been identified, prenatal diagnosis or preimplantation genetic diagnosis for a pregnancy at increased risk for LHON may be an option that a couple may wish to consider.
    1. LHON:
        1. Prenatal diagnosis for pregnancies at increased risk: possible by amniocentesis or CVS.
        2. MtDNA mutation in the mother must be identified before prenatal testing can be performed.
        3. Reasons for difficult accurate interpretation of a positive prenatal test:
            1. The mtDNA mutational load in amniocytes and chorionic villi is unlikely to correspond to that of other fetal or adult tissues because of mitotic segregation.
            2. The presence of the mtDNA mutation does not predict the occurrence, age of onset, severity, or rate of progression of this typically adult-onset disease.
    2. DOA:
        1. Prenatal diagnosis for pregnancies at an increased risk is possible by amniocentesis or CVS.
        2. The disease-causing allele of an affected family member must be identified before prenatal testing can be performed.
3. Management:
    1. LHON:
        1. Mainly supportive:
            1. Provision of visual aids
            2. Registration with the relevant social services
        2. ECG may reveal a preexcitation syndrome in both affected and unaffected LHON carriers.
        3. Risk factors for additional vision loss, such as smoking and consuming alcohol (Meyerson et al. 2015).
        4. Currently, the most promising compounds are short-chain quinones that have been shown to protect the vision of LHON patients during the early stages of the disease (Gueven and Faldu 2013).
    2. DOA:
        1. Supportive.
        2. Treatment of decreased visual acuity.
        3. Patients are advised to avoid alcohol and tobacco consumption, as well as the use of medications that may interfere with mitochondrial metabolism (Lenaers et al. 2012).
    3. In vitro fertilization: in addition to neuroprotective strategies for rescuing retinal ganglion cells from irreversible cell death, innovative in vitro fertilization techniques are providing the tantalizing prospect of preventing the germ line transmission of pathogenic mtDNA mutations, eradicating in so doing the risk of disease in future generations (Yu-Wai-Man et al. 2014).
    4. Gene therapy for Leber hereditary optic neuropathy (Feuer et al. 2016):
        1. No serious safety problems were observed in the first five participants enrolled in this phase I trial of virus-

based gene transfer in this mitochondrial disorder.

2. Additional study follow-up of these and additional participants planned for the next 4 years are needed to confirm these preliminary observations.

Fig. 1 A 10-year-old boy was relatively healthy until last year when he suddenly started having trouble seeing and complained constant headache. He was noted to have painless visual failure, optic nerve atrophy in his left eye, and exophthalmos. He has also experienced minor tremors, muscle weakness, nausea, and movement disorder. Family history revealed similarly affected males in two generations on the maternal side of the family. Molecular genetic analysis detected an apparently homoplasmic m.11778G > A mutation. This mutation in *ND4* gene is commonly associated with Leber hereditary optic neuropathy (LHON). The result confirms the carrier/affected status of this boy for a mitochondrial DNA disorder

Mitochondrial Myopathies

Contents

Mitochondrial myopathies here imply the disorders of the respiratory chain that exclusively or predominantly affect the skeletal muscle (DiMauro and Gurgel-Gianneti 2006). They frequently present with multisystem dysfunction and have a broad variety of phenotypes and genetic etiologies. They can be classified genetically into two major groups: those due to mutations in mitochondrial DNA (mtDNA) and those due to mutations in nuclear DNA (nDNA). The prevalence of mitochondrial disorders as a whole is approximately 1 in 10,000 (Schaefer et al. 2008), although the carrier frequency of mtDNA mutations is about 1 in 200 (Elliott et al. 2008).

Synonyms and Related Disorders

Ataxia neuropathy syndromes (ANS); Infantile myopathy with COX deficiency; Kearns-Sayre syndrome (KSS); Leber's hereditary optic neuropathy (LHON); Leigh syndrome; Mitochondrial DNA depletion syndrome; Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS); Mitochondrial recessive ataxia syndrome (MIRAS); Myoclonus epilepsy and ragged-red fibers (MERRF); Myoclonic epilepsy myopathy sensory ataxia (MEMSA); Myopathy, neurogastrointestinal encephalopathy (MNGIE); Pearson syndrome; Progressive external ophthalmoplegia (PEO); Sensory ataxia neuropathy dysarthria ophthalmoplegia (SANDO); Spinocerebellar ataxia with epilepsy (SCAE)

Genetics/Basic Defects

1. Possible mechanisms for a mitochondrial disease to be confined to skeletal muscle (Dimauro 2006; DiMauro and Gurgel-Gianneti 2006):
   1. Occurrence of mutations in tissue-specific nuclear genes: although reasonable, this concept lacks verification.
   2. Somatic mtDNA mutation: these spontaneous, de novo mutations occur in the oocyte or the embryo, affect myoblasts after germ layer differentiation, and are best exemplified by myopathies due to mutations in mtDNA protein-encoding genes (Andreu et al. 1999).
   3. Skewed heteroplasmy: "garden-variety" pathogenic mutations in mtDNA are heteroplasmic and ubiquitous but have such a skewed predominance in the skeletal

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_280

muscle that they surpass a pathogenic threshold only in this tissue, resulting in myopathic phenotypes.

2. Disorders due to mutations in mtDNA:
   1. Impair mitochondrial protein synthesis in toto:
      1. mtDNA rearrangements (Pfeffer and Chinnery 2013):
         1. Deletions: single large-scale deletions are typically due to sporadic events and are usually not inherited, although inherited deletions have been described (Chinnery et al. 2004). The deletions can be associated with sporadic progressive external ophthalmoplegia (PEO), either alone or in the context of the multisystemic Kearns-Sayre syndrome (Hays et al. 2006).
         2. Depletion (loss of mtDNA) and multiple deletions are typically secondary effects of faulty mtDNA maintenance, from mutation of nDNA-encoded mitochondrial proteins.
         3. Duplications.
      2. Mutations in tRNA genes:
         1. A3243G mutation in $tRNA^{LEU(UUR)}$ in 50% of patients with MELARS (Karrpa et al. 2005)
         2. The 7472-insertion mutation in $tRNA^{Ser(UCN)}$ associated with a patient with MERRF and a patient with pure myopathy (Pulkes et al. 2005)
      3. Mutations in rRNA genes
   2. Impair specifically the activity of the respiratory chain complex whose subunit is mutated: mutations in protein-encoding genes:
      1. One protein-encoding gene that is rapidly attaining the status of "pathogenic hot spot" is *ND5*, which encodes subunit 5 of complex I (DiMauro and Davidzon 2005):
         1. Although none of the mutations in *ND5* causes a pure myopathy, the muscle is involved in multisystem disorders ranging from MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes) to LHON (Leber's hereditary optic neuropathy), Leigh syndrome, and MERRF (myoclonus epilepsy and ragged-red fibers), often overlapping in individual patients.
         2. From the myopathological point of view, it is worth noting that muscle biopsies from these patients only occasionally exhibit ragged-red fibers (RRF), which are invariably cytochrome c oxidase (COX) positive.
      2. Mutations in *ND1* and in *ND*4 have been associated with pure myopathy (Hays et al. 2006).
      3. A mutation in *ND2* (G4810A) joins the list of mutations causing severe exercise intolerance (chronic fatigue syndrome) followed by mild ptosis and PEO (Pulkes et al. 2005).
3. Disorders due to mutations in nDNA affecting the mitochondrial respiratory chain directly fall into the following 3 major groups:
   1. "Direct hits" (mutations in respiratory chain subunits):
      1. Complexes I and II
      2. Coenzyme Q10 (CoQ10): variable presentation of CoQ10 deficiency (Lalani et al. 2005; Hirano et al. 2006; Horvath et al. 2006)
   2. "Indirect hits" (mutations in ancillary proteins that are needed for the correct assembly and function of respiratory chain complexes): complexes III, IV, and V.
   3. Defects in intergenomic signaling (mutations in nuclear genes that control the abundance and quality of mtDNA and result in multiple deletions of mtDNA or mtDNA depletion or both conditions at once): mutations in *POLG* gene cause autosomal dominant PEO (adPEO) and also autosomal recessive PEO (arPEO) (Spinazzola and Zeviani 2005).

Clinical Features

1. Onset (Pfeffer and Chinnery 2013):
   1. Occur at any age

2. More severe phenotypes typically present earlier in life, e.g., so-called deletion syndromes (caused by sporadic, large-scale deletions of mtDNA) (Pearson syndrome)
3. More moderate syndrome present in early childhood or adolescence, e.g., Kearns-Sayre syndrome.
4. Milder phenotype typically present later in life, e.g., progressive external ophthalmoplegia

2. Clinical course:
   1. Usually progressive conditions
   2. Can produce significant disability
   3. Premature death, in some instances, often due to non-muscle involvement such as cardiac conduction defects or seizures (Schapira 2006)
3. Clinical features by organ systems:
   1. Central nervous system:
      1. Neurologic central:
         1. Ataxia
         2. Movement disorder
         3. Spasticity
         4. Seizures
         5. Stroke-like episodes
         6. Migraine
         7. Encephalopathy
         8. Cognitive impairment
      2. Neuropsychiatric:
         1. Depression
         2. Fatigue
         3. Psychosis
   2. Ocular system:
      1. Myopathy: ophthalmoplegia and/or ptosis
      2. Optic nerve atrophy
      3. Pigmentary retinopathy
      4. Cataract
   3. Musculoskeletal system:
      1. Myopathy (skeletal muscle: ocular > axial/proximal > bulbar > distal muscles)
      2. Myalgia
   4. Cardiac system:
      1. Conduction abnormalities
      2. Cardiomyopathy: hypertrophic > dilated
   5. Endocrine system:
      1. Diabetes mellitus
      2. Hypothyroidism
      3. Hypoparathyroidism
      4. Gonadal failure
      5. Growth hormone deficiency
   6. Renal system:
      1. Renal tubular acidosis
      2. Toni-Fanconi-Debre syndrome
   7. Gastrointestinal system:
      1. Dysphagia
      2. Dysmotilty:
         1. Gastroparesis
         2. Diarrhea
         3. Constipation
         4. Pseudo-obstruction
   8. Neurologic peripheral:
      1. Axonal polyneuropathy
      2. Sensory ataxia
      3. Sensorineural hearing loss
      4. Autonomic dysfunction
   9. Others:
      1. Short stature
      2. Spontaneous abortion
4. Mitochondrial myopathy syndromes presenting with ocular myopathy:
   1. Progressive external ophthalmoplegia (PEO):
      1. Ptosis
      2. Ophthalmoplegia
      3. Proximal myopathy often present
      4. Other clinical features variably present
   2. Kearns-Sayre syndrome (KSS):
      1. PEO
      2. Ptosis
      3. Pigmentary retinopathy
      4. Cardiac conduction abnormality
      5. Ataxia
      6. CSF elevated protein
      7. Diabetes mellitus
      8. Sensorineural hearing loss
      9. Myopathy
   3. Ataxia neuropathy syndromes (ANS) including mitochondrial recessive ataxia syndrome (MIRAS), spinocerebellar ataxia with epilepsy (SCAE), sensory ataxia neuropathy dysarthria ophthalmoplegia

(SANDO), and myoclonic epilepsy myopathy sensory ataxia (MEMSA):
1. SANDO:
    1. PEO
    2. Dysarthria
    3. Sensory neuropathy
    4. Cerebellar ataxia
2. Other PEO: variable presence of PEO and/or myopathy

4. Myopathy, neurogastrointestinal encephalopathy (MNGIE):
    1. PEO
    2. Ptosis
    3. GI dysmotility
    4. Proximal myopathy
    5. Axonal polyneuropathy
    6. Leukodystrophy
5. Mitochondrial myopathy typically presenting without PEO:
    1. Childhood or adult onset:
        1. Myopathy, encephalopathy, lactic acidosis, stroke-like episodes (MELARS):
            1. Stroke-like episodes with encephalopathy, migraine, and seizures
            2. Variable presence of myopathy, cardiomyopathy, deafness, endocrinopathy, and ataxia
            3. PEO: present in a minority of patients
        2. Myoclonus, epilepsy, and ragged-red fibers (MERRF):
            1. Stimulus-sensitive myoclonus
            2. Generalized seizures
            3. Ataxia
            4. Cardiomyopathy
            5. PEO: present in a minority of patients
        3. Ataxia neuropathy syndromes (ANS) including MIRAS, SCAE, SANDO, and MEMSA:
            1. Sensory axonal neuropathy with variable degrees of sensory and cerebellar ataxia
            2. PEO: present in 50% of patients
            3. Epilepsy and dysarthria: present in some patients
    2. Congenital or infant onset:
        1. Mitochondrial DNA depletion syndrome:
            1. Diffuse myopathy
            2. Hepatocerebral syndrome
        2. Infantile myopathy with COX deficiency:
            1. Diffuse myopathy
            2. Lactic acidosis
            3. Encephalopathy

Diagnostic Investigations

1. Electromyography: often shows evidence of active or inactive myopathy (Pfeffer and Chinnery 2013).
2. Muscle biopsy:
    1. Light microscopy (Pfeffer and Chinnery 2013):
        1. Ragged-red fibers on modified trichrome Gomori stain.
        2. Ragged-blue fibers on SDH stain.
        3. Absence of COX staining: the COX reaction has subunits in the nuclear and mitochondrial DNA that make the COX stain valuable in diagnosing mitochondrial myopathies (Taylor et al. 2004).
    2. Muscle immunohistochemical findings may appear normal in patients who have genetic study results consistent with mitochondrial dysfunction (Taylor et al. 2004; Schaefer et al. 2005).
3. Confirmatory tests for organ dysfunction in mitochondrial myopathy:
    1. EEG for seizures/encephalopathy
        1. Epileptiform abnormality
        2. Diffuse slowing
    2. MRI of the brain for stroke-like episodes: high-signal T2 abnormality not conforming to vascular territories, posterior predominant
    3. Nerve conduction studies for sensory neuropathy: axonal sensory or sensorimotor neuropathy
    4. CK for myopathy:
        1. Normal or slightly elevated
        2. May be very high in CoQ_{10} deficiency
    5. EMG for myopathy: normal or myopathic changes

6. PFTs and sleep studies for respiratory failure:
    1. Decreased FVC
    2. Apneic episodes during sleep
7. EKG/echocardiogram for cardiac abnormalities:
    1. Conduction abnormalities
    2. Cardiomyopathy
8. Fasting glucose, glucose tolerance test, hemoglobin A1C, TSH, calcium, PTH, cortisol, synacthen test for endocrinopathy: abnormalities consistent with type 2 diabetes mellitus, and/or hypothyroidism, and/or hypoparathyroidism, and/or adrenal failure
9. Mental status testing for cognitive dysfunction: may indicate cognitive impairment
10. Audiography for hearing loss: sensorineural-type hearing loss
11. Ophthalmology referral for ocular symptoms/signs:
    1. Oculomotor abnormalities
    2. Optic atrophy
    3. Pigmentary retinopathy
12. Swallowing studies (video fluoroscopy or manometry) for dysphagia: cricopharyngeal achalasia or esophageal dysmotility
13. Other general tests:
    1. Serum lactate: normal or elevated
    2. CSF lactate: normal or elevated
    3. CSF analysis: normal or elevated protein
    4. CT of the brain: normal or basal ganglia calcifications +/− atrophy
    5. MRI of the brain:
        1. Basal ganglia signal abnormalities
        2. Nonspecific white matter abnormalities
        3. Stroke-like lesions
        4. Cerebellar or brain stem atrophy
        5. Normal
    6. MR spectroscopy of the brain: may demonstrate elevated lactate

4. Comprehensive next-generation sequence analyses (Cui et al. 2013; Milone and Wong 2013):
    1. Sanger sequencing does not detect mtDNA heteroplasmy less than 20%. This limitation hinders accurate genetic counseling. Next-generation deep sequencing of the circular mitochondrial genome allows the detection of low heteroplasmic mtDNA mutations, accurate diagnosis, and counseling.
    2. For example, an affected proband had 99.5% and 16% of mtDNA mutation in her muscle and blood, respectively, while her mother did not carry the mutation in her blood. Since this was detected and determined by next-generation deep sequencing, which provides reliable quantitative heteroplasmy results, we can conclude that the mutation is de novo in the proband, although germline mosaicism cannot be ruled out. Should the heteroplasmy be determined by Sanger sequencing or other less accurate methods, we would not be able to conclude that the mother did not carry the mutation because Sanger sequencing or other methods cannot detect low levels of heteroplasmy.
    3. On the other hand, an affected woman with 37% mtDNA mutation heteroplasmy in the muscle, but absolutely none in the blood, has almost zero chances of passing the mutation to her children, because the mutation is somatic in her muscle. This was confirmed by her unaffected sibling and daughter, who both did not carry mutation.

Genetic Counseling

1. Recurrence risk (Chinnery 2014):
    1. Patient's sib:
        1. Mitochondrial DNA defects:
            1. The risk to sibs depends on the genetic status of the mother.
            2. If the mother has the mtDNA pathogenic variant, all sibs are at risk of inheriting it.
            3. When a proband has a single mtDNA deletion, the current best estimate of

the recurrence risk to sibs is 1/24 (Chinnery et al 2004).

2. Nuclear DNA defect:
    1. Autosomal recessive inheritance: 25% risk.
    2. Autosomal dominant inheritance: 50% risk if one parent is affected.
    3. X-linked inheritance: 50% risk if the mother has a pathogenic variant (male sibs who inherit the pathogenic variant will be affected; female sibs who inherit the pathogenic variant will be carriers); if the proband represents a simplex case and if the pathogenic variant cannot be detected in the leukocyte DNA of the mother, the risk to sibs is low but greater than that of the general population because of the possibility of maternal germline mosaicism.

2. Patient's offspring:
    1. Mitochondrial DNA inheritance:
        1. Offspring of males with an mtDNA pathogenic variant will not inherit the variant.
        2. All offspring of females with an mtDNA pathogenic variant are at risk of inheriting the pathogenic variant.
    2. Nuclear gene defects:
        1. Autosomal recessive inheritance: not increased (all offspring are obligate heterozygotes) unless the spouse is a carrier.
        2. Autosomal dominant inheritance: 50% risk.
        3. X-linked inheritance: all daughters of an affected male are carriers; none of his sons will be affected.

2. Prenatal diagnosis (Milone and Wong 2013; Chinnery 2014):
    1. Prenatal molecular genetic testing and interpretation for mtDNA disorders are difficult because of mtDNA heteroplasmy.
    2. Since the mutant load in one tissue does not necessarily reflect the mutant loads in other tissues, prenatal diagnosis of mtDNA mutations cannot be accurately offered.
    3. It is also a danger to provide preimplantation genetic diagnosis for pregnant mother who carries mtDNA heteroplasmic mutations (Treff et al. 2012).
    4. For severe autosomal recessive disorders, carrier status of parents should be confirmed before prenatal diagnosis is considered; prenatal diagnosis for severe nuclear gene disorders is recommended.
    5. Biochemical genetic testing: prenatal biochemical testing for pregnancies at risk for respiratory chain complex defects is possible, provided the specific biochemical abnormality has been identified in an affected family member, using cultured amniocytes obtained from amniocentesis usually performed at about 15–18 weeks' gestation (Poulton and Turnbull 2000).

3. Management:
    1. Currently no disease-modifying therapy available for mitochondrial myopathy.
    2. Although extremely rare, myopathy caused by CoQ_{10} deficiency will sometimes respond to CoQ_{10} supplementation (Ikejiri et al. 1996; Montini et al. 2008).
    3. Supportive therapy:
        1. Seizures: anticonvulsants
        2. Stroke-like episodes: L-arginine, a possible therapy
        3. Respiratory failure: CPAP or BiPAP
        4. Cardiac abnormalities: antiarrhythmics, pacemaker, ACE inhibitors
        5. Endocrinopathy: oral antihyperglycemic agents, insulin, L-thyroxine, hydrocortisone
        6. Hearing loss: auditory aids, cochlear implantation
        7. Ocular symptoms: corrective lenses, surgery for strabismus or ptosis
        8. Dysphagia: dietary modification

Fig. 1 A 2-year-old Caucasian female (*left*) was evaluated for failure to thrive, developmental delay, and hypotonia. She was born after a full-term pregnancy via Cesarean section due to mother's gestational diabetes and narrow birth canal. Her muscle tone was initially tight at birth but later hypotonic

Fig. 2 (**a**, **b**) The previous patient was seen again at 7 years of age (**a**) with her family. Her younger, older sister, older brother, and mother had similar muscle problems (**b**). The patient was evaluated for muscle weakness and tightness of the body. She does not pedal the tricycle, trouble going up or down the stairs. The fine motor was delayed with slight difficulty drawing a diamond and trouble with shoe laces. The nerve conduction test showed electrophysiological evidence of a diffuse myopathy with normal spontaneous activity. The muscle biopsy demonstrated a myopathic change with single necrotic fibers and the fibers demonstrating mitochondrial proliferation. The muscle specimen did not show any known deleterious mtDNA mutation but discovered an apparently homoplasmic familial m.13819 T > C (p.F495L, ND5) variant. The 9-year-old brother, who was completely floppy and extremely weak and has leg muscle weakness after birth, was found to have abnormal nerve conduction test and the same mtDNA variant. The mother was noted to getting more muscle weakness as she got older. She also showed apparent homoplasmic for the m.13819 T > C (p.F495L, ND5) variant in her blood (collaboration with Dr. Arun Kalra)

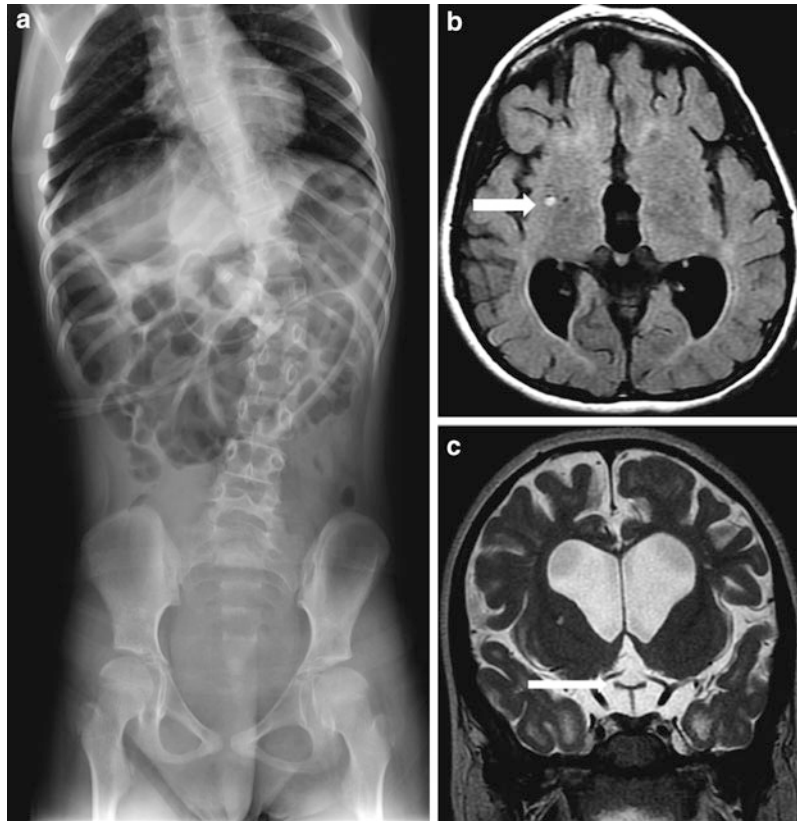

Fig. 3 (**a**–**c**) A 10-year-old girl was seen with mitochondrial disease characterized by severe multisystem involvement. She was the product of a 39-week gestation with induced delivery. The birth weight was 5 lbs 15 ozs. She was noted to have low fetal movements. She had a history of global developmental delay, chronic neutropenia, left ventricular dysfunction, GI dysmotility with GERD, neuromuscular scoliosis, severe sleep dysfunction, exercise intolerance, severe renal tubular acidosis, chronic transaminase elevation, swallowing dysfunction, and aspiration for which she was on continuous gastrojejunal tube feeds, ataxia, seizures, and mitochondrial encephalopathy. She had a generalized myopathic syndrome with hypotonia of the trunk and dystonic spasticity of the limbs. Muscle biopsy of her left thigh at 1 year of age revealed complex I and III disease and a chronic lactic acidosis. Previous molecular genetic study showed mutations (c.1067delG:p.Gly356AlafsX15 and c.1790A > C:p.Gln597Pro) in the *FBXL4* gene, which was considered as the genetic cause for her complex mitochondrial disease (Gai et al. 2013). POLG sequencing also identified maternally inherited G517V mutation (Tan et al. 2011). No deletion or mutation has been found on other alleles, and no additional POLG abnormalities were identified through research-based testing of fibroblasts. A body radiography (**a**) showed GJ tube placement, a severe thoracolumbar levoscoliosis, and bilateral coxa valgus. MRI of the brain (**b**, **c**) demonstrated extensive generalized cerebral atrophy, supratentorial white matter volume loss, and periventricular white matter signal abnormality with ventriculomegaly. Focal abnormality was present in the right basal ganglia (**b**, *arrow*), central tegmental tracts in the midbrain and in the posterior pons, which are consistent with the known mitochondrial encephalopathy. In addition, diffusely thinning corpus callosum and optic nerves (**c**, *arrow*) were observed (courtesy of Dr. Grace Guo)

Mowat-Wilson Syndrome

Contents

In 1998, Mowat et al. (1998) described a new syndrome, now known as Mowat-Wilson syndrome (MWS), consisting of Hirschsprung disease or severe constipation, microcephaly, mental retardation, and characteristic facial features, including hypertelorism, medially flared and broad eyebrows, prominent columella, pointed chin, and uplifted earlobes.

The prevalence of MWS is currently unknown. However, it seems probable that the syndrome is underdiagnosed, particularly in patients without Hirschsprung disease. Approximately 171 patients with *ZEB2* mutations, deletions, or cytogenetic abnormalities have been reported and over 100 mutations have been described.

Synonyms and Related Disorders

Hirschsprung disease-mental retardation syndrome; Microcephaly, mental retardation, and distinct facial features with or without Hirschsprung disease

Genetics/Basic Defects

1. Caused by heterozygous mutations and deletions in the gene ZEB2 on chromosome 2 (2q22-q24.1) (also known as ZFHX1B or SIP-1) (Yoneda et al. 2002; Cerruti Mainardi et al. 2004; Ishihara et al. 2004) in approximately 81% of cases
2. Typically resulting from a de novo dominant mutation
3. Mutations in SIP1 (Smad interacting protein 1) result in a complex developmental disorder with a great variety of clinical features including a syndromic Hirschsprung disease (Cacheux et al. 2001; Yamada et al. 2001; Zweier et al. 2002; Garavelli et al. 2003)
4. Atypical ZFHX1B mutation associated with a mild Mowat-Wilson syndrome phenotype (Zweier et al. 2006)
5. Cytogenetic deletions or translocations of the chromosome 2q21-q23 region were found in several patients

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_160

Clinical Features

1. Typical facial features (Adam et al. 2006)
    1. Seen in all individuals with this combination of characteristics were found to have mutations (Garavelli and Mainardi 2007) or deletions in the *ZEB2* gene (Zweier et al. 2005)
        1. Ocular hypertelorism
        2. Medially flared and broad eyebrows
        3. Prominent columella
        4. Prominent or pointed chin
        5. Open-mouthed expression
        6. Uplifted earlobes with a central depression
            1. Earlobes described as resembling "orecchiette pasta" or "red blood corpuscles."
            2. Ear configuration not changing significantly with age with the exception of the central depression, which is less obvious in adults.
    2. Additional suggestive facial features (Mowat et al. 2003; Adam et al. 2013)
        1. Telecanthus
        2. Deep-set eyes
        3. Broad nasal bridge with prominent and rounded nasal tip
        4. Full or everted lower lip
        5. Posteriorly rotated ears
    3. Natural history of facial phenotype (Wilson et al. 2003; Horn et al. 2004)
        1. More pronounced facial phenotype with age, making diagnosis easier in older individuals
        2. Lengthening of the nasal tip and becoming more depressed
        3. More pronounced columella, leading to appearance of a short philtrum
        4. Elongation of the face
        5. More prominent jaw
        6. Eyebrows becoming heavier with an increased medial flare
2. Spectrum of structural anomalies
    1. Gastrointestinal anomalies
        1. Hirschsprung disease
            1. A strong cross-reference marker when present
            2. Not a constant finding
            3. Present in approximately 45% of cases (Coyle and Puri 2015)
        2. Pyloric stenosis
    2. Genitourinary anomalies, particularly hypospadias in males
    3. Congenital heart defects, including abnormalities of the pulmonary arteries and/or valves
    4. Agenesis or hypogenesis of the corpus callosum
    5. Ophthalmologic malformations (Bourchany et al. 2015)
        1. Although rare, should be considered as a part of the clinical spectrum of the condition
        2. Microphthalmia
        3. Axenfeld anomaly
        4. Iris/chorioretinal/optic disk coloboma
        5. Optic nerve atrophy
        6. Retinal epithelium atrophy
        7. Cataract
        8. Korectopia
    6. Teeth anomalies
        1. Widely spaced teeth
        2. Dental crowding
        3. "Malpositioned" teeth
        4. Delayed tooth eruption
3. Other features
    1. Mental retardation/intellectual disability (Kilic et al. 2016), typically in the moderate to severe range, with severe speech impairment but relative preservation of receptive language
    2. Sleep disturbance (Evans et al. 2016)
    3. Seizures
    4. Growth retardation (short stature) with microcephaly
    5. Chronic constipation in those without Hirschsprung disease

Diagnostic Investigations

1. Cytogenetic testing
    1. Chromosomal rearrangements that disrupt the *ZEB2* gene cause MWS in

approximately 2% of cases (Lurie et al. 1994; Dastot-Le Moal et al. 2007)
2. FISH analysis: Large deletions encompassing all or part of the *ZEB2* gene detectable by FISH in approximately 15% of cases (Mowat et al. 2003; Dastot-Le Moal et al. 2007)
3. Smaller intragenic deletions will not be detected by FISH analysis.

2. Molecular genetic testing
   1. Pathogenic variant and deletions in *ZEB2* (also known as ZFHX1B or SIP-1) are known to cause MWS in approximately 100% of cases (Amiel et al. 2001; Kääriäinen et al. 2001; Wakamatsu et al. 2001; Dastot-Le Moal et al. 2007; Garavelli et al. 2009).
   2. Of 12 patients with the distinct facial gestalt of Mowat-Wilson syndrome analyzed, eight had truncating mutations and four had large-scale deletions, thus giving a ZFHX1B defect in 100% of patients and a deletion rate of 33% (Zweier et al. 2003).
   3. Chromosome microarray analysis: reported a case with a 393.68-kb deletion on chromosome 2q22.2q22.3 encompassing the ZEB2 gene and a 1.24 Mb duplication on chromosome 22q11.23, a variant of unknown clinical significance (Buraniqi and Moodley 2015)
   4. No evidence of locus heterogeneity for MWS
3. Hirschsprung disease evaluation
4. MRI imaging of the brain for CNS anomalies
5. Echocardiograph for congenital heart disease
6. Ophthalmologic evaluation for eye anomalies
7. Renal ultrasound for renal anomalies
8. EEG for seizures

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. De novo mutation: low recurrence risk
      2. Possibility of constitutional and/or germline mosaicism: low recurrence risk but greater than that of the general population (1–2%)
         1. Possibility of germline mosaicism suggested in two families with two (McGaughran et al. 2005) and three affected sibs, respectively
         2. Low-level paternal mosaicism observed in a family with two affected sibs has been reported
   2. Patient's offspring: individuals with MWS and an unbalanced chromosome rearrangement unlikely to reproduce
2. Prenatal diagnosis (Adam et al. 2013)
   1. Ultrasonography (Zhou et al. 2014).
      1. Despite well-reported association, the difficulty in prenatal detection is that the corpus callosum is not fully formed until 18–20 weeks (Schell-Apacik et al. 2008).
      2. It is not easy to be demonstrated in routine morphology scan.
   2. Prenatal diagnosis of a pregnancy at theoretically increased risk because of constitutional and/or germline mosaicism in a clinically unaffected parent.
      1. Disease-causing allele of an affected family member being identified prior to prenatal diagnosis
      2. Molecular genetic analysis on DNA extracted from fetal cells obtained by amniocentesis or chorionic villus sampling
      3. Second-trimester detection of Mowat-Wilson syndrome using comparative genomic hybridization microarray testing (Choy et al. 2010)
   3. Prenatal diagnosis of a pregnancy at increased risk because of parental balanced structural rearrangement: possible by chromosome analysis of fetal cells obtained by amniocentesis or chorionic villus sampling.
   4. Preimplantation genetic diagnosis: available for families at increased risk because of parental mosaicism in which the disease-causing mutations have been identified.

3. Management
    1. Mostly supportive including seizure control and developmental intervention
    2. Specific management for structural anomalies, including Hirschsprung disease

Fig. 1 (**a**–**d**) A three-and-a-half-year-old boy was noted to have Mowat-Wilson syndrome. Note the unusual facies (hypertelorism, telecanthus, strabismus, wide prominent nasal bridge, an unusual nose with a rounded tip and prominent columella, a prominent chin, and unusual ears with fleshy uplifted ear lobes), long tapering fingers, and an unusual stereotypic use of his hands in which he moves his fingers in front of his face and regards them. He is severely developmentally delayed and has hypotonia. Chromosome microarray analysis revealed a loss in copy number in the long arm of chromosome 2, detected with two clones, spanning at least 100 kb (including the ZFHX1B gene), and confirmed by FISH analysis. Deletions in this region have been associated with Mowat-Wilson syndrome

Mucolipidosis 2

Contents

Mucolipidosis II (ML II), or I-cell disease, is a rare autosomal recessively inherited storage disorder of lysosomal enzyme hydrolase trafficking due to deficient activity of the multimeric enzyme UDP-*N*-acetylglucosamine-1-phosphotransferase. The term "I-cell disease" is derived from the observation that fibroblasts from affected individuals show dense inclusions filled with storage material.

Synonyms and Related Disorders

I-cell disease; Inclusion cell disease; Leroy I-cell disease; ML II; Mucolipidosis II alpha/beta (ML alpha/beta)

Genetics/Basic Defects

1. Inheritance: autosomal recessive (Leroy et al. 1971)
2. Uridine diphosphate (UDP)-*N*-acetylglucosamine-1-phosphotransferase (GlcNAc-PT) (Beck et al. 1995)
   1. An enzyme that transfers phosphate groups onto oligosaccharide units of lysosomal enzyme precursors.
   2. Deficient in mucolipidosis II (also in mucolipidosis III) (Bargal et al. 2006).
   3. Consequences of the enzyme deficiency.
      1. Not generating common phosphomannosyl recognition marker of acid hydrolases
      2. The enzymes not targeting the lysosomes
      3. Secretion of the enzymes into the extracellular space (high activities found in the serum of the patients)
      4. Considerable reduction of the enzyme levels inside the cells (fibroblasts)
   4. GlcNAc-PT is made up of three subunits: α, β, and γ (Reitman and Kornfeld 1981; Reitman et al. 1981).
      1. The α/β subunits are encoded by the *GNPTA* gene (Tiede et al. 2005) and have a catalytic function.
      2. The γ subunit which is encoded by the *GNPTAG* gene (Raas-Rothschild et al. 2000) has a recognition and regulation function.
   5. Mutations in *GNPTAB*, which encodes the α/β subunit, cause ML II and ML III α/β (Tiede et al. 2005). The γ subunit is encoded by *GNPTG*, and mutations in this gene lead

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_166

to the clinically milder condition known as ML III γ (Raas-Rothschild et al. 2000).

3. Genotype-phenotype correlations (Leroy et al. 2012)
    1. *GNPTAB* gene sequencings have confirmed that homozygous and compound heterozygous genotypes that predict enzyme inactivation (caused by premature translation termination and/or frameshift effects) result in the ML II phenotype.
    2. The combination of less "morbid" mutations, such as missense and most of the splice-site mutations that may decrease but not abolish enzyme activity, often yields the more slowly evolving ML III phenotype alpha/beta with later clinical onset (Paik et al. 2005; Tiede et al. 2005; Bargal et al. 2006; Kudo et al. 2006).
    3. Some children have clinically intermediate phenotypes between the delineated ML II and ML III alpha/beta.
    4. Correlating these phenotypes with the specific mutant genotypes requires more detailed and extensive clinical research efforts that are ongoing (Cathey et al. 2008).

Clinical Features

1. Symptoms and signs of ML II are similar to those encountered in patients with mucopolysaccharidoses and to a lesser extent gangliosidoses: characterized by coarse facial features, short stature, hyperplastic gums, organomegaly, and retarded psychomotor development (Maroteaux and Lamy 1966; Okada et al. 1985; Leroy and Opitz 1969).
2. A wide range of inter- and intrafamilial variability (Beck et al. 1995)
    1. Age of onset: present at birth or appear in the first few months of life
    2. Organ manifestation
    3. Radiological findings
    4. Unusual findings in some patients
        1. Pericardial effusion
        2. Profound brain atrophy
3. Features evident in affected newborn
    1. Coarse facial (gargoyle-like) features (Lee and O'Donnell 2003)
        1. Puffy eyelids with slight exophthalmia
        2. Excessive prominence of the epicanthal folds
        3. Depressed nasal bridge
        4. Full cheeks exhibiting multiple fine telangiectasia
        5. Gingival hyperplasia and alveolar enlargement with buried teeth
        6. Thick tongue
    2. Restricted joint mobility
    3. A tight, thickened skin
4. Early clinical features (Sprigz et al. 1978)
    1. Low birth weight
    2. Congenital hip dislocation
    3. Pes equinovarus
    4. Joint contractures
    5. Inguinal hernias
    6. Generalized hypotonia
    7. Ocular abnormalities (Libert et al. 1977)
        1. Corneal clouding
        2. Glaucoma
        3. Megalocornea
5. Older patients
    1. Predominant features
        1. Skeletal deformities (dysostosis multiplex)
        2. Progressive failure to thrive
        3. Developmental delay with variable mental retardation
    2. Other features
        1. Short stature
        2. Craniosynostosis (Aynaci et al. 2002)
        3. Progressive stiffness of all joints, first apparent in the shoulders
        4. Variable hepatosplenomegaly
        5. Congestive heart failure
        6. Recurrent pulmonary infections
6. Natural history (Leroy and Martin 1975)
    1. Slowly progressive course
    2. Fatal outcome usually before 4 years of age
7. ML III (see next chapter "▶ Mucolipidosis 3")
    1. Genetically heterogeneous
    2. A milder disorder with attenuated characteristics and survival to adult life (Kelly et al. 1975)

8. Differential diagnosis with other lysosomal storage disease (Leroy et al. 2012)
    1. Mucopolysaccharidosis type 1 H (see the chapter "► Mucopolysaccharidosis I (MPS I)")
    2. GM1 gangliosidosis type 1
        1. More severe hepatomegaly
        2. Dysostosis multiplex indistinguishable
        3. Beta-D-galactosidase deficiency in leukocytes and plasma
    3. Infantile galactosialidosis
        1. Storage phenomena less pronounce than in GM1 gangliosidosis but more than in ML II
        2. Absence of acid sialidase and of beta-D-galactosidase activity in leukocytes in addition to cathepsin A deficient in leukocytes and cultured fibrocytes
        3. May present as congenital nonimmune hydrops fetalis
    4. Infantile sialidosis (formerly sialidosis type 2 or ML I)
        1. May present as congenital nonimmune hydrops fetalis
        2. More chronic disorder with moderate organomegaly, dysostosis multiplex that is milder than that of ML II
        3. Mild limitation of joint mobility
        4. Growth and cognitive development considerably better than in children with ML II
    5. Infantile free sialic acid storage disease
        1. Excessive amounts of free sialic acid in the urine
        2. Deficient acid sialidase only
        3. Less facial dysmorphism and much less dysostosis multiplex than ML II

Diagnostic Investigations

1. Elevated activities of multiple lysosomal enzymes in serum or plasma, including the following enzymes: Activity of nearly all lysosomal hydrolases is 5- to 20-fold higher in plasma and other body fluids than in normal controls because of improper targeting of lysosomal acid hydrolases to lysosomes in ML II.
    1. Arylsulfatase A
    2. α-Mannosidase
    3. β-Glucuronidase
    4. β-Hexosaminidase
2. Deficient enzyme activities in cultured fibroblasts (Leroy et al. 1972), including the following enzymes:
    1. β-Galactosidase
    2. Arylsulfatase A
    3. β-Hexosaminidase
    4. β-Glucuronidase
    5. α-Galactosidase
3. Primary biochemical defect: decreased or absent *N*-acetylglucosamine-1-phosphotransferase in cultured fibroblasts and leukocytes.
4. Excessive urinary excretion of oligosaccharides.
5. Normal excretion of urinary mucopolysaccharide.
6. Radiography.
    1. Fetal radiography
        1. Diffuse decrease in bone mineralization
        2. A coarse, lacy, trabecular pattern
        3. Overall shortening and undermodeling of the long bones
        4. Subperiosteal bone deficiency in the diaphysis giving the appearance of periosteal new bone (cloaking)
        5. Retarded ossification of the vertebral bodies
        6. Hypoplasia of the anterior superior aspect of the upper lumbar vertebral bodies
        7. Broad ribs
        8. Abnormal pelvis with squared iliac wings and flattened acetabular roofs
        9. Brachyphalangy
        10. Mild tapering of the proximal ends of the metacarpals
        11. A small irregular calcaneal "ossification center"
    2. Radiographic findings in early infancy (Patriquin et al. 1977)
        1. Diffuse demineralization
        2. Metaphyseal cupping and fraying

3. Excessive periosteal new bone formation
4. Diaphyseal expansion of the long tubular bones
5. Irregular trabeculation without differentiation between the cortical and medullary zones
6. Mild anteriosuperior hypoplasia of the upper lumbar bodies
7. Pelvic dysplasia
8. Occasional punctate calcifications and bone defects following intrauterine calcific deposits
9. Skeletal changes in the neonatal I-cell disease resembling those of rickets, osteomyelitis, and hyperparathyroidism (David-Vizcarra et al. 2010)

3. Dysostosis multiplex
   1. Neurocranium
      1. Long/enlarged and thick skull
      2. Thickened and sclerotic cranial base
   2. Hypoplastic epiphyses
   3. Thickened diaphyses
   4. Widened/spatulate ribs
   5. Kyphoscoliosis
   6. Anterior beaking and wedging of the vertebral bodies
   7. Lumbar gibbus deformity
   8. Cloaking appearance of the long tubular bones
   9. Proximal pointing of the metacarpals
   10. Bullet-shaped phalanges
   11. Claw hand deformities
7. Slit lamp examination to demonstrate corneal clouding
8. Echocardiography for valve thickening and valve insufficiency
9. MRI or CT scan: mild brain atrophy in most cases
10. MRI/MR spectroscopy: delayed myelination or hypomyelination with decreased choline on MR spectroscopy (Takanashi et al. 2012)
11. Light microscopy and electron microscopy
    1. Inclusion bodies in peripheral lymphocytes in blood smear (Rapola et al. 1974)
    2. An increased number of empty, large vacuoles that may fill the cytoplasm of cultured skin fibroblast cells (Rapola et al. 1974; Cipolloni et al. 1980)
    3. Presence of numerous intracytoplasmic inclusions in cells of mesenchymal origin
       1. Membrane-bound vacuoles filled with fibrillogranular material
       2. Appear to contain a variety of lipids, mucopolysaccharides, and oligosaccharides
    4. Cytoplasmic inclusions also observed in various types of cells in fetal I-cell disease (Blank and Linder 1974; Abe et al. 1976)
12. Molecular genetic diagnosis (Leroy et al. 2012)
    1. Sequence analysis: Bidirectional sequencing of the entire *GNPTAB* coding region detects two disease-causing mutations in more than 95% of persons with ML II.
    2. Deletion/duplication analysis is also clinically available.
    3. Targeted next-generation sequencing (Yang et al. 2013).

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: 25%
   2. Patient's offspring: not surviving to reproductive age
2. Prenatal diagnosis (Carey et al. 1999)
   1. Ultrasonography with previous affected sibling.
      1. Intrauterine growth retardation (Lees et al. 2001)
      2. Short tubular bones
      3. Short femur and periosteal cloaking of the femur and humerus (Lees et al. 2001)
   2. Radiography (Babcock et al. 1986; Aggarwal et al. 2014).
      1. Prenatal skeletal dysplasia phenotype in severe MLII alpha/beta with novel *GNPTAB* mutation
      2. Short and broad long bones with wide diaphyses and massive periosteal cloaking, dense metaphyses, and epiphyseal stippling
      3. Cardiomegaly

3. Measuring the levels of lysosomal enzymes (elevated activity of several lysosomal hydrolases) in cell-free amniotic fluid or cultured amniocytes (Aula et al. 1975).
4. Assay of the transferase activity (deficient) in fresh or cultured CVS cells (Poenaru et al. 1984; Ben-Yoseph et al. 1988) and amniocytes (Besley et al. 1990).
5. Electron microscopy of chorionic villus biopsy tissue for detection of inclusion bodies.
6. Prenatal diagnosis and preimplantation genetic diagnosis for at-risk pregnancies require prior identification of the disease-causing mutations in the family (Leroy et al. 2012).

3. Management
   1. Supportive care
      1. Low-impact therapies to avoid joint and tendon strain, including aqua therapy
      2. Cognitive stimulation through interactive programs
      3. Gingivectomy as needed for oral health
      4. Myringotomy tube placement as needed for recurrent ear infections
      5. Supplementation of gamma globulin is useful in prophylaxis of infection for hypogammaglobulinemia patients (Maarschalk-Ellerbroek et al. 2011; Shibazaki et al. 2016)
      6. Difficult airway management (Mallen et al. 2015)
   2. Prevention of secondary complications
   3. Bone marrow transplant from an HLA-identical carrier sibling (Grewal et al. 2003)
      1. Neurodevelopmental gains
      2. Prevention of cardiopulmonary complications
      3. No alteration to the course of musculoskeletal disease
   4. Hematopoietic stem cell transplantation (HSCT): Although HSCT has demonstrated efficacy in treating some lysosomal storage disorders, the neurologic outcome and survival for patients with MLII were poor (Lund et al. 2014).
   5. Umbilical cord blood transplantation: no improvements in the clinical course (Shibazaki et al. 2016)

Yang, Y., Wu, J., Liu, H., et al. (2013). Two homozygous nonsense mutations of GNPTAB gene in two Chinese families with mucolipidosis II alpha/beta using targeted next-generation sequencing. *Genomics, 102*, 169–173.

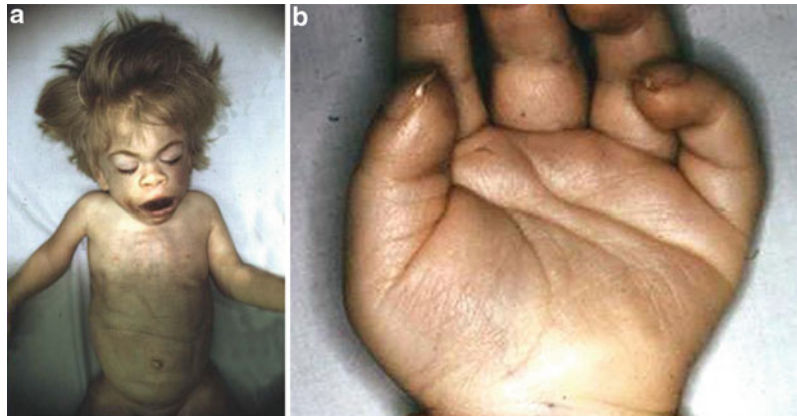

Fig. 1 (**a**, **b**) An 8-year-old girl with I-cell disease (**a**). She had severe growth retardation (67 cm), coarse facial features, claw hands (**b**), severe skeletal dysplasia, marked gingival hypertrophy, cardiomegaly with marked thickening and deformity of mitral and tricuspid valves, and bilateral duplication of ureters. Histological investigations showed foam cell infiltration in renal glomeruli, splenic corpuscles, atrioventricular valves, and thymus (Courtesy of Dr. Samuel Yang)

Fig. 2 Radiographs showed generalized dysplastic changes in the chest and upper and lower extremities. The ribs were extremely wide. Some vertebral bodies were slightly hook shaped. The pedicles were long and there was slight gibbus (**a**). Midshafts of the humerus, radius, and ulna were wide and the neck of the humerus in varus position (**b**). Widening of the midshafts of the lower extremities was less marked than in the upper extremities (**c**). Metacarpals and phalanges were wide, but distal phalanges were short and thin. Metacarpal bones pointed proximally. Carpal bones were hypoplastic (**d**)

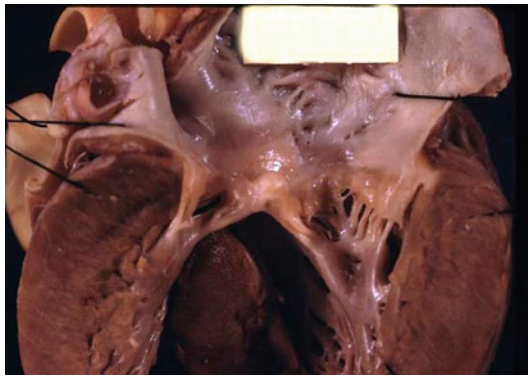

Fig. 3 Mitral valve was thickened and deformed

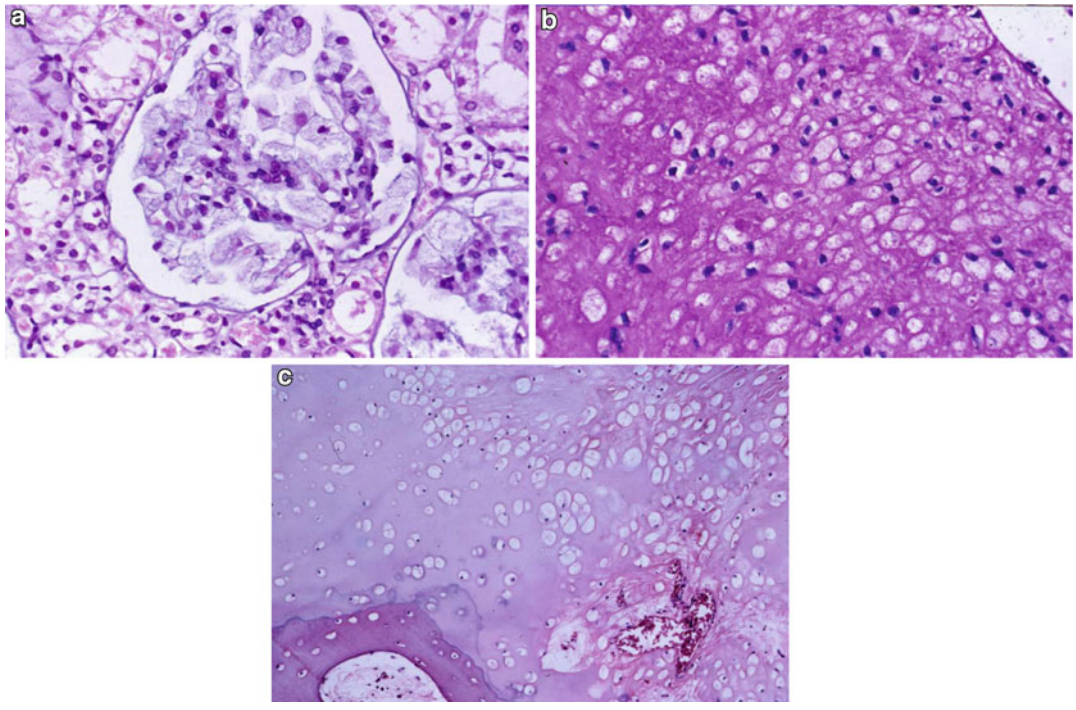

Fig. 4 (**a**–**c**) Foam cells were present in the renal glomeruli (**a**), mitral valve (**b**), and chondrocytes of cartilage (**c**)

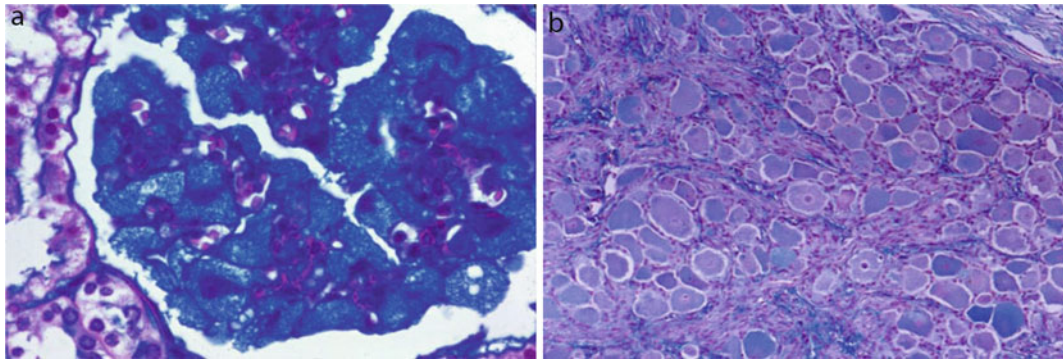

Fig. 5 (**a**, **b**) The foamy material was reactive with colloidal iron stain (renal glomeruli) (**a**) and sympathetic ganglion (Alcian blue stain) (**b**), indicating the presence of mucopolysaccharide

Mucolipidosis 3

Contents

In 1966, Maroteaux and Lamy first described four girls with pseudo-Hurler polydystrophy, a condition milder in severity than the Hurler syndrome and similar to the Scheie syndrome but without hepatosplenomegaly, cloudy cornea, or mucopolysaccharidiuria. In 1970, Spranger and Wiedemann (1970) designated pseudo-Hurler polydystrophy as mucolipidosis III because of Hurler-like features and vacuolated bone marrow cells (Kelly et al. 1975a, b).

Synonyms and Related Disorders

ML γ; Mucolipidosis (ML) III α/β (Pseudo-Hurler polydystrophy)

Genetics/Basic Defects

1. Inheritance: autosomal recessive
2. Basic defect
    1. Resulting from deficiency of the enzyme UDP-*N*-acetylglucosamine: lysosomal protein precursor *N*-acetyl glucosamine 1-phosphate transferase (G1cNAcPT) (Mucolipidosis II also caused by deficiency of the same enzyme) (Mueller et al. 1983; Bargal et al. 2006)
    2. Genetic complementation analysis of cultured fibroblasts derived from patients with mucolipidosis III identified complementation groups A, B, and C (Honey et al. 1982; Little et al. 1986).
    3. Inability to form the correct recognition marker on lysosomal enzymes resulting in a marked intracellular deficiency of most lysosomal enzymes in various tissues, impairment of many lysosomal catabolic processes, and concomitant increase in lysosomal enzymes in plasma (Tylki-Szymanska et al. 2002)
3. Recent finding of molecular basis for mucolipidosis IIIC (variant pseudo-Hurler polydystrophy): a mutation, in C at codon 167, in the γ subunit of the G1cNAcPT in mucolipidosis IIIC (Raas-Rothschild et al. 2000). Mutations in *GNPTAB*, which encodes the α/β subunit, cause ML II and ML III α/β (Tiede et al. 2005).
4. Three novel mutations of the *GNPTG* gene cause of MLIII gamma (Liu et al. 2014)
    1. In exon seven [c.425G > A (p.Cys142Val)] and [c.515dupC (p.His172Profs27X)]
    2. In exon eight [c.609 + 1G > C]

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_167

5. Mucolipidosis III GNPTG missense mutations cause misfolding of the γ subunit of GlcNAc-1-phosphotransferase (van Meel and Kornfeld 2016)

Clinical Features

1. ML III α/β
    1. Onset of disease
        1. Usually appear at 2–4 years of age
        2. Progress slowly
        3. First sign: stiffness in the hands and shoulders
    2. Short stature (Robinow 1974)
    3. Mild Hurler-like facial dysmorphism, usually apparent after age 6 years
    4. Ophthalmologic abnormalities (Traboulsi and Maumenee 1986)
        1. Constant ocular features
            1. Corneal opacities consisting of fine, peripheral infiltrates
            2. Hyperopic astigmatism
        2. Optic nerve head swelling
        3. Surface wrinkling maculopathy
        4. Retinal vascular tortuosity
    5. Mild mental retardation
    6. Mild organomegaly
    7. Mitral and aortic valve insufficiencies: the most common form of cardiac involvement (Abualsuod et al. 2014)
    8. Orthopedic problems
        1. Stiffness of the hands progressing to claw hand deformities by 6 years of age in all patients
        2. Slow progression of the skeletal dysplasia during school years, the resulting physical disability most apparent in the hands, hips, elbows, and shoulders
        3. Generalized joint stiffness (limited joint mobility)
        4. Spine abnormalities
            1. Kyphosis
            2. Lordosis
            3. Gibbus
        5. Hip pain
        6. Hip dysplasia
        7. Less common clinical features (Smuts et al. *2009*)
            1. Claw hand deformities
            2. Carpal tunnel syndrome further complicates the claw hand deformities.
            3. Recurrent, intermittent trigger fingers
            4. Claw toes
    9. Natural course of the illness
        1. Survive into beyond the fifth to sixth decade (Umehara et al. 1997)
        2. Cardiopulmonary complications are the usual causes of mortality
2. Mucolipidosis III γ (also known as variant ML III)
    1. Clinical features similar to but milder than those observed in individuals with mucolipidosis III alpha/beta (ML III alpha/beta)
    2. Affected individuals are mostly of Middle Eastern descent (Raas-Rothschild et al. *2000*, *2004*; Cathey et al. *2007*).
3. Differential diagnosis (Leroy et al. *2012*)
    1. Lysosomal storage diseases
        1. Attenuated MPS I (formerly called Hurler-Scheie syndrome or Scheie syndrome)
        2. Attenuated MPS II (Hunter syndrome)
        3. Morquio disease type B (MPS IV B)
        4. Maroteaux-Lamy disease type B (MPS VI B)
        5. Sly disease type B (MPS VII B)
    2. Disorders clinically allied to the oligosaccharidoses
        1. Late infantile sialic acid storage disorder or Salla disease (free sialic acid storage disorders) and mucosulfatidosis: In both disorders, the neurodegenerative aspects are much more prominent.
        2. In free sialic acid storage disorders, dysostosis multiplex is absent or minimal, and urinary excretion of free sialic acid is excessive.
        3. In mucosulfatidosis, urinary acid mucopolysaccharides and sulfatides are excessive.
    3. Osteochondrodysplasias

Diagnostic Investigations

1. Multiple elevated serum and urine enzyme activities (Herd et al. 1978)
2. Radiography showing dysostosis multiplex (Melhem et al. 1973; Freisinger et al. 1992)
    1. Pelvis
        1. Flaring of the iliac wings
        2. Constriction of the iliac bodies
        3. Oblique acetabular roofs
    2. Vertebral bodies
        1. Moderately flattened
        2. Presenting as a roughly ovoid contour
        3. Underdevelopment of posterior parts in the dorsal spine
        4. Hypoplasia of anterior third in the lumbar spine
        5. Irregular endplates
        6. Scoliosis secondary to vertebral abnormalities
    3. Tubular bones
        1. Shortened and wide
        2. The most striking changes observed in the proximal femur
            1. A small, flattened and irregular epiphysis
            2. Coxa valga deformity of the neck
            3. Subluxation
        3. Hands
            1. Short first metacarpals
            2. Mild proximal pointing of the metacarpals
            3. Mild to moderate claw hand deformities
            4. Relatively wide diaphysis of some phalanges
        4. Retarded bone age
    4. Skull: normal despite the presence of craniostenosis in some patients
3. Thoracolumbar X-ray and MRI-T2 (Zarza and Morrondo 2014)
    1. Irregularity of the vertebral end plates
    2. Intraspongy lumbar hernias
4. Cardiac MRI (Abualsuod et al. 2014)
    1. Frequent premature ventricular complexes (PVCs)
    2. Nonsustained ventricular tachycardia
5. Nerve conduction test and electromyography to confirm the carpal tunnel syndrome
6. Slit-lamp examination for cornea opacification
7. Normal urinary excretion of acid mucopolysaccharides
8. Presence of cytoplasmic inclusions within cultured fibroblasts as demonstrated by phase-contrast or dark-field microscopy
9. Bone marrow: large, vacuolated plasmocytes
10. ML III alpha/beta (Leroy et al. 2012)
    1. Activity of nearly all lysosomal hydrolases: up to tenfold higher in plasma and other body fluids than in normal controls because of inadequate targeting to lysosomes (also in ML III gamma).
    2. Urinary excretion of oligosaccharides, a nonspecific finding, can be excessive but is not always present.
    3. Significant deficiency (1–10% of normal) of the activity of the enzyme UDP-*N*-acetylglucosamine: Lysosomal hydrolase *N*-acetylglucosamine-1-phosphotransferase (GNPTA), encoded by *GNPTAB*, confirms the diagnosis.
11. Molecular genetic testing
    1. ML III alpha/beta (Leroy et al. 2012).
        1. Bidirectional sequencing of the entire *GNPTAB* coding region detects two disease-causing mutations in more than 95% of individuals with ML III alpha/beta. Such testing is clinically available.
        2. Duplication/deletion analysis is also available.
    2. In ML III gamma: Molecular testing of *GNPTG* detects two disease-causing mutations in more than 95% of individuals with ML III gamma (Raas-Rothschild and Spiegel 2012).

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: 25%

   2. Patient's offspring: not increased unless the spouse is a carrier
2. Prenatal diagnosis (Falik-Zaccai et al. 2003)
   1. Diagnosis confirmed by markedly reduced lysosomal enzyme activities in cultured chorionic villi.
   2. Identification of the disease-causing mutation in fetal DNA in a newly recognized large Bedouin-Moslem kindred, allowing prenatal diagnosis, carrier detection, and identification of couples at risk.
   3. Prenatal diagnosis and preimplantation genetic diagnosis for at-risk pregnancies require prior identification of the disease-causing mutations in the family.
3. Management (Hetherington et al. 1999)
   1. Physiotherapy for joint stiffness and contractures
   2. Padded insoles for clawing of toes
   3. Carpal tunnel decompression for the median nerve entrapment
   4. Pelvic osteotomy for severe hip dysplasia
   5. Intravenous pamidronate treatment for osteodystrophy (Robinson et al. 2002)

Fig. 1 (**a**, **b**) Patient 1 (9-year-old boy) with mucolipidosis III showing short stature, mild coarse facial features, and flexion contractures of knees, hips, elbows, wrists, and fingers. Fibroblast lysosomal acid hydrolase study revealed β-galactosidase 0.06 (control: 0.36 μmol/h/mg protein), β-glucuronidase 0.05 (0.21), β-glucosaminidase 0.03 (3.9), α-L-iduronidase 0.12 (0.87), and arylsulfatase A 0.10 (0.67)

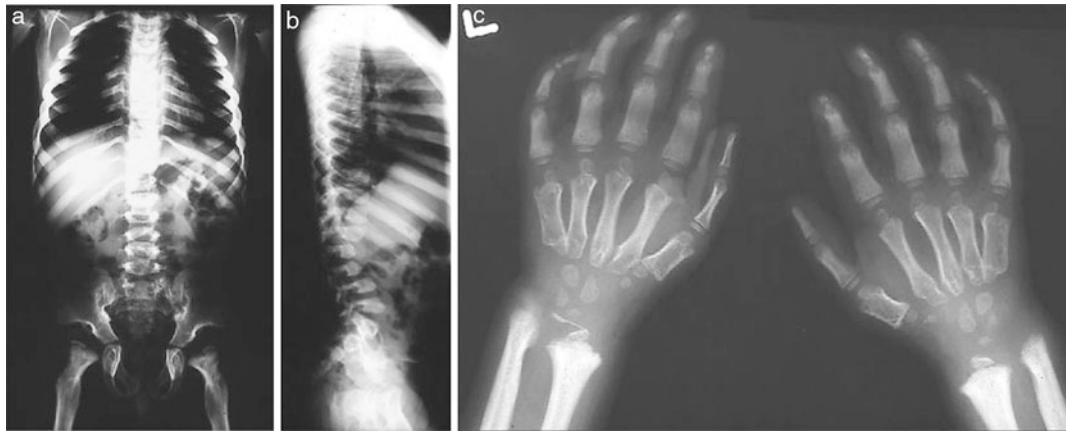

Fig. 2 (**a**–**c**) Radiographs of patient 1. Lateral lumbar spines showed severe hypoplasia with characteristic "beaked" configuration along their inferior aspects. Iliac bones were narrow and the basilar portions were hypoplastic with slanting acetabular roofs. Coxa valga deformity was present. Mild claw hand deformities with retarded bone age were evident

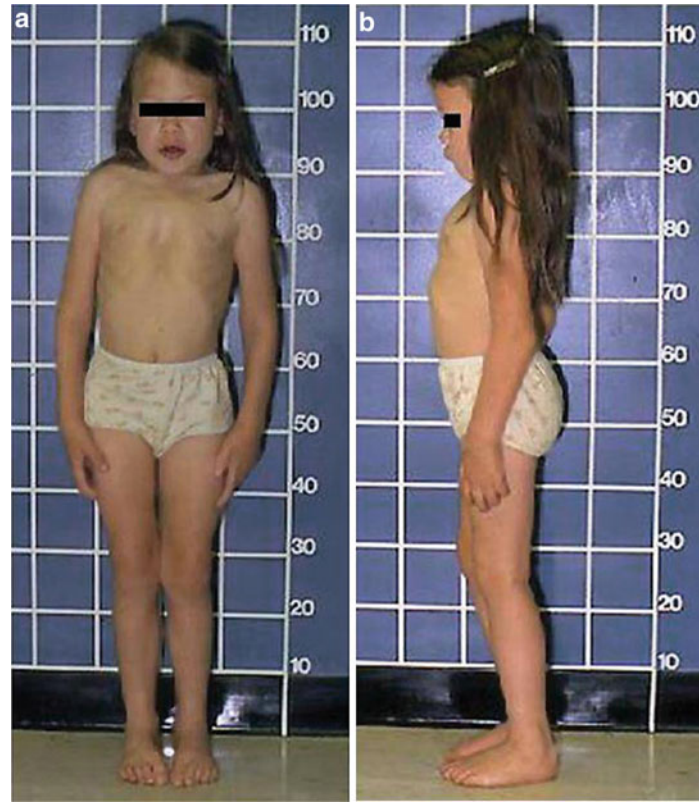

Fig. 3 (**a**, **b**) Patient 2 (sister of the patient 1) at age 7 years and 6 months showing similar clinical findings

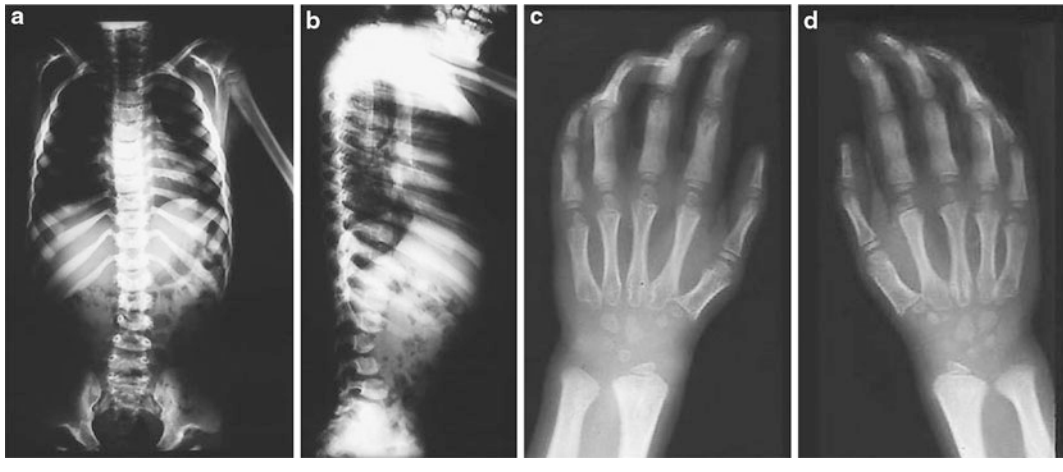

Fig. 4 (**a**–**d**) Radiographs of patient 2 showing similar radiographic findings

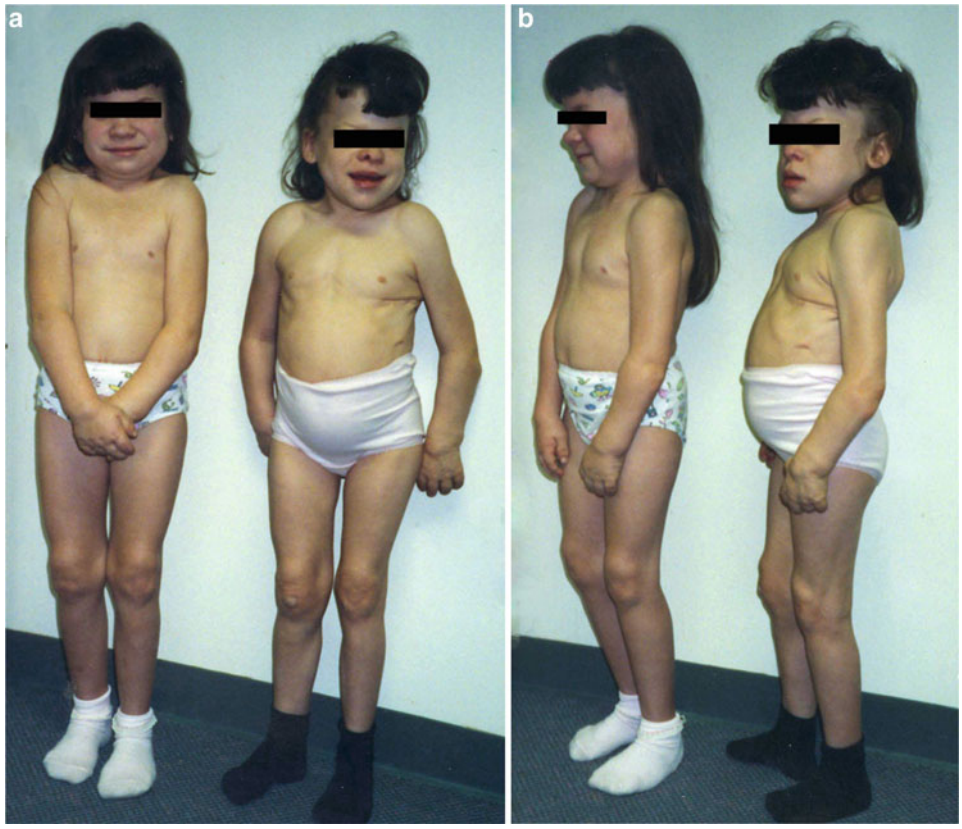

Fig. 5 (**a**, **b**) Two sisters (ages 10 years and 9 years) with mucolipidosis III showing developing delay, coarse facial features, claw hands, and more severe joint contractures. Radiographs (not shown) revealed bullet-shaped proximal phalanges, small carpal bones, and misshapen femoral heads

Mucopolysaccharidosis 2

Contents

In 1917, Hunter described the syndrome in two brothers. Hunter syndrome is an X-linked recessive form of the mucopolysaccharidosis. Severe and mild (attenuated) forms of the syndrome are caused by the same enzyme deficiency, iduronate-2-sulfatase with consequent increase of the urinary concentration of the glycosaminoglycan (GAG), dermatan sulfate and heparan sulfate. The estimated incidence is approximately 1 in 100,000 births.

Synonyms and Related Disorders

Hunter syndrome; Iduronate-2-sulfatase deficiency

Genetics/Basic Defects

1. Inheritance (Beighton 1993)
    1. X-linked recessive inheritance from pedigree data
    2. The gene for iduronate sulfatase mapped to Xq28
2. Primary biochemical defect and pathophysiology (Defendi 2015)
    1. Deficient iduronate-2-sulfatase (*IDS*), the enzyme required for cleavage of sulfate from iduronic acid moieties of dermatan and heparan sulfates
    2. Excessive intracellular accumulation of acid mucopolysaccharides (dermatan sulfate and heparan sulfate) due to deficient iduronate sulfatase activity, leading to multiple organ system involvement, including the musculoskeletal, integumentary, cardiovascular, pulmonary, and ocular systems
3. Molecular defect
    1. Mutations of *IDS* gene (Bunge et al. 1993; Goldenfum et al. 1996; Lissens et al. 1997; Froissart et al. 1998; Vafiadaki et al. 1998).
        1. Missense and nonsense mutations
        2. Mutations affecting splicing
        3. Small insertions and deletions
        4. Partial gene deletions
        5. Deletions and rearrangements (Froissart et al. 1993)
        6. Almost all recurrent point mutations involve CpG sites (Rathmann et al. 1996)
    2. Major structural alterations and gross deletions of the *IDS* gene result in the most

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_162

severe forms of Hunter syndrome (Timms et al. 1997).
3. Single-base substitutions causing diminished but not obliterated enzyme activity is observed in mild disease.

4. Genetic heterogeneity (Lichtenstein et al. 1972; Young et al. 1982a)
5. Hunter syndrome in females: an exceedingly rare event possibly due to the following mechanisms:
   1. As the offspring of a carrier female and affected male or an unaffected male whose sperm carries a new mutation
   2. Uniparental disomy of the mutant X chromosome from a heterozygous female or an affected male
   3. Genetic rearrangement: for example, translocation or deletion (Broadhead et al. 1986) resulting in nonrandom lyonization toward expression of a mutant allele
   4. Mucopolysaccharidosis type II in a female patient with a reciprocal X;9 translocation and skewed X chromosome inactivation (Lonardo et al. 2014)

Clinical Features

1. Clinical presentation showing a spectrum of mild to severe forms as a result of different mutations in the functional gene (Young et al. 1982; Beighton 1993)
2. Severe Hunter syndrome (MPS IIA) (Young and Harper 1983)
   1. Onset: usually between 2 and 4 years of age with progressive neurologic and somatic involvement
   2. More common than the mild form
   3. Short stature not pronounced
   4. Coarse facial features
      1. Frontal bossing
      2. Depressed nasal bridge
      3. Wide nostrils
      4. Depressed nasal bridge
      5. Thick lips
      6. Hypertrophic gums
      7. A large tongue
   5. Skeletal deformities
      1. Kyphosis
      2. Digital contractures
      3. Claw hands
      4. Joint stiffness
      5. Absence of gibbus
   6. CNS manifestations (Al Sawaf et al. 2008)
      1. Mental retardation
      2. Hydrocephalus
      3. Seizures
      4. Sleep apnea
      5. Cerebral infarction
      6. Spinal cord compression/cervical myelopathy
      7. Other CNS lesions
         1. Enlarged perivascular spaces
         2. Widening of subarachnoid spaces
         3. White-matter lesions
         4. Delayed myelination
   7. Ocular manifestations
      1. Absence of corneal clouding
      2. Thickened sclera
      3. Optic atrophy
      4. Papilledema
      5. Retinitis pigmentosa-like retinal fundus
      6. Night blindness
      7. Scotomas
   8. Hearing loss
   9. Respiratory difficulties (Yoskovitch et al. 1998)
      1. Upper airway obstruction due to adenoid hypertrophy, nasal congestion, and thick rhinorrhea
      2. Mouth breathing secondary to choanal stenosis
      3. Sonorous breathing, frank obstructive sleep apnea, and even death secondary to adenoid hypertrophy, tongue enlargement, and supraglottic swelling
      4. In adult MPS II patients, central airways diameters are strikingly reduced and upon expiration there is extensive collapse of the trachea and main bronchi. This central airways obstruction explains the severe respiratory symptoms in MPSII patients (Young and Harper 1979; Rotten et al. 2016)

10. Cardiovascular disorders
    1. Cardiac valvular involvement leading to congestive heart failure, the leading cause of death in affected individuals
    2. Mild thickening and shortening of the chordae tendineae contributing to the regurgitated valve dysfunction
11. Gastrointestinal problems
    1. Chronic diarrhea secondary to autonomic nervous system involvement and mucosal dysfunction
    2. Hepatosplenomegaly
    3. Umbilical and inguinal hernias
12. Thick skin often with nodular skin lesions over the scapular area or arms
13. Psychosocial problems (Young and Harper 1981)
14. Peripheral nervous system manifestations
    1. Carpal tunnel syndrome secondary to median nerve compression
    2. Cubital tunnel syndrome
15. Additional features of most severely affected patients caused by large deletions that include iduronate sulfate sulfatase and contiguous genes
    1. Hurler-like symptoms
    2. Early onset of seizures
    3. Ptosis
16. Prognosis: typically advancing to cachexia and death before 15 years

3. Mild Hunter syndrome (MPS IIB) (Young and Harper 1982; Young et al. 1982)
    1. Diagnosed slightly later than the severe form
    2. Much less frequent than the severe form
    3. Preservation of normal intelligence
    4. No central nervous system involvement
    5. Somatic involvement less progressive
    6. Hearing impairment
    7. Cardiovascular disorders
    8. Joint stiffness
    9. Cervical myopathy due to a narrowed spinal canal and cord compression
    10. Carpal tunnel syndrome more frequent and severe compared to the severe form
    11. Loss of hand function resulting from joint stiffness and carpal tunnel syndrome
    12. Prognosis
        1. Longer survival
        2. Typically surviving to adulthood
        3. Possible death in early adulthood or even in the late teens due to airway obstruction and cardiac failure

Diagnostic Investigations

1. Echocardiography
2. Electrocardiography
3. Radiographic features
    1. Kyphosis
    2. Claw hands
    3. Thick cortex of the bones progressively becoming thinner as the marrow cavities expand
    4. Large calvarium with shoe-shaped sella
    5. Broad and spatulate lower ribs
    6. Hypoplasia and beaking of the lumbar vertebrae
4. MRI of the brain (Al Sawaf et al. 2008)
    1. Most common findings: widely distributed white-matter lesions, predominantly found peri- and supraventricularly as well as in the basal ganglia and the corpus callosum. These changes were regarded as filling defects rather than immaturity of white matter and are suspected to progress with age.
    2. Even before the development of white-matter lesions, clearance of MPS deposits in white matter may result in demyelination. In addition, delay of myelination may also occur in Hunter disease.
    3. Common findings with questionable clinical relevance.
        1. Enlargement of the perivascular spaces
        2. Ventriculomegaly
        3. Mega cisterna magna
        4. Widening of the subarachnoid spaces
5. Biochemical/molecular studies (Liebaers and Neufeld 1976)
    1. Measurement of mucopolysaccharides in the urine: abnormal excretion of a large amount of dermatan sulfate and heparan sulfate in the urine.

2. Deficient iduronate sulfatase in leukocytes and fibroblasts.
3. Excessive intracellular accumulation of dermatan sulfate and heparan sulfate.
4. Peripheral lymphocytes, when stained with toluidine blue, exhibit metachromatic granules within vacuoles.
5. The gold standard for diagnosis of MPS II in a male proband is assay of I2S enzyme activity in white cells or serum (Martin 2007).
6. Molecular genetic testing of *IDS*, the only gene known to be associated with MPS II, is used to confirm the diagnosis in a male proband with an unusual phenotype or a phenotype that does not match the results of GAG testing (Martin 2007).
    1. Sequence analysis
    2. Deletion testing for exonic and whole gene deletions
    3. Southern blot analysis: used to detect complex rearrangements resulting from recombination with the pseudogene and accounting for 9% of all mutations (Froissart et al. 2007)
7. Highlight the utility of whole-exome sequencing in expanding the recognized phenotypic spectrum of known syndromes such as MPS II (Nikkel et al. 2014).

6. Heterozygote detection (Timms et al. 1998)
    1. Carrier detection by enzyme analysis for MPS II is unreliable (Archer et al. 1983; Zlotogora and Bach 1984)
    2. Identification of *IDS* gene mutations (Bunge et al. 1994)
    3. Germline and somatic mosaicism in a female carrier of Hunter disease (Froissart et al. 1997)

Genetic Counseling

1. Recurrence risk.
    1. Patient's sib
        1. Carrier mother: 50% of brothers affected, 50% of brothers normal, 50% of sisters carriers, 50% of sisters normal
        2. Noncarrier mother (mother of a sporadic case): recurrence possible due to presence of gonadal mosaicism
    2. Patient's offspring
        1. Severe form: not surviving to reproduction
        2. Mild form: none of the sons affected, all daughters carriers
2. Prenatal diagnosis (Muenzer 1986; Fensom and Benson 1994; Keulemans et al. 2002).
    1. Maternal serum analysis (Zlotogora and Bach 1986)
        1. Consistent increase of iduronate sulfate sulfatase in the serum of pregnant women from prepregnancy levels toward the end of pregnancy
        2. No change in the serum enzyme levels of heterozygous mothers until the affected fetuses are aborted
    2. Amniocentesis (Archer et al. 1984)
        1. Reduced enzyme activity in the amniotic fluid (Liebaers et al. 1977)
        2. Low enzyme levels in cultured amniotic cells
        3. Abnormal $^{35}SO_4$ incorporation into cultured amniotic fluid cells (Kleijer et al. 1979)
        4. Karyotyping for fetal sex
        5. Direct detection of *IDS* gene mutation, provided the disease-causing mutation in the family has been identified previously
    3. CVS (Pannone et al. 1986)
        1. Diminished enzyme activity in uncultured chorionic villi of affected male fetuses. This may be seen in female carrier fetuses (Cooper et al. 1991)
        2. Karyotyping for fetal sexing
        3. Direct detection of *IDS* gene mutation, provided the disease-causing mutation in the family has been identified previously
    4. Umbilical fetal blood sampling: severe deficiency of iduronate sulfate sulfatase in the plasma of affected male fetuses (Lissens et al. 1988)
    5. Preimplantation diagnosis for at-risk pregnancies requires prior identification of the disease-causing mutation in the family.

3. Management (Beighton 1993).
    1. Tympanostomy, adenoidectomy, and provision of hearing aids for management of otologic complications
    2. Symptomatic management of airway obstruction (sleep apnea)
    3. Ventriculoperitoneal shunting for hydrocephalus, a relatively rare complication of Hunter syndrome
    4. Difficulties during anesthesia secondary to the following factors:
        1. Rigid thoracic cage
        2. Abdominal distention
        3. Macroglossia
        4. Temporomandibular ankylosis
        5. Atlantoaxial instability
        6. Short and wide neck
    5. Prophylactic antibiotics for at-risk procedures in patient with mucopolysaccharidosis.
    6. Surgical repair of inguinal and umbilical hernias.
    7. Surgical release to preserve apposition of the thumbs at the earliest sign of an electrophysical evidence of progressive median nerve compression.
    8. Musculoskeletal complications.
        1. Shoe orthotics and ankle braces well tolerated and useful in maintaining mobility
        2. Achilles tendon release in some patients with advanced disease
        3. Surgical stabilization of the spine rarely indicated for kyphoscoliosis which is only mildly progressive and not usually resulting in spinal cord compression
    9. To varying degrees, patients with the severe form manifest behavioral disorders such as hyperactivity, aggression, impulsivity, anxiety, and sleep disturbances. Medications, such as antipsychotics, benzodiazepines, and anticonvulsants, have been tried with varying degrees of success. Behavioral management strategies may be a worthwhile approach, although published data are lacking. For sleep disturbances, behavioral modification plus melatonin or benzodiazepine may be effective treatments (Roberts et al. 2016).
    10. Attenuated MPS II patients have increasing somatic disease burden and poor physical quality of life as they develop as well as decreasing self-esteem and sense of adequacy. Psychosocial quality of life, adaptive skills, and attention improve. Recognition of and intervention around these issues will be beneficial to MPS II attenuated patients who have the resources to use such assistance to improve their long-term outcomes (Shapiro et al. 2016).
    11. Bone marrow transplantation (McKinnis et al. 1996).
        1. Possible reduction in hepatosplenomegaly, improvement in airway disease, and reduction in urinary glycosaminoglycan excretion
        2. Long-term prognosis for longevity, cardiac complications, and neurologic outcome after marrow transplantation still remained to be determined (Bergstrom et al. 1994)
    12. Hematopoietic stem cell transplantation (HSCT) has been performed in numerous individuals with varying degrees of severity of MPS II but limited success and significant risk; therefore, HSCT is not currently recommended for individuals with MPS II (Martin et al. 2008).
    13. Enzyme replacement therapy (ERT) (Burrow and Leslie 2008; da Silva et al. 2014).
        1. Recently, recombinant iduronate-2-sulfatase (idursulfase, Elaprase®; Shire Human Genetic Therapies, Inc., Cambridge, MA), a recombinant human I2S produced in a human cell line, was approved in the United States and the European Union as a safe and effective treatment for individuals with MPS II.
        2. The rationale for therapy is that exogenous I2S would replace the iduronate-2-sulfatase that is deficient in patients and either stop or reverse disease progression.

3. Recent clinical trials have shown promise in the treatment of MPS II, with potential to help many patients, providing that it is started early in the course of the disease (Wraith et al. 2008).
4. ERT involves the intravenous administration of a recombinant human enzyme into individuals in whom the enzyme is missing or defective.
5. The recombinant enzyme undergoes receptor-mediated cell uptake and subsequent intracellular trafficking into the lysosomes, where it carries out its specific function.
6. Elaprase® does not cross the blood–brain barrier; thus, no effect on CNS disease is anticipated. Thus, CNS disease remains a major challenge, and an innovative approach to treatment will be needed if this is to be addressed fully (Wraith et al. 2008).

Mucopolysaccharidosis 3

Contents

In 1962 and 1963, Sanfilippo et al. described eight children with mental retardation and heparan sulfate mucopolysaccharidoses and delineated the syndrome which now bears his name. Earlier in 1961, Harris reported a 6-year-old girl with hepatosplenomegaly, a normal skeletal survey, and excretion of large amounts of heparan sulfate in the urine. Sanfilippo syndrome is one of the most common mucopolysaccharidoses (MPS) (1/24,000–1/200,000).

Sanfilippo syndrome is comprised of four biochemically heterogeneous types (MPS IIIA, IIIB, IIIC, and IIID), which are clinically indistinguishable. Because the deficiency of these four various lysosomal enzymes involved the same breakdown of heparan sulfate, their clinical phenotype is similar. Type A is the most common type of MPS III in Northwest Europe, while type B is the most frequent type in Southeast Europe (Meikle et al. 1999; Poorthuis et al. 1999; Baehner et al. 2005). Types C and D appear to be much rarer (Valstar et al. 2008).

Synonyms and Related Disorders

Sanfilippo Syndrome

Genetics/Basic Defects

1. Inheritance: autosomal recessive.
2. Genetic heterogeneity (Van de Kamp et al. 1981).
3. Failure to degrade heparan sulfate may result from deficiency of one of the following four lysosomal enzymes (Bodamer et al. 2014):
   1. MPS IIIA caused by deficient heparan *N*-sulfatase (sulfamidase) (Karpova et al. 1996; Blanch et al. 1997; Bunge et al. 1997; Chabas et al. 2001)
   2. MPS IIIB caused by deficient α-*N*-acetylglucosaminidase (Beesley et al. 1998, 2005; Bunge et al. 1999)
   3. MPS IIIC caused by deficient acetyl-CoA:α-glucosaminide-*N*-acetyltransferase
   4. MPS IIID caused by deficient *N*-acetyl-α-glucosamine-6-sulfatase (Beesley et al. 2003)
4. Four subtypes of MPS III (Bodamer et al. 2014):
   1. Clinically indistinguishable
   2. Each characterized by deficiency of a different enzyme

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_163

3. MPS IIIA mapped to 17q25.3
4. MPS IIIB mapped to 17q21
5. MPS IIIC mapped to 8p11.1
6. MPS IIID mapped to 12q14

Clinical Features

1. Severe CNS involvement (Nidiffer and Kelly 1983):
    1. Developmental milestones near normal prior to age 3–4 years.
    2. Developmental delay, especially in speech (first stage usually starts between 1 and 4 years of age).
    3. Behavioral problems (second stage usually starts around 3–4 years):
        1. Aggressiveness
        2. Hyperactivity
        3. Attention deficit
        4. Temper tantrums
        5. Destructive behavior
        6. Physical aggression
        7. Sleep disturbance:
            1. Setting difficulties
            2. Night walking
            3. Sometimes awake all night
            4. Crying out
            5. Wandering around the house
            6. Entering parents' bed
            7. Talking in sleep
            8. Body rocking
            9. Chewing bedclothes
        8. Poor attention span
        9. Marked mood swings
        10. Self-injury
    4. Progressive motor difficulties due to spasticity and joint stiffness and slowly disappearing behavioral problems, starting about 10 years of age (marking the third and final stage).
    5. Severe hearing loss common in the moderate to severely affected patient.
    6. Severe neurologic degeneration occurring in most patients by 6–10 years of age, accompanied by rapid deterioration of social and adaptive skills (mental deterioration).
    7. Progressive dementia resulting in withdrawal and losing contact with the environment.
    8. Seizures: uncommon.
    9. Patients usually die at the end of the second or beginning of the third decade of life, although survival into the fourth decade has been reported.
2. Mild somatic disease:
    1. Coarse hair (hirsutism): hypertrichosis often present, especially on the back
    2. Macrocephaly
    3. Copious nasal discharge
    4. Repeated upper respiratory tract infections
    5. Cardiac signs and symptoms much lesser degree compared to other types of mucopolysaccharidosis
    6. Mild hepatosplenomegaly
    7. Joint stiffness
    8. Recurrent and sometimes severe diarrhea, usually improves in later childhood
    9. Early onset of puberty
3. Prognosis:
    1. Type A:
        1. The most severe type
        2. Earlier onset
        3. More rapid progression of symptoms (natural history) (Buhrman et al. 2014):
            1. Severe hearing loss and speech delay, followed by a rapid decline in cognitive skills by 3 years of age.
            2. Significant somatic disease occurs in more than half of the patients.
            3. Behavioral difficulties presented between 2 and 4 years of age during a rapid period of cognitive decline.
            4. Gross motor abilities are maintained during this period, which results in an active child with impaired cognition.
            5. Sleep difficulties are concurrent with the period of cognitive degeneration.
        4. Shorter survival: death usually by late teens
    2. Type B: known to remain functional into the third or even fourth decades
    3. Type C: clinically heterogeneous

4. Type D (Jones et al. 1997):
    1. Least common type
    2. Clinically heterogeneous

Diagnostic Investigations

1. Increased urinary excretion of heparan sulfate.
2. Quantitative urinary glycosaminoglycan analysis (Bodamer et al. 2014) is strongly recommended, and measurement of disaccharides, heparin cofactor II–thrombin complex, and gangliosides is also used (Andrade et al. 2015).
3. Growth charts for height and weight for males and females are available for MPS III (de Ruijter et al. 2014).
4. Imaging features:
    1. Radiography: mild degree of dysostosis multiplex
    2. Echocardiography for rare cardiac abnormalities
    3. CT:
        1. Mild to moderate cortical atrophy at onset
        2. Severe cortical atrophy at late stage
    4. MRI (Barone et al. 1999):
        1. Cortical atrophy.
        2. Corpus callosum atrophy.
        3. Abnormal or delayed myelination.
        4. MRI findings may precede the onset of overt neurological symptoms.
5. Biochemical analysis (Defendi and Varma 2009):
    1. Biochemical differentiation of the different forms within MPS II is possible, and diagnosis is confirmed by specific enzymatic assay:
        1. Deficient heparan *N*-sulfatase (type A)
        2. Deficient *N*-acetylglucosaminidase (type B)
        3. Deficient α-glucosamine-*N*-acetyltransferase (type C)
        4. Deficient *N*-acetyl-α-glucosamine-6-sulfatase (type D)
    2. Enzymatic activity for all types of MPS III may be assayed in cultured skin fibroblasts and in peripheral blood leukocytes.
    3. Enzyme activity of the different enzymes in blood serum, leukocytes, or fibroblasts and mutational analysis for *SGSH*, *NAGLU*, *HGSNAT*, or *GNS* genes are required to confirm diagnosis and differentiate four subtypes of MPS III (Andrade et al. 2015).
6. Mutation studies are available clinically by sequence analysis and deletion/duplication analysis:
    1. MPS IIIA (Beesley et al. 2000; Yogalingam and Hopwood 2001; Lee-Chen et al. 2002a; Di Natale et al. 2003):
        1. Missense mutations (most common)
        2. Premature termination mutations
        3. Small deletion mutations
    2. MPS IIIB (Zhao et al. 1996; Yogalingam and Hopwood 2001; Lee-Chen et al. 2002b):
        1. Great molecular heterogeneity
        2. Most mutations: private mutations
    3. MPS IIIC: no mutation analysis available currently
    4. MPS IIID: frameshift and premature termination mutation
7. Very recent breakthroughs in high-throughput methods for sequencing only the protein-coding regions of the genome, called whole exome sequencing or targeted exome capture, present tempting future screening and diagnostic possibilities (Bodamer et al. 2014).
8. Carrier detection (Vance et al. 1981; Toone and Applegarth 1988).

Genetic Counseling

1. Recurrence risk:
    1. Patient's sib: 25%
    2. Patient's offspring: not reproducing due to mental retardation
2. Prenatal diagnosis (Di Natale et al. 1999):
    1. Fetuses at risk for MPS IIIA:
        1. Measuring sulfamidase activity using radioactive assay in CVS and amniocytes (Thompson et al. 1993)

2. Using fluorimetric sulfamidase assay in CVS and amniocytes (Kleijer et al. 1996)
3. Molecular diagnosis in characterized families

2. Fetuses at risk for MPS IIIB:
   1. Assay of α-*N*-acetylglucosaminidase activity in cultured amniocytes (Mossman et al. 1983) and CVS (Kleijer et al. 1984; Minelli et al. 1988)
   2. Increased level of heparan sulfate in amniotic fluid by two-dimensional electrophoresis of glycosaminoglycans: used as an adjunctive method in prenatal diagnosis
   3. Molecular diagnosis in characterized families
3. Fetuses at risk for MPS IIIC:
   1. Assay of acetyl-CoA:α-glucosamine-*N*-acetyltransferase in amniocytes (Maire et al. 1993) and CVS (di Natale et al. 1987; He et al. 1994)
   2. Molecular diagnosis in characterized families
4. Fetuses at risk for MPS IIID:
   1. Spectrophotometric assay for the *N*-acetyl-α-glucosamine-6-sulfatase activity (Nowakowski et al. 1989)
   2. Molecular diagnosis in characterized families
5. Diagnostics using free fetal DNA or fetal cells recovered from maternal circulation to directly detect mutations causing the MPS III phenotype will enable prenatal diagnosis of MPS III without the need of invasive sampling procedures (Dhallan et al. 2004).

3. Preimplantation genetic diagnosis (Hopwood 2005):
   1. Allows embryos to be tested for MPS III before they enter the uterus and pregnancy begins.
   2. This requires embryos, obtained by in vitro fertilization, to undergo a biopsy procedure in which one or two cells are removed and tested for the specific disorder.
   3. Only embryos shown to be free of MPS III are then implanted (Thornhill and Snow 2002).

4. Management (Cleary and Wraith 1993):
   1. Supportive treatments:
      1. Antibiotics for otitis media and respiratory tract infections
      2. Anticonvulsants for seizure activities
   2. Muscle relaxants for painful spasms.
   3. Gastrostomy to maintain adequate nutrition.
   4. Special education program.
   5. Behavioral management to allow the family to function as near normal as possible:
      1. Alteration to the physical environment within home
      2. Drug treatment to control hyperactivity and aggression
   6. Physical therapy to maintain joint mobility.
   7. Recommend monitoring bone mineral density by dual-energy X-ray absorptiometry and checking vitamin D metabolism to assess low bone mass and fracture risk in older MPS III patients with immobility (Nur et al. 2016).
   8. Wheelchair for transportation.
   9. Respite care: availability of suitable respite accommodation.
   10. Identify professional and community resources.
   11. Risperidone treatment of behavioral disorder in children with MPS IIIA: appeared to be safe and effective (Ucar et al. 2010).
   12. Bone marrow transplantation (Vellodi et al. 1992; Sivakumur and Wraith 1999):
      1. Biochemical correction readily achievable
      2. Disappointing intellectual outcome
   13. Hematopoietic cell transplantation for mucopolysaccharidosis patients is safe and effective (Aldenhoven et al. 2015).

Fig. 1 (**a**–**c**) A child with MPS IIIA at 8 months (**a**) and 3 years (**b**, **c**)

Fig. 2 A 32-year-old male with Sanfilippo syndrome type A showing mental retardation and severe behavioral problems. Molecular genetic analysis revealed heparan sulfamidase (SGSH) gene mutations. A C > T substitution was detected at nucleotide 892 resulting in a serine being replaced by a proline at amino acid 298 (S298P). The second nucleotide change resulted in insertion of a cystine at nucleotide 1,028 which creates a frameshift and premature truncation of protein (1028insC). The detection of two mutations in the heparan sulfamidase gene is associated with Sanfilippo A syndrome

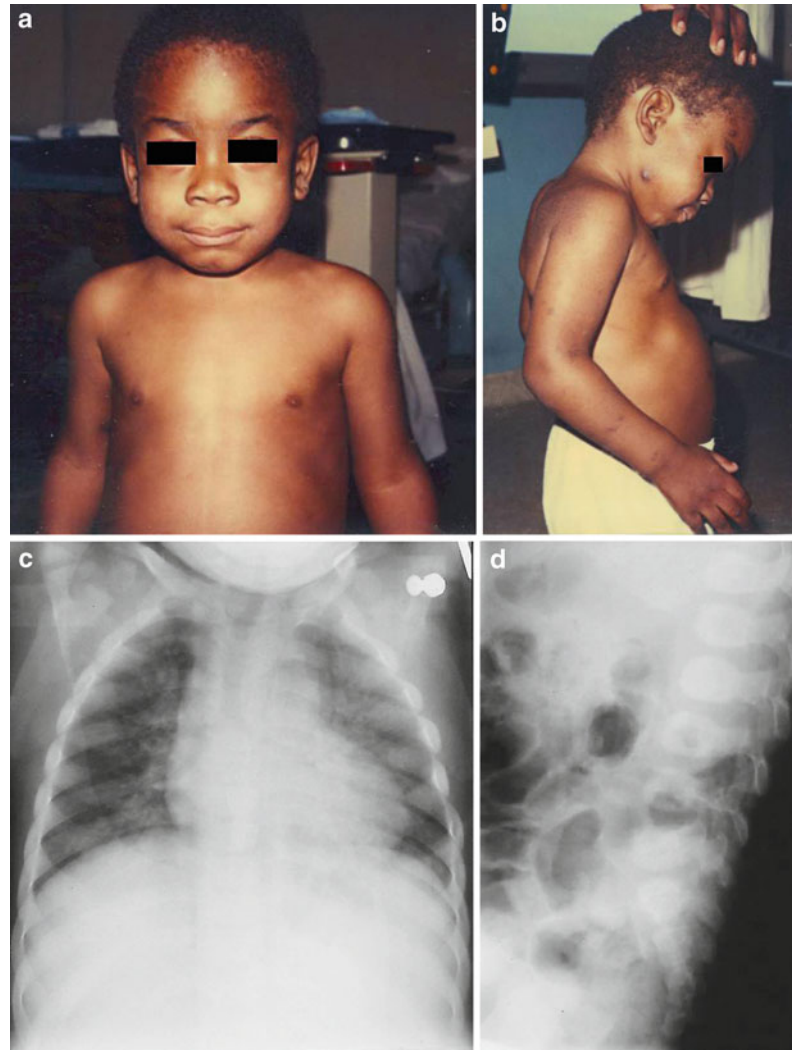

Fig. 3 (**a**–**d**) A child with MPS IIIB at 3 years of age (**a**, **b**). The radiographs (**c**, **d**) show mild degree of dysostosis multiplex

Mucopolysaccharidosis 4

Contents

In 1929, Morquio and Brailsford independently described cases of what is now believed to be Morquio syndrome (Brailsford 1929; Morquio 1929). The exact incidence is unknown but is estimated to be 1 in 75,000-1 in 200,000.

Synonyms and Related Disorders

Galactosamine-6-sulfatase deficiency; Morquio disease; Morquio syndrome; MPS IVA; MPS IVB

Genetics/Basic Defects

1. Genetic inheritance: autosomal recessive (Beck et al. 1987)
2. Two forms of MPS IV
    1. MPS IVA
        1. Deficient *N*-acetyl-galactosamine-6-sulfate sulfatase (*GALNS*) gene, which is mapped to 16q24.3 (Baker et al. 1993; Masuno et al. 1993).
        2. Excessive allelic heterogeneity among patients with Morquio A syndrome (Bunge et al. 1997). Heteroallelic missense mutations lead to GALNS deficiency and mild MPS IVA (Cole et al. 1996).
        3. Wide spectrum of clinical manifestations (Nelson et al. 1988; Tylki-Szymanska et al. 1998).
    2. MPS IVB (Paschke et al. 2001)
        1. Deficient β-galactosidase (*GLB1*) gene
        2. Wide spectrum of clinical manifestations
3. Pathogenesis (Braverman and Hoover-Fong 2003)
    1. Defective degradation of keratan sulfate secondary to deficiency of either *N*-acetyl-galactosamine-6-sulfate sulfatase (*GALNS* gene) in MPS IVA or β-galactosidase (*GLB1* gene) in MPS IVB
    2. Cartilage and cornea: the major organs affected in Morquio syndrome since keratan sulfate is predominantly found in these tissues

Clinical Features

1. MPS IVA
    1. Classic form

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_164

1. The most common form
2. Appears normal at birth
3. Skeletal symptoms occurring between 1 and 3 years of age
4. Clinical diagnosis usually not made until 3–15 years of age
5. Skeletal manifestations
    1. Marked dwarfism
    2. Waddling gait with tendency to fall
    3. Short neck
    4. Hypoplasia or absence of the odontoid process of the axis with risk of resulting in life-threatening atlantoaxial subluxation (Blaw and Langer 1969). Odontoid dysplasia in the absence or presence of atlantoaxial instability in all cases (Nelson and Thomas 1988)
    5. Cervical myelopathy (Rigante et al. 1999)
    6. Gibbus
    7. Restrictive chest wall movement
    8. Pectus carinatum
    9. Kyphoscoliosis
    10. Genu valgum
    11. Semicrouching stance
    12. Progressive skeletal deformities frequently resulting in neurologic compromise
6. Joint manifestations
    1. Hypermobile due to ligamentous laxity
    2. Decreased mobility in large joints (e.g., hips, knees, elbows)
7. Unusual facial appearance
    1. Coarse facies
    2. Prognathism
    3. Broad mouth
8. Eye manifestations
    1. Mild corneal clouding
    2. Glaucoma
    3. Cataract
9. Dental features (Nelson and Kinirons 1988; Rølling et al. 1999)
    1. Abnormally thin enamel
    2. Spade-shaped incisors
    3. Pointed cusps
    4. Pitted buccal surfaces
    5. Frequent caries formation
10. Cardiac manifestations
    1. Aortic valve insufficiency or stenosis
    2. Mitral valve thickening and stenosis
    3. Cardiac failure
11. Progressive deafness
12. Hepatomegaly
13. Upper airway obstruction
    1. Obstructive sleep apnea
    2. Nocturnal dyspnea
14. Intelligence usually normal, rarely with progressive mental regression

2. Mild form
    1. Almost normal stature
    2. Mild skeletal abnormalities
        1. Odontoid dysplasia but without atlantoaxial instability
        2. Pectus carinatum deformity
        3. Dysplastic hips
        4. Waddling gait
        5. Kyphoscoliosis
        6. Deformity of femoral heads
        7. Platyspondyly
        8. Limitation of joint movement
        9. Deformities of metacarpals
    3. Enamel hypoplasia
    4. Mild corneal clouding
    5. Absent keratosulfaturia

2. MPS IVB
    1. Severe form: clinical manifestations as severe as MPS IVA
    2. Mild form
        1. Less severe progression of skeletal dysplasia
        2. Less severe short stature
3. Prognosis
    1. Atlantoaxial instability and subsequent cervical myelopathy
        1. Cord transection and subsequent quadriparesis or death secondary to a minor fall or extension of the neck
        2. Bowel and bladder dysfunction and apnea secondary to cervical myelopathy

3. Prolonged periods of hypoxia, pulmonary hypertension, and even death from obstructive sleep apnea
4. Airway obstruction secondary to thickening of tissue in the upper airway from mucopolysaccharide deposition

2. Predisposition to pulmonary infection because of progressive truncal deformity and immobility
3. Early-onset coronary heart disease and valve thickening (aortic and mitral) with resultant cardiac dysfunction
4. Visual disturbance and photophobia secondary to corneal clouding
5. Predisposition to dental caries secondary to enamel abnormalities

Diagnostic Investigations

1. Urine MPS spot tests: associated with false-positive and false-negative results. Mildly affected individuals do not always excrete keratan sulfate fragments (Chih-Kuang et al. 2002; Braveman 2014).
2. Excessive urinary excretion of keratan sulfate: determination by spectrophotometric assays with dimethylmethylene blue.
3. Metachromatic granules in cultured fibroblasts.
4. Diagnosis confirmed by direct enzymatic assay in leukocytes or fibroblasts.
   1. *N*-Acetylgalactosamine-6-sulfatase deficiency (classic form)
   2. β-Galactosidase deficiency (mild form)
5. Radiographic features (Langer and Carey 1966).
   1. Short trunk dwarfism
   2. Dysostosis multiplex
   3. Spondyloepiphyseal dysplasia (the hallmark of the syndrome)
   4. Odontoid hypoplasia
   5. Sternal protrusion
   6. Platyspondylia
   7. Kyphosis
   8. Hyperlordosis
   9. Scoliosis
   10. Ovoid deformities of the thoracic vertebrae
   11. Hook-shaped lumbar bodies
   12. Long pelvic configuration
   13. Coxa valga
   14. Genu valgum
   15. Ulnar deviation of the wrist
   16. Valgus deformity of the elbow
   17. Inclinations of distal ends of radius and ulna toward each other
   18. Metacarpal deformities
   19. Short phalanges
   20. Epiphyseal deformities of the tubular bones
   21. Wide metaphysis
   22. Osteoporosis
6. CT and MRI of the brain and cervical spine for evaluation of odontoid hypoplasia and cord compression (Borlot et al. 2014; Braveman 2014).
7. Echocardiography for cardiac involvement.
   1. Aortic valve insufficiency or stenosis
   2. Mitral valve thickening and stenosis
   3. Ventricular hypertrophy
8. Slit-lamp examination for corneal clouding.
9. Molecular genetic diagnosis.
   1. Sequence analysis
   2. Deletion/duplication analysis
10. Molecular testing of Morquio A: novel *GALNS* mutations (Morrone et al. 2014).
    1. Missense alleles
    2. Nonsense alleles
    3. Deletions
    4. Alterations affecting splice sites

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: 25%
   2. Patient's offspring: not increased unless the spouse is a carrier in which case there will be 50% of offspring affected

2. Prenatal diagnosis (von Figura et al. 1982; Mossman and Patrick 1982; Zhao et al. 1990; Beck et al. 1992; Kleijer et al. 2000)
    1. Demonstration of GalNac-6S or Gal-6S sulfatase deficiency in cultured amniotic fluid cells or chorionic villi
    2. Abnormal glycosaminoglycan electrophoretic pattern in amniotic fluid
    3. Mutation analysis in amniocytes or chorionic villi, provided the disease-causing mutation has been identified in the family member
3. Preimplantation genetic diagnosis of Morquio syndrome: accomplished by mutation analysis from the embryos following whole-genome amplification of single blastomeres using multiple displacement amplification (Qubbaj et al. 2008)
4. Management (Mikles and Stanton 1997)
    1. Orthopedic management
        1. Surgery to stabilize the upper cervical spine, usually by spinal fusion, can be lifesaving for occipito-spinal cord compression (Blaw and Langer 1969; Northover et al. 1996; Ransford et al. 1996)
        2. Bilateral osteotomies to correct the knock-knee deformity (severe coxa valgum)
    2. Anesthetic difficulties (Bartz et al. 1999; Morgan et al. 2002)
        1. Difficult endotracheal intubation due to odontoid hypoplasia and atlantoaxial instability
        2. Compression of the cord during hyperextension of the neck
        3. Reduction in vital capacity, functional residual capacity, and total lung capacity due to chest cage dysfunction (kyphoscoliosis and pectus carinatum)
    3. Infection control
    4. Medications for glaucoma
    5. Cornea transplant not very helpful
    6. Hearing aids helpful
    7. Hernia repairs
    8. Cardiac management
        1. Aortic regurgitation
        2. Endocarditis prophylaxis
        3. Cardiac valve replacement historically not considered for these patients
9. Potential strategies for treatment including enzyme replacement, gene therapy, and allogenic bone marrow transplantation in which engrafted cells provide the normal enzyme
10. International guidelines for management and treatment of Morquio A syndrome (Hendriksz et al. 2015)
    1. Enzyme replacement therapy with recombinant human GALNS (elosulfase alfa) has recently been approved for Morquio A syndrome, providing a systemic treatment approach. Elosulfase alfa has shown to be effective with a favorable safety profile.
    2. Multidisciplinary approach.
    3. Hip subluxation: using pelvic and femoral osteotomy, shelf acetabuloplasty, or total hip arthroplasty.
    4. Knee valgus: using guided growth (8-plate hemiepiphysiodesis) effective in growing child; knee osteotomy or knee arthroplasty, an option for older patients.
    5. Ankle valgus: generally by orthotics.
    6. Spinal cord compression: spinal decompression, fusion, or a combination of both.
    7. Respiratory impairment: supportive therapies (regular influenza and pneumococcus vaccinations, bronchodilators, and aggressive and prompt treatment of upper respiratory infections), tonsillectomy and/or adenoidectomy frequently required in patients with obstructed upper airways, sleep disordered breathing (obstructive sleep apnea or sustained hypoventilation) generally managed successfully by continuous positive airway pressure or noninvasive ventilator support.

8. Cardiovascular abnormalities: valve replacement for severe aortic or mitral valve disease.
9. Ophthalmological manifestations: refractive correction or low vision aids for impaired vision filtering glasses and hats for photosensitivity, corneal transplantation for corneal clouding, cataract surgery for cataracts.
10. Hearing loss: ventilation tubes for conductive hearing loss due to retained middle ear fluid, post-aural hearing aids for progressive neurosensory hearing loss.
11. Hernia repair for umbilical, inguinal, or bilateral diaphragmatic hernias.
12. Dental caries: fluoride supplementation, fissure sealing of dentition.

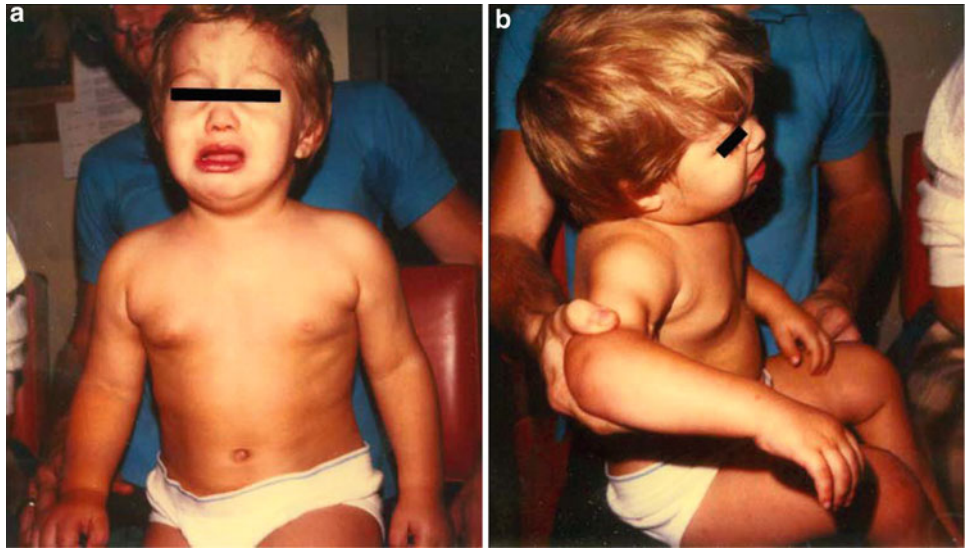

Fig. 1 (**a**, **b**) A boy with MPS IVB showing coarse facial appearance and short trunk

Fig. 2 Lateral view of the spine showing platyspondyly, anterior beaking of vertebral bodies, and lumbar gibbus similar to those seen in Hurler syndrome

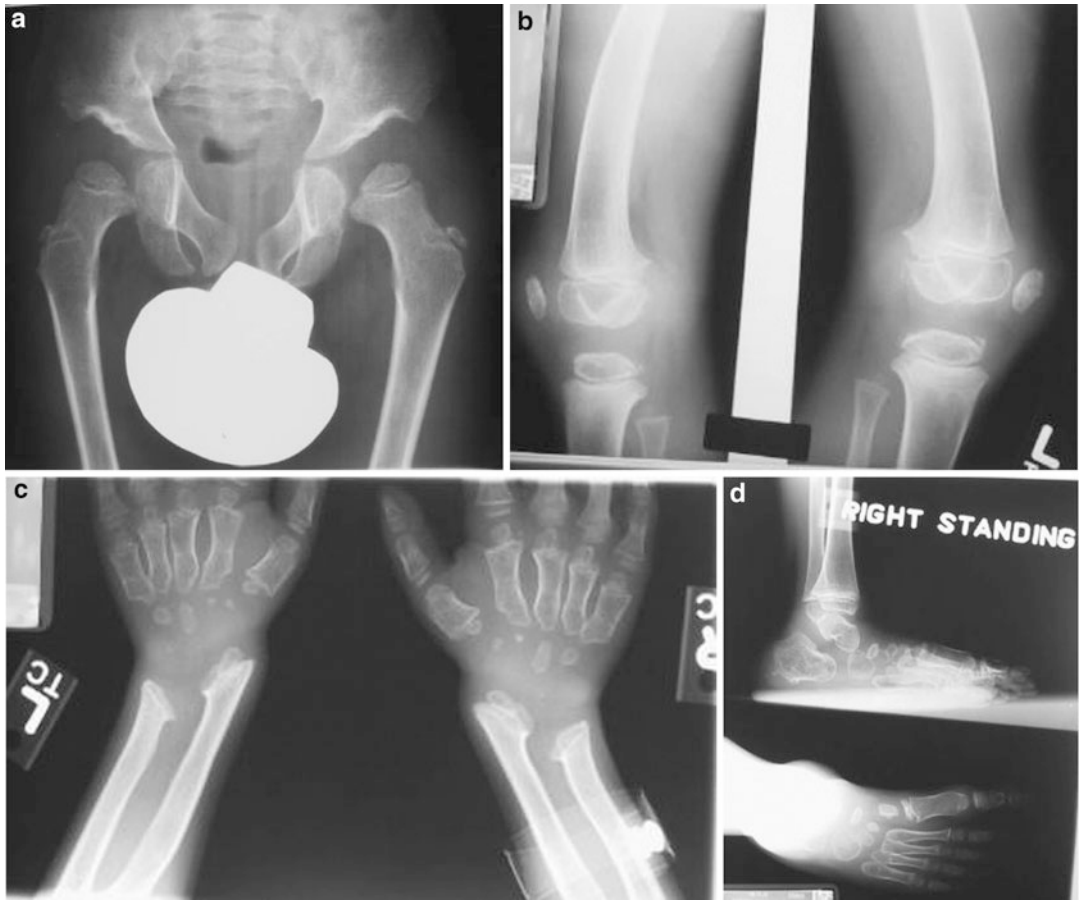

Fig. 3 (**a**–**d**) Radiographic studies showing dysostosis multiplex with proximal conical metacarpals and angling of the ulna toward the radius with dysplastic ulnar and radial growth plates

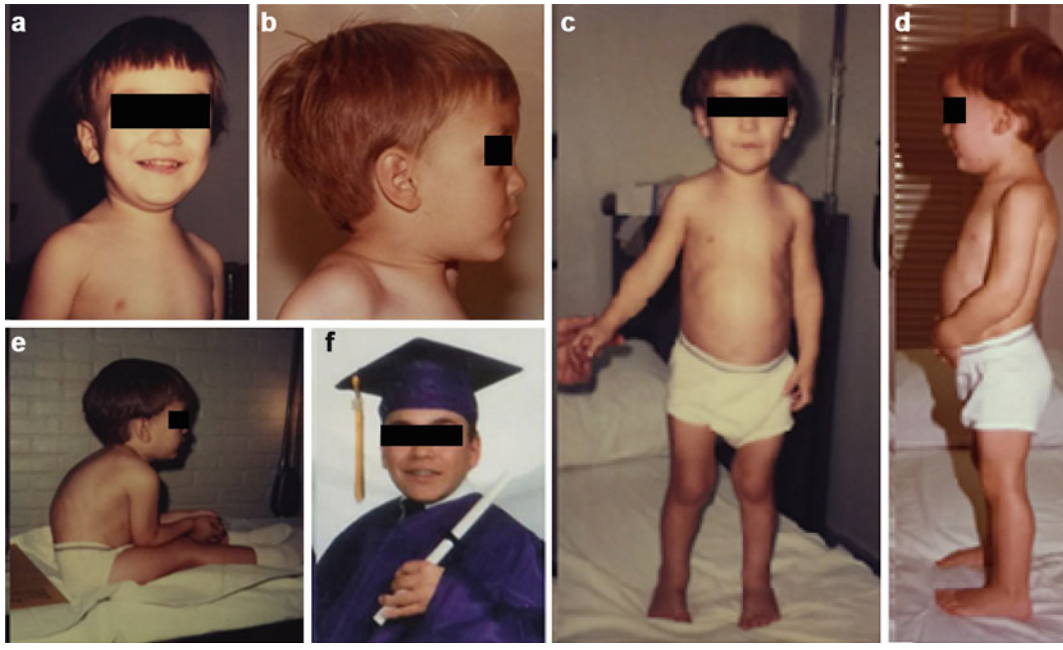

Fig. 4 (**a**–**f**) This French-Canadian (Acadian) boy was first seen at 2 years of age because of abnormal posture of kyphosis when sitting. He was evaluated again at 5 years of age, showing mild coarse facial appearance and short neck (**a**, **b**), short stature, mild pectus carinatum, and mild crouching stance (**c**, **d**) and kyphosis (**e**). His high school graduation photo is shown here in (**f**). The proband's blood keratin sulfate (KS) concentration was threefold higher than age-matched controls and higher than age-matched MPS IVA patients. The urine KS was over 3.5-fold higher than age-matched controls and lower than the age-matched MPS IVA patients. Gene mutation study showed the patient was homozygous for M41L. M14L mutation was found previously in one patient originated from Acadian with a homozygous form (performed at Dr. Tomatsu Shunji's Laboratory). Given all data from specimens, the patient has MPS IVA with substantial excessive excretion of KS in the urine and the blood (Courtesy of Dr. Susonne Ursin)

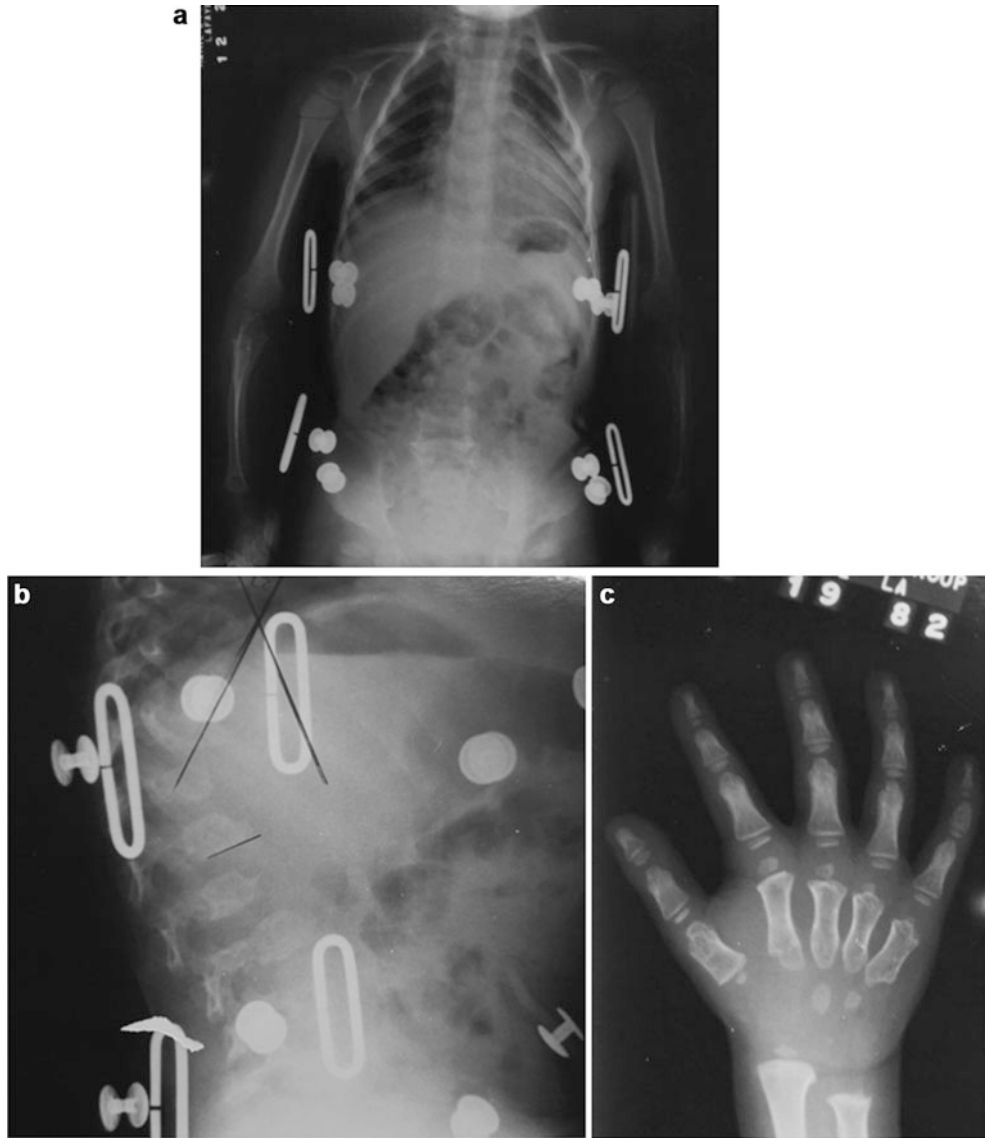

Fig. 5 (**a**–**c**) AP (**a**) and lateral view (**b**) of the spine showed platyspondyly of thoracolumbar vertebrae, anterior beaking of vertebral bodies, and lumbar gibbus. Radiographic studies showed dysostosis multiplex with proximal conical metacarpals and deficiency of carpal ossification centers (**c**) (Courtesy of Dr. Susonne Ursin)

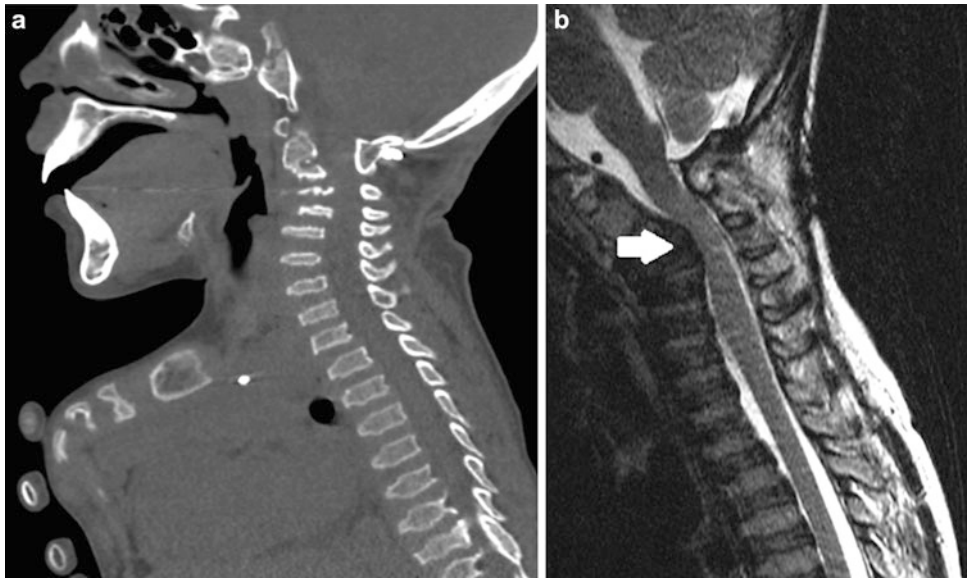

Fig. 6 (**a, b**) A 9 year old male with a history of mucopolysaccharidosis IV (Morquio syndrome), cervical spine instability, restrictive lung disease, hearing loss, and arrythmia. Multiple imaging studies demonstrated generalized osteopenia and Morquio syndrome related bony deformities (not shown). Sagital cervical CT (**a**) image showed skeletal dysplasia with flattened irregular vertebral bodies with posterior offset of the C3 and C4 vertebral bodies, resulting in a stenosis of spinal canal. Anterior beak deformity was present at multiple levels of the spine. There was a chest deformity (pectus carinatum). Sagital cervical MRI (**b**) showed significant spinal canal stenosis again with mild to moderate compression of the cord (*arrow*). (Courtesy of Dr. Grace Guo)

Mucopolysaccharidosis 6

Contents

Mucopolysaccharidosis (MPS) VI was first recognized by Maroteaux and coworkers in 1963 as a Hurler-like syndrome but with preservation of intelligence and excretion of dermatan sulfate unaccompanied by heparan sulfate. Milder forms of MPS VI have been recognized since the initial description of the disorder. The estimated birth incidence of MPS VI ranges from 1 in 100,000 to 1 in 1,300,000 in various populations (Harmatz et al. 2004).

Synonyms and Related Disorders

Arylsulfatase B (ASB) deficiency; Maroteaux-Lamy syndrome; *N*-acetylgalactosamine-4-sulfatase

Genetics/Basic Defects

1. Genetic inheritance: autosomal recessive
2. Cause
    1. Caused by deficiency of *N*-acetylgalactosamine-4-sulfatase (arylsulfatase B) (Matalon et al. 1974) which:
        1. Is deficient in both mild and severe forms
        2. Is involved in the degradation of dermatan sulfate and chondroitin 4-sulfate
        3. Causes intralysosomal storage and urinary excretion of the glycosaminoglycan, dermatan sulfate
        4. The gene encoding *N*-acetylgalactosamine-4-sulfatase (ASB) mapped to chromosome 5q13-q14 (Litjens et al. 1989)
    2. Mutations: The vast majority of MPS VI mutant alleles are either unique to a patient or are present in a small number of patients (Litjens and Hopwood 2001).
        1. Null mutations
            1. Frameshift mutations
            2. Nonsense mutations
        2. Missense mutation giving rise to:
            1. Severe disease
            2. Intermediate disease
            3. Mild disease
    3. Genotype/phenotype correlation for missense mutations in MPS VI: not reliable enough for prognosis or counseling.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_165

Clinical Features

1. Variable clinical phenotypes (mild to severe) causing considerable difficulty in recognition and diagnosis of the syndrome
2. The severe form
    1. Somatic involvement similar to that in Hurler syndrome.
    2. Growth.
        1. Normal growth for the first few years of life
        2. Growth retardation (short stature) first noted at the age of 2–3 years
        3. Ultimate height of 110–140 cm in severely affected patients
    3. Other skeletal involvements.
        1. An enlarged head at birth
        2. Deformed chest at birth
        3. Joint stiffness (knee, hip, and elbow) developing in the first years of life
        4. Progressively restricted articular movements
        5. Crouching stance
        6. Shortened limbs
        7. Claw-hand deformities secondary to flexion contractures of the fingers
        8. Carpal tunnel syndrome contributing to the hand abnormality
        9. Shortened trunk
        10. Anterior sternal protrusion
        11. Lumbar gibbus
        12. Prominent lumbar lordosis/kyphosis
        13. Genu valgum
    4. Mental development usually normal.
    5. The facies.
        1. Mild coarseness of facies in some patients
        2. Coarse facies characteristic of Hurler syndrome in other patients
    6. Ocular findings.
        1. Corneal opacities (clouding) developing early, resulting in significant visual impairment
        2. Glaucoma (Cantor et al. 1989)
        3. Pigmented retinopathy
    7. Dentigerous cysts.
    8. Ear/labyrinth disorders: most commonly hearing impairment and otitis media.
    9. Upper airway obstruction.
    10. Cardiovascular involvement.
        1. Thickened atrioventricular valves of the heart (Tan et al. 1992)
        2. Endomyocardial fibroelastosis (Miller and Partridge 1983)
        3. Infantile/dilated cardiomyopathy (Hayflick et al. 1992)
    11. Associated neurologic complications.
        1. Not typically associated with progressive impairment of mental status (Vestermark et al. 1987), although physical limitations may impact learning and development
        2. Hydrocephalus (Goldberg et al. 1970)
        3. Spinal cord compression (Young et al. 1980; Wald and Schmidek 1984)
            1. Cervical cord compression (cervical myelopathy) is a common manifestation of MPS VI and can affect all patients at an early age, irrespective of phenotype (Solanki et al. 2016)
            2. Atlantoaxial subluxation associated with craniovertebral canal stenosis (Thorne et al. 2001)
            3. Hypertrophy of the posterior longitudinal ligament
            4. Dural thickening secondary to the deposition of glycosaminoglycans
        4. Spastic paraplegia resulting from compressive myelopathy
        5. Arachnoid cysts
        6. Pachymeningitis
        7. Nerve entrapment syndromes, particularly of the carpal tunnel
        8. Occasional hearing loss due to recurrent otitis media
    12. Abdomen and visceral involvement.
        1. Hepatomegaly always present after the age of 6 years
        2. Splenomegaly in 50% of patients
        3. Prominent abdomen
        4. Inguinal/umbilical hernias common
    13. Skin.
        1. Tightness
        2. Hirsutism

14. Most reported patients with the severe form died from heart failure in the second to third decades.

3. The mild (Di Ferrante et al. 1974; Paterson et al. 1982) to intermediate form (MPS VIB)
   1. Clinical recognition often delayed till 5 years of age
   2. Mildly affected
   3. Minimal dysostosis multiplex
   4. Aortic and mitral valvular dysfunction
      1. Primarily due to calcified thickened and stenotic valves
      2. The most prominent cardiac involvement in the milder phenotypes
   5. Spinal cord compression from thickening of the dura in the upper cervical spinal canal with resultant myelopathy: a frequent occurrence in patients with the milder forms
   6. Compression myelopathy associated with a kyphoscoliotic deformity of thoracolumbar spine

Diagnostic Investigations

1. Increased urinary excretion of glycosaminoglycans (Valayannopoulos et al. 2010).
   1. Dermatan sulfate accumulation
   2. The absence of chondroitin 4-sulfate, heparan sulfate, keratan sulfate, or hyaluronate using thin layer chromatography (TLC) or high-resolution electrophoresis fractionation
2. Biochemical diagnosis (Valayannopoulos et al. 2010; Harmatz and McGovern 2014).
   1. Demonstration of deficient *N*-acetylgalactosamine-4-sulfatase (arylsulfatase B) in cultured skin fibroblasts or leukocytes (generally less than 10% of the lower limit of normal ASB activity)
   2. Identification of normal enzyme activity of a different sulfatase to exclude the diagnosis of multiple sulfatase deficiency
3. Demonstration by an accredited laboratory of intermediate levels of leukocyte ASB enzyme activity in both parents to support diagnosis of carriers
4. Dried blood spot sampled via heel stick of the newborn (Civallero et al. 2006)
5. Slit-lamp examination for corneal opacities
6. Radiographic features
   1. Skeletal changes similar to radiographic findings of Hurler syndrome in the severe form
   2. Striking examples of dysostosis multiplex, particularly severe pelvic changes
      1. Acetabular hypoplasia
      2. Small flared iliac wings
   3. Macrocephaly with a large sella
   4. Vertebrae
      1. Ovoid deformity of vertebral bodies
      2. A hood-shaped deformity or blunt anterior hypoplasia of vertebral bodies of L1 or L2
      3. Epiphyseal dysplasia of the proximal femur
      4. An elongated femoral neck in a valgus position
      5. Irregular diaphyseal distension of tubular bones
      6. Vertebral subluxation, especially atlantoaxial joint
7. Routine MRI assessments from the time of MPS VI diagnosis are critical for the prevention of irreversible spinal cord damage (Solanki et al. 2016).
8. Confirmation by mutational analysis of the *ARSB* gene (Karageorgos et al. 2007) should be considered if the diagnosis is in question and is important in carrier testing or prenatal diagnosis.
   1. Sequence analysis
   2. Duplication/deletion analysis

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: 25%
   2. Patient's offspring: not increased unless the spouse is a carrier
2. Prenatal diagnosis (Valayannopoulos et al. 2010)

1. Demonstration of deficient *N*-acetylgalactosamine-4-sulfatase (arylsulfatase B) on viable fetal cells from chorionic villi or cultured amniotic-fluid cells from the pregnancy at risk (Kleijer et al. 1976; Van Dyke et al. 1981)
2. Mutation analysis of amniocytes and CVS in characterized families

3. Management (Giugliani et al. 2007)
    1. Supportive care.
        1. Optimizing general health with nutrition counseling
        2. Occupational and physical therapy
        3. Management of individual symptom complications
            1. Respiratory insufficiency requiring oxygen and/or positive airway pressure during sleep, tonsillectomy, adenoidectomy, or tracheostomy
            2. Cardiac failure requiring medications
    2. Keratoplasty for progressive opacification of the cornea and corneal transplantation (Varssano et al. 1997).
    3. Surgery to improve common nerve entrapment syndromes, particularly of the carpal tunnel.
    4. Successful single and double (aortic and mitral) valve replacements have been reported in MPS.
    5. Successful cardiac valve operations in patients with MPS VI are feasible, although extracardiac disease may have an impact on hospital morbidity. Even if mitroaortic involvement is common, we advise avoiding prophylactic replacement of mildly affected valves because the opportunity exists for enzyme replacement therapy to significantly delay the progression of cardiac valve disease (Torre et al. 2016).
    6. Substantial improvement following laminectomy and excision of the markedly thickened dura in myelopathy due to spinal canal stenosis.
    7. Bone marrow transplantation (Krivit et al. 1984; Herskhovitz et al. 1999) or hematopoietic stem cell transplantation in patients with the severe form of MPS VI.
        1. Efficacy
            1. Arylsulfatase B activity increased to normal levels in peripheral lymphocytes and granulocytes
            2. Decreased urinary excretion of acid mucopolysaccharide
            3. Decreased inclusions in the liver
            4. Improved cardiopulmonary function
            5. Improved visual acuity and joint mobility
            6. May provide better life quality (improved motor function, exertional dyspnea, severe snoring, and vertigo) (Wang et al. 2008)
        2. Not universally performed due to lack of a suitable donor and is associated with significant morbidity and mortality
    8. Allogeneic CD34-selected peripheral stem cell transplant with rapid hemopoietic and biochemical reconstitution (Alvaro et al. 1998).
    9. Successful umbilical cord blood transplantation (Lee et al. 2000).
    10. Enzyme replacement therapy (ERT).
        1. Clinical trials of enzyme replacement therapy with recombinant human *N*-acetylgalactosamine-4-sulfatase (rhASB) (Harmatz et al. 2006; 2004).
            1. Well tolerated
            2. Reduces lysosomal storage as evidenced by a dose-dependent reduction in urinary glycosaminoglycan
            3. An increase in distance walked
            4. Stair-climbing ability
            5. Shoulder range of motion
            6. Decrease in pain and arthritis
        2. The largest gains occurred in patients with advanced disease receiving high-dose rhASB.
        3. Before enzyme replacement therapy (ERT) with galsulfase (Naglazyme®), clinical management was limited to supportive care and hematopoietic stem cell transplantation. Galsulfase is now widely available and is a specific

therapy providing improved endurance with an acceptable safety profile (Valayannopoulos et al. 2010; Harmatz et al. 2014). Therapeutic response may be influenced by disease stage, and early intervention may lead to better outcomes (El Dib and Pastores 2009).

4. Long-term galsulfase ERT was beneficial and safe for Taiwanese patients with MPS VI. This treatment reduced urinary GAG and had positive effects on a wide range of clinical functional assessments including endurance, mobility, joint function, pulmonary function, liver and spleen size, cardiac hypertrophy, and diastolic dysfunction (Lin et al. 2016).

Mucopolysaccharidosis I (MPS I)

Contents

Mucopolysaccharidosis I consists of three clinical entities with varying degrees of clinical manifestations, all due to the same lysosomal enzyme deficiency, α-L-iduronidase. Hurler (MPS I-H) and Scheie (MPS I-S) syndromes represent phenotypes at the two ends of the clinical spectrum; the Hurler–Scheie syndrome (MPS I-H/S) represents a phenotype of intermediate clinical severity. In most instances, the subtype of MPS I can only be assigned on the basis of clinical criteria, including the rate of progression of symptoms. The incidences for MPS I-H, MPS I-H/S, and MPS I-S are estimated to be 1/76,000–1/144,000, 1/280,000, and 1/840,000–1/1,300,000 live births, respectively.

Synonyms and Related Disorders

α-L-Iduronidase deficiency; Hurler (MPS I-H); Hurler–Scheie (MPS I-H/S); Scheie (MPS I-S) syndromes

Genetics/Basic Defects

1. Inheritance: autosomal recessive
2. The *IDUA* gene (Scott et al. 1990)
   1. Localized to chromosome 4p16.3, close to the Huntington disease gene
   2. Spans 19 kb including 14 exons
3. Caused by mutations in the α-L-iduronidase (*IDUA*) gene (Scott et al. 1992, 1993, 1995; Lee-Chen et al. 1999)
   1. Two major alleles (W402X and Q70X) (Bunge et al. 1994; Beesley et al. 2001) and a minor allele (P533R) accounting for over half the MPS I alleles in the Caucasian population.
   2. No functional enzymes produced by above-mentioned alleles, giving rise to the severe form of α-L-iduronidase deficiency (MPS I-H).
   3. Limited mutations expected to cause the attenuated clinical phenotypes of MPS I-S or MPS I-H/S.
   4. One of the mutations resulting in Scheie syndrome is a base substitution in intron 7 that creates a new splice site and produces a frameshift. Since the old splice site is not obliterated, some normal enzymes still can be made to overcome the worst features of MPS I.
   5. Most other alleles that lead to MPS I-S or MPS I-H/S carry missense mutations (Lee-Chen and Wang 1997).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_161

6. In the Japanese population studied, MPS I-H/S results from compound heterozygosity of two mutations (704ins5 and R89Q), which, in homozygous form, would give rise to MPS I-H and MPS I-S, respectively (Yamagishi et al. 1996).

4. Genotype–phenotype correlations
   1. General principle (McKusick et al. 1972; Mueller et al. 1984)
      1. Any combination of two severe alleles leads to severe MPS I. A severe allele is one that produces the severe phenotype in either the homozygous state or compound heterozygous state.
      2. Intermediate and mild MPS I: usually associated with one severe allele and another allele that permits production of some residual enzyme activity.
   2. Alleles associated with severe phenotype
      1. Two common severe mutations (W402X and Q70X) always confer a severe phenotype whether present in a homozygous state or in a compound heterozygous state.
      2. Additional mutations (474-2a-g, A327P, P533R, A75T, L218P).
   3. Alleles associated with mild phenotype
      1. 678-7a-g
      2. R89Q
5. Pathophysiology
   1. Underlying molecular defect leads to a loss or marked reduction in α-L-iduronidase (*IDUA*), a lysosomal enzyme involved in the degradation of glycosaminoglycans heparan sulfate and dermatan sulfate.
   2. Because of the enzyme deficiency, excessive accumulation of acid mucopolysaccharides (glycosaminoglycans) in the tissue occurs, leading to a wide effect on various systems and remarkable changes in the morphogenesis.

Clinical Features

1. Hurler syndrome (MPS I-H)
   1. General clinical characteristics
      1. The prototype of MPS representing the severe end of clinical spectrum
      2. A progressive disorder with multiple organ and tissue involvement, leading to death in childhood
      3. Normal phenotype at birth and in early infancy but deteriorates progressively afterward
      4. Diagnosis usually made between 4 and 18 months of age
      5. Short stature (linear growth stops at 2–3 years of age)
      6. Developmental delay by age 12–24 months, with a maximum functional age at the level of 2–4 years, followed by progressive mental deterioration
   2. Coarse facial features (one of the earliest signs)
      1. Ocular hypertelorism
      2. Prominent eyes
      3. Bushy eyebrows
      4. Depressed nasal bridge
      5. Wide nostrils
      6. Large and thickened lips
      7. Large tongue
      8. Hypertrophy of the gum and the bony alveolar ridge
   3. Other craniofacial features
      1. A large scaphocephalic head with frontal bossing.
      2. Communicating hydrocephalus common after age 2–3 years. Shunting procedures may be beneficial for relieving increased intracranial pressure for some children.
      3. Noisy breathing with persistent nasal discharge (chronic rhinorrhea).
      4. Upper respiratory and ear infections.
   4. Ophthalmologic features
      1. Progressive clouding of the cornea (the hallmark of the syndrome) beginning at the first year of life, leading to impaired vision
      2. Open-angle glaucoma
      3. Retinal degeneration resulting in decreased peripheral vision
      4. Night blindness
   5. Auditory features
      1. Frequent sensorineural or mixed deafness

2. Contributing factors:
    1. Frequent middle ear infection from Eustachian tube dysfunction, caused by storage of glycosaminoglycans within the oropharynx
    2. Dysostosis of the ossicles of the middle ear
    3. Scarring of the tympanic membrane
    4. Damage to the eighth nerve
6. Cardiovascular features
    1. Cardiac valvular disease resulting from storage of mucopolysaccharide in the mitral, aortic, tricuspid, or pulmonary valves, leading to congestive heart failure.
    2. Thickened coronary artery valves, leading to angina pectoris and myocardial infarction.
    3. Possible fatal cardiomyopathy as a presenting feature for some MPS I infants less than 1 year old. Endocardial fibroelastosis has been noted postmortem in these patients.
    4. Aortic stenosis and uncontrolled hypertension (Taylor et al. 1991; Eakins and Kan 2010): although uncommon, aortic stenosis should be included in the differential diagnoses in children with Hurler syndrome and poorly controlled hypertension.
7. Gastrointestinal features
    1. Protuberant abdomen
    2. Progressive hepatosplenomegaly
8. Skeletal abnormalities: dysostosis multiplex
    1. Short neck
    2. Characteristic kyphoscoliosis when attempting to sit
    3. Ultimate frank gibbus deformity
    4. Stiff joints with limited mobility
    5. Claw hands (flexed stubby fingers and broad hands)
9. Connective tissue abnormalities
    1. Inguinal and umbilical hernias: common findings and usually present at birth
    2. Thick skin
10. Prognosis
    1. Bedridden before the end of the juvenile period
    2. Early demise prior to 10 years of age
    3. Usual causes of death
        1. Obstructive airway disease (Shapiro et al. 1985)
        2. Respiratory infection
        3. Cardiac complications

2. Scheie syndrome (MPS I-S)
    1. The mildest form of MPS I
    2. Normal stature
    3. Normal intelligence
    4. Onset of significant signs usually after 5 years
    5. Diagnosis commonly made between 10 and 20 years of age
    6. Coarse facial features
    7. Deafness in some patients
    8. Joint stiffness
        1. Claw hands
        2. Stiff painful foot
    9. Carpal tunnel syndrome
    10. Pes cavus
    11. Genu valgum
    12. Ocular manifestations
        1. Corneal clouding
        2. Glaucoma
        3. Retinal degeneration
    13. Aortic valvular disease (stenosis and regurgitation due to mucopolysaccharide deposits in the valves and chordae tendineae)
    14. Obstructive airway disease with sleep apnea in some patients
    15. Mild hepatosplenomegaly
    16. Mild dysostosis multiplex
    17. Less common pachymeningitis cervicalis (compression of the cervical cord by thickened dura) than MPS I-H/S
    18. Potential normal life span
3. Hurler–Scheie compound (MPS I-H/S)
    1. Clinical phenotype intermediate between Hurler and Scheie syndromes (Kajii et al. 1974; Kaibara et al. 1979)
    2. Progressive somatic involvement, including dysostosis multiplex, with little or no intellectual dysfunction

3. Age of onset: usually between 3 and 8 years
4. Survival to adulthood: common
5. Deafness
6. Craniofacial features
    1. Coarse facial features: less obvious
    2. Micrognathia in some patients
    3. Broad mouth
    4. Square jaw
    5. Short neck
7. Ophthalmologic features
    1. Corneal clouding in all patients
    2. Glaucoma
    3. Retinal degeneration
    4. Optic atrophy
8. Valvular heart disease (mitral valve insufficiency) developing by the early to mid-teens
9. Skeletal features
    1. Short stature
    2. Small thorax
    3. Severe joint involvement (stiffness)
    4. Kyphoscoliosis
    5. Back pain
    6. Characteristic claw hand deformity
    7. Carpal tunnel syndrome
10. Gastrointestinal features
    1. Varying degrees of hepatomegaly
    2. Hernias
11. Pachymeningitis cervicalis (compression of the cervical cord due to mucopolysaccharide accumulation in the dura)
12. Communicating hydrocephalus uncommon in patients who have normal intelligence
13. Spondylolisthesis of the lower spine, leading to spinal cord compression
14. Causes of death (age around teens and 20s)
    1. Upper airway obstruction
    2. Cardiac involvement

Diagnostic Investigations

1. Developmental assessment
2. Ophthalmologic examination
3. ECG and echocardiography for cardiovascular status (Nelson et al. 1990)
4. Cranial ultrasound for hydrocephalus
5. Skeletal survey
    1. Dysostosis multiplex
    2. Skull
        1. Large, thickened calvarium
        2. Premature closure of lambdoidal and sagittal sutures
        3. Shallow orbits
        4. Enlarged J-shaped sella
        5. Abnormally spaced teeth with dentigerous cysts
    3. Ribs
        1. Oar shaped and narrowed at the vertebral ends
        2. Flat/broad at the sternal ends
    4. Vertebra
        1. Beaked anteriorly (anterior hypoplasia) of lumbar vertebrae with kyphosis (an early sign)
        2. Scalloped posteriorly
        3. Thoracolumbar gibbus, resulting from anterior wedging of the vertebrae
        4. Hypoplasia of the odontoid, leading to atlantoaxial subluxation
    5. Pelvis
        1. Poorly formed pelvis
        2. Small femoral heads
        3. Coxa valga
    6. Long bones
        1. Widened diaphysis of the long bones
        2. Lack of normal modeling and tabulation
        3. Irregular metaphysis
        4. Poorly developed epiphyseal centers
        5. Distal ends of the radius and ulna angulate toward each other
        6. Claw hands
        7. Thickened and bullet-shaped phalanges
        8. Coarsening of the trabeculae of the phalanges and metacarpals
        9. Proximal narrowing of the metacarpals
        10. Marked irregularity and retarded ossification of the carpal bones
    7. Other bones
        1. Short, thickened, and irregular clavicles
        2. Shortened and trapezoid-shaped phalanges with widened diaphyses

6. Biochemical/molecular studies for MPS I-H, MPS I-HS, and MPS I-S
    1. Excessive urinary excretion of glycosaminoglycans (dermatan and heparan sulfates): a useful preliminary test
    2. Metachromatic staining of fibroblasts and leukocyte inclusions (nonspecific lab findings)
    3. Enzyme assay: deficient α-L-iduronidase in WBC, serum, cultured fibroblast, and CSF
    4. Accumulation of glycosaminoglycans in cultured fibroblasts correctable by uptake of α-L-iduronidase
    5. Mutation analysis or sequence analysis of *IUDA* gene: possible to identify both *IDUA* mutations in 95% of patients with MPS I
    6. Characterization of gene mutation: worthwhile for phenotype prediction and genetic counseling
7. Carrier testing
    1. Measurement of α-L-iduronidase enzyme activity: not a reliable method, requiring testing of obligatory carriers within the family first to determine if their levels of IDUA enzyme activity can be distinguishable from the normal
    2. Molecular genetic testing of *IUDA* to identify carriers among at-risk family members when both mutation alleles have been identified in an affected family member

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: 25% chance of being affected
    2. Patient's offspring:
        1. MPS I-S: not increased unless the spouse is a carrier
        2. MPS I-H and MPS I-H/S: not surviving to reproductive age
2. Prenatal diagnosis from samples of CVS, amniocentesis, and fetal blood (Fratantoni et al. 1969; Ikeno et al. 1981; Muenzer 1986; Young 1992; Fensom and Benson 1994)
    1. Enzyme assays (deficient α-L-iduronidase) and increased level of ^{35}S-sulfate incorporation measured in cultured cells obtained from amniocentesis or CVS for pregnancy at risk
    2. Mutation analysis of the *IDUA* gene in fetal DNA extracted from cells obtained by CVS or amniocentesis if both mutant *IDUA* alleles have been identified in a previously affected sib or in the parents of the at-risk fetus
3. Preimplantation genetic diagnosis (PGD) for at-risk pregnancies: requires prior identification of both *IDUA* disease-causing mutations in the family
4. Management (Clarke and Heppner 2011; Muenzer and Fisher 2004)
    1. Supportive care
        1. Early infant stimulation programs
        2. Eye care: corneal transplantation successful but donor grafts eventually becoming cloudy
        3. Range of motion exercises to preserve joint function
        4. Physical therapy
    2. Orthopedic surgery (Peters et al. 1998; Van Heest et al. 1998)
        1. Surgical decompression of the median nerve for carpal tunnel syndrome resulting in various restorations of motor hand activity
        2. Trigger digits
        3. Genu valgum
        4. Kyphoscoliosis
        5. Acetabular dysplasia
        6. Atlantooccipital stabilization
    3. Ventriculoperitoneal shunting for hydrocephalus
        1. Generally palliative
        2. May improve quality of life
    4. Tracheotomy or high-pressure continuous positive airway pressure with supplemental oxygen
    5. Tonsillectomy and adenoidectomy to correct Eustachian tube dysfunction and to decrease upper airway obstruction
    6. Cardiovascular care
        1. Bacterial endocarditis prophylaxis

2. Valve replacement surgery
3. Management of severe dilated cardiomyopathy: enzyme replacement therapy pre-transplant can improve cardiac function sufficiently to permit safe allogenic hematopoietic stem cell transplantation using myeloablative conditioning (Wiseman et al. 2013)
7. Surgical repair of inguinal hernias
8. Early surgical intervention to prevent severe complications from progressive compression of the spinal cord
9. Major anesthetic risks exhibited by patients with MPS I (Walker et al. 1994; Moores et al. 1996)
    1. Avoid hyperextension of the neck since dysostosis multiplex can lead to instability of the spine including the atlantoaxial joint.
    2. Difficulty in induction of anesthesia due to inability to maintain an adequate airway.
    3. Require fiberoptic laryngoscopy for intubation.
    4. Slow recovery from anesthesia.
    5. Common postoperative airway obstruction.
10. Allogenic bone marrow transplantation from an unaffected, HLA-compatible donor (Peters et al. 1996, 1998; Guffon et al. 1998)
    1. Beneficial effect: replacement of deficient macrophages by marrow-derived donor macrophages to provide ongoing source of normal enzyme capable of gaining access to the various sites of storage.
    2. Slows the course of cognitive decline if the therapy starts before the developmental delay is evident.
    3. Improves survival (Whitley et al. 1993), reducing facial coarseness, hepatosplenomegaly, hearing, and normal cardiac function.
    4. Skeletal manifestations (Vellodi et al. 1997) and corneal clouding continue to progress despite successful transplantation. Surgeries will be required for the persistent orthopedic problems.
    5. Significantly limited by the availability of donors. The immunosuppressive therapy for the prevention of rejection carries significant toxicity.
    6. The procedure of the transplantation carries a high risk of morbidity and mortality. Failure to achieve stable engraftment and development of graft-versus-host disease is a significant barrier to successful bone marrow transplantation for many children.
    7. Hematopoietic stem cell transplantation: the treatment of choice for a child with Hurler syndrome who is younger than 2 years of age and has minimal or no central nervous system disease (Muenzer 2004).
11. Cord blood transplantation (Staba et al. 2004)
    1. Use cord blood transplants from partially HLA-matched, unrelated donors.
    2. Donors readily available.
    3. An excellent source of stem cells for transplantation.
    4. Sustained engraftment can be achieved without total-body irradiation in young children.
    5. Low incidence for acute graft-versus-host disease (GVHD).
    6. Absence of extensive chronic GVHD.
    7. As effective as bone marrow transplantation.
    8. Unrelated umbilical cord blood transplantation was associated with improved somatic disease and neurodevelopment (Coletti et al. 2015).
12. Enzyme replacement therapy (ERT) (Kakkis et al. 2001; Kakkis 2002)
    1. An etiology-specific treatment that seeks to address the underlying

pathophysiology of MPS I by delivering sufficient IDUA activity to reverse and prevent glycosaminoglycan accumulation (Wraith et al. 2004)

2. Effectiveness depending on the ability of recombinant enzymes injected intravenously to enter cells and localize to the lysosome, the appropriate intracellular site
3. Use of recombinant human α-L-iduronidase (laronidase: Aldurazyme)
    1. Aldurazyme®: currently licensed in the USA, Europe, and Canada for use in treating non-CNS manifestations of MPS I. The current dose regime involves premedication with an anti-inflammatory and antihistamine drugs and intravenous weekly infusion of 100 U/kg of Aldurazyme® over 4 h (Clarke and Heppner 2011).
    2. Significant reduction in liver size.
    3. Increase in height and weight.
    4. Decrease in joint restriction.
    5. Improvement in breathing (respiratory function) and sleep apnea.
    6. Decreased glycosaminoglycan storage.
    7. Improvements in cardiopulmonary function, airway obstruction, and joint mobility in Hurler–Scheie syndrome (nonneuronopathic MPS I) (Bijarnia et al. 2009).
    8. Recommended for patients with milder or attenuated forms of MPS I. Infusions of recombinant enzyme are a safer alternative for treating the somatic disease and improving the quality of life of such patients. An intravenously administered enzyme is not expected to cross the blood–brain barrier and affect central nervous system disease (Muenzer 2004).
    9. Enzyme replacement therapy with laronidase can be used with pre- and peri-hematopoietic stem cell transplant, which is now the gold standard treatment in those patients diagnosed under 2.5 years of age (Jameson et al. 2013).
13. Hematopoietic stem cell transplantation (HSCT) (Bijarnia et al. 2009): treatment of choice for children <2 years of age with MPS I-H who have minimal or no central nervous disease
14. Combination of ERT followed by HSCT in neuronopathic Hurler syndrome
    1. Corrects the enzyme deficiency until endogenous enzyme production is established
    2. Reverses airway obstruction and cardiovascular complications, thus reducing mortality and morbidity at the time of transplant

Fig. 1 (**a**, **b**) A child with Hurler syndrome showing a large head with frontal bossing, coarse facial features, ocular hypertelorism, cloudy (steamy) cornea, depressed nasal bridge, large tongue, short neck, protuberant abdomen, umbilical hernia, stiff joints, and claw hands

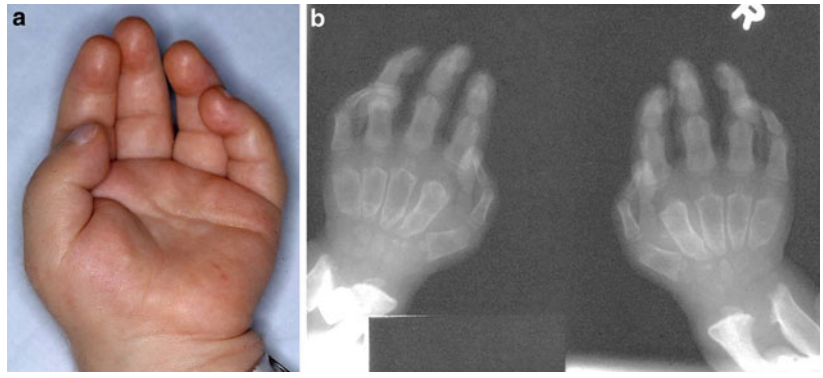

Fig. 2 (**a**, **b**) Claw hand. The radiographs show thick bullet-shaped phalanges, proximal narrowing of the metacarpals, poorly ossified carpal bones, and angulation toward each other of the distal ends of the radius and the ulnar

Fig. 3 (**a**, **b**) Radiographs showing oar-shaped ribs with relatively narrow proximal portion, narrow iliac bodies and flaring wings, shallow acetabula, coxa valga, anterior wedging of the lumbar vertebrae, decreased AP diameter of the vertebral bodies with posterior scalloping, and marked thoracolumbar gibbus

Fig. 4 (**a**, **b**) Radiograph of the upper extremities shows the lack of normal modeling and tabulation of the diaphyses, leading to short tubular bones. The radial and ulnar articular surfaces are angulated toward each other. Marked irregularity and retarded ossification of the carpal bones are noted. The findings in the lower extremities are less marked

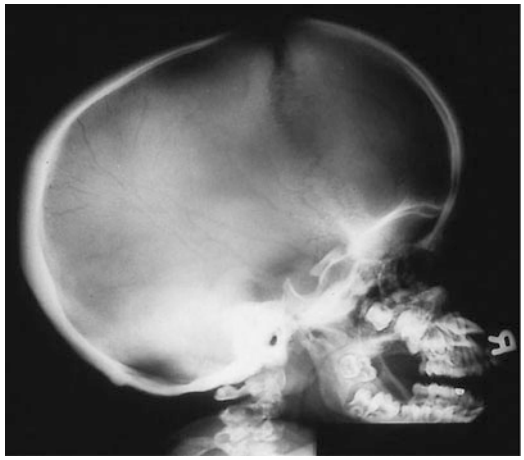

Fig. 5 Skull radiograph showing a large scaphocephalic calvarium with early appearance of the J-shaped sella turcica

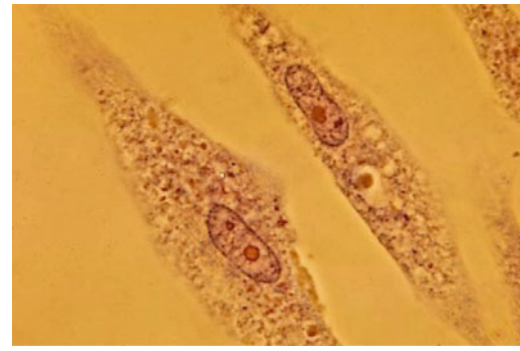

Fig. 7 Metachromasia of the cultured fibroblasts

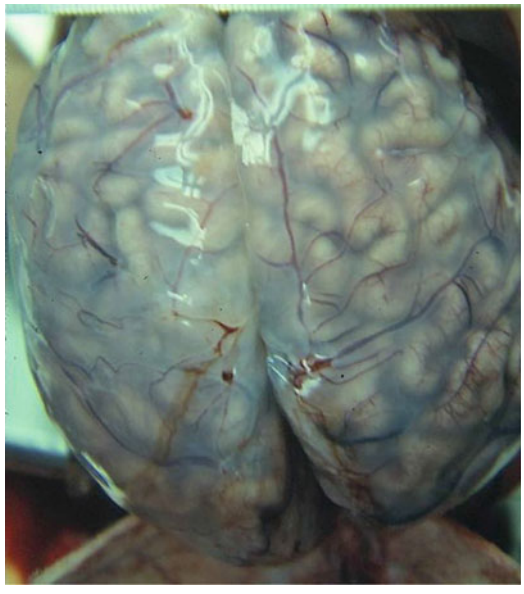

Fig. 6 Postmortem findings of the brain showing cloudy leptomeninges secondary to cloudy CSF

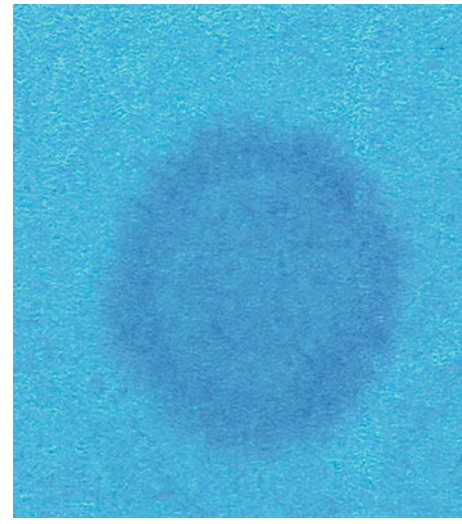

Fig. 8 Positive MPS spot test

Fig. 9 (**a**, **b**) A 14-month-old boy with Hurler syndrome showing a large head, coarse facies, protuberant abdomen, umbilical hernia, a lumbar gibbus, and claw hands. The radiographs showed cardiomegaly, thickened ribs, and beaked vertebral body (L2). The α-L-iduronidase enzyme level was 0.0 (87.10–190.50 nmol/mg/h)

Fig. 10 A 14-year-old boy with Hurler–Scheie compound showing short stature, semi-crouching stance, joint stiffness (**a**, **b**), coarse facies (**c**, **d**), and claw hands (**e**). When he was 3½ years old, he started to complain difficulty in raising his arms above his head and difficulty in moving his hands and fingers because of bent fingers and joint contractures. He was noted to have dwarfism; coarse thickened skin; hirsutism; a big head with frontal bossing; coarse facies with hypertelorism; cloudy cornea; large lips and large tongue; short neck; short trunk with a mild kyphosis; hepatomegaly; claw hands; anteriorly converted shoulders; protuberant abdomen; flexion contractures of elbows, wrists, and knees; and crouching stance. The urine was positive for mucopolysaccharide, and the blood was positive for metachromasia. Skin fibroblasts were deficient in α-L-iduronidase

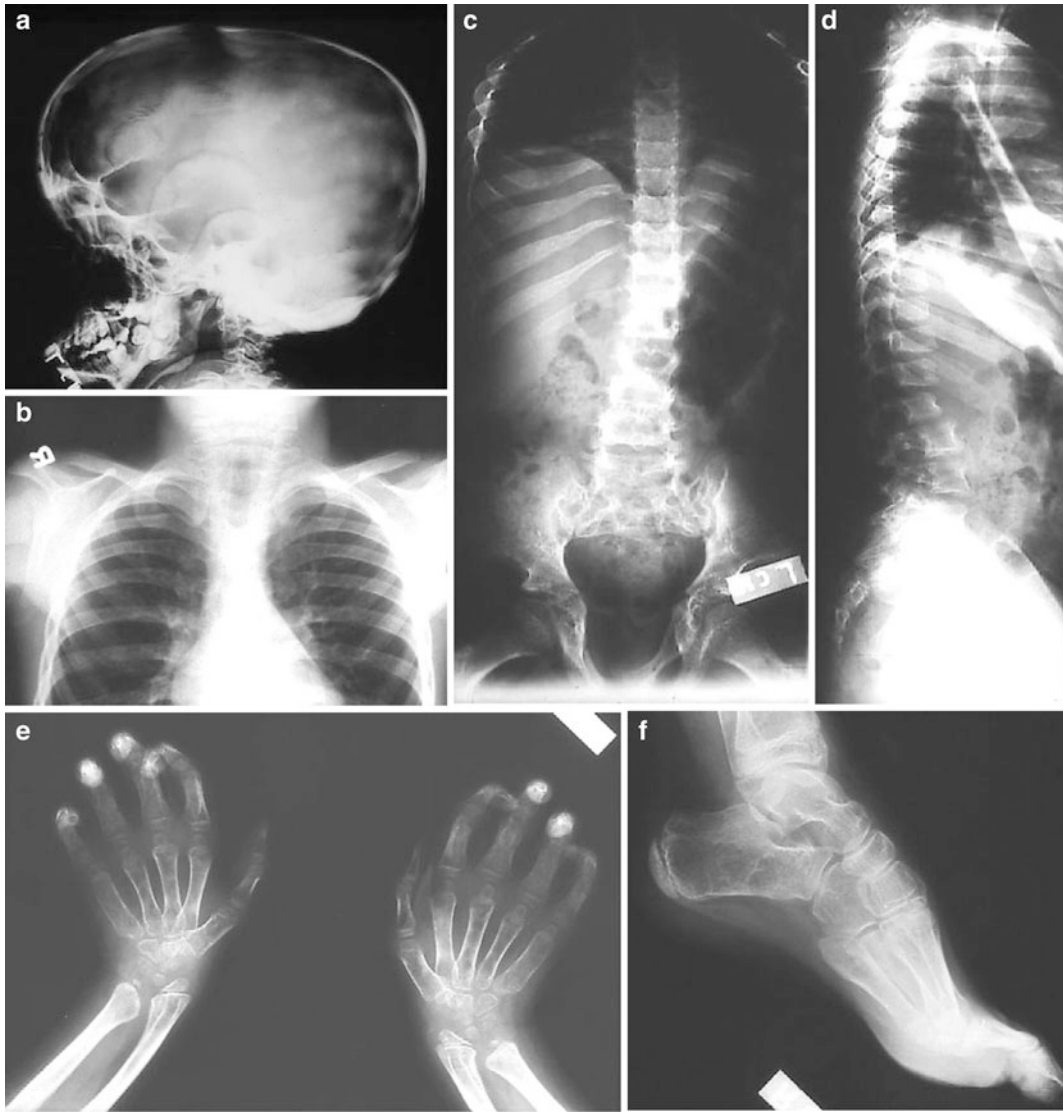

Fig. 11 Radiographs. The skull (**a**) shows macrocephaly, frontal bossing, small and airless mastoids, and anterior pocketing of the sella turcica ("shoe-shaped" or "J-shaped" sella). Clavicles (**b**) are short with widened medial aspects of both clavicles. Ribs are oar shaped and wide in their lateral and anterior portions with moderate narrowing of the paravertebral portions of the lower ribs (**c**, **d**). Vertebral bodies have concaved anterior and posterior margins and decreased in sagittal diameters. The second lumbar vertebra was hypoplastic with anterior inferior beaking forming almost a hook-shaped deformity. Claw hands were present with tapering of both distal ends of radius and ulna to form a "V shape" (**e**). Carpal bones were small, irregular, and crowded together. Metacarpals and phalanges were wide and short with proximal pointing of metacarpals. Bone age was retarded. Pes cavus was present (**f**)

Fig. 12 (**a**–**e**) A 7-year-old girl was diagnosed to have Hurler syndrome at the age of 2. She received a male, 4/6 HLA-matched unrelated umbilical cord blood transplant. She engrafted quickly with an absolute neutrophil count greater than 500 on day +28. Her transplant complications included a *Klebsiella* UTI prior to admission, mucositis, medicine-induced hypertension controlled with nifedipine, diarrhea treated with Flagyl empirically, and graft-versus-host disease. Presently, she has less coarse facial features, resolving cloudy cornea, and improved cognitive capacity, but still has some claw hands and lumbar gibbus which are illustrated radiographically

Fig. 13 (**a**–**d**) This is a 2 year-old girl evaluated originally for possible partial biotinidase deficiency from a newborn screening test. After a series of testings, she was found to be just a carrier for biotinidase deficiency (please see the chapter on "► Biotinidase Deficiency"). During the course of evaluation, she was noticed to have global delay, short stature, coarse facies, claw hands, and semi-crouching stance with knee crawling. The clinical and the following radiographic features (dysostosis multiplex) suggest Hurler syndrome. Urinary excretion of dermatan sulfate and heparin sulfate was elevated. Mucopolysaccharides were 171.9 which is markedly elevated (control:

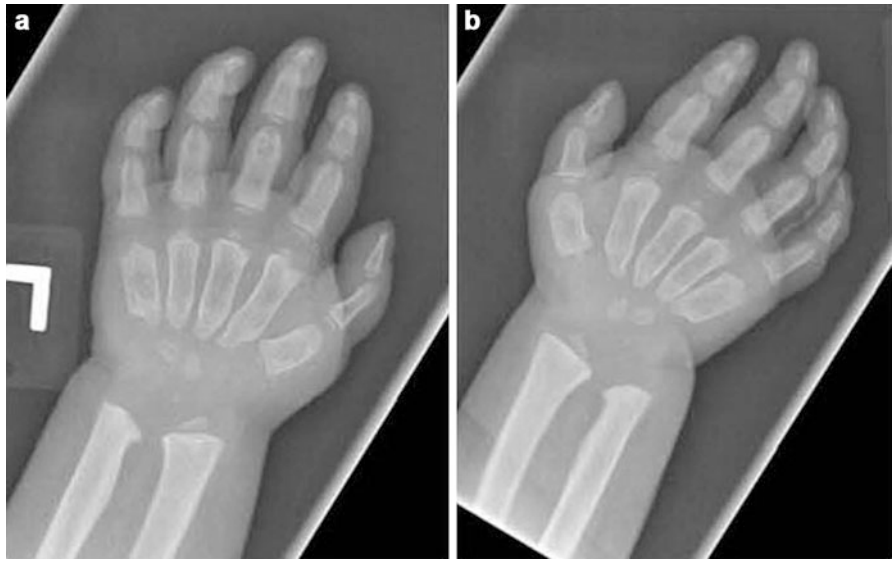

Fig. 14 (**a**, **b**) Radiographs of both hands showed claw hands, thickened bullet-shaped phalanges, proximal tapering of second to fifth metacarpals with widening of distal metacarpals, markedly retarded carpal bones, and slight tilting of distal radius and ulnar

Fig. 13 (continued) <24.0 mg/mmol). Lysosomal enzyme panel showed absent alpha-L-iduronidase activity which was consistent with the diagnosis of Hurler syndrome. IDUA gene sequencing showed homozygous in the IDUA gene for a sequence variant defined as c.1205G > A and predicted to result in premature termination p.Trp402Stop. This variant was documented as causative for MPS I. This result is consistent with diagnosis of MPS I. Interestingly, chromosome microarray analysis showed multiple regions of homozygosity >5 Mb including 4p16.3-p15.2 in which Hurler syndrome gene is located in 4p16.3

Fig. 15 AP view of the chest showed levoscoliotic curvature of lower thoracic spine, slight constriction of the posterior ribs at the costochondral joint junction (right, 9th to 11th; left, 11th), thickened scapula, and short and irregular clavicles

Fig. 17 Lateral view of the skull showed J-shaped sella turcica

Fig. 16 Lateral lumbar spine showed anterior beaking of L1 and L2

Multiple Endocrine Neoplasia Syndromes

Contents

The multiple endocrine neoplasia (MEN) syndromes are rare autosomal dominant conditions predisposing affected individuals to benign and malignant tumors of the pituitary, thyroid, parathyroid, adrenal, endocrine, pancreas, paraganglion, or nonendocrine organs. The classic MEN syndromes include MEN type 1 (MEN1) and MEN type 2 (MEN2). The prevalence of MEN1 is estimated to be 1 in 20,000–40,000 individuals and that of MEN2 is estimated to be 1 in 35,000 individuals (DeLellis et al. 2004).

MEN1 is a rare endocrine disorder presenting with various combinations of parathyroid, gastroenteropancreatic, and anterior pituitary tumors, but it can also include various combinations of more than 20 endocrine and nonendocrine tumors such as foregut, bronchial, and thymic carcinoids, lipomas and skin tumors (Gagel and Marx 2007). Generally, tumors in MEN1 are benign, although gastrinomas and foregut carcinoids may exhibit a malignant course (Falchetti et al. 2008).

MEN2 is a rare hereditary syndrome characterized by medullary thyroid carcinoma (MTC), unilateral or bilateral pheochromocytoma, and other hyperplasia and/or neoplasia of different endocrine tissues (Falchetti et al. 2008). If not diagnosed precociously, MTC can be fatal. MEN2 includes three clinical subtypes: MEN2A, MEN2B, and familial medullary thyroid carcinoma (FMTC).

Synonyms and Related Disorders

Familial medullary thyroid carcinoma; MEN1 (multiple endocrine adenomatosis, Wermer syndrome); MEN2A (pheochromocytoma and amyloid-producing medullary thyroid carcinoma, Sipple syndrome); MEN2B (mucosal neuroma syndrome)

Genetics/Basic Defects

1. MEN1
    1. Caused by a germline mutation in the *MEN1* gene, which encodes the tumor suppressor protein menin
    2. Mutated gene: *MEN1* (inactivating mutations of the MEN1 gene)
        1. Mapped on chromosome 11q13.
        2. Menin: consists of ten exons with noncoding first exon and produces a 610-amino acid protein.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_168

3. Two independent somatic mutations must occur within a single cell for tumor formation.
4. A single mutation is required in an individual with *MEN1*, since the first mutation is already present in all of the patient's cells (Pack et al. 1998; Vortmeyer et al. 1999).
5. This accounts for the multiple tumors and the tumors occurring at an earlier age.
6. Approximately 700 different somatic and germline mutations have been identified (Thakker 2001).

3. No genotype-phenotype correlations observed

2. MEN2 (Marquard and Eng 2015)
   1. Caused by germline-activating missense mutations of the rearranged during transfection (*RET*) proto-oncogene which:
      1. Mapped on chromosome 10q11.2
      2. Encodes a receptor tyrosine kinase that functions as a signal transducer upon interaction with the glial-derived neurotrophic factor family of ligands (Santoro et al. 2004)
      3. MEN2-associated mutations: almost always located in exons 10, 11, or 13 through 16, although mutations in exons 5 and 8 have been reported on rare occasions (Dvorakova et al. 2005; Da Silva et al. 2003)
   2. MEN2 is a genetic syndrome caused by mutations in the RET proto-oncogene with different penetrance producing three variants, MEN2A, MEN2B, and FMTC, each of which is characterized by MTC (Krampitz and Norton 2014).
   3. Strong genotype-phenotype correlations exist with respect to Raue and Frank-Raue (2012) and Romei et al. (2012).
      1. The MEN2 syndromes: characterized by a strong genotype-phenotype correlation and a specific RET mutation may be responsible for a particular phenotype and a more or less aggressive clinical course.
      2. This close association was firstly identified in an early study of 477 families affected by MEN2 (Eng et al. 1996) and confirmed by several other studies.
      3. MEN2 subtypes.
         1. MEN2A: at least 95% of individuals with MEN2A have an identifiable *RET* mutation (Schuffenecker et al. 1994; Mulligan et al. 1994).
         2. MEN2B: an identifiable *RET* mutation in at least 98% of patients. The mutation is almost invariably M918T. Some individuals with mutation A883F (Mulligan et al. 1995; Gimm et al. 1997).
         3. FMTC: mutated gene (*RET proto-oncogene*).
      4. Clinical subtype and associated diseases.
         1. MEN2A: cutaneous lichen amyloidosis, Hirschsprung disease
         2. MEN2B: ganglioneuromatosis, marfanoid habitus
         3. FMTC: rare
      5. Typical age at onset (years).
         1. MEN2A (10)
         2. MEN2B (2)
         3. FMTC (30)
3. MEN4 (Molatore and Pellegata 2010; Pellegata 2012)
   1. Heterozygous germline mutations in the human homologue, *CDKN1B*: identified in patients with multiple endocrine tumors.
   2. As a consequence of these observations, a novel human MEN syndrome, named MEN4, was recognized which is caused by mutations in p27.
   3. The recognition of both the MENX (rat) and the MEN4 (human) syndromes has demonstrated that Cdkn1b/CDKN1B is a new tumor susceptibility gene for multiple neuroendocrine tumors in both species.

Clinical Features

1. MEN1 (Marini et al. 2006a, b; Callender et al. 2008; Falchetti et al. 2008; Thakker et al. 2012; Giusti et al. 2015)

1. The presence of intrafamilial and interfamilial variation: highly variable in terms of the number of organ systems involved and the age of onset of tumors and symptoms
2. MEN1 should be considered in patients with the following diagnoses:
    1. Primary hyperparathyroidism under age of 30 years
    2. Primary hyperparathyroidism resulting from multigland involvement
    3. Familial primary hyperparathyroidism
    4. Zollinger-Ellison syndrome
    5. Multifocal pancreatic endocrine tumors or two or more MEN1-related tumors
3. Clinical diagnosis of MEN1 should be considered in:
    1. Patients with tumors in two of the three most commonly affected endocrine organs (parathyroid, pituitary, and pancreatic/duodenal endocrine tumors)
    2. Patients with one such tumor and a family history of MEN1
4. Clinical signs and symptoms: in order of decreasing frequency (Doherty 2005)
    1. Hypercalcemia
    2. Nephrolithiasis
    3. Peptic ulcer disease
    4. Hypoglycemia
    5. Visual field loss
    6. Hypopituitarism
    7. Acromegaly
    8. Galactorrhea-amenorrhea syndrome
    9. Rarely Cushing's syndrome
5. Includes varying combinations of more than 20 endocrine and nonendocrine tumors
6. Characteristic endocrine tumors (Schussheim et al. 2001)
    1. Parathyroid tumors: adenoma (90%).
        1. The main MEN1-associated endocrinopathy; onset in 90% of individuals is between ages 20 and 25 years with hypercalcemia evident by age 50 years.
        2. Hypercalcemia causes lethargy, depression, confusion, anorexia, constipation, nausea, vomiting, diuresis, dehydration, hypercalciuria, kidney stones, increased bone resorption/fracture risk, hypertension, and shortened QT interval.
    2. Pituitary tumors.
        1. Prolactinoma (20%): the most common which manifests as oligomenorrhea/amenorrhea and galactorrhea in females and sexual dysfunction in males
        2. GH and GH plus prolactin (10%)
        3. NF1 (5%)
        4. ACTH (2%)
        5. TSH and others (rare)
    3. Well-differentiated endocrine tumors of the gastroenteropancreatic tract.
        1. Gastrinoma (40%): can manifest as Zollinger-Ellison syndrome
        2. Insulinoma (10%): hypoglycemia
        3. Nonfunctioning including pancreatic polypeptide (20%)
        4. Glucagonoma: hyperglycemia, anorexia, glossitis, anemia, diarrhea, venous thrombosis, and skin rash
        5. Vasoactive intestinal peptide (VIP)-secreting tumor: watery diarrhea, hypokalemia, and achlorhydria syndrome
        6. Somatostatinoma
    4. Foregut carcinoid.
        1. Nonfunctioning (non-hormone-secreting) gastric enterochromaffin-like cell tumor (10%): can manifest as a large mass after age 50 years
        2. Bronchial carcinoid (2%)
        3. Thymic carcinoid (2%)
    5. Adrenocortical tumors can be associated with primary hypercortisolism or hyperaldosteronism.
7. Nonendocrine tumors
    1. Facial angiofibromas
    2. Collagenomas
    3. Lipomas
    4. Meningiomas
    5. Ependymomas
    6. Leiomyomas

8. Prognosis
    1. Decreased life expectancy, with a 50% probability of death by age of 50, and one half of MEN1 patients die as a result of a malignant tumoral process or sequela of the disease (Wilkinson et al. 1993; Doherty et al. 1998; Dean et al. 2000).
    2. Pancreatic neuroendocrine tumors are responsible for significant morbidity and mortality in MEN1 kindreds.
2. MEN2 (Marquard and Eng 2015)
    1. Following characteristics in a single patient
        1. Hallmark of MEN2: an extremely high lifetime risk of developing medullary thyroid carcinoma (MTC) (>95% in untreated patients)
        2. Unilateral or bilateral pheochromocytoma
        3. Other hyperplasia and/or neoplasia of different endocrine tissues
    2. Signs and symptoms (Richards 2015)
        1. Hypertension if a pheochromocytoma presents
        2. Chronic constipation: constant finding in MEN2B patients resulting from hyperplasia of the intrinsic autonomic ganglia in the intestinal wall
        3. A neck mass or dominant thyroid nodule with nontender anterior neck lymph nodes arising insidiously with progressive enlargement: may signify regional metastasis
        4. MEN2B patients
            1. Marfanoid habitus (high-arched palate, pectus excavatum, bilateral pes cavus, and scoliosis).
            2. Neuromas on the eyelids, conjunctiva, nasal and laryngeal mucosa, tongue, and lips (Wray et al. 2008).
            3. Prominent hypertrophied lips leading to a characteristic facies.
    3. The presence of three clinical subtypes
        1. MEN2A
        2. MEN2B
        3. Familial MTC (FMTC)
3. MEN2A
    1. The most common subtype.
    2. Associated with MTC.
    3. Risk of developing pheochromocytoma (approximately 50%).
    4. Risk of developing primary hyperparathyroidism (30–40%).
    5. Diagnosed clinically by the occurrence of two or more specific endocrine tumors (medullary thyroid carcinoma, pheochromocytoma, or parathyroid adenoma/hyperplasia) in a single individual or in close relatives.
    6. Familial MTC: diagnosed in families with four or more cases of MTC in the absence of pheochromocytoma or parathyroid adenoma/hyperplasia.
    7. Typical age at onset of biochemical evidence of MTC in untreated patients with MEN2A: 15–20 years. However, MTC is frequent in children ages 10 years and younger (Lips et al. 1994; Machens et al. 2003; O'Riordain et al. 1994).
    8. Rare variants of MEN2A can be associated with paraneoplastic syndromes.
        1. Cutaneous lichen amyloidosis
        2. Excessive production of corticotrophin
        3. Hirschsprung disease
4. MEN2B (also formerly known as MEN3) (Wray et al. 2008)
    1. Diagnosed clinically by the presence of early onset MTC, mucosal neuromas of the lips and tongue, as well as medullated corneal nerve fibers, distinctive facies with enlarged lips, and an asthenic "marfanoid" body habitus (American Thyroid Association Guidelines Task Force et al. 2009).
    2. The rarest and most aggressive subtype.
        1. Associated with the earliest onset (usually 10 years earlier than that for MEN2A) and most aggressive type of MTC
        2. Pheochromocytomas (40–50% of patients)
        3. Multiple neuromas and/or diffuse ganglioneuromatosis of the gastroenteric mucosa (approximately 40% of patients)
    3. Characteristic facial appearance: resulting from mucosal neuromas in the tongue, lips, and eyelids (Schimke et al. 1968).
        1. Enlarged lips

2. A "bumpy" tongue
3. Eversion of the eyelids

4. Often with a thin and lanky (Marfanoid) habitus with increased joint mobility and with decreased subcutaneous fat.
5. Frequently with thickening of the corneal nerves or ganglioneuromatosis of the gastrointestinal tract, which can result in abdominal distention, megacolon, constipation, or diarrhea.
6. The physical traits: usually evident in early childhood.
7. Without prophylactic thyroidectomy at a young age (before 1 year of age), most patients with MEN2B develop metastatic MTC in childhood or adolescence (O'Riordain et al. 1994).
8. Patients with MEN2B do not develop primary hyperparathyroidism.

5. Familial medullary thyroid carcinoma (FMTC)
   1. MTC is the only clinical feature.
   2. Refers to occurrence of medullary thyroid cancer in at least four affected members within the same family with documented absence of other endocrinopathies.
   3. Clinical course of MTC.
      1. More benign than that of MEN2A and MEN2B
      2. Prognosis: relatively good in most cases
6. MEN4 (Pellegata et al. 2006; Molatore and Pellegata 2010; Marinoni and Pellegata 2011; Lee and Pellegata 2013a, 2013b; Grajo et al. 2016)
   1. Pituitary tumors
      1. Prolactinomas
      2. Somatotropinomas
      3. Adrenocorticotrophinomas
   2. Parathyroid tumors: parathyroid adenoma
   3. Others
7. Mortality (Diaz-Thomas 2014)
   1. Complicated peptic ulcer disease.
   2. Metastases of endocrine pancreatic tumors.
   3. Severe hypercalcemia with arrhythmias.
   4. Metastatic MTC.
   5. Catecholamine release-related arrhythmias.
   6. Coronary heart disease.
   7. Stroke.
   8. Heart failure.
   9. Arrhythmias from cardiac myxomas.
   10. Zollinger-Ellison syndrome (ZES) is the major cause of morbidity and mortality in type 1 MEN.
   11. Mortality in type 2B MEN is mainly due to the aggressive nature of MTCs.
8. Differential diagnosis of other categories of MEN (Hoff et al. 2000; Callender et al. 2008)
   1. Von Hippel-Lindau syndrome (VHL)
      1. Mutated gene: *VHL*
      2. Manifestations
         1. Pheochromocytoma
         2. Retinal and central nervous system hemangioblastoma
         3. Renal cysts and clear cell carcinoma
         4. Pancreatic cysts and islet cell tumors
         5. Endolymphatic sac tumors
         6. Papillary cystadenomas of the epididymis and broad ligament
   2. Familial pheochromocytoma/paraganglioma syndrome
      1. Mutated gene: *SDHB*, *SDHC*, *SDHD*
      2. Manifestations: multiple paragangliomas and pheochromocytoma
   3. Cowden syndrome
      1. Mutated gene: *PTEN*
      2. Manifestations
         1. Nonmedullary thyroid cancer (usually follicular rather than papillary)
         2. Benign and malignant tumors of the skin, oral mucosa, breast, and uterus
   4. Carney complex
      1. Mutated gene: *PRKAR1A*
      2. Manifestations
         1. Endocrine tumors (including thyroid, pituitary, and primary pigmented nodular adrenocortical diseases)
         2. Characteristic skin pigmentation
         3. Myxomas
         4. Melanotic schwannomas

5. Familial isolated hyperparathyroidism
    1. Mutated gene: *MEN1*, *HRPT2*, *CASR*, and others
    2. Manifestations: nonsyndromic primary hyperparathyroidism
6. Hyperparathyroidism-jaw tumor syndrome
    1. Mutated gene: *HRPT2*
    2. Manifestations
        1. Primary hyperparathyroidism (usually single adenoma)
        2. Ossifying fibromas of maxilla or mandible
        3. Renal cysts and hamartomas
        4. Fifteen percent risk of parathyroid carcinoma
7. Familial hypocalciuric hypercalcemia
    1. Mutated gene: *CASR*
    2. Manifestations
        1. Benign hypercalcemia.
        2. Hypocalciuria.
        3. Low to normal parathyroid hormone levels.
        4. Renal calcium-to-creatinine clearance ratio <0.01.
        5. Parathyroidectomy does not cure hypercalcemia.
8. Neurofibromatosis type I
    1. Mutated gene: *NF1*
    2. Manifestations
        1. Pheochromocytoma
        2. Characteristic physical features (e.g., café-au-lait spots, neurofibromas, axillary and inguinal freckling)
9. Familial adenomatous polyposis
    1. Mutated gene: *APC*
    2. Manifestations
        1. Hundreds of adenomatous colon polyps
        2. Colon cancer
        3. Cribriform-morular variant of papillary thyroid cancer
10. Familial nonmedullary thyroid cancer
    1. Mutated gene: unknown
    2. Manifestations: nonsyndromic nonmedullary thyroid cancer

Diagnostic Investigations

1. Diagnosis of component tumors in MEN1 (Callender et al. 2008)
    1. Hyperparathyroidism
        1. An elevated or high-normal serum calcium level in concordance with an inappropriately elevated serum parathyroid hormone level.
        2. A 24-h urine collection documenting no evidence of hypocalciuria (urinary calcium excretion <100 mg/24 h) should be performed to exclude the possibility of familial hypocalciuric hypercalcemia.
    2. MEN1-related pituitary adenomas
        1. Most common functioning tumors produce prolactin (prolactinomas), growth hormone (somatotropinomas), or corticotropin
        2. Approximately 15% of tumors are nonfunctioning with no hormone production (DeLellis et al. 2004)
    3. Pancreatic and duodenal tumors
        1. Gastrinomas
            1. Gastrin level usually $>1{,}000$ pg/mL.
            2. A rise in the gastrin level of >200 pg/mL by a secretin stimulation test confirms the diagnosis.
            3. Tumors localized by a combination of octreotide scan, CT, and endoscopic ultrasonography.
        2. Insulinomas presents as "Whipple's triad":
            1. Fasting- or exercise-induced hypoglycemia
            2. Plasma glucose level <50 mg/dL
            3. Reversal of symptoms with administration of glucose
            4. Localized by CT and endoscopic ultrasonography
        3. Glucagonomas
            1. A serum glucagon level $>1{,}000$ pg/mL.
            2. A secretin stimulation test may be useful.
            3. Localized with an octreotide scan, CT, and endoscopic ultrasonography.

4. Vasoactive intestinal peptide tumors (VIPomas)
    1. Fasting plasma vasoactive intestinal peptide (VIP) levels >200 pg/mL
    2. VIPomas: usually located in the body and tail of the pancreas and are localized by an octreotide scan, CT, and endoscopic ultrasonography
5. Somatostatinoma
    1. A fasting somatostatin level of >100 pg/mL
    2. Localized with an octreotide scan, CT, and endoscopic ultrasonography
6. Nonfunctioning MEN1-associated pancreatic endocrine tumors: localized by an octreotide scan, CT, and endoscopic ultrasonography

4. Other tumor types: not part of the diagnostic criteria for MEN1, but their presence helps to support a diagnosis of MEN1
    1. Foregut (thymic, bronchial, or gastric) carcinoid tumors
    2. Adrenal cortex tumors (adenomas, pheochromocytoma, adrenocortical carcinomas)
    3. Thyroid tumors (follicular adenomas, goiters, nonmedullary thyroid carcinoma)
    4. Benign facial angiomas
    5. Collagenomas of the neck, upper limbs, and chest
    6. Subcutaneous or visceral lipomas
    7. Uterine or esophageal leiomyomas
    8. Meningiomas
    9. Spinal ependymomas

2. Diagnosis of component tumors in MEN2 (Falchetti et al. 2008; Marquard and Eng 2015).
    1. Medullary thyroid carcinoma and C-cell hyperplasia.
        1. The presence of an elevated plasma calcitonin concentration, a specific and sensitive marker.
        2. Pentagastrin or calcium stimulation to evaluate calcitonin secretion: earlier detection of MTC.
        3. Ultrasonography, CT, or MRI: localized tumor extension and possible distant metastases.
    2. Pheochromocytoma.
        1. Suspected when biochemical screening reveals elevated excretion of catecholamines and catecholamine metabolites (e.g., norepinephrine, epinephrine, metanephrine, and vanillylmandelic acid (VMA)) in plasma.
        2. 24-h measurement of urinary excretion of catecholamines and their metabolites to assess adrenal gland function: recommended on an annual basis.
        3. CT and MRI to localize the tumor.
    3. Primary hyperparathyroidism
        1. Diagnosis: made by elevated serum parathyroid hormone (PTH) and calcium concentrations.
        2. Postoperative parathyroid localizing studies with 99mTc-sestamibi scintigraphy may be helpful if hyperparathyroidism recurs.
        3. For preoperative adenoma localization, three-dimensional single-photon emission CT (SPECT) may also be used (Brenner and Jacene 2008).

3. Routine surveillance of presymptomatic patients and treated patients who are currently without evidence of disease (Brandi et al. 2001).
    1. Annual biochemical testing for all tumor types
        1. Parathyroid: serum calcium, parathyroid hormone (starts to screen at age of 8 years)
        2. Gastrinoma: serum gastrin (starting at age of 20 years)
        3. Insulinoma: fasting serum glucose, insulin (starting at age of 5 years)
        4. Other enteropancreatic: chromogranin A, glucagons, proinsulin (starting at age of 20 years)
        5. Anterior pituitary: prolactin, insulin-like growth factor 1 (starting at age of 5 years)

2. Imaging studies (CT or MRI) every 3 years
    1. Other enteropancreatic: octreotide scan, CT, or MRI (starting at age of 20 years)
    2. Anterior pituitary: MRI of the brain (starting at age of 5 years)
    3. Foregut carcinoid: CT (starting at age 30 years)
4. An excellent comprehensive imaging review (ultrasound, CT, PET-CT, MRI findings): available on multiple endocrine neoplasia syndromes (Grajo et al. 2016).
5. Molecular genetic testing for MEN1.
    1. Should be offered to patients in whom a diagnosis of MEN1 is being considered.
    2. The benefit of offering genetic testing: a diagnosis of MEN1 at an early age allows patients to be monitored for the development of subsequent MEN1-related tumors.
    3. Sensitivity of genetic testing: varies, depending on the combination of affected organs and whether the patient is an index or familial case.
    4. Mutations can be identified in only 75–90% of patients with a clinical diagnosis of MEN1.
        1. A negative test result cannot definitively rule out the risk for further MEN1-related tumors.
        2. Follow-up screening recommendations in such cases are controversial and require careful consideration of the index of suspicion of MEN1 based on the patient's personal and family history.
6. Molecular genetic testing for MEN2 (Moline and Eng 2010; Marquard and Eng 2015).
    1. MEN2A
        1. Approximately 95% of families with MEN2A have a *RET* mutation in exon 10 or 11.
        2. Other rare mutations, including codon 804 alterations, have been reported in a few cases.
    2. MEN2B
        1. Approximately 95% of individuals with the MEN2B phenotype have a single point mutation in the tyrosine kinase domain of the *RET* gene at codon 918 in exon 16 (M918T).
        2. Other rare mutations include second mutation at codon 883 in exon 15 (A883F) and two mutations (V804M and Y806C) in cis configuration.
7. Molecular genetic testing for FMTC (Moline and Eng 2010; Marquard and Eng 2015): approximately 88% of families with FMTC have an identifiable *RET* mutation.

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: a 50% risk if a parent is affected or has a disease-causing mutation
    2. Patient's offspring: a 50% risk of inheriting the mutation
2. Prenatal diagnosis and preimplantation genetic diagnosis: possible for pregnancies at increased risk by analysis of DNA extracted from fetal cells by amniocentesis or CVS, provided the disease-causing allele of an affected family member must be identified or linkage established in the family
3. Management
    1. MEN1 (Callender et al. 2008)
        1. Parathyroidectomy for parathyroid tumors
        2. Transcervical thymectomy because there is an increased risk of supernumerary parathyroid glands and developing carcinoid tumors in the thymus
        3. Pituitary tumors
            1. Surgery (usually from a minimally invasive transsphenoidal approach)
            2. Medication for patients with prolactin- or growth hormone-producing tumors with dopamine agonists, such as bromocriptine or cabergoline, and a GH receptor antagonist, respectively
            3. Radiation
        4. Gastrinomas
            1. Proton pump inhibitors for medical control of acid hypersecretion
            2. Surgical approaches: no consensus
        5. Insulinomas
            1. Manage surgically

2. Treat unresectable tumors with diazoxide (Proglycem)
6. VIPoma
   1. Manage surgically
   2. Octreotide (Sandostatin) for diarrhea control

2. MEN2 (Falchetti et al. 2008)
   1. Medullary thyroid carcinoma
      1. Total thyroidectomy with lymph node dissection of at least the central compartment.
      2. An elevated serum calcitonin level after surgery can be a sign of persistent, recurrent, or generalized MTC.
      3. Total thyroidectomy within the first month of life should be performed in patients with the highest risk mutations (MEN2B, codons 883 and 918) (Lewis and Yeh 2008).
   2. Pheochromocytoma
      1. Surgical laparoscopy excision.
      2. Recommend lifelong follow-up after surgery.
      3. Long-term drug treatment with α and β adrenergic blockers should only be considered in those patients in whom the tumor is unresectable.
   3. Primary hyperparathyroidism
      1. Subtotal parathyroidectomy or total parathyroidectomy with autotransplantation of normal fresh or cryopreserved tissue in the forearm.
      2. All individuals who have undergone partial or total parathyroidectomy with autotransplantation need to be monitored for possible recurrences.

Fig. 1 (**a**–**c**) The patient, a 13-year-old Caucasian female, was seen initially because of a history of weight loss of approximately 17 pounds over a period of 4–6 weeks and a mass in her neck. The biopsy of the neck mass revealed a medullary thyroid carcinoma. She has a long history of developmental delay and an unusual appearance with a thin body habitus, long face, and full lips. *MEN2* mutation screening revealed a sequence change in exon 16 of 2,753 T > C (ATG > ACG) with an amino acid change of M918T (Met918Thr). The presence of this mutation in codon 918 of the RET proto-oncogene is consistent with a clinical diagnosis of MEN2B

Multiple Epiphyseal Dysplasia

Contents

In 1945, Fairbank first described multiple epiphyseal dysplasia (MED). MED is a type of short-limbed dwarfism characterized by impaired endochondral ossification affecting multiple epiphyses and premature degenerative joint disease.

Synonyms and Related Disorders

Autosomal dominant multiple epiphyseal dysplasia (Fairbank type, Ribbing type); Autosomal recessive multiple epiphyseal dysplasia (with bilayered patellae, with clubfoot)

Genetics/Basic Defects

1. Inheritance: genetically heterogeneous (Deere et al. 1995)
   1. Autosomal dominant (Maudsley 1955; Murphy et al. 1973; Briggs et al. 2015)
      1. Multiple epiphyseal dysplasia type I (EDM1)
      2. Multiple epiphyseal dysplasia type II (EDM2)
      3. Multiple epiphyseal dysplasia type III (EDM3)
      4. Multiple epiphyseal dysplasia type V (EDM5)
      5. Multiple epiphyseal dysplasia type VI (EDM6)
   2. Autosomal recessive: multiple epiphyseal dysplasia type IV (EDM4) (Bonafé et al. 2014)
2. Causes
   1. EDM1: mutations in the gene (*COMP*) encoding cartilage oligomeric matrix protein (COMP) on the centromeric region of 19p (19p13.1-p12) (Oehlmann et al. 1994), same locus as (allelic to) pseudoachondroplasia (the disease that shares some clinical features with multiple epiphyseal dysplasia) (Briggs et al. 1995, 1998; Ballo et al. 1997; Deere et al. 1999; Ikegawa et al. 1998; Unger and Hecht 2001)
   2. EDM2 (Muragaki et al. 1996): mutations in the type IX collagen, alpha-2 polypeptide gene (*COL9A2*) on 1p33-p32.2
   3. EDM3: caused by heterozygous mutation in the *COL9A3* gene on 20q13 (Paassilta et al. 1999)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_169

4. EDM4 (Bonafé et al. 2014)
    1. Mutations in the diastrophic dysplasia sulfate transporter gene (*DTDST*) (SLC26A2) on 5q32-q33.1.
    2. Recessive mutations in the *DTDST* gene also cause a spectrum of osteochondrodysplasias, including achondrogenesis type IB, atelosteogenesis type II, and diastrophic dysplasia (Superti-Furga et al. 1999, 2000).
5. EDM5 (Chapman et al. 2001): mutations in the gene (*MATN3*) encoding matrilin-3 on 2p24-p23
6. EDM6: (Czarny-Ratajczak et al. 2001; Mortier et al. 2001): mutations in the type IX collagen, alpha-1 polypeptide gene (*COL9A1*) on 6q13

3. Mutations in extracellular matrix proteins, COMP, types II and IX collagens, and matrilin 3
    1. Produce a spectrum of mild to severe chondrodysplasias characterized by epiphyseal and vertebral abnormalities
    2. Disrupt protein processing and excessive accumulation of some of these proteins in the rough endoplasmic reticulum (rER) that appears to compromise cellular function
4. Genotype-phenotype correlations (Unger et al. 2001; Briggs et al. 2015)
    1. Patients with *COMP* mutations
        1. Significant involvement at the capital femoral epiphyses
        2. Irregular acetabuli
    2. Patients with type IX collagen defects
        1. More severe involvement of the knees
        2. Relative sparing of the hips
    3. Patients with *MATN3* mutations
        1. Abnormalities similar to those in patients with *COL9A2* mutations: more severe hip abnormalities.
        2. More intrafamilial/interfamilial variability.
        3. Clinical manifestations of MED caused by *MATN3* were milder than manifestations of the COMP mutation group. These differences in clinical manifestation and prognosis justify molecular differentiation between the two genotypes (Seo et al. 2014).

Clinical Features

1. Broad historical classification: has not proved useful (Chapman et al. 2003)
    1. Ribbing: milder form with flat epiphyses and minimal involvement of the hands and feet
    2. Fairbank: more severe form with late-appearing epiphyses and greater involvement of the hands and feet
2. Onset usually in childhood: as a rule, not recognizable at birth or during the first 1–2 years of life
    1. Joint pain after exercise initially: a common presenting sign
    2. Limp, pain, and stiffness in hip, knee, and ankle joints
    3. Waddling gait
    4. Easy fatigue
3. Mild to moderate short stature with normal body proportion
4. Mild short-limbed dwarfism
5. Stubby hands and feet
6. Osteoarthritis: severe osteoarthritis of the hip develops in early childhood.
7. Limited joint motions
8. Proximal muscle weakness with mild variability in muscle fiber size in EDM3
9. Association with diabetes mellitus in early infancy (Wolcott-Rallison syndrome)
10. Consider MED (Unger et al. 2008) in
    1. Any child with bilateral Perthes disease
    2. Any child with noninflammatory joint pain, especially involving the knees
    3. Family history of early joint replacement
11. Prognosis
    1. Normal life expectancy
    2. Joint deformities resulting from abnormal epiphyseal ossification frequently leading to early degenerative arthroses
12. Distinctive features of the different forms of MED (Unger et al. 2008)
    1. EDM1 (COMP-MED)
        1. Distinctive clinical features
            1. Muscular hypotonia
            2. Pseudomyopathy

3. Joint laxity
4. Mild genu vara

2. Distinctive radiographic features
1. Hand: carpal bones more delayed than phalangeal epiphyses; ragged carpal bones, small, rounded phalangeal epiphyses
2. Proximal femoral epiphyses: round and small
3. Knee: small epiphyses with lateral thinning, additional ossification centers with "glacier crevice" sign before puberty

2. EDM2 (*COL9A2*)
1. Rare but may be under reported
2. Knee epiphyses: more affected than proximal femoral epiphyses

3. EDM3 (*COL9A3*)
1. Rare but may be under reported
2. Knee epiphyses: more affected than proximal femoral epiphyses

4. EDM4 (rMED)
1. Homozygous and compound heterozygous mutations in the *DTDST* gene lead to a relatively mild phenotype that seems to be clinically dominated by a tendency to recurrent dislocation of a bilateral multilayered patella and by early onset osteoarthritis of the hip joints (Miyake et al. 2008; Cho et al. 2010; Hinrichs et al. 2010).
2. Distinctive clinical features.
1. Clubfeet at birth
2. Genu valga rather than genu vara
3. Joint contractures
4. Mild to moderate brachydactyly
3. Distinctive radiographic features.
1. Hand: phalangeal epiphyses delayed, but maturation of carpal bones normal or advanced; flat epiphyses or phalanges and radius; "snow cap" sign of metacarpals
2. Proximal femoral epiphyses: small and flat
3. Knee: double-layered patella

5. EDM5 (MATN3-MED)
1. Distinctive clinical features: not specific
2. Distinctive radiographic features
1. Hand: unspecific changes at the hands
2. Proximal femoral epiphyses: small but not as rounded as in COMP-MED
3. Knee: small epiphyses with "harlequin hat" appearance; metaphyseal striations

6. EDM6 (*COL9A1*): very rare (only single family reported)

Diagnostic Investigations

1. Radiography (Chapman et al. 2003; Mäkitie et al. 2004).
1. Radiographic abnormalities may be present before the onset of physical symptoms.
2. Predominantly epiphyseal involvement.
1. Initial stage: delayed appearance of epiphyseal ossification
2. Later stage in the appearance of epiphysis
1. Usually small ossification centers.
2. Sometimes fragmented ossification centers with irregular contours.
3. Adjacent metaphyseal borders may be slightly abnormal.
3. Adulthood
1. Flattened and dysplastic articular surfaces
2. The presence of early features of osteoarthrosis
4. Characteristic epiphyseal involvement
1. Epiphyses of the hips and knees: most affected
2. Ivory epiphyses in the hands
3. Schmorl nodes in the spine
4. Double-layered patella (Sheffield 1998; Superti-Furga et al. 1999)
3. Vertebrae.
1. Ovoid vertebral bodies
2. Mildly irregular vertebral endplates

4. Limbs.
    1. Late ossifying epiphyses
    2. Small, irregular, fragmented, and in some cases flattened epiphyses
    3. Osteoarthritis
    4. Short femoral neck
    5. Markedly dysplastic capital femoral epiphyses
    6. Often initially diagnosed as Legg-Perthes disease (avascular necrosis of the femoral head)
    7. Genu varum or valgum
    8. Short metacarpals and phalanges with irregular epiphyses
    9. Small, irregular carpal and tarsal bones
    10. Normal metaphyses
5. Irregular acetabuli.
6. Patella.
    1. Double-layered
    2. Dislocation or subluxation
7. The absence of severe spinal involvement and minimal metaphyseal defects allows differentiating multiple epiphyseal dysplasia from other disorders with similar clinical features such as spondyloepimetaphyseal dysplasia and spondyloepiphyseal dysplasia.

2. Histology: chondrocytic inclusion (ultrastructurally, a dilated rER containing accumulated material) (Stanescu et al. 1993).
3. Molecular genetic diagnosis is important for accurate prognosis and genetic counseling: mutation analyses are available on clinical basis.
    1. Mutations in the *COMP* gene
    2. Mutations in the *COL9A1* gene
    3. Mutations in the *COL9A2* gene
    4. Mutations in the *COL9A3* gene
    5. Mutations in the *MATN3* gene
    6. Mutations in the *DTDST* gene

Genetic Counseling

1. Recurrence risk.
    1. Autosomal dominant inheritance
        1. Patient's sib
            1. 50% if one of the parent is affected
            2. Not increased if parents are normal
        2. Patient's offspring: 50%
    2. Autosomal recessive inheritance (Bonafé et al. 2014)
        1. Patient's sib: 25%
        2. Patient's offspring: not increased unless the spouse is also carrying the gene
2. Prenatal diagnosis and preimplantation genetic diagnosis for pregnancies at risk for *COMP* and other mutations is possible if the disease-causing allele of an affected family member has been identified (Bonafé et al. 2014; Briggs et al. 2015).
    1. Amniocentesis
    2. CVS
3. Management (Briggs et al. 2015).
    1. Initial aims of management.
        1. Control pain
            1. Can be difficult
            2. Combination of analgesics and physiotherapy including hydrotherapy
        2. Limit joint destruction and the development of osteoarthritis
    2. Weight control.
    3. Avoid exercise that causes repetitive strain on affected joints.
    4. Realignment osteotomy and/or acetabular osteotomy to slow the progression of symptoms.
    5. Total joint arthroplasty in some cases.
    6. Psychosocial support to address issues of short stature, disability, and employment.

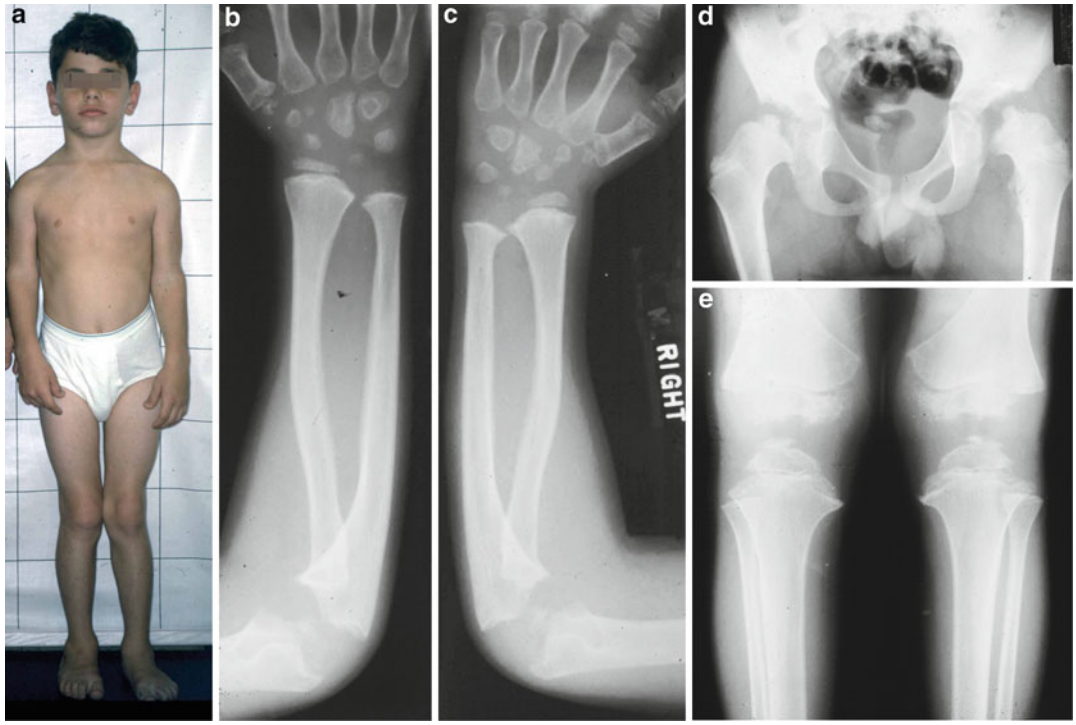

Fig. 1 (**a**–**e**) A boy with multiple epiphyseal dysplasia showing short stature (**a**) and epiphyseal dysplasia in the wrists (**b**, **c**), hips (**d**), and knee joints (**e**)

Fig. 2 (**a**, **b**) A girl (**a**) and an adult female (**b**) with multiple epiphyseal dysplasia showing mild short stature with normal body proportion

Fig. 3 Radiograph of the pelvis of a 12-year-old boy with multiple epiphyseal dysplasia showing poorly developed acetabular fossae and flat, fragmented femoral heads

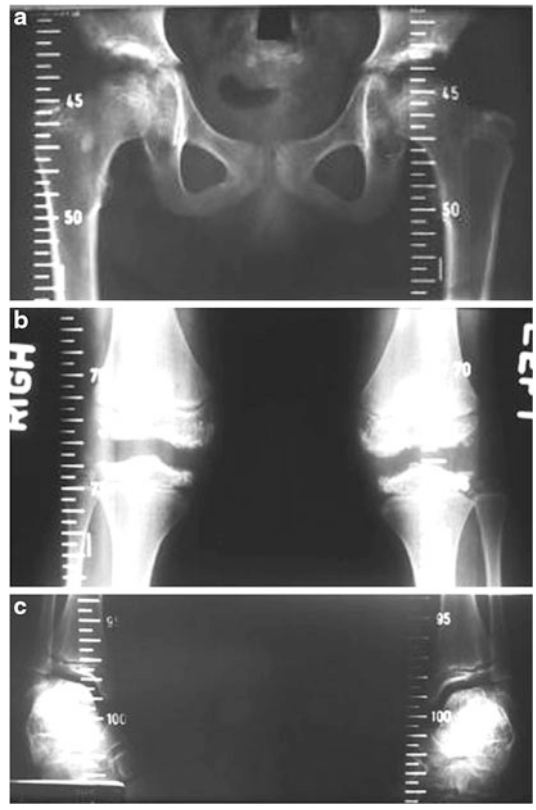

Fig. 4 (**a**–**c**) Radiographs of another patient with multiple epiphyseal dysplasia showing poorly formed acetabular fossae, poorly ossified femoral heads (**a**), and flattened epiphyses of the knees (**b**) and ankles (**c**)

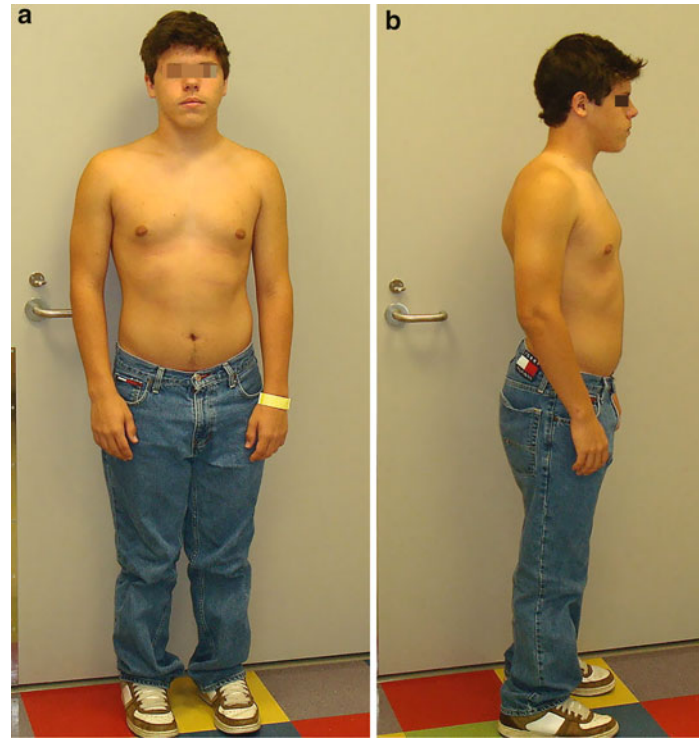

Fig. 5 (**a**, **b**) A 13-year-old boy with multiple epiphyseal dysplasia has been complaining of pain in the knees, legs, and feet since 4 years of age. He was also noted to have limp, joint stiffness, and worsening waddling gait. Mutation analysis showed a heterozygous G > A nucleotide substitution in exon 16, resulting in the replacement of an aspartic acid codon (GAC) with an asparagine codon (AAC) at amino acid position 605 (c.1813G > A or p. Asp605Asn (D605N)). The D605N missense mutation in the COMP gene has been reported previously in association with multiple epiphyseal dysplasia and is consistent with the diagnosis of this patient

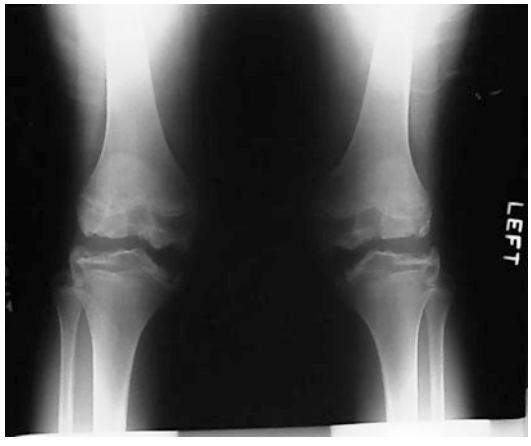

Fig. 6 Radiographs of the same patient showing epiphyseal dysplasias at the distal femoral epiphyses and the proximal tibial epiphyses causing weakness and pains at the knees

Fig. 7 (**a**, **b**) A 12-year-old boy (**a**) with multiple epiphyseal dysplasia. Radiograph of the pelvis at 8 years of age showed poorly developed acetabular fossae and flat femoral heads (**b**)

Fig. 8 A 10-year-old girl was seen because of short stature. The radiographs were consistent with multiple epiphyseal dysplasia. DNA sequencing revealed a c.1445A > G transition in exon 13 of the *COMP* gene. This change converts a codon for aspartic acid (GAC) to a codon for glycine (GGC). The patient is heterozygous for the mutation. The mutation confirms the diagnosis of multiple epiphyseal dysplasia. She was also diagnosed to have growth hormone deficiency and was receiving daily Humatrope injection

Fig. 9 Note the short upper arms with short fingers

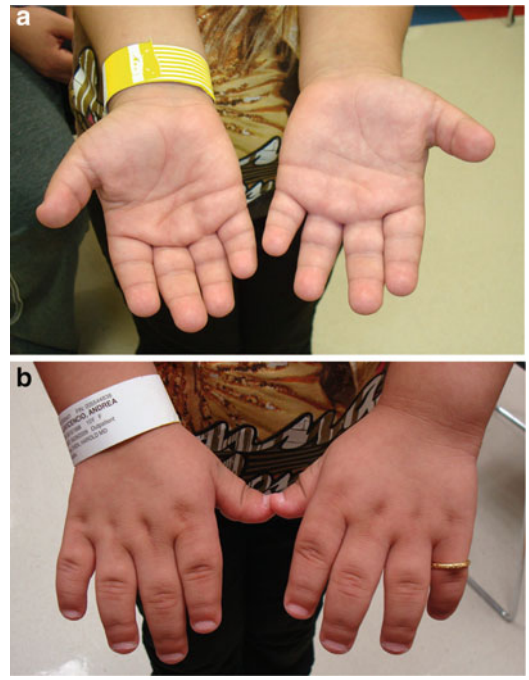

Fig. 10 (**a**, **b**) Note the short and stubby fingers

Fig. 11 Note short and stubby toes

Fig. 12 Hip radiograph 6 months earlier shows poorly developed acetabular fossae and flat fragmented femoral heads

Fig. 13 Knee radiograph shows flattened epiphyses of the knees

Fig. 14 Hand radiograph shows short and broad phalanges

Fig. 15 Radiograph of left upper extremity shows relatively short tubular bones with small proximal epiphysis of the left humerus

Fig. 16 Radiograph of feet shows short and stubby phalanges

Fig. 17 A 9-year-old female presented to clinic with a diagnosis of multiple epiphyseal dysplasia. She was short and had intermittent complaints of knee pain and discomfort with difficulty in going up and down the stairs. Radiograph of bilateral lower extremities demonstrated mild lobulation along bilateral acetabulum. Flattened epiphyses were seen with mild lobular contour along the long bones. Tibial and femoral condyles were hypoplastic with shallow intercondylar notch (Courtesy of Dr. Grace Guo)

Multiple Pterygium Syndrome

Contents

Multiple pterygium syndrome is a distinct syndrome consisting of a constellation of congenital anomalies characterized by pterygia of the neck, antecubital, popliteal, and intercrural areas, numerous flexion contractures of the joints, growth retardation, ptosis, antimongoloid slant with or without epicanthal folds, cleft palate, scoliosis, vertebral anomalies, rocker-bottom deformity of the feet, and genital anomalies.

Synonyms and Related Disorders

Escobar syndrome (Escobar et al. 1978); Fetal akinesia deformation sequence; Lethal multiple pterygium syndrome

Genetics/Basic Defects

1. Inheritance: genetic heterogeneity (Chen 2015)
    1. Autosomal recessive inheritance in most cases
        1. Presence of similarly affected siblings born to normal parents (Gillin and Pryse-Davis 1976; Stoll et al. 1980; Fryns et al. 1988; Aslan et al. 2000) or to consanguineous parents (Naguib et al. 1987)
        2. A relatively common disorder among Arabs (Teebi and Daoud 1990)
        3. Recessive forms of MPS: clinically and genetically heterogeneous
            1. May result from early-onset fetal akinesia
            2. Traditionally classified into prenatally lethal MPS and nonlethal Escobar variant-MPS
        4. Escobar syndrome: Mutations in *CHRNG* gene, which encodes the acetylcholine receptor γ-subunit, cause the autosomal recessive Escobar syndrome, one of the most common types of MPS, although other genes may be involved (Hoffmann et al. 2006; Morgan et al. 2006; Prontera et al. 2007)
        5. Fetal akinesia deformation sequence (FADS) and/or MPS (Escobar syndrome) has been recently described as a prenatal form of myasthenia associated with recessive mutations in genes of the neuromuscular junction (*CHRNG*, *CHRNA1*, *CHRNB1*, *CHRND*, *CHRNG*, *CNTN1*, *DOCK7*, *RAPSN*,

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_170

and SYNE1) (Hoffmann et al. 2006; Morgan et al. 2006; Michalk et al. 2008; Vogt et al. 2008; Chen 2012). This observation expands the cause of Escobar variant-MPS to a component of the contractile apparatus
6. The first report of the clinical expression of the complete absence of TPM2 in human indicated that TPM2 expression at the early period of prenatal life plays a major role for normal fetal movements (Monnier et al. 2009)
7. Clinical features
   1. Multiple joint contractures with marked pterygia
   2. Dysmorphic facies (flat, sad, motionless facial appearance)
   3. Cervical vertebral anomalies
8. Truncating CHRNG mutations associated with interfamilial variability of the severity of the Escobar variant of multiple pterygium syndrome (Kariminejad et al. 2016)

2. Autosomal dominant inheritance in some cases (Mckeown and Harris 1988)
   1. Caused by mutations in embryonic myosin heavy chain (*MYH3*) (Chong et al. 2015)
   2. Great variation in severity between affected individuals
   3. Characterized by multiple pterygia with or without mental retardation
3. X-linked inheritance (MacArthur and Pereira 1996)
4. Sporadic occurrence (Ramer et al. 1988; Spranger et al. 1995; Aslani et al. 2002)

2. Phenotypic analysis
   1. Multiple congenital pterygia, joint contractures, and severe foot defects: deformation sequence secondary to reduced frequency of fetal movement
   2. Micrognathia: resulting from reduced use and represents "disuse hypotrophy"
   3. Cleft palate: a mechanical disruption due to presumed interposition of tongue between palatine shelves
   4. Neck pterygia
      1. Able to exert a downward pull on facial structures
      2. Responsible for the following effects:
         1. Down-turned angles of the mouth
         2. Long philtrum
         3. Antimongoloid slant of palpebral fissures
         4. Low posterior hairline
         5. Anteversion and apparently low-set position of auricles
         6. Often with strikingly abnormal directional hair patterning in posterior and posterior-lateral areas of scalp
      3. Short neck due to:
         1. Lateral cervical pterygia
         2. Secondary fusion of upper vertebrae
   5. Congenital scoliosis: secondary to abnormal prenatal position, movement, and/or muscle pull
   6. Genital anomalies
      1. Small scrotum and apparently absent or hypoplastic labia majora: resulting from the pull of the intercrural pterygia which affects a flattening of these structures
      2. Cryptorchidism: representing mechanical obstruction of the processus vaginalis from pull of intercrural web or some intrinsic defect of the gubernaculums testis which is unable to effect descent of the gonads
3. Pathogenesis
   1. The underlying pathogenesis of the secondary deformities and distortions, hypotrophies, disruptions, bony fusions, and incomplete or impeded morphogenetic movements is unknown
   2. A neuromuscular disease causing fetal akinesia (Chen et al. 1980; Bhargava et al. 2002) is suspected
   3. Intrauterine crowding and oligohydramnios are contributory factors to joint contractures associated with MPS (Chen 2015)

Clinical Features

1. Intrafamilial variability of clinical features (Naguib et al. 1987; Kariminejad et al. 2016)
2. Short stature

3. Cutaneous and musculoskeletal (Penchaszadeh and Salszberg 1981; Thompson et al. 1987)
    1. Pterygia involving the following areas:
        1. Neck
        2. Axillary
        3. Antecubital
        4. Popliteal
        5. Digital
        6. Intercrural
    2. Limb pterygia and multiple joint contractures (Hall et al. 1982)
    3. Rib or vertebral anomalies
    4. Scoliosis (Di Gennaro et al. 1996)/lordosis
    5. Rocker-bottom feet with vertical talus
4. Standing with a crouching or semi-crouching stance
5. Orofacial features
    1. A flat, sad, motionless facial appearance
    2. Epicanthal folds
    3. Ptosis
    4. Antimongoloid palpebral fissure
    5. Long philtrum
    6. Pointed, receding chin
    7. Down-turned angles of the mouth
    8. Cleft lip+/− palate
    9. Apparent low-set ears
6. Genitalia
    1. Males
        1. Small penis and scrotum
        2. Cryptorchidism
    2. Females
        1. Apparent aplasia of the labia majora
        2. A small clitoris
7. Association with myopathy
    1. Absence of β-tropomyosin is a new cause of Escobar syndrome associated with nemaline myopathy (Monnier et al. 2009)
    2. Progressive form of multiple pterygium syndrome in association with nemalin myopathy (Papadia et al. 1987)
    3. Multicore myopathy associated with multiple pterygium syndrome and hypertrophic cardiomyopathy (Ohkubo et al. 1996)
8. Phenotypic characteristics of autosomal dominant MPS (Frias et al. 1973; Kawira and Bender 1985; McKeown and Harris 1988; Prontera et al. 2006; Chong et al. 2015)
    1. Downslanting palpebral fissures
    2. Ptosis
    3. Camptodactyly of the fingers
    4. Scoliosis
    5. Vertebral fusions
    6. Short stature
    7. Neck webbing

Diagnostic Investigations

1. Radiography
    1. Multiple joint contractures
    2. Fusion of cervical vertebrae
    3. Scoliosis/lordosis
    4. Flexion contractures of fingers
    5. Rocker-bottom feet with vertical talus
2. Pathological evaluations of muscle and nerve tissue (Wee et al. 1990): no consistent abnormality
3. Genetic analysis of mutations in the genes associated with neuromuscular junction may unveil the pathogenetic cause of FADS/MPS, and the information acquired is helpful for genetic counseling and clinical management (Chen 2012)

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. Autosomal recessive inheritance: 25%
        2. Autosomal dominant inheritance: not increased unless a parent is also affected
    2. Patient's offspring
        1. Autosomal recessive inheritance: not increased unless the spouse is a carrier
        2. Autosomal dominant inheritance: 50%
2. Prenatal diagnosis possible by ultrasonography usually for the family at risk
    1. Decreased fetal movement, oligohydramnios, and arthrogryposis (Bissinger and Koch 2014)
    2. Micrognathia
    3. Low-set ears
    4. Hypertelorism

5. Cystic hygroma colli (Fryns et al. 1984)
6. Rocker-bottom feet
7. Fetal akinesia deformation sequence associated with multiple pterygium syndrome may phenotypically overlap with the lethal type of multiple pterygium syndrome (please see the chapter of "► Lethal Multiple Pterygium Syndrome") (Chen 2012)
8. Prenatal diagnosis of fetal akinesia along with cystic hygroma, increased nuchal translucency, nuchal edema, hydrops fetalis, arthrogryposis, pterygia, and other structural abnormalities should include a differential diagnosis of neuromuscular junction disorders (Chen 2012)

3. Management (McCall and Budden 1992)
   1. Correction of the hand deformities
      1. Attention given to any deformities in the shoulder and elbow to maximize function of the limb before initiating correction of hand deformities
      2. Intensive physiotherapy and occupational therapy preferable to surgery for management of the upper extremity and hand anomalies
   2. Correction of mild hip flexion contractures of $<30^\circ$ due to inguinal webbing and crouched stance: responding well to active and passive stretching programs
   3. Correction of popliteal webbing
      1. Physiotherapy
      2. Traction
      3. Popliteal skin web Z-plasty with serial casting or with cable grafting the sciatic nerve (to achieve further knee extension and independent ambulation)
      4. Arthrodesis
      5. Amputation
      6. Excision of a significant fibrous band extending from the ischium to the calcaneus allows significant improvement in extension
   4. Correction of knee flexion contracture $<25^\circ$ without severe ambulatory limitations: conservative, consisting of a stretching program and night splints
   5. Correction of knee flexion contracture of $25–90^\circ$
      1. Physiotherapy followed by popliteal Z-plasty, fibrous band excision, and lengthening of all tense structures that are not neurovascular
      2. Post-operative serial casting
      3. Cable grafting or femoral shortening for neurovascular compromised cases
   6. Correction of knee flexion contracture of $>90^\circ$ which poses significant ambulatory difficulty
      1. Arthroses in extension
      2. Disarticulation
   7. Correction of vertical talus
      1. Children 6 years or younger: treated with soft tissue procedures and/or Grice subtalar arthrodesis
      2. Children over 6 years: undergo triple arthrodesis at age 12

Fig. 1 (**a**–**f**) Two Honduran siblings (a 5-year-old girl (**a**–**c**) and a 9-year-old boy (**d**–**f**)) with multiple pterygium syndrome showing multiple pterygia involving neck, axillary, antecubital, popliteal, and intercrural areas. In addition, they had multiple joint contractures affecting hips, elbows, and interphalangeal, and popliteal joints; semi-crouching stance; and rocker-bottom feet due to vertical tali. Vigorous physiotherapy was performed initially for both upper and lower extremity contractures. Popliteal Z-plasty with release of the posterior capsule and excision of a fibrous band extending from the ischial tuberosity to the calcaneus resulted in better knee extension, but further correction was limited by tight neurovascular structures. Vertical tali were addressed surgically with triple arthrodeses on the boy at age 12, and soft tissue release combined with a Grice subtalar arthrodesis on the girl at age 6. Both children attained painless plantigrade feet at discharge

Fig. 2 (**a**–**i**) Three Nicaraguan siblings (parents are third cousins) with multiple pterygium syndrome showing similar features. Radiographs showed rocker-bottom feet with vertical talus (**b**, **e**) and the fusion of cervical vertebrae (**i**). Patient 1 (**a**) (a 7-year-old boy) had motionless facial appearance, cleft palate, multiple flexion contractures, and severe webbing at the antecubital and popliteal fossae, and interphalangeal regions. He also had severe foot

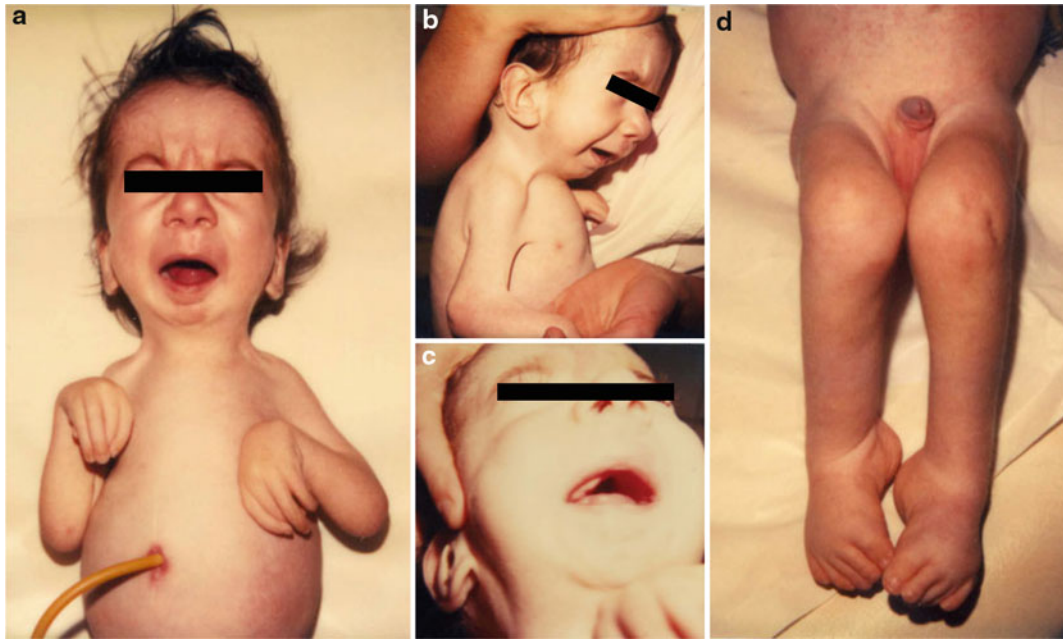

Fig. 3 (**a**–**d**) A boy with a sporadic case of multiple pterygium syndrome showing multiple pterygia, long philtrum, receding chin, cleft palate, low-set ears, and multiple contractures

Fig. 2 (continued) deformities with calcaneus heels and vertical talus (**b**). Patient 2 (**c**, **d**) (a 9-year-old girl) crawled at 4 years of age but had never walked. She was much more severely affected. Patient 3 (**f**–**i**) (an 11-year-old boy) walked with difficulty but much less severely affected than younger brother and sister. Digital deformities were addressed surgically with some recurrence of original deformities. Hip flexion contractures were addressed with an active stretching program and prone positioning, resulting in satisfactory resolution. Popliteal webbing was treated by either physiotherapy alone and/or operative procedures. Bilateral congenital tali were treated by either bilateral talectomy or arthodesis with partial talectomies

Fig. 4 (**a**–**c**) An 11-year-old girl with typical Escobar syndrome (**a**) with severe kyphoscoliosis (**b**), illustrated by radiograph (**c**). She was seen recently at 18 years of age (**d**)

Myotonic Dystrophy Type 1

Contents

Myotonic dystrophy type 1 (DM1) is the most common form of muscular dystrophy affecting adults with an estimated incidence of 1 in 8,000 among Caucasians (Brook et al. 1992).

Synonyms and Related Disorders

Myotonic dystrophy type 1 (dystrophia myotonica 1; Steinert disease); Myotonic dystrophy type 2 (dystrophia myotonica 2, proximal myotonic myopathy, proximal Ricker syndrome)

Genetics/Basic Defects

1. Inheritance: autosomal dominant with an anticipation phenomenon (Harley et al. 1993)
2. Molecular genetic perspective (Brook et al. 1992)
    1. Considerable variability of phenotype between affected individuals even within the same family
    2. An association of myotonic dystrophy with specific haplotypes in the population, indicating that most cases have resulted from a small number of genetic events
    3. Multisystemic nature of the phenotype
    4. An apparent increase in severity of symptoms and reduction in age at onset that is observed during transmission of the gene within families
3. Genetic defect: caused by an expanded CTG (cytosine-thymine-guanine) repeat in the dystrophia myotonica phosphokinase (*DMPK*) gene (Thornton 1999)
    1. Encodes for a serine-threonine protein kinase
    2. Mapped on chromosome 19q13.3
4. CTG triplet repeat (Gennarelli et al. 1996; Gharehbaghi-Schnell et al. 1998)
    1. Transcribed and located in the 3′ untranslated region of an mRNA that is expressed in tissues affected by myotonic dystrophy
    2. Repeat size
        1. Highly variable in the normal population (5–36 triplets)
        2. Undergoing expansion in myotonic dystrophy patients (50 to several thousand copies)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_171

1. Expansion of at least 50 repeats in patients who are minimally affected
2. Expansion of up to several thousands of such repeat in more severely affected patients

3. Intergenerational instability (unstable CTG expansion at mitotic and meiotic levels with a bias toward length increase in the successive generations)
   1. Accounting for anticipation (the CTG repeat size increases in successive generations in parallel with increasing severity of the disease)
   2. Accounting for somatic instability and mosaicism (the CTG repeat size varies considerably among different tissues and organs with coexistence in the same subject of cell lines with different CTG repeats)
4. Genotype-phenotype correlations (Finsterer et al. 2001)
   1. Size of the CTG trinucleotide repeats generally correlated with the age of onset and clinical severity of the disease.
   2. Longer CTG repeat expansions correlate, in general, with an earlier age of onset and more severe disease.
   3. Relation of cardiac abnormalities and CTG repeat size in myotonic dystrophy.
      1. Increased cardiac involvement with increasing CTG repeat size in patients age 21–50.
      2. The number of CTG repeats needed to develop a reasonable cardiac involvement is higher in young patients than in older patients.
      4. Occasionally difficult to diagnose: the pleomorphic manifestations, due to a dynamic mutation in the length of CTG repeat, lead to difficulty in clinical identification of asymptomatic or mildly affected patients.

Clinical Features

1. Highly variable phenotypic expression and age of onset.
   1. The mildest form
      1. Seen in middle or old age (>50).
      2. Characterized by cataracts and baldness with little or no muscle involvement.
      3. CTG repeats: 50–100.
   2. The classic (juvenile or adult) form
      1. The more common form
      2. Usually becoming evident between the ages of 15 and 35 years
      3. CTG repeats: 100–1,000
      4. Phenotypically variable
      5. Characteristic clinical features
         1. Myotonia (sustained muscle contraction)
         2. Muscle weakness
         3. Cardiac arrhythmias
         4. Male balding (frontoparietal alopecia)
         5. Hypogonadism
         6. Psychocognitive dysfunction
         7. Glucose intolerance
   3. The childhood form
      1. Age at onset: 1–10
      2. CTG repeats: 50 $\geq$ 2,000
      3. Clinical manifestations
         1. Hypotonia
         2. Learning difficulties
         3. Limited motor skills
   4. The most severe (congenital) form (CMD) (Harper 1975a; Pearse and Howeler 1979; Hageman et al. 1993)
      1. Recognized at birth or in the neonatal period
      2. CTG length: >1,000
      3. Pregnancy
         1. Maternal polyhydramnios
         2. Reduced fetal movement
         3. Breech presentation
         4. Prematurity
      4. Associated with generalized muscular hypotonia
      5. Respiratory distress
         1. Aspiration pneumonia
         2. Recurrent bronchitis
         3. Hypoventilation
         4. Sleep apnea
         5. Bronchiectasis

6. Feeding difficulties
7. Dysphagia
8. Nasal regurgitation
9. Facial diplegia with a "tented-shaped" mouth
10. Delayed motor development
11. Joint deformities
12. Mental retardation
13. High neonatal mortality
14. Those survived invariably exhibiting the classical form of the disease in late childhood or adolescence
15. Almost all congenital cases are exclusively maternally transmitted (Harper 1975b; Dufour et al. 1997)
16. CTG repeats: 1,000–5,000
17. The phenomenon of anticipation often most strikingly manifested in a family producing a congenitally affected child

2. Neurologic manifestations.
    1. Myotonia (100%) (Miller 2008)
        1. Delayed relaxation of muscles after an initial voluntary contraction or percussion.
        2. Muscle stiffness that improves with repeated use of the muscle, the so-called warm-up phenomenon.
        3. On examination, myotonia may be apparent from the first handshake, presenting with inability to quickly release a handgrip (grip myotonia). This can also be appreciated by asking the patient to repeatedly grip and release the examiner's fingers. Another helpful maneuver is to ask the patient to repeatedly close the eyes tightly. After the first closure, there may be lag in opening the eyes, but this will improve with repeated efforts.
        4. Myotonia may be provoked by percussion of muscle, e.g., by percussion of the thenar eminence with a reflex hammer (percussion myotonia). The muscle stiffens, often adducting the thumb.
    2. Muscle weakness and atrophy
        1. Muscles most prominently affected
            1. Superficial facial muscles
            2. Levator palpebrae superioris
            3. Temporalis
            4. Sternocleidomastoids
            5. Distal muscles of forearm
            6. Dorsiflexors of foot
        2. Other muscles commonly affected
            1. Quadriceps
            2. Diaphragm and intercostals
            3. Intrinsic muscles of hand and feet
            4. Palate and pharyngeal muscles
            5. Tongue
            6. External ocular muscles
    3. Percussion myotonia and voluntary myotonia aggravated by cold
    4. Dysarthria
    5. Slow nasal indistinct speech
    6. Foot drop
    7. Step page gait
    8. Contractures of the Achilles tendon
    9. Diminished deep tendon reflexes
    10. Cognitive and behavioral abnormalities
3. Craniofacial appearance.
    1. Long thin face
    2. Flat, sagging, sad, and expressionless face
    3. Frontal bossing
    4. Hollow temple secondary to atrophy of temporalis
    5. Bilateral facial weakness (facial diplegia)
    6. Tented mouth
    7. Micrognathia
    8. Swan neck appearance (sternocleidomastoid muscle wasting)
4. Ocular findings.
    1. Cataracts (>85%)
    2. Ptosis
    3. Extraocular weakness
    4. Peripheral retinal changes
    5. Coloboma of retina/choroid
    6. Optic atrophy
    7. Blepharospasms
    8. Decreased ocular pressure
5. Cardiac involvement (76%).
    1. An integral part of myotonic dystrophy targeting
        1. Almost selectively the conduction system
        2. Less specifically the myocardium
    2. Electrocardiographic conduction abnormalities

1. Manifesting with or without ventricular tachyarrhythmias or bradyarrhythmias
2. The first-degree atrioventricular (AV) block (most common)
3. Intraventricular conduction abnormalities (premature ventricular complexes like couplets and triplets)
4. Atrial arrhythmias (atrial fibrillation and flutter)

3. A high incidence of sudden death
4. Possible cardiomyopathy
5. Congestive heart failure (6%)

6. Gastrointestinal findings.
   1. Achalasia
   2. Gastroparesis
   3. Constipation
   4. Megacolon
   5. Gallstones
7. Genitourinary findings.
   1. Dysuria
   2. Urinary retention
   3. Polycystic kidneys
   4. Testicular atrophy
8. Endocrine findings.
   1. Hypogonadism
   2. Male infertility secondary to testicular atrophy
   3. Hypothyroidism
   4. Goiter/hyperparathyroidism
   5. Multiple endocrine neoplasia type 2A (pheochromocytoma and amyloid-producing medullary thyroid carcinoma)
   6. Dysmenorrhea
   7. Postprandial hyperinsulinemia
9. Orthopedic problems.
   1. Arthrogryposis
   2. Talipes
   3. Kyphoscoliosis
10. Female patients.
    1. Decreased total reproductive rate
    2. Obstetrical complications (Dufour et al. 1997; Rudnik-Schöneborn and Zerres 2004)
       1. Higher rate of spontaneous abortions
       2. Ectopic pregnancies
       3. Abnormal placentation
       4. Urinary tract infections
       5. Premature delivery
       6. Hydrops
       7. In utero demise
       8. Difficulty in expulsion
       9. Hemorrhage during delivery
       10. Anesthetic accidents
11. Occasional accompanying benign or malignant neoplasms.
    1. Pilomatrixoma
    2. Parathyroid adenoma
    3. Small bowel carcinoma
    4. Neurofibromatosis
    5. Thymoma
    6. Pleomorphic adenoma of the parotid gland
    7. Pituitary adenoma
    8. Ovarian cancer
    9. Ovarian cyst
    10. Laryngeal cancer (Osanai et al. 2000)
12. Natural history (Mathieu et al. 1999).
    1. Usually progressive
    2. Usually leading to severe disability within 15–20 years
    3. Greatly reduced life expectancy, particularly in the case of an early disease onset and proximal muscle involvement
    4. The high mortality rate reflecting an increase in deaths due to
       1. Respiratory diseases
       2. Cardiovascular diseases
       3. Neoplasms
       4. Sudden deaths induced by cardiac arrhythmias
13. Consensus for the new nomenclatures (International Myotonic Dystrophy Consortium (IDMC) 2000): all multisystemic myotonic disorders including myotonic dystrophy, proximal myotonic myopathy, proximal myotonic dystrophy, and myotonic dystrophy type 2 are collectively called "myotonic dystrophies."
14. Differential diagnosis of myotonic disorders (Meola 2000; Miller 2008; Bird 2013).
    1. Myotonic dystrophy type 2 (DM2) (Day et al. 2003; Dalton et al. 2013)
       1. Clinical characteristics similar to those of DM1 but more benign: an adult-onset muscular dystrophy associated with

1. Myotonia (90% of affected individuals)
2. Muscle dysfunction: weakness, pain, and stiffness
3. Iridescent posterior subcapsular cataracts
4. Cardiac conduction defects or progressive dilated cardiomyopathy
5. Facial and respiratory muscles: relatively spared
6. Insulin-insensitive type 2 diabetes mellitus
7. Infertility of males (testicular failure)
8. Hypogammaglobulinemia
9. Absence of congenital form of DM2 comparable with DM1

2. Molecular basis of DM2: caused by a *CNBP* expansion of a cytosine-cytosine-thymine-guanine (CCTG) repeats in the zinc finger protein 9 (*ZNF9*) gene on chromosome 3q21 (Day et al. 1999; Liquori et al. 2001)

2. Myotonia congenita
   1. Myotonia: prominent clinical symptom.
      1. Stiffness especially when first starting an activity in severe classic myotonia
      2. Perform activities at a normal or advanced level, including competitive sports, once warmed up.
      3. Presents in early childhood, described by the parents as weakness and clumsiness in addition to or instead of stiffness.
      4. Despite the reported difficulties, affected children appear "athletic," with increased muscle bulk, presumably because of the sustained muscle activity.
      5. The myotonic symptoms often improve with age but do not completely disappear.
   2. Caused by a mutation in the gene encoding skeletal muscle chloride channel-1 (*CLCN1*) (Renner and Ptacek 2002). The chloride channel defect leads to an elevation of the resting membrane potential and thus a tendency toward repeated muscle contractions.
   3. Inheritance: either autosomal dominant (Thomsen myotonia congenita) or autosomal recessive (Becker myotonia congenita).
3. Schwartz-Jampel syndrome (chondrodystrophic myotonia)
   1. Caused by loss-of-function mutation in the *HSPG2* gene, which encodes perlecan, a heparan sulfate proteoglycans secreted into basement membranes (Nicole et al. 2000)
   2. Clinical manifestations
      1. Severe myotonia: one of the first symptoms present in childhood. No warm-up phenomenon for the myotonia
      2. Short stature
      3. Muscular hypertrophy
      4. Diffuse bone disease
      5. Ocular and facial abnormalities
      6. Joint contractures
4. Proximal myotonic myopathy: characterized by early involvement of proximal limb muscles with long-term survival more favorable than that of patients with myotonic dystrophy (Meola and Sansone 1996; Udd et al. 1997; Thornton 1999)

Diagnostic Investigations

1. Clinical examination to search muscle and nonmuscle manifestations (Meola 2000)
2. Lab: mildly elevated serum creatine kinase in affected individuals but normal in asymptomatic individuals
3. Electromyography to identify subclinical myotonia (Day et al. 1999)
4. Slit-lamp examination to detect characteristic posterior subcapsular cataracts (red and green iridescent opacities)
5. Muscle biopsy
   1. Diagnostic but not indicated or useful for routine clinical evaluation

2. Atrophic small type I fibers
3. An increase in central nuclei
4. Ringed fibers
5. Fibrosis and fatty infiltration

6. Light microscopy of hairs (Amorosi et al. 1999)
   1. Hair twisting
   2. Hair swelling
   3. Trichoschisis (presence of broken or split hairs)
7. Radiography
   1. Kyphosis of cervical spine
   2. Thin ribs observed in neonates suffering from myotonic dystrophy
8. Electrocardiogram abnormalities (60–70%) (Finsterer et al. 2001)
   1. ST abnormalities
   2. AV block I
   3. Increased QTC interval
   4. Tall R and/or S waves
   5. Left anterior hemiblock
   6. Supraventricular ectopic beats
   7. T wave abnormalities
   8. Pacemaker
   9. Missing R progression
   10. Abnormal U wave
   11. Left bundle branch block
9. Echocardiography (Finsterer et al. 2001)
   1. Septal thickness >11 mm
   2. Posterior wall thickness >11 mm
   3. Fractional shortening <30%
   4. E/A ratio >1
   5. Left ventricular end-diastolic diameter >57 mm
   6. Valve abnormalities
10. DNA testing for CTG repeat size: detects mutations in nearly 100% of affected individuals and is clinically available (Bird 2013)
    1. Gold standard for the diagnosis of DM1.
    2. CTG repeat size
       1. Normal alleles: 5–34 CTG repeats
       2. Premutation (mutable normal alleles): 35–49 CTG repeats. Individuals with premutation range are asymptomatic but their children are at increased risk of inheriting a larger repeat size and thus having symptoms (Martorell et al. 2001).
       3. Full penetrance alleles (associated with disease manifestations): >50 CTG repeats.
    3. Clinical testing by targeted mutation analysis
11. Presymptomatic carrier testing
    1. Leukocyte DNA analysis: provides an earlier opportunity to diagnose DM1 in family members at risk who are clinically asymptomatic
    2. Providing more aggressive monitoring program to detect
       1. Early cardiac conduction disturbance
       2. Cataract formation
       3. Respiratory difficulties
       4. At risk of developing anesthetic complications, especially delayed-onset apnea
12. Reporting guidelines for DM1 genetic testing according to Kamsteeg et al. (2012) with the influence of gender of the transmitting parent (Pavicevic et al. 2013)
    1. No expansion homozygous or heterozygous for allele in the size range of 5–35 repeats (normal alleles)
       1. DM1 diagnosis is excluded.
       2. When it concerns a fetus, it is not affected.
    2. A heterozygous expansion in the size range of 36–50 repeats (premutation alleles)
       1. DM1 diagnosis is excluded; when it concerns a fetus, it is not affected.
       2. Premutations may or may not expand in next generations.
       3. Transmission by female mostly results in stable inheritance or small changes in repeat copy number, while when transmitted by men, they are more prone to expand, even reaching the disease-associated mutation in a single generation, thus raising the risk of having affected child.
       4. Relatives (including offspring) of the counselee may be at risk of developing DM1 and should be offered counseling. An offer of repeat-length analysis to those relatives is warranted.

3. A heterozygous expansion in the size range of 51–150 repeats
    1. When symptoms are evident, the diagnosis of DM1 is confirmed. When symptoms of DM1 are not evident (asymptomatic family member or fetus), the individual is at risk of developing DM1, although individuals with a repeat expansion of this size may also remain symptomless.
    2. Counselees in the reproductive age are warranted. Smaller repeat expansion of this size range can be stably transmitted by female, while larger repeat expansion of this size range raising the risk of having a child with even congenital form of DM1.
    3. When transmitted by male repeat expansion of this size range almost invariably results in a large increase into the disease-associated mutation, raising the risk of having affected offspring.
    4. Relatives (including offspring) of the counselee may be at risk of developing DM1. Due to anticipation in DM1, offspring may be more severely affected. Relatives should therefore be offered counseling. An offer of repeat-length analysis to those relatives is warranted.
4. A heterozygous expansion in the size over 50 repeats
    1. When symptoms are evident, the diagnosis of DM1 is confirmed.
    2. When symptoms of DM1 are not evident (asymptomatic family member), the individual is at risk of developing DM1, although individuals with a repeat expansion of this size range may rarely remain symptomless.
    3. When it concerns a fetus, it is very likely to be affected and has a high risk to be more severely affected than the affected parent.
    4. Counselees in the reproductive age are warranted. Women are, especially, at risk of having children with the congenital form of DM1.
    5. Relatives (including offspring) of the counselee may be at risk of developing DM1. Due to anticipation in DM1, the offspring may be more severely affected. Therefore, relatives should be offered counseling. An offer of repeat-length analysis to those relatives is warranted.

Genetic Counseling

1. Recurrence risk (Koch et al. 1991; Magee et al. 2002; Bird 2013)
    1. General principle for genetic counseling
        1. A normal molecular analysis excludes the risk of developing or transmitting myotonic dystrophy in essentially all situations.
        2. For women who have had a child with congenital myotonic dystrophy, almost all subsequently affected pregnancies are likely to be severely affected.
        3. Clinically affected women, in general, have around a 30% chance that an affected child would have congenital or severe childhood myotonic dystrophy. The risk of a congenitally affected child is related to maternal repeat size.
        4. The risk for the healthy sib of a congenitally affected patient developing the disorder after childhood is low.
        5. For the adult healthy sib of an adult-onset case, the risk of carrying the mutation is also low (around 10%), with about half of this developing clinically significant disease.
    2. Patient's sib: recurrence risk depending on the genetic status of the parents
        1. Not increased if both parents are normal
        2. Fifty percent risk if one parent has an expanded *DMPK* allele
    3. Patient's offspring
        1. Offspring of an individual with an expanded allele (>34 CTG repeats) have a 50% chance of inheriting the mutant allele.

2. Disease-causing alleles may expand in length during gametogenesis, resulting in the transmission of longer CTG trinucleotide repeat alleles that may be associated with earlier onset and more severe disease than that observed in the parent.

2. Prenatal diagnosis (Geifman-Holtzman and Fay 1998)
   1. Prenatal ultrasonography in congenital myotonic dystrophy
      1. Polyhydramnios
      2. Talipes
      3. Decreased fetal movements reflecting the neuromuscular failure of swallowing and movement
   2. Prenatal diagnosis of CMD (Geifman-Holtzman and Fay 1998)
      1. Based on history and clinical symptoms during pregnancy in addition to the fetal and maternal CTG repeat sizes (>300 repeats and 600 repeats, respectively)
      2. Using 30–4,300 repeat size in amniocytes or villi to anticipate (to exclude as well as to identify severe risk in the fetus with CMD) (Redman et al. 1993)
   3. Prenatal diagnosis: possible by using mutation analysis (requires prior confirmation of the diagnosis of DM1 by molecular genetic testing of DMPK in an affected family member) and detection of the CTG repeat expansion with the *DMPK* gene in amniocytes or chorionic villi
   4. More challenging by using the CTG repeat test to determine whether the fetus is at risk for the severe form of myotonic dystrophy
      1. Generally, in amniocytes, congenital myotonic dystrophy is associated with CTG repeat expansion larger than that of the affected mother.
      2. CTG repeat size may change over time in CVS or amniocentesis, providing different CTG repeat size at different gestational ages.
   5. Counseling of pregnant patients affected with myotonic dystrophy
      1. An explanation of the risk associated with anticipation, which is the tendency toward large intergenerational expansion of the CTG repeat during maternal transmission, resulting in offspring with congenital myotonic dystrophy.
      2. CTG repeat number provides only an approximate guide to prognosis or to pregnancy outcome. Most cases with over 2,000 repeats will have congenital or severe childhood-onset disease; most individuals with 50–100 repeats will not have significant neuromuscular disease.
      3. An intergenerational contraction of the CTG fragment observed in approximately 7% of cases. Clinical anticipation was seen despite the reduced CTG repeat size, resulting in congenital myotonic dystrophy in the offspring.
      4. Prenatal diagnosis (PND) is available; however, the decision to terminate affected pregnancies is difficult as the extent of disability is hard to predict from the size of the expansion.
   6. Preimplantation genetic diagnosis (PGD) genetic analysis: available and is carried out before the establishment of pregnancy (Kakourou et al. 2008)

3. Management
   1. No specific treatment available for the progressive weakness that is responsible for most of the disability in patients with myotonic dystrophy.
   2. Patients with myotonic dystrophy usually do not seek treatment for the myotonia per se, or they are not compliant with medication regimens to treat it, either because myotonia is much milder than their other symptoms or because they avoid medical treatment as part of their personality (Conravey and Santana-Gould 2010).
   3. To alleviate myotonia by drugs.
      1. Quinine, quinidine, dilantin, carbamazepine, procainamide, diamox to alleviate myopia not universally successful
      2. Encouraging results with mexiletine (Logigian et al. 2010) and tocainide
   4. Avoid cold which may induce myotonia.
   5. Prescription for orthoses, wheelchairs, or other assisted devices.

6. Treat cataracts, diabetes mellitus, hypothyroidism, and sleep apnea.
7. Avoid surgery and anesthesia (sensitive to narcotics and sedatives) (Mathieu et al. 1997).

Fig. 1 An adult (**a**) with myotonic dystrophy showing hard to release after shaking hand (**b**) and thenar myotonia after tapping (**c**)

Fig. 2 An adult with myotonia dystrophy showing long thin face with frontal bossing (**a**) and thenar myotonia after tapping (**b**)

Fig. 3 A 23-year-old mother and her 21-month-old daughter with myotonia congenita type 1 (**a**). The mother has myotonia (hard to relax after shaking hand) (**b**), thenar myotonia after tapping (**c**), and absent tendon reflexes. The pregnancy was complicated by polyhydramnios, feeble fetal movement, and breech presentation. After scheduled cesarean section, the baby breathed only once and needed intubation for 5 days. She was very floppy and just started to walk about 2 months prior to the clinic visit. She chokes easily and does not chew and talk. On physical examination, in addition to hypotonia, there is a long and sagging face with marked tented mouth (**a**). Molecular genetic testing of the daughter showed CTG repeats of 1,050

Möbius Syndrome

Contents

Möbius syndrome (MBS) (Möbius 1988) is a rare congenital disorder characterized by complete or partial facial diplegia accompanied by other cranial nerve palsies and musculoskeletal anomalies.

Synonyms and Related Disorders

Möbius sequence; Poland anomaly; Poland syndrome

Genetics/Basic Defects

1. Multifactorial etiology
    1. The term "Möbius sequence" represents a pattern of multiple anomalies due to multiple etiologies, compared with the designation "syndrome" which implies a single cause.
2. It is usually a sporadic occurrence, but familial descriptions have been rarely reported (Briegel 2006; Graziadio et al. 2010).
3. Genetic heterogeneity (Legum et al. 1981)
    1. Familial cases usually without associated anomalies
    2. Low incidence of familial cases with associated anomalies such as limb defects and mental retardation
    3. Autosomal dominant inheritance (Verzijl et al. 1999)
        1. Autosomal dominant Möbius syndrome has been linked to markers on 3q21–q22 in a large Dutch family (Kremer et al. 1996).
        2. A second gene for autosomal dominant Möbius syndrome is localized to chromosome 10q in a second large Dutch family.
    4. Autosomal recessive inheritance (Criado and Aytes 1999)
    5. X-linked recessive inheritance
4. Four genetic loci for MBS have been described to date (Van Der Zwaag et al. 2002).
    1. MBS1 on chromosome 13q12.2–q13 (Ziter et al. 1977; Slee et al. 1991), based on the following observations:
        1. A reciprocal translocation of 13q12.2–q13 cosegregating with the disease in a three-generation MBS family

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_159

2. An MBS patient with a deletion of chromosome 13q12.2
2. MBS2 on chromosome 3q21–q22 (Kremer et al. 1996)
3. MBS3 on chromosome 10q21.3–22.1 (Verzijl et al. 1999)
4. MBS4 on chromosome 1p22 (Donahue et al. 1993; Nishikawa et al. 1997), based on
   1. A t(1;11)(p22;p13) in a patient with Möbius syndrome
   2. A t(1;2)(p22.3;q21.1) in a patient with Möbius-like syndrome
5. *HOXA1* mutations are not a common cause of sporadic Möbius syndrome in the general population (Rankin et al. 2010).
   1. The *HOXA1*-related syndromes result from autosomal recessive truncating mutations in the homeobox transcription factor, *HOXA1*.
   2. Limited horizontal gaze and sensorineural deafness are the most common features.
   3. Affected individuals can also have facial weakness, mental retardation, autism, motor disabilities, central hypoventilation, and carotid artery and/or conotruncal heart defects.
   4. Möbius syndrome is also phenotypically heterogeneous, with minimal diagnostic criteria of nonprogressive facial weakness and impaired ocular abduction; mental retardation, autism, motor disabilities, additional eye movement restrictions, hearing loss, hypoventilation, and craniofacial, lingual, and limb abnormalities also occur.
6. *PLXND1* and *REV3L* mutations (Tomas-Rocas et al. 2015)
   1. De novo mutations in *PLXND1* and *REV3L* cause Möbius syndrome.
   2. PLXND1 and REV3L represent totally unrelated pathways involved in hindbrain development: neural migration and DNA translesion synthesis, essential for the replication of endogenously damaged DNA, respectively.
7. Chromosome abnormalities (Verzijl et al. 1999)
8. Ischemia: vascular disruption in the subclavian artery territory (Bavinck and Weaver 1986; Bouwes-Bavinck and Weaver 1986; Charles et al. 1993)
9. Teratogens
   1. Thalidomide
   2. Alcohol
   3. Benzodiazepines
   4. Cocaine
   5. Ergotamine
   6. Infections
   7. Hyperthermia
   8. Trauma
   9. Misoprostol (a synthetic prostaglandin analogue used in the therapy of upper gastrointestinal ulceration or self-administered by the mothers in Brazil as an abortifacient) (Blanchard et al. 1998; Pastuszak et al. 1998; Strömland et al. 2002; Guedes 2014)

2. Pathogenesis (Van Der Zwaag et al. 2002; Graziadio et al. 2010)
   1. A primary metameric defect in the brain stem nuclei in the region of the tegmentum
   2. An ischemic process resulting from an interruption of the vascular supply of the brain stem (Ghabrial et al. 1998)
   3. Disruption of the developing vascular system, affecting vasculogenesis (in situ differentiation of endothelial cells) and/or angiogenesis (sprouting of new capillaries from preexisting ones) (Bouwes-Bavinck and Weaver 1986; Abramson et al. 1998)
3. An etiopathologic classification (Towfighi et al. 1979; Pedraza et al. 2000)
   1. Type or group I (central lesion in the brain stem nuclei due to congenital origin)
   2. Type or group II (primary peripheral nerve involvement)
   3. Type or group III (central lesion in the brain stem nuclei due to an anoxic-infectious cause)
   4. Type or group IV (without CNS or cranial nerve lesions who had wasting of

skeletal muscle tissue due to myopathic cause)

Clinical Features

1. Congenital onset
2. Complete or partial facial diplegia (essential for the diagnosis of Möbius syndrome), often accompanied by other cranial nerve palsies (Palmer 2014)
    1. Signs and symptoms
        1. Incomplete eyelid closure during sleep
        2. Drooling
        3. Difficulty in sucking
        4. Inability to smile
        5. Lack of facial movement when crying (masklike facies)
        6. Asymmetry of the angles of the mouth
        7. Indistinct speech secondary to the inability to close the lips leading to labial sounds
    2. Involved cranial nerves (Kumar 1990)
        1. Facial nerve (VII) palsy (all cases), resulting in masklike facies and flattened facial expression
        2. Abducens nerve (VI) palsy (75%), less commonly oculomotor (III) and trochlear (IV) nerve palsies, resulting in marked internal strabismus, lateral gaze paralysis, and ophthalmoplegia
        3. Hypoglossal nerve (XII) palsy (25%), leading to paralysis, hypoplasia, and atrophy of the tongue
        4. Paresis of cranial nerves V (trigeminal), IX (glossopharyngeal), and X (vagus), leading to bulbar weakness (swallowing and speech difficulties due to velopharyngeal insufficiency)
3. Involvement of cerebellum, hypothalamus, and pituitary gland
4. Oculofacial abnormalities (Strömland et al. 2002)
    1. Masklike facial appearance: may create profound difficulties in social interactions with other people, especially strangers who are unfamiliar with the syndrome
    2. Epicanthal folds
    3. Ptosis
    4. Refractive error (Cronemberger et al. 2001)
        1. Astigmatism
        2. Lagophthalmos
        3. Amyopia
    5. Strabismus
    6. Nystagmus
    7. Micrognathia
    8. Tongue abnormalities
        1. A common anomaly
        2. A small asymmetric tongue with irregular atrophic areas: characteristic of Möbius syndrome
        3. Impaired motility and fasciculations
    9. At risk for caries and periodontal disease
    10. Impaired speech (Meyerson and Foushee 1978)
        1. A severe and disabling condition
        2. Factors affecting speech development
            1. Cognitive and language skills
            2. Hearing
            3. Communication ability
            4. Orofacial anatomy
            5. Oral motor function
        3. Dysarthria caused by cranial nerve dysfunction, worsened by orofacial anomalies, mental retardation, and autism
5. Frequent occurrence of limb malformations
    1. Reduction malformation of limbs
    2. Hypoplasia to aplasia of digits
    3. Brachydactyly
    4. Syndactyly
    5. Ectrodactyly
    6. Talipes deformities (clubfoot)
    7. Clinodactyly
    8. Polydactyly
    9. Joint contractures
6. Other musculoskeletal features
    1. Rib defects
    2. Klippel-Feil anomaly
    3. Aplasia of muscles
7. Mental retardation (10%)
8. Autistic behavior (30–40%) (Gillberg and Steffenburg 1989; Johansson et al. 2001)
9. Association with other anomalies or syndromes

1. Poland anomaly/syndrome (Sugarman and Stark 1973; Gadoth et al. 1979)
    1. Hypoplasia/aplasia of pectoralis major muscle.
    2. Ipsilateral symbrachydactyly.
    3. Generally unilateral.
    4. Associated with mammary hypoplasia of the same side.
    5. Poland syndrome, Möbius syndrome, and Möbius-Poland syndrome may be a spectrum of the same condition.
2. Hypoglossia-hypodactyly
3. Arthrogryposis multiplex congenita
4. Dextrocardia
5. Robin syndrome
6. Carey-Fineman-Ziter syndrome (congenital nonprogressive myopathy with Möbius and Robin sequence)
7. Kallmann syndrome (association with anosmia and hypogonadotropic hypogonadism)

10. Several similar syndromes (Strömland et al. 2002)
    1. Oromandibular limb hypogenesis syndrome
        1. Characteristic features
            1. Micrognathia
            2. Cranial nerve palsies
            3. Limb anomalies
            4. Sometimes combined with aplasia of the pectoral muscle (Poland anomaly)
        2. Entities included:
            1. Möbius syndrome
            2. Hanhart syndrome
            3. Hypoglossia-hypodactyly (aglossia/adactyly)
            4. Glossopalatine ankylosis
    2. Terminal transverse defects with orofacial malformations
        1. Orofacial features
            1. Micrognathia
            2. Cleft palate
            3. Tongue anomalies
            4. Ear anomalies
            5. Dental anomalies
        2. Limb malformations
            1. Syndactyly
            2. Clubfeet
            3. Toe deformities
            4. Symbrachydactyly
            5. Absent digits (ectrodactyly)
            6. Amputation-type defects of the limbs

Diagnostic Investigations

1. CT of the head: normal in most patients (Beerbower et al. 1986; Kuhn et al. 1990; Pedraza et al. 2000).
    1. Medial deviation of the eyes
    2. Hypoplastic or dysplastic brain stem
    3. Hypoplastic cerebellum consistent with Dandy-Walker variant malformation
    4. Bilateral calcifications adjacent to the fourth ventricle floor at the level of the VIth cranial nerve nuclei
2. Autopsies in patients with normal CT studies (D'Cruz et al. 1993).
    1. Focal necrosis and calcifications
    2. Hypoplasia to agenesis of the respective cranial nerve nuclei
3. MRI of the brain.
    1. Calcification in the pons within the abducens nuclei
    2. Hypoplasia of the brain stem
    3. Hypoplasia of the cerebellum
4. Neurophysiological studies may be helpful in locating the site of the lesion.
    1. Abnormal nerve conduction studies
    2. Electromyography (EMG) of facial muscles (Jaradeh et al. 1996):
        1. Reveals multifocal chronic neurogenic changes
        2. Indicates a brain stem process predominantly affecting the facial nuclei and their internuclear connections rather than a supranuclear or muscular site of involvement

3. Abnormal brain stem evoked potential
5. Array-CGH analysis of familial Poland anomaly identified three maternally inherited copy number variants in three patients (1p31.1, Xp11.22, and 16q23.1 duplication). These results do not allow any conclusive remarks on the probable molecular basis of the disease, mainly due to the small number of tested families (Baban et al. 2012).

Genetic Counseling

1. Recurrence risk
   1. Lower recurrence risk (2%) for Möbius syndrome with congenital sixth and seventh nerve paralysis with skeletal defects (MacDermot et al. 1991)
   2. Higher recurrence risk (25–30%) for Möbius syndrome with isolated facial palsy, deafness, ophthalmoplegia, and digital contractures without skeletal defects (MacDermot et al. 1991)
   3. Autosomal recessive inheritance
      1. Patient's sib: 25%
      2. Patient's offspring: not increased unless the spouse is a carrier
   4. Autosomal dominant inheritance
      1. Patient's sib: 50% if a parent is affected; otherwise not increased
      2. Patient's offspring: 50%
   5. X-linked recessive inheritance
      1. Patient's sib: 50% affected in the brothers if the mother is a carrier; otherwise not increased
      2. Patient's offspring: 50% carrier risk in the daughters
2. Prenatal diagnosis possible in the Möbius-Poland spectrum (Sherer and Spafford 1994)
3. Management
   1. Supportive care
   2. Intervention programs
      1. Physical therapy useful for congenital orthopedic problems or postoperative orthopedic intervention
      2. Occupational therapy to help activities of daily living, especially in patients with absent hands or digits
      3. Speech therapy for patients affected by severe facial nerve paralysis or lower cranial nerve deficit
   3. Dental hygiene
   4. Treat corneal ulcerations or abrasions secondary to exposure keratitis and conjunctivitis secondary to incomplete eyelid closure
   5. Splints and prostheses for congenital limb anomalies
   6. Surgical care
      1. Clubfoot.
      2. Tracheotomy to support the airway and permit tracheobronchial clearing when airway functions are compromised.
      3. Feeding gastrostomy tube required in some cases.
      4. Ocular surgical procedures in some cases.
      5. Combinations of microsurgical procedures and aesthetic techniques are being used to restore some movement to the expressionless face of these patients by nerve and muscle transplantation (Terzis and Noah 2003).

Nager Acrofacial Dysostosis

Contents

Nager acrofacial dysostosis, described by Nager and deRenier in 1948, is a mandibulofacial dysostosis associated with preaxial limb abnormalities. It is a very rare disorder with <100 reported cases by 2009 (Ansart-Franquet et al. 2009).

Synonyms and Related Disorders

Nager syndrome; Preaxial acrofacial dysostosis

Genetics/Basic Defects

1. Heterogeneous causes
    1. Most cases are sporadic
    2. Autosomal recessive inheritance (Chemke et al. 1988; Kennedy and Teebi 2004)
    3. Autosomal dominant inheritance (Hall 1989; Aylsworth et al. 1991; McDonald and Gorski 1993)
2. Del(1q12-q21.1 or q21.3), which encompasses *SF3B4*, was observed in a child characteristic of Nager syndrome (Waggoner et al. 1999)
3. Whole-exome sequencing recently identified mutations in the *SF3B4* gene as causative mutations underlying the etiology of Nager syndrome (Bernier et al. 2012)
4. Whole-exome sequencing study confirmed the *SF3B4* gene is mutated in about 50% of patients with clinical diagnosis of Nager syndrome (Czeschik et al. 2013)

Clinical Features

1. Craniofacial features
    1. Downward slanting of the palpebral fissures
    2. Midface retrusion (malar hypoplasia)
    3. Absent medial lower lid eyelashes
    4. Retromicrognathia
    5. Glossoptosis
    6. Cleft palate
    7. External ear anomalies including microtia and atresia of external auditory canal, leading to bilateral conductive hearing loss
    8. Intelligence: typically normal
    9. Speech difficulties and upper airway obstruction: common secondary to otologic and oral/mandibular abnormalities
2. Preaxial limb defects
    1. Usually affecting radial elements of the forelimbs
        1. Hypoplasia or agenesis of the radius

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_266

2. Proximal radioulnar synostosis
3. Hypoplasia or agenesis of the thumbs
4. Duplication of thumbs
5. Triphalangeal thumbs
6. Symphalangism

2. Phocomelia of the upper limbs
3. Occasional lower-limb defects (Le Merrer et al. 1989)

3. Skeletal anomalies and other malformations (McDonald and Gorski 1993)
   1. Skeletal anomalies
      1. Thoracolumbar scoliosis
      2. Cervical vertebral and rib anomalies
   2. Genitourinary abnormalities
      1. Vesicoureteral reflux
      2. Unilateral renal agenesis
      3. External genital hypoplasia
      4. Duplicated ureter
      5. Bicornuate uterus
   3. Gastrointestinal abnormalities
      1. Gastroschisis
      2. Hirschsprung disease
   4. Cardiovascular malformations
      1. Tetralogy of Fallot
      2. Ventricular septal defect
      3. Subvalvular muscular obstruction of the right ventricular outflow tract
   5. Central nervous system anomalies
   6. Microcephaly
   7. Aqueduct stenosis resulting in hydrocephalus
   8. Polymicrogyria
4. Differential diagnosis:
   1. Treacher Collins syndrome: Please see the chapter on ▶ "Treacher-Collins Syndrome"
   2. At least 18 different forms of acrofacial dysostoses have been described (Wieczorek 2013)
   3. Miller syndrome(Trainor and Andrews 2013)
      1. The presentation of anterior forelimb anomalies as opposed to posterior forelimb anomalies and the general lack of hind limb malformations distinguishes Nager syndrome from Miller syndrome, another rare acrofacial disorder
      2. Craniofacial anomalies similar to Treacher Collins syndrome
         1. Micrognathia
         2. Orofacial clefts
         3. Malar hypoplasia
         4. Aplasia of the medial lower lid eyelashes
         5. Coloboma of the lower eyelid
         6. Cup-shaped ears
      3. Postaxial limb deformities (Genee 1969; Wiedemann 1973; Miller et al. 1979)
         1. Apparent absence of either the fifth or both the fourth and fifth rays of the hands and feet
         2. With or without ulnar and fibular hypoplasia
      4. Molecular basis was identified via
         1. Whole-exome sequencing shown to correlate with mutations in dihydroorotate dehydrogenase (*DHODH*) (Ng et al. 2010)
         2. Recently additional biallelic mutations in *DHODH* were identified in four unrelated families with typical clinical features of Miller syndrome (Rainger et al. 2012)

Diagnostic Investigations

1. Radiography
   1. Craniofacial anomalies
      1. Malar hypoplasia
      2. Retro/micrognathia
      3. External ear anomalies
   2. Preaxial limb anomalies: variable often asymmetric
      1. Hypoplasia or aplasia of the thumb
      2. Duplicated thumb
      3. Symphalangism
      4. Radial hypoplasia or aplasia often associated with proximal radioulnar synostosis
      5. Lower-limb involvement usually mild and rare: phocomelia, talipes equinovarus, metatarsus varus, absent tibia/fibula, and toe abnormalities
   3. Abnormalities of the axial skeleton
      1. Thoracolumbar scoliosis
      2. Cervical vertebral and rib anomalies

2. Facial CT
   1. Micrognathia
   2. Mandibular hypoplasia
   3. Absence or near-complete absence of zygomatic arch
   4. Atresia of bony external auditory canals
3. Molecular genetic analysis of *SF3B4*
   1. Deletion/duplication analysis
   2. Sequence analysis of the entire coding region

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Autosomal recessive: 25%
      2. Autosomal dominant: recurrence risk not increased unless one of the parents is affected
   2. Patient's offspring
      1. Autosomal recessive: recurrence risk not increased unless the spouse is a carrier or affected
      2. Autosomal dominant: a 50% risk
2. Prenatal diagnosis
   1. Ultrasonography (Couyoumjian et al. 2008)
      1. Marked micrognathia
      2. Abnormal ears: low set and posteriorly rotated
      3. Short humerus with pronounced shortening of radius and ulna
      4. Abnormally appearing thumb
   2. Molecular genetic analysis: Prenatal testing for pregnancies at increased risk is possible if the family specific disease-causing mutation is known
3. Management (Opitz et al. 2000)
   1. Tracheostomy or mandibular advancement for severe airway obstruction shortly after birth
   2. Primary velopharyngoplasty
   3. Bronchoscopic intubation
   4. Surgical cleft repair
   5. Early correction of micrognathia by surgical distraction of the mandible, a means of improving facial esthetics relatively early in order to enhance the patient's chances regarding his psychosocial quality of life
   6. Mandibular elongation and remodeling by distraction
   7. Speech and language management must be focused on receptive and expressive language skills and linguistic conceptualization, correct phonetic placement, and the modification of hypernasality and nasal emission
   8. Multidisciplinary team approach to speech and hearing problems
   9. Amplification through the use of a properly fitted hearing aid, preferred therapy for conductive and mixed hearing loss (Herrmann et al. 2005)

Wiedemann, H. R. (1973). Malformation-retardation syndrome with bilateral absence of the 5th rays in both hands and feet, cleft palate, malformed ears and eyelids, radioulnar synostosis (author's transl). *Klinische Pädiatrie, 185*, 181–186.

Fig. 1 (**a**–**c**) A 13-month-old girl was evaluated for Nager acrofacial dysostosis. Facial features (**a**) were characterized by antimongoloid slant of the palpebral fissures, ptosis of lower lids, hypoplasia of lower lid eyelashes, malar hypoplasia, and mandibular hypoplasia with severe microretrognathia. She also had multiple limb abnormalities including short forearms, radioulnar synostosis, limited elbow extension, three fingers on both hands with absent thumbs and presence of transverse palmar crease on the left (**a**, **b**), and partial syndactyly of the 5th toes (**c**)

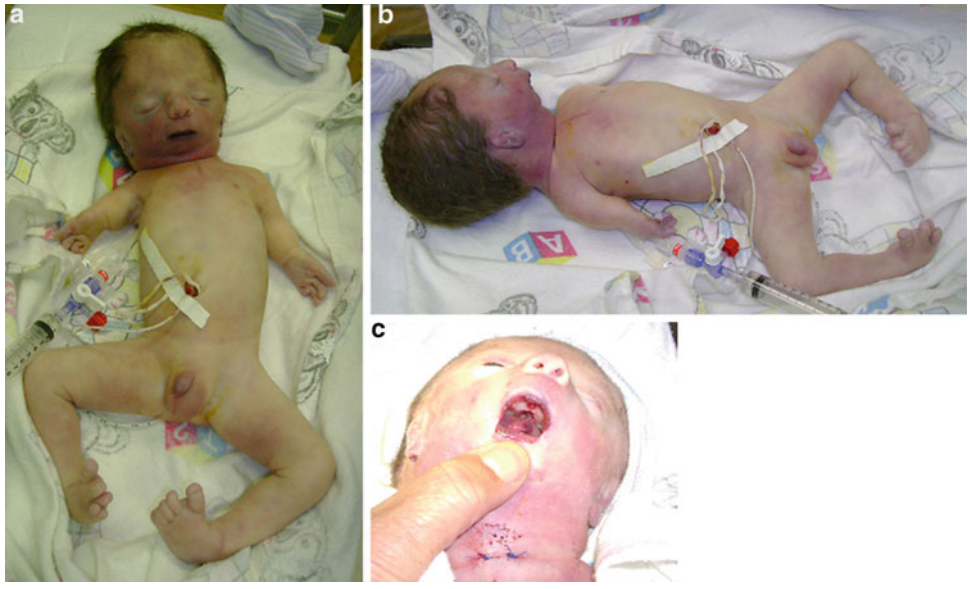

Fig. 2 (**a**–**c**) A newborn boy was evaluated for Nager acrofacial dysostosis. Craniofacial anomalies (**a**, **b**) were much more severe than the previous case. In addition, he had cleft palate (**c**), short neck, short upper extremities with near phocomelia on the right, missing thumb and camptodactyly on both hands, and bilateral talipes equinovarus

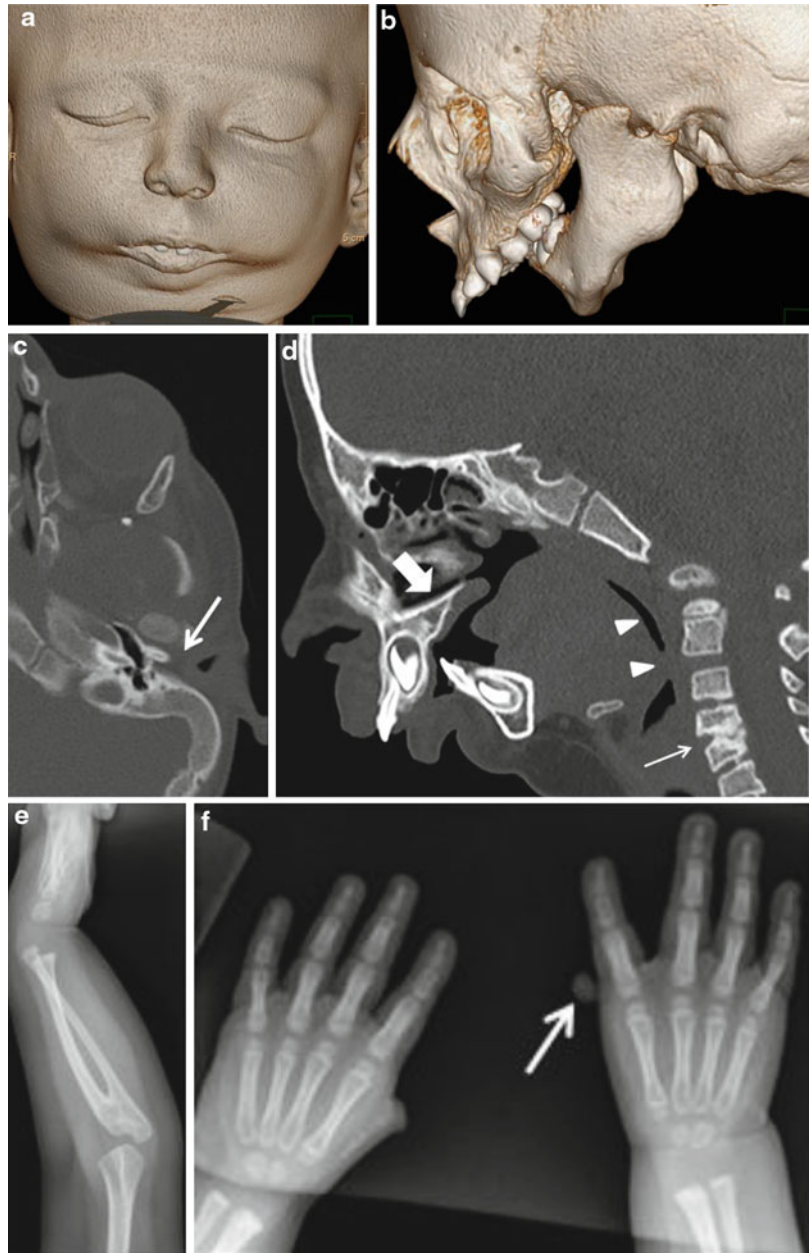

Fig. 3 (**a**–**f**) The 2-year-old girl (**a**) was evaluated for Nager acrofacial dysostosis. 3D reconstruction images of facial CT show marked symmetric mandibular hypoplasia and an increased angle of the body and ramus of the mandible. The mandibular condyles and mandibular fossa are present bilaterally with dysmorphic coronoid processes. There is absence of right zygomatic arch and near-complete absence on the left (**b**). CT images of bilateral temporal bones show bilateral bony external auditory canal atresia (**c**) (*arrows*). Sagittal CT image (**d**) demonstrates again micrognathia with foreshortened hard palate (*large arrow*), posterior displacement of the tongue compatible with glossoptosis (*arrow heads*), and cervical anomaly with fusion of C4–5 (*small arrow*). Radiography of the both forearms demonstrates proximal radioulnar synostosis with dysmorphic radius (only left side was shown here) (**e**). Radiography of bilateral hands (**f**) shows severely hypoplastic left thumb with tiny metacarpal and a phalanx and absent right thumb with only a small soft tissue remnant (*arrow*) (Courtesy of Dr. Grace Guo)

Nail-Patella Syndrome

Contents

In 1820, Chatelain (1951) first observed the nail-patella syndrome in a patient with a triad of abnormal nails, elbows, and knees. The hereditary nature of the syndrome was first described by Pye-Smith in 1883 in the English literature. The presence of iliac horns was first noted by Kieser (1939) in 1939 and later by Fong (1946) in 1946. In 1948, Mino et al. described the tetrad of abnormal nails, elbows, knees, and iliac horns for which the name hereditary onycho-osteodysplasia was coined by Duncan and Souter in 1963.

Synonyms and Related Disorders

Hereditary onycho-osteodysplasia (Duncan and Souter 1963; Carbonara and Alpert 1964)

Genetics/Basic Defects

1. Genetic heterogeneity (Ghoumid et al. 2015)
2. An autosomal dominant disorder with complete penetrance (Lucas and Opitz 1966; Beals and Eckhardt 1969; Figueroa-Silva et al. 2016)
3. An autosomal recessive inheritance: reported in a Saudi Arab family with nail-patella syndrome (Al-Dawsari et al. 2015). Genetic analysis of the *LMX1B* gene detected a previously reported homozygous mutation (c.268C > TP. Leu90Phen) in exon 2 of the *LMX1B* gene in both of the affected sisters. Both of the parents were confirmed to be heterozygous for the same mutation
4. Case reports of donor insemination, embryo donation (Figueroa-Silva et al. 2016)
5. *LMX1B*
    1. The only gene known to be associated with nail-patella syndrome (NPS)
    2. A LIM-homeodomain transcription factor involved in normal patterning of the dorsoventral axis of the limb during development and early morphogenesis of the glomerular basement membrane (Bongers et al. 2002)
    3. Targeted disruption of *Lmx1b* results in skeletal defects, including hypoplastic nails, absent patellae, and a unique form of renal dysplasia (Chen et al. 1998)
    4. *LMX1B* gene maps to 9q in the same region as the NPS locus by fluorescence in situ hybridization. Three unrelated NPS patients carried *de novo* heterozygous mutations in this gene (Dreyer et al. 1998)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_172

6. A microdeletion of chromosome 9q33.3 encompassing the entire *LMX1B* gene have been reported in a Chinese family with nail-patella syndrome (Jiang et al. 2014)
7. Demonstration of association between the haplotype of the mutant allele and the variability in the nail score ($p = 0.024$) (Dunston et al. 2005a)
8. Genotype/phenotype correlations (Bongers et al. 2005a)
    1. Individuals with an *LMXB1* mutation located in the homeodomain showed significantly more frequent and higher values of proteinuria than subjects with mutations in the LIM domains
    2. No clear genotype-phenotype association was apparent for extrarenal manifestations (McIntosh et al. 1998)

Clinical Features

1. Inter- and intrafamilial phenotypic variabilities (Lee et al. 2009)
2. Classic clinical tetrad
    1. Onychodysplasia (Sweeney et al. 2003): the most constant feature of the syndrome (approximately 98% of cases)
        1. Variable
        2. Absent, hypoplastic, or dystrophic nails usually noted at birth
        3. Spoon-shaped nails (Koilonychia)
        4. Pitting, discoloration, thin/thick nails
        5. Often bilateral or symmetrically involved
        6. Longitudinally or horizontally ridged (grooved) nails
        7. Thin or less often thickened nails
        8. Triangular lunules (lunulae): a characteristic feature of the syndrome
        9. Most pronounced involvement in thumbnails, decreases in severity ulnarward
        10. Dysplasia of toenails usually less marked, often affecting little toenails, and less frequent than that of the fingernails
        11. Report of nail changes in the mother and son (Neri et al. 2015)
            1. Mother: missing ulnar half of the first fingernail, triangular lunula associated with pseudopterygium/fissure/furrow
            2. Son: anonychia of the first fingernail, koilonychia of the third fingernail, triangular lunula associated with pseudopterygium/fissure/furrow
    2. Knee dysplasia (approximately 74% of cases)
        1. Small, irregularly shaped, or absent patella that is prone to dislocate
        2. May be asymmetrically involved
        3. Hypoplastic patella often located laterally and superiorly, even though not actually dislocated
        4. May be associated with prominent medial femoral condyles, hypoplastic lateral femoral condyles, and prominent tibial tuberosities
        5. Appearance of flattened profile of knee joints
    3. Elbow dysplasia (approximately 70% of cases)
        1. May be asymmetrical
        2. The deformity is characterized by hypoplasia of the capitellum, commonly by secondary dysplasia and dislocation, usually posteriorly, of the radial head, associated with limitation of rotation (pronation and supination) of variable degree
        3. Triceps hypoplasia with antecubital pterygia, a frequent accompaniment of the syndrome, further limiting extension resulting in cubitus valgus
    4. "Iliac horns" (Cottereill and Jacobs 1961)
        1. Clinically palpable
        2. Generally symmetrical
        3. Known to develop a secondary center of ossification
        4. The iliac horns can be present at birth by X-ray examination
    5. To the classical clinical tetrad of involvement of the nails, knees, and elbows and

presence of iliac horns, kidney disease, and glaucoma had been added as recognized parts of the syndrome (McIntosh et al. 2005)

3. Other skeletal abnormalities
    1. Talipes equinovarus, talipes calcaneovalgus deformities, and flat feet
    2. Mild short stature
    3. Adults with nail-patella syndrome have a bone mineral density (BMD) that is 8–20% lower than controls, which is associated with an increase in the prevalence of fractures and scoliosis (Towers et al. 2005)
4. Associated nephropathy (Darlington and Hawkins 1967; Eisenberg et al. 1972; Bennett et al. 1973) (30–50% of cases) (renal failure in approximately 5% of cases)
    1. Proteinuria
        1. Usually the first sign of renal involvement
        2. With or without hematuria
        3. May present at any age from birth onward
        4. May be intermittent
        5. May remit spontaneously, remain asymmetric, progress to nephritic syndrome, and occasionally to renal failure
        6. May be exacerbated during pregnancy
    2. Relatively benign although fatality at a young age from this complication has been described (Leahy 1966)
    3. Progression to chronic glomerulonephritis leading rarely to renal failure
        1. May occur rapidly
        2. May occur after many years of asymptomatic proteinuria
5. Eye involvement
    1. Primary open-angle glaucoma
    2. Ocular hypertension
    3. Iris pigmentary changes: frequent observation of a zone of darker pigmentation shaped like a cloverleaf or flower around the central part of the iris (Lester's sign)
6. Gastrointestinal involvement (about one third of cases)
    1. Constipation
    2. Irritable bowel syndrome
7. Neurologic and vasomotor symptoms are also part of the NPS phenotype (Sweeney et al. 2003)
    1. Neurological involvement
        1. Intermittent numbness, tingling, and burning sensations in the hands and feet in some cases
        2. Epilepsy (6% of cases)
        3. Neurologic symptoms: considered particularly interesting in light of the role of Lmx1b in neuronal migration in the mouse and in the developing brain (Dunston et al. 2005b)
    2. Vasomotor problems in some cases
        1. Poor peripheral circulation, presenting as very cold hands and feet even in warm weather
        2. Raynaud's phenomenon
8. Dental problems
    1. Weak, crumbling teeth
    2. Thin dental enamel
9. Differential diagnoses (Bongers et al. 2005b; Sweeney et al. 2014)
    1. Small patella syndrome (ischiopatellar dysplasia, coxo-podo-patellar syndrome, Scott-Taor syndrome) (Bongers et al. 2004)
        1. Similarities: small or absent patellae, recurrent patella dislocations, pelvic anomalies
        2. Differences, defective ossification at the ischiopubic junction, ischial hypoplasia, infra-acetabular "axe-cut" notch, no nail changes, no elbow changes, no renal involvement, no ocular involvement
    2. Patella aplasia-hypoplasia
        1. Familial occurrence (Bernhang and Levine 1973; Braun 1978)
        2. A family segregating PTLAS mapping to 17q21-q22 (Mangino et al. 1999)
        3. Similarities: isolated aplasia or hypoplasia of the patella
        4. Differences: no nail changes, no elbow changes, no renal involvement, no ocular involvement
    3. Familial recurrent dislocation of the patella (Carter and Sweetnam 1960; Miller 1978; Borochowitz et al. 1988)

1. Similarities: familial tendency toward patella dislocation (autosomal dominant inheritance)
2. Differences: absence of other NPS features

4. Meier-Gorlin syndrome (ear-patella-short stature syndrome) (Shalev and Hall 2003; Bicknell et al. 2011)
   1. Caused by homozygous or compound heterozygous mutation in the ORC1 gene on chromosome 1p32
   2. Similarities: Absent patellae, dislocation of the radial head
   3. Differences: microtia, markedly short stature, delayed bone age, characteristic facial appearance, autosomal recessive inheritance
5. Genitopatellar syndrome (Cormier-Daire et al. 2000; Sankararaman et al. 2012) (please see the chapter on "► Genitopatellar Syndrome")
   1. Similarities: absent patellae, renal anomalies, flexion deformities of the knees and hips, club foot
   2. Differences: hypoplasia of the ischia and iliac bones, genital anomalies, facial dysmorphism, microcephaly, intellectual disability, structural (multicystic kidneys or hydronephrosis) rather than functional abnormalities, renal manifestations
6. DOOR syndrome (deafness, onychodystrophy, osteodystrophy, mental retardation, and seizures syndrome) (Cantwell 1975; Nevin et al. 1982; James et al. 2007)
   1. Caused by homozygous or compound heterozygous mutation in the *TBC1D24* gene on chromosome 16p13 (Campeau et al. 2014)
   2. Similarities: absent or poorly formed nails
   3. Differences: long thumbs and big toes, often with triphalangy, other fingers and toes short as the result of an absent or hypoplastic distal phalanx, bilateral ptosis, short broad nose with a broad nasal tip and large nostrils, structural renal tract abnormalities, cataracts, optic atrophy, Dandy-Walker malformation, seizures, autosomal recessive inheritance
7. Trisomy 8 mosaicism (Jones 1997) (please see the chapter on "► Trisomy 8 Mosaicism Syndrome")
   1. Similarities: absent or hypoplastic patellae, limited elbow supination, abnormal nails
   2. Differences: significant learning difficulties, variable facial dysmorphism, camptodactyly, and progressive joint restriction, usually of the fingers and toes
8. Coffin-Siris syndrome (Vergano and Deardorff 2014)
   1. Caused by heterozygous mutation in the *ARID1B* gene on chromosome 6q25 (Wieczorek et al. 2013)
   2. Similarities: absence or hypoplasia of the nails and patellae, elbow dislocation
   3. Differences: nail hypoplasia, usually affecting the little finger nails, facial dysmorphism
9. RAPADILINO syndrome (Kääriäinen et al. 1989)
   1. The acronym RAPADILINO stands for the characteristic main features: RAdial and PAtellar aplasia or hypoplasia, cleft or highly arched PAlate, infantile DIarrhea and DIslocated joints, LIttle size and LImb malformation, and long slender NOse and NOrmal intelligence
   2. Caused by homozygous or compound heterozygous mutation in the DNA helicase gene *RECQL4* on chromosome 8q24 (Siitonen et al. 2009)
   3. Similarities: absent or hypoplastic patellae, dislocated joints
   4. Differences: cleft palate, facial dysmorphism, short stature, radial defects, including absent or hypoplastic thumbs and radii, autosomal recessive inheritance
10. Senior syndrome (Brachymorphism-onychodysplasia-dysphalangism syndrome) (Senior 1971; Verloes et al. 1993)
    1. Similarities: small nails

2. Differences: characteristic facial appearance, short stature, mild intellectual impairment

Diagnostic Investigations

1. Diagnosis based on clinical and radiographic findings
2. Laboratory studies
    1. Urinalysis: proteinuria, hematuria
    2. Plasma urea, BUN, creatinine concentrations
3. Radiologic features
    1. The characteristic "NPS knee" consists of a combination of easily recognizable malformations (Tigchelaar et al. 2016)
        1. A small or absent patella and a number of malformations of the femoral condyles, encompassing shortening of the lateral femoral condyle, a prominent anterior surface of the lateral femoral condyle and a flat anterior surface of the medial femoral condyle
        2. At least one of these malformations is observed in all patients with NPS and at least three of them are observed in the majority of cases
    2. Elbow involvement
        1. Dysplasia of the radial head
        2. Hypoplasia of the lateral epicondyle and capitellum
        3. Prominence of the medial epicondyle
        4. Dislocation of the radial head, usually posteriorly
    3. Iliac horns
        1. Bilateral, conical, bony processes that project posteriorly and laterally from the central part of the iliac bones of the pelvis
        2. Present in about 70% of cases
        3. Considered pathognomonic of the syndrome (Goshen et al. 2000)
        4. Pelvic X-ray
            1. Usually necessary for detection of iliac horns, but large horns may be palpable clinically
            2. Iliac horns: may be observed at birth
            3. An epiphysis at the apex of iliac horns: may be present in children
    4. MRI
        1. For possible bone/soft tissue abnormalities
        2. For a subluxated or dislocated patella (Konrads et al. 2016)
    5. Ultrastructural (electron microscopic) abnormalities (Morita et al. 1973): the most specific histologic changes seen in nail-patella syndrome
        1. Collagen fibril deposition within the basement membrane and the mesangial matrix
        2. Irregular thickening of the glomerular basement membrane with electron-lucent areas giving a mottled "moth-eaten" appearance
        3. The skin revealed epidermal basement membrane thickening and redundancy in addition to significant perivascular basal lamina reduplication by electron microscopy (Burkhart et al. 1980)
    6. Renal histopathology (Browning et al. 1988)
        1. Characteristic changes in the glomeruli at age 27 months
        2. Strong immunofluorescent staining, particularly for IgM, raised the possibility of superimposed immune complex disease
    7. Molecular genetic testing: *LMX1B* gene mutation analysis available clinically

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. An affected parent: a 50% risk
        2. Clinically unaffected parents
            1. A low risk in a case of de novo mutation in the proband
            2. An increased risk if germline mosaicism exists in a parent (not been reported)
    2. Patient's offspring
        1. A 50% risk
        2. Affected person has a risk of about 1 in 4 of having a child with nail-patella syndrome nephropathy and a risk of about 1 in 10 of having a child in whom renal failure will develop (Looij et al. 1988)

2. Prenatal diagnosis
    1. Use of ultrasound in 3rd trimester diagnosis of NPS (Feingold et al. 1998)
    2. Use of five DNA markers flanking the LMX1B locus demonstrated that a fetus was affected (McIntosh et al. 1999). The pregnancy was terminated at 15 weeks
    3. Demonstration of the disease-causing mutation previously identified in the proband on fetal DNA obtained from amniocentesis or CVS
    4. Preimplantation genetic diagnosis (PGD) may be an option for some families in which the LMX1B pathogenic variant has been identified (Sweeney et al. 2014)
3. Management
    1. Patella dysplasia: most patients asymptomatic, rarely require surgical treatment
    2. Physiotherapy for orthopedic complaints
    3. Surgical treatment
        1. Bilateral elbow soft tissue release
        2. Bilateral radial head excisions
        3. Foot and ankle reconstructive procedures for equinus, pes cavus, calcaneovalgus, congenital vertical talus, and clubfoot deformities
        4. Knee extensor realignments and foot posteromedial releases had overall good results. Knee flexion contractures required full posterior capsular releases. Elbow reconstructive procedures were rarely indicated (Guidera et al. 1991)
        5. Occurrence of secondary patella dislocation is common in NPS. The most likely cause is a medial patellofemoral ligament (MPFL) tear and corrective surgery should be aimed at reconstructing the ligament. Reconstruction using gracilis tendon is a safe and effective method and can be used in NPS cases caused by an MPFL tear (Gong et al. 2016)
        6. Subluxated or dislocated patella (Konrads et al. 2016): early surgical treatment via resection of the trochlear septum and soft tissue balancing of the patella. When the septum displaces the patella and prevents physiological articulation of the patella with the trochlea femoris, early septum resection is likely to be important for a good functional outcome and proper development of the patellofemoral joint during growth
    4. Screening for proteinuria
    5. Screening for glaucoma
    6. Course of pregnancy: complicated by further deterioration of renal function with superimposed pre-eclampsia resulting in early delivery. Such pregnancies should be regarded as high risk and managed jointly with the renal physician in a tertiary care center to ensure an optimal outcome to the mother and baby (Chua et al. 2002)

Fig. 1 (**a**–**i**) A 10-year-old boy (**a**, **b**) has classic nail-patellar syndrome. Note webbings of the neck and the elbows causing marked elbow contractures, abnormal muscle distribution of the upper extremities, nail hypoplasia (**c**, **d**), and absent patella (**e**, **f**). The radiographs show "iliac horn" sign of the pelvis (**g**) and patella agenesis (**h**, **i**)

Nasal Obstruction in Neonates and Children

Contents

Nasal obstruction in the neonate may lead to serious consequences including respiratory distress or failure to thrive. While bilateral nasal obstruction often presents in the neonatal period, unilateral nasal obstruction may not present until much later in life, with chronic nasal drainage, skin irritation, and congestion (Gnagi and Schraff 2013).

Synonyms and Related Disorders

Choanal atresia; Nasal dermoid; Nasal encephalocele; Nasal Glioma; Nasal obstruction; Nasolacrimal duct cyst; Pyriform aperture stenosis

Genetics/Basic Defects

1. Congenital malformations secondary to aberrant embryogenesis of both the internal and external nose potentially causing nasal obstruction include the following but not limited to (Gnagi and Schraff 2013):
    1. Midfacial hypoplasia
    2. Craniosynostosis
    3. Arhinia (complete absence of the nose)
    4. Nasal hypoplasia (congenitally absent nasal bones)
    5. Complete or partial nasal duplication
    6. Single centrally placed nostril
    7. Supernumerary teeth in the nose
    8. Thornwaldt cyst (a common incidental benign midline nasopharyngeal mucosal cyst)
    9. Nasopharyngeal stenosis (incomplete separation of the soft palate and posterior pharyngeal wall)
    10. Others
2. The most common and clinically significant congenital anomalies: please see the differential diagnosis section.

Clinical Features

1. Signs and symptoms of nasal obstruction (Gnagi and Schraff 2013):
    1. Stuffy nose
    2. Rhinorrhea
    3. Mucus
    4. Stertor
    5. Snoring/snorting
    6. External deformity
    7. Nasal flaring

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_267

8. Chest retractions
9. Cyanosis (+/− cyclical nature)
10. Feeding difficulties
11. Hyponasal cry
12. Failure to thrive
13. Dyspnea/apnea
14. Aerophagia with abdominal distention
15. Difficulty sleeping
16. Epiphora

2. Differential diagnosis (Adil et al. 2012; Gnagi and Schraff 2013):
    1. The most common and clinically significant congenital anomalies:
        1. Choanal atresia:
            1. The most common congenital nasal anomaly
            2. Most commonly associated with CHARGE syndrome (please see the chapter)
            3. Can also be seen with Apert, Crouzon, and Treacher Collins syndromes (please see the chapters)
        2. Congenital nasal pyriform aperture stenosis:
            1. Pyriform aperture: the pear-shaped, bony opening of the nasal cavity
            2. Pyriform aperture stenosis: caused by a bony overgrowth of the medial nasal processes of the maxilla, usually bilateral causing nasal obstruction in neonates
            3. May occur as an isolated anomaly or in association with the absence of the anterior pituitary, diabetes insipidus, submucous cleft palate, and hypoplastic maxillary sinuses or as part of the holoprosencephaly sequence
        3. Midnasal stenosis;
            1. A rare clinical entity secondary to bilateral bony overgrowth midway through the nasal cavity
            2. Usually occurs in children with midfacial hypoplasia
        4. Nasolacrimal duct cysts (dacryocystoceles) (Brugger et al. 2010):
            1. Fluid accumulation and distension of the nasolacrimal duct.
            2. Unilaterally in 50.6% or bilaterally in 49.4%.
            3. Can resolve spontaneously during intrauterine life.
            4. Bilateral involvement with substantial intranasal extension may develop respiratory distress syndrome (Bachelard-Serra et al. 2013).
            5. Usually seen as an isolated abnormality but can be associated with other congenital anomalies (Yazici et al. 2010).
        5. Midline nasal masses:
            1. Nasal/nasopharyngeal dermoid: the most common of the congenital midline nasal mass
            2. Glioma (neuroglial heterotopia)
            3. Encephalocele/meningocele: caused by defective development of the skull and herniation of intracranial contents/meninges
            4. Thornwaldt cyst
    2. Neoplasms:
        1. Teratoma
            1. Histologically containing all three germ cell layers.
            2. Tumors: composed of immature cells carrying a higher risk of malignancy with a worse prognosis.
            3. Alpha-fetoprotein and beta-hCG tumor markers may be elevated.
        2. Hamartoma
        3. Vascular lesions (hemangiomas, arteriovenous malformations, vascular malformations)
        4. Lymphangioma
        5. Lipoma
        6. Neurofibroma
        7. Rhabdomyosarcoma
        8. Lymphoma
    3. Infectious:
        1. Upper respiratory infection
        2. Respiratory syncytial virus
        3. Sexually transmitted diseases:
            1. Chlamydia
            2. Gonorrhea
            3. Syphilis

4. Foreign body:
5. Traumatic/iatrogenic:
    1. Septal dislocation
    2. Septal hematoma
    3. Nasal tip depression
    4. Rhinitis medicamentosa
    5. Instrumentations: suction trauma, nasogastric tube, CPAP, and nasal prongs
2. Inflammatory:
    1. Allergic rhinitis (cow's milk, soy)
    2. Gastroesophageal reflux
    3. Recurrent emesis
    4. Idiopathic
3. Metabolic: hypothyroidism
4. Maternal:
    1. Estrogenic stimuli
    2. Drug ingestion (methimazole, methyldopa, opiates, tricyclic antidepressants, propranolol)
5. Associated syndromes:
    1. Cystic fibrosis
    2. Kartagener syndrome
    3. Charge association
    4. Apert syndrome
    5. Crouzon syndrome
    6. Treacher Collins syndrome
    7. Fetal alcohol syndrome
    8. Down syndrome

Diagnostic Investigations

1. Clinical procedures (Gnagi and Schraff 2013):
    1. Anterior rhinoscopy with an otoscope: help visualize anterior stenosis, masses, or obstructive mucus.
    2. Gently passing a small (5 or 6 French) catheter through the nose into the nasopharynx to confirm an open communication:
        1. Obstruction at the anterior inlet may suggest pyriform aperture stenosis, while obstruction posteriorly (approximately 32 mm) may suggest choanal atresia (Myer and Cotton 1983).
        2. Visualizing or palpating the tube through the mouth confirms that the tube is not coiled in the nose to prevent misdiagnosis. In infants with craniofacial abnormalities or visible nasal masses, care must be taken when attempting to pass a nasal catheter, as these may be associated with skull base defects and risk intracranial passage of the catheter (Ramsden et al. 2009).
    3. Additional studies to assess nasal patency include the use of a tympanometer placed at the nares to confirm or exclude a closed cavity (Effat 2005).
    4. Nasal endoscopy:
        1. A simple and minimally invasive diagnostic procedure.
        2. When a nasal mass is identified on endoscopy, it should be assumed to have intracranial extent until proven otherwise. Therefore, no biopsy of a mass should be performed until appropriate imaging has been undertaken (Jaffe 1981).
2. Radiologic imagings (Adil et al. 2012; Gnagi and Schraff 2013):
    1. Plain radiographs with radiopaque contrast in the nasal cavity: rarely employed because of poor sensitivity and specificity
    2. CT scans: best allow bony definition and typically the test of choice to assess choanal atresia and pyriform aperture stenosis
    3. MRI: better choice to evaluate nasal masses to delineate intracranial involvement and extent

Genetic Counseling

1. Recurrence risk: Recurrence risk depends on the etiology of the nasal obstruction:
    1. Patient's sib:
        1. Autosomal recessive: 25%
        2. Autosomal dominant: not increased unless a parent is affected or having gonadal mosaicism
        3. Sporadic: unknown, probably not increased
    2. Patient's offspring:
        1. Autosomal recessive: not increased unless the spouse is also a carrier

2. Autosomal dominant: 50%
3. Sporadic: unknown, probably not increased

2. Prenatal diagnosis:
   1. Ultrasonography:
      1. Nasal gliomas detected at mid-trimester (De Basio et al. 2006; Grzegorczyk et al. 2010; Tonni et al. 2011; Beegun et al. 2012).
      2. A huge fetal facial mass protruded through the left nostril at 33 weeks of gestation: computed tomography of the neonate suggested a transethmoidal encephalocele. However, MRI showed a huge mass occupying the nasopharynx and the nasal cavity and protruding externally to the face without any intracranial connection. Pathologic examination revealed intranasal glioma (Okumura et al. 2012).
      3. Dacryocystocele: anechogenic cystic masses located anteromedially in the orbits and centered on the medial canthus (Bianchini et al. 2004).
   2. Fetal MRI has been used to confirm the diagnosis of dacryocystoceles with the following triad (Bianchini et al. 2004):
      1. Paraocular cystic mass in the medial canthus region
      2. Nasolacrimal duct enlargement
      3. Intranasal cyst
3. Management (Adil et al. 2012; Gnagi and Schraff 2013): secure an adequate airway (the first goal of therapy):
   1. Choanal atresia:
      1. Delay repair of unilateral atresia until school age to allow the nasal cavity to mature.
      2. Transnasal endoscopic repair: most popular technique today.
      3. Transpalatal approach may also be used.
   2. Congenital nasal pyriform aperture stenosis:
      1. Bilateral balloon dilation
      2. Short-term stenting of the nasal pyriform apertures
      3. May require surgical intervention to drill and widen the pyriform aperture
   3. Nasolacrimal duct cysts:
      1. May resolve spontaneously within the first year of life (Peterson and Robb 1978)
      2. Conservative management: warm compresses and gentle massage for simple dacryocystoceles without intranasal extension
      3. Probing the duct and/or surgical marsupialization of the intranasal cyst (Leonard et al.. 2008)
   4. Congenital frontonasal masses (nasal dermoid, encephalocele, glioma, other neoplasms): surgical intervention with multiple surgical subspecialties
   5. Infectious etiologies: treat the underlying cause
   6. Iatrogenic etiologies: treat the underlying cause
   7. Inflammatory, systemic, and other etiologies: treat the underlying cause
   8. Syndrome associations: treat according to the underlying syndrome

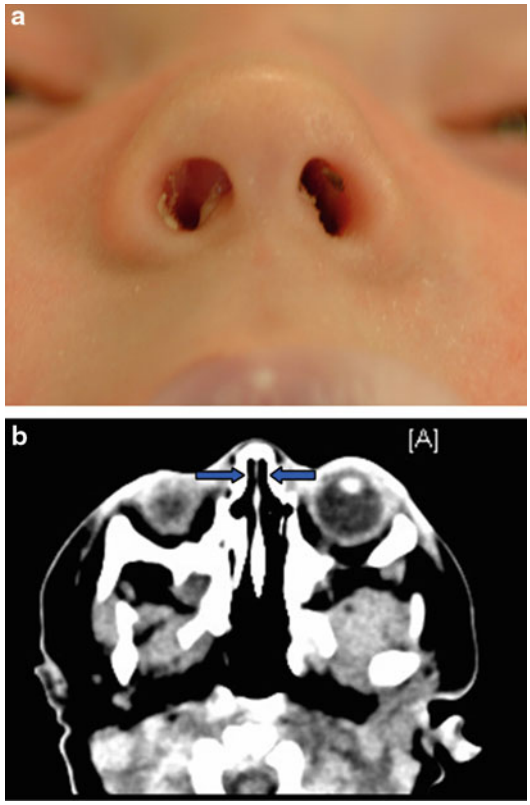

Fig. 1 (**a**, **b**) A 3-week-old Caucasian boy was seen for respiratory distress and inability to feed. Nasal catheters could not be passed on either nasal side and he was referred for evaluation of possible choanal atresia (**a**). He struggled with breathing and desaturated every time he ate. Nasal obstruction was persistent. A flexible pediatric (2.4 mm diameter) endoscope was unable to insert beyond the nasal vestibule on either side. Rigid pediatric endoscope (2 mm Hopkins rod) could not be passed through either nasal passage. A non-contrast axial CT scan (**b**) showed CNPAS with a bilateral combined nasal vestibular aperture width of 5.03 mm (*arrows*) and normal choanae. He underwent bilateral balloon dilation and short-term stenting of the nasal pyriform apertures without the need for additional procedures and remained patent after 12 months at follow-up (Gungor and Reiersen 2014) (Courtesy of Dr. Anil Gungor)

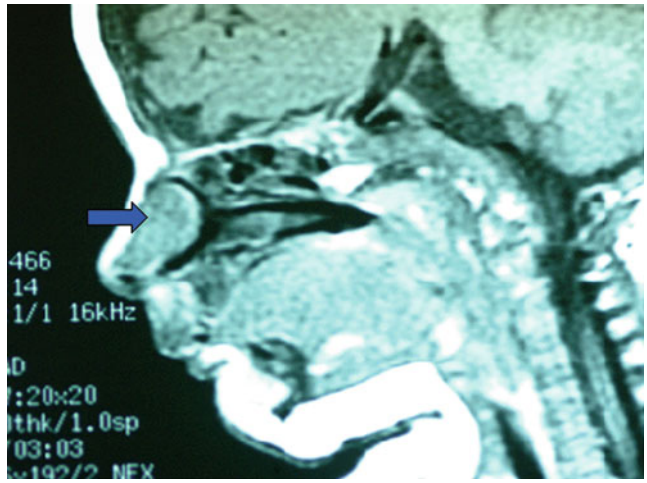

Fig. 2 A 3-month-old boy was seen for a nasal mass present since birth. The mass grew slowly bigger in size, causing nasal obstruction and difficulty in his nasal breathing, accompanied by occasional snoring and intermittent episodic epistaxis. Anterior rhinoscopy showed a large mass originating from the lower lateral cartilage and completely obstructing the right nostril. It appeared to extend to the superior part of the vestibule, but the extent of the entire lesion could not be determined by anterior rhinoscopy alone. Palpation of the mass showed a smooth, rubbery lesion that did not blanche with direct pressure. The lesion was nonpulsatile and did not change in size when the patient cried. A computed tomographic scan and a magnetic resonance imaging scan showed a $0.7 \times 1.8 \times 1.1$ cm soft tissue mass in the anterior right nasal cavity (*arrow*), without extension into the bony nasal framework, nasopharynx, paranasal sinuses, or skull base. No bony erosion was observed. A transnasal excision of the mass was performed with endoscopic guidance. The mass was excised from vestibular skin without difficulty, and a small mucosal attachment from the inferior turbinate was freed with electrocautery. Grossly, the lesion, which was dense and glistening, was a small, tan, white, and focally red mass. Histologically, the mass was a heterotopic neuroglial tissue (nasal glioma) (Roy and Gungor 2014) (Courtesy of Dr. Anil Gungor)

Neonatal Herpes Simplex Infection

Contents

Hass (1935) in *1935* described a fatal case of neonatal herpes simplex virus (HSV) infection with hepatoadrenal necrosis and intranuclear inclusion bodies. Neonatal herpes is defined as the diagnosis of HSV infection in an infant within the first 28 days of life.

Synonyms and Related Disorders

Fetal/intrauterine herpes simplex infection; HSV-1 infection; HSV-2 infection; Maternal genital herpes infection

Genetics/Basic Defects

1. HSV-1 and HSV-2 (Kimberlin 2004)
    1. Belong to Herpesvirus family
        1. Herpes simplex viruses
            1. Enveloped, double-stranded DNA viruses
            2. Exist as two serotypes, 1 and 2 (HSV-1 and HSV-2)
    2. Infections with HSV-1 generally involve the face and skin "above the waist" and are associated with orolabial disease. Most infections occur during childhood. HSV-1 also can cause genital infection, resulting more frequently from oral-genital contact.
    3. Infections with HSV-2 usually involve the genitalia and skin "below the waist" in sexually active adolescents and adults, usually resulting from sexual intercourse. Most HSV disease in neonates is due to HSV-2. HSV-2 also causes oral lesions in approximately 25% of the infected population.
2. Viruses are transmitted from infected to susceptible individuals during close personal contact.
3. Recurrent HSV infections occur in over one third of the world's population due to the rare fatal nature of the infection and a latency period.
4. Infections in children and nonpregnant adults.
    1. Recurrent herpes labialis: the largest reservoir of HSV infections in the community
    2. Genital herpes
        1. A first-episode primary infection occurs in a person with no prior HSV-1 or HSV-2 antibody.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_173

2. A first-episode nonprimary infection occurs in a person with preexisting HSV-1 antibody acquiring HSV-2 genital infection.
3. Recurrent infections can result from viral reactivation from latency and subsequent antegrade translocation of virus back to the skin and mucosal surfaces.

5. Maternal genital infections (Kimberlin 2004; Brown et al. 2005; Pinninti and Kimberlin 2014; James and Kimberlin 2015).
   1. Genital herpes infections are caused by either HSV-1 or HSV-2, and the majority of infections are asymptomatic.
   2. Twenty-two percent of pregnant women are seropositive for herpes simplex virus (HSV)-2, and more than 2% of women acquire genital herpes during pregnancy.
   3. Recurrent genital herpes infections: the most common form of genital HSV infections during gestation.
   4. The most devastating complication of genital HSV is infection of the neonate caused by contact with infected genital secretions at the time of delivery.
   5. Woman with primary genital HSV disease: at highest risk of transmitting the virus to her baby.
   6. Neonatal transmission occurs in the peripartum period, provided the gravid woman is shedding virus, either symptomatically or asymptomatically, at the time of delivery.
   7. Factors influencing transmission from mother to neonate.
      1. Type of maternal infection (primary versus recurrent): Mothers with a first episode of genital HSV infection near term are at much greater risk of developing neonatal herpes than those whose mothers have recurrent genital herpes.
      2. Maternal antibody status.
      3. Duration of rupture of membranes: Cesarean delivery within 4 h of membrane rupture in a woman with active genital lesions can reduce the infant's risk of acquiring HSV.
      4. Integrity of mucocutaneous barriers (e.g., use of fetal scalp electrodes).
      5. Mode of delivery (cesarean section versus vaginal): effective in the prevention of HSV transmission to the neonate from a mother actively shedding virus from the genital tract. Neonatal infection has occurred in spite of cesarean delivery performed prior to the rupture of membranes.
   6. Incidence of neonatal disease: estimated at approximately 1 in 3,200 deliveries (an estimated 1,500 cases of neonatal HSV infection annually in the United States).
   7. Transmission of HSV disease to neonates occurs in the following three distinct time intervals (Pinninti and Kimberlin 2014).
      1. Intrauterine (in utero): 5% infected with HSV in utero
      2. Peripartum (perinatal): overwhelming majority (85%) of infected neonates
      3. Postpartum (postnatal): an additional 10% of infected neonates
   8. Disease classification of HSV infections acquired either peripartum or postpartum: predictive of both morbidity and mortality.
      1. Disease localized to the skin, eyes, and/or mouth (SEM disease, accounting for 45% of cases of neonatal HSV)
      2. Encephalitis, with or without SEM involvement (CNS disease, accounting for 30% of cases of neonatal HSV)
      3. Disseminated infection involving multiple organs, including the CNS, lungs, liver, adrenal glands, skin, eyes, and/or mouth (disseminated disease, accounting for 25% of cases of neonatal HSV)
2. Two biologic properties of HSV that directly influence human diseases
   1. Latency: a period of reactivation of virus multiplication, resulting in clinically apparent disease (lesions) or clinically inapparent (asymptomatic, or subclinical) infection.
   2. Neurovirulence: an affinity with which HSV is drawn to and propagated in neuronal

tissue, resulting in profound disease with severe neurologic sequelae.
    1. Neonatal HSV central nervous system (CNS) disease
    2. Herpes simplex encephalitis in older children and adults
3. Epidemiology (James and Kimberlin 2015)
    1. Humans are the only known natural reservoir of HSV.
    2. Seroprevalence studies indicate that HSV-1 and HSV-2 infections are common worldwide, in both developed and undeveloped countries (Smith and Robinson 2002).
    3. Acquisition of HSV results in lifelong infection, with periodic clinical or subclinical viral reactivation.
    4. Interaction of herpes simplex virus types 1 and 2: Combining data from prospective studies show a trend towards a protective effect for previous HSV-1 infection against infection with HSV-2 (Looker and Garnett 2005).

Clinical Features

1. Intrauterine infection (Hutto et al. 1987; Baldwin and Whitley 1989; Kimberlin 2004)
    1. Incidence: approximately 1 in 300,000 deliveries.
    2. Intrauterine HSV infection can occur as a consequence of either primary or recurrent maternal infection and has severe consequences for the fetus.
    3. In utero disease unlikely to be missed due to the extent of involvement of affected babies.
    4. A triad of clinical findings.
        1. Cutaneous manifestations
            1. Scarring
            2. Active lesions
            3. Hypo-/hyperpigmentation
            4. Aplasia cutis
            5. Erythematous macular exanthem
        2. Ophthalmologic findings
            1. Microphthalmia
            2. Retinal dysplasia
            3. Optic atrophy
            4. Chorioretinitis
        3. Neurologic involvement
            1. Microcephaly
            2. Encephalomalacia
            3. Hydranencephaly
            4. Intracranial calcification
2. Neonatal HSV infection (Waggoner-Fountain and Grossman 2004)
    1. May occur between birth and 4 weeks of age.
    2. Neonatal disease may present as:
        1. Disseminated disease involving multiple organs, most prominently the liver and lungs and possibly with a central nervous system (CNS) component
        2. Disease localized to any area of the skin, eyes, and mouth (SEM)
        3. Localized CNS disease
    3. When HSV infection occurs within the first several weeks of life, viral replication is poorly controlled and the majority of infants will die without treatment. However, acquisition of HSV after this period is typically mild or even asymptomatic (Gantt and Muller 2013).
3. Initial presentation of neonatal presentation of neonatal herpes simplex virus infection (Pinninti and Kimberlin 2014; Curfman et al. 2016)
    1. Disseminated disease (Kimberlin 2004) involving multiple organs, most prominently the liver and lungs and possibly with a central nervous system (CNS) component
        1. Incidence: approximately 25% of all children with neonatal HSV disease.
        2. Has the earliest age of onset, often during the first postnatal week.
        3. Encephalitis: about 60–75% of infants with disseminated disease.
        4. Vesicular rash: over 20% of neonates with disseminated HSV disease do not develop cutaneous vesicles during the course of their illness.
        5. Hepatitis: alanine aminotransferase (ALT) ($\geq \times 1.5$ normal) (McGoogan et al. 2011).

6. HSV pneumonitis: severe respiratory distress or failure with radiographic evidence of opacities in the setting of HSV disease.
7. Disseminated intravascular coagulation: defined as decreased platelets and clotting factors as evidenced by platelets $<$150,000/μL or prothrombin time, international normalized ratio, or partial thromboplastin time above normal range.
8. Death relates primarily to the severe coagulopathy, liver dysfunction, and pulmonary involvement of the disease.

2. Localized CNS disease with or without SEM involvement (Kimberlin 2004; Pinninti and Kimberlin 2014): observed in almost one third of all neonates with HSV infection and has the latest age of onset, usually between the second and third weeks after birth
   1. Account for one third of cases of neonatal herpes disease
   2. Clinical manifestations
      1. Hypotonia
      2. Seizures (both focal and generalized)
      3. Lethargy
      4. Irritability
      5. Tremors
      6. Poor feeding
      7. Temperature instability
      8. Bulging fontanelle
      9. Associated skin vesicles in 60% and 70% of babies classified as having CNS disease
      10. Death usually caused by devastating brain destruction, with resulting acute neurologic and autonomic dysfunction
3. SEM disease
   1. Incidence: approximately 45% of all cases of neonatal HSV disease
   2. Infection confined to the skin, eye, and/or mouth of newborn
   3. Since the introduction of antiviral therapy, ~45% of infants with neonatal HSV disease present with SEM disease (Whitley et al. 1988)
   4. Infants present around day 10–12 of life
   5. 80% of infants with SEM disease present with a vesicular rash
4. Factors affecting the severity of neonatal disease
   1. Prompt diagnosis: PCR assay to detect HSV DNA in neonates has improved early diagnosis of disease.
   2. Initiation of antiviral (intravenous acyclovir) therapy.
      1. Reduces mortality and morbidity among neonates with skin, eye, and mouth disease
      2. Unable to reduce morbidity associated with disseminated or CNS disease
5. Despite early intervention with high-dose antiviral therapy, 30% of infants with disseminated disease die, and 40% of survivors of CNS disease have severe neurologic damage. Therefore, prevention of neonatal infection is critical.

Diagnostic Investigations

1. Clinical diagnosis based on:
   1. Typical findings (HSV culture not necessary):
      1. Herpes labialis
      2. Gingivostomatitis
      3. Genital herpes
   2. Atypical HSV infections (culture and antiviral susceptibility testing needed to guide antiviral therapy)
      1. Immunocompromised patients
      2. HSV conjunctivitis and keratitis: need an ophthalmologist consultation
2. Diagnostic evaluations obtained prior to initiation of acyclovir therapy
   1. HSV cultures: remains the definitive diagnostic method of establishing HSV disease
      1. Skin vesicles, if present
      2. Oropharynx
      3. Conjunctivae
      4. Urine
      5. Blood
      6. Stool

7. Rectum
8. Cerebrospinal fluid (CSF)

2. Liver transaminase: Elevated levels suggest disseminated HSV infection.

3. Serologic testings
   1. Type-specific antibody assays to distinguish between HSV-1 and HSV-2 antibodies.
   2. Identifies only past infection but cannot identify the site of HSV infection.
   3. Patients with cold sores due to HSV-1 will test HSV-1 seropositive regardless of presence or absence of genital HSV-1 infection.
   4. Possible to identify serodiscordant couples in which the woman is HSV-2 seronegative and the partner is seropositive. Women in such couples are at risk for acquiring primary genital HSV infection during pregnancy and are thus at higher risk of transmitting the virus to their babies during birth.
   5. Serologic studies, in general, play no role in the diagnosis of neonatal HSV disease.
4. Cytological examination (Tzanck test) of material obtained from the base of the vesicles becomes extremely important as it can reveal giant multinucleated epithelial cells (Bittencourt et al. 2016)
5. Classification of genital HSV based on serologic and viral detection test results: important in pregnancy because the risk of perinatal HSV transmission varies accordingly
   1. Primary first episode: characterized by isolation of HSV-1 or HSV-2 from genital secretions in the absence of HSV antibodies in serum
   2. Nonprimary first episode: characterized by isolation of HSV-2 from genital secretions in the presence of HSV-1 antibodies in serum
   3. Reactivation disease: characterized by isolation of HSV-1 or HSV-2 from the genital tract in the presence of HSV antibodies of the same serotype as the isolate
6. PCR amplification
   1. Able to correctly diagnose neonatal HSV disease, especially in patients without overt manifestations such as skin vesicles
   2. Able to assess the response to therapy
      1. Having HSV DNA detected in CSF at or after the completion of intravenous therapy is associated with poor outcomes.
      2. Repeat lumbar puncture of all patients with CNS HSV involvement is indicated at the end of intravenous acyclovir therapy to determine that the specimen is PCR negative in a reliable laboratory and to document the end-of-therapy CSF indices. Persons who remain PCR positive should continue to receive intravenous antiviral therapy until PCR negativity is achieved.
7. Canadian Paediatric Society Position Statement: laboratory diagnostics for NHSV (Allen et al. 2014)
   1. Whenever a diagnosis of NHSV is being considered, it is essential to order laboratory testing for HSV in addition to performing skin and mucous membrane examinations:
      1. The standard tests for HSV include CSF PCR and swabs of vesicular lesions and mucous membranes (tested by the method recommended by the local laboratory). Also, blood for HSV PCR may be tested, if available.
      2. Serum hepatic transaminase levels should be measured to provide supporting evidence for disseminated HSV infection.
   2. When evaluating NHSV infection in exposed asymptomatic infants, mucous membrane swabs should be obtained from the mouth, nasopharynx and conjunctivae at least 24 h after delivery. Additional swabs may be obtained (e.g., from sites of scalp electrodes, if present).
   3. PCR testing for CSF HSV DNA is the diagnostic method of choice for CNS HSV.
   4. For all the above tests, clinicians and laboratory staff should work together to minimize the turn-around time for test results.
   5. Direct immunofluorescent antibody staining of skin lesions.
   6. Enzyme immunoassays for HSV antigens in skin lesion.
8. Patients with CNS disease (Curfman et al. 2016) have either

1. Positive HSV CSF PCR or viral culture, with or without CSF or neurologic abnormalities or
2. Positive HSV PCR of blood or skin lesion accompanied by neurologic abnormality and CSF pleocytosis

9. SEM disease (Curfman et al. 2016): characterized by
   1. PCR or viral culture positive for HSV from the skin, conjunctiva, and/or mouth, with or without a positive blood HSV PCR, and
   2. No evidence of other end organ involvement
10. Neuroimaging (Bajaj et al. 2014): a significant correlation between early diffusion-weighted imaging and neurologic sequelae, suggesting that MRI is the most valuable imaging modality in neonatal HSV.

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Unknown
      2. No cases in siblings reported
   2. Patient's offspring
      1. Unknown
2. Prenatal diagnosis
   1. Genetic counseling complicated due to:
      1. Fetal infection may follow primary or recurrent disease.
      2. Fetal infection can occur at any time in gestation.
      3. Only approximately one third of cases have a history suggestive of maternal herpes infection during pregnancy.
   2. Isolation of the virus from amniotic fluid obtained at amniocentesis does not necessarily imply fetal infection (Zervoudakis et al. 1980)
   3. Currently no accurate risk estimate available for congenital malformations following maternal herpes infection during pregnancy
      1. Appears to be small
      2. Highest risk for women with primary infection during the first trimester
3. Management (Kimberlin 2004)
   1. Antiviral drugs
      1. Vidarabine (1-β-D-arabinofuranosyladenine): the first systemically administered antiviral medication with activity against HSV for which the therapeutic efficacy outweighed its toxicity
         1. Administered over prolonged infusion times and in large volumes of fluid
         2. Management of life-threatening HSV and varicella zoster virus infections, HSV encephalitis, and herpesvirus infections in immunocompromised patients
      2. Acyclovir
         1. Lower dose: lower toxicity and improved ease of administration
         2. Higher dose: improved outcome in mortality and morbidity achieved with use of higher-dose acyclovir
   2. Antibody therapy
      1. Use of passive immunotherapy as an adjuvant to active antiviral interventions.
      2. Neonates with higher neutralizing antibody titers: less likely to become infected with HSV following perinatal exposure and being more likely to have localized disease (and less likely to have disseminated disease) once they are infected.
      3. Intravenous gamma globulin currently not recommended for the management of neonates with HSV disease due to variable amount of anti-HSV antibodies present in conventional intravenous gamma globulin preparations.
      4. A monoclonal antibody directed against γD may be available for clinical investigation as an adjuvant therapeutic agent by the NIAID Collaborative Antiviral Study Group in the future.
   3. Prevention of neonatal HSV infections (Pinninti and Kimberlin 2014)
      1. Prevention strategies
         1. Identification of women at risk for HSV acquisition during pregnancy by testing women and possibly their partners for HSV antibodies

2. Provide counseling to prevent transmission to women in late pregnancy
2. Cesarean section
   1. Reduces the infant's risk of acquiring HSV in women with active genital lesions present at the time of delivery.
   2. Limitations: 60–80% of babies who develop neonatal HSV disease are born to women without a history of genital herpes, and thus, infection in these babies may not be prevented by this approach, and women with recurrent infections who are shedding virus at the time of delivery are at low risk of their babies developing neonatal HSV disease.
3. Antiviral therapy during pregnancy
   1. Oral acyclovir near the end of pregnancy to suppress genital HSV recurrences becoming increasingly common in clinical practice.
   2. Additional studies are needed to more definitively establish the effectiveness and safety of late-pregnancy maternal HSV suppression.
4. Vaccine development for genital herpes
   1. Currently, no vaccine has proven to be effective for preventing acquisition of HSV-1 or HSV-2.
   2. A candidate HSV-2 gD subunit vaccine adjuvanted with alum combined with 3-deacylated monophosphoryl lipid A has recently demonstrated promising results in preventing HSV-1 or HSV-2 genital herpes disease and HSV-2 infection, efficacy limited only to women who were HSV-1 and HSV-2 seronegative prior to vaccination.

4. Avoid unnecessary invasive procedures in labor.
   1. Vaginal delivery in women with genital herpes but without lesions or symptoms at the time of labor
   2. Avoid the following procedures to lessen the risk of HSV transmission, except when critical to obstetric care:
      1. Artificial rupture of membranes
      2. Fetal scalp electrodes
      3. Vacuum or forceps delivery
5. HSV infections of the CNS are devastating and require prompt diagnosis and institution of therapy. Heightened awareness of the disease is essential regardless of whether in a newborn or in an adult (Whitley 2015).

Nephrogenic Diabetes Insipidus

Contents

Hereditary nephrogenic diabetes insipidus (NDI) is a rare disorder of defective vasopressin-stimulated water reabsorption via the luminal water channels in the cortical and medullary collecting ducts (Knoers and Deen 2001). In other words, NDI is caused by inability of the kidneys to concentrate urine by reabsorbing water in the collecting duct (Bockenhauer and Bichet 2015).

Synonyms and Related Disorders

Aquaporin 2 diabetes insipidus; Congenital nephrogenic diabetes insipidus

Genetics/Basic Defects

1. Causes of diabetes insipidus (Linshaw 2007; Robertson 2016)
    1. Central: hypothalamic/pituitary lesions leading to insufficient production or release of antidiuretic hormone (ADH)
        1. Postoperative brain surgery
        2. Intracranial lesions (cysts, aneurysms, tumors of pituitary, brainstem)
        3. Infiltrative malignancies (lymphoma, leukemia)
        4. Infections, including encephalitis, meningitis, abscess
        5. Head trauma
        6. Hypoxic injury
        7. Congenital, inherited as an autosomal dominant disorder
    2. Nephrogenic: renal resistance (lack of response of the distal nephron) to ADH from lesions interfering with the renal concentrating mechanism
        1. Acquired metabolic aberrations
            1. Hypokalemia (chronic, Bartter syndrome)
            2. Hypercalcemia
            3. Hypercalciuria (rare)
            4. Diabetes mellitus
        2. Medullary damage
            1. Chronic pyelonephritis
            2. Infiltrative disease (leukemia, lymphoma, amyloidosis)
            3. Sickle cell disease
            4. Cystinosis
            5. Other forms of chronic renal failure
            6. Obstructive uropathy

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_174

3. Drugs
    1. Lithium
    2. Demeclocycline
    3. Amphotericin B
    4. Diphenylhydantoin
4. Inherited
    1. X-linked recessive: approximately 90% of cases of hereditary nephrogenic diabetes insipidus
    2. Autosomal recessive: approximately about 9% of cases
    3. Autosomal dominant: about 1% of cases

2. Adult patients can develop acquired NDI (Sands and Bichet 2006). The most common cause is lithium therapy for bipolar disorders. Other causes of acquired NDI are prolonged hypokalemia, hypercalcemia, protein malnourishment, and the release of bilateral or unilateral ureteral obstruction. In addition, normal aging can result in partial NDI
3. X-linked inheritance
    1. Caused by mutations in the arginine vasopressin V2 receptor (*AVPR2*) gene (Vargas-Poussou et al. 1997) on the X chromosome (mapped on Xq28), encoding the arginine vasopressin receptor type 2 (VR2): molecular basis for lack of concentration of urine
    2. The spectrum of mutations varies from rare gene variants or polymorphisms not causing NDI to rare mutations causing NDI, among which arginine and tyrosine are the most common missense (Spanakis et al. 2008)
    3. Novel large deletion in AVPR2 gene causing copy number variation in a patient with X-linked nephrogenic diabetes insipidus (Cho et al. 2016)
    4. Males who carry the defective gene
        1. Do not concentrate urine after administration of arginine vasopressin (AVP): defined as the excretion of increased (>30 ml/kg/day) volumes of diluted urine (<250 mmol/kg) (Fujiwara and Bichet 2005)
        2. Tend to have more serious symptoms
            1. Polydipsia (excessive thirst)
            2. Polyuria (excessive urine production)
    5. Females who carry the defective gene: can have variable (rarely severe) degrees of polydipsia and polyuria because of skewed X chromosome inactivation (Arthus et al. 2000)
4. Autosomal recessive inheritance (Hochberg et al. 1997)
    1. Caused by aquaporin 2 (*AQP2*, mapped on 12q13) mutations (Hoekstra et al. 1996; Vargas-Poussou et al. 1997; Fujiwara and Bichet 2005; Bircan et al. 2008; Duzenli et al. 2012; Sasaki et al. 2013)
    2. Polyuria and polydipsia are usually present at, or shortly after, birth
    3. Disease tends to be more severe, with urine osmolality generally not exceeding approximately 200 mOsm/kg water
5. Autosomal dominant inheritance
    1. A few *AQP2* mutations have been described to cause autosomal dominant disease (Vargas-Poussou et al. 1997; Mulders et al. 1998; Kuwahara et al. 2001; Marr et al. 2002; Kamsteeg et al. 2003)
    2. Clinical expression
        1. Tends to become noticeable after 6–12 months or even later
        2. May not be as severe (urine osmolality may be higher)
        3. Transient response to ADH may be present
    3. AQP2-R254W is associated with a partial nephrogenic DI phenotype with some ability to concentrate urine when dehydrated (Dollerup et al. 2015)

Clinical Features

1. Medical history (Linshaw 2007)
    1. Failure to thrive
    2. Extreme thirst
    3. Unexplained fever
    4. Irritability
    5. Constipation
    6. Impressive polyuria
    7. Vomiting
    8. Seizures

2. Physical features
   1. Dry mouth and eyes
   2. Poor skin turgor
   3. Sunken eyes and anterior fontanelle
   4. Mottled skin
   5. Decreased peripheral pulses
   6. Low blood pressure
   7. Multiple abdominal masses/fecaliths
   8. Low cognitive and psychosocial functioning: current prevalence considerably lower than suggested in literature (Hoekstra et al. 1996)
3. Urologic complications in patients with NDI ($n = 173$) (Fujimoto et al. 2014)
   1. Hydronephrosis 47
   2. Hydroureter 24
   3. Renal failure 11
   4. Vesicoureteral reflux 11
   5. Slightly dilatation of renal pelvic 7
   6. Dilatation of bladder 3
   7. Renal atrophy/dwarf kidney 3
   8. Neurogenic bladder 2
   9. Acidosis 1
4. Four different types of diabetes insipidus: differential diagnosis and management (Babey et al. 2011; Robertson 2016)
   1. Pituitary DI (neurohypophyseal)
      1. Basic defect: deficient production and secretion of AVP
      2. Causes: acquired or genetic
      3. Treatment: antidiuretic hormone, arginine vasopressin (AVP), desmopressin, chlorpropamide, tegretol
   2. Primary polydipsia
      1. Basic defect: suppressed secretion of AVP due to excessive fluid intake
      2. Causes: abnormal thirst (dipsogenic) or abnormal cognition (psychogenic)
      3. Treatment: education, psychotherapy?
   3. Gestational diabetes insipidus
      1. Basic defect: increased degradation of AVP during pregnancy
      2. Causes: placental vasopressinase
      3. Treatment: Management of DI of pregnancy depends on the pathophysiology of the disease; forms of DI that lack AVP can be treated with desmopressin (DDAVP), while forms of DI that involve resistance to AVP require evaluation of the underlying causes (Ananthakrishnan 2016)
   4. Nephrogenic diabetes insipidus
      1. Basic defect: renal insensitivity to antidiuretic effect of AVP
      2. Causes: acquired or genetic
      3. Treatment: thiazide and/or amiloride with or without Indomethacin

Diagnostic Investigations

1. Laboratory features (Knoers 2012; Linshaw 2007)
   1. Hypernatremia: serum sodium concentration >143 mEq/L in the presence of a low urine specific gravity and in the absence of excessive sodium intake: highly suggestive of diabetes insipidus
   2. Failure to concentrate the urine in the presence of high plasma vasopressin concentration and in the presence of parenteral administration of vasopressin or desmopressin: diagnostic of NDI
   3. Hyperchloremia
   4. Metabolic acidosis
   5. Normal potassium concentration
   6. Hyperuricemia
   7. High serum and low urine osmolality
2. DDAVP (vasopressin analogue 1-desamino-8-D-arginine vasopressin) test (Bockenhauer and Bichet 2015): upon administration of the DDAVP, phosphorylation of AQP2 at Ser256, Ser264, and Ser269 is abundantly increased, whereas phosphorylation at Ser261 is decreased (Kortenoeven and Fenton 2014)
3. All families with hereditary diabetes insipidus should have their molecular defect identified (Bichet and Bockenhauer 2016)
4. Molecular identification underlying X-linked NDI (*AVPR2*): immediate clinical significance because early diagnosis and treatment of affected infants can avert the physical and mental retardation that results from repeated episodes of dehydration (Fujiwara and Bichet 2005)

5. Molecular identification underlying autosomal recessive and autosomal dominant NDI (*AQP2*)

Genetic Counseling

1. Recurrence risk (Knoers 2012)
    1. Patient's sib
        1. X-linked recessive: risks of sibs depending on the genetic status of the proband's mother
            1. If the mother is a carrier: 50% of male sibs will be affected (inheriting the maternal *AVPR2* mutation); 50% of female sibs will be carriers
            2. A low recurrence risk but not zero due to possible germline mosaicism if the proband is the only one affected in the family and the disease-causing mutation cannot be detected in the DNA of the mother
        2. Autosomal recessive inheritance: risk of recurrence 25%
        3. Autosomal dominant inheritance
            1. Recurrence risk of 50% if a parent is affected
            2. A low recurrence risk if both parents are normal
    2. Patient's offspring
        1. X-linked recessive: All daughters of affected males will be carriers. All sons of an affected male will be normal
        2. Autosomal recessive inheritance
            1. Obligatory carriers for a disease-causing mutation in the *AQP2* gene
            2. A low recurrence risk unless the spouse is affected or a carrier
        3. Autosomal dominant inheritance: a 50% risk of offspring affected (inheriting the *AQP2* mutation)
2. Prenatal diagnosis
    1. X-linked recessive: available for pregnancies at increased risk if the *AVPR2* mutation has been identified in an affected family member by amniocentesis of CVS if the fetal karyotype is 46,XY
    2. Autosomal recessive and autosomal dominant: available for pregnancies at increased risk for the *AQP2* mutation
    3. Preimplantation genetic diagnosis may be available for families in which the disease-causing mutation(s) has/have been identified.
3. Management (Linshaw 2007; Bockenhauer and Bichet 2015)
    1. Current treatment approaches for congenital NDI focus on ameliorating the symptoms rather than curing the disease
    2. If possible, treatment of acquired NDI should target the underlying cause, such as relief of urinary obstruction or amiloride therapy in lithium-associated NDI (Batlle et al. 1985)
    3. Patients with NDI should be treated with hypotonic fluids, either enterally (using water or milk) or if necessary intravenously (using 5% dextrose in water). Hypotonic fluids must never be administered as an intravenous bolus; instead, the infusion rate should only slightly exceed the urine output. The aim is to provide just enough water to safely normalize plasma sodium concentration at a rate of <0.5 mmol/l per h (<10–12 mmol/l per day). The main risk of a rapid decrease in plasma sodium is cerebral edema and potentially death (Kahn et al. 1979; Cansick et al. 2009; Fang et al. 2010; Sterns 2015)
    4. The usual prescription of overnight dehydration should not be used in patients, and especially children, with severe polyuria and polydipsia. Great care should be taken to avoid any severe hypertonic state, arbitrarily defined as a plasma sodium of >155 mEq/l
    5. Sufficient water to maintain normal electrolytes
    6. Low renal solute load to minimize water loss
    7. Adequate calories to support growth
    8. Pharmacotherapy
        1. Prostaglandin synthesis inhibitors have become essential components in the treatment of NDI, particularly in the

first years of life when management is the most complicated. The effect of these drugs can be quite marked when first initiated. Indeed, hyponatremic seizures associated with rapid lowering of plasma sodium levels as a result of commencing indomethacin and hydrochlorothiazide have been reported (Boussemart et al. 2009)

2. Thiazide
    1. Hydrochlorothiazide: 1–3 mg/kg/day bid
    2. Hypokalemia
    3. Hyponatremia
    4. Alkalosis
    5. Hypercalcemia
    6. Hyperglycemia
    7. Hyperuricemia
    8. Hepatitis
    9. Intestinal symptoms
    10. Bone marrow suppression
3. Indomethacin
    1. 1.5–2.5 mg/kg/day tid
    2. Gastrointestinal discomfort
    3. Gastrointestinal bleeding
    4. Headaches
4. Amiloride
    1. 20 mg/1.73 m^2/day bid-tid
    2. Hyperkalemia
    3. Headaches
    4. Gastrointestinal discomfort
    5. Renal toxicity
    6. Hematopoietic adverse effects

9. With appropriate treatment, complications of NDI, such as failure to thrive and mental retardation resulting from repeated hypernatremic dehydration, can be avoided

Fig. 1 A 3-year-old girl was evaluated because her father has nephrogenic diabetes insipidus. He has problems with dehydration, polyuria, and polydipsia. His mother is a carrier and his maternal grandfather died of nephrogenic diabetes insipidus. The girl was found to have a mutation in the *AVPR2* gene. The mutation detected is g692-693delCT where two bases (CT) in codon 111 are deleted. The deletion causes a frameshift mutation that begins with a change of the amino acid at position 111 and results in a premature termination of protein synthesis at codon 190. This mutation has been reported to cause nephrogenic diabetes insipidus (NDI). The genetic data along with the family history are consistent with this female being a carrier of X-linked NDI

Netherton Syndrome

Contents

Netherton syndrome is a rare hereditary disorder of keratinization. It was described by Comèl (1949) in 1949 and Netherton (1958) in 1958. The syndrome is sometimes called Comèl-Netherton syndrome (De Felipe et al. 1997). The incidence is about 1 in 200,000 (Bitoun et al. 2002b).

Synonyms and Related Disorders

Comel-Netherton syndrome; Ichthyosis linearis circumflexa; Netherton disease; Trichorrhexis invaginata

Genetics/Basic Defects

1. Inheritance: autosomal recessive (Bitoun et al. 2002b)
2. Defective gene in Netherton syndrome
    1. Serine protease inhibitor, Kazal type 5 (*SPINK5*) mapped on chromosome 5q31-32 (Chavanas et al. 2000a, b).
    2. The protein encoded by *SPINK5* is highly expressed in thymus and mucous epithelia, thereby termed LEKTI for lymphoepithelial Kazal type-related inhibitor (Bitoun et al. 2003).
        1. LEKTI possibly plays a role in anti-inflammatory and/or antimicrobial protection of mucous epithelia.
        2. LEKTI possibly have similar function in the epidermis.
    3. Compound heterozygous mutation of the SPINK5 gene inherited from both parents (Chao et al. 2003).
    4. A compound synonymous mutation c.474G>A with p.Arg578X mutation in *SPINK5* causes splicing disorder and mild phenotype in Netherton syndrome (Numata et al. 2016).
    5. Lethal Netherton syndrome due to homozygous p.Arg371X mutation in *SPINK5* (Diociaiuti et al. 2013).
    6. Severe lethal phenotype of a Japanese case of Netherton syndrome with homozygous founder mutations of SPINK5 c.375_376delAT (Itoh et al. 2015).
    7. Complete maternal isodisomy of chromosome 5 with a pathogenic SPINK5 mutation in a Japanese patient with Netherton syndrome was reported (Numata et al. 2014). The most likely cause of UPD in this patient

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_175

is fertilization of a normal egg by a nullisomic sperm with subsequent salvage of a monosomy by post-fertilization duplication of the maternal chromosome 5, resulting in homozygosity for the *SPINK5* locus containing the mutation p. Arg578X (Kotzot and Utermann 2005). The other case of Netherton syndrome reported previously by Lin et al. (2007) was caused by a homozygous missense mutation p.Arg267Glu in *SPINK5*, resulting from a de novo mutation in combination with segmental maternal isodisomy.

Clinical Features

1. Clinical triad.
    1. Congenital ichthyosis
        1. Extent of involvement: highly variable
        2. Natural course
            1. At birth: usually normal-appearing skin.
            2. Within a few weeks of age: the skin becomes erythematous and develops serpiginous double-edged scales typical of ichthyosis linearis circumflexa or ichthyosiform erythroderma.
        3. Severe congenital generalized exfoliative erythroderma in newborns and infants: a possible sign of Netherton syndrome (Hausser and Anton-Lamprecht 1996)
    2. Hair abnormality (Stevanovic 1969)
        1. Trichorrhexis invaginata/nodosa.
            1. Sparse and brittle scalp hair with a characteristic “bamboo” shape under light microscope due to invagination of the distal part of the hair shaft to its proximal part
            2. The major diagnostic sign (considered pathognomonic) but may be difficult to detect in infancy and early childhood (Ansai et al. 1999)
            3. May not affect all hair and can be limited to the lateral part of the eyebrows
        2. Pili torti.
        3. Eyelashes and eyebrows (Powell 2000) may be affected.
    3. Atopic manifestations (Bitoun et al. 2002b)
        1. Eczema-like rashes
        2. Atopic dermatitis
        3. Pruritus
        4. Allergic rhinitis
        5. Asthma
        6. Urticaria/angioedema
        7. Mimicking pustular psoriasis (Small and Cordoro 2016)
2. Prognosis: poor (Bitoun et al. 2002b).
    1. Frequent life-threatening complications during the neonatal period
        1. Hypernatremic dehydration (Jones et al. 1986; Stoll et al. 2001)
        2. Hypothermia
        3. Extreme weight loss
        4. Recurrent infections
        5. Bronchopneumonia
        6. Sepsis
    2. Failure to thrive common during childhood resulting from:
        1. Malnutrition
        2. Metabolic disorders
        3. Chronic erythroderma
        4. Persistent cutaneous infections
        5. Severe enteropathy with villous atrophy
        6. Growth retardation
    3. Other abnormalities
        1. Renal failure
        2. Aminoaciduria
        3. Congenital heart defects
        4. Hydroureter
        5. Infantile pyloric stenosis
        6. Increased susceptibility to skin cancer (Krasagakis et al. 2003)
            1. Squamous cell carcinoma (Sahari et al. 2002)
            2. Vulvar cancer
3. Intrafamily and interfamilial phenotype variation and immature immunity in patients with Netherton syndrome and Finnish *SPINK5* founder mutation (Hannula-Jouppi et al. 2016).
4. Genotype-phenotype correlations suggested that homozygous nucleotide changes resulting

in early truncation of LEKT1 are associated with a severe phenotype (Sprecher et al. 2001).

5. Differential diagnosis of Netherton syndrome with neonatal presentations of selected ichthyoses (Craiglow 2013).
    1. Collodion baby (please see the chapter of "► Collodion Baby")
    2. Harlequin ichthyosis (please see the chapter of "► Harlequin Ichthyosis")
    3. X-linked ichthyosis (please see the chapter of "► X-Linked Ichthyosis")
    4. Epidermolytic ichthyosis (EI) (also known as bullous congenital ichthyosiform erythroderma or epidermolytic hyperkeratosis)
        1. An autosomal dominant disorder caused by mutations in the genes *KRT1* and *KRT10*, encoding keratin 1 and keratin 10, respectively (Rothnagel et al. 1992).
        2. Presents at birth with blistering and areas of denuded skin: This presentation may initially be confused with epidermolysis bullosa, staphylococcal scalded skin syndrome, or toxic epidermal necrolysis.
        3. A similar but milder presentation can be seen in infants with ichthyosis bullosa of Siemens, where blisters tend to be smaller and arise at sites of trauma. Over time, the blistering and denudation seen in EI diminishes, and hyperkeratosis becomes the prominent cutaneous manifestation, with dark, thick scales, often in a corrugated or ridged pattern.
6. Differential diagnosis of Netherton syndrome with syndromic forms of inherited ichthyosis (Yoneda 2016).
    1. Sjögren-Larsson syndrome: an autosomal recessive disorder characterized by congenital ichthyosiform exanthema, spastic paralysis of the limbs, and mental retardation.
    2. Refsum syndrome: an autosomal recessive disorder characterized by pigmentous retinitis, peripheral neuritis, cerebellar ataxia, and an increase in the cerebrospinal fluid level of protein. In addition, symptoms, such as anosmia, hemeralopia, vision disorder, cataract, muscular atrophy, cardiomyopathy, bone disorder, progressive myelin degeneration, functional disorder of the nervous system, cochlear hearing loss, ichthyosis, and renal failure, are observed.
    3. Multiple sulfatase deficiency ichthyosis.
        1. Caused by homozygous or compound heterozygous mutation in the sulfatase-modifying factor-1 (*SUMF1*) gene.
        2. Patients show symptoms related to the concomitant development of three disease groups:
            1. Metachromatic leukodystrophy with the deposition of sulfatide in the nerve tissue or kidney, resulting from abnormalities in arylsulfatase A
            2. Acidic mucopolysaccharidosis with the accumulation of heparan sulfate or dermatan sulfate in a large number of cells, including fibroblasts, resulting from abnormalities in arylsulfatase B
            3. Ichthyosis related to steroid sulfatase abnormalities
    4. Keratitis-ichthyosis-deafness syndrome (please see the chapter of "► KID Syndrome").
    5. Congenital hemidysplasia, ichthyosiform erythroderma or nevus, and limb defects syndrome.
        1. X-linked recessive or X-linked dominant inheritance (male lethal)
        2. Caused by *NSDHL* gene (3-β-hydroxysteroid dehydrogenase) mutations
    6. Ichthyosis, brittle hair, impaired intelligence, decreased fertility, and short stature.
        1. An autosomal recessive disorder
        2. Classified into three types:
            1. Trichothiodystrophy (TTD)/XPD, in which excision-repair, complementing defective, in Chinese hamster, 2 (ERCC2)/xeroderma pigmentosum, complementation group D (XPD) gene mutations are detected
            2. TTD/XPB, in which ERCC3/XPB gene mutations are detected
            3. TTD-A

7. Conradi-Hünermann-Happle syndrome (please see the chapter of "▶ Chondrodysplasia Punctata"
8. Dorfman-Chanarin syndrome.
    1. An autosomal recessive disorder.
    2. Caused by homozygous mutation in the comparative gene identification-58 (CGI58) gene.
    3. Clinical symptoms resemble those of non-bleb-type congenital ichthyosiform erythroderma (patients are not collodion babies at the time of birth), severe pruritus, decreased sweat volume, liver dysfunction, muscular weakness, cataract, renal dysfunction, deafness, mental retardation, nervous diseases, and a short stature.
9. Ichthyosis follicularis with alopecia and photophobia.
    1. X-linked recessive inheritance is suggested.
    2. Caused by mutation in the *MBTPS2* gene on chromosome Xp22.
10. Hystrix-like ichthyosis with deafness: caused by heterozygous mutation in the connexin-26 gene, *GJB2*, located at human chromosome 13q12.11.

Diagnostic Investigations

1. Clinical laboratory
    1. Increased serum immunoglobulin E levels (Smith et al. 1995).
    2. Hypereosinophilia.
    3. No consistent or significant abnormalities of immune function (Judge et al. 1994).
    4. IgG abnormalities (both hypo- and hyper-IgG).
    5. T-cell and neutrophil defects may also occur.
    6. Selective humoral deficiency to bacterial polysaccharide antigens has been described (Stryk et al. 1999).
    7. Specific IgE antibodies against airborne and food allergens frequently present.
2. Dermatoscopy (trichoscopy) (Sun and Linden 2005; Burk et al. 2008; Rakowska et al. 2009; Akkurt et al. 2014; Bittencourt et al. 2015)
    1. Trichorrhexis invaginata (bamboo hairs).
        1. A focal defect of the hair shaft that produces development of torsion nodules and invaginated nodules.
        2. The proximal element of the node overlaps the distal portion, causing an intussusception.
    2. Golf tee-like endings of hair shafts: If hair is pulled distally from this focal defect, a golf tee-like deformity is left. Hence, any hairs examined should be cut, rather than plucked.
    3. The hair shaft nodules caused by this defect are sometimes able to be seen by the naked eye. These hair defects can be found in scalp, eyebrow, or eyelash hairs. Grossly, scalp hair is described to be sparse and brittle.
    4. The hair shaft abnormality was reported to be secondary to intermittent incomplete formation of disulfide bonds in the keratogenous zone (Ito et al. 1984).
    5. Other hair shaft abnormalities.
        1. Pili torti
        2. Trichorrhexis nodosa
        3. Helical hairs (Lurie and Garty 1995)
        4. "Matchstick" eyebrow hairs: a dermoscopic clue to the diagnosis of Netherton syndrome (Goujon et al. 2010)
3. Classic histological criteria of Netherton syndrome (Berthold et al. 2016)
    1. Trichorrhexis invaginata
    2. Parakeratosis
    3. Acanthosis
    4. Lack of stratum granulosum
    5. Increased dermal vascularization
    6. Sparse perivascular inflammatory infiltrate
4. Immunohistochemistry using anti-LEKTI antibodies: shows a complete absence of LEKTI in the skin samples (Shimomura et al. 2005)
5. Histology and ultrastructural studies of skin sections
    1. Incomplete keratinization or defective cornification of the epidermis
    2. Dermal lymphocytic infiltrate
    3. Ultrastructure of the stratum corneum: characterized by premature degradation of

corneodesmosomes with separation of corneocytes (Chao et al. 2005)

6. Molecular genetic testing of *SPINK5*: clinically available
   1. Mutation analysis of patients
   2. Carrier testing

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: 25 %
   2. Patient's offspring: not increased unless the spouse is a carrier of the gene
2. Prenatal diagnosis (Bitoun et al. 2002a)
   1. Ultrastructural examination of fetal skin biopsies for defective cornification of the epidermis is not reliable, since fetal skin keratinization does not begin until the 24th week of gestation, whereas in utero, fetal skin biopsy is usually performed between 19 and 22 weeks.
   2. DNA-based prenatal diagnosis on fetal DNA obtained from amniocentesis or CVS.
      1. *SPINK5* mutation detection
         1. First case of prenatal diagnosis by mutation detection (Sprecher et al. 2001).
         2. A recurrent homozygous mononucleotide deletion (153delT) in exon 3 of *SPINK5* gene, resulting in a severe case of Netherton syndrome exhibiting exfoliative erythroderma with lethal outcome at the age of 4 months and its application in prenatal testing in a subsequent pregnancy of the mother (Müller et al. 2002).
         3. Two consanguineous Turkish families (two sisters married with two brothers) for prenatal diagnosis of Netherton syndrome and successful intracytoplasmic sperm injection (ICSI) pregnancies using planned prenatal genetic diagnosis (Bingol et al. 2011). Homozygous mutation was found in exon 4 as 238 insG, and this mutation was confirmed by direct sequencing analysis with DNA samples from father and mother (Bingol et al. 2011).
      2. Indirect genotype analysis at the *SPINK5* locus using linkage analysis
         1. This approach is reliable since there is no evidence of locus heterogeneity.
         2. Presence of a large number of SPINK5 intragenic restriction fragment length polymorphisms (RFLPs) showing a high percentage of heterozygosity.
3. Management
   1. No specific treatment available.
   2. Emollients.
   3. Keratolytics.
   4. Antibiotics for recurrent infections.
   5. Topical corticosteroids.
   6. Topical tacrolimus and pimecrolimus with good control of skin disease without toxic effect (Saif and Al-Khenizan 2007).
   7. Medium dose of psoralen-UVA1 phototherapy may be effective and tolerated in adult (Capezzera et al. 2004).
   8. NS is a complex disorder, where defects in epidermal integrity and cohesion may induce the appearance of aggressive skin cancers. Strict surveillance for human papillomavirus-related lesions and skin malignancies and caution in administrating immunosuppressive drugs or phototherapy are strongly recommended for these patients (Guerra et al. 2015).
   9. A trial of intravenous immunoglobulin (the TNF-α inhibitor infliximab) is a rational treatment approach for patients with severe disease (Small and Cordoro 2016).

Fig. 1 A neonate (**a**) with Netherton syndrome showing erythroderma. The patient had markedly elevated serum total IgE levels of 409 IU/mL at age 8 months and 285 IU/mL at 14 months of age. Molecular genetic analysis of *SPINK5* showed a compound heterozygote with a mutation 316DelGA in exon 5 inherited from the mother and a mutation 2441+1delGTGA in exon 25 inherited from the father. The same patient at age 3 years (**b**) showed generalized erythroderma and marked growth retardation (height age of 7 months and weight age of 4 months). Microscopic analysis of the hair (**c** and **d**, lower and higher magnification) showed trichorrhexis invaginata/nodosa (*bamboo hair*) (*pink arrows*), pili torti (*yellow arrow*), and fractured hair shaft at the site of invagination (*blue arrow*)

Neu-Laxova Syndrome

Contents

The Neu-Laxova syndrome (NLS) is a lethal disorder characterized by multiple congenital malformations. Microcephaly, lissencephaly, absence of corpus callosum, facial anomalies (notably absent eyelids), short broad neck, peripheral edema, ichthyosis, limb anomalies, and other malformations are common findings. The syndrome was described first by Neu et al. in 1971 and Laxova et al. in 1972 (Neu et al. 1971; Laxova et al. 1972).

Genetics/Basic Defects

1. Inheritance: autosomal recessive inheritance (Abdel Meguid and Temtamy 1991; King et al. 1995; Badakali et al. 2012; Mattos et al. 2015).
2. Genetic heterogeneity: can be caused by mutations in all three genes (*PHGDH*, *PSAT1*, and *PSPH*) encoding enzymes of the L-serine biosynthesis pathway (Acuna-Hidalgo et al. 2014).
    1. *PHGDH* missense mutations were identified in three unrelated families (Shaheen et al. 2014).
    2. Furthermore, an overlapping homozygous chromosome 9 region containing *PSAT1* was mapped in four consanguineous families. This gene encodes phosphoserine aminotransferase, the enzyme for the second step in L-serine biosynthesis. Six families with three different missense and frameshift *PSAT1* mutations fully segregating with the disease were also identified.
    3. In another family, a homozygous frameshift mutation in *PSPH*, the gene encoding phosphoserine phosphatase, which catalyzes the last step of L-serine biosynthesis, was identified.
    4. Interestingly, all three identified genes have been previously implicated in serine-deficiency disorders, characterized by variable neurological manifestations. The findings expand our understanding of NLS as a disorder of the L-serine biosynthesis pathway and suggest that NLS represents the severe end of serine-deficiency disorders, demonstrating that certain complex syndromes characterized by early lethality could indeed be the extreme end of the phenotypic spectrum of already known disorders.
    5. Serine biosynthesis defects present in a broad phenotypic spectrum that includes, at the severe end, Neu-Laxova syndrome,

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_176

a lethal multiple congenital anomaly disease; intermediately, infantile serine biosynthesis defects with severe neurological manifestations and growth deficiency; and at the mild end, the childhood disease with intellectual disability (El-Hattab 2016; El-Hattab et al. 2016). A serine transport defect resulting from deficiency of the ASCT1, the main transporter for serine in the central nervous system, has been recently described in children with neurological manifestations that overlap with those observed in serine biosynthesis defects. L-serine therapy may be beneficial in preventing or ameliorating symptoms in serine biosynthesis and transport defects.

3. Based on previous associations of mutations in the *PHGDH* with a milder NLS phenotype, as well as cases of serine deficiency, these observations lend further support to a genotype-phenotype correlation between the degree of *PHGDH* inactivation and disease severity (Mattos et al. 2015).
4. Pathogenesis (Coto-Puckett et al. 2010): remains unknown and differing etiologies have been postulated.
    1. A form of neuroectodermal dysplasia given the CNS and skin findings (Lazjuk et al. 1979; Ejeckam et al. 1986; Muller et al. 1987; Naveed and Sreenivas 1990)
    2. CNS pathology described as a neuronal migration defect with arrest of development early at 12–14 weeks of embryogenesis (Muller et al. 1987; Ostrovskaya and Lazjuk 1988)
    3. A neurodegenerative disorder with abnormal cell death causing neuronal atrophy and depletion (Allias et al. 2004)
    4. Limb deformities: caused by failure of muscle, bone, nerve, and arterial development in early embryogenesis (Shved et al. 1985)
    5. Contractures: secondary to reduced fetal movements or fetal akinesia/hypokinesia (Fitch et al. 1982; Russo et al. 1989)
    6. Ichthyotic skin changes: the cause of the deformed limbs, reduced movement, massive edema, and IUGR (Karimi-Nejad et al. 1987; Russo et al. 1989)
    7. Mechanism of ichthyosis proposed as hypoproteinemia caused by protein leakage through skin fissures as the primary pathogenesis of Neu-Laxova syndrome (Karimi-Nejad et al. 1987)
    8. It is the restrictive dermopathy that leads the various authors to characterize Neu-Laxova syndrome as a malformation sequence

Clinical Features

1. Considerable intrafamilial and interfamilial variation in clinical features
2. Prenatal history
    1. Severe intrauterine growth retardation
    2. Polyhydramnios
3. Clinical characteristics (Manning et al. 2004; Badakali et al. 2012; Mattos et al. 2015)
    1. Spectrum of skin lesions
        1. Edema over the dorsum of the foot and hand, often associated with hypoplastic phalanges
        2. Thick, waxy, and stretched in appearance
        3. Peeling of skin, scaling, and extensive plaque formation over the scalp, face, neck, back, and arm
        4. Translucent flexible membrane covering most of the skin
        5. Varying degrees of lamellar ichthyosis
        6. Absence of scalp hair
    2. Craniofacial features
        1. Receding forehead
        2. Ocular hypertelorism
        3. Exophthalmos (protruding eyes)
        4. Absence of the eyelids
        5. Flat, abnormal nose
        6. Ectropion: abnormal eversion (turning outward) of the lower eyelid margin away from the eye globe
        7. Eclabium: turning outward of the lip
        8. Cataract
        9. Micrognathia
        10. Cleft palate/lip
        11. Hypodontia
        12. Low-set, malformed ears

3. CNS abnormalities
    1. Microcephaly
    2. Lissencephaly
    3. Hypoplastic or abnormal cerebellum
    4. Agenesis or dysgenesis of the corpus callosum
    5. Decreased or absent gyri
    6. Dilatation or abnormal ventricles
    7. Dandy-Walker malformation
    8. Choroid plexus cysts
4. Limb anomalies
    1. Deformed digits
    2. Deformed limbs
    3. Flexion deformity
    4. Severe edema of the hands with short, spaced fingers (rubber glove appearance) (AL-Lawama and Basha 2010) and feet
    5. Syndactyly
    6. Rocker-bottom feet
5. Other features
    1. Short broad neck
    2. Cystic hygroma
    3. Subcutaneous edema
    4. Small thorax
    5. Hypoplastic or atelectatic lungs
    6. Transposition of great vessels
    7. Small abdomen
    8. Hypoplastic genitalia
    9. Short umbilical cord
    10. Absence of hair
    11. Muscle atrophy

4. Classification proposed by Curry (1982): may represent heterogeneity of the condition or different grades of severity, representing the wide spectrum of varying expressivity of the heterogeneous condition (Coto-Puckett et al. 2010)
    1. Group I
        1. Joint contractures
        2. Partial syndactyly
        3. Thin scaly skin
        4. Mild ichthyosis
        5. Poor mineralization of bones
    2. Group II
        1. Massive swelling of hands and feet
        2. More severe ichthyosis
        3. Undermineralized bones leading to intrauterine fractures
    3. Group III
        1. Hypoplastic digits
        2. Most severe ichthyosis (harlequin-like fetus)
        3. Short limbs
        4. Stick-like long bones
5. Prognosis
    1. Stillborn
    2. Die shortly after birth
6. Differential diagnosis (Tarim and Bolat 2010)
    1. Harlequin fetus/ichthyosis (please see the chapter of "▶ Harlequin Ichthyosis")
    2. Restrictive dermatopathy (dermopathy) (Kulkarni et al. 2006; Khanna et al. 2008)
        1. A rare autosomal recessive disorder characterized by extreme tautness of the skin causing restricted intrauterine movement and a fetal akinesia deformation sequence
        2. Uniformly mostly neonatally fatal
        3. Diagnostic findings
            1. Skin tautness with near absence of the dermal elastic fibers, usually with no or only minor anomalies of the internal organs
            2. Abnormal face
            3. Absence of skin cracking (tight skin)
            4. Absence of skin edema
            5. Arthrogryposis multiplex
        4. Secondary skeletal changes with variable radiographic findings which when present is pathognomonic of restrictive dermatopathy
            1. Poorly mineralized skull with large fontanelle
            2. Micrognathia
            3. Thin dysplastic clavicles
            4. Ribbonlike ribs
            5. Overtubulated humerus and forearm bones
    3. Lethal arthrogryposis with ichthyosis (Thakur et al. 2004)
        1. A lethal condition with joint contractures
        2. Subcutaneous edema, ectropion
        3. A severely flattened nose
        4. "O"-shaped open mouth
        5. Extensive peeling of the skin (skin changes of ichthyosis)

4. Cerebro-ocular-facial-skeletal (COFS) syndrome (Gershoni-Baruch et al. 1991)
    1. Microcephaly with brain hypoplasia
    2. Flexion contractures
    3. Micrognathia
    4. Typical, deep set eyes with blepharophimosis and prominent root of the nose: different from the protruding eyes and flattened nose seen in NLS
5. Cerebro-arthro-digital syndrome (Spranger et al. 1980)
    1. Arthromyodysplasia
    2. Dyscephaly
    3. Sacral dysgenesis
    4. Brain malformation
    5. Hypoplastic digits
    6. Suspected environmental causes (ergotamine exposure in one case and diazoxide intake in another)
6. Lethal multiple pterygium syndrome (please see the chapter of "► Lethal Multiple Pterygium Syndrome")
7. Fetal akinesia/hypokinesia sequence (please see the chapter of "► Fetal Akinesia Deformation Sequence")
8. Smith-Lemli-Opitz syndrome (please see the chapter of "► Smith–Lemli–Opitz Syndrome")
9. Miller-Dieker syndrome (please see the chapter of "► Miller-Dieker Syndrome")

Diagnostic Investigations

1. Radiography
    1. Multiple contractures
    2. Hemivertebrae
    3. Kyphoscoliosis
    4. Abnormal occipital bone and biphalangeal fingers (Al-Lawama and Basha 2010)
2. Histopathology of the skin
    1. Hyperkeratosis
        1. With or without parakeratosis
        2. Associated with abundant subcutaneous tissue and excess of fat
    2. Myxomatous connective tissue associated with excess subcutaneous adipose tissue
    3. Epidermal and dermal atrophy
3. Ultrasound of the brain for CNS anomalies
4. Brain CT scan (AL-Lawama and Basha 2010)
    1. Microcephaly
    2. Lissencephaly
    3. Intraventricular hemorrhage
    4. Intracerebral hemorrhage
5. Normal chromosomes

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: 25%
    2. Patient's offspring: a lethal entity not surviving to reproductive age
2. Prenatal ultrasonography including 3-D U/S (Shapiro et al. 1992; Gülmezoğlu and Ekici 1994; Durr-e-Sabih et al. 2001; Rode et al. 2001; Aslan et al. 2002; Driggers et al. 2002; Shivarajan et al. 2003; Manning et al. 2004; Mattos et al. 2015)
    1. Severe growth retardation: a major feature
    2. Polyhydramnios
    3. Microcephaly/deficient calvarial ossification
    4. CNS abnormalities (banana-shaped cerebellum, hypoplastic cerebellar vermis, enlarged cisterna magna, Dandy-Walker anomaly, choroid plexus cysts)
    5. Abnormal facies including receding forehead
    6. Exophthalmos
    7. Cataract
    8. Flattened nasal bridge
    9. Prominent lips
    10. Micrognathia
    11. Cystic hygromas/hydrops
    12. Pulmonary hypoplasia
    13. Flexion contractures/arthrogryposis
    14. Shortened limbs
    15. Excessive edema of the hands and feet
    16. Syndactyly
    17. Clubbing of the feet (talipes equinovarus)
    18. Absence of breathing movements, sucking, swallowing, or normal isolated arm and leg movements
    19. Restricted fetal movement (Kainer et al. 1996)

3. Prenatal MRI (Mattos et al. 2015)
   1. Proportional growth restriction
   2. Arthrogryposis with contracted upper limbs and club feet
   3. Microcephaly
   4. Hypoplastic cerebellum and micrognathia
   5. Absence of the corpus callosum
   6. Lissencephaly
   7. Micrognathia
   8. A hypersignal with thickening of the cranial subcutaneous tissues
4. Prenatal molecular genetic testing (Mattos et al. 2015)
   1. DNA was extracted from fetal and parental peripheral blood; all coding exons of *PHGDH* were PCR-amplified and subjected to Sanger sequencing.
   2. Sequencing of PHGDH identified a homozygous premature stop codon mutation (c.1297C>T; p.Gln433*) in fetal DNA, both parents (first cousins) being heterozygotes.
5. Management
   1. No specific treatment for the uniformly lethal disorder
   2. Mainly supportive with initial management of ventilatory, thermal, and nutritional support

Neural Tube Defects

Contents

Neural tube defects (NTDs) are among the most common severe congenital malformations of the central nervous system. Approximately 1 in 500 to 1 in 1,000 pregnancies results in NTDs. About 4,000 fetuses are affected each year in the USA. The incidence varies with geographic areas and ethnic groups. The incidence, however, appears to be decreasing recently.

Synonyms and Related Disorders

Anencephaly; Cephalocele; Cranial meningocele; Cranio-/spinal rachischisis; Cranium bifidum occultum; Encephalocele; Iniencephaly; Meningomyelocele; Spina bifida

Genetics/Basic Defects

1. Caused by a defect in closure of the neural tube, which is normally closed by 28 days.
2. Etiology: complex, involving environmental and genetic factors that interact to modulate the incidence and severity of the developing phenotype.
3. Specific causes are identified in less than 10% of affected infants.
    1. Chromosomal abnormalities
    2. Single-gene mutations
    3. Teratogens
4. Defects in the neural tube closure linked to 5,10-methylenetetrahydrofolate reductase deficiency and defects in the metabolism of folic acid.
5. Low erythrocyte folate in the first trimester of pregnancy: associated with an increased risk of neural tube defects.
6. Mildly elevated homocysteine in some pregnant women who subsequently give birth to infants with NTDs (Akar et al. 2000).
7. Genetic factor (van der Put et al. 1995): *MTHFR C677T* polymorphism: a specific mutation known as *C677T* polymorphism
    1. More common in parents of children affected with NTDs.
    2. This polymorphism affects the enzyme methylenetetrahydrofolate reductase (MTHFR), causing it to require more folic acid to work properly.
8. Major epidemiologic finding in NTDs: the protective effect of perinatal folic acid supplementation that reduces risk by 60–70% (Hall and Soelhdin 1998).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_177

9. Genetic studies in NTDs
    1. Have focused mainly on folate-related genes and identified a few significant associations between variants in these genes and an increased risk for NTDs.
    2. However, we are witnessing a rapid and impressive progress in understanding the genetic basis of NTDs, based mainly on the development of whole genome innovative technologies and the powerful tool of animal models (Bassuk and Kibar 2009).
    3. NTDs are not vitamin-deficiency disorders in the way that rickets results from early vitamin D deficiency. Rather, folate one-carbon metabolism is a key mechanism in the development of NTDs that is affected by, and interacts with, both genetic and environmental factors. The application of new genomic technologies to NTDs should herald the identification of many further risk factors, enabling understanding of the entire range of causative factors that affect the mother and her neurulation stage embryo (Copp et al. 2013).

Clinical Features

There are several morphologic types of NTDs: open NTDs (anencephaly, cranial or spinal rachischisis, iniencephaly, meningomyelocele, cranioectomesodermal hypoplasia), closed NTDs (cranial meningocele, cranial encephalocele, spinal meningocele alone or with spinal cord abnormality), and myelocystocele.

1. Anencephaly (Lemire et al. 1978)
    1. Refers to an absence of the brain and the calvarium covering the brain
    2. The most severe form of NTDs
    3. Incidence: about 1/1,000 live births
    4. Responsible for about 50% of all NTDs
    5. Infants with anencephaly
        1. Stillborn
        2. Die shortly after birth
    6. Anterior pituitary, eyes, and brainstem usually spared
    7. Remaining tissue covering the basal cranium: a highly vascular and friable membrane referred to as area cerebrovasculosa
    8. Striking craniofacial appearance
        1. Absent cranial vault
        2. An angiomatous membranous mass lying on the floor of the cranium
        3. An absent or backward sloping of the forehead
        4. Frog-like eyes (ocular proptosis)
        5. Puffy eyelids
        6. A flattened nose
        7. Large folded-down ears
        8. Often an open mouth
        9. A short neck
    9. Syndromes associated with anencephaly
        1. Chromosomal disorders [e.g., r(13), trisomy 18, del(13q)]
        2. Monogenic disorder (e.g., Meckel syndrome)
        3. Disruptive sequences (e.g., amniotic bands, maternal hyperthermia)
        4. Associations (e.g., spina bifida, holoprosencephalic face syndrome, craniofacial duplication)
2. Craniorachischisis or spinal rachischisis.
    1. Rachischisis: refers to anencephaly with a contiguous spinal defect involving at least the cervical spine region and extending for varying degrees down the spinal column.
    2. The area cerebrovasculosa and the area medullovasculosa fill the skeletal defects of the cranium and of the spinal column.
    3. Short neck.
    4. Upward-turned face.
    5. Ears touching the shoulders.
    6. Frequent polyhydramnios.
    7. Frequently stillborn.
    8. Neurologic involvement
        1. Primarily limited to brainstem and spinal reflexes
        2. Occasional seizures resembling infantile spasms
3. Iniencephaly (Doğan et al. 1996; Balci et al. 2001).
    1. The name iniencephaly is derived from an abnormality of the neck (inion) and the brain (cephaly) (Kulaylat and Narchi 2000).

2. Triad (Erdincler et al. 1998; Sahid et al. 2000).
    1. Deficient cranial bone
    2. Cervical dysraphism (rachischisis)
    3. Fixed retroflexion of the fetal head and severe lordosis of the cervicothoracic spine
3. Closed or open lesions
    1. A closed lesion when the occipital bone is not malformed
    2. An open lesion when the occipital bone is hypoplastic
4. Site of the neural tube lesion: at the level of the cervical spine
5. Severity of lesion
    1. Spina bifida with intact skin
    2. Meningomyeloencephalocele
    3. Open rachischisis
6. Associated CNS malformations
    1. Anencephaly
    2. Encephalocele
    3. Microcephaly
    4. Hydrocephaly
    5. Holoprosencephaly
    6. Posterior fossa defects
    7. Spinal defects such as cervical dysraphism
    8. Fixed cervical hyperlordosis
7. Other associated malformations
    1. Diaphragmatic hernia
    2. Omphalocele
    3. Thoracic cage deformities
    4. Hypoplastic lungs
    5. Genitourinary malformations
    6. Cyclopia
    7. Cleft lip and palate
    8. Imperforate anus
    9. Clubfoot
    10. Single umbilical artery
8. Die within a few hours in most newborns

4. Cranium bifidum occultum.
    1. The most benign type.
    2. Generally asymptomatic.
    3. Skull defects often close over time.
    4. Persistent parietal foramina (sometimes called "Catlin marks" after the family for which it was described; transmitted as an autosomal dominant trait via a gene located on 11p)
    5. Persistent wide fontanelle
5. Cranial meningocele.
    1. Associated with a defect in the skull
    2. Associated with protrusion of the leptomeninges
6. Encephalocele (Cohen and Lemire 1982; Hall and Soelhdin 1998).
    1. A type of cephalocele (a herniation of cranial contents though a skull defect) that contains the brain
    2. Incidence: 1/10,000 live births
    3. Occurring most frequently in the occipital region (80–90%) and commonly associated with a variety of syndromes, notably Meckel-Gruber syndrome and Walker-Warburg syndrome
    4. Anterior encephaloceles: found more commonly in Roberts syndrome
    5. An isolated malformation of frontal encephalocele: more commonly seen in southeast Asia
    6. Outcome depending on the position of the defect and on the associated anomalies
    7. Chromosome syndromes associated with encephalocele (Hall and Soelhdin 1998)
        1. Trisomy 13
        2. Trisomy 18
        3. Del(13q)
        4. Del(2)(q21 → q24)
        5. Dup(1q)
        6. Dup(6) (q21 → qter)
        7. Dup(7)(qter → p11)
        8. Dup(8)(q23 → qter)
        9. Turner syndrome
    8. Monogenic disorders associated with encephalocele
        1. Meckel syndrome
        2. Cryptophthalmos syndrome
        3. Silverman-Handmaker type and Rolland-Desbuquois type of dyssegmental dysplasias
        4. Knobloch syndrome
        5. Chemke syndrome
        6. Roberts syndrome
        7. Walker-Warburg syndrome
        8. van Voss-Cherstovy syndrome
    9. Disruptive sequences associated with encephalocele

1. Maternal hyperthermia
2. Warfarin embryopathy
3. Amniotic bands

10. "Associations" associated with encephalocele
    1. Absent corpus callosum
    2. Dandy-Walker malformations
    3. Arnold-Chiari malformation
    4. Holoprosencephaly
    5. Craniosynostosis
    6. Ectrodactyly
    7. Frontonasal dysplasia
    8. Hypothalamic-pituitary dysfunction
    9. Klippel-Feil anomaly
    10. Iniencephaly
    11. Myelomeningocele
    12. Oculoauriculovertebral spectrum

7. Spina bifida cystica (the most common lesion).
    1. Myelomeningoceles (meningomyeloceles)
        1. A herniation of the spinal cord and/or nerves through a bony defect of the spine.
        2. Usually open defects in which meninges and/or neural tissue is exposed to the environment associated with leaking CSF.
        3. The most common type of spina bifida cystica (about 90%).
        4. Approximately 20% of affected infants have additional congenital anomalies, such as gastrointestinal, cardiac, and urogenital malformations.
        5. Surviving infants with spina bifida likely have severe, lifelong disabilities and psychosocial maladjustment.
        6. Medical problems
            1. Paralysis
            2. Hydrocephalus
            3. Arnold-Chiari type II malformation (herniation of the cerebellar vermis and brainstem below the foramen magnum)
            4. Endocrine abnormalities
            5. Tethered cord
            6. Syringomyelia (cavitation of the spinal cord whose walls are composed of glial tissue)
            7. Syringobulbia
            8. Deformed limbs and spine
            9. Bladder/bowel/sexual dysfunction
            10. Learning disabilities
        7. Neonates with Arnold-Chiari malformation presenting with
            1. Stridor secondary to vocal cord paralysis
            2. Central apnea
            3. Aspiration
            4. Dysphagia
            5. Hypotonia
            6. Progressive brainstem dysfunction
            7. Myelopathy
            8. Quadriparesis
            9. Nystagmus
            10. Strabismus
            11. Poor sucking
            12. Swallowing difficulties
    2. Meningoceles
        1. A saccular herniation of meninges and CSF through a bony defect of spine and usually covered by normal skin
        2. No herniation of the spinal cord or nerve roots into the dorsal dural sac
        3. A cystic mass full of cerebrospinal fluid
        4. Without associated neurologic problems such as hydrocephalus and Chiari II malformation
    3. Lipomeningocele or lipomyelomeningocele
        1. A lipomatous mass herniating through the bony defect and attaching to the spinal cord, tethering the cord and often its nerve roots
        2. Presentation with a skin-covered mass above the buttocks and eventual neurologic deficits
        3. Absent associated hydrocephalus
    4. Myelocystocele
        1. A large terminal cystic dilatation of the spinal cord secondary to hydromyelia giving rise to a large terminal skin-covered sac.
        2. Constituting 4–6.5% of the skin-covered masses overlying the lower spine.
        3. The majority of cases are dorsally located; only rarely (about 0.5%) are ventral in location.

4. The ventral type is an anterior sacral meningocele, most often presenting as a pelvic mass in females.
5. Cervical myelocystocele.
6. Lumbar myelocystocele.
7. Terminal myelocystoceles accompanying midline abdominal and pelvic defects such as part of the OEIS (*o*mphalocele-*e*xstrophy of the bladder-*i*mperforate anus-*s*pinal defects) complex.
8. Chiari malformation less frequent since the lesion is covered by dura with regular hydrodynamics of the cerebrospinal fluid.
9. Other associated malformations
    1. Genitourinary tract anomalies
    2. Intestinal malrotation
    3. Club feet
10. Differential diagnoses
    1. Meningomyelocele
    2. Lumbosacral and sacrococcygeal teratomas
    3. Lipomas
    4. Lipomyelomeningoceles
    5. Hamartomas

5. Lifelong disability risks in infants with spina bifida
    1. At risk for psychosocial maladjustment
    2. Medical problems resulting from the neurologic defects or from its repair
        1. Paralysis
        2. Hydrocephalus
        3. Arnold-Chiari malformation
        4. Endocrine abnormalities
        5. Tethered cord
        6. Syringomyelia
        7. Syringobulbia
    3. Medical problems as sequelae of the neurologic deficits
        1. Deformations of the limbs and spine
        2. Bowel, bladder, and sexual dysfunction
        3. Learning disabilities

8. Spina bifida occulta.
    1. A bony defect of the spine occurs most often at S1 and/or S2 and is covered by normal skin (a closed lesion)
    2. No herniation of the meninges through the bony defect
    3. Without associated hydrocephalus or Chiari II malformations
    4. Paraspinal cutaneous lesions with high index of suspicion pointing toward the underlying spina bifida (Drolet 2000)
        1. Hypertrichosis or hairy patches.
        2. Lumbosacrococcygeal dimples and sinuses.
        3. Acrochordons (skin tags): a small, flesh-colored to dark brown, sessile or pedunculated lesion consisting of a hyperplastic epidermis enclosing a dermal stalk of connective tissue.
        4. True tails: a caudal midline appendage capable of spontaneous or reflex motion consisting of skin covering muscle, adipose, connective tissue, blood vessels, and nerves but lack vertebrae and abnormal tissue.
        5. Pseudotails: a caudal protrusion composed of adipose (lipoma), teratomatous elements, or cartilage.
        6. Lipomas.
        7. Hemangiomas: indicator for tethered cord syndrome.
        8. Aplasia cutis congenita (congenital absence of skin) or scar.
        9. Dermoid cyst or sinus: 12–35% of children with spina bifida occulta have sacrococcygeal dermoid cysts or sinuses, which rarely connect with the intraspinal canal. Lesions above these levels along the spine are more likely to connect with the intraspinal canal and increasingly associated with spina bifida occulta.
    5. Paraspinal cutaneous lesions with low index of suspicion (Drolet 2000)
        1. Telangiectasia
        2. Capillary malformation (port-wine stain)
        3. Hyperpigmentation (lentigines or café-au-lait-like lesions)
        4. Melanocytic nevi
        5. Teratomas: most common in the sacrococcygeal region in infancy
    6. Neurologic deficits (Jallo 2013)
        1. Weakness of leg or legs

2. Leg atrophy or asymmetry
3. Loss of sensation
4. Painless sores
5. Hyperreflexia
6. Unusual back pain
7. Abnormal gait
8. Radiculopathy
9. Neurogenic bladder
10. Incontinence

9. Multiple NTDs at different sites (Ahmad et al. 2008): The presence of meningomyelocele and/or encephaloceles at multiple (two or more) sites along the vertebral axis is a very rare event occurring in 1% of cases.
   1. Double NTDs
   2. Triple NTDs

Diagnostic Investigations

1. Neurological examination of neonates
   1. Size, site, and level of the lesion
   2. Motor and sensory level
   3. Presence of associated hydrocephalus
   4. Presence of associated symptomatic hindbrain herniation such as Chiari II malformation
   5. Presence of associated orthopedic deformity
2. Neonatal cranial ultrasonography to demonstrate hydrocephalus
3. Radiography
   1. Occult spinal disorders in children (Jallo 2013)
      1. Lamina defects
      2. Hemivertebrae
      3. Scoliosis
      4. Widening of interpedicular distance
      5. Butterfly vertebrae
   2. Generally to detect bony defects
4. CT
   1. Cranial defects
   2. Spinal defects
5. MRI: provides exquisite detail of both the cranial defect and the herniated contents
   1. Cranial defects
   2. Cerebral defects
      1. Hydrocephalus
      2. Gray matter heterotopia
      3. Schizencephaly
      4. Gyral abnormalities
      5. Agenesis and thinning of the corpus callosum
      6. Abnormal thalami
      7. Abnormal white matter
   3. Herniated contents in Chiari malformations
   4. Associated lesions
      1. Diastematomyelia
      2. Syringomyelia
      3. Hydromyelia
      4. Tethered cord

Genetic Counseling

1. Recurrence risk
   1. Affected first-degree relatives
      1. One sib affected (5%)
      2. Two sibs affected (10%)
      3. Three sibs affected (21%)
      4. One parent affected (3–4.5%)
      5. One parent and one sib affected (13%)
   2. Affected second-degree relative: uncle/aunt, half sib (2%)
   3. Third-degree relative: first cousin (1% or less)
2. Prenatal diagnosis (Cameron and Moran 2009)
   1. Risk assessment prior to biochemical and/or ultrasonic screening
      1. The most significant risk factor: a history of having a previous child affected with neural tube defect
      2. Other independent (nongenetic) risk factors (Cameron and Moran 2009; Copp and Greene 2010)
         1. Valproic acid
         2. Folic acid antagonists (methotrexate, aminopterin, carbamazepine, fumonisin, trimethoprim)
         3. Vitamin A
         4. Maternal diabetes
         5. Maternal obesity
         6. Hyperthermia
         7. Micronutrient deficiencies (folate, inositol, vitamin B12, zinc)

2. Two approaches used for NTD screening in low-risk population
    1. Biochemical testing of maternal blood for alpha-fetoprotein (AFP)
        1. Measurement of maternal serum alpha-fetoprotein (MSAFP): a useful tool for mass screening of pregnant women for NTDs.
        2. All cases of anencephaly and about 65% of cases of spina bifida are identified by measurement of MSAFP and ultrasonography.
        3. Not effective in closed NTDs (10% of lesions) which do not increase AFP.
        4. AFP needs to be expressed as multiples of the median (MoM), since the maternal serum level of AFP varies with gestation.
        5. Using 2.5 MoM as screen positive in singleton pregnancies, the detection rate for anencephaly is expected to be >95% and for open NTD between 65% and 80%.
        6. False-positive rates should lie between 1% and 3% (Bradley et al. 2005). A raised serum AFP is not diagnostic for open NTD as it can be associated with other abnormalities including gastroschisis, omphalocele, congenital nephrosis, and fetal demise.
    2. Use of 2D/3D ultrasonography (Budorick et al. 1995)
        1. Used both as a screening test and as a follow-up test after positive results on MSAFP screening (Robinson et al. 1980; Lindfors et al. 1987).
        2. First-trimester detection rates for anencephaly and encephalocele: typically quoted as >90% for anencephaly and encephalocele and lower rates for spina bifida (44%).
        3. Second-trimester scanning improves the detection of spina bifida, typically to 92–95%.
        4. Direct demonstration of the spinal defect.
        5. Indirect signs: lemon sign (referring to a symmetrical bifrontal narrowing of the skull) and banana sign (cerebellar abnormality) (Nicolaides et al. 1986; Campbell et al. 1987; Van den Hof et al. 1990).
        6. Carefully evaluate the whole fetus because of associated malformations in around 20% (Stoll et al. 2007).
    3. Fetal MRI (Saleem et al. 2009)
        1. An important adjunct to the USA in assessing NTD (Kölble et al. 2001)
        2. Can identify topography and contents of sacs and add CNS and non-CNS findings
        3. Influence management decision
    3. Prenatal diagnosis of iniencephaly by careful sonography
        1. Marked fixed retroflexion of the head and neck
        2. Rachischisis
        3. Extreme lordosis of the fetus
    4. Prenatal diagnosis of cephalocele in the first trimester: associated with a high rate of termination of pregnancy and early intrauterine fetal demise (Sepulveda et al. 2015)
    5. Amniotic fluid alpha-fetoprotein (AFAFP) and amniotic fluid acetylcholinesterase (AFAChE): confirmatory tests for spina bifida
3. Management: complex and challenging
    1. Prevention (Smithells et al. 1983; Milunsky et al. 1989; American Academy of Pediatrics & Committee on Genetics 1999; Toriello 2005; Green and Copp 2014; Salib et al. 2014)
        1. Folic acid supplementation of 0.4 mg/day to all women capable of becoming pregnant: decrease the first occurrence of NTDs by at least 40%
        2. Folic acid supplementation of 4 mg/day in families with previous children born with NTDs: decrease risk of recurrence by 70%
        3. Periconceptional use of folic acid supplementation will prevent 50–70% of NTDs (Czeizel and Dudas 1992; Molloy et al. 1999; Botto et al. 1999; Iqbal 2000)

2. Medical management
    1. Antibiotic prophylaxis to prevent meningitis and ventriculitis
    2. Urological management
    3. Management of rectal incontinence
    4. Preventable conditions
        1. Urinary tract infections
        2. Calculi
        3. Skin ulcerations
        4. Latex allergy and sensitization
3. Surgical treatment
    1. Closing all but the prognostically worst cases
    2. Concurrent shunting of coexisting hydrocephalus often necessary
    3. Decompression of the posterior fossa and/or cervical cord in Chiari II malformations
    4. Spina bifida occulta: prophylactic surgical repair more effective than waiting for patients to experience a significant neurologic deficit such as a neurogenic bladder or leg weakness from these occult spinal lesions
    5. Orthopedic management of scoliosis
4. Fetal spina bifida repair (Fichter et al. 2008)
    1. Position statement on fetal myelomeningocele (MMC) repair by MMC Maternal-Fetal Management Task Force (Cohen et al. 2014).
    2. Several reports of intrauterine repair of meningomyelocele with benefits to motor function and a decreased incidence of shunt-dependent hydrocephalus and a reversal of hindbrain herniations (Bruner et al. 1999; Talipan et al. 1999; Rintoul et al. 2002).
    3. Especially fetuses treated before 26 weeks of gestational age, with small ventricles (<14 mm) at the time of surgery, and lesion levels below L2 seem to profit from fetal surgery.
    4. However, the clinical relevance of the observed regression of Chiari II malformation is still in dispute, and a positive effect on sensorimotor function could only be observed for patients with higher lumbar and thoracic spinal defects in the early postnatal period.
    5. Rehabilitation programs
        1. Physical therapy
        2. Occupational therapy
        3. Speech therapy
        4. Recreational therapy

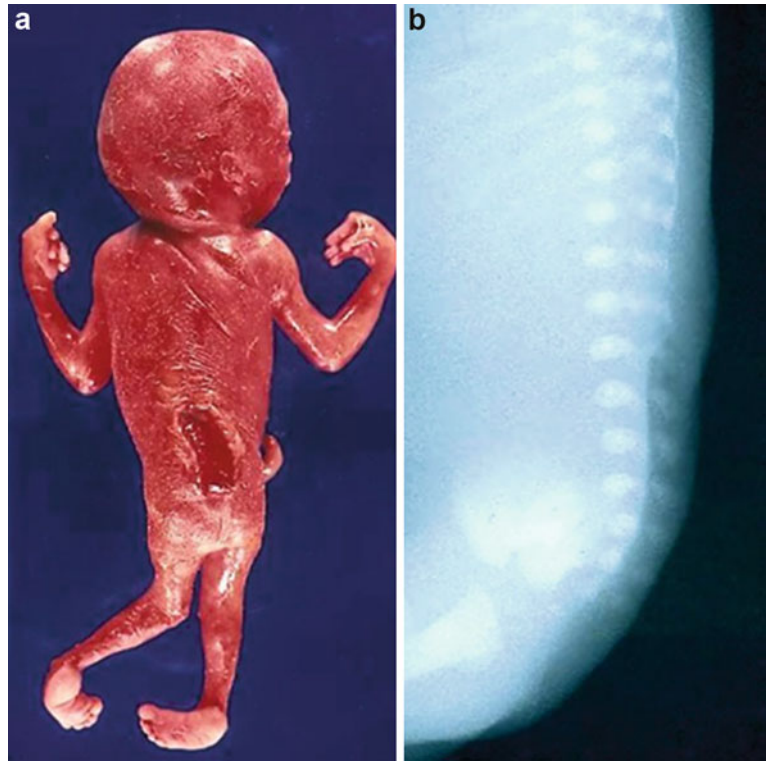

Fig. 11 (**a**, **b**) A fetus with trisomy 18 and open lumbosacral spina bifida (**a**), illustrated by lateral radiograph (**b**)

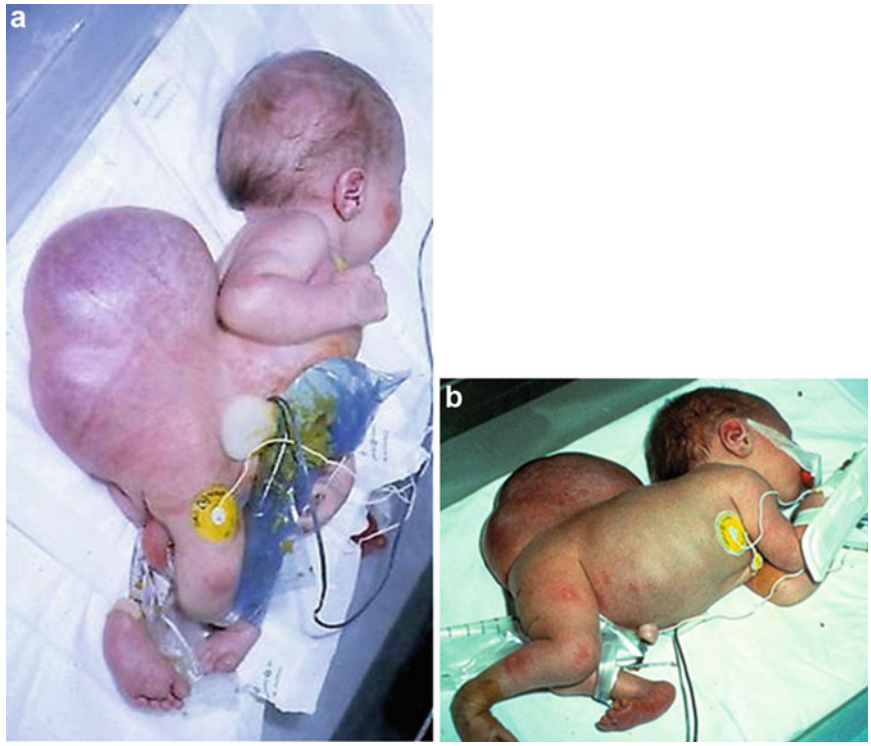

Fig. 12 (**a**, **b**) Two infants (**a**, **b**) with a large lumbosacral myelocystocele covered with skin

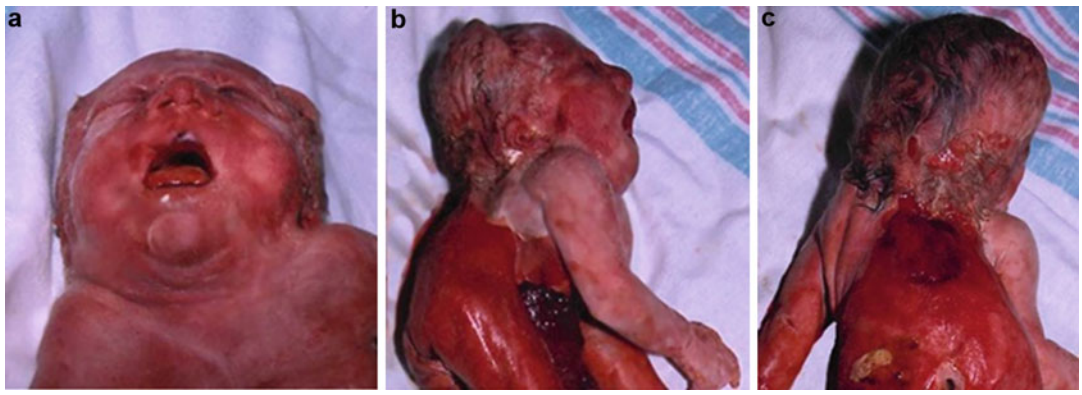

Fig. 13 (**a**–**c**) A stillborn with iniencephaly showing deficient cranium, short neck, cervical rachischisis, fixed retroflexion of the head, and severe lordosis of the cervicothoracic spine (**a**–**c**)

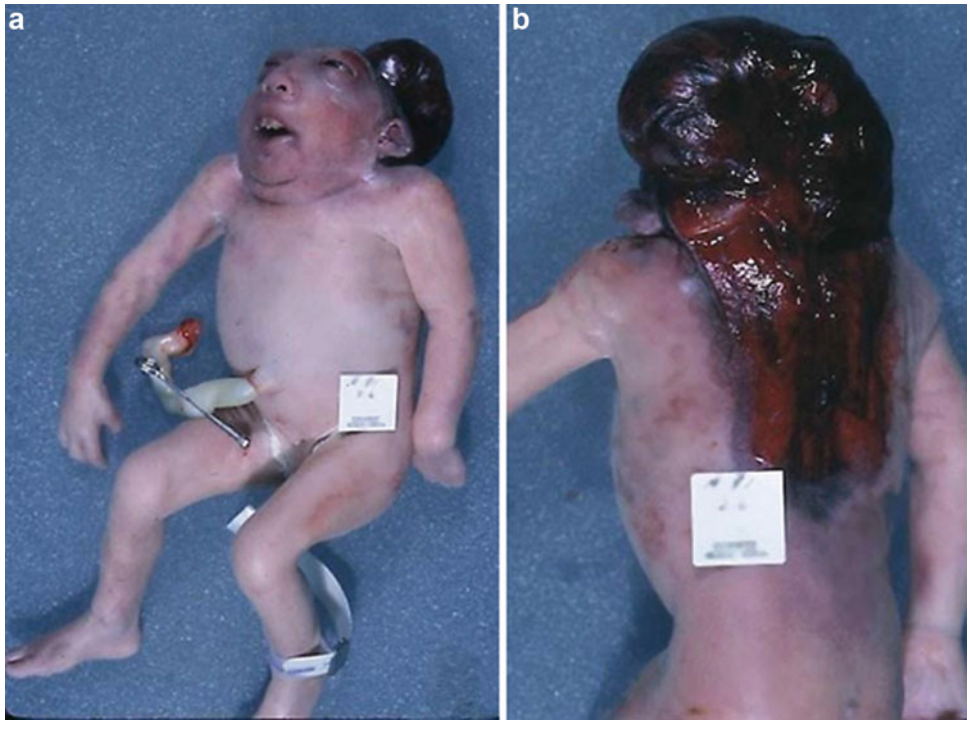

Fig. 14 (**a**, **b**) A stillborn with craniorachischisis showing anencephaly with a contiguous spinal defect involving cervical spine region and extending down the spinal column, short neck, upward-turned face, and ears touching the shoulders (**a**–**b**)

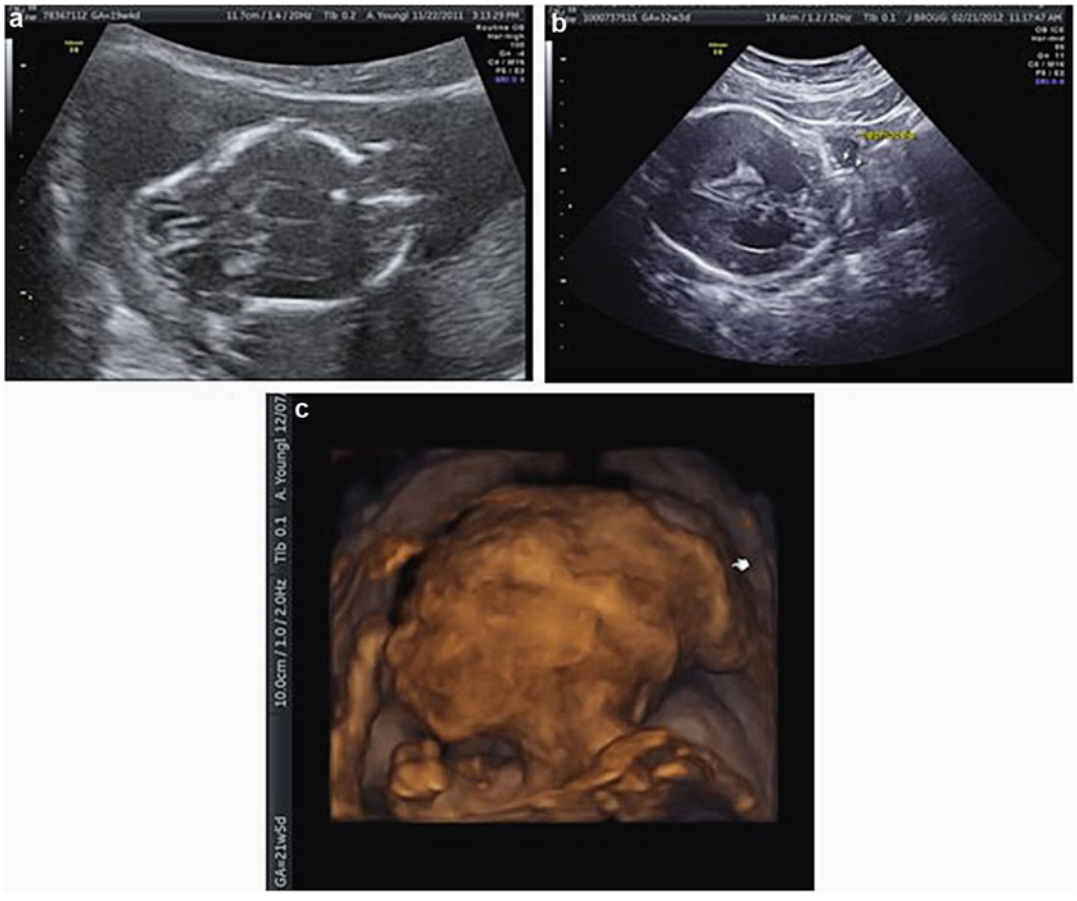

Fig. 15 (**a**–**c**) Ultrasound at 19w4d (**a**) showed occipital cephalocele. Ultrasound at 32w3d (**b**) showed lateral ventriculomegaly and occipital cephalocele. 4D real-time ultrasound (**c**) showed lateral view of the fetal craniofacial structures with occipital cephalocele (*arrow*) (Courtesy of Dr. Rose Brouillette)

Neurofibromatosis 1

Contents

Neurofibromatosis 1 (NF1) was described in 1882 by von Recklinghausen (1882) who gave the disease its first full description, including recognition that the tumors arose from the fibrous tissue surrounding small nerves, leading to his designation of these tumors as "neurofibromas." Thus, it is also called von Recklinghausen disease. It is one of the most common dominantly inherited genetic disorders affecting about 1 in 3000 newborns (Friedman 1999) and 1,000,000 people worldwide.

Synonyms and Related Disorders

Neurofibromatosis-Noonan syndrome; Peripheral-type neurofibromatosis; von Recklinghausen disease

Genetics/Basic Defects

1. Inheritance
   1. Autosomal dominant
   2. High spontaneous mutation rate
      1. One of the highest in humans (1×10^{-4} per gamete per generation).
      2. 50% of the cases are due to new mutations (Friedman 1999).
      3. Most patients are expected to have different mutations due to the high mutation rate at the *NF1* locus.
   3. Full penetrance (Carey et al. 1979; Riccardi and Lewis 1988): essentially 100% in adults after careful examination by a slit-lamp examination
   4. Widely variable expressivity even among family members with the same mutation (Carey et al. 1979, 1986; Riccardi and Lewis 1988; Rasmussen and Friedman 2000; Korf and Rubenstein 2005)
   5. Highly pleiotropic
2. The *NF1* gene
   1. Mapped to pericentromeric region of 17q11.2 (Barker et al. 1987).
   2. Entire sequence of the expressed *NF1* gene has been identified by a positional cloning strategy.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_178

3. A large size of the gene spanning over 350 kb of genomic DNA.
4. Consisting of at least 60 exons.
5. Translated into a 240-kDa protein, neurofibromin.

3. Mutations of the *NF1* gene
   1. Most described mutations are unique to a particular family.
   2. Type of mutations (over 250 different mutations described)
      1. Stop codon
      2. Substitutions
      3. Deletions of only one or a few base pairs, multiple exons, or the entire gene
      4. Insertions
      5. Intronic changes affecting splicing
      6. Alterations of the 3′ untranslated region of the gene
      7. Gross chromosomal rearrangements
   3. Severe truncation of the gene product in about 70% of the germ-line mutations
   4. *NF1* gene usually classified as a tumor suppressor gene (Shen et al. 1996) since mutations in both *NF1* alleles are detectable in malignant tumors associated with NF1 and in benign tumors, such as neurofibromas
4. *NF1* microdeletion syndrome (Moles et al. 2012)
   1. Approximately 5% of individuals with NF1 have a 1.4-Mb heterozygous 17q11.2 deletion encompassing *NF1*, formed through nonallelic homologous recombination (NAHR) between the low-copy repeats that flank this region
   2. NF1 microdeletion syndrome is more severe than NF1 caused by gene mutations, with individuals exhibiting:
      1. Facial dysmorphisms
      2. Developmental delay
      3. Intellectual disability
      4. Excessive neurofibromas
5. *NF1* microduplication syndrome (Moles et al. 2012)
   1. Clinical features seen in more than one individual with this microduplication include:
      1. Developmental delay
      2. Facial dysmorphisms
      3. Variable intellectual disability
      4. Seizures
   2. Other major features seen in single cases include:
      1. Microcephaly
      2. Macrocephaly
      3. Autism
      4. Cleft lip and palate
      5. Polymicrogyria
      6. Iris coloboma
   3. Neurofibromas were not noted in any of these individuals.
6. Knudson two-hit hypothesis is also applicable to explain the mechanism by which the manifestations of *NF1* occur (Dupuis and Nezarati 2001):
   1. A mutated tumor suppressor gene (the first hit)
      1. Inherited from a parent
      2. Presents in every cell of the body
   2. A second mutation (hit) in some somatic cells of the individual
      1. Knocks out the other copy of the gene
      2. Resulting in complete loss of the gene product and unregulated cell growth/division
      3. Resulting in a predisposition to cancer in the cells
7. Pathogenesis of NF1 (Boyd et al. 2009)
   1. Neurofibromin
      1. The *NF1* gene protein product.
      2. A tumor suppressor expressed in many cells, primarily in neurons, glial, and Schwann cells, and early in melanocyte development (Stocker et al. 1995; Zhu and Parada 2001).
      3. A regulator of ras guanosine triphosphatase activity (GTPase-activating protein, GAP), and as such, serves as a regulator of signals for cell proliferation and differentiation (Korf and Rubenstein 2005).
      4. Neurofibromin interacts with the proto-oncogene RAS to suppress tumor formation (Karajannis and Ferner 2015). Loss of function of neurofibromin may, therefore, remove

this regulation and lead to uncontrolled cell proliferation.
5. Neurofibromin is expressed in blood vessel endothelial and smooth muscle cells, and NF1 vasculopathy may result from an alteration of neurofibromin function in these cells (Hamilton and Friedman 2000).

2. Schwann cells in neurofibromas and melanocytes in café-au-lait macules:
1. Have a mutation in both *NF1* alleles, including a germ-line and an acquired somatic mutation.
2. Considered the primary tumor cell in their respective cutaneous manifestation.
3. Based on these findings, it is likely that NF1 functions as a tumor suppressor gene (Maertens et al. 2007; de Schepper et al. 2008).
4. Both of these cell types are descendants of neural crest.
5. The exact timing of the acquired mutation is unknown but is crucial in the development of the various manifestations:
1. Experiments have shown that *NF1* gene inactivation at the neural crest stage and mature Schwann cell stage do not lead to tumor formation.
2. However, in a progenitor intermediate step between these two stages, tumor formation occurs with *NF1* gene inactivation (Wu et al. 2008).

8. Marked heterogeneity in NF1
1. Whole gene deletion with distinctive phenotype
1. Early onset of cutaneous neurofibromas
2. Facial anomalies
1. Macrocephaly
2. Hypertelorism
3. Ptosis
4. Down-slanting palpebral fissures
5. Short nose
6. Low-set ears
7. Micrognathia
3. Developmental delay
4. Other standard features of NF1
2. Alternate forms of NF1 (conditions with incomplete/atypical features)
1. Mixed neurofibromatosis
2. Localized neurofibromatosis
1. Segmental neurofibromatosis (occasional localized café-au-lait spots, segmental distribution of dermal neurofibromas, no systemic manifestations, uncommon internal manifestations of neurofibromas)
2. Gastrointestinal neurofibromatosis
3. Familial spinal neurofibromatosis (multiple café-au-lait spots and neurofibromas involving spinal cord, lack dermal neurofibromas, and Lisch nodules)
4. Familial café-au-lait spots (autosomal dominant café-au-lait spots in rare multi-generation families, lack of neurofibromas, axillary freckling, and Lisch nodules)
3. Related forms of NF1 (conditions with additional features)
1. Neurofibromatosis/Noonan syndrome (may or may not fit the criteria of NF1 but with features of Noonan syndrome)
2. Watson syndrome
1. Multiple café-au-lait spots
2. Pulmonary stenosis
3. Intertriginous freckling
4. Short stature
5. Low intelligence

9. Several pathways are thought to be involved in the development of tumors associated with NF1 (Brems et al. 2009):
1. Rat sarcoma viral oncogene homologue (RAS)-mitogen-activated protein kinase (MAPK): Neurofibromin is involved in the downregulation of RAS-MAPK pathway, and NF1 belongs to the group of RAS-MAPK disorders that include Noonan, cardiofaciocutaneous, Costello, LEOPARD, and NF1-like syndrome.
2. Mammalian target of rapamycin (mTOR).
3. P21 protein (Cdc42/Rac)-activated kinase 1 (PAK1).

10. Variable expressivity (one of the hallmarks of NF1)

1. Intrafamilial variability (marked phenotypic differences may be observed within the same family)
2. Interfamilial variability (full spectrum of the disease, mild to severe form, may be present in different families in which affected individuals have the same NF1 mutation)

11. Prototype of a pleiotropic congenital multiple dysplasia syndrome involving CNS, vascular and skeletal systems, and a predilection for hamartomas, dysplasia, and malignancies.
12. The terms "mosaic generalized neurofibromatosis 1" and "mosaic localized neurofibromatosis 1" were introduced to reflect the disease pathogenesis and, more specifically, the time of the mutational event (Ruggieri and Huson 2001; Hardin et al. 2014):
    1. Somatic mutations giving rise to limited disease, such as SNF, are manifestations of mosaicism because an individual has a mixture of cells, some that have normal copies of the gene of interest and others that have an abnormal copy of that same gene.
    2. If the mutation occurs before tissue differentiation (early somatic mutation), the clinical phenotype will be generalized disease and clinically indistinguishable from nonmosaic form.
    3. Mutations that occur later in development (late somatic mutation) give rise to disease that is confined to a single region, often described as segmental form.
    4. It is known that early somatic mutations cause generalized disease, whereas mutations late in embryogenesis give rise to an affected single region or organ (localized disease) (Redlick and Shaw 2004).
    5. Individuals with the mosaic form:
        1. Less likely to have severe disease even with a generalized phenotype
        2. Lower offspring recurrence risk than individuals with the nonmosaic form
13. NF1 genotype-phenotype correlations (Pasmant et al. 2012; Shafty et al. 2016)
    1. Difficult to identify because of the complexity of the NF1 phenotype, its strong age dependency, the relatedness of many clinical features, and the huge heterogeneity of pathogenic NF1 mutations.
    2. Some NF1 patients with a given *NF1* mutation may develop very severe disease, while others with the same mutation have only mild symptoms.
    3. This phenotypic variability may be due to both modifier genes and environmental factors.

Clinical Features

1. Extreme interfamilial and intrafamilial clinical variability (Riccardi 1981)
    1. NF1 has a highly variable and unpredictable expression, even among affected individuals with the same mutation and within the same family (Ko et al. 2013).
    2. In neoplasms, the "second hit" theory explains the high variability even within members of the same family (Shafty et al. 2016).
2. Often not diagnosed at birth, especially a new mutation case
3. Cutaneous manifestations
    1. Café-au-lait spots (analogy of the color to coffee with milk).
        1. Present in nearly all patients
        2. Round or oval, discrete, well-circumscribed, uniformly light-brown-pigmented, macular lesions
        3. Usually present at birth but continue to increase in number and size during the first decade
        4. Six or more café-au-lait spots exceeding 0.5 cm in diameter in prepubertal children or exceeding 1.5 cm in broadest diameter in postpubertal individuals: the pathognomonic sign for NF1
    2. Hyperpigmentation patches may be associated with underlying plexiform neurofibromas, which are congenital in origin and

which may lead to extensive localized hypertrophy.
3. Freckles in the axillary, groin, and intertriginous areas (almost 90%): a helpful diagnostic feature.
4. Dermal neurofibromas, usually present in adults with NF1.
5. Xanthogranulomas (2–5%).
6. Hemangiomas (5–10%).

4. Lisch nodules (asymptomatic pigmented iris hamartomas)
   1. An extremely important diagnostic feature
      1. A characteristic sign of NF1 present in 97% of postpubertal patient
      2. Lesions typically not detected before 5 years of age
      3. Often appear before development of neurofibromas
   2. Best observed with slit-lamp examination
   3. Raised, often pigmented nodules of the iris, pathologically representing hamartomas
   4. Never resulting in significant disease
5. Peripheral neurofibromas
   1. Benign histologically
   2. May involve the viscera, such as the bowel, bladder, and liver, causing bleeding and obstruction
   3. May result in functional compromise and cosmetic disfigurement
   4. Increase in size and number during puberty and pregnancy
6. Gross forms of neurofibromas (Woodruff 1999)
   1. Localized cutaneous neurofibromas (nodular or polypoid): the most common form of neurofibromas. Numerous localized cutaneous neurofibromas are the hallmark of NF1.
   2. Localized intraneural neurofibromas (causing fusiform enlargement of the affected nerve).
   3. Plexiform neurofibromas (25%) (Korf 1999):
      1. Diffuse lesion involving nerve, muscle, connective tissue, vascular elements, and overlying skin
      2. Commonly leading to overgrowth of surrounding tissues during childhood
      3. Usually congenital
      4. Almost invariably apparent by 4 or 5 years of age
      5. One of the most common and debilitating complications of NF1
      6. Account for substantial morbidity, including disfigurement, functional impairment, and life-threatening complications
      7. Subject to transformation into malignant peripheral nerve sheath tumor (2–5%)
   4. Diffuse neurofibromas involving skin and subcutaneous tissue
   5. Massive soft-tissue neurofibromas (extreme neurofibromatous growth-producing massive, diffuse infiltration of soft tissue of a body part, often a distal extremity, leading to localized gigantism, cape formation, or, at the extreme end of the spectrum, formation of disfiguring redundant soft-tissue masses)
7. Certain selected clinical features of NF1 in different age groups (Riccardi 1992)
   1. Infancy
      1. Pseudarthrosis
      2. Seizures
      3. Constipation
      4. Congenital glaucoma
      5. Deafness
      6. Optic gliomas
   2. Childhood
      1. Optic gliomas
      2. Other brain tumors
      3. Kyphoscoliosis
      4. Genu valgum
      5. Seizures
      6. Cognitive disorders
         1. Developmental delay
         2. Learning disabilities
         3. Mental retardation
      7. Speech impediments
      8. Short stature
      9. Macrocephaly
      10. Early puberty
      11. Hypertension
      12. Embryonal tumors
      13. Leukemia

3. Preadolescence and adolescence: worsening of previous problems such as:
    1. Scoliosis
    2. Cosmetic disfigurement
    3. Major psychologic burden
    4. Malignancy (neurofibrosarcoma)
4. Early adulthood
    1. Increase in the number and size of cutaneous, subcutaneous, and plexiform neurofibromas
    2. Cosmetic disfigurement
    3. Functional compromise
        1. Pain
        2. Paralysis
        3. Gastrointestinal hemorrhage
        4. Renovascular hypertension
5. Adulthood
    1. An increased risk of developing a specific cancer (2–5% of patients with NF1)
    2. Neurofibrosarcoma and malignant peripheral nerve sheath tumor commonly arise in a plexiform neurofibroma in a young adult with symptoms of pain or rapid growth.

8. Skeletal involvement (50% of cases)
    1. Short stature (30%)
    2. Scoliosis
        1. Observed in approximately 20% of children with NF1
        2. The most common skeletal defect
        3. With or without classic dystrophic features such as vertebral scalloping and rib penciling
    3. Kyphosis
    4. Cervical spine abnormalities
    5. Spondylolisthesis
    6. Congenital pseudarthroses (3%), frequently with bowing of the tibia and fibula (2–5%)
        1. A peculiar and uncommon complication
        2. First noted as bowing, particularly of the tibia and fibula, in young children
        3. May progress to thinning of the cortex, pathologic fracture, and severe difficulties with nonunion of the fragments
        4. May go on to form a pseudarthrosis, or false joint, leaving the limb severely compromised
    7. Macrocephaly (40%)
    8. Skull bony defects
        1. Posterosuperior orbital wall bony defect
        2. Overgrowth of cranial bones
        3. Craniofacial asymmetry
        4. Sphenoid wing dysplasia (5–10%)
    9. Ocular hypertelorism
    10. Hemihyperplasia of a limb or digit
    11. Spina bifida
    12. Absent patella
    13. Elevated scapulas
    14. Congenital dislocation (hip, radius, ulna)
    15. Clubfoot
    16. Syndactyly
    17. Complete or partial absence of the limb bones
9. Endocrine abnormalities
    1. Sexual precocity (2–5%, the most common endocrine abnormality)
    2. Hypopituitarism
    3. Hypogonadism
    4. Gigantism
    5. Acromegaly
    6. Delayed sexual development
    7. Obesity
    8. Hypoglycemia
    9. Diabetes insipidus
    10. Goiter
    11. Myxedema
    12. Hyperparathyroidism
10. Cardiovascular diseases
    1. Vasculopathy
        1. Asymptomatic throughout life in many patients
        2. Symptomatic vasculopathy: uncommon
        3. Affect vessels, from the aorta to small arterioles, and result in vascular stenosis, occlusion, aneurysm, pseudoaneurysm, rupture, or fistula formation
        4. Renal arteries: the most frequently involved site
        5. NF1-associated cerebrovascular disease in children: presents with weakness, involuntary movements,

headaches, or seizures as a result of cerebral ischemia
6. NF1-related cerebrovascular disease in adults: similar symptoms and signs as a result of intracranial hemorrhage

2. Hypertension
1. Extremely common in adult patients with NF1 (33%)
2. Causes
1. Essential hypertension
2. Renal artery stenosis
3. Pheochromocytomas

3. Congenital heart disease (0.4–6.4%)
1. Pulmonary stenosis (recognized feature of Watson syndrome, NF1-Noonan syndrome, and individuals with large deletions of the NF1 gene)
2. Left heart obstruction (aortic stenosis or coarctation)
3. Other CHD

11. Neuropsychological impairment (Gutmann 1998; Ozonoff 1999; Kayl and Moore 2000; North 2000)
1. Cognitive impairments (30–65%)
2. Learning disabilities including attention deficit hyperactivity disorder and deficits in visuospatial processing (40–60%)
1. Easy distractibility
2. Impulsiveness
3. Deficient visual-motor coordination
4. Language and vocabulary deficits

3. Behavioral difficulties
4. Emotional and psychosocial difficulties
5. Mental retardation (4–8%)
6. Hydrocephalus (5%)
7. Neurosensory hearing loss (5%)

12. Tumor types associated with NF1 (Brems et al. 2009)
1. Non-nervous system tumors
1. Adulthood
1. Gastrointestinal stromal tumor
2. Somatostatinoma
3. Pheochromocytoma
4. Breast cancer

2. Childhood: rhabdomyosarcoma

2. Nervous system tumors
1. Adulthood and childhood
1. Astrocytoma
2. Malignant peripheral nerve sheath tumor

2. Childhood: neuroblastoma

13. Lifetime risk of different tumors in children and adults with neurofibromatosis 1 (Korf 2000; Lakkis and Tennekoon 2000; Hirbe and Gutmann 2014)
1. Glioma of the optic pathway (15–20%)
2. Other brain tumors (more than fivefold increase)
3. Malignant peripheral nerve sheath tumors (8–13%)
4. Gastrointestinal stromal tumor (4–25%)
5. Duodenal carcinoid tumor (1%)
6. Leukemia (about sevenfold increase)
7. Breast cancer (about fivefold increase)
8. Rhabdomyosarcoma (1.4-6%)
9. Pheochromocytoma (0.1–5.7%)

14. Major complications (Liebermann and Korf 1999)
1. Central nervous system
1. Optic glioma
2. Astrocytoma
3. Learning disability
4. Cord compression

2. Peripheral nervous system: nerve compression
3. Cutaneous
1. Cosmetic impairment due to neurofibromas
2. Pruritus: generalized itching or itching localized to newly developing neurofibromas experienced by many individuals

4. Orthopedic
1. Limb overgrowth
2. Scoliosis; long bone dysplasia

5. Vascular stroke
1. Hypertension
2. Aneurysm

6. Endocrine: precocious puberty
7. Gastrointestinal
1. Constipation: observed especially in patients with plexiform neurofibromas in the pelvic area which interfere with autonomic innervation of the colon and

produce both bowel and bladder problems
2. Obstruction
8. Ophthalmologic
1. Optic glioma
2. Glaucoma
9. Headache (10–20%)
1. Bothersome but usually not a disabling complaint.
2. Headache possibly indicates the presence of an intracranial tumor but no identifiable etiology in many patients.

15. Pathological manifestations of NF1 (Woodruff 1999)
1. Epidermis (pigmented macule or café-au-lait spot).
2. Iris (Lisch nodule, optic glioma).
3. Skeleton (malformations).
4. Blood vessels (mesodermal vascular dysplasias): Intrinsic lesions of arterial walls (vasculopathy) are important manifestations of NF1. It appears to contribute to excess mortality of young patients with NF1.
1. Asymmetric
2. Renal artery stenosis with consequent hypertension
3. Occlusion resulting in cerebral or visceral infarcts
4. Aneurysms resulting in hemorrhage
5. Arteriovenous fistulae
5. Brain
1. Glial hamartomas
2. Astrocytomas
6. Adrenal (pheochromocytoma)
7. Intestine
1. Somatostatinoma
2. Gastrointestinal autonomic nerve tumor
8. Peripheral nerve sheath
1. Neurofibromas
2. Malignant peripheral nerve sheath tumors

16. NIH diagnostic criteria (National Institutes of Health 1988)
1. National Institutes of Health consensus development conference identified seven important components of neurofibromatosis. Two or more of these components must be present for a diagnosis of neurofibromatosis:
1. Six or more café-au-lait spots, which are more than 5 mm in diameter in prepubertal patients and more than 15 mm in diameter in postpubertal individuals
2. Two or more neurofibromas of peripheral nerves of any type or one plexiform neurofibroma
3. Freckling in the axillary or inguinal region
4. Optic glioma (age of presentation at preschool years) (Gutmann 1998)
5. Two or more Lisch nodules (hamartomas of the iris)
6. A distinctive bony lesion such as dysplasia of the sphenoid at the base of the skull or pseudarthrosis or thinning of the long bone cortex, with or without complete interruption of the bone
7. A first-degree relative (parent, sib, or offspring) affected with neurofibromatosis type 1 which was diagnosed according to the preceding criteria
2. These diagnostic criteria have been shown to be both highly specific and sensitive for adults with NF1 (Gutmann et al. 1997).
3. Because some of the criteria may not manifest until later in life, they are not as sensitive in children, especially those under the age of 8.
4. A 2000 retrospective review of nearly 1900 cases of NF1 found that 46% of sporadic cases did not meet criteria by age 1; however, 97% met criteria by age 8, and all fulfilled them by age 20 (DeBella et al. 2000).

17. Syndromes related to NF1 (Ruggieri 1999)
1. Neurofibromatosis type 2 (bilateral vestibular neurofibromatosis)
1. Clinically and genetically distinct from NF1.
2. *NF2* gene is mapped to chromosome 22.
3. Inheritance: autosomal dominant.

4. Often with a small number of café-au-lait spots (rarely more than six).
5. Often with one or two peripheral neurofibromas (usually not more).
6. Occasionally with Lisch nodules.
7. Posterior subcapsular cataracts detected by ophthalmologic examination in a sizable proportion of patients.
8. The hallmark of NF2: development of bilateral eighth cranial nerve tumors, properly called vestibular schwannomas rather than acoustic neuromas (by age 30 years in 95% of patients).
9. Other tumors of cranial and cervical nerve roots common.
10. NF2 much less common than NF1, affecting approximately 1 in 40,000 individuals.

2. Segmental or mosaic NF1
   1. Caused by somatic mutation of the *NF1* gene (Tinschert et al. 2000).
   2. Presence of NF1 features (café-au-lait spots, freckling and peripheral or plexiform neurofibromas, and Lisch nodules) in an individual with a segment of the body affected, which varies from a narrow strip to one quadrant and occasionally to one half of the body (Ruggieri and Huson 2001).
   3. Family history with invariably normal parents who, on rare occasions, can have a child with classic NF1.
   4. Presence of strong circumstantial evidence suggests somatic mutation of the *NF1* gene early in embryogenesis so that derivatives of that mutant line display the features of NF1.
   5. May transmit the disease if the mosaicism involves the germ line.
   6. Germ-line mosaicism for an *NF1* gene mutation has been observed in a clinically unaffected father of a child with new onset NF1.
   7. Somatic mosaicism for an *NF1* gene deletion has been detected in an individual with NF1 (Colman et al. 1996). Somatic mosaicism plays an important role in phenotypic and genetic aspects of NF1 and may even be a relatively common phenomenon.
   8. Possibility of demonstrating similar somatic mosaicism if cases of segmental NF1 are analyzed.
3. Watson syndrome
   1. Pulmonary stenosis with café-au-lait spots
   2. Dull intelligence
   3. Short stature
   4. A small number of neurofibromas
   5. Lisch nodules
   6. Deletions present in the NF1 gene in at least two families: no distinguishing aspect between the deletions causing Watson syndrome and those associated with more classic NF1
4. Neurofibromatosis 1-Noonan syndrome (Opitz and Weaver 1985)
   1. A Noonan syndrome phenotype in patients with NF1 (about 12%).
   2. Clinical features in addition to NF1
      1. Ocular hypertelorism
      2. Down-slanting palpebral fissures
      3. Low-set ears
      4. Webbed neck
      5. Pulmonic stenosis
      6. Pectus excavatum
      7. Mild hypertelorism
      8. Short stature
   3. Relatives affected with NF1 present with or without concomitant features of Noonan syndrome.
   4. Current understanding: The phenotype of NF1 can include features overlapping with those described in Noonan syndrome, but these disorders are probably genetically distinct.
5. Predominance of spinal tumors and relatively few peripheral neurofibromas identified in rare families
   1. Locus heterogeneity
   2. Not representing a distinct subtype of NF

18. Prognosis of NF1
    1. Progression of the disease with time
    2. Pregnancies in women with NF1

1. Normal pregnancies in most patients but serious complications have been noted in some patients.
2. Rapid increase in the number (60%) and size (52%) of neurofibromas during pregnancy (Dugoff and Sujansky 1996).
3. First onset of hypertension or marked exacerbation of preexisting hypertension during pregnancy.
4. Delivery complicated by large pelvic or genital neurofibromas often necessitates cesarean section in pregnant women with NF1.

3. Anesthetic risk
   1. Intraoral lesions compromising the airway (5%)
   2. Coexisting kyphoscoliosis (2%) and fibrosing alveolitis (20%) complicating the perioperative period
   3. Careful regional anesthesia to monitor the existence of neurofibromas affecting peripheral nerves and nerve roots
   4. Possible long-term muscular blockade following the use of suxamethonium and non-depolarizing muscle relaxants
4. Average life expectancy overall reduced by at least 15 years
   1. Malignancy and hypertension contributing to increased morbidity and mortality in adults with NF1 (Zöller et al. 1995)
   2. Risk for neurofibromatosis-related malignancy (8%)
   3. Most common malignancy: malignant peripheral nerve sheath tumors (Poyhonen et al. 1997)
   4. Better prognosis in patients with only mild and cosmetic symptoms of the disease

Diagnostic Investigations

1. Diagnosis of neurofibromatosis 1 based largely on clinical criteria despite progress in defining the molecular genetics of the disorder
2. Slit-lamp examination of the eyes to detect Lisch iris nodules
3. Radiography to detect bony abnormalities
   1. Skull
      1. Macrocephaly
      2. Absence of the greater and lesser wings of the sphenoid
      3. Absence of the orbital floor
      4. Hypoplasia of the lesser wings of the sphenoid
      5. Enlarged orbits
      6. Enlargement of cranial foramina
      7. Enlargement of orbital margins
      8. Sclerosis in the vicinity of the optic foramen (optic nerve sheath meningioma)
      9. Facial asymmetry
      10. Hypoplasia of the paranasal sinuses
      11. Mandibular abnormalities
      12. Mandibular hypoplasia with flattening of the external contour
      13. Thinning of the ramus
      14. Coronoid hyperplasia
      15. Widening of the lateral and medial coronoid spaces
      16. Calvarial defects adjacent the left lambdoid suture
      17. Osseous defects associated with multiple frontonasal osseomeningeal defects causing cerebrospinal fluid (CSF) rhinorrhea
   2. Chest
      1. Inferior rib notching
      2. Twisted ribbonlike ribs in the upper thoracic cage
      3. Posterior mediastinal masses secondary to intrathoracic meningoceles
      4. Mediastinal and lung masses secondary to neurofibromas
      5. Dumbbell neurofibromas
      6. Progressive pulmonary interstitial fibrosis leads to formation of bullae and honeycomb lung.
      7. Increased incidence of spontaneous pneumothorax and hemothorax
      8. Dilatation/enlargement of the central pulmonary arteries and peripheral pruning of vessels secondary to changes of

interstitial lung disease and pulmonary hypertension

3. Spine
    1. A sharply angled kyphoscoliosis centered at the thoracolumbar junction in 50% of patients
    2. Enlargement of the intervertebral foramina
    3. Scalloping of the vertebral bodies (anterior, posterior, lateral)
    4. Hypoplasia of the vertebral pedicles
    5. Wedged-shaped vertebrae
    6. Spondylolisthesis
    7. Spinal clefts
    8. Osteolysis
    9. Spindling of the transverse processes
4. Appendicular skeleton
    1. Bowing of long bones
    2. Hyperplasia or hypoplasia of long and short bones
    3. Pseudarthrosis
    4. Erosions
    5. Periosteal dysplasia
    6. Intramedullary longitudinal osteosclerotic streaks
    7. Single or multiple cystic bone lesions
    8. Focal gigantism
    9. Protrusio acetabuli
    10. Dislocation of the hip
    11. Dislocation of the radius and ulna
    12. Absence of a patella
    13. Neuropathic arthropathy of the knee
5. Gastrointestinal
    1. Neurofibromas within the stomach, small and large bowels, and rectum
    2. Intussusception of the bowel presenting with intestinal obstruction
    3. Bowel obstruction simulating Hirschsprung disease secondary to plexiform neurofibroma of the colon
    4. Pseudoobstruction
    5. Biliary strictures and bile duct intraluminal neurofibromas rarely reported
6. Urinary tract
    1. Renal collecting system and bladder intrinsically involved or extrinsically compressed or displaced by neurofibromas
    2. Intravenous urogram providing useful information regarding the nature and site of obstruction and function
4. Echocardiography for pulmonic stenosis, aortic coarctation, or other CHD
5. CT imaging
    1. Solid fusiform masses
        1. Present in the distribution of nerves, with central areas of low attenuation and calcification
        2. May present in the paravertebral, laryngeal, mediastinal, abdominal, and pelvic/ischiorectal fossae
    2. Plexiform neurofibromas seen as widespread sheets of nodular tissue.
    3. Paraspinal neurofibromas, seen at every level, vary in size, may be dumbbell shaped, or may comprise fusiform/spherical soft-tissue masses.
    4. Mesenteric plexiform neurofibromas trap mesenteric fat within an entangled network.
    5. Nonneoplastic cerebral and cerebellar calcification and choroid plexus calcification on cranial CT scans.
    6. Hydrocephalus in NF1 results from benign aqueduct stenosis or a glioma of the tectum/tegmentum of the mesencephalon.
    7. Intracranial nerve sheath tumors with associated bone erosions.
    8. Meningiomas with associated changes in the calvarium/skull.
    9. Extrinsic bladder involvement, intrinsic infiltrative processes, or extrinsic compression of the renal collecting system by a neurofibroma.
    10. A role in the investigation of thoracic, abdominal, and pelvic complications of NF1.
6. MRI imaging (Vézina 2015)
    1. Brain (Van Es et al. 1996)
        1. T2 hyperintensities (64%).
        2. T1 hyperintensities (32%).
        3. Optic nerve glioma (22%).

4. An intracranial tumor (ependymoma) and sphenoid wing dysplasia were evident in individual patients.
2. Internal lesions
1. Mediastinal masses
2. Spinal cord tumors
3. Deep plexiform neurofibromas
4. Neurofibromas of the brachial or sacral plexus
5. Neurofibromatosis-related vasculopathy

7. Histopathology
1. Confirmation of neurofibromas
1. Arisen from cells in the peripheral nerve sheath
2. Consist of a mixture of cell types, including Schwann cells, fibroblasts, mast cells, and vascular elements
3. Low-power view of neurofibroma: the myelinated and nonmyelinated fibers and s Schwann cell with abundance of collagen (Brasfield and DasGupta 1972)
2. Verification of malignant transformation to neurofibrosarcoma

8. Linkage analyses using polymorphic markers that segregate with the disease in familial cases.
9. Either FISH, loss of heterozygosity, or Southern blotting analyses reveal 5% of patients with large deletions of *NF1* gene encompassing part or the whole *NF1* gene (Kluwe et al. 2004).
10. Mutation analysis in sporadic and familial cases (Friedman 2014):
1. Protein truncation test based on the detection of truncated proteins via in vitro transcription and translation from RT-PCR fragments spanning the entire *NF1* cDNA
1. *NF1* mutations detected
1. Nonsense mutations
2. Frameshift mutations
3. Splicing mutations
2. Method of exploring the RNA for changes that are compatible with mutations in the gene
3. Positive in 80% of the cases
2. Gene sequencing: specific search of exon by exon for the mutation

11. Multistep detection protocol: preferred because of the large size of the NF1 gene and the lack of mutation hotspots:
1. Testing methods
1. Protein truncation assay yielding identification of mutations in 73% of patients (Park and Pivnick 1998)
2. Sequence analysis
3. FISH: provides a simple and rapid means of identification of NF1 gene deletions (Wu et al. 1995, 1997)
4. Long-range RT-PCR
5. Southern blot analysis
6. Cytogenetic analysis
2. NF1 mutations detected
1. Nonsense mutations
2. Frameshift mutations
3. Splicing mutations
4. Missense mutations
5. Deletions
6. Other rearrangements
3. Mutation detection rate in patients with a clinical diagnosis of NF1: >95%

12. Presymptomatic/preconceptional genetic testing: molecular characterization in familial and in sporadic cases
13. Limitation of genetic testing
1. Lack of genotype-phenotype correlations: A positive test will not predict disease severity or outcome.
2. Two exceptions
1. Complete loss of the *NF1* gene along with multiple contiguous genes
1. Occurs in 4–5% of patients with NF1 (Kluwe et al. 2004).
2. Patients with whole gene deletion present with a very large neurofibroma burden, more severe cognitive impairment, large hands and feet, and dysmorphic facial features and have a higher lifetime risk of developing malignant peripheral nerve sheath tumors (MPNST) (Leppig et al. 1997; De Raedt et al. 2003).

2. A 3-base pair in-frame deletion in exon 17 of the *NF1* gene: Patients with this genetic mutation have an absence of cutaneous neurofibromas and appear to have a lower incidence of serious complications.

Genetic Counseling

1. Recurrence risk
    1. Patient's sibling
        1. Risk not increased unless a parent is affected or has gonadal mosaicism.
        2. If a parent is affected, the risk to the sibs is 50%.
        3. Possibility of germ-line mosaicism in a clinically normal parent: recurrence risk based on the percentage of the germ-line mosaicism.
    2. Patient's offspring
        1. Risk: 50% of inheriting the disease with extremely variable disease manifestations.
        2. Risk of having a child with NF1 in a patient affected with segmental NF1
            1. A small but greater than the general population risk.
            2. A lower offspring recurrence risk than individuals with the nonmosaic form (Ruggieri and Huson 2001).
            3. A low probability of transmitting the disease in segmental NF1 (Sloan et al. 1990).
            4. Some cases of segmental NF1 apparently being "transmitted" to offspring; the mechanism (if one exists) behind this is unclear (Boyd et al. 2009).
            5. Segmental neurofibromatosis is believed to be due to somatic mosaicism for a mutation in the NF gene. The mutation occurred postconceptionally and present in the limited population of cells. Gonadal cells may or may not have a mutation (Dupuis and Nezarati 2001).
            6. Postzygotic mutation may occur in both somatic and gonadal cell lines (Messiaen et al. 2011). Gonadal mosaicism is responsible for instances of individuals with mosaic neurofibromatosis having children with generalized neurofibromatosis (Gabhane et al. 2010). As a result, patients diagnosed as mosaic NF1 who are considering having children should be made aware of the small risk of having a child with classic NF1, with the exact risk of this occurring still unknown (Hardin et al. 2014).
2. Prenatal diagnosis
    1. Influence of knowledge of the disease in the reproductive decisions of affected individuals (Ars et al. 1999)
        1. Interest in prenatal test by 41% of the subjects considering becoming pregnant
        2. Only 10% considering terminating an affected pregnancy
    2. Prenatal diagnosis of NF1 difficult to be made in the past due to the following reasons (Vitale et al. 2002):
        1. Large size of the NF1 gene
        2. Lack of any hotspots where the mutations arise
        3. Variable expression even within members of a family with NF1
        4. Lack of a tight genotype-phenotype correlation
        5. High spontaneous mutation rate
    3. Molecular genetic testing. The disease-causing allele of an affected family member must be identified before prenatal testing can be performed (van Minkelen et al 2014).
        1. Direct characterization of the mutation from a parent affected by NF1
        2. Analysis of the genomic DNA mutation from the fetus either by amniocentesis or CVS
        3. Indirect linkage analysis to familial cases using informative polymorphic markers
        4. Protein truncation test
        5. Fluorescence in situ hybridization

4. Molecular diagnosis, unfortunately, cannot predict clinical expression of the disease in the fetus.
5. Preimplantation genetic diagnosis: may be an option for some families in which the NF1 pathogenic variant has been identified (Spits et al. 2005; Chen et al. 2011; Friedman 2014). Advances in biopsy and diagnostic techniques which increase the number of unaffected embryos identified may improve live birth rates for patients with NF1 (Merker et al. 2015).

3. Management
    1. Health supervision for children with neurofibromatosis is available from American Academy of Pediatrics Committee on Genetics (1995).
    2. Developmental assessment in children.
    3. Medical management for itching, pain, depression, and other psychological and social problems.
    4. Treatment of hypertension depending on the etiology.
        1. Pheochromocytomas
        2. Renal artery stenosis
    5. Laser or electrocautery for small discrete cutaneous or subcutaneous neurofibromas.
    6. Surgical resection of tumors.
        1. Resection of neurofibromas pressing on vital structures, obstructing vision, or rapidly growing lesions causing irritation, discomfort, and pain
        2. Plexiform neurofibromas: extremely difficult to approach surgically and often recur after resection because of residual cells resting deeply in the soft tissues
        3. Resection of spinal cord tumors: quite difficult but often is necessary to prevent progressive paraplegia or quadriplegia
    7. Surgical treatment of disfigurement.
        1. Excision of multiple neurofibromas
        2. Reconstructive surgery for plexiform neurofibromas
    8. Children should be watched carefully for signs of malignant transformation and undergo biopsy for neurofibromas that exhibit rapid growth. Management of sarcomas should be aggressive with consideration given to re-excision, placement of brachytherapy catheters, metastasectomy, and limb salvage with adjuvant therapy when possible (Neville et al. 2001).
    9. Orthopedic care indicated for rapidly progressive scoliosis and for some severe bony defects.
    10. Optic pathway gliomas in most children with NF1 (Jett and Friedman 2010).
        1. Usually do not require treatment.
        2. Chemotherapy is the treatment of choice for progressive tumors.
        3. Surgical treatment: reserved for cosmetic palliation in a blind eye.
        4. Radiotherapy usually avoided because of the risk of inducing malignancy or moyamoya in the exposed field.
    11. Treatment of congenital pseudarthrosis of the tibia: challenging (Vitale et al. 2002)
        1. Bracing mainly of early treatment before fracture develops
        2. A knee-ankle-foot orthosis when weight bearing
        3. Intramedullary rod fixation, often in combination with autogenous bone grafting of the pseudarthrosis site
    12. Advise high-risk pregnancy care to pregnant patient with neurofibromatosis (Blickstein et al. 1988)
        1. Maternal hypertension
        2. Aggravating features of neurofibromatosis
    13. A case of neurofibromatosis-Noonan syndrome (NFNS) diagnosed to have growth hormone deficiency (GHD) who received GH treatment until reaching final height (Vuralli et al. 2016). The findings in this patient show that short stature is a feature of NFNS and can be caused by GHD.
    14. A multidisciplinary approach to care, entailing a dedicated team of specialists throughout the lifetime of the patient (Hirbe and Gutmann 2014).
    15. Recent advances have implicated several crucial signaling pathways involved in malignant peripheral nerve sheath tumor

malignant growth and uncovered new potential drug targets. These include the use of chromatin remodelers to restore the epigenetic status of SUZ12 deficiency as well as to identify targets to block angiogenesis and cell migration that are commonly upregulated in malignant peripheral nerve sheath tumors, including the STAT3/HIF and RHO/ROCK signaling pathways (Rad and Tee 2016).

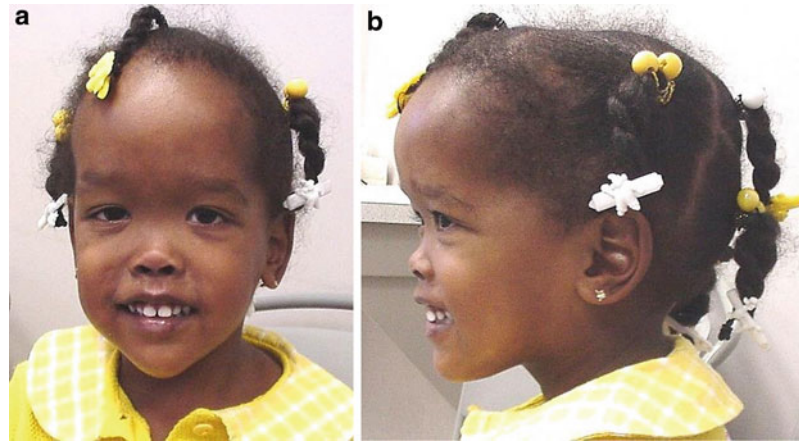

Fig. 6 (**a**, **b**) Macrocephaly with prominent forehead and depressed nasal bridge

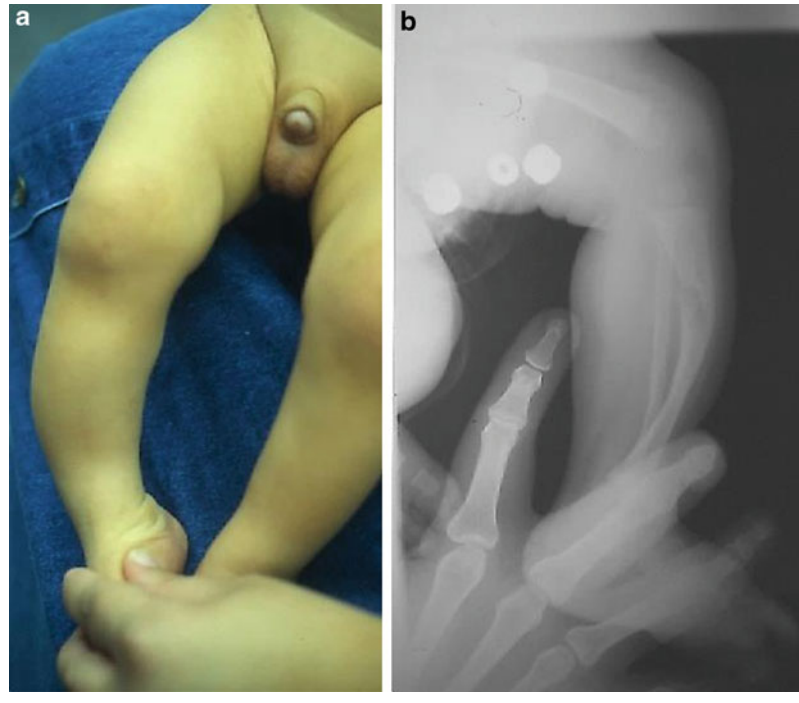

Fig. 7 (**a**, **b**) Pseudarthrosis of right tibia manifesting as bowed leg

Fig. 8 (**a**, **b**) A child with NF1 (**a**) having pseudarthrosis of the left tibia and fibula resulting in fractures (**b**)

Fig. 9 Localized intraneural neurofibromas of a median nerve, causing fusiform enlargement of the affected nerve

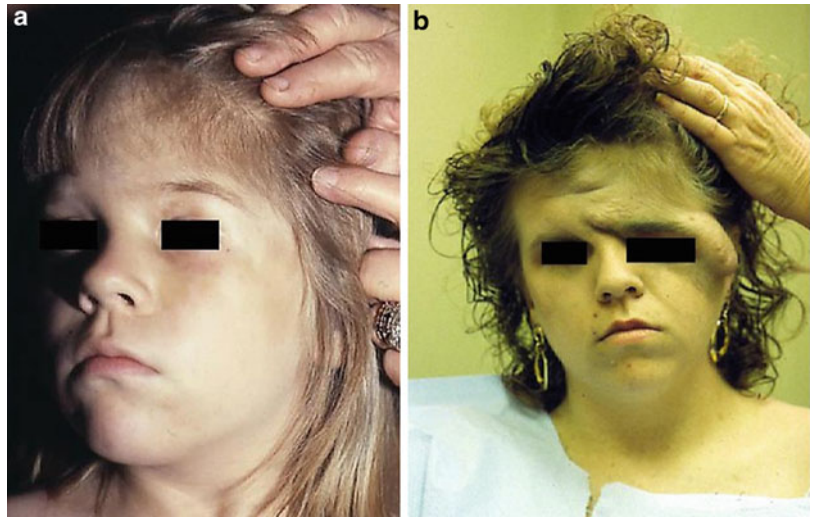

Fig. 10 (**a**, **b**) Plexiform neurofibromas affecting left orbital region in different ages (**a**, **b**)

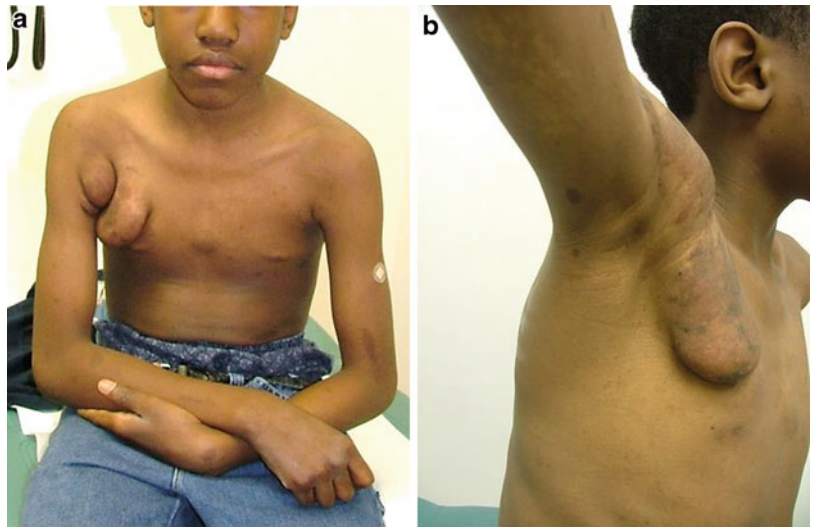

Fig. 11 (**a**, **b**) A 12-year-old boy with NF1 showing a large plexiform neurofibroma on the right upper chest

Fig. 12 (**a**–**d**) A man with NF1 showing plexiform neurofibromas on the left cheek (**a**, **b**), right upper back (**c**), and sole of the foot (**d**)

Fig. 13 (**a**–**c**) Massive soft-tissue neurofibromas affecting two patients (**a**, **b**, **c**). Extreme neurofibromatous growth producing massive, diffuse infiltration of soft tissue of the thigh producing disfiguring redundant soft-tissue masses

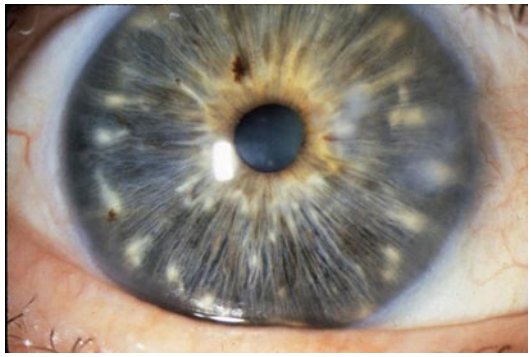

Fig. 14 Tannish-white iris Lisch nodules in a patient with NF1

Fig. 15 MRI of the brain showing a hamartomatous lesion of the right globus pallidus. This patient has numerous cutaneous café-au-lait spots of varying size and typical axillary freckles. He was shown to have a truncating mutation in the segment 3 of the neurofibromin (*NF1*) gene

Fig. 16 (**a**–**d**) A 26-year-old female with segmental neurofibromatosis showing axillary freckles (**a**), multiple small neurofibromas, and hyperpigmentation, all involving the right side of the body (**c**, **d**). Left side of the body is spared, including left axilla which showed no freckles (**b**)

Fig. 17 (**a**–**d**) A 36-year-old father (**a**, **b**) presents with >8 large café-au-lait spots, bilateral axillary freckling, several cutaneous, intradermal, and subcutaneous neurofibromas. A heterozygous missense alteration in exon 13 of the *NF1* gene was identified (c.2072 T > C) (p.Leu691Pro). The 2-year and 3-month-old daughter (**a**) was found to have multiple café-au-lait spots (**c**) with a single neurofibroma on the right scalp (**d**)

Fig. 18 A 14-month-old infant was seen because of multiple café-au-lait spots without neurofibroma. A splice mutation was identified in the *NF1* gene, 6641 + 1 G > T, leading to skipping of exon 35. This finding confirms the diagnosis of NF1 in this patient

Fig. 19 A 13-year-old boy with multiple café-au-lait spots, axillary freckles, and small neurofibromas throughout the body. The molecular study revealed a recurrent deep intronic splicing mutation in the *NF1* gene (c.5749 + 322 A > G). This mutation leads to missplicing of intron 30. This finding confirms the diagnosis of neurofibromatosis 1

Neurofibromatosis 2

Contents

Historically, neurofibromatosis 2 (NF2) has been previously known as bilateral acoustic neurofibromatosis or central neurofibromatosis. It has frequently been confused with the more common neurofibromatosis 1 (NF1), also known as von Recklinghausen disease or peripheral neurofibromatosis (MacCollin and Mautner 1998). Gardner and Frazier in 1930 were the first to persuasively argue that bilateral vestibular tumors can be clinically and pathologically distinguished from both von Recklinghausen neurofibromatosis and from sporadic tumors from studying a large family with 38 affected members over five generations. The first clear description of NF2 was made by Wishart in 1822 (Wishart 1822). NF2 occurs in about 1 in 25,000 live births.

Synonyms and Related Disorders

Bilateral acoustic neurinoma; Bilateral acoustic neurofibromatosis; Bilateral acoustic schwannomas; Central neurofibromatosis

Genetics/Basic Defects

1. An autosomal dominant disorder: resulting from a mutation in the *NF2* tumor suppressor gene on chromosome 22q12 (Asthagiri et al. 2009):
   1. Truncating mutations (nonsense and frameshifts): most frequent germ line event causing the most severe disease.
   2. Single and multiple exon deletions are also common.
2. *NF2* tumor suppressor gene: consists of 17 exons that encode for a 69-kDa protein product called merlin (moesin-ezrin-radixin-like protein) or schwannomin (Rouleau et al. 1993; Trofatter et al. 1993)
3. Consistent with Knudson's two-hit hypothesis for tumorigenesis (tumor formation initiates when both alleles of this gene are inactivated) (Knudson 1971):

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_179

1. Patients inherit a germ line mutation of one affected allele from a parent or acquire a de novo mutation of an allele at the postzygotic stage of embryogenesis.
2. Subsequent development of tumors in susceptible target organs, such as nervous system, eyes, and skin, from cells that lose function of the wild-type (normal) *NF2* allele.

4. Abnormal or absent merlin function can disrupt tumor suppression in NF2.
5. High frequency of somatic mosaicism in patients with de novo mutations (Kluwe and Mautner 1998; Moyhuddin et al. 2003; Evans et al. 2007):
   1. Mutation takes place after conception in patients with mosaicism, resulting in two separate cell lineages.
   2. Patients with mosaicism tend to have mild generalized or even localized disease (e.g., unilateral vestibular schwannoma with ipsilateral tumors).
   3. Only a portion of the germ cells in a person with *NF2* mosaicism are likely to carry the mutation:
      1. Risk of transmission to offspring will be less than the expected one in two (50%) for an inherited mutation.
      2. Children who inherit the mutation from a mosaic parent will probably have more severe disease than will the parent because the mutation will be present in all their somatic cells.

Clinical Features

1. Young adulthood (age 20–30 years) (Asthagiri et al. 2009):
   1. Hearing loss from a vestibular schwannoma, often unilateral initially
   2. Accompanied symptoms
      1. Tinnitus
      2. Dizziness
      3. Imbalance
   3. A significant proportion of cases (20–30%) present with:
      1. Headaches and/or seizures from an intracranial meningioma
      2. Pain, muscle weakness, and/or paresthesia from spinal tumor
      3. Cutaneous tumor-induced symptoms
2. Children (up to 30%):
   1. May present with the same symptoms as adults
   2. More frequently present with the following:
      1. Visual disturbance:
         1. Cataract
         2. Hamartomas
         3. Intracranial tumors
      2. Skin tumors
      3. Mononeuropathy:
         1. Facial paresis
         2. Foot drop
      4. Symptomatic spinal cord tumors
      5. Non-vestibular intracranial tumors
3. Lesions associated with NF2:
   1. Neurological lesions (Borofsky and levy 2013):
      1. Bilateral vestibular schwannomas (90–95%) (the hallmark of NF2, a disease exhibits considerable phenotypic variability) and other cranial nerve schwannomas (24–51%): hearing loss, dizziness, headaches, diplopia, and facial weakness (the most common presenting clinical symptoms)
      2. Intracranial meningiomas and glioma (50–60%)
      3. Spinal tumors, most frequently ependymomas (63–90%):
         1. Extramedullary tumors (55–90%)
         2. Intramedullary tumors (18–53%)
      4. Peripheral neuropathy ($\leq$66%)
   2. Ophthalmological lesions:
      1. Cataracts (60–81%)
      2. Epiretinal membranes (12–40%)
      3. Retinal hamartomas (6–22%)
   3. Cutaneous lesions:
      1. Skin tumors (59–68%)
      2. Skin plaques (41–48%)
      3. Subcutaneous tumors (43–48%)
      4. Intradermal tumors (rare)
   4. Segmental neurofibromatosis type 2 presenting multiple schwannomas confined to one limb (Castellanos et al. 2015)

4. Diagnostic criteria for NF2 including the NIH criteria (National Institutes of Health Consensus Development Conference 1988) with additional criteria (Manchester criteria which expanded the previous NIH diagnostic criteria and were designed to include patients with neither a family history of NF2 nor bilateral vestibular schwannomas, but who had multiple schwannomas or meningiomas) (Evans et al. 2005; Evans 2009a, b; Baser et al. 2002b; Asthagiri et al. 2009):
    1. Major criteria:
        1. Bilateral vestibular schwannomas
        2. First-degree family relative with NF2 plus unilateral vestibular schwannoma or two NF2-associated lesions (meningioma, glioma, neurofibroma, schwannoma, or cataract)
    2. Additional criteria:
        1. Unilateral vestibular schwannoma plus any two NF2-associated lesions (meningioma, glioma, neurofibroma, schwannoma, or cataract)
        2. Multiple meningiomas plus unilateral vestibular schwannoma or two other NF2-associated lesions (glioma, neurofibromas, schwannoma, or cataract)
5. The Baser criteria for diagnosis of NF2 (Baser et al. 2011):
    1. First-degree relative with NF2 diagnosed by these criteria: 2 (if present at or before the age of 03), 2 (if present after the age of 30)
    2. Unilateral vestibular schwannoma: 2 (if present at or before the age of 03), 1[a] (if present after the age of 30)
    3. Second vestibular schwannoma: 4 (if present at or before the age of 03), 3[a] (if present after the age of 30)
    4. One meningioma: 2 (if present at or before the age of 03), 1 (if present after the age of 30)
    5. Second meningioma (no additional points for $>$ 2meningiomas): 2 (if present at or before the age of 03), 1 (if present after the age of 30)
    6. Cutaneous schwannoma (*one or more*): 2 (if present at or before the age of 03), 1 (if present after the age of 30)
    7. Cranial nerve tumor (excluding vestibular schwannoma) (*one or more*): 2 (if present at or before the age of 03), 1 (if present after the age of 30)
    8. Mononeuropathy: 2 (if present at or before the age of 03), 0 (if present after the age of 30)
    9. Cataract (*one or more*): 2 (if present at or before the age of 03), 2 (if present after the age of 30)
    10. A diagnosis of definite NF2 is established if the total number of points is $\geq$6 ([a]points are not given for unilateral or second vestibular schwannoma if age at diagnosis is $>$70 years)
    11. NF2 mutation testing is indicated if the total number of points is 4 or 5:
        1. A diagnosis of definite NF2 is established if a constitutional pathogenic *NF2* mutation is found on mutation testing
        2. If no constitutional pathogenic *NF2* mutation is found on mutation testing:
            1. A diagnosis of mosaic NF2 is established if mosaicism for a pathogenic *NF2* mutation is found in the blood or no detectable pathogenic *NF2* mutation is found in the blood, but the same pathogenic *NF2* mutation is found in two separate NF2-associated tumors.
            2. Otherwise, a temporary diagnosis of possible NF2 is made, pending further clarification. Clarification may occur if the patient is established to have a different condition (e.g., schwannomatosis or multiple meningiomas) by standard diagnostic criteria or if evolution of the patient's disease over time permits establishing a diagnosis of definite NF2 or mosaic NF2 according to the criteria given above.
6. Patient populations at risk for NF2 (Evans et al. 2005):

1. First-degree relative with NF2 (affected parent, sibling, or children)
2. People younger than age 30 years with a unilateral vestibular schwannoma or meningiomas
3. People with multiple spinal tumors (schwannomas, meningiomas)

7. Recommended intervals for screening children of an affected parent (Evans et al. 2005):
   1. Ophthalmological examination yearly from infancy.
   2. Neurological examination yearly from infancy.
   3. Audiology with auditory brain stem evoked potentials yearly from infancy.
   4. Presymptomatic genetic testing: one test from 10 years of age.
   5. Cranial MRI at 10–12 years of age.
   6. Spinal MRI at 10–12 years of age (every 2–3 years).
   7. For presymptomatic genetic testing, cranial MRI, and spinal MRI, screening may start earlier than age 10 years in severely affected families and families in which early detection of disease would aid family preparation for future events related to NF2.
8. Variable expressivity of NF2 among individuals:
   1. Varying size, location, and number of tumors.
   2. Although these tumors are not malignant, their anatomical location and multiplicity lead to great morbidity and early mortality.
   3. The average age of death is 36 years.
   4. Actuarial survival from the time of establishing the correct diagnosis is 15 years.
   5. Survival is improving with earlier diagnosis and better treatment in specialty centers (Baser et al. 2002a; Evans et al. 2005).
   6. Under recognized in children in whom skin tumors and ocular findings may be the first manifestations (NF2 is usually considered an adult-onset disease).
9. Penetrance: 100%.
10. Differential diagnosis:
    1. Main differential diagnosis of NF2: schwannomatosis (multiple schwannomas without the vestibular schwannomas that are diagnostic of NF2)
    2. Multiple non-cranial schwannomas: Some patients turn out to have mosaic NF2 (Moyhuddin et al. 2003; Evans et al. 2007).
    3. Neurofibromatosis 1
11. Prognosis is adversely affected by:
    1. Early age at onset
    2. A higher number of meningiomas
    3. Having a truncating mutation

Diagnostic Investigations

1. Clinical and family history (Evans 2009a).
2. Physical examination including cutaneous and ophthalmic (slip lamp).
3. Craniospinal MRI.
4. Hearing evaluation, including BAER.
5. Chromosome analysis: Gross chromosomal changes are rare but may reveal a variety of chromosome abnormalities:
   1. Cytogenetically visible deletions encompassing the NF2 gene: may cause mental retardation and multiple congenital abnormalities (Barbi et al. 2002):
      1. Ring chromosome 22 (Tsilchorozidou et al. 2004).
      2. Can cause multiple meningiomas and vestibular schwannomas fulfilling NF2 diagnostic criteria, NF2 locus itself is usually present within the ring, but the ring itself is frequently loss as a result of instability.
      3. Apparently balanced chromosomal translocations disrupting the *NF2* gene causing NF2.
      4. Fluorescence in situ hybridization (FISH) to identify smaller deletions that remove multiple exons of the NF2 gene or the whole gene.

6. Molecular genetic analysis:
    1. Sequence analysis/mutation scanning of *NF2* gene (Evans et al. 2007):
        1. In 73% of families with NF2, sequence analysis identified a mutation in a member of the second generation.
        2. In simplex cases (a single occurrence in a family), the mutation detection rate is approximately 60%.
        3. Approximately 25–33% of mutations are not detected as a result of somatic mosaicism.
        4. Mutations with mosaicism levels >10% can be detected in lymphocyte DNA.
        5. Identification of the remainder of mosaic mutations usually requires testing of tumor material.
    2. Deletion/duplication analysis:
        1. Systematically detects whole exon deletions and duplications.
        2. Most large deletions and, less commonly, duplications of single exons or multiple exons can be detected by multiple ligation-dependent probe amplification (MLPA).
    3. Linkage analysis:
        1. In families in whom no disease-causing mutation is identified, and at least two family members of different generations are affected.
        2. Modified linkage analysis using both constitutional and tumor DNA can exclude NF2 in those children of a simplex case who have not inherited the allele lost in the tumor.
7. Presymptomatic genetic testing is an integral part of the management of NF2 families:
    1. At-risk relatives whose genetic status is unknown can be tested for presence of the *NF2* mutation (either constitutional or somatic mosaic) identified in an affected relative.
    2. In the rare instance in which an *NF2* mutation cannot be identified, linkage analysis can be used in families with at least two affected family members of different generations, or tumor DNA can be used to clarify the genetic status of children of a simplex case.

Genetic Counseling

1. Recurrence risk: presence of an affected parent in approximately 50% of individuals with NF2 (other 50% have NF2 as the result of a de novo mutation; 20–33% of simplex cases without family history are mosaic for an *NF2* mutation) (Evans 2009a):
    1. Patient's sib:
        1. Affected parent: a 50% risk
        2. Asymptomatic parents: a low risk since the age of onset of symptoms is relatively uniform within families:
            1. A single case of germ line mosaicism in a clinically normal parent has been reported.
            2. Somatic mosaicism which may include germ line mosaicism is found in 25–33% of individuals with NF2 who are simplex cases.
    2. Patient's offspring:
        1. The risk of disease transmission is 50% in the second generation and beyond.
        2. The risk of transmission in people with new NF2 mutations is less than 50% due to mosaicism, in which only a proportion of cells have the mutated *NF2* gene (Evans et al. 1998; Kluwe and Mautner 1998).
2. Prenatal diagnosis and preimplantation genetic diagnosis: possible for at risk pregnancies, provided prior identification of the disease-causing mutation in the family.
3. Management:
    1. Surgery remains the focus of current management:
        1. Surgical removal of symptomatic cranial and spinal tumors
        2. More difficult to determine the timing of removal of vestibular schwannomas
    2. Stereotactic radiosurgery, most commonly with the gamma knife, may be an alternative to surgery.
    3. Important to balance the use of microsurgery and radiation treatment, which can have a role in patients who have particularly aggressive tumors, or who are poor surgical risks, or who refuse surgery.

4. Hearing preservation and augmentation with hearing aids or auditory rehabilitation with a cochlear or auditory brainstem implants (Matthies et al. 2014; Schwartz 2014).
5. Watchful waiting with careful surveillance and occasionally radiation treatment have a role.
6. Patients should be assessed in a multidisciplinary center with experience in managing NF2 (Szudek et al. 2012):
    1. Goal of treating vestibular schwannomas: to maximize the duration of useful hearing while minimizing morbidity to the facial nerve and brainstem
    2. Treatment options for vestibular schwannomas: traditional approach of initial observation or tumor resection with attempted hearing preservation
    3. Choice of treatment: depends on patient factors and preferences as well as the available surgical expertise

Fig. 1 (**a**, **b**) A 23-year-old female had resection of anterior fossa meningioma 2 years previously. She complained worsening headaches with intermittent vomiting and blurry vision recently. She underwent a posterior fossa craniectomy and resection of a large cervical medullary tumor, consistent with a spindle cell tumor (schwannoma). She also has history of bilateral hearing loss and balance dysfunction. Molecular genetic testing revealed a truncating mutation in the *NF2* gene (c.553delG) confirming the diagnosis of NF2 in this patient

Fig. 2 (**a**–**e**) An 11-year-old African-American boy was reevaluated for possible neurofibromatosis 2. Family history, pregnancy history, and birth history were noncontributory. He had mild developmental delay. He was thought to have neurofibromatosis 1 (*NF1*) because of multiple café-au lait spots on his back and legs and several soft tissue masses. The detail examination showed soft diffuse subcutaneous mass on the right supraorbital region (**a**) and upper lip (**b**). Multiple café-au-lait spots were noted primarily on the trunk, appeared to be much darker than the usual Café-au-lait spots and some were excoriated (**c**). There were several separate large, soft, diffuse subcutaneous lesions. He also had numerous hyperpigmented macules on the back, chest, and legs (**d**). No axillary or inguinal freckling was noted. His left foot was smaller than the right (**e**) as well as left calf size. The comprehensive NF1 mutation analysis was negative. MRI of the brain showed an enhancement adjacent to the VIII cranial nerve suspicious of bilateral acoustic neuroma. The boy presented recently with headache, a small cataract of the right eye, and mild hearing impairment. Mutation analysis of *NF2* gene identified a heterozygous mutation in the *NF2* gene (c.1000-?_1446+?del) (deletion of *NF2* exons 11–12). This finding confirms the diagnosis of *NF2* in this patient (Collaboration with Dr. Susonne Ursin)

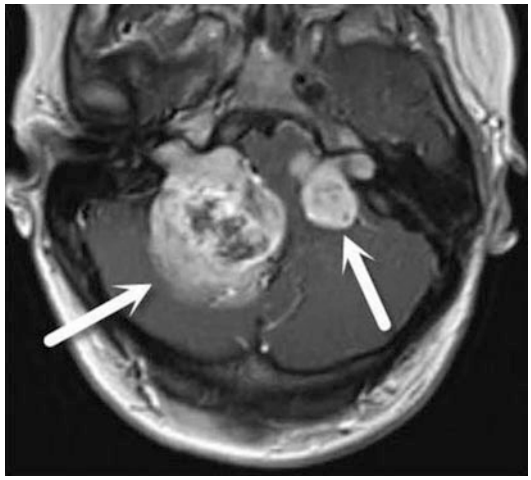

Fig. 3 Post contrast MRI image of brain on a 16-year-old female presenting with hearing loss demonstrates avidly enhancing extra-axial masses bilaterally in the posterior fossa (*arrows*). These masses are herniating into and causing expansion of the internal auditory canal without any bony destruction consistent with bilateral acoustic schwannomas. Mass effect on the brainstem and cerebellum is also identified (Courtesy of Dr. Grace Guo and Dr. Arabinda Choudhary)

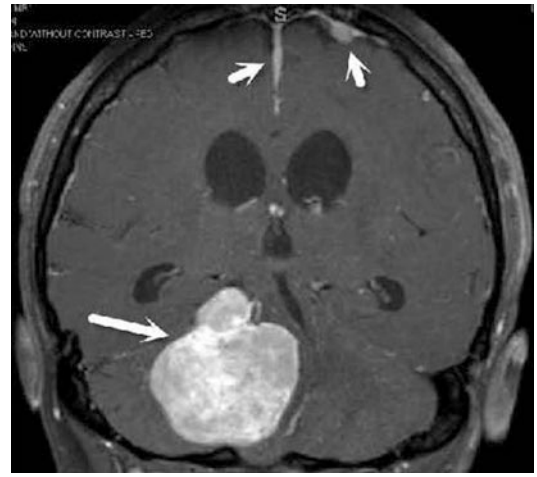

Fig. 4 Her other post contrast MRI image of brain also demonstrates avidly enhancing extra-axial masses bilaterally in the posterior fossa (*large arrow*). Mass effect on the brainstem and cerebellum is also identified. Smaller enhancing dural masses are also identified along the left interhemispheric fissure and overlying the left parietal lobe consistent with meningiomas (*small arrows*) (Courtesy of Dr. Grace Guo and Dr. Arabinda Choudhary)

Niemann-Pick Disease

Contents

Niemann-Pick disease has been used to designate a heterogeneous group of autosomal recessive lysosomal lipid storage disorders (acid sphingomyelinase deficiency) (types A and B), with common features of hepatosplenomegaly and sphingomyelin storage in reticuloendothelial and parenchymal tissues, with or without neurological involvement. Niemann-Pick type C disease (NP-C) evolved from that of a sphingomyelin storage disorder to that of a cholesterol storage disorder (Pentchev et al. 1994).

Synonyms and Related Disorders

Acid sphingomyelinase deficiency; Niemann-Pick disease types A, B, C

Genetics/Basic Defects

1. Niemann-Pick disease types A and B
    1. A rare lysosomal storage disease.
    2. Inherited as autosomal recessive traits.
    3. Result from allelic mutations in the sphingomyelin phosphodiesterase (*SMPD*) genes, located within the chromosomal region 11p15.4.
    4. Caused by deficient activity of acid sphingomyelinase (ASM).
    5. The acid sphingomyelinase defect leads to the accumulation of sphingomyelin in the cells of the liver, spleen, bone marrow, lungs, and, in some patients, brain (Schneider and Kennedy 1967; Marathe et al. 1998; Rodriguez-Lafrasse and Vanier 1999; Schuchman and Desnick 2001a, b).
2. Niemann-Pick disease type C (Vanier 2010)
    1. Biochemically, genetically, and clinically distinct from type A disease and type B disease
    2. Caused by autosomal recessive inheritance of mutations in two genes, *NPC1* (18q11.2) in 95% of cases or *NPC2* (14q24.3) in about 4% of cases, resulting in a disruption of intracellular cholesterol transport and accu-

DOI 10.1007/978-1-4939-2401-1_277

mulation of excessive amounts of cholesterol within liver and spleen and other lipids in the brain

Clinical Features

1. Niemann-Pick disease type A (Vanier 2010; Adolina 2014)
   1. A severe neurodegenerative disease with little or no enzyme activity.
   2. Ashkenazi Jewish predilection (gene frequency estimated to be 1:100).
   3. Overall frequency of types A and B: 1:250,000 (Meikle et al. 1999).
   4. Onset in infancy.
      1. Abdominal enlargement due to hepatosplenomegaly
      2. Feeding difficulties
      3. Macular cherry-red spot
   5. Progressive loss of acquired motor skills.
   6. Peripheral neuropathy (Gumbinas et al. 1975; Landrieu and Saïd 1984).
      1. Hypotonia
      2. Absent reflexes
   7. Increased accumulation of sphingomyelin in ganglion cells of the central nervous system leads to neurologic disturbances and mental retardation generally resulting in death by 3 years of age (McGovern et al. 2006).
2. Niemann-Pick disease type B (Guillemot et al. 2007; McGovern et al. 2013)
   1. A milder disease with the same gene defect as type A but has more residual enzyme activity
   2. Panethnic
   3. Characterized by phenotypic heterogeneity
   4. Broad range of severity
   5. Ocular manifestations (primary retinal including macular halos and cherry-red maculae) (Lowe et al. 1986; McGovern et al. 2004a)
   6. Onset in preteen years with the enlargement of the liver and spleen (hepatosplenomegaly)
   7. In adulthood, infiltrative pulmonary disease and ataxia are the major complications
   8. Other features
      1. Hyperlipidemia
      2. Liver dysfunction
      3. Cardiac disease
      4. Excessive bleeding and bruising
      5. Recurrent respiratory infections
      6. Retinal stigmata
      7. Growth retardation/developmental delay
      8. Skeletal manifestations
         1. Osteoporosis
         2. Osteopenia
      9. Peripheral neuropathy
   9. Absence of central nervous system involvement in most patients
   10. Serious morbidities: clinically significant hepatic, cardiac, and pulmonary disease especially in pediatric population
   11. Major causes of death: pneumonia/respiratory failure
3. Niemann-Pick disease type C (Patterson et al. 2012)
   1. Perinatal fetus.
      1. Fetal hydrops
      2. Fetal ascites
   2. Neonates/infants.
      1. Prolonged neonatal cholestatic icterus appearing in the first days or weeks of life (most cases resolve spontaneously by 2–4 months of age), usually associated with progressive hepatosplenomegaly in approximately 50% of patients (Vanier et al. 1988; Kelly et al. 1993; Yerushalmi et al. 2002)
      2. Ascites and severe liver disease resulting from infiltration of the liver
      3. Respiratory failure resulting from infiltration of the lungs
      4. Infants with severe early infantile neurologic onset form
         1. Hepatosplenomegaly almost invariably present
         2. Central hypotonia
         3. Developmental delay of motor milestones
         4. Loss of acquired motor skills, followed by pronounced spasticity with pyramidal tract involvement
         5. Intentional tremor frequently present

3. Mid-to-late childhood: classic presentation occurs during this period.
    1. Insidious onset of ataxia
    2. Vertical supranuclear gaze palsy (a clinical hallmark, often the initial sign)
    3. Dementia
    4. Action dystonia
    5. Seizures
    6. Dysarthria
    7. Dysphagia
    8. Develop pyramidal signs and spasticity at a late stage
    9. Eventual disabling
    10. Death usually occurring in the late second or third decade from aspiration pneumonia
4. Adults.
    1. Dementia
    2. Psychiatric signs
        1. Psychosis including paranoid delusions, auditory or visual hallucinations, and interpretative thoughts
        2. Depressive syndrome
        3. Behavioral problems with aggressiveness
        4. Social isolation
        5. Others

Diagnostic Investigations

1. Radiology.
    1. Type A: chest X-ray and CT scan for demonstrating interstitial lung disease.
    2. Type B:
        1. Chest X-ray and CT scan demonstrate interstitial lung disease (presence of "crazy paving" sign: ground-glass opacities, intermixed thickened interlobular septa and intralobular lines) (Mendelson et al. 2007).
        2. MRI of the brain: may show pronounced cerebellar and mild supratentorial atrophy (Obenberger et al. 1999).
    3. Type C: MRI at late stages of the illness may reveal marked atrophy of the superior/anterior cerebellar vermis, thinning of the corpus callosum, mild cerebral atrophy, and increased signal in the periatrial white matter reflecting secondary demyelination; MRS (magnetic resonance spectroscopy) may be more sensitive than standard MRI (Tedeschi et al. 1998).
2. Pulmonary function test. The lack of correlation between functional pulmonary impairment and the findings at radiography and thin-section CT may be due to the pathologic basis of the lung abnormalities in type B Niemann-Pick disease.
3. Biochemical/histological analyses (Mendelson et al. 2007; Schuchman 2007; Cruse 2013).
    1. NPD type A
        1. Absence of residual acid sphingomyelinase activity and subsequent lysosomal accumulation of sphingomyelin (Graber et al. 1994)
        2. Decreased high-density lipoprotein (HDL) cholesterol, hypertriglyceridemia, and increased LDL cholesterol (McGovern et al. 2004b)
        3. Large lipid laden foam cells: observed in the reticuloendothelial system of the spleen, bone marrow, lymph nodes, blood vessels, peripheral nerve Schwann cells, central nervous system, and retinal cells (Wenger et al. 1981)
        4. Electron microscopy: reveals lysosomal inclusions and myelin inclusions in peripheral nerves, indicating a severe myelinopathy (Landrieu and Saïd 1984)
    2. NPD type B
        1. Demonstration of reduced ASM activity in isolated leukocytes and/or cultured skin fibroblast
        2. High triglycerides and LDL cholesterol
        3. Low HDL cholesterol (most consistent laboratory finding)
        4. Thrombocytopenia secondary to hypersplenism in most patients
        5. Liver involvement: infiltration of foamy histiocytes, ballooning of hepatocytes, and fibrosis (Takahashi et al. 1997)
    3. NPD type C (Patterson et al. 2012)
        1. Impaired cholesterol esterification

2. Positive filipin staining in cultured fibroblasts
4. Molecular genetic analysis
   1. NPD types A and B: identification of *SMPD1* gene mutation
   2. NPD type C: molecular testing of *NPC1* and *NPC2* detects disease-causing mutations in approximately 94% of individuals with NPD type C

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: 25%
   2. Patient's offspring: not increased unless the spouse is a carrier or affected
2. Prenatal diagnosis
   1. Type A or B
      1. Measure sphingomyelinase activity in amniotic fibroblasts (Wenger et al. 1978; Vanier 2002)
      2. Molecular genetic testing if both disease-causing *SMPD1* alleles have been identified in an affected family member (McGovern and Schuchman 2011)
   2. Type C (Patterson et al. 2012)
      1. Chorionic villus sampling at 10–12 weeks or fetal cells obtained by amniocentesis at 15–18 weeks: available for pregnancies at 25% risk for type C.
      2. Biochemical testing can be done only when the proband has the typical biochemical phenotype.
      3. Molecular genetic testing: possible when the two disease-causing *NPC1* or *NPC2* mutations have been identified in the proband.
3. Carrier testing: available by molecular testing if the *NPC1* or *NPC2* gene mutation has been identified in the proband
4. Management (Vanier 2010)
   1. Symptomatic management
      1. Antiepileptic drugs for seizures.
      2. Anticholinergic agents for dystonia and tremor.
      3. Physiotherapy for spasticity and prevention of contractures.
      4. Melatonin may be used to treat insomnia.
      5. Special schooling.
      6. Proper management of infections.
      7. Gastrostomy for feeding difficulties.
   2. Bone marrow transplantation
      1. Regression of hepatomegaly and lung infiltration (Hsu et al. 1999).
      2. Unfortunately neurologic status continues to deteriorate.
   3. Liver transplantation with cirrhosis does not influence the course of neurologic deterioration (Gartner et al. 1986).
   4. A rationale supporting early hematopoietic stem cell transplantation in NPC2 patients because the NPC2 protein is soluble, secreted, and recaptured (Verot et al. 2007; Bonney et al. 2010).
   5. Miglustat.
      1. A controlled clinical trial was initiated in neurologically symptomatic patients, first in adolescents and adults (12 years and above) (Patterson et al. 2007), then in children (4–12 years). Overall, the disease course stabilized in 72% of patients treated for 1 year or more.
      2. In January 2009, the European Union has extended the indication of miglustat to the treatment of progressive neurological manifestations in adult and pediatric patients with NP-C, and the drug is now approved for this indication in several other countries. This represents the first specific treatment for NP-C.
      3. An international, multicenter observational cohort study in 66 patients treated off-label with miglustat (Iturriaga et al. 2006; Pineda et al. 2009) further showed a significant reduction in the annual rate of progression of the disease in a majority of patients. Late-onset forms generally appeared as the best responders. A further case series from Spain has been documented (Pineda et al. 2010).
      4. Longer term studies will be important to better evaluate the disease progression

following the stabilization phase (Jacklin et al. 2010).

5. It has been recommended to treat patients as soon as they show neurological manifestations of any type.
6. Miglustat, however, is not expected to have an effect on the systemic manifestations of NP-C.

Fig. 1 This is an 18-year-old Caucasian female who was seen because of abnormal neurologic symptoms. Early developmental milestones were on target. At 1 year of age, she was noted to walk with an unusual gait. She began staggering and waggling, accompanied with pronate wrists and "stiff arms." As she gets older, she started to have slurring speech, drooling, and choking when drinking or eating. She was also noted to have vertical gaze palsy especially with downward motion, seizures, ataxia, and loss of previously attained speech. The ophthalmology evaluation revealed inferior and superior rectus paralysis and monitor myopia. Her brother has similar clinical symptoms. He has abnormal cholesterol esterification studies with less than 10% of normal cultured fibroblast control assay results. Niemann-Pick type C mutation analysis from his fibroblast culture revealed a heterozygous sequence change in exon 8: c.1211G > A (DNA change of p.2903A > G), which is a known pathogenic mutation. He also has a heterozygous sequence change in exon 19: c.2903A > G. The significance of this sequence change is unknown. Fibroblasts from this patient displayed depressed but not absent cholesterol esterification (20% of normal control cells). Filipin staining of free cholesterol was also seen although not as dramatic as a bona fide Niemann-Pick type C patient. Her Niemann-Pick type C mutation analysis revealed the same heterozygous sequence changes in exon 8 and exon 19. The molecular findings of this patient and her brother are consistent with Niemann-Pick disease type C (Courtesy of Dr. Susonne Ursin)

Noonan Syndrome

Contents

Noonan syndrome (NS) is a relatively common but genetically heterogeneous autosomal dominant malformation syndrome. The incidence of Noonan syndrome is estimated to be 1 in 1,000–1 in 2,500 live births (Tartaglia et al. 2001).

Synonyms and Related Disorders

Female pseudo-Turner syndrome; Male Turner syndrome; Turner phenotype with normal karyotype

Genetics/Basic Defects

1. Inheritance (Allanson 1987; Tartaglia et al. 2010)
    1. Autosomal dominant inheritance
    2. Many affected individuals with de novo mutations
    3. Affected parent recognized in 30–70% of families
2. Caused by mutations in the *PTPN11* (Tartaglia et al. 2001), *SOSI*, *KRAS*, *NRAS*, *RAF1*, *BRAF*, and *MEK1* (*MAP2K1*) genes: accounting for approximately 70% of affected individuals
    1. The gene *PTPN11* (protein tyrosine phosphatase, nonreceptor type 11), mapped on 12q24.1, encoding the protein tyrosine phosphatase SHP-2.
        1. Heterozygous point mutations in the gene *PTPN11* identified in the following:
            1. Families showing linkage to the *NS1* locus in 12q24
            2. Some sporadic cases with NS
        2. All mutations detected to date: missense mutations (Kosaki et al. 2002)
        3. The majority of mutations found in exons 3 and 8, which correspond to the interacting regions of the N-SH2 and protein tyrosine phosphatase domains of the gene (Maheshwari et al. 2002)
        4. Genotype-phenotype correlation of *PTPN11* mutations (Tartaglia et al. 2002; Zenker et al. 2004)
            1. Increased frequency of *PTPN11* mutations observed in individuals with Noonan syndrome with pulmonary stenosis (70%)
            2. Infrequent frequency of *PTPN11* mutations observed in individuals with hypertrophic cardiomyopathy (6%)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_180

2. SHP-2 (encoded by *PTPN11*), SOS1, BRAF, RAF1, and MEK1 positively contribute to RAS-MAPK signaling and possess complex autoinhibitory mechanisms that are impaired by mutations.
3. Similarly, reduced GTPase activity or increased guanine nucleotide release underlies the aberrant signal flow through the MAPK cascades promoted by most *KRAS* mutations.

3. Mutation in *SHOC2*
   1. Encodes a cytoplasmic scaffold positively controlling RAF1 activation.
   2. Has been discovered to cause a closely related phenotype previously termed Noonan-like syndrome with loose anagen hair.
   3. This mutation promotes aberrantly acquired *N*-myristoylation of the protein, resulting in its constitutive targeting to the plasma membrane and dysregulated function.
4. *PTPN11*, *BRAF*, and *RAF1* mutations
   1. Also account for approximately 95% of LEOPARD syndrome.
      1. A condition which resembles NS phenotypically
      2. Characterized by multiple lentigines dispersed throughout the body, café au lait spots, and a higher prevalence of electrocardiographic conduction abnormalities, obstructive cardiomyopathy, and sensorineural hearing deficits
   2. These recent discoveries demonstrate that the substantial phenotypic variation characterizing NS and related conditions can be ascribed, in part, to the gene mutated and even the specific molecular lesion involved.

Clinical Features

1. Clinical features (Collins and Turner 1973; Mendez and Opitz 1985; Allanson 1987; Ranke et al. 1988; Noonan 1994)
   1. Growth
      1. Average length at birth, 47 cm
      2. Generally normal birth weight but can be high due to subcutaneous edema
      3. Prepubertal growth parallel to the third centile (40%) with a relatively normal growth velocity
      4. Pubertal growth spurt often reduced or absent
   2. Craniofacial features: change with age (Allanson et al. 1985)
   3. Ocular abnormalities (observed up to 95% of cases)
      1. Strabismus
      2. Refractive errors
      3. Amblyopia
      4. Nystagmus
      5. Anterior segment and fundal changes
   4. Congenital heart defects (two thirds of cases)
      1. Pulmonary valvular stenosis (50%)
      2. Hypertrophic cardiomyopathy (20–30%): may be present at birth or appears in infancy or childhood
      3. Atrial septal defect (10%)
      4. Asymmetrical septal hypertrophy (10%)
      5. Ventricular septal defect (5%)
      6. Persistent ductus arteriosus (3%)
      7. Other cardiac defects
         1. Pulmonary artery branch stenosis
         2. Mitral valve prolapse
         3. Ebstein anomaly
         4. Single ventricles
   5. Genitourinary abnormalities
      1. Males: ranging from normal prepubertal virilization to delayed fertility and inadequate secondary sexual development associated with deficient spermatogenesis secondary to earlier cryptorchidism (60%)
      2. Females: normal or delayed puberty but fertile in majority of cases
   6. Skeletal abnormalities
      1. Characteristic pectus deformity
      2. Common features
         1. Cubitus valgus (50%)
         2. Hand anomalies including clinobrachydactyly and blunt fingertips (30%)

3. Vertebral and sternal anomalies (25%)
4. Dental malocclusion (35%)

7. Ectodermal abnormalities
   1. Various skin manifestations
      1. Café au lait patches (10%)
      2. Pigmented nevi (25%)
      3. Lentigines (2%)
      4. Keratosis pilaris atrophicans faciei
   2. Several instances of neurofibromatosis and the Noonan phenotype documented
8. Bleeding diathesis (Witt et al. 1988; Artoni et al. 2014)
   1. Twenty percent of patients with the Noonan syndrome had a history of severe bleeding diathesis and another 20% of moderate bleeding diathesis.
   2. Bleeding episodes occurred not only during surgical interventions but also spontaneously.
9. Lymphatic abnormalities (Witt et al. 1987; Ogata et al. 2003)
   1. Congenital dysplasia, hypoplasia, or aplasia of lymphatic channels (20%)
   2. General lymphedema
   3. Peripheral lymphedema
   4. Pulmonary lymphangiectasia
   5. Intestinal lymphangiectasia
   6. Hydrops fetalis
   7. Cystic hygroma
10. Rare associated features
    1. Autoimmune thyroiditis
    2. Pheochromocytoma
    3. Ganglioneuroma
    4. Malignant schwannomas
    5. Congenital contractures
    6. Chiari malformation with syringomyelia
    7. Skin and oral xanthomas
    8. Odontogenic keratosis
11. Behavioral and developmental abnormalities
    1. Failure to thrive in infancy (40%)
    2. Motor developmental delay (26%)
    3. Learning disability with specific visual-constructional problems and verbal-performance discrepancy (15%)
    4. Language delay (20%) secondary to perceptual motor disabilities, mild hearing loss (12%), or articulation abnormalities (72%)
    5. Intelligence
       1. IQ: 64–127 with a median of 102
       2. IQ: ten points below that of unaffected family members
       3. Mild mental retardation reported in up to 35% of cases

2. Changing phenotype with age (Allanson 1987)
   1. Newborn period
      1. Marked edema
         1. Contributing to a normal-to-high birth weight
         2. Rapid reduction after birth simulating failure to thrive
      2. Excess nuchal skin
      3. Sloping and broad forehead
      4. Apparent ocular hypertelorism
      5. Downslanting palpebral fissures
      6. A deep philtrum
      7. Mild retrognathia
      8. Posteriorly angulated ears with a thick helix
   2. Neonatal period to 2 years
      1. Head
         1. Relatively large appearance
         2. Flat malar eminence
         3. Bitemporal narrowing accentuated by lateral supraorbital fullness
         4. "Coarse" and occasional asymmetric facial appearance
      2. Eyes
         1. Prominent and round
         2. Ocular hypertelorism
         3. Telecanthus
         4. Lessening downslanting of the palpebral fissures
         5. Occasional strabismus
         6. Thick eyelid hooding the upper iris
         7. Sharp arched eyebrows
      3. Nose
         1. Depressed nasal root
         2. Low nasal bridge
         3. Wide nasal base
         4. Bulbous nasal tip
         5. Anteverted nares

6. Short columella
4. Deep philtrum
5. Arched upper lip with high and wide peaks of the vermilion border
6. Ears
   1. Posteriorly rotated
   2. Occasionally small or square
7. Neck
   1. Short
   2. Less excess skin than in the newborn period
   3. A low posterior hairline
8. Often failure to thrive and hypotonia
9. Occasional hepatosplenomegaly, swarthy skin, and wispy hair
10. 12–18 months of age
    1. Changing body shape with stocky and square upper body
    2. Occasional presence of an umbilical hernia or diastasis recti
    3. The limbs becoming relatively longer and thinner secondary to resolving edema
    4. Blunt fingertips

3. Childhood
   1. Face
      1. Appearance remaining coarse
      2. Becoming more triangular as the chin lengthens
      3. Forehead becoming lower and may be bossed
      4. Flatter malar eminence
   2. Eyes
      1. Less prominent eyes with reduced epicanthus
      2. Increasing ptosis
      3. Increasing lateral supraorbital fullness
      4. Higher nasal root and bridge
   3. Full lips with sublabial protrusion
   4. Neck
      1. Appearing longer
      2. Accentuating webbing
      3. Prominent trapezius
   5. Thorax
      1. Broad
      2. An inverted pyramid shape
      3. Increasing pectus
      4. Upper chest length that increases with relatively low-set nipples and axillary webbing which persist to adulthood
   6. Scapula
      1. Round shape
      2. Winged scapulae
   7. Limbs
      1. Thin
      2. Marked cubitus valgus
      3. Flat feet
   8. Skin
      1. Lentigines
      2. Nevi
      3. Café au lait spots
   9. Often markedly curly or woolly hair
4. Teenage and young adulthood
   1. Facial shape becoming increasingly triangular
   2. Facial features becoming sharper
   3. Less prominent eyes with occasional ptosis
   4. Nose
      1. Thinner
      2. A pinched root
      3. Higher bridge
      4. Wide base
      5. Pointed tip
      6. A longer columella
   5. Eyebrows becoming sparse
5. Older adulthood
   1. Prominent nasolabial folds
   2. Higher anterior hairline
   3. Occasional sloping forehead
   4. Transparent wrinkled skin
6. Prominent abnormalities at all ages
   1. Striking blue or blue-green irides
   2. Increased number of fingertip whorls
   3. Posteriorly angulated ears with a thick helix
   4. Characteristic pectus deformity
      1. Pectus carinatum superiorly
      2. Pectus excavatum inferiorly

3. Disorders clinically related to Noonan syndrome (Jorge et al. 2009; Tartaglia et al. 2010)
   1. LEOPARD syndrome (Please see the chapter of “LEOPARD syndrome”)
   2. Cardiofaciocutaneous syndrome

1. A rare sporadic multiple congenital anomalies/mental retardation syndrome characterized by:
    1. Failure to thrive
    2. Severe feeding problems
    3. Developmental delay
    4. Short stature
    5. Distinguished face
    6. Abnormalities of the skin, gastrointestinal tract, and CNS
    7. Cardiac defects (pulmonary stenosis, hypertrophic cardiomyopathy)
2. Genetically heterogeneous, with mutations in the *KRAS*, *BRAF*, *MEK1*, and *MEK2* genes occurring in approximately 60–90% of affected individuals

3. Costello syndrome
    1. Clinical features
        1. Prenatal overgrowth
        2. Followed by postnatal feeding difficulties and severe failure to thrive
        3. Distinctive "coarse" facial features
        4. Mental retardation
        5. Short stature
        6. Cardiac defects (pulmonary stenosis, hypertrophic cardiomyopathy)
        7. Musculoskeletal (joint laxity) and skin abnormalities
    2. Caused by germline missense mutations in the *HRAS* proto-oncogene
    3. Other causative genes: *KRAS*, *BRAF*, and *MEK1*

4. Neurofibromatosis-Noonan syndrome (NFNS) (Abuelo and Meryash 1988)
    1. Most individuals with NFNS harbor an *NF1* mutation and that a single mutation can be sufficient to engender the trait.
    2. Double heterozygosity for *NF1* and *PTPN11* mutations rarely causes NFNS, and it is not yet clear how frequently mutations in other NS disease genes co-occur with *NF1* defects in the disorder.
    3. These findings support the view that NFNS is genetically distinct from NS and emphasize the extreme phenotypic variability associated with lesions in the *NF1* gene.
    4. The identification of specific *NF1* alleles recurring in NFNS, the evidence that these alleles cosegregate with the condition in families, and the observation of a peculiar mutational spectrum strongly suggest that the term "NFNS" does characterize a phenotypic variant of NF1, which manifests with a lower incidence of plexiform neurofibromas, skeletal anomalies, and internal tumors, in association with hypertelorism, ptosis, low-set ears, and congenital heart defects.
    5. Some of the mutations identified in patients with NFNS have also been reported in NF1 without any feature suggestive of NS.

5. Legius syndrome
    1. Previously known as neurofibromatosis type 1-like syndrome.
    2. An autosomal dominant disorder.
    3. Clinical features.
        1. Multiple axillary freckling
        2. Café au lait spots
        3. Macrocephaly
        4. NS-like facial dysmorphism in some individuals
    4. Caused by loss-of-function mutations of the *SPRED1* gene, which encodes a negative modulator of RAS-MAPK signaling (Brems et al. 2007).
    5. *SPRED1* mutational analysis of sporadic or familial cases with a diagnosis of NF1 or with a phenotype suggestive of the disorder indicates that mutations account for approximately 0.5–1% of *NF1* mutation-negative cases.

Diagnostic Investigations

1. Growth curves for height for males and females with Noonan syndrome now available (Witt et al. 1986; Noonan et al. 2003)
2. Echocardiography for previously described congenital heart defects (Burch et al. 1993)
3. Electrocardiography

1. A wide QRS complex
2. Left axis deviation
3. Giant Q wave
4. A negative pattern in the left precordial leads

4. Radiography: pectus deformity
5. Renal ultrasound for renal anomalies
6. Coagulation studies, mainly platelet function abnormalities in 90% of patients (Artoni et al. 2014)
7. Chromosome analysis: normal karyotype
8. Molecular genetic testing available clinically
   1. Mutations in the gene *PTPN11* identified in 50% of patients (familial and sporadic cases)
   2. Germline mutations
      1. Detected in 59% of patients with familial Noonan syndrome
      2. Detected in 37% of individuals with sporadic Noonan syndrome
   3. Target next-generation sequencing (NGS): Molecular testing of RASopathies by targeted NGS could allow an early and accurate diagnosis of Noonan syndrome and related disorders, enabling a prompt diagnosis especially for those patients with mild, nonspecific, or atypical features, in whom the detection of the causative mutation usually requires prolonged diagnostic timings when using standard routine. This approach strongly improved genetic counseling and clinical management (Lepri et al. 2014).

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Fifty percentage if a parent is affected
      2. If both parents had only possible or no signs of Noonan syndrome, an empiric recurrence risk is 5% subsequent to the birth of the first child with Noonan syndrome (Sharland et al. 1993)
   2. Patient's offspring: 50% affected
2. Prenatal diagnosis (Allanson and Roberts 2011)
   1. Ultrasonography (Achiron et al. 2000) for pregnancies at 50% risk: no definitive ultrasonographic diagnostic criteria early in gestation.
      1. Septated cystic hygroma
      2. Scalp edema
      3. Polyhydramnios
      4. Facial features
         1. Posteriorly angulated, apparently low-set ears
         2. Depressed nasal bridge
      5. Pleural and pericardial effusions
      6. Cardiac defects
         1. Pulmonic stenosis
         2. Hypertrophic cardiomyopathy
      7. Ascites
      8. Hydrops fetalis
   2. Molecular genetic testing of fetal DNA extracted from amniocentesis or CVS for *PTPN11* mutations. The disease-causing allele of an affected family member must be identified before prenatal testing can be performed.
   3. Preimplantation genetic diagnosis: may be available for families in which the disease-causing mutation has been identified.
3. Management (Allanson 2001)
   1. Plotting of growth parameters on growth charts for Noonan syndrome.
   2. Ophthalmological care.
   3. Cardiac management of congenital heart defects and hypertrophic cardiomyopathy.
   4. Hearing evaluation and management.
   5. Physical and occupational therapies for hypotonia.
   6. Speech therapy for articulation deficiencies.
   7. Infant stimulation program for developmental delay.
   8. Multidisciplinary developmental intervention program.
   9. Hearing aids for sensorineural hearing loss.
   10. In case of bleeding episodes or surgical interventions in patients with platelet function abnormalities, recommend administration of vitamin K in patients with low levels of FVII and prolonged PT, general hemostatic agents such as tranexamic acid and desmopressin,

and, in the most severe cases, platelet transfusion (Artoni et al. 2014).

11. Orthopedic management of musculoskeletal abnormalities.
12. Growth hormone treatment of short stature (Kirk et al. 2001): final height not improved substantially in most patients. When long-term GH therapy is intended to promote growth in children with NS, it has to be considered in relation to the genotype, the effective promotion of growth, and the potentially increased tumor risk (Binder 2009).
13. Successful pregnancy possible in women with Noonan syndrome.

Fig. 1 Two boys (**a**–**d**; **e**–**f**) with Noonan syndrome showing various features: downslanting palpebral fissures, hypertelorism, short and webbed neck with a low posterior hairline, pectus, and cubitus valgus

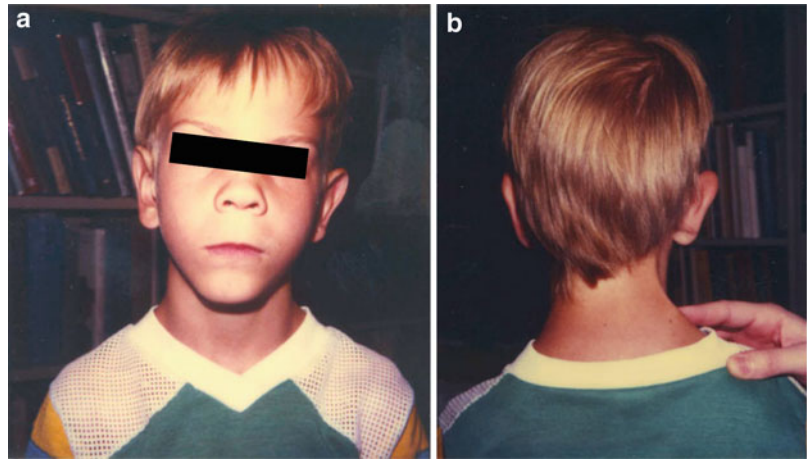

Fig. 2 (**a**, **b**) A boy with Noonan syndrome showing characteristic facial features and webbed neck

Fig. 3 Familial Noonan syndrome in a mother and a daughter

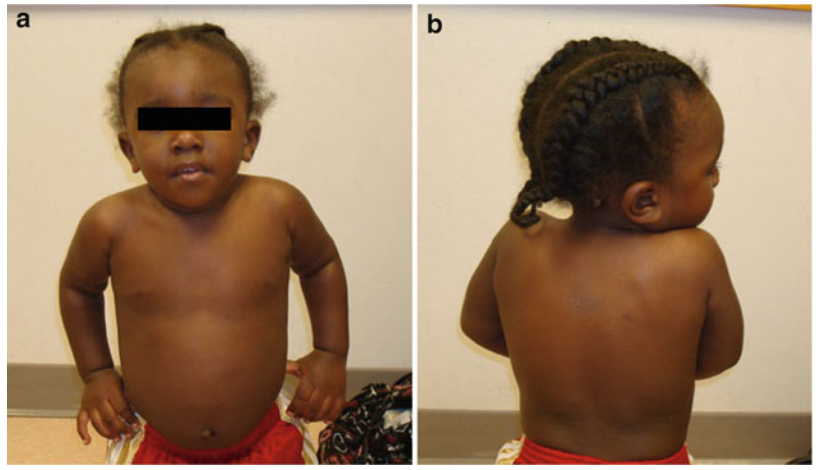

Fig. 4 (**a**, **b**) A 21-month-old boy was evaluated for possible Noonan syndrome because of antimongoloid slant of the palpebral fissures, depressed nasal bridge, slightly low-set ears, short neck, a shield-like chest with distally displaced nipples, and pulmonary stenosis. PTPN11 select exon analysis revealed a heterozygous G > A nucleotide substitution in exon 3, resulting in the replacement of a glycine codon (GGT) with a serine codon (AGT) at amino acid position 60 of the tyrosine phosphatase SHP-2 protein (p.Gly60Ser or G60S) (c.178G > A)

Fig. 5 A 12-year-old Caucasian female was evaluated for short stature and failure to thrive as an infant, a repaired AV canal, repaired intestinal malrotation, developmental delay, and dysmorphic features. Physical examination revealed small for her age (weight 27.3 kg, 0%tile, length 141.5 cm, 1%tile, head circumference 49 cm, <2%tile) with mild webbing of the neck, a broad forehead, and downslanting palpebral fissures. Her internipple distance is 17.5 (~75% tile) and appears to be wide. Chromosome microarray analysis showed normal female microarray profile. Molecular genetic analysis showed heterozygous for the T73I mutation in the *PTPN11* gene, consistent with the diagnosis of a disorder in the Noonan syndrome spectrum (Courtesy of Dr. Susonne Ursin)

Oblique Facial Cleft Syndrome

Contents

Oblique facial clefts are extremely rare congenital anomalies occurring in about 1/100 to 12/1,000 of facial clefts (Rintala et al. 1980).

Synonyms and Related Disorders

Mandibular process clefts; Naso-ocular clefts; Oculomaxillofacial dysplasia with oblique facial cleft; Oroaural clefts; Oro-ocular clefts; Tessier clefts

Genetics/Basic Defects

1. Genetic heterogeneity (Richieri-Costa and Gorlin 1994).
    1. Sporadic in most cases
    2. A disruptive event resulting from amniotic band rupture sequence considered as a main etiological agent (Coady et al. 1998; Kara and Ocsel 2001)
        1. Twenty-six percent of nonsyndromal craniofacial cleft displays congenital limb anomalies.
        2. Thirteen percent of nonsyndromal craniofacial cleft shows evidence of limb ring constrictions.
    3. Occasional association with malformation syndrome (e.g., Fryns anophthalmia-microphthalmia-oblique clefting syndrome)
    4. Rare autosomal recessive inheritance
2. Classification of facial clefts: A universally accepted classification scheme that fully encompasses, accurately describes, and integrates all the various types of orofacial and craniofacial clefts does not exist (Stellzig et al. 1997; Eppley et al. 2005).
    1. The American Association for Cleft Palate Rehabilitation (1962) divided facial clefts into four major groups according to the anatomic location:
        1. Mandibular process clefts
        2. Naso-ocular clefts
        3. Oro-ocular clefts
        4. Oroaural clefts
    2. Boo-Chai (1990) proposed a subdivision of the oro-ocular group into
        1. Medial (Type I)
        2. Lateral (Type II)
    3. Tessier (1976) presented an anatomic classification of the facial clefts by using numbers 0–14 anticlockwise to point the location of the cleft when the orbit is used as the central point.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_181

1. Commonly used by surgeons because it is purely descriptive and makes no pretense at causation and developmental relationships.
2. Proven validity in analyzing complex facial deformities.
3. Careful examination in confirming the diagnosis and in managing the patients.
4. The Tessier classification includes numbered clefts from 0 (midline cleft of the lip and nose) to 30 (clefting of lower face or a mandibular cleft).
5. Tessier cleft numbers 4, 5, and 6 are oro-ocular clefts.
6. Tessier cleft numbers 7, 8, and 9 are lateral facial or commissural clefts.
7. The oblique clefts: indicated by Tessier cleft numbers 3 through 5 and 9 (Darzi and Chowdri 1993; Eppley et al. 2005).
8. Tessier number 3 cleft (oral-nasal-ocular cleft): (da Silver Freitas et al. 2010)
    1. A paranasalmedial orbitomaxillary cleft running across the lacrimal segment of the lower eyelid and over the lacrimal groove.
    2. The frontal process of the maxilla may be totally absent, as well as the medial wall of the maxillary sinus. It passes around the nasal ala in the nasolabial groove to finally cross the lip and the alveolus like a "harelip."
    3. It represents one of the most difficult and challenging malformations to correct for the reconstructive surgeon.

3. Classification of orofacial clefts (Tolarová and Cervenka 1998)
    1. Isolated anomaly (61.63%)
        1. Cleft lip
        2. Cleft lip and palate
        3. Cleft palate
        4. Atypical facial cleft
    2. Sequence (3.9%)
        1. Robin sequence
        2. Holoprosencephaly sequence
        3. Frontonasal dysplasia sequence
        4. Amyoplasia congenital disruption sequence
    3. Chromosome aberrations (8.79%)
        1. Trisomy 21 syndrome
        2. Trisomy 13 syndrome
        3. Trisomy 18 syndrome
        4. Other trisomies
        5. Other chromosomal aberrations
    4. Monogenic syndromes (6.02%)
        1. Autosomal dominant
            1. Stickler syndrome
            2. Craniosynostosis syndromes
            3. Van der Woude syndrome
            4. Others
        2. Autosomal recessive
            1. Smith-Lemli-Opitz syndrome
            2. Meckel syndrome
            3. Others
        3. X-linked dominant
    5. Known environmental cause (0.2%)
        1. Fetal alcohol syndrome
        2. Dilantin embryopathy
        3. Congenital syphilis
    6. Associations (0.79%)
        1. CHARGE association
        2. VATER association
    7. Multiple congenital anomalies (MCA) (18.5%)
        1. MCA of malformation origin
        2. MCA of deformation origin
        3. MCA of malformation and malformation origin
        4. MCA of other combinations
    8. Conjoined twins
4. Oblique clefts (Kubaček and Pěnkava 1974)
    1. Considered as late or secondary defects resulting from outgrowth of one or more bone centers in membranous bones
    2. Including certain types of Tessier classification (1976): oblique clefts corresponding to the numbers 3–6 distally or "southward" and 8–11 proximally or "northward" from the orbit in the extreme forms (Rintala et al. 1980)
    3. Arbitrary classification in some instances
    4. Presence of intermediate forms of facial clefts

Clinical Features

1. Clinical variability
2. Oblique facial clefts (Boo-Chai 1970; Key 1973)
   1. Naso-ocular clefts
      1. Whole stretch from the lip through the nose to the eyelid and orbit
      2. Nasolacrimal duct always involved
      3. Defective and upwardly dislocated ala nasi
   2. Oro-ocular clefts
      1. Type I (medial): cleft medial to infraorbital region of the nasolabial groove to end in the inner canthus or the lower eyelid
      2. Type II (lateral): cleft extending from the angle of the mouth upward to the orbit ending in the lateral canthus or in a coloboma in the midportion of the lower eyelid
      3. Twice as frequent as the naso-ocular types
   3. Bilateral clefts in 20–35% of cases (Sakurai et al. 1966; Sano et al. 1983)
   4. Presence of complete or incomplete forms
   5. Possible involvement of palate and extending into the temporal region
3. Concordant clinical signs
   1. Short stature
   2. Sparse eyebrows
   3. Sparse eyelashes
   4. Lower lid coloboma
   5. Abnormal nose (Schweckendiek 1974)
   6. Involvement of the nasolacrimal duct
   7. Malar hypoplasia
4. Other variable clinical signs
   1. Mental retardation
   2. Anophthalmia/microphthalmia (Schlenker et al. 1979; Tsu et al. 1991; Warburg et al. 1997)
   3. Hemimelia (possibly resulting from in utero vascular accident in some cases)
5. Associated anomalies
   1. Amniotic bands (Mayou and Fenton 1981; Eppley et al. 1998)
      1. Amniotic band affecting premaxillary-nasal-ocular areas of the midface producing oblique tissue disruptions
      2. Intrauterine amputation
      3. Constriction rings
      4. Distal lymphedema
      5. Distal pseudosyndactyly
      6. Remnant of amniotic band still attached to the lesion
   2. CNS abnormalities
      1. Encephalocele
      2. Hydrocephaly
   3. Aplasia cutis congenita
   4. Talipes equinovarus

Diagnostic Investigations

1. Radiography for craniofacial anomalies
2. Three-dimensional CT reconstruction scan for visualization of the extent and location of the cleft (David et al. 1989)
3. MRI of the brain for CNS anomalies
4. Blood for chromosome analysis to rule out chromosome etiology (Dasouki et al. 1988)

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Recurrence risk not increased since most cases are sporadic, especially in a case where amniotic band rupture sequence is considered to be the etiological factor
      2. Recurrence risk possibly increased in occasional cases of autosomal recessive inheritance
   2. Patient's offspring: not increased
2. Prenatal diagnosis: possible by ultrasonographic documenting oblique facial cleft associated with other commonly associated anomalies (CNS anomaly, anophthalmia, and findings of amniotic band disruption sequence)

3. Management
   1. Early orthopedic treatment
      1. To achieve both the proper alignment of the maxillary segments and a reduction of cleft width in cases of unilateral cleft lip, alveolus, and palate
      2. Presurgical orthopedic devices to approximate the distorted segments and to facilitate lip closure in the treatment of maxillary clefts
   2. Surgical repair of facial cleft (Chiong et al. 1981)
      1. General principle
         1. Accurate approximation of each tissue layer
         2. Meticulous layered closure to prevent loss of anatomical continuity and a depressed scar along the site of the operative procedure
         3. Multiple Z-plasty when the repair crosses lines of minimal skin tension or when there is loss of length
      2. Closure of the cleft and reconstruction of the underlying bony deficiencies at a very early age
      3. Followed by subsequent correction of orbital hypertelorism between the ages of 2 and 5 years
      4. Followed by orthognathic correction of maxillary and mandibular deformities in the teens
   3. Management of Tessier number 3 clefts
      1. Eyelid, nose, and upper lip deformities should be treated in sequential stages, positioning the medial canthus, ala, and upper lip, using the contralateral side as the reference (da Silver Freitas et al. 2010).
      2. Tessier number 3 clefts can be associated with multiple other craniofacial anomalies making reconstruction challenging. Soft tissue and bony reconstruction must be considered separately, and a variety of tools may be employed to accomplish each goal (Allam et al. 2014).
   4. Multidisciplinary approach to early intervention

Fig. 1 (**a**, **b**) An infant with oblique facial cleft syndrome (at birth and postoperative) showing unilateral oro-ocular cleft with cleft beginning at the angle of the mouth and ending in a coloboma of the lower eyelid and corneal opacity

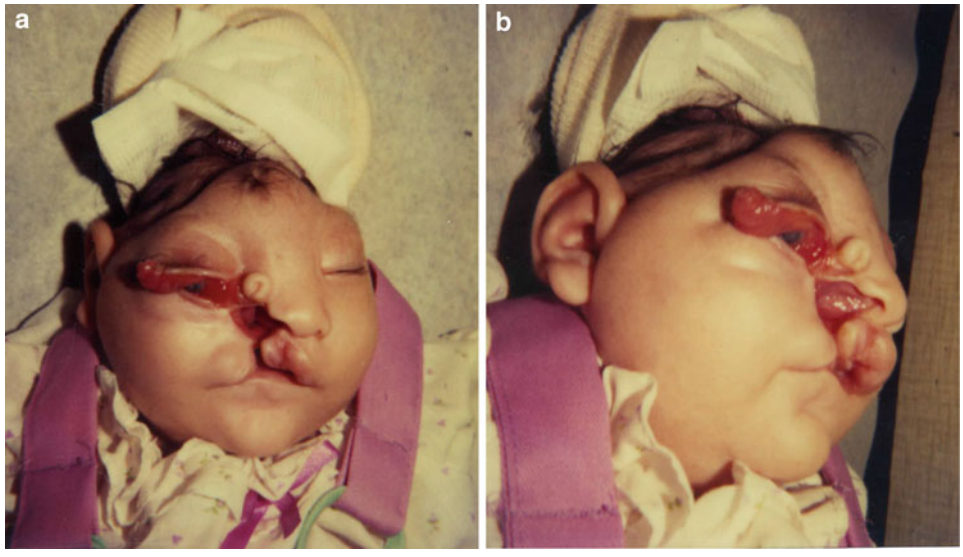

Fig. 2 (**a**, **b**) An infant with oblique facial cleft syndrome showing extensive unilateral oro-naso-ocular cleft and encephalocele

Fig. 3 (**a**–**c**) A newborn with oblique facial cleft syndrome associated with amniotic band syndrome and cutis aplasia congenita of the scalp showing bilateral frontonasal clefts, scalp defect, pseudotail, hypertelorism, anophthalmia, clubhands, digital amputation, constriction bands, and an amniotic band still attached to the left finger. The infant also had hydrocephalus, atrial septal defect, and clubfoot

Fig. 4 (**a**–**d**) A 4-year-and-11-month-old boy was seen for Tessier complex orofacial cleft. He was born without right eyeball, absent right nostril, and large oblique orofacial cleft. The photographs show before and after operations

Fig. 5 (**a**–**d**) An infant with Tessier number 7 cleft with a 3D reconstruction CT

Fig. 6 (**a**, **b**) This 6-month-old boy was evaluated for oblique facial cleft syndrome. He has clefting of the left mouth angle contiguous with a long linear depression/scar connecting to left preauricular tag, which was surgically removed

Oligohydramnios Sequence

Contents

Oligohydramnios is defined as deficiency of amniotic fluid, i.e., decrease in the volume of amniotic fluid. It may result from decreased urinary production or excretion or fluid loss from rupture of membranes. The incidence is estimated to be 0.5–8% of all pregnancies.

Synonyms and Related Disorders

Anhydramnios; Chronic abruption–oligohydramnios sequence; Oligohydramnios; Potter sequence; Potter syndrome; Renal agenesis; Renal tubular dysgenesis

Genetics/Basic Defects

1. Associated maternal conditions (Peipert and Donnenfeld 1991)
    1. Uteroplacental insufficiency
        1. Antiphospholipid antibodies
        2. Chronic hypertension
        3. Collagen vascular diseases
        4. Diabetic vasculopathy
        5. Maternal hypovolemia
        6. Preeclampsia/pregnancy-induced hypertension
    2. Drugs
        1. Prostaglandin synthetase inhibitors
        2. Angiotensin-converting enzyme inhibitors
    3. Placental
        1. Abruption
        2. Twin-to-twin transfusion
    4. Maternal hydration status
2. Associated fetal conditions
    1. Renal malformations (Newbould and Barson 1994)
        1. Bilateral agenesis (34%)
        2. Bilateral cystic dysplasia (34%)
        3. Unilateral cystic dysplasia/agenesis (9%)
        4. Meckel syndrome
        5. Infantile polycystic kidneys
        6. Infantile nephronophthisis can present in utero with oligohydramnios sequence (limb contractures, pulmonary hypoplasia, and facial dysmorphisms) or postnatally with renal manifestations that progress to end-stage renal disease before age 3 years (Stokman et al. 2016)
        7. Renal tubular dysgenesis (Lacoste et al. 2006)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_182

1. Probably an under recognized disorder.
2. An autosomal recessive disorder.
3. Should be considered for fetuses who present early oligohydramnios, normal or nearly normal kidneys on ultrasound examination, and skull ossification defects.
4. Abnormal renal renin expression confirms the diagnosis and may point toward the gene involved in cases with *REN* null mutations (Gribouval et al. 2012).

8. Posterior urethral valves.
9. Renal hypoplasia.
10. Horseshoe kidney.

2. Other congenital anomalies
   1. Amniotic band syndrome
   2. Branchio-oto-renal syndrome
   3. Cystic hygroma
   4. Encephalocele
   5. Endocardial fibroelastosis
   6. Holoprosencephaly
   7. Hypophosphatasia (homozygous dominant form)
   8. MURCS association
   9. Sacral agenesis (caudal regression)
   10. Sirenomelia
   11. VATER association
   12. Others
3. Chromosome abnormalities
   1. Trisomy 13
   2. Trisomy 18
4. Twin-to-twin transfusion syndrome ("stuck twin syndrome") (Mahony et al. 1990; Bromley et al. 1992)
   1. A complication of monochorionic diamniotic twinning
   2. One twin stucked because of severe oligohydramnios and compressed by the significant polyhydramnios associated with its co-twin
   3. Perinatal mortality associated with severe oligohydramnios/polyhydramnios sequence in a monochorionic twin pregnancy before 28 weeks: 70–100%
5. Intrauterine growth retardation
6. Intrauterine fetal demise
7. Postmaturity possibly caused by a decline in placental function
8. Premature rupture of membranes: the most common cause of oligohydramnios
   1. Preterm (Spong 2001): Preterm premature rupture of the fetal membranes complicated by oligohydramnios may have significant impact and sequelae on pregnancy outcome.
   2. Prolonged (Rib et al. 1993).
      1. Major maternal morbidity: chorioamnionitis.
      2. The overall perinatal survival was 47%, but in infants exceeding 24 weeks' gestation or 500-g weight, the survival increased to 75%.
      3. No significant limb abnormalities, facial anomalies, growth retardation, or pulmonary hypoplasia occurred in the study population.
      4. Long-term follow-up demonstrated that 28% of infants exhibited major neurologic or developmental deficits.
      5. Lung hypoplasia: diagnosed after rupture of the membranes of $\geq$7 days with onset before 29 weeks of gestation (Rotschild et al. 1990). Gestational age at onset of rupture of the membranes is the best single predictor of occurrence of pulmonary hypoplasia (Vergani et al. 1994).
9. Idiopathic

3. Dynamic of amniotic fluid (Sherer 2002)
   1. Presence of amniotic fluid throughout gestation
      1. Enables normal development of the fetal respiratory, gastrointestinal, and urinary tracts and musculoskeletal system
      2. Continued fetal growth in a nonrestricted, sterile, and thermally controlled environment
      3. Amniotic fluid volume is gestational-age dependent
   2. Factors contributing to the formation and removal of amniotic fluid

1. Formation
    1. Fetal urination
    2. Tracheal secretions
    3. Intramembranous pathway including transfers between amniotic fluid and fetal blood perfusing the fetal surface of the placenta, fetal skin, and umbilical cord
    4. Transmembranous pathway involving direct exchange across the fetal membranes between amniotic fluid and maternal blood within the uterus
2. Removal: fetal swallowing
3. Significance of oligohydramnios
    1. A sign of potential fetal compromise
    2. Associated with an increased incidence of adverse perinatal morbidity and mortality, especially in conjunction with the following:
        1. Structural fetal anomalies
        2. Fetal growth restriction
        3. Postdates pregnancies
        4. Maternal disease

Clinical Features

1. Consequences of severe fetal constraints secondary to early and prolonged oligohydramnios.
    1. Potter facies (Potter 1946): associated with renal agenesis and any other cause of severe oligohydramnios
        1. Hypertelorism
        2. Deep crease under the eyes
        3. Epicanthal folds
        4. Flat nose
        5. Receding chin
        6. Low-set, aberrantly folded ears
    2. Lung hypoplasia
        1. Respiratory insufficiency
        2. Death
    3. Limb positional anomalies
        1. Arthrogryposis
        2. Spade-like hands
        3. Talipes equinovarus
    4. Genitourinary abnormalities (Mandel et al. 1992)
    5. Intrauterine growth retardation: one of the most common complications associated with sever oligohydramnios
2. Thirty cases of arthrogryposis associated with long-standing oligohydramnios were identified among 2,500 cases of arthrogryposis (1.2%) and were reviewed for clinical features and natural history (Hall 2014).
    1. None had renal agenesis or renal disease.
    2. Twenty-two had a history of known rupture of membranes.
    3. Only 50% had pulmonary hypoplasia at birth and only two died (7%).
    4. Sixty percent (18/30) seemed to have their multiple congenital contractures primarily on the basis of compression related to the long-standing oligohydramnios and responded well to physical therapy.
    5. On average they did not have intrauterine growth restriction.
    6. "Potter" facies and remarkable skin changes were present in all.
    7. An excess of males was observed in spite of the lack of genitourinary anomalies.
3. Presence of fetal abnormalities in cases associated with severe oligohydramnios (Shipp et al. 1996).
    1. 50.7% in the second trimester
    2. 22.1% in the third trimester
    3. Rate of aneuploidy: at least 4.4%
4. Correlation of the rate of survivors and the gestation when the severe oligohydramnios is diagnosed (Shipp et al. 1996).
    1. 10.2% survivors in the second trimester
    2. 85.6% survivors in the third trimester
5. First and early-second trimester oligohydramnios: a predictor of poor fetal outcome (Barss et al. 1984; Mercer and Brown 1986), except in iatrogenic oligohydramnios post chorionic villus biopsy (Bronshtein and Blumenfeld 1991).
6. The prognosis of early onset renal oligohydramnios is poor. Predictive determinants of survival are (Grijseels et al. 2011).
    1. Gestational age at diagnosis

2. Nature of renal anomaly (hydronephrosis vs other)
3. Presence of associated anomalies

7. 88% of the fetuses with severe oligohydramnios or anhydramnios had lethal outcomes, compared with 11% in the mild/moderate group (Moore et al. 1989).
8. The incidence of adverse outcomes was approximately 15% in preterm small for gestational age (SGA) infants. SGA infants born with oligohydramnios may be at increased risk for cerebral palsy or death (14.7%) compared to those with normal amniotic volume (Sasahara et al. 2016).
9. Renal oligo- and anhydramnios: both renal and pulmonary dysfunction lead to a poor outcome in those patients (Klaassen et al. 2007; Kemper and Mueller-Wiefel 2007; Grijseels et al. 2011; Spiro et al. 2015).
10. Chronic abruption–oligohydramnios sequence (Kobayashi et al. 2014): a clinical condition with lasting vaginal bleeding and oligohydramnios because of chronic placental abruption, which seems to cause preterm labor and neonatal chronic lung disease.

Diagnostic Investigations

1. Ultrasonography
   1. Ultrasonographic modalities to assess oligohydramnios
      1. Single deepest vertical pocket (range, <0.5–<3 cm)
      2. Two-diameter pocket (vertical X horizontal <15 cm)
      3. Amniotic fluid index (AFI) (range, <5–<8 cm)
   2. Defines oligohydramnios
      1. Amniotic fluid index less than 7 cm
      2. Absence of a fluid pocket of 2–3 cm in depth
   3. Variable effects of oligohydramnios on the biparietal diameter and the cephalic index: rapid and marked effect that oligohydramnios can have on the shape of the fetal head and cephalic index can be normal despite an abnormal cranial configuration (Hill et al. 1984)
   4. Assesses fetal growth
   5. Pulmonary hypoplasia (Laudy and Wladimiroff 2000)
   6. Visualizes fetal kidneys, collecting system, and bladder
   7. Improves fetal structures by amnioinfusion
2. Role of diagnostic and therapeutic transabdominal amnioinfusion in oligohydramnios (Fisk et al. 1991)
3. Chromosome analysis for aneuploidy
4. Autopsy for verification of etiology

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: depends on etiology
   2. Patient's offspring: depends on etiology
2. Prenatal diagnosis
   1. Ultrasonography
   2. Amniocentesis
3. Management
   1. Maternal bed rest.
   2. Maternal hydration.
   3. Serial amnioinfusions to prevent pulmonary hypoplasia (complications including preterm labor, amnionitis, and perinatal deaths).
   4. The risks of maintaining the fetus in utero must be weighed against the morbidities and mortalities of premature delivery.
   5. Bilateral renal disease with oligohydramnios indicates significant global fetal renal dysfunction and is a risk factor for the development of pulmonary hypoplasia. This is in striking contrast to the dramatic progress that has been made in neonatal intensive care including pulmonary management.
   6. Recent advances in treatment of infants and children with chronic kidney disease and end-stage renal disease have improved prognosis and also for infants with renal insufficiency considerably (Klaassen et al. 2007).

7. Therapeutic amnioinfusion for chronic abruption–oligohydramnios sequence: a possible prevention of the infant respiratory disease (Morita et al. 2014).
8. In term or post-term pregnancies, isolated oligohydramnios is associated with increased risk of obstetric interventions, but outcomes are similar to those of pregnancies with normal AF (Rossi and Prefumo 2013).

Omphalocele

Contents

Omphalocele is a congenital herniation of viscera into the base of the umbilical cord, covered by a membranous sac. The incidence of omphalocele is approximately 1 in 4000 births (Baird and MacDonald 1981).

Synonyms and Related Disorders

Gastroschisis; OEIS complex; Omphalocele, autosomal dominant; Omphalocele, autosomal recessive; Omphalocele, diaphragmatic hernia, and radial ray defects; Omphalocele, X-linked; Omphalocele-cleft palate syndrome; Shprintzen omphalocele syndrome

Genetics/Basic Defects

1. Embryogenesis
    1. Failure of the cranial, caudal, and lateral folds to fuse before myotome invasion is the most likely explanation for the failure of physiologically herniated midgut returning to the abdomen during the first trimester.
    2. Exomphalos (omphalocele) (Duhamel 1963)
        1. Upper celosomia (herniae of the abdominal wall or ventral herniae)
            1. Omphalocele and defect of sternum, diaphragm, pericardium, and heart
            2. Omphalocele, diaphragmatic hernia, and ectopia cordis abdominalis
            3. Omphalocele and diaphragmatic hernia
        2. Middle celosomia: omphalocele alone
        3. Lower celosomia
            1. Omphalocele and bladder exstrophy
            2. Omphalocele, hindgut agenesis, vesicointestinal fissure, and bladder exstrophy
2. Inheritance
    1. Usually sporadic
    2. Single-gene disorders associated with omphalocele (Chitayat et al. 1997)
        1. Autosomal recessive disorders
            1. Agonadism with multiple internal malformation
            2. Agonadism, XY, with mental retardation, short stature, retarded bone age, and multiple extragenital malformations

Clinical Features

1. General features
   1. Prematurity
   2. IUGR
2. Herniated sac
   1. Size ranging from 2 to 10 cm
   2. Covering avascular sac consists of fused layers of peritoneum and amnion
   3. Contents of hernia include thoracic and abdominal viscera
      1. Liver
      2. Large intestine
      3. Small intestine
      4. Stomach
      5. Gall bladder
      6. Urinary bladder
      7. Pancreas
      8. Spleen
      9. Internal genitalia
   4. The sac may be torn or ruptured (10–20%)
   5. Necrotizing enterocolitis and malabsorption only if sac is ruptured
3. Umbilical cord inserting into the apex of the sac
4. At increased risk for associated anomalies or syndromes (45–67%)
   1. Cleft lip/palate: Reports of the two cases of co-occurrence of omphalocele and cleft palate raise the possibility of a new syndrome (Upadhyay et al. 2016)
   2. Gastrointestinal abnormalities
      1. Diaphragmatic hernia
      2. Midgut volvulus

3. Meckel diverticulum
4. Intestinal atresia
5. Intestinal duplication
6. Intestinal malrotation
7. Colonic agenesis
8. Imperforate anus

3. Congenital heart defects
4. Neural tube defects
5. Genitourinary: exstrophy of the bladder
6. Skeletal defects (Loder and Guiboux 1993)
   1. Limb deformity
   2. Spinal deformity
7. Beckwith-Wiedemann syndrome
   1. Macroglossia
   2. Hypoglycemia
   3. Organomegaly
   4. Gigantism
8. Epigastric omphalocele associated with pentalogy of Cantrell (Cantrell et al. 1958)
   1. Cardiac abnormalities
      1. Ventricular septal defect most common
      2. Occasional diverticulum of the left ventricle
   2. Sternal cleft
   3. Epigastric omphalocele
   4. Anterior diaphragmatic hernia
   5. Ectopia cordis

5. Prognosis depending on (Mayer 1980; Langer 1996; Kilby et al. 1998):
   1. Size of the omphalocele (Christison-Legay et al. 2011)
      1. Better prognosis with smaller defects (10% of all omphaloceles diagnosed on prenatal US) (Heider et al. 2004): better prognosis (Tucci and Bard 1990)
      2. Large omphalocele (up to 60% of infants with a large omphalocele) (Koivusalo et al. 1999; Biard et al. 2004)
         1. Intractable respiratory insufficiency
         2. Recurrent lung infections or asthma
         3. Gastroesophageal reflux
         4. Feeding difficulty with failure to thrive
   2. Presence or absence of the associated anomalies, especially cardiac defects
   3. Presence of chromosome anomalies: Abnormal karyotypes were significantly associated with the absence of liver from the omphalocele sac and sonographically detectable concurrent malformations (Nyberg et al. 1989)
   4. Gestation at delivery
6. Comparison of characteristics of omphalocele and gastroschisis (please see the chapter on "▶ Gastroschisis") (Christison-Legay et al. 2011; Ledbetter 2012)
   1. Omphalocele
      1. Sac: present
      2. Associated anomalies: Common
      3. Location of the defect: umbilicus
      4. Herniated abdominal organs: bowel and sometimes liver
      5. Maternal age: average
      6. Mode of delivery: cesarean/vaginal
      7. Surgical management: not urgent
      8. Prognostic factors: associated anomalies
   2. Gastroschisis
      1. Sac: absent
      2. Associated anomalies: uncommon
      3. Location of the defect: right of umbilicus
      4. Herniated abdominal organs: Bowell
      5. Maternal age: younger
      6. Mode of delivery: vaginal
      7. Surgical management: urgent
      8. Prognostic factors: condition of bowel

Diagnostic Investigations

1. Routine blood work
2. Abdominal radiography
3. Abdominal ultrasound
4. Echocardiography
5. Chromosome analysis
6. Initiate studies for associated single-gene disorder or malformation syndrome

Genetic Counseling

1. Recurrence risk: depends on the mode of transmission and associated chromosome anomalies
2. Prenatal Diagnosis

1. Elevated maternal serum alpha-fetoprotein (MSAFP): MSAFP screening sensitivity was greater for gastroschisis than for omphalocele at any given cutoff (Palomski et al. 1988)
2. Prenatal 2D ultrasonography
    1. Maternal polyhydramnios
    2. A circumscribed mass containing liver and/or intestines at the cord insertion site
    3. Covering sac composed of amnion and peritoneum
    4. Ruptured omphalocele: a rare complication
    5. Identifies other malformations and allows diagnosis of recognizable syndromes such as pentalogy of Cantrell and prune belly syndrome
3. Prenatal 3D ultrasonography (Bonilla-Musoles et al. 2001)
    1. A useful complement to 2D ultrasonography
    2. Improved definition of omphalocele
    3. Identifies other malformations and allows diagnosis of recognizable syndromes such as pentalogy of Cantrell and prune belly syndrome
    4. Allows isolation and better evaluation of the anomalous structure of interest when there is oligohydramnios or fetal contact with the uterine wall or placenta
4. Ultrasound findings in fetal abdominal wall defects (Prefumo and Izzi 2014)
    1. Omphalocele
        1. Covering membrane: yes
        2. Site of defect: umbilical insertion
        3. Umbilical cord insertion: omphalocele membrane
    2. Gastroschisis (please see the chapter on "► Gastroschisis")
        1. Covering membrane: no
        2. Site of defect: right of umbilical insertion
        3. Umbilical cord insertion: normal insertion
    3. Umbilical hernia
        1. Covering membrane: yes
        2. Site of defect: no umbilical ring defect
        3. Umbilical cord insertion: normal insertion
    4. Pentalogy of Cantrell
        1. Covering membrane: yes
        2. Site of defect: above umbilical insertion
        3. Umbilical cord insertion: omphalocele membrane
        4. Additional findings: anterior diaphragmatic hernia, sternal clefting, ectopia cordis, and intracardiac defect
    5. OEIS complex
        1. Covering membrane: yes
        2. Site of defect: umbilical insertion
        3. Umbilical cord insertion: omphalocele membrane
        4. Additional findings: bladder exstrophy, imperforate anus, and spina bifida
    6. Body-stalk anomaly (please see the chapter on "► Body Stalk Anomaly")
        1. Covering membrane: herniated organs in extraembryonic coelom
        2. Site of defect: whole anterior abdominal wall
        3. Umbilical cord insertion: cord absent or shortened
        4. Additional findings: kyphoscoliosis, cranial defects, and limb defects
    7. Bladder exstrophy (please see the chapter on "► Bladder Exstrophy")
        1. Covering membrane: not applicable
        2. Site of defect: below umbilical insertion
        3. Umbilical cord insertion: low insertion
        4. Additional findings: nonvisualization of bladder, lower abdominal bulge (exstrophied bladder), small penis with anteriorly displaced scrotum (if male), and widening of the iliac crests
    8. Cloacal exstrophy (please see the chapter on "► Cloacal Exstrophy")
        1. Covering membrane: not applicable
        2. Site of defect: below umbilical insertion

3. Umbilical cord insertion: low insertion
4. Additional findings: renal anomalies, neural tube defect, omphalocele, vertebral anomalies, nonvisualization of the bladder, distended bladder, hydrocolpos, dilated or echogenic bowel, umbilical cord cyst, separated pubic bones, and "elephant trunk" sign

5. Prenatal US detection rate at discovery of omphalocele by type of malformation (Barisic et al. 2001)
   1. Isolated (62%)
   2. Syndromic (86%)
   3. Chromosomal (83%)
   4. Multiple (90%)
6. Absence of liver in the omphalocele predicts an abnormal karyotype (Benacerraf et al. 1990): Prenatal US diagnosis would suggest an abnormal karyotype in these fetuses
7. Fetal echocardiography for evaluation of cardiac anomalies: an association between large omphalocele and inferior vena cava with azygos continuation to the superior vena cava (Mlczoch and Carvalho 2015)
8. Fetal MRI (Mann et al. 2008; Nakagawa et al. 2013)
   1. On MRI, a mass consisting of herniated viscera covered by a peritoneal–amniotic membrane is apparent in the anterior abdominal wall of the fetus.
   2. The umbilical cord is inserted into the apex of the surrounding membrane.
   3. The sac of omphalocele commonly contains the liver and small bowel.
   4. The ascites, large bowel, stomach, and spleen can also be present.
   5. Useful for viewing anatomical details where visualization is limited by maternal body habitus or amniotic fluid volume (Pumberger et al. 2003).
   6. Volumetric calculations of lung volume (Cannie et al. 2006).
   7. Evaluation of abdominal contents (Takada et al. 2006).
9. Amniocentesis
   1. Elevated amniotic fluid alpha-fetoprotein
   2. Positive acetylcholinesterase
10. Chromosome analysis
    1. Amniocentesis
    2. CVS
    3. Fetal blood sampling

3. Management (Mann et al. 2008)
   1. Mode of delivery: Owing to the potential intrapartum risk of dystocia (Paidas et al. 1994), sac rupture, and trauma to abdominal viscera, delivery of fetuses with giant omphaloceles should be by cesarean section.
   2. Attempts at primary repair: difficult due to a small abdominal cavity resulting from extraabdominal location of the viscera in utero.
   3. Emergency care
      1. Insertion of an orogastric tube
         1. To decompress the stomach
         2. To prevent swallowed air from causing bowel distention
      2. Cover the intact omphalocele sac with a sterile dressing and protect it from injury or rupture: Rupture of the sac increases the risk of infection and can lead to intestinal or hepatic trauma but, worse, destroys options for delayed closure strategies
      3. Use of a silastic silo to reduce the viscera over time. The silo is attached to the skin with nonabsorbable suture and is hung above the abdomen to use gravity to help reduce the viscera. The silo is tightened each day as the viscera reduce. Once all of the viscera have been reduced, the silo is removed and the fascia and skin are closed (Kelly and Ponsky 2013)
      4. Administer intravenous fluids and parenteral antibiotics
      5. Assess cardiorespiratory status and additional anomalies
   4. Pulmonary hypoplasia can be severe in these neonates with giant omphalocele and may require prolonged mechanical ventilation and tracheostomy (Edwards et al. 2007; Islam 2012)

5. Pulmonary hypertension (PH) was observed in 37% of giant omphalocele (GO) patients. PH represents a significant complication of GO, and management of pulmonary dysfunction is a critical consideration in improving clinical outcomes in these patients (Partridge et al. 2014)
6. The advent of total parenteral nutrition (TPN) was an important factor in decreasing the mortality, and with a better knowledge of the mechanical ventilation of the neonate the results are better and involve the survival of a greater number of patients with serious associated malformations (Yazbeck et al. 1986)
7. Direct primary closure of the abdominal wall for small omphalocele (2 cm)
8. Use of silver sulfadiazine dressing changes for initial nonoperative management of giant omphaloceles: safe and effective bridge to delayed closure (Lee et al. 2006)
9. Staged closure: using a Dacron-reinforced Silastic silo as a temporary housing for the bowel for medium to large omphalocele
10. Giant omphalocele can be safely repaired in the neonatal period without opening the amniotic sac. Intestinal malrotation should be excluded and Ladd's procedure can be performed laparoscopically at a later stage (Pacilli et al. 2005)

Management of a giant omphalocele with non–cross-linked intact porcine-derived acellular dermal matrix (Strattice) combined with vacuum therapy (Travassos et al. 2015)

Opitz Trigonocephaly Syndrome

Contents

Opitz trigonocephaly syndrome, also known as C syndrome, is a malformation syndrome characterized by trigonocephaly, severe mental retardation, hypotonia, variable cardiac defects, redundant skin, and dysmorphic facial features including upslanted palpebral fissures, epicanthal folds, depressed nasal bridge, and low-set posteriorly rotated ears (Kaname et al. 2007) (Fig. 1).

Synonyms and Related Disorders

Bohring–Opitz syndrome; C-like syndrome; C syndrome; Opitz C syndrome; Trigonocephaly syndrome

Genetics/Basic Defects

1. Evidence suggests onset of gene action in the primary field during the establishment of the progenitor fields of major organ systems including central nervous system, cardiac anomalies, a bona fide primary connective tissue dysplasia, and craniofacial-axial midline involvement and possibly involving a defect of the sonic hedgehog (SHH)/PTC/GLI3 pathway (Opitz et al. 2006)
2. Caused by mutation in the *CD96* gene (Kaname et al. 2007)
    1. 46,XY,t(3;18)(q13.13;q12.1) was observed in a patient with C syndrome (Chinen et al. 2006).
    2. The *CD96* gene, located at 3q13.13 breakpoint, was disrupted by the translocation in exon 5, probably leading to premature termination or loss of expression CD96 protein.
    3. No deletions or duplications were detected from surveyed copy number variation for the whole genome in this patient.
3. Inheritance: autosomal recessive
4. Phenotypic overlap with Bohring–Opitz syndrome (caused by heterozygous mutation in the *ASXL1* gene on chromosome 20q11.21) (Fisher et al. 2003)

Clinical Features

1. Prenatal history (Opitz et al. 2006)
    1. May document an apparently normal pregnancy
    2. Anhydramnios in case of severe urogenital anomalies

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_264

2. Central nervous system
    1. Mental retardation: generally moderate to severe, but normal intelligence has been reported (Lalatta et al. 1990; Stratton et al. 1990)
    2. Brain anomalies (Zampino et al. 1997)
        1. Agenesis of the corpus callosum
        2. Cerebellar vermis hypoplasia
        3. Cerebral atrophy/ventriculomegaly
        4. Megacysterna magna
        5. Generalized reduction in white matter
        6. Dandy–Walker malformation
        7. Occipital meningocele
    3. Hypotonia in most affected infants
    4. Seizures: may develop
3. Growth
    1. Short stature
    2. Failure to thrive
4. Craniofacial phenotype: complex and highly characteristic
    1. Cranial features
        1. Trigonocephaly with prominence of metopic suture
        2. Hypotelorism: in case of premature fusion of the metopica
        3. Hypertelorism: frequent and indicates a primary deficiency of the frontal lobes without premature fusion of the metopic suture
        4. Progressively smaller head size to microcephaly
        5. Becoming dolichocephalic skull shape
    2. Facial features
        1. Upward slant of palpebral fissures
        2. Thick epicanthic folds
        3. Squint
        4. Depressed bridge and broad tip of the nose
        5. Short, thick nasal septum and columella
        6. Variable length of the upper lip with flat philtrum and thin vermilion borders
        7. Micrognathia
    3. Oral features
        1. Broad alveolar ridges with rugose anterior palatal mucosa
        2. Highly arched/cleft palate with upper midline thick buccogingival frenulum with subsequent diastema
        3. There may be multiple additional, mostly upper buccogingival frenula
        4. Increased width of upper central incisors
    4. Other features
        1. Posteriorly angulated auricles with multiple minor, mostly modeling defects and deficient cartilage
        2. Hearing loss (Nacarkucuk et al. 2003)
        3. Capillary hemangiomata: may be confined to the midline of the face (upper lip, nose, glabella, forehead) but also involve upper lids
5. Neck: short and appears to be an effect of residual nuchal lymphedema
6. Connective tissue dysplasia
    1. Generalized and extremely stretchy skin over trunk
    2. Wrinkling of skin over distal limbs
7. Limbs
    1. Short, especially rhizo/acromelic segments
    2. Hypermobile elbows with crepitus
    3. Polydactyly, usually postaxial of 1, 2, 3, or 4 limbs, with variable degrees of syndactyly of toes
    4. Fingers: short with thumbs described at times as “spatulate,” Rubinstein–Taybi like, or digitalized
    5. Knee joints: tend to be hypermobile, rarely dislocated as in the spectacular examples of Opitz et al. (1969)
    6. Distal phalanges: may be deficient
8. Back: usually straight with sacral dimple and at times with hirsutism
9. Trunk: may appear short secondary to platyspondyly
10. Chest
    1. Deformed with thin, deformed ribs
    2. Short sternum with reduced number of ossification centers but more normal length of manubrium and xiphisternum
11. Cardiovascular malformation

    1. Common cardiac anomalies: tetralogy of Fallot, ASD, VSD, and PDA
    2. Vascular anomalies
12. Other features
    1. Umbilical hernia
    2. Omphalocele: at times
    3. Inguinal herniae
    4. Enlarged clitoris
    5. Small penis
    6. Cryptorchidism
    7. Diaphragmatic hernia
13. Phenotypic overlap with Bohring–Opitz syndrome (or C-like syndrome): with more severe features than C syndrome (Bohring et al. 1999)
14. A very high mortality rate: almost 50% of patients die within the first year of life (Opitz et al. 2006)

Diagnostic Investigations

1. Cytogenetic analysis: to identify any chromosome abnormality
2. Molecular analysis of *CD96* mutation: not available clinically
3. CT of the head for trigonocephaly
4. MRI of the brain for CNS anomalies
5. Echocardiography for congenital heart defects
6. EEG for seizures

Genetic Counseling

1. Recurrence risk according to autosomal recessive inheritance
    (a) Patient's sib: a 25% risk
    (b) Patient's offspring: not increased unless the spouse is also a carrier
2. Prenatal diagnosis: has not been described, although ultrasonography may identify congenital anomalies
3. Management: supportive

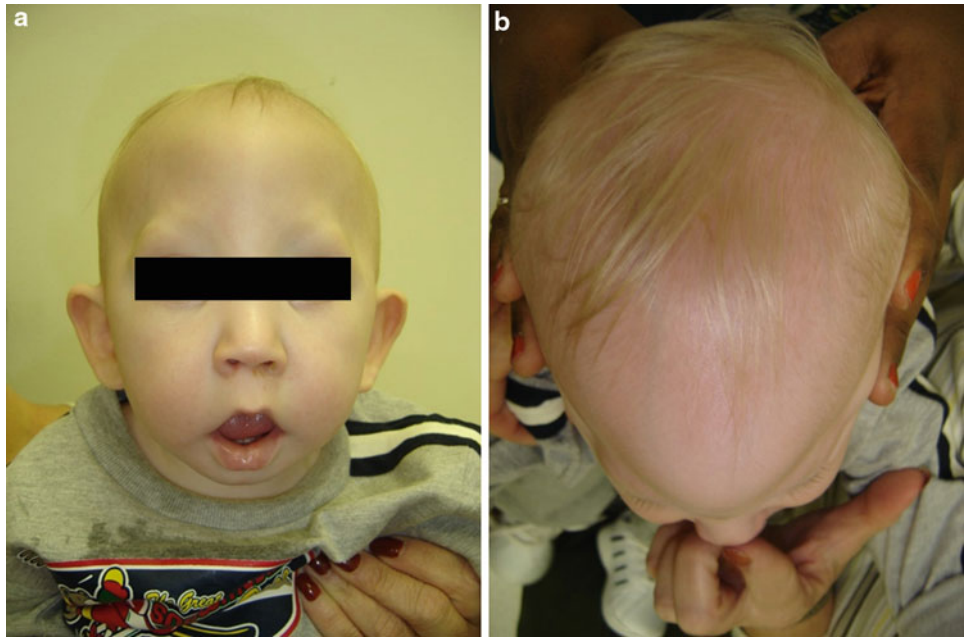

Fig. 1 (**a**, **b**) This 1-year-old Caucasian male infant (**a**) was evaluated for trigonocephaly (**b**) and to rule out Opitz trigonocephaly syndrome. He also has developmental delay, a flat nasal bridge, bilateral epicanthal folds, retromicrognathia, low-set ears, posteriorly rotated ears, bilateral preauricular pit, bicuspid aortic valve, G-tube placement due to poor suck reflex, presacral pit, and hyperextensible joints

Oral-Facial-Digital Syndrome

Contents

In 1941, Mohr reported a family in which the propositus had oral (high-arched palate, lobate tongue with papilliform outgrowths), facial (broad nasal root, hypertelorism), and digital (syndactyly, brachydactyly, polydactyly of the hands and feet) findings. This report was the first description of an oral-facial-digital syndrome (OFD). Mohr concluded that the condition was due to sex-linked recessive sublethal gene. A later report of the same family identified a similarly affected individual born to consanguineous parents, thus leading to the conclusion that the condition was inherited as an autosomal recessive trait, now known as OFD II or Mohr syndrome.

A similar phenotype, described by Papillon-Leage and Psaume in 1954, was identified as an X-linked dominant trait, now known as OFD I. After the identification of OFD I and OFD II, the phenotype spectrum was further expanded with extra oral-facial-digital manifestations, leading to the definition of the new types (Toriello 1988; Al-Qattan and Hassanain 1997). To date, 13 types have been distinguished based on the characteristic clinical manifestations. The oral-facial-digital syndromes result from the pleiotropic effect of a morphogenetic impairment affecting almost invariably the mouth, face, and digits.

Synonyms and Related Disorders

OFD I (papillon-Leage-Psaume syndrome); OFD II (Mohr syndrome); OFD III (Sugarman syndrome); OFD IV (Baraitser-Burn syndrome or Mohr-Majewski syndrome); OFD V (Thurston syndrome); OFD VI (Varadi-Papp syndrome); OFD VII (Whelan syndrome); OFD VIII (Edwards syndrome); OFD IX (Gurrieri syndrome); OFD X (Figuera syndrome); OFD XI (Gabrielli syndrome); OFD XII (Moran-Barroso syndrome); OFD XIII (Degner syndrome); OFD XIII (Degner syndrome); OFD XIV; Orofaciodigital syndrome (OFD)

Genetics/Basic Defects

1. OFD I (Papillon-Leage-Psaume syndrome) (Wahrman et al. 1966): X-linked dominant (lethal in males): *OFD1* is the only gene currently known to be associated with oral-facial-digital syndrome type I. Caused by mutation in the OFD1 protein gene (Rakkolainen et al. 2002; Romio et al. 2003)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_184

2. OFD II (Mohr syndrome): autosomal recessive
3. OFD III (Sugarman syndrome): autosomal recessive
4. OFD IV (Mohr-Majewski syndrome, Baraitser-Burn syndrome): autosomal recessive, caused by mutation in the TCTN3 gene
5. OFD V (Thurston syndrome): autosomal recessive, caused by mutation in the DDX59 gene
6. OFD VI (Varadi-Papp syndrome): autosomal recessive, caused by mutation in the C5ORF42 gene
7. OFD VII (Whelan syndrome): autosomal or X-linked dominant
8. OFD VIII (Edwards syndrome): X-linked recessive
9. OFD IX (Gurrieri syndrome): X-linked recessive
10. OFD X (Figuera syndrome): autosomal dominant
11. OFD XI (Gabrielli syndrome): isolated cases
12. OFD XII (Moran-Barroso syndrome): autosomal recessive
13. OFD XIII (Degner syndrome): autosomal recessive
14. OFD XIV: autosomal recessive, caused by mutation in the C2CD3 gene on chromosome 11q13 (Thauvin-Robinet et al. 2014)

Clinical Features

1. OFD I (Papillon-Leage-Psaume syndrome) (Gorlin and Psaume 1962; al-Qattan and Hassanain 1997; Ferrante et al. 2001; Thauvin-Robinet et al. 2006; Gurrieri et al. 2007; Papagrigoraskis et al. 2010; John et al. 2013; Toriello and Franco 2013)
    1. Characterized by anomalies of the face, oral cavity, and digits with a high degree of phenotypic variability even within the same family, possibly due to different degrees of somatic mosaicism resulting from random X-inactivation
    2. Abnormalities of the oral cavity: primarily affecting the tongue, palate, and teeth
        1. Lobed tongue often described as bifid or trifid.
        2. Tongue nodules, usually hamartomas or lipomas, also occur in at least one third of individuals.
        3. Ankyloglossia attributable to a short lingual frenulum common
        4. Cleft hard or soft palate, submucous cleft palate, or highly arched palate: occurring in more than 50% of affected individuals.
        5. Trifurcation of the soft palate reported.
        6. Alveolar clefts and accessory gingival frenula are common. These fibrous bands are hyperplastic frenula extending from the buccal mucous membrane to the alveolar ridge, resulting in notching of the alveolar ridges.
        7. Dental abnormalities include missing teeth (most common), extra teeth, enamel dysplasia, and malocclusion.
    3. Craniofacial abnormalities
        1. Median pseudoclefting of the upper lip
        2. Irregular margin of the lips
        3. Facial asymmetry
        4. Downslanting palpebral fissures
        5. Ocular hypertelorism
        6. Telecanthus
        7. Micrognathia
        8. Broadened nasal ridge
        9. Hypoplasia of the malar bones and nasal alar cartilages
        10. Frontal bossing
        11. Vanishing milia of the face and ears, usually disappear before the third year of life
        12. Dryness, brittleness, and/or alopecia of the scalp hair
    4. Digital abnormalities
        1. Brachydactyly.
        2. Syndactyly of varying degrees.
        3. Clinodactyly of the fifth finger.
        4. The third (i.e., middle) finger showing variable radial or ulnar deviation.

5. Duplicated hallux (great toe) occurs in fewer than 50% of affected individuals but if present is usually unilateral.
6. Preaxial or postaxial polydactyly of the hands occurring in 1–2% of affected individuals.
7. Radiographs of the hands often demonstrate fine reticular radiolucencies, described as irregular mineralization of the bone, with or without spicule formation of the phalanges.

5. Other associated anomalies
   1. CNS anomalies (Towfighi et al. 1985; Holubu et al. 2005):
      1. Microcephaly
      2. Intracerebral cysts
      3. Agenesis of the corpus callosum
      4. Cerebellar agenesis with or without Dandy-Walker malformation
      5. Type 2 porencephaly (schizencephalic porencephaly)
      6. Pachygyria and heterotopias
      7. Hydrocephalus
      8. Cerebral or cerebellar atrophy
      9. Berry aneurysms
   2. Intelligence: about 50% of individuals with OFD1 with some degree of mental retardation or learning disability.
   3. Polycystic kidney disease (Connacher et al. 1987; Donnai et al. 1987; Feather et al. 1997): occurring in fewer than 50% of individuals with OFD1. Renal cysts can develop from both tubules and glomeruli, most often in adulthood.

2. OFD II (Mohr syndrome) (Mohr 1941; Rimoin and Edgerton 1967; Goldstein and Medina 1974; Silengo et al. 1987; Gillerot and Koulischer 1988; Prpic et al. 1995; Balci et al. 1999; Hsieh and Hou 1999)
   1. Oral anomalies
      1. Lobulated/cleft tongue
      2. Tongue hamartomas
      3. Duplicated frenulum
      4. Absent central incisors
   2. Facial anomalies: bifid nasal tip
   3. Digital anomalies (Michels et al. 1985)
      1. Hands: clinodactyly, syndactyly, polydactyly
      2. Feet: preaxial or postaxial polydactyly, synpolydactyly, of both big toes
   4. CNS anomalies
      1. Hydrocephalus
      2. Porencephaly
      3. Mental retardation
   5. Features overlapping with OFD I
      1. Orofacial manifestations: tongue nodules, midline clefts of the lip, thick frenula, and dystopia canthorum
      2. Digital manifestations: clinobrachydactyly, syndactyly, and polydactyly
   6. Subtle clinical differences between types I and II
      1. Greater thickness of the alveolar ridge than in type I, which is normal in type II.
      2. Presence of hair and skin abnormalities in type I.
      3. Presence of bilateral polysyndactyly of the halluces in type II rather than unilateral polysyndactyly, which is usually found in type I.
      4. Conductive hearing impairment may occur in type II.
      5. Central nervous system can also be affected in this form mainly with porencephaly and hydrocephaly.
   7. Distinctive difference in the mode of inheritance: OFD type II is caused by mutations of an as yet unidentified autosomal recessive gene versus X-linked dominant inheritance in OFD type I.
   8. Expanding phenotype spectrum in OFD type II: congenital heart defects such as atrioventricular canal and endocardial cushion defects.
   9. A Y-shaped central metacarpal, usually considered typical of OFD type VI, has also been reported in patients with clinical characteristics falling within the OFD II spectrum, suggesting the existence of transitional OFD types that may turn out to be

allelic forms once the genetic defects of all OFD types are discovered.

3. OFD III (Sugarman syndrome) (Sugarman et al. 1971; Sugarman 1983; Smith and Gardner-Medwin 1993)
   1. Oral anomalies
      1. Lobulated tongue with hamartoma
      2. Cleft palate
      3. Extra small teeth
   2. Facial anomalies
      1. Hypertelorism
      2. Broad nose
      3. Choanal atresia
      4. Low-set ears
   3. Digital anormalies
      1. Hands: oligodactyly, syndactyly
      2. Feet: postaxial polydactyly
   4. CNS anomalies
      1. Dandy-Walker malformation
      2. Cerebellar anomalies
      3. Ceaseless seesaw (continuous alternating) winking of the eyelids
      4. Myoclonic jerks
      5. Mental retardation
   5. Other features: short sternum, hyperconvex nails
4. OFD IV (Mohr-Majewski syndrome, Baraitser-Burn syndrome) (oral-facial-digital syndrome with tibial defects) (Burn et al. 1984; Baraitser et al. 1986; Nevin and Thomas 1989; Meinecke and Hayek 1990; Nevin et al. 1992; Ades et al. 1994; Digilio et al. 1995; Toriello et al. 1997; Moerman and Fryns 1998; Tuysuz et al. 1999)
   1. Oral anomalies: lobulated tongue with hamartoma, duplicated frenulum, median cleft lip
   2. Minor facial anomalies: hypertelorism, broad nose, epicanthal folds, micrognathia, low-set ears
   3. Digital anomalies: hands (polydactyly), feet (preaxial and postaxial polydactyly, clubfoot)
   4. Mesomelic limb shortening limited to tibial defects (tibial dysplasia)
   5. Other features: joint dislocations, pectus excavatum, short stature
   6. Expansion of phenotypic spectrum
      1. Occipitoschisis
      2. Brain malformation (porerncephaly, cerebral atrophy)
      3. Hearing loss
      4. Ocular colobomas
      5. Hypoplastic epiglottis
      6. Intrahepatic cyst
      7. Renal cysts
      8. Anal atresia
      9. Joint dislocations
5. OFD V (Thurston syndrome) (Thurston 1909; Khoo and Saad 1980; John et al. 2013)
   1. The mildest form within the OFD group
   2. Oral anomalies
      1. Median cleft lip
      2. Duplicated frenulum
      3. Enamel hypoplasia
      4. High-arched palate
      5. Supernumerary teeth
   3. Postaxial polydactyly of the hands and feet
   4. Normal intelligence
   5. Reported exclusively in individuals of Indian ethnicity
6. OFD VI (Varadi-Papp syndrome) (Varadi et al. 1980; Muenke et al. 1990, 1991; Toriello 1993; Stephens et al. 1994; Wey et al. 1994; Doss et al. 1998)
   1. Distinguished features
      1. First report in endogamic gypsies
      2. Oral anomalies: lobulated tongue with hamartoma, duplicated frenulum, median cleft lip, deep palate
      3. Facial anomalies: microphthalmia, micrognathia
      4. Digital anomalies
         1. Clinodactyly and syndactyly of the hands
         2. Y-shaped metacarpals/metatarsals: forked third or fourth metacarpals/metatarsals, indicating central polydactyly
      5. Expanded phenotype spectrum
         1. Penile agenesis (Yildirim et al. 2002).
         2. Abnormal clavicles.

3. Vermis hypoplasia/aplasia.
4. Dandy-Walker anomaly.
5. Absent pituitary gland (Al-Gazali et al. 1999).
6. Hypothalamic hamartoma with precocious puberty, which is almost constantly found in Pallister-Hall syndrome, an autosomal dominant condition characterized by postaxial polydactyly, imperforate anus, and hypothalamic hamartoma. The phenotypic overlap between OFD VI and Pallister-Hall syndrome has been noted, and lumping of the two conditions as the same entity has been proposed.
7. GLI3 mutations identified in Pallister-Hall syndrome suggest that GLI3 analysis should also be carried out in patients with OFD VI to find out if these two conditions are allelic.
8. A single report of neuropathologic findings in OFD VI showed disruption or dysgenesis of glial architecture, suggesting a primary glial cell defect. This observation is interesting in light of the recent discovery that OFD I is caused by a failure of the ciliary system, which is involved in cellular migration during embryogenesis.

6. Represents a rare phenotypic subtype of Joubert syndrome and related disorders

7. Diagnostic criteria (Poretti et al. 2012)
   1. Molar tooth sign (a neuroanatomical feature characterized by thickened, elongated, and horizontally located superior cerebellar peduncles and an abnormally deep interpeduncular fossa) and one or more of the following:
   2. Tongue hamartoma(s) and/or additional frenula and/or upper lip notch
   3. Mesoaxial polydactyly of one or more hands or feet
   4. Hypothalamic hamartoma

8. OFD VII (Whelan syndrome) (Whelan et al. 1975; Nowaczyk et al. 2003): a single report of mother and daughter
   1. Oral anomalies: lobulated tongue with hamartoma, duplicated frenulum, cleft palate, median cleft lip
   2. Facial anomalies: asymmetry of the face, hypertelorism
   3. Digital anomalies: clinodactyly of the hands
   4. Preauricular skin tag
   5. Hydronephrosis
   6. Possibly same entity as OFD 1 since mother and daughter later developed cystic kidney disease, although mutation analysis for OFD I failed to detect a pathogenic mutation
9. OFD VIII (Edwards syndrome) (Edwards et al. 1988; Toriello 1993)
   1. Oral anomalies: lobulated tongue with hamartoma, median cleft lip, missing teeth
   2. Facial anomalies: telecanthus, broad/bifid nose
   3. Digital anomalies: hands (pre- or postaxial polydactyly), feet (preaxial polydactyly)
   4. Limb anomalies: short tibiae and radii
   5. Other features: delay of developmental milestones, hypoplastic epiglottis
   6. Distinguished from OFD II by X-linked recessive inheritance
10. OFD IX (Gurrieri syndrome) (Gurrieri et al. 1992; Nevin et al. 1994; Nagai et al. 1998)
    1. Oral anomalies: lobulated tongue with hamartoma, duplicated frenulum, median cleft lip
    2. Facial anomalies: hypertelorism
    3. Retinal anomaly (colobomata): a distinctive feature
    4. Digital anomalies: hands (brachydactyly, postaxial oligodactyly), feet (usually consist of hallucal duplication detectable radiologically)
11. OFD X (Figuera syndrome) (Figuera et al. 1993)
    1. Oral anomalies: Cleft palate, duplicated frenulum
    2. Facial anomalies: telecanthus

3. Digital anomalies: hands and feet (preaxial polydactyly and postaxial oligodactyly)
4. Limb anomaly: fibular agenesis

12. OFD XI (Gabrielli syndrome) (Gabrielli et al. 1994; Ferrero et al. 2002): in addition to the oral, facial, and digital anomalies, this type is characterized by following craniovertebral anomalies:
    1. Oral anomalies: bifid tongue, duplicated frenulum, median cleft lip, cleft palate, midline cleft extending to ethmoid and crista galli
    2. Facial anomalies: wide nose, bulbous tip, hypertelorism, blepharophimosis, deformed earlobes
    3. Digital anomalies: postaxial polydactyly of the hands and feet
    4. Additional anomalies
        1. Apophysis
        2. Vertebral malformations
            1. Fusion of vertebral arches in C1, C2, and C3
            2. Clefts of vertebral bodies
        3. Conductive deafness, cardiac interventricular septal hypertrophy, mucosal subaortic spur
13. OFD XII (Moran-Barroso syndrome) (Moran-Barroso et al. 1998)
    1. Oral anomalies: lobulated tongue with hamartoma, duplicated frenulum, median cleft lip
    2. Myelomeningocele
    3. Stenosis of the aqueduct of Sylvius
    4. Cardiac anomalies
14. OFD XIII (Degner syndrome) (Degner et al. 1999)
    1. Oral anomalies: lobulated tongue with hamartoma, duplicated frenulum, median cleft lip
    2. CNS anomalies
        1. Psychiatric symptoms (major depression)
        2. Epilepsy
        3. Brain MRI findings of leukoaraiosis (patched loss of white matter of unknown pathogenetic origin, possibly of ischemic nature, considered to increase the risk of stroke)
15. OFD XIV (Thauvin-Robinet et al. 2014)
    1. Craniofacial: microcephaly, trigonocephaly, facial dysmorphism, telecanthus, upslanting palpebral fissures, retinitis, cleft palate, cleft tongue, lobulated tongue, lingual hamartoma, buccal frenule, absent epiglottis, supernumerary teeth
    2. Genitourinary: micropenis
    3. Skeletal; postaxial polydactyly of hands, broad/duplicated halluces
    4. CNS: severe intellectual disability, corpus callosum hypoplasia, vermian hypoplasia, molar tooth sign, subarachnoid cysts, incomplete myelinization

Diagnostic Investigations

1. Diagnostic approach
    1. First, ascertain oral, facial, and digital findings.
    2. Obtain family history to determine if a mode of inheritance can be established.
    3. In patients with clear X-linked dominant transmission and even in sporadic female patients, it is necessary to rule out mutations in the OFD1 gene.
    4. Additional studies to delineate specific type, given the fragmentary nosology of OFD.
        1. Brain MRI
        2. Abdominal ultrasound
        3. Skeletal survey
        4. Ophthalmologic evaluation
        5. Audiometric test
        6. Chromosome analysis to detect submicroscopic rearrangements by array-CGH analysis
2. Diagnosis of OFD I (Toriello and Franco 2013)
    1. Established at birth in some infants on the basis of characteristic oral, facial, and digital anomalies
    2. Diagnosis is suspected in some patients only after polycystic kidney disease is identified in later childhood or adulthood

3. Molecular genetic testing (sequence analysis and duplication/deletion analysis) of *OFD1*, the only gene currently known to be associated with OFD I: clinically available for confirmatory diagnostic testing and prenatal diagnosis of OFDI
3. Diagnosis of OFD VII (includes unilateral cleft lip and hydronephrosis, only been described in one mother-daughter pair, who were later found to have a mutation in *OFD1*): either allelic to OFD1 or demonstrates variable expression of OFD1

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. Autosomal recessive (OFD types II, III, IV, V, VI, possibly types XI, XII, XIII)
            1. A 25% risk
            2. A 50% risk of being a carrier
        2. Autosomal dominant (OFD X)
            1. A small recurrence risk if neither parent is affected
            2. A 50% risk if one parent is affected
        3. X-linked dominant with male lethality (OFD I, OFD VII) (Toriello and Franco 2013)
            1. Approximately 75% of affected individuals are simplex cases (no family history of OFD1).
            2. A female proband with OFD1 may have the disorder as the result of a de novo gene mutation; however, the proportion of cases caused by de novo mutations is unknown.
            3. When the mother of an affected female is also affected, the risk to sibs of inheriting the disease-causing *OFD1* allele at conception is 50%; however, most male conceptuses with the disease-causing *OFD1* allele miscarry (Macca and Franco 2009). Thus, at delivery the expected sex ratio of offspring is 33% unaffected females; 33% affected females; 33% unaffected males.
            4. If no family history of OFD1 exists, the risk that the unaffected mother of an affected female will have another female with OFD1 is less than 1%.
        4. X-linked recessive (OFD VIII): risk to the sibs depending on the carrier status of the mother
            1. Mother is a carrier: a 50% of risk of having a male sib with OFD VIII
            2. Mother is not a carrier: a low recurrence risk
    2. Patient's offspring
        1. Autosomal recessive: a low recurrence risk unless the spouse is also affected or a carrier
        2. Autosomal dominant: a 50% risk if the spouse is normal
        3. X-linked dominant with male lethality (Toriello and Franco 2013)
            1. At conception, the risk to the offspring of females with OFD1 of inheriting the disease-causing OFD1 allele is 50%; however, most male conceptuses with the disease-causing allele miscarry.
            2. At delivery, the expected sex ratio of offspring: 33% unaffected females, 33% affected females, and 33% unaffected males.
        4. X-linked recessive
            1. No sons will be affected.
            2. All daughters will be carriers.
2. Prenatal diagnosis
    1. Prenatal ultrasound
        1. Prenatal diagnosis of OFD type II reported in a fetus
            1. Polydactyly with bifid thumbs in both hands
            2. Bilateral polysyndactyly of halluces
            3. Lateral polysyndactyly and bilateral pes equinovarus
        2. Prenatal diagnosis of OFD type IV (Mohr-Majewski) possible: findings showing overlap between OFD type II (Mohr) and lethal short rib-polydactyly syndrome type II (Majewski) (Rosing et al. 2008)

3. Prenatal ultrasound examination of OFD type I (Toriello and Franco 2013) may detect structural brain malformations (Shipp et al. 2000) and/or duplication of the hallux.
2. Molecular genetic analysis: prenatal diagnosis and preimplantation genetic diagnosis for families in which the disease-causing mutation has been identified is clinically available.

3. Management (Toriello and Franco 2013)
1. Surgery
1. Cleft lip/palate
2. Tongue nodules
3. Accessory frenula
4. Polysyndactyly
5. Removal of accessory teeth
6. Orthodontia for malocclusion
2. Management of renal disease and seizures
3. Speech therapy
4. Special education
5. Surveillance
1. Annual monitoring of renal function
2. Speech and hearing assessment if cleft palate is present

Fig. 1 Patient 1 with OFD I. Note the lingual frenulum and hypoplastic alar nasi

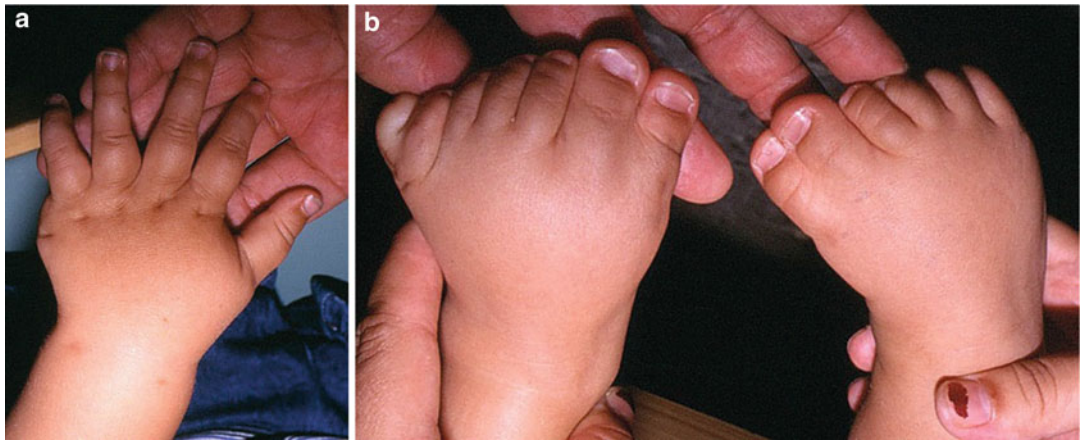

Fig. 2 (**a**, **b**) The patient's bilateral postaxial polydactyly of both hands, duplicated hallux of both feet, and postaxial polydactyly of the left foot

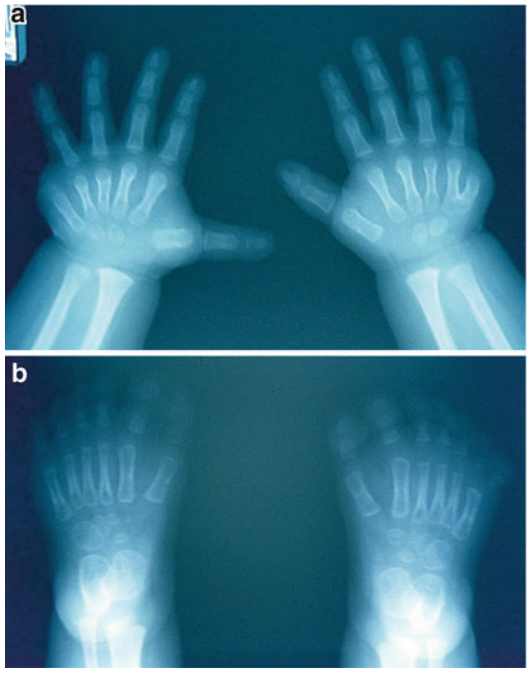

Fig. 3 (**a**, **b**) Radiographs of hands and feet of patient 1

Fig. 4 (**a**, **b**) Patient 2 with OFD II. Note bifid nasal tip, medial cleft of the upper lip, and ocular hypertelorism

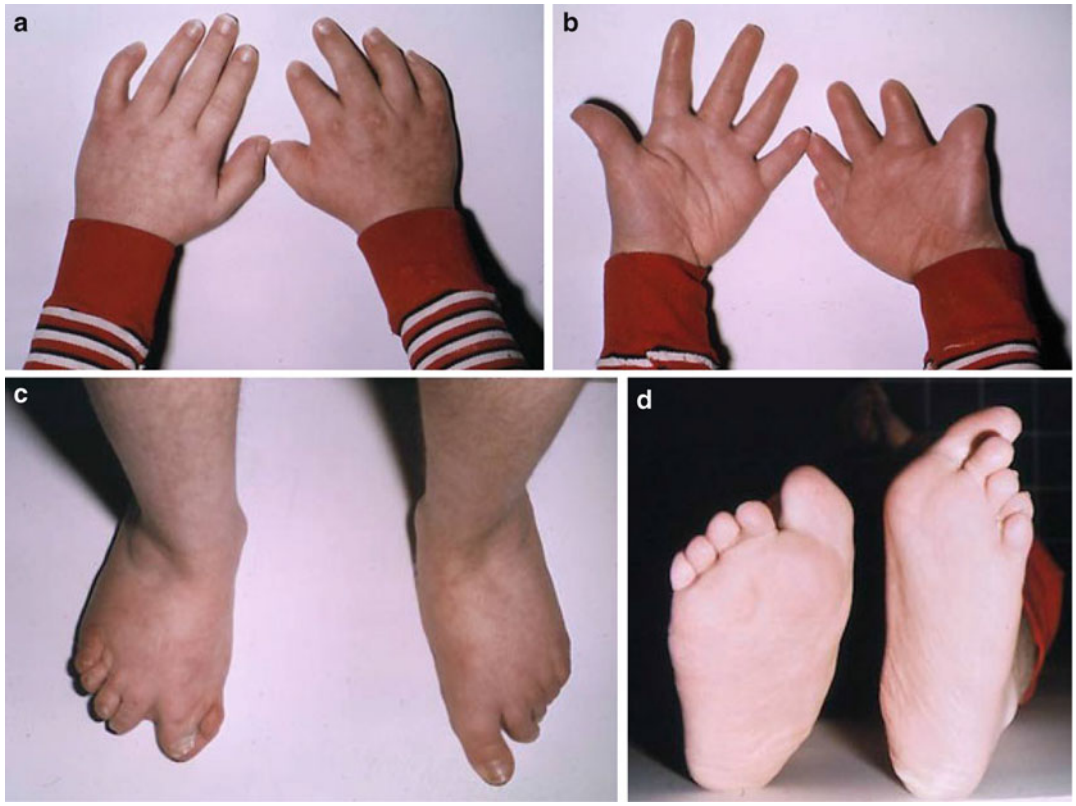

Fig. 5 (**a**–**d**) Note the clinobrachydactyly and syndactyly of the hands and polydactyly of the right hallux

Fig. 6 (**a**–**d**) Patient 3 with OFD II. Note the ocular hypertelorism, bifid tip of the nose, lingual frenulum, and brachysyndactyly

Fig. 7 (**a**–**d**) Patient 4 with unclassified OFD. Note frontal bossing, ocular hypertelorism, strabismus, pseudocleft of the upper lip, preaxial polydactyly of the hands, hepatomegaly, and genu valgum

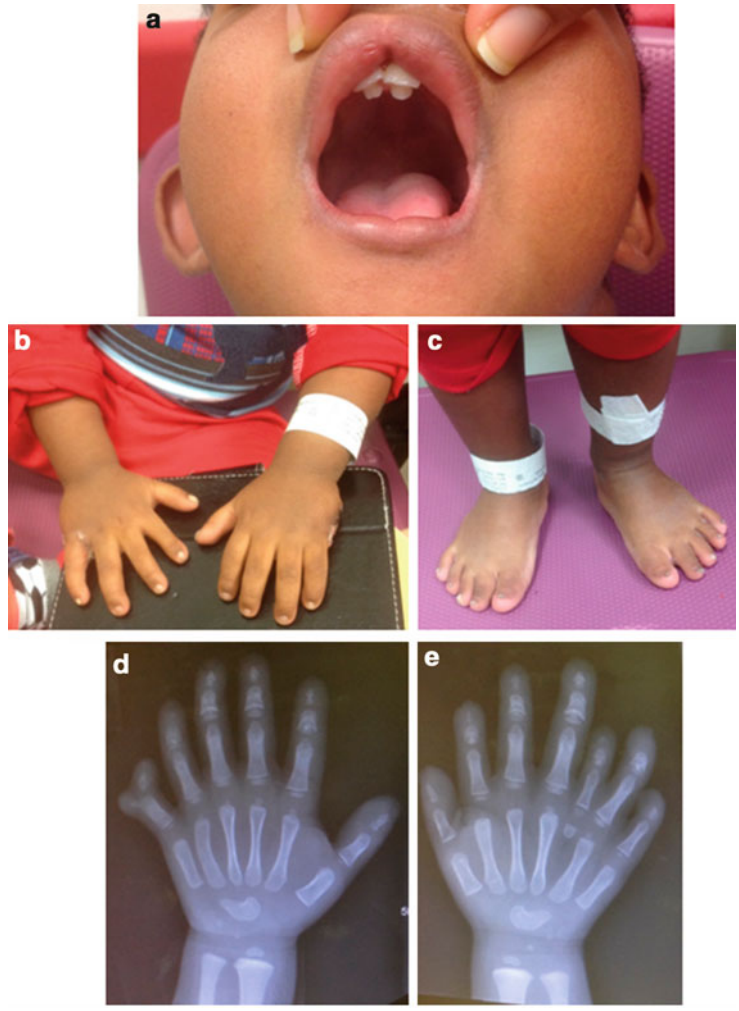

Fig. 8 (**a**–**e**) This 3-year-old Hispanic boy from Panama was seen for abnormal dentition and brachydactyly and polydactyly of both hands. Orofacial features were characterized by slight hypertelorism, flat nasal bridge, and presence of median pseudocleft of the upper lip and double rows of upper central incisors with absence of other teeth (**a**). Radiographic imaging of oromandibular areas with panoramic and cephalometric projection showed no permanent maxillary laterals and complete absence of all central and lateral mandibular teeth (not shown). The fingers were short with postaxial polydactyly of both hands (seven fingers on the right and six fingers on the left with duplicated distal end of the last finger) (Status post incision of polydactylies and post reconstruction of both hands is shown here) (**b**). There was no polydactyly of the toes, but the great toes were slightly broad. Radiograph of left hand (**d**) showed duplication of the fifth ray with dysplasia and hypoplasia of the distal and middle phalanges. Radiograph of the right hand (**e**) showed duplication of the fourth and fifth rays with dysplasia and hypoplasia of the distal and middle phalanges. Dysplastic fusion of the capitate and hamate was present in both wrists (**d, e**)

Osteogenesis Imperfecta

Contents

Osteogenesis imperfecta (OI) is a generalized, hereditary disorder of connective tissue involving bone, tendon, ligament, fascia, and dentin, resulting from mutations affecting the amount or structure of type I collagen. OI affects about 1 in 10,000 individuals.

Synonyms and Related Disorders

Osteogenesis imperfecta with blue sclerae; Osteogenesis imperfecta with normal sclerae; Perinatal lethal osteogenesis imperfecta; Progressively deforming osteogenesis imperfecta with normal sclerae

Genetics/Basic Defects

1. Clinicopathological classification (Glorieux 2008; Basel and Steiner 2009; Fratzl-Zelman et al. 2015): The classification system of Sillence et al. (1979) divides OI into four severity-based types with type IV representing the most clinically diverse group (Cole 1997). It is from this heterogeneous group that types V, VI, VII, and VIII have been identified on the basis of distinct clinical and histological features (Glorieux et al. 2000, 2002; Ward et al. 2002). The most clinically relevant characteristic of all types of OI is bone fragility, the severity of which increases in the order type I < types IV, V, VI, VII, VIII < type III < type II. Heredity follows an autosomal dominant pattern in types I through V and is autosomal recessive in types VI, VII, and VIII. Mutations affecting collagen type I are usually present in types I through IV and types VII and VIII, but are absent in types V and VI. This classification scheme is likely to change as additional information is gathered on newly described forms caused by *CRTAP* and *LEPRE* mutations:
    1. OI I:
        1. Autosomal dominant disorder
        2. Fresh mutation in 15% of cases
        3. The most common and mildest form of osteogenesis imperfecta
        4. Estimated prevalence at between 1 in 10,000 and 1 in 25,000 or may be more frequent because of its relatively mild presentation and the possibility of underdiagnosis

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_185

2. OI II:
    1. Autosomal dominant disorder (new mutations in almost all instances) (Young et al. 1987)
    2. The most severe form, resulting in death in the perinatal period
    3. Autosomal recessive disorder (rare)
    4. Further subdivided into IIA, IIB (same as type III), and type IIC (Cole and Dalgleish 1995)
    5. Estimated frequency of 1 in 20,000–1 in 60,000 births
3. OI III:
    1. Autosomal dominant disorder
    2. Autosomal recessive disorder (uncommon)
    3. The rarest form of OI
    4. Known as the progressive deforming form
4. OI IV:
    1. Autosomal dominant with mutations in *COL1A1* and *COL1A2*
    2. The most clinically diverse group
    3. Represents the moderately severe spectrum of OI
    4. Marked intra-/interfamilial variability of expression
5. OI V (Biggin and Munns 2014):
    1. The first noncollagen OI type to be identified and mutations of the IFITM5 gene have recently been shown to cause this autosomal dominant form of OI (Cho et al. 2012).
    2. The moderately deforming form.
    3. Associated mutations: *IFITM5*.
6. OI VI:
    1. The moderately to severely deforming form
    2. Associated mutations: *SERPINF1*
7. OI VII:
    1. Overlaps with types II and III; milder forms also documented
    2. Associated mutations: hypomorphic expression of *CRTAP*
8. OI VIII:
    1. Overlaps with types II and III; milder forms also documented
    2. Associated mutations: *LEPRE1* (Willaert et al. 2009)
9. OI IX: associated mutations *PPIB* (van Dijk et al. 2009)

2. Molecular basis (Beyers et al. 1991; Minch and Kruse 1998):
    1. Type I collagen:
        1. Found in the skin, bone, tendons, and ligaments.
        2. Composed of three α chains (two α_1 chains and one α_2 chain).
        3. Each α chain forms a helix which consists of three amino acids per turn.
        4. The chains are held together by disulfide bonds at the C-terminal ends of the protein.
        5. There are three amino acids per turn in the helix.
        6. Every third amino acid is glycine, giving a repeat of Gly-X-Y, where X and Y represent other amino acid residues:
            1. About 10% of the X residues are proline.
            2. About 10% of the Y residues are hydroxyproline.
        7. A mutant collagen is produced by missense mutations that result in a substitution of the glycine residue by another amino acid.
    2. OI I:
        1. Affected individuals produce only 50% of the normal amount of type I collagen, produced by the normal allele.
        2. Mechanisms:
            1. Splicing in α_1 gene
            2. Null mutation in α_1 gene
    3. OI II, OI III, and OI IV:
        1. Affected individuals produce only 25% of the normal amount of type I collagen and 75% of mutant or defective collagen.
        2. Mechanism: A missense mutation arises in the α_1 gene resulting in a defective α_1 chain which is incorporated into the final collagen molecule and destroys its function.

3. Severity of the disease:
    1. Related to the position of the missense mutation within the gene and the amino acid substitution that occurs.
    2. Generally, the disease is more severe when the mutation is closer to the C-terminal end of the protein.
4. OI V:
    1. Caused by mutations in *IFITM5*.
    2. Autosomal dominant inheritance.
    3. Defective protein: Bone-restricted ifitm-like protein (BRIL).
    4. Biochemical effects on collagen biosynthesis: BRIL is an osteoblast-specific small transmembrane protein that might regulate early mineralization steps.
    5. Phenotypes.
5. OI VI:
    1. Caused by mutation in *SERPINF1* (Becker et al. 2011).
    2. Alkaline phosphatase may be elevated.
6. OI VII:
    1. Caused by mutation in *CRTAP.*
    2. The disease has been assigned to chromosome 3p22-24.1 (Labuda et al. 2002).
    3. Colocalizing with the gene encoding CRTAP, a cartilage-associated protein, whose expression is 90% reduced in homozygote patients (Morello et al. 2006).
7. OI VIII
    1. Caused by *LEPRE1* mutations
    2. Defective protein: prolyl 3-hydroxylase (P3H1)
8. OI IX:
    1. Caused by *PPIB* mutation
    2. Defective protein: peptidyl-prolyl cis-trans isomerase B (PPIB) (also called cyclophilin B, CyPB)
9. OI X:
    1. Caused by *SERPINH1* mutation
    2. Defective protein: heat-shock protein 47 (HSP47)
10. OI XI:
    1. Caused by *FKBP10* mutation
    2. Defective protein: FKBP65
11. OI-unclassified:
    1. *PLOD2* mutation: lysyl hydroxylase 2 (LH2) (defective protein)
    2. *BMP1* mutation: Bone morphogenic protein 1 (BMP1) (defective protein)
    3. *C-propeptide cleavage site* mutation: C-propeptide cleavage site (defective protein)
    4. *SP7/OSX* mutation: SP7/osterix (defective protein)
    5. *WNT1* mutation: WNT1 (defective protein)
    6. *TMEM38B* mutation: TRIC-B (defective protein)
    7. *CREBL1* mutation: endoplasmic reticulum stress transducer (OASIS) (old astrocyte specifically induced substance) (defective protein)
    8. *PLS3* mutation: actin-binding protein plastin 3 (defective protein)
3. Allelic connective tissue disorders (Basel and Steiner 2009):
    1. Several patients have been described with joint hypermobility and skin laxity, a clinical phenotype more in keeping with Ehlers-Danlos syndrome but who have an increased disposition to fractures.
    2. Mutations not involving the glycine residues within the triple helix of COL1 and mutations involving cysteine residues have been described in a subset of these patients (Malfait et al. 2006, 2007; Cabral et al. 2007).
    3. N-terminal mutations in COL1 appear to result in abnormal protein folding, which leads to a milder OI/Ehlers-Danlos syndrome p (Makareeva et al. 2006).
4. Very few individuals or families share the same mutation, although more than hundreds of unique mutations of the type I collagen genes have been identified.
5. Phenotypic variations among different families and within same family.

Clinical Features

1. OI type I (mild type) (Glorieux 2008):
    1. Fractures:

1. Rarely fracture in utero or in the perinatal period.
2. Usual onset of fractures: when the child begins to walk.
3. A few to more than 50 fractures before puberty.
4. Number of fractures gradually decreases after puberty.
5. Involve any bones of the body, but primarily long bones of the arms and legs, ribs, and small bones of the hands and feet
6. Increasing fractures often after menopause in affected women and in the sixth or eighth decades in affected men.
7. Healing rapidly with evidence of good callus formation and without deformity.

2. Cranial features:
   1. Soft thin calvarium
   2. Wide fontanels
   3. Wormian bones
   4. Frontal and temporal bulging
   5. Occipital flattening
3. Blue sclera (secondary to a thin sclera allowing partial visualization of the choroid):
   1. Readily apparent at birth
   2. Gradually lightens to blue gray in the adulthood
4. Other ocular features:
   1. Occasional embryotoxon (opacity in the peripheral cornea)
   2. Occasional keratoconus or megalocornea
5. Teeth abnormalities:
   1. Rare dentinogenesis imperfecta
   2. Hypoplasia of pulp
   3. Yellow or gray teeth
   4. Susceptible to caries
   5. Irregular placement
   6. Late eruption
6. Hearing loss:
   1. Early onset in about 50% of families beginning in late teens.
   2. Gradually leading to profound hearing loss in the end of fourth or fifth decades secondary to otosclerosis.
   3. Primarily conductive hearing loss in the early phase secondary to fractured and fused bones of the middle ear.
   4. Early hearing loss typically of the high-frequency type resulting in a characteristic bifid compliance curve by tympanometry.
   5. Later hearing loss becoming mixed in type and surgical intervention may be less successful.
7. Skin and joint abnormalities:
   1. Mild joint hypermobility
   2. Easy bruising
   3. Thinner translucent skin
   4. Capillary fragility
   5. Inguinal or umbilical hernia
   6. Flat feet
   7. Joint dislocation
   8. Poorly developed muscles
   9. Decreased thrombocyte function leading to increased bleeding
8. Cardiovascular abnormalities:
   1. Mitral valve prolapse
   2. Aortic valvular insufficiency
   3. Slightly larger than normal aortic root diameter without significant risk of progression to dissection, identified in a small number of patients
   4. Increased bleeding tendency secondary to increased capillary fragility
9. Prognosis:
   1. Usually normal stature but may lose some height in later decades due to spine involvement.
   2. In general, with good orthopedic cares, fractures heal quickly without deformities.
   3. No decrease in fertility or longevity in affected individuals.

2. OI type II (perinatal lethal type) (Sillence et al. 1984):
   1. Lethality during perinatal period resulting from:
      1. Pulmonary insufficiency
      2. Congestive heart failure
      3. Infection

2. Prenatal history:
    1. Intrauterine growth retardation (dwarfism, low birth weight)
    2. Prematurity
    3. Nonimmune hydrops
3. Short-limbed dwarf
4. Characteristic craniofacial features:
    1. Extremely soft calvarium
    2. Dark-blue sclerae
    3. Beaked nose
    4. Micrognathia
5. Chest:
    1. Very small
    2. Beaded ribs
    3. Lung hypoplasia
6. Extremities:
    1. Short and deformed limbs
    2. Bowed legs
7. Hip: flexed and abducted (frog position)
8. Prognosis: death resulting from pulmonary insufficiency, congestive heart failure, or infection:
    1. Usually during the first few hours of life
    2. More than 60% of infants with OI type II during the first day
    3. Eighty percent within the first month
    4. Rare survival beyond a year

3. OI type III (progressively deforming type) (Sillence et al. 1986; Biggin and Munns 2014):
    1. Dwarfism and moderate deformities resulting from in utero fractures, detectable on antenatal ultrasound scan.
    2. The most severe form of OI that is associated with long-term survival.
    3. Craniofacial features:
        1. Typical triangular faces
        2. Relatively large cranium
        3. Grey sclera
    4. Fractures:
        1. Very common
        2. Progressive long bone deformities with growth
        3. Marked deformities of most bones
    5. Significant kyphoscoliosis leading to cardiopulmonary insufficiency, a major cause of early death in these individuals.
    6. Sclerae
        1. Often pale blue at birth
        2. Generally becomes normal hue by puberty
    7. Abnormal dentinogenesis involving both primary and permanent teeth: common.
    8. Hearing loss: common.
    9. Prognosis:
        1. Death resulting from cardiac decompensation, pulmonary insufficiency, or basilar impression with compression of the brain stem
        2. Long-term survival possible with multiple fractures and deformities
        3. Primary objective to lead a satisfying and productive life
        4. Major limitations (severe bone fragility and deformity, muscle weakness, joint contractures that develop from inactivity, progressive scoliosis resulting in life-threatening cardiopulmonary decompensation, marked short stature)
4. OI type IV (moderately severe type) (Biggin and Munns 2014):
    1. Significant intrafamilial and interfamilial phenotypic variation.
    2. Fractures:
        1. Occurring in utero, during labor and delivery, or in the newborn period.
        2. Fractures at birth, not observed in all affected infants.
        3. Some affected infants with only mild femoral bowing.
        4. Early recognition of these fractures is essential to prevent accusation of child abuse when the first fractures occur, and the previous, now healed, fracture (s) is/are detected by routine skeletal survey.
    3. Variable short stature.
    4. Normal white or grayish sclera.
    5. Occasional hearing loss.
    6. Common dentinogenesis imperfecta.
    7. Mild to moderate bone deformity.
    8. Severe kyphoscoliosis may compromise cardiopulmonary function.

9. Prognosis:
    1. Life span near normal in the absence of severe cardiopulmonary complications
    2. Treatment objectives (to minimize the long-term complications of kyphoscoliosis and to assure independence and mobility)
5. OI type V (Biggin and Munns 2014):
    1. Represents 4–5% of the OI population seen in hospitals (Rauch and Glorieux 2004)
    2. Moderate to severe bone fragility (Glorieux et al. 2000)
    3. Does not have blue sclera or dentinogenesis imperfecta
    4. Distinctive clinical features:
        1. Common occurrence of radial head dislocation/subluxation and calcification of the interosseous membrane between the radius and ulna (Lee et al. 2006; Fassier et al. 2007).
        2. Frequent development of hypertrophic calluses at fracture sites.
        3. Early calcification of the interosseous membranes between the bones of the forearm, limiting pronation, and supination.
        4. Normal scleral color.
        5. Presence of a radio-opaque metaphyseal band immediately adjacent to the growth plates on x ray.
        6. Upon histological examination, the bone organization has an irregular mesh-like appearance, clearly distinct from the normal lamellar pattern seen in OI types I and IV (Cheung et al. 2007).
    5. The calcified interosseous membrane often severely limits the pronation/supination of the hand and may lead to secondary dislocation of the radial head.
    6. The hyperplastic callus that may develop after fractures or surgical interventions may mimic osteosarcoma.
6. OI type VI (Biggin and Munns 2014):
    1. Moderate to severe skeletal deformities: may represent in approximately 4% of moderately to severely affected OI patients (Rauch and Glorieux 2004).
    2. Clinically indistinguishable from OI type IV.
    3. Lack blue sclera or dentinogenesis imperfecta and Wormian bones of the skull (Glorieux et al. 2002).
    4. Inheritance: autosomal recessive.
    5. Distinctive histological features: The hallmark is abnormal bone mineralization on histological examination:
        1. A characteristic "fish-scale" pattern of the bone lamellation on bone histology (Glorieux et al. 2002).
        2. The presence of excessive osteoid accumulation on bone-forming surfaces, suggesting a mineralization defect reminiscent of osteomalacia, but there is no abnormality in mineral homeostasis, and growth plate mineralization proceeds normally.
7. OI type VII:
    1. Moderate to severe skeletal deformities and bone fragility.
    2. Lacks blue sclera and dentinogenesis imperfecta.
    3. Coxa vara may be present even in infancy.
    4. Distinctive clinical feature: rhizomelic shortening of the humerus and femur.
    5. "Popcorn" epiphyses often seen in severe forms.
    6. To date, only been observed in a community of Native Americans in northern Quebec, where it exhibits autosomal recessive inheritance.
8. OI type VIII (Shapiro and Sponsellor 2009):
    1. Severe, lethal form
    2. Seen in South African blacks
    3. "Popcorn" epiphyses often seen in severe forms
9. Establishing a diagnosis (Basel and Steiner 2009): The following list of features would be typical in an individual presenting with OI:
    1. Family history of OI or recurrent fractures.
    2. Fractures with minimal or no trauma in the absence of other factors, such as inflicted physical abuse or other known disorders of bone.
    3. Short stature or stature shorter than predicted based on stature of unaffected

family members, often with bone deformity.
4. Blue sclera.
5. Dentinogenesis imperfecta.
6. Progressive, postpubertal hearing loss.
7. Ligamentous laxity and other signs of connective tissue abnormality.
8. Family history of OI, usually consistent with autosomal dominant inheritance.
9. Fractures of varying ages and stages of healing, often of the long bones but may also involve ribs and skull. The metaphyseal chip fractures characteristic of child physical abuse can be seen in a small number of children with OI.
10. "Codfish" vertebrae, which are the consequence of spinal compression fractures, seen primarily in the adult.
11. Wormian bones, defined as "sutural bones that are 6 mm by 4 mm (in diameter) or larger, in excess of 10 in number, with a tendency to arrangement in a mosaic pattern." Wormian bones are suggestive of, but not pathognomonic for, OI. They are present in up to 60% of affected children.
12. Protrusio acetabuli, in which the socket of the hip joint is too deep and the acetabulum bulges into the cavity of the pelvis causing intrapelvic protrusion of the acetabulum.
13. Low bone density detected by dual energy X-ray absorptiometry. There seems to be a correlation between bone mineral density and fracture risk in OI (Huang et al. 2006; Bachrach 2007).

10. Differential diagnosis (Basel and Steiner 2009):
    1. In utero: Prenatal ultrasound examination of severe OI may lead to following skeletal dysplasias which all present with relative macrocephaly and rhizomelic shortening of the limbs (OI type II with ultrasound findings of crumpled long bones and beaded ribs):
        1. Hypophosphatasia
        2. Thanatophoric dysplasia
        3. Campomelic dysplasia
        4. Achondrogenesis
    2. Infancy and childhood:
        1. Nonaccidental trauma (child abuse) (Ricci and Botash 2001)
        2. Infantile hypophosphatasia: See the chapter on "► Hypophosphatasia."
        3. Bruck syndrome:
            1. An autosomal recessive condition.
            2. Bone fragility.
            3. Congenital joint contractures.
            4. Clubfeet.
            5. Normal or blue sclera.
            6. Wormian bones.
            7. It results from defects in the lysyl hydroxylase (PLOD2) that hydroxylates the amino-terminal lysyl residues involved in crosslink formation.
        4. Osteoporosis pseudoglioma syndrome:
            1. Bone fragility and fractures
            2. Other skeletal deformities
            3. Pseudoglioma with blindness in infancy
            4. Other anomalies
            5. Caused by mutations in the gene encoding the lipoprotein receptor-related protein
        5. Cole-Carpenter syndrome:
            1. Bone deformities
            2. Multiple fractures
            3. Ocular proptosis
            4. Shallow orbits
            5. Orbital craniosynostosis
            6. Frontal bossing
            7. Hydrocephalus
        6. Hadju-Cheney syndrome:
            1. Short stature
            2. Failure to thrive
            3. Conductive hearing loss
            4. Dysmorphic features
            5. Early tooth loss
            6. Genitourinary anomalies
            7. Osteopenia
            8. Pathologic fractures
            9. Wormian bones
            10. Failure of suture ossification
            11. Basilar impression
            12. Vertebral abnormalities
            13. Kyphoscoliosis

14. Cervical instability
15. Joint laxity
16. Dislocation of the radial head
17. Long-bowed fibulae
18. Pseudoclubbing
19. Short distal digits
20. Acroosteolysis
21. Hirsutism

7. Gerodermia osteodysplastica:
   1. Dwarfism
   2. Lax skin
   3. Osteoporosis
   4. Wormian bones
   5. Fractures
   6. Vertebral compression
   7. Wizened facial appearance because of facial skin laxity
8. Idiopathic juvenile osteoporosis:
   1. Typically presents in preadolescents with fractures and osteoporosis.
   2. The fracture susceptibility and osteoporosis usually resolve spontaneously with puberty.
   3. The etiology is unknown.
9. Dentinogenesis imperfecta: can occur separately from OI as an isolated familial condition as a result of mutations in the DSPP gene on chromosome 4

11. Importance of diagnosis in the newly affected infant for whom there is no family history (Kleinman 1990):
   1. To facilitate genetic counseling
   2. To reassure the family about prognosis
   3. To remove the concern of child abuse in some families (Steiner et al. 1996):
      1. Fractures considered "highly specific" for child abuse: present in 33% (2/6) of cases with OI:
         1. Metaphyseal fractures
         2. Posterior rib fractures
         3. Scapular spinous process
         4. Sternal fractures
      2. Fractures considered "moderately specific" for abuse: present in 50% (3/6) of cases with OI:
         1. Multiple fractures, especially bilateral
         2. Fractures of different ages
         3. Epiphyseal separations
         4. Digital fractures
         5. Complex skull fractures
      3. Fractures considered "low specificity" for child abuse: present in 17% (1/6) cases of OI:
         1. Clavicular fractures
         2. Long bone shaft
         3. Linear skull fractures
   4. General signs of child abuse:
      1. Multiple fractures as described
      2. Clinical findings highly indicative of child abuse:
         1. Retinal hemorrhage
         2. Cephalohematoma
         3. Subdural hemorrhage
         4. Evidence of bodily abuse (bruises, lacerations, burns)
         5. Evidence of sexual abuse
      3. Incompatible history with physical examination
      4. History of domestic violence, corporal punishment, and child maltreatment
   5. Useful for families to have a letter from the child's physician stating the diagnosis of the osteogenesis imperfecta

Diagnostic Investigations

1. Radiography (Spranger et al. 2002):
   1. OI type I:
      1. None to multiple fractures with little bone deformities
      2. Fractures primarily in long bones (may occur with minimal trauma, decreased dramatically in puberty, increase at later ages, normal healing with callus formation)
      3. Osteopenia (generalized demineralization) which can be documented by densitometry
      4. Thin bones (cortices)
      5. Little trabeculae with fragility
      6. Bowing
      7. Platyspondyly

8. Retarded ossification of the cranial vault with multiple Wormian bones
9. Flattening of vertical axis
10. Widening in the transverse axis of the skull
11. Small facial bones
12. Susceptible to osteoporosis and compression fractures of the vertebrae
13. Pectus carinatum/excavatum

2. OI type II (Thompson et al. 1987; Sillence 1988):
   1. Short-limbed dwarfism
   2. Rhizomelic limb shortening
   3. Severely retarded (virtual absence) calvarial mineralization
   4. Generalized osteoporosis
   5. Multiple fractures with callus formation
   6. Small chest
   7. Beaded and broad ribs
   8. Shortened crumpled long bones especially compressed ("telescoped" or "accordion-like") femurs and/or humeri
   9. Externally rotated and abducted femurs
   10. Bowed lower legs
   11. Angulated tibiae
   12. Usually flexed and abducted hip (frog-leg position)
   13. Flattened acetabulae and iliac wings
   14. Platyspondyly
   15. Type IIA: short and squared tubular bones, continuous beading of the ribs
   16. Type IIB/III: thicker tubular bones, compressed vertebrae, better ossification of the cranial bones, more normally appearing ribs and scapulae
   17. Type IIC: thin, deformed tubular bones, severely twisted long tubular bones
3. OI type III:
   1. Undermineralized calvarium with a large fontanel and Wormian bones
   2. Initially normal or mildly shortening long bones
   3. Fractures present at birth or during the first year of life with evidence of deformity
   4. Thin gracile ribs prone to fracture
   5. Gracile long bones showing evidence of intrauterine fractures with callus formation
   6. Marked angulation or bowing of long bones (especially tibias and femurs, reducing the efficiency of weight bearing and increasing the likelihood of fracture)
   7. "Accordion-like" short and deformed femurs
   8. Later metaphyseal and diaphyseal widening with "popcorn" calcification appearance of cystic metaphyses
   9. Codfish appearance of vertebrae
   10. Fractures with minimal trauma and progressive deformities
   11. Severe and generalized osteopenia
4. OI type IV:
   1. Bowed femurs in the newborn period but tend to straighten with time
   2. Osteopenia/osteoporosis
   3. Thin bones
   4. Fractures with deformities
   5. Scoliosis

2. Bone density analysis:
   1. Still experimental
   2. Dual energy X-ray absorptiometry (DEXA)
3. Bone histology:
   1. Thin cortices
   2. Decreased trabecular bone volume
   3. Smaller apatite crystals
   4. Defective microvascular system
   5. Defective collagen fibril diameter
4. Biochemical analyses (Sillence 1981).
5. Collagen synthesis analyses by cultured fibroblasts from skin biopsy. In OI type I, about half the normal amount of type I procollagen is synthesized.
6. Gene sequence analysis (Basel and Steiner 2009): Genomic DNA can be isolated from peripheral leukocytes in blood or from any other tissue samples:
   1. Sequence analysis of *COL1A1* and *COL1A2* cDNA to detect mutations in the coding sequence and sequence analysis of *COL1A1* and *COL1A2* genomic DNA to detect mutations that alter either sequence

or stability of mRNA identify between 80% and 85% of mutations in the type I collagen genes.
2. The mutations in most families are unique; only a few recurrent mutations (mostly CpG dinucleotides) are seen in more than one family.
3. Mutation detection rate varies by COLA1-related OI type; a comprehensive database of all 850 known mutations has been published along with a genotype-phenotype correlation.
4. For patients in whom no collagen type I mutation is identified, sequencing of *CRTAP* and *LEPRE1* is available commercially and is a reasonable next step in sequential sequencing to identify a mutation.
5. The importance of identifying these mutations is to establish a genetic risk for future offspring as the parents of an affected individual would be at a 25% risk of conceiving another child with the disorder, and it would be imperative for them to be counseled accurately, and adequately, of antenatal services available to them.

Genetic Counseling

1. Recurrence risk for OI I:
    1. Patient's sib: not increased unless a parent is affected or with gonadal mosaicism
    2. Patient's offspring:
        1. Fifty percent affected if an affected parent marrying a normal spouse.
        2. Twenty-five homozygously affected infant (likely to be perinatally lethal or severely affected) if both parents are affected with OI type I.
2. Recurrence risk for OI II:
    1. Patient's sib: an empiric recurrence risk of 2–3% to 6–7% among siblings resulting from parental mosaicism for the mutation that is lethal in the infant who is heterozygous for the same mutation or due to the rare recessive form (Cohn et al. 1990; Cole and Dalgleish 1995; Lund et al. 1996)
    2. Patient's offspring: none surviving beyond infancy
3. Recurrence risk for OI III (also called type IIB):
    1. Patient's sib:
        1. Autosomal dominant form: not increased unless a parent is affected or with gonadal mosaicism
        2. Autosomal recessive form: 25%
        3. An empiric recurrence risk of 7–8% (germinal mosaicism, homozygosity of *COL1A2* mutations, and autosomal recessive inheritance)
    2. Patient's offspring:
        1. Autosomal dominant form: 50%
        2. Autosomal recessive form: not increased unless a spouse is a carrier or affected
4. Recurrence risk for OI IV:
    1. Striking intrafamilial variability making clinical classification difficult for OI IV, OI III, or OI I
    2. Patient's sib: not increased unless a parent carries gonadal mosaicism
    3. Patient's offspring:
        1. Fifty percent when an affected parent marrying a normal spouse
        2. Rare possibility of having children with lethal OI phenotype by a parent with OI IV as a consequence of parental mosaicism for the lethal mutations
5. Prenatal diagnosis (Pepin et al. 1997):
    1. OI type I:
        1. Identification of the mutant allele including segregation studies with an appropriate family structure (Lynch et al. 1991)
        2. Identification of the COL1A1 null-allele in mRNA from the fetus (Nuytinck et al. 1999)
        3. Direct identification of the mutation (CVS at 11–12 weeks gestation)
        4. Recognition of fracture or bowing of long bones by ultrasound
    2. Type II:
        1. Diagnosis by prenatal ultrasonography accomplished between 14 and 18 weeks

gestation (short femurs, fractures, small thoracic cage, minimal calvarial mineralization, or polyhydramnios)
2. Analysis of chorionic villi for the presence of abnormal collagens
3. Analysis of collagens synthesized by cells grown from chorionic villi
4. Direct mutation analysis in families of an identified DNA mutation in a previously affected infant

3. Type III:
1. Diagnosis by prenatal ultrasonography not feasible until 20–22 weeks gestation
2. Direct mutation analysis of collagens synthesized by chorionic villus cells or DNA isolated directly from the tissue

4. Type IV:
1. Linkage analysis with *COL1A2* polymorphisms in the dominant families
2. Direct mutation analysis
3. Analysis of proteins produced by cells grown from CVS biopsies
4. Little value of ultrasound analysis because of the late appearance of short or deformed bones

5. *CRTAP*-related OI and *LEPRE1*-related OI: Prenatal diagnosis is available provided the mutations are previously identified in the family member.

6. Management (Cole 1988, 1993; Lee et al. 2001; Biggin and Munns 2014):
1. Improving bone mass:
1. Use of bisphosphonates (cyclic intravenous pamidronate) to decrease the resorption of bone and to increase the formation of bone (Bembi et al. 1997; Glorieux 2000). Hopefully, early commencement of bisphosphonate treatment will prevent serious deformities (Plotkin et al. 2000).
2. Bisphosphonate therapy does not constitute a cure of OI, but is an adjunct to physiotherapy, rehabilitation, and orthopedic care. These drugs have brought clear improvement to the lives of patients suffering from moderate to severe OI. In contrast, children and adolescents with OI who have few fractures and no functional limitations have less to gain from treatment. It therefore appears advisable not to treat such patients unless clinical benefit can be demonstrated in placebo-controlled studies (Glorieux 2008).
3. Use of bone marrow transplantation as means of introducing normal mesenchymal stromal cells that have the capacity to differentiate into normal osteoblasts (Horwitz et al. 2001).

2. Fractures:
1. Meticulous orthopedic care.
2. Corrective osteotomies.
3. Intramedullary roddings to improve mobility, prevent fractures, and correct and prevent progressive deformity.
4. Avoid unnecessary immobilization.
5. Avoid malunions.

3. Progressive scoliosis in adolescence requires spinal fusion with instrumentation.

4. Orthotics:
1. To stabilize lax joints such as the ankle and subtalar joints
2. To prevent progressive deformities and fractures
3. Commonly used devices include ankle-foot, knee-ankle-foot, and forearm orthoses

5. Recognition and management of hearing loss

6. Care of dentinogenesis imperfecta

7. Psychologic care

8. Physical therapy and comprehensive rehabilitation (Binder et al. 1993)

9. Novel therapies on the horizon:
1. Denosumab: a RANKL antibody that has been shown to reversibly reduce bone resorption in four children with OI VI (Semler et al. 2012).
2. Sclerostin antibody: to stimulate osteoblasts via the canonical Wnt signaling pathway. In a murine model of moderate severe OI, 2 weeks of sclerostin antibody therapy resulted in improved bone mass and reduced long-bone fragility (Sinder et al. 2013).

10. Prenatal and postnatal transplantation of mesenchymal stem cells to treat OI: limited experience (Chan and Götherström 2014; Götherström et al. 2014):
    1. Prenatal transplantation of allogeneic MSC in OI is safe. The cell therapy is of likely clinical benefit with improved linear growth, mobility, and reduced fracture incidence. Unfortunately, the effect is transient. For this reason, postnatal booster infusions using same-donor MSC have been performed with clinical benefit and without any adverse events.

Fig. 1 A boy with osteogenesis imperfecta type I showing blue sclera

Fig. 2 (**a**–**c**) Familial osteogenesis imperfecta type I in two sibs. Radiographs show fracture of a femur in the boy and that of humerus in the girl. Their father is also affected. Molecular testing revealed c.578^579insC of COL1A1 gene mutation in this family

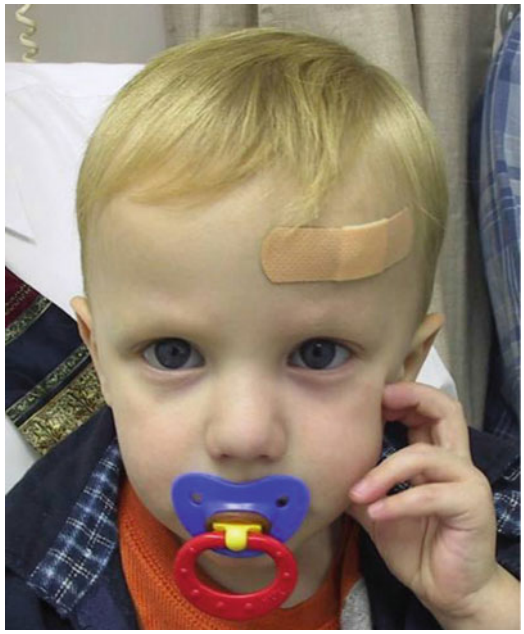

Fig. 3 A 22-month-old boy with osteogenesis imperfecta type I showing blue sclera. He has heterozygous mutation Arg75Stop of the COL1A1 gene by molecular genetic analysis

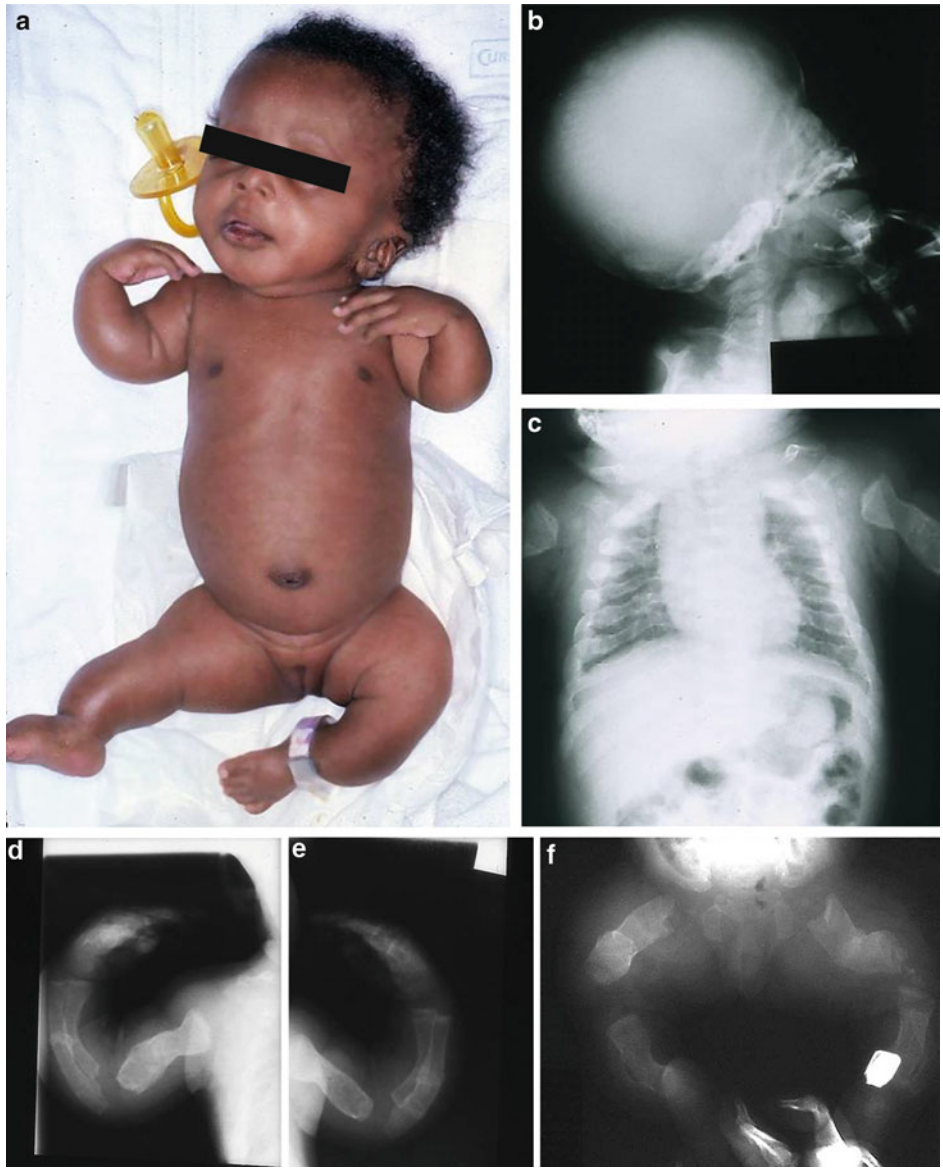

Fig. 4 (**a**–**f**) An infant with osteogenesis imperfecta type II showing severe dwarfism, characteristic craniofacial features, short and deformed limbs, and bowed legs. Radiographs showed short-limb dwarfism, rhizomelic limb shortening, severely retarded calvarial mineralization, multiple fractures with callus formation, beaded and broad ribs, and "telescoped" femurs and humeri

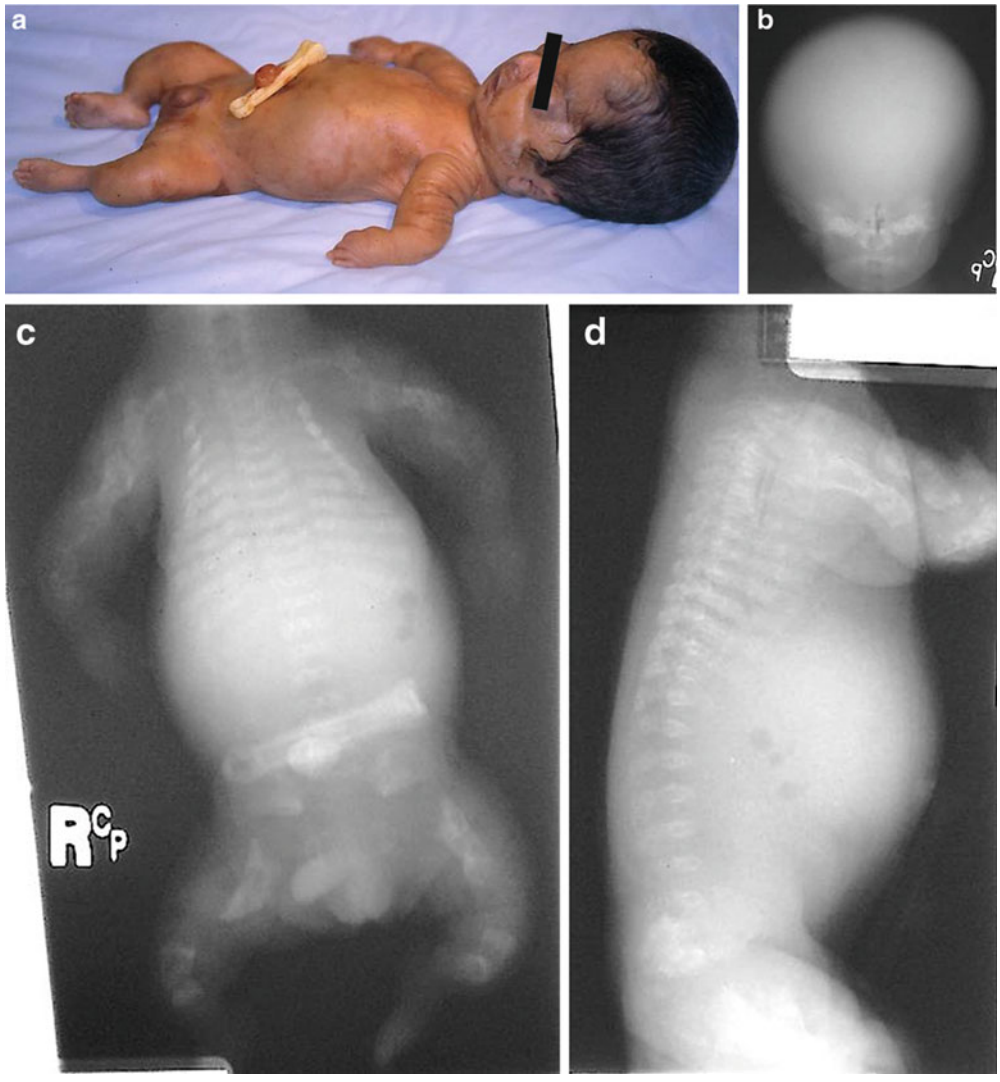

Fig. 5 (**a**–**d**) Another case of osteogenesis imperfecta type II showing the similar features

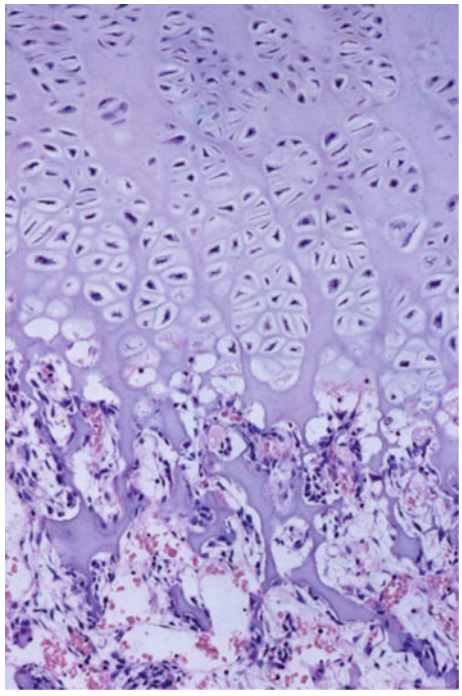

Fig. 6 Photomicrograph of rib of another case with type II osteogenesis imperfecta. The columns of cartilage in the metaphysis are covered by minimal amounts of basophilic primitive woven bone. Normal ossification is absent. The physeal growth zone is moderately disorganized

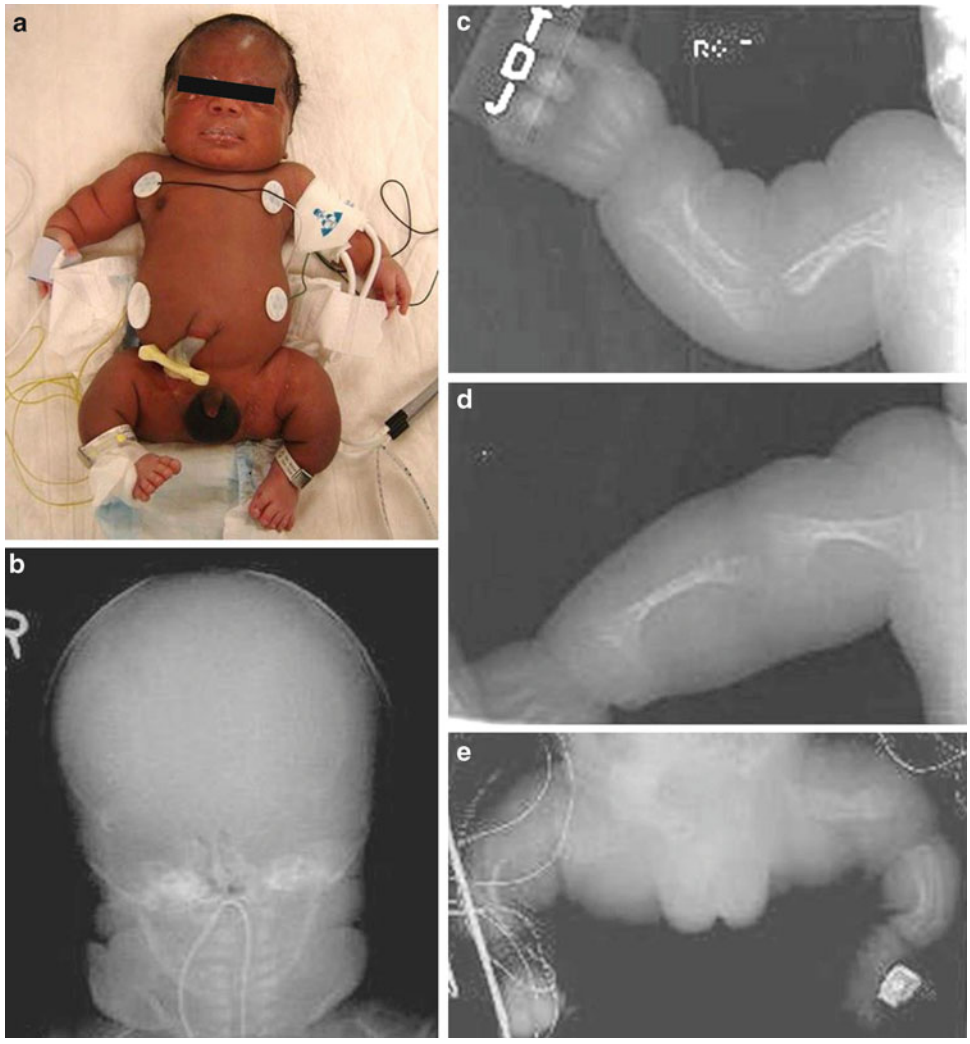

Fig. 7 (**a**–**e**) A neonate with osteogenesis type III showing short-limbed dwarfism, large head, short neck, short thigh, and curbed lower legs. Radiographs showed generalized osteopenia; poor mineralization of the skull; thin ribs with sixth, seventh, and eighth rib fractures with callus formation; short limbs; and bowed femurs with multiple fractures with callus formation. Molecular study showed heterozygous mutation of COL1A2 gene (del of three base pairs [GTT] at cDNA position c.763–765). This mutation has been reported in patients with osteogenesis imperfecta type III

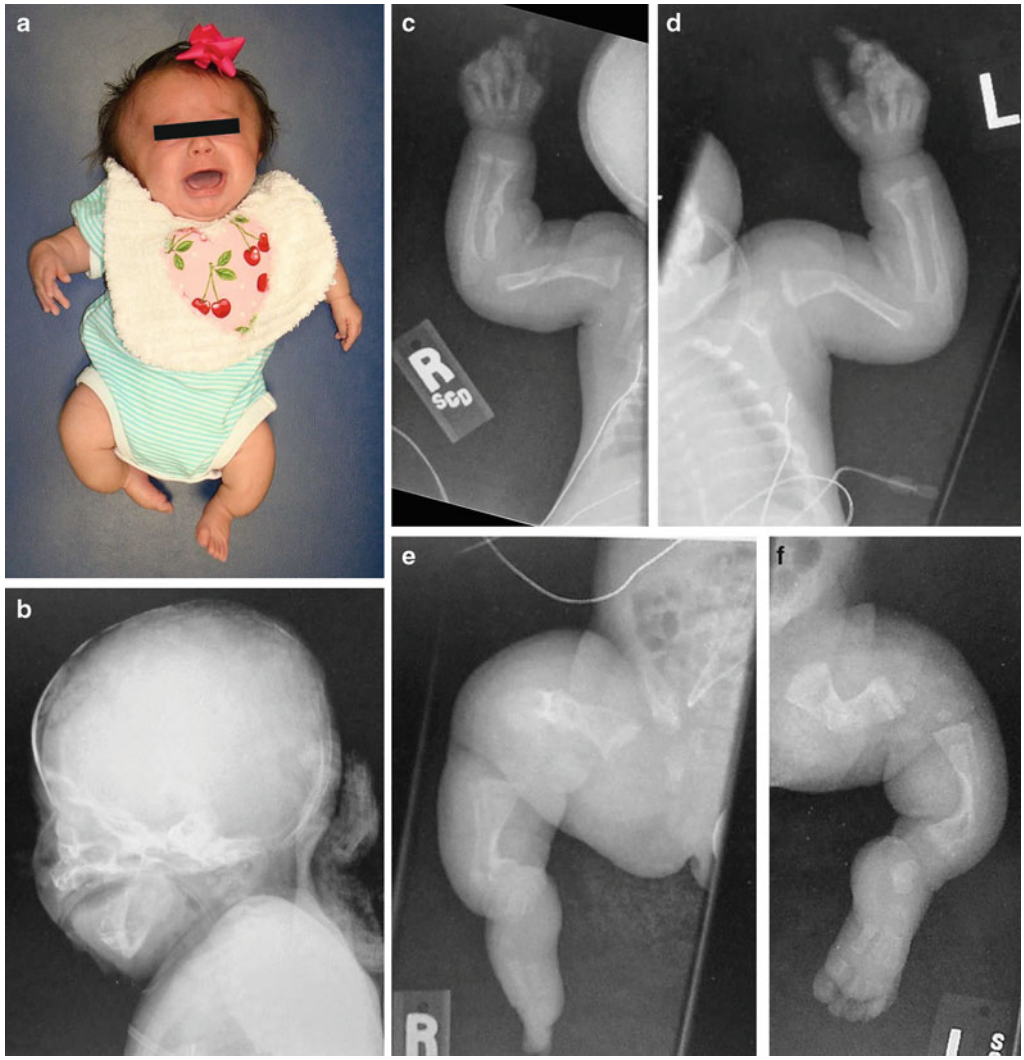

Fig. 8 (**a**–**f**) A neonate with osteogenesis type III showing short-limbed dwarfism, large head, short neck, and short and curbed upper and lower extremities. Radiographs showed generalized osteopenia, poor mineralization of the skull, and short and bowed limbs with multiple fractures with callus formation. Molecular study by sequence analysis indicated a variation in the fragment containing exon 21 and the flanking sequences of the *COL1A2* gene. Sequencing revealed a nucleotide G to A substitution that converted a codon for glycine-289 (GGA) to a codon for glutamic acid (GAA) at cDNA position c.866. The patient thus showed a heterozygous mutation of *COL1A2* gene (Gly289Glu). This mutation has not been reported previously

Fig. 9 (**a**–**h**) Three other infants with osteogenesis imperfecta type III showing dwarfism, moderate deformities resulting from in utero fractures, and typical triangular face with relatively large cranium. Radiographs showed undermineralized calvarium with a large fontanel and marked angulation or bowing of long bones, especially tibias and femurs

Fig. 10 An infant girl with osteogenesis imperfecta type IV

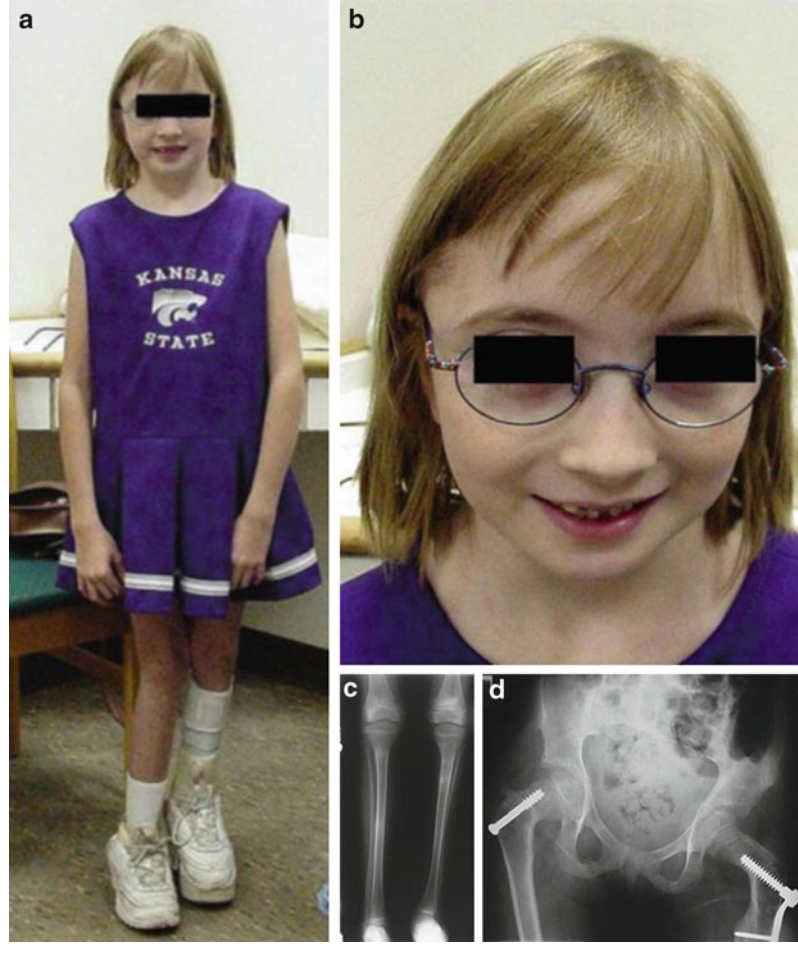

Fig. 11 (**a**–**d**) A girl with Cole-Carpenter syndrome showing ocular proptosis, craniosynostosis, and bone fragility with fractures

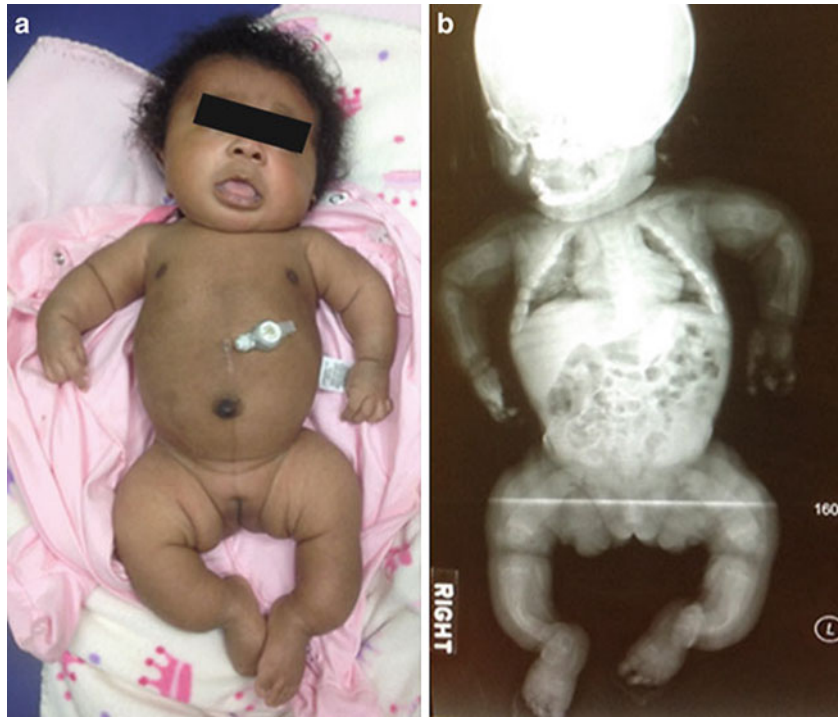

Fig. 12 (**a**, **b**) This 7-month-old female infant (**a**) was evaluated for osteogenesis imperfecta. Prenatal ultrasound showed short fetal bones. Chromosome microarray and chromosome analyses from amniotic fluid were normal. At birth, she was noted to have severe dwarfism, blue sclera, short neck and thorax, and short and deformed limbs. Radiograph (**b**) showed general osteoporosis, short-limb dwarfism, short neck and thorax, beaded and short ribs, "telescoped" humeri and femurs, and angulated tibiae. The *COL1A1/COL1A2* gene analysis showed no deletion or duplication. Individuals with OI type V, VI, VII, or VIII have mutations genes other than COL1A1 or COL1A2 (Byers and Pyott 2012; Shapiro et al. 2013). Apparent homozygosity for a mutation (c.1080 + 1G > T, or IVS5 + 1G > T) in *LEPRE1*, the gene that encodes prolyl 3-hydroxylase 1 (P3H1), was identified in this patient, confirming the diagnosis of type VIII osteogenesis imperfecta (Collaboration with Dr. Susanne Ursin)

Osteogenesis Imperfecta/Ehlers-Danlos Syndrome Overlap Syndrome

Contents

Helical mutations near the amino (N)-proteinase cleavage site have been suggested to result in a mixed osteogenesis imperfecta (OI)/Ehlers-Danlos syndrome (EDS) phenotype (Malfait et al. 2013).

Synonyms and Related Disorders

Ehlers-Danlos syndrome; Mixed OI/EDS phenotype; Osteogenesis imperfecta

Genetics/Basic Defects

1. Most of the patients studied harbored a *COL1A1*/*COL1A2* mutation residing within the most N-terminal part of the type I collagen helix (Nicholls et al. 1992; Feshchenko et al. 1998; Raff et al. 2000; Cabral et al. 2005) (Malfait et al. 2013).
2. These mutations affect the rate of type I collagen N-propeptide cleavage and disturb normal collagen fibrillogenesis.

Clinical Features

1. Mainly present as EDS signs (Malfait et al. 2013)
    1. Severe joint hyperlaxity
    2. Soft and hyperextensible/translucent skin
    3. Abnormal wound healing
    4. Easy bruising
    5. Mild abnormal scarring
    6. Sometimes signs of arterial fragility
2. Show only subtle signs of OI
    1. Blue sclera
    2. Osteopenia
    3. Fractures
    4. Relatively short stature
3. Hypotonia
4. Clinical overlap with other EDS subtypes, including the classic, hypermobility, vascular, arthrochalasis, and kyphoscoliosis types

Diagnostic Investigations

1. Biochemical collagen analysis: a powerful tool necessary to establish the diagnosis because of clinical overlapping with other EDS subtypes
2. Molecular sequencing of *COL1A1* and *COL1A2*: allows identification of

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_265

heterozygous mutations in the triple helical region close to the procollagen type I N-proteinase cleavage site (Malfait et al. 2013)

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: if a parent of the proband is affected, the risk to each sib is 50%.
   2. Patient's offspring: a 50% chance of inheriting the mutation and developing the disorder.
2. Prenatal diagnosis: has not been accomplished.
3. Management: please see the chapters of osteogenesis and Ehlers-Danlos syndrome.

Fig. 1 (**a**–**c**) This 3-year-old Caucasian boy was evaluated for collarbone fractures, blue sclera, hypotonia, and hypermobile joints and to rule out osteogenesis imperfecta. He was noted to have hyperextensible fingers/wrists, knees, and ankles and bruise throughout the body. COL1A2 sequencing identified c.432 + 4_432 + 5insAA in one allele of COL1A2, the gene that encodes the pro-alpha 2 (I) chain of type I procollagen. The reference laboratory was able to characterize the outcome of splicing to have resulted in skipping of exon 9 and a mixed osteogenesis imperfecta and Ehlers-Danlos syndrome phenotype with fractures and joint hypermobility.

Osteopetrosis

Contents

Osteopetrosis is a heterogeneous group of sclerosing bone diseases due to impaired bone and cartilage resorption, resulting from absence or defective function of osteoclasts (Steward 2003). The overall incidence of these conditions is difficult to estimate, but autosomal recessive osteopetrosis has an incidence of 1 in 250,000 births, and autosomal dominant osteopetrosis has an incidence of 1 in 20,000 births (Stark and Savarirayan 2009).

Synonyms and Related Disorders

Autosomal dominant osteopetrosis type I; Autosomal dominant osteopetrosis type II (Albers-Schőnberg disease); Hereditary sclerosing bone dysplasias; Infantile malignant osteopetrosis; Marble bone disease; Osteopathia striata (Voorhoeve disease); Osteoclast-poor osteopetrosis; Osteopetrosis congenita (malignant osteopetrosis) (Carolino et al. 1998); Osteopetrosis tarda (benign adult form of osteopetrosis)

Genetics/Basic Defects

1. Inheritance of recognized subtypes of human osteopetrosis: genetic heterogeneity (Stark and Savarirayan 2009; Kocher and Kasser 2003; Steward 2003, 2010; Coudert et al. 2015)
    1. Chloride channel CLCN7 mutations: responsible for severe recessive, dominant, and intermediate osteopetrosis (Frattini et al. 2003; Sobacchi et al. 2016)
        1. Autosomal recessive osteopetrosis (ARO)
            1. Classic (infantile malignant osteopetrosis) (vacuolar proton pump deficiency (*ATP6i*/*TCIRG1*) (locus 11q13.3-q13.5)): mutations in the gene encoding the a3 subunit of the proton pump are a rather common cause of infantile malignant osteopetrosis (Kornak et al. 2000)
            2. Neuropathic (osteopetrosis and infantile neuroaxonal dystrophy): CLC7 (chloride channel 7) chloride pump deficiency (loss of function *CLCN7* mutations) (locus 16p13.3) (Campos-Xavier et al. 2003) and *OSTM1* mutations cause an extremely severe form of autosomal recessive osteopetrosis with frequent

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_186

CNS involvement (Pangrazio et al. 2006)

3. Autosomal recessive osteopetrosis with renal tubular acidosis (Jacquemin et al. 1998)
   Caused by mutations in *CA2*, the gene encoding carbonic anhydrase II
   Generalized osteosclerosis
   Cerebral calcifications
   Associated with intellectual disability
4. Autosomal recessive osteopetrosis secondary to *PLEKHM1* mutations: mild phenotype and can regress with increasing age (van Wesenbeeck et al. 2007). A relatively malignant form of osteopetrosis was reported to be caused by *PLEKHM1* gene (Bo et al. 2016)

2. More benign osteopetrosis primarily affecting adults: two subtypes based on radiographic features
   1. Autosomal dominant osteopetrosis (ADO) type I (locus 11q12-13) (Van Hul et al. 2002)
   2. Autosomal dominant osteopetrosis (ADO) type II (Albers-Schönberg disease): Genetically homogeneous because of a single gene on chromosome 16p13.3 (Bénichou et al. 2001): caused by *CLCN7* mutations (Waguespack et al. 2003). Because some ARO patients have mutations in both copies of the *CLCN7* gene, ADO II is allelic with a subset of ARO cases (Cleiren et al. 2001). 1p21 is probably a minor locus in ADO II (Bénichou et al. 2000a)
3. Intermediate recessive osteopetrosis (IRO): Children presenting beyond 2 years of age often have a slower progressive disease
   1. An autosomal recessive disease with milder mutations: carbonic anhydrase isoenzyme type II deficiency (CAII) and *CLCN7* mutations (Bénichou et al. 2001)
   2. Early diagnoses of the more severe end of the autosomal dominant spectrum

2. Gene mutated in osteopetrotic patients (Coudert et al. 2015)
   1. *TCIRG1* (loss of function; α3 subunit V-ATPase)
   2. *CLCN7* (loss of function; chloride channel 7)
   3. *OSTM1* (loss of function; osteopetrosis associated transmembrane protein)
   4. *PLEKHM1* (loss of function; pleckstrin homology domain containing family M, member I): ARO
   5. *SNX10* (loss of function; sorting nexin 10): ARO
   6. *TNFSF11* (loss of function; receptor activator for nuclear factor κB ligand): ARO
   7. *TNFRSF11A* (loss of function; receptor activator for nuclear factor κB): ARO
   8. *CAII* (loss of function; carbonic anhydrase II): IRO
   9. *CLCN7* (dominant negative; chloride channel 7): ADO II
3. RANKL deficiency (Askmyr et al. 2008)
   1. Recently discovered in a screen of 40 patients with recessive osteopetrosis with unknown genetic defects (Sobacchi et al. 2007)
   2. Characterized by a decrease in osteoclast numbers
   3. Less severe with a slower progression than the classical malignant forms of osteopetrosis
   4. The gene that is mutated encodes RANKL, one of the osteoclast-promoting cytokines produced by stromal cells in the bone marrow
4. Osteopetrosis associated with ectodermal dysplasia, lymphedema, and immunodeficiency
   1. X-linked (Smahi et al. 2002)
   2. Resulting from a hypomorphic mutation in IKBKG [also known as NEMO (NF-kB essential modulator)]
   3. Most hypomorphic mutations do not cause osteopetrosis but mild ectodermal dysplasia and immunodeficiency in males
5. Osteopetrosis with agenesis of corpus callosum: autosomal recessive

6. Dysosteosclerosis
    1. Autosomal recessive
    2. X-linked also reported
2. Basic defects: Absence or defective function of osteoclasts results in defective remodeling of bone with partial or complete obliteration of marrow cavities, producing bone which is dense but has an increased tendency to fracture
3. Potential clinical consequences of aberrant resorption and remodeling of bones caused by defective osteoclast function (Steward 2010)
    1. Fractures
        1. Undertubulated bones break easily
        2. Common fracture sites (Cheow et al. 2001)
            1. Long bones of the arms and leg
            2. Posterior ribs
            3. Acromial processes
    2. CNS and eye involvements (Abinun et al. 1999; Steward 2003)
        1. Bony overgrowth, or lack of remodeling, results in compression of nerves or blood vessels that pass through bones, especially the optic nerve (resulting in partial or complete visual loss) and, more rarely, the auditory and facial nerves.
        2. Arteries or venous sinuses within the skull can also be constricted, as can the foramen magnum.
        3. Early fusion of bones may result in craniosynostosis.
        4. Some patients have primary neurometabolic (neuronopathic) forms of osteopetrosis and may have abnormal retinal pigmentation and cerebral atrophy.
    3. Cytopenia/pancytopenia (Steward et al. 2005)
        1. Bony encroachment on medullary cavities results in extramedullary hemopoiesis with hepatosplenomegaly and the potential for hypersplenism.
        2. Anemia and thrombocytopenia result and blood films often show a markedly leukoerythroblastic picture, with a high white blood cell count and high numbers of circulating stem cells.
    4. Growth: Most children with osteopetrosis fall below the tenth percentile on growth charts, and some have severe dwarfism (Gerritsen et al. 1994; Driessen et al. 2003).
    5. Hypocalcemia: Defective osteoclast function can disturb calcium homeostasis, which may manifest as symptomatic hypocalcemia in the first few months of life, despite high total body calcium reserves (Gerritsen et al. 1994; Srinivasan et al. 2000).
    6. Respiratory compromise (Wong et al. 1978)
        1. The skull base, choanal bones, and jaw are often severely affected, which produces persistent snuffling, noisy breathing, and upper airway obstruction and may predispose patients to pulmonary arterial hypertension.
        2. Patients often suffer increased ear, nose, and throat infections and respiratory infections.
    7. Dentition (Luzzi et al. 2006)
        1. Tooth eruption often delayed.
        2. Poor tooth quality.
        3. Osteomyelitis of the jaw can occur.
    8. Other organ system involvement: The genes involved may have roles in other organs. For example, a small proportion of children have severe neurometabolic disease, and abnormalities of lymphocytes and immunoglobulin production are now recognized in some variants (Villa et al. 2009; Mazzolari et al. 2009).

Clinical Features

1. Malignant infantile osteopetrosis (Steward 2003)
    1. Usually diagnosed during the first year of life
    2. Signs and symptoms
        1. Presenting signs
            1. Blindness
            2. Failure to thrive
            3. Seizures due to hypocalcemia
            4. Infections

5. Pathologic fractures
2. Neurovascular involvement: The most serious consequences of the osteopetrosis are cranial nerves, blood vessels, and the spinal cord compression by either gradual occlusion or lack of growth of skull foramina.
3. Visual impairment
    1. Optic atrophy: Some degrees of optic atrophy are present in most patients. Blindness is observed in many children with severe forms of autosomal recessive osteopetrosis.
    2. Nystagmus
    3. Strabismus
    4. Proptosis
    5. Limited extraocular movement
4. Compression of facial and trigeminal nerves
    1. Produce paralysis, spasm, or neuralgia.
    2. Involvement of the trigeminal nerve tends to occur in type I autosomal dominant osteopetrosis.
    3. Involvement of the facial nerve is predominant in type II disease.
5. Hearing loss
    1. Poor drainage of the middle ear
    2. Narrowing of the internal acoustic meatus
    3. Osteosclerosis
6. Blood vessel compression
    1. Stenosis of arterial supply (internal carotid artery, vertebral artery)
    2. Stenosis of venous supply
7. Craniofacial features
    1. Macrocephaly
    2. Frontal bossing
    3. Hypertelorism
    4. Exophthalmos
    5. Flat nasal bridge
    6. Chronic rhinitis
    7. Jaw: a frequent site of osteomyelitis
    8. Obligate mouth breathing in most children secondary to obstruction of the upper airway
8. Compromised nutritional state due to difficulty in eating and breathing resulting from limited posterior nasophrynx from bony overgrowth
9. Psychomotor retardation
    1. Secondary to hydrocephalus
    2. Secondary to apnea due to upper airway obstruction
    3. Common in carbonic anhydrase isoenzyme type II deficiency
10. Bone marrow failure
    1. Results from bone marrow encroachment
    2. Leads to extramedullary hematopoiesis and hepatosplenomegaly (abdominal protuberance)
    3. Frequently progresses to hypersplenism and pancytopenia
    4. Signs secondary to thrombocytopenia (petechiae, ecchymoses, epistaxis, melena, gingival bleeding, intracerebral hemorrhages)
    5. Carries a high mortality (early death)

2. Autosomal dominant osteopetrosis type I
    1. Chronic bone pain
    2. Cranial nerve palsies
    3. Hearing loss
    4. Not associated with increased fracture rate (el-Tawil and Stoker 1993)
3. Autosomal dominant osteopetrosis type II (Albers-Schőnberg disease) (Bénichou et al. 2000b)
    1. Originally described by Albers-Schőnberg in 1904
    2. The most common form of osteopetrosis
    3. The prevalence: 5.5 in 100,000
    4. The term “benign osteopetrosis”: a misnomer for autosomal dominant osteopetrosis type II because of the possibility of severe clinical complications
    5. Most prominent symptoms
        1. Bone pain
        2. Multiple fractures: frequent (78%), perhaps due to the reduced elasticity of the brittle bone

3. Cranial nerve palsies
4. Mandibular osteomyelitis

6. Other signs
1. Hip osteoarthritis
2. Thoracic or lumbar scoliosis
3. Hearing loss
4. Visual loss
5. Optic atrophy
6. Multiple dental abscesses
7. Multiple and deep dental decays
8. Bone (except mandibular) joint (hip) sepsis

4. "Intermediate" form of osteopetrosis
1. Usually diagnosed during the first decade and survive into adulthood
2. Short stature
3. Frontal bossing
4. Mild hepatosplenomegaly

5. Carbonic anhydrase isoenzyme type II (CA II) deficiency
1. An autosomal recessive disorder
2. Most cases have been reported from Middle East or the Mediterranean region
3. Osteopetrosis with renal tubular acidosis (usually distal type)
4. Short stature
5. Fractures
6. Psychomotor retardation
7. Cranial nerve compression (>50%)
8. Optic atrophy and visual loss
9. Cerebral calcifications
10. Minor hematological impairment
11. Craniofacial features
1. Micrognathia
2. Narrow prominent nose
3. Poorly developed philtrum
12. Abnormal dentition
1. Peg-shaped carious teeth with malocclusion
2. Delayed eruption of the teeth
3. Retained primary dentition
13. Visual failure
14. Episodic hypokalemic paralysis in some patients

6. Vacuolar proton pump deficiency
1. Visual failure
2. Symptomatic hypocalcemia in the first month (50%)
1. Early or late neonatal convulsions
2. Irritability
3. Jittering episodes
3. Fractures
4. Mild to severe hematological impairment
5. Hepatosplenomegaly
6. Failure to thrive
7. Poor growth
8. Reduced life span

7. CLCN-7 chloride pump deficiency: severe osteopetrosis

8. Neuronopathic osteopetrosis
1. Causing rapid neurodegeneration and death within the first year
2. Widespread axonal spheroids and accumulation of ceroid lipofuscin
3. Often accompanied by severe hematological impairment
4. Gross hepatosplenomegaly
5. Severe anemia/thrombocytopenia
6. High arched palate
7. Gum hypertrophy
8. Hyperreflexia
9. Clonus
10. Opisthotonos
11. Fisting
12. Poor head control
13. Irritability
14. Early death

9. Autosomal recessive osteopetrosis with renal tubular acidosis (Whyte 1993)
1. A milder course
2. Renal tubular acidosis
3. Cerebral calcifications
4. Fractures
5. Short stature
6. Dental abnormalities
7. Cranial nerve compression
8. Developmental delay

10. X-linked osteopetrosis, lymphedema, anhidrotic ectodermal dysplasia, and immunodeficiency (OLEDAID)
1. Common variable immune deficiency in association with a particular subtype of osteoclast-poor autosomal recessive osteopetrosis (Guerrini et al. 2008)
2. Leukocyte adhesion deficiency syndrome (Kilic and Etzioni 2008; Mory et al. 2008)

11. Osteopetrosis with agenesis of corpus callosum: possible variant to neuronopathic osteopetrosis
12. Dysosteosclerosis
    1. Bone fractures
    2. Developmental delay with occasional mental retardation
    3. Cranial nerve impingement
        1. Visual loss (optic atrophy)
        2. Hearing loss
        3. Facial nerve paralysis
    4. Osteomyelitis of the mandible
    5. Macular atrophy of the skin
    6. Flattened fingernails
13. Differential diagnosis (Manusov et al. 1993; Ihde et al. 2011; Sobacchi et al. 2016)
    1. Hyperostosis corticalis generalisata: Endosteal cortical thickening involving the long bones, skull (leading to cranial nerve palsies), and facial bones; mandible enlargement
        1. Van Buchem syndrome
            1. An autosomal recessive disorder
            2. *SOST* (sclerostin)-related sclerosing bone dysplasia
            3. Diffuse/widespread sclerosis of the cortex, usually sparing spine
            4. Facial nerve palsy
            5. Generalized osteosclerosis
            6. Hyperphosphatasemia
        2. Sclerosteosis (Hamersma et al. 2003)
            1. An autosomal recessive disorder
            2. Facial nerve palsies
            3. Syndactyly
            4. Bone overgrowth (tall stature)
            5. Can be lethal as a result of increased intracranial pressure
        3. Worth disease
            1. An autosomal dominant disorder
            2. Caused by *LRP5* (lipoprotein receptor-related protein 5) mutation
            3. No cranial nerve palsy
            4. Torus palatinus
    2. Craniometaphyseal dysplasia (please see the chapter on "► Craniometaphyseal Dysplasia")
        1. Autosomal recessive craniometaphyseal dysplasia (AR-CMD) (OMIM)
            1. Typical features of CMD
               Macrocephaly
               Hearing loss
               Skull hyperostosis with paranasal bossing (metaphyseal widening) but less pronounced calvarial thickening (Iughetti et al. 2000)
            2. Due to diaphyseal osteosclerosis the disorder can occasionally resemble mild forms of osteopetrosis. Pathogenic variants in GJA1 are causative (Hu et al. 2013)
        2. Autosomal dominant craniometaphyseal dysplasia (AD-CMD)
            1. The clinical hallmark of CMD is skull hyperostosis leading to deep-set eyes and paranasal bossing.
            2. Facial nerve palsy is common and occurs more frequently than optic nerve compression (Braun et al. 2001).
            3. The femur shows a modeling defect but no osteosclerosis.
            4. Susceptibility to fractures is not increased.
            5. Pathogenic variants in ANKH are causative (Nürnberg et al. 2001).
    3. Oculo-dento-osseous dysplasia
        1. An autosomal dominant disorder
        2. Enlarged mandible
        3. Focal osteosclerosis in the pelvis
        4. Other findings
            1. Microphthalmia
            2. Large jaw
            3. Hypoplasia of tooth enamel
    4. Osteitis deformans (Paget disease)
        1. Localized osteosclerosis in one or a few regions of the skeleton
        2. Local pain
        3. Bone marrow biopsy finding
    5. Progressive diaphyseal dysplasia (Camurati-Engelmann disease)

1. An autosomal dominant disorder with variable expression
2. Caused by domain-specific mutations of the TGFB gene located on chromosome 19q13 encoding transforming growth factor β-1
3. Associated with progressive sclerosis of the diaphyses of all the long bones due to thickening of the cortices
4. Major clinical features
    1. Leg pain
    2. Muscular weakness
    3. Waddling gait
    4. Failure to thrive
5. Major radiographic features
    1. Fusiform sclerosis of cortical surfaces and subendosteum
    2. Sclerosis of the skull base

6. Pyknodysostosis (de Vernejoul and Bénichou 2001)
    1. An autosomal recessive disorder
    2. Caused by cathepsin K gene mutations, resulting in no immunologically detectable protein (Gelb et al. 1996; Hou et al. 1999)
    3. Hyperostosis of long bones with preserved medullary cavities
    4. Acro-osteolysis
    5. Wormian bones
    6. Dysmorphic features
    7. Generalized osteosclerosis
    8. Frequent fractures
    9. Open fontanel
    10. Associated with mental retardation and dwarfism
7. Dysosteosclerosis
    1. Short stature
    2. Sandwich vertebrae
    3. Platyspondyly
    4. Metaphyseal widening and sclerosis
    5. Often diaphyseal thickening
    6. Campeau et al. (2012) identified biallelic *SLC29A3* variants in two individuals with dysosteosclerosis
8. Osteopoikilosis (please see the chapter on "► Osteopoikilosis")
    1. An autosomal dominant disorder
    2. Caused by *LEMD3* mutation
9. Osteoparthia striata
    1. An X-linked disorder
    2. Dense striations in metadiaphyses of long bones
    3. No other associated abnormalities
10. Progressive diaphyseal dysplasia
    1. An autosomal dominant disorder
    2. Caused by LAP of TGF-β1 mutation
    3. Bilateral/symmetric periosteal and endosteal cortical thickening involving long bones and/or calvaria
    4. Gait disturbances
    5. Pain
    6. Weakness
11. Hereditary multiple diaphyseal sclerosis
    1. An autosomal recessive disorder
    2. Unilateral/asymmetrical cortical thickening, involving long bones only
    3. Milder neuromuscular symptoms than with progressive diaphyseal dysplasia
12. Leukocyte adhesion deficiency type III (LAD-III) (OMIM)
    1. Affected individuals present with recurrent infections and a bleeding diathesis regardless of platelet or leukocyte count.
    2. Pathogenic variants in *FERMT3* (encoding fermitin family homolog 3) are causative.
    3. In some individuals with LAD-III, a high bone density can be found, since fermitin family homolog 3 (also referred to as kindlin-3) signaling is required for osteoclast-mediated bone resorption (Crazzolara et al. 2015).
13. Nonhereditary disorders
    1. Intramedullary osteosclerosis
        1. A more recently described entity associated with increased bone formation within the medullary cavity of the long bones of the lower extremities

2. Typically discovered at radiography performed in a patient with chronic leg pain that increases with physical activity
2. Melorheostosis (Leri disease)
   1. A type of mixed sclerosing bone dysplasia, with disturbances in both endochondral and intramembranous ossification
   2. Sporadic and typically manifests in late childhood or early adulthood
   3. Clinically, may present with pain and stiffness of the involved bones
   4. When the osseous abnormality involves a joint, contractures can occur
3. Heavy metals (lead, bismuth)
   1. Presence of radiodense lines (Harris lines)
   2. Elevated levels of heavy metals
4. Mastocytosis
   1. Poorly demarcated sclerosis in the pelvis, ribs, vertebrae, skull, and proximal long bones
   2. Not uniformly symmetric
   3. Elevated histamine level
5. Renal osteodystrophy
   1. Widespread sclerosis of the skeleton
   2. Increased density less clear
   3. Elevated serum parathyroid hormone
   4. Elevated renal function test
6. Metastatic carcinomas (breast, prostate, lung, kidney, and thyroid)
   1. Dispersed in random fashion
   2. Bone marrow biopsy often diagnostic

Diagnostic Investigations

1. Laboratory work-up for infantile malignant osteopetrosis (Lam et al. 2007)
   1. Anemia
   2. Leukopenia
   3. Thrombocytopenia
   4. Reticulocytosis
   5. Pancytopenia
   6. Hypocalcemia
   7. Inconsistent hypophosphatemia
   8. Defective superoxide generation in peripheral leukocytes
   9. Secondary hyperparathyroidism with elevated serum calcitriol: common (Key et al. 1984; Cournot et al. 1992)
   10. Increased serum acylphosphatase (ACP)
   11. Presence of the brain isoenzyme of creatine kinase (BB-CK) in the serum is a biochemical marker for osteopetrosis
   12. ACP and BB-CK originate from osteoclasts (Whyte et al. 1996)
2. Radiographic features (de Vernejoul and Bénichou 2001)
   1. Pathognomonic radiographic findings of osteopetrosis (Landa et al. 2007)
      1. Generalized sclerosis
      2. Endobone (bone-within-bone) formation
      3. Vertebral end plate thickening
   2. Infantile malignant osteopetrosis (IMO)
      1. Diffuse skeletal densification: increased density of the entire skeleton
      2. Complete absence of the medullary canal in severe cases
      3. Lack of remodeling gives rise to metaphyseal widening or a "club-shaped" appearance of the long bones
      4. "Bone-within-a-bone" phenomena or "endobones" seen especially in the pelvis, vertebrae, hands, and feet
      5. Transverse radiolucent bands within the metaphyseal regions of the long bones: attributed to periodic variations in the ability to resorb bone
      6. Longitudinal striations in the long bones: attributed to periosteal elevation by trauma or microfractures
      7. Increasingly thickened skull with a "hair-on-end" appearance
      8. "Mask sign" (skull)
      9. Common occurrence of fractures
         1. Especially epiphyseal separations and femur fractures
         2. Diaphyseal and metaphyseal fractures: usually transverse or short oblique pattern

10. Some radiological signs are common to all patients with IMO (increased bone density, bone-within-bone appearance, and metaphyseal remodeling), but some genetic defects such as TCIRG1 are associated with the most severe radiological findings (Simanovsky et al. 2016)

3. Various subtypes of osteopetrosis
    1. Vacuolar proton pump deficiency
        1. Generalized increased bone density
        2. Bone-within-bone appearance due to periosteal new bone formation
        3. Modeling deformities
        4. Pseudorickets (widened and irregular metaphyses)
        5. Metaphyseal lucencies in some children
        6. Fractures: common particularly affecting acromial processes, long bones, posterior ribs, and pubic bones
        7. Identified as the primary defect in the autosomal recessive syndrome of osteopetrosis with renal tubular acidosis and cerebral calcification
        8. A lack of expression of the vacuolar proton pump has been observed in osteoclasts of a patient with craniometaphyseal dysplasia (Felix et al. 1996)
    2. Carbonic anhydrase isoenzyme type II deficiency
        1. Diffuse skeletal densification
        2. Thick sclerotic skull base
        3. Generalized osteopetrosis
        4. Faulty modeling of metaphyses
        5. Transverse striations in metaphyses
        6. Arcuate striations in iliac bones
        7. Bone-within-bone appearance
        8. Sandwich vertebrae
        9. Intracranial calcifications
    3. Neuronopathic osteopetrosis
        1. Typical findings of severe malignant infantile osteopetrosis
        2. Mild to severe cerebral atrophy
    4. Osteopetrosis with agenesis of the corpus callosum
        1. As with neuronopathic osteopetrosis
        2. Absence of the corpus callosum
    5. Dysosteosclerosis
        1. Thickening and sclerosis of cranial vault, base of skull, ribs, and clavicle
        2. Sclerotic long bones with splayed submetaphyseal clear zones
        3. Platyspondyly
        4. Retarded white matter myelination
        5. Intracerebral calcifications
    4. Autosomal dominant osteopetrosis type I
        1. Generalized/diffuse osteosclerosis affects especially the cranial vault
        2. Sclerotic skull base
        3. Vertebral bodies comparatively normal but the vertebral arches appearing dense
    5. Autosomal dominant osteopetrosis type II (Albers-Schőnberg disease)
        1. A spectacular radiological appearance with the segmental distribution of dense bone
        2. Characterized by diffuse osteosclerosis, predominantly involving spine, pelvis, and skull base
            1. Thickened vertebral end plates (“sandwich vertebrae,” Rugger-Jersey spine)
            2. Classic “bone-within-bone” appearance/endobone structures (especially in pelvis)
            3. Thickened (dense) skull base
        3. Common sclerotic bands in the metaphyses
        4. Fractures
            1. Common (78%)
            2. Heal slowly
        5. Mandibular osteomyelitis
        6. Hip osteoarthritis (27%)
        7. Thoracic or lumbar scoliosis (24%)
        8. Cranial nerve encroachment leading to hearing loss, bilateral optic atrophy, and/or facial palsy (16%)
3. Major pathologic features
    1. General features for malignant infantile osteopetrosis
        1. Obliteration of the marrow spaces by unresorbed primary trabecular bone and calcified cartilage

2. The cartilage cores not remodeled despite an increased number of osteoclasts
3. Absent or diminished ruffled border of the osteoclast by electron microscopy

2. Vacuolar proton pump deficiency: increased osteoclasts
3. ClC-7 chloride pump deficiency: normal numbers of osteoclasts (in mice)
4. Neuronopathic osteopetrosis
   1. Autofluorescent neuronal ceroid lipofuscin
   2. Widespread eosinophilic neuroaxonal spheroids
5. Autosomal dominant osteopetrosis type I: normal appearance of trabecular bone remodeling
6. Autosomal dominant osteopetrosis type II (Albers-Schőnberg disease)
   1. Defective trabecular bone remodeling.
   2. Increased number of osteoclasts.
   3. Frequent delayed healing of fractures.
   4. Increased total acid phosphatase probably reflects the increased number of osteoclasts that are unable to resorb bone.
   5. Observation of large multinucleated osteoclasts suggests a defect in osteoclast function rather than differentiation, as in infantile osteopetrosis.
7. Intermediate form
   1. Mild to marked increased bone density of the axial skeleton and long bones
   2. Defects of modeling seen especially at the distal femurs which may have "Erlenmeyer flask" deformity
   3. Frequent coxa vara and pathologic long bone fractures
   4. Problematic dental malocclusion and caries

4. Genetic diagnosis using whole exome analysis in malignant osteopetrosis of infancy (MOI) (Demir et al. 2015; Shamriz et al. 2016)
   1. Until now, homozygous or compound heterozygous mutations in seven genes (*TNFRSF11A*, *TNFSF11*, *TCIRG1*, *CLCN7*, *OSTM1*, *SNX10*, and *PLEKHM1*) have been found in 80% of children with MOI (Sobacchi et al. 2013).
   2. Detection of the exact cause and provision of genetic counseling via individual mutation analysis of all these genes would be expensive and time consuming.
   3. Whole exome sequencing is being increasingly used given that its cost and the time needed for analysis are similar to that of single-gene sequencing (Campeau et al. 2012; Sui et al. 2013).
   4. In addition, whole exome sequencing offers the probability to detect novel causative genes in the remaining 20% of patients with MOI.

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Autosomal recessive disorder: 25%
      2. Autosomal dominant disorder: low unless one of the parent is affected or has gonadal mosaicism
      3. X-linked recessive
         1. Carrier mother: 50% of male sibs affected; 50% of female sibs carriers
         2. Noncarrier mother: still with a small risk of having further affected offspring due to gonadal mosaicism
   2. Patient's offspring
      1. Autosomal recessive disorder: low unless the spouse is a carrier
      2. Autosomal dominant disorder: 50%
      3. X-linked recessive
         1. No sons will inherit the mutant allele and therefore will not be affected with osteopetrosis.
         2. All daughters will be carriers for osteopetrosis.
2. Prenatal diagnosis (Sobacchi et al. 2016)
   1. Prenatal radiography (Oğur et al. 1995; Stark and Savarirayan 2009): possible for families with severe autosomal recessive osteopetrosis and unknown mutations
      1. Made at the 25th week of pregnancy at risk for autosomal recessive osteopetrosis

2. Fetal radiographic findings
    1. Marked sclerosis of osteopetrotic bone
    2. Metaphyseal splaying and clubbing of both femurs
2. Prenatal diagnosis available for pregnancies with a 25% risk for fetuses affected with malignant osteopetrosis by amniocentesis or CVS
    1. Using linkage analysis in the region of chromosome 11q12-13 (Kapelushnik et al. 2001; Shalev et al. 2001)
    2. DNA mutation analysis of fetal DNA for the pregnancy at risk for malignant autosomal recessive osteopetrosis by amniocentesis or CVS when the mutation is previously characterized in the family
3. Preimplantation diagnosis is theoretically possible in families, in whom the genetic mutation has been identified
4. If a family decides to continue with an affected pregnancy, hematopoietic stem cell transplantation before the age of 3 months can be planned with the aim of improving neurological outcomes (Stark and Savarirayan 2009)

3. Management (Wilson and Vellodi 2000)
    1. Medical treatment of osteopetrosis is based on efforts to stimulate host osteoclasts or provide an alternative source of osteoclasts. Stimulation of host osteoclasts has been attempted with calcium restriction, calcitrol, steroids, parathyroid hormone, and interferon (Kocher and Kasser 2003).
    2. ARO (Sobacchi et al. 2016)
        1. Calcium supplementation for hypocalcemic convulsions
        2. Management of calcium homeostasis per individual needs
        3. Erythrocyte or platelet transfusions as needed
        4. Antibiotics for leukocytopenia
        5. Immunoglobulins for hypogammaglobulinemia
        6. Surgical decompression of the optic nerve
        7. Treatment of fractures by an experienced orthopedist
        8. Dental care with attention to tooth eruption, ankylosis, abscesses, cysts, and fistulas
    3. ADOII (Sobacchi et al. 2016)
        1. Orthopedic treatment for fractures and arthritis with attention to potential postsurgical complications (delayed union or nonunion of fractures, infection)
        2. Fractures near joints may require total joint arthroplasty
    4. Supportive care
    5. Blood transfusion for anemia secondary to a failure of bone marrow development
    6. Risk of recurrent infections viewed as an indication for bone marrow transplantation
    7. Optical nerve decompression successful only in mildly affected older children
    8. Early insertion of ventilatory “grommet” tube for hearing impairment secondary to a combination of bony compression of the nerve, sclerosis of the middle ear ossicles, and/or chronic middle ear effusion
    9. Nasal gastric feeding for children with chronic anemia and feeding problems caused by bulbar nerve involvement, nasal congestion, and recurrent infections
    10. A high risk of anesthetic morbidity and mortality in patients with malignant osteopetrosis primarily related to airway and respiratory factors
    11. Manage osteomyelitis
        1. Pus drainage
        2. Appropriate antibiotic therapy
        3. Surgical debridement
        4. Reconstruction if indicated
    12. Patient with osteopetrosis with osteomyelitis in both jaws was treated prosthetically, and they fulfilled the requirements of the patient. Prosthetic rehabilitation included the separation of nasal cavity from oral cavity with obturator prosthesis in maxilla and the replacement of missing teeth with removable prosthesis in the mandible (Celakil et al. 2016)

13. Orthopedic cares: complicated by the difficulty of working with extremely hard, brittle, marble bone (Landa et al. 2007)
    1. Fracture fixation
        1. Difficulty inserting pins and screws
        2. Failure of load-bearing plate devices
        3. Increased time to union
    2. Arthroplasty
        1. Iatrogenic fracture during implant placement
        2. Increased risk of osteomyelitis
        3. Obliteration of medullary canal by cortical bone
    3. General considerations
        1. Overheating and breakage of drill bits
        2. Longer surgical time
14. Surgical management of the skeletal problems is reasonable in certain circumstances and is especially indicated for coxa vara and femoral neck fracture (Armstrong et al. 1999)
    1. For most long-bone fractures, nonoperative management works well.
    2. When surgery is required, technical problems due to extreme bone hardness are to be anticipated, and delayed or nonunion is more likely than average.
    3. Patients and surgeons must be aware that the ultimate outcome of surgery may be good, but the postoperative course can be unpredictable and prolonged.
15. Total joint arthroplasty is an effective treatment for painful hip and knee osteoarthritis in patients with osteopetrosis (Xie et al. 2015). Total hip and knee arthroplasty in a patient with osteopetrosis: a case report and review of the literature. *BMC Musculoskeletal Disorders, 16*, 259–263
16. Patients with profound hearing loss caused by osteopetrosis may benefit from cochlear implantation (Szymanski et al. 2015)
17. Corticosteroids and calcitriol (1,25-hydroxyvitamin D) with some short-term initial benefit but with debatable long-term benefit
18. Recombinant human gamma interferon (Eapen et al. 1998)
    1. Enhances bone resorption and leukocyte function (Key et al. 1995)
    2. Effects on morbidity and survival remain unclear
19. Bone marrow or peripheral blood stem cell transplantation
    1. Rational: Osteoclasts are derived from hematopoietic stem cells.
    2. Long-term disease-free survival has been achieved in approximately 70% of infants receiving transplants from matched sibling donors (Cheow et al. 2001).
        1. Repopulating the bones with functioning osteoclasts by successful infusion of donor marrow
        2. Beginning the process of remodeling and restoration of normal calcium homeostasis
        3. Radiographic changes of osteopetrosis expected to gradually returning to normal 4 months to 2 years following bone marrow transfusion
        4. Improvement and resolution of the rachitic changes: the first observation after bone marrow transplantation
        5. Immune recovery
        6. Improved growth
        7. Bone marrow transplant has been used with cure for infantile malignant osteopetrosis (Kocher and Kasser 2003)
20. Improving results with the use of high-dose peripheral blood stem cell grafts for infantile osteopetrosis from alternative donors, including those from parents mismatched for up to one half of their HLA-type (haploidentical)
21. So far, the only cure for children with severe osteopetrosis is allogeneic hematopoietic stem cell transplantation (HSCT), but without a matching donor this form of

therapy is far from optimal (Askmyr et al. 2008)

22. Early diagnosis and timely HSCT is the only curative treatment approach for malignant infantile osteopetrosis, an otherwise fatal disease (Essabar et al. 2014)
23. Patients with OP lacking HLA-matched donors can be successfully treated by transplantation of purified blood progenitor cells from HLA-haploidentical donors (Schulz et al. 2002)
24. Hematopoietic stem cell transplantation in patients with osteopetrosis: associated with disease-specific problems that require careful management, including the potential for life-threatening posttransplant hypercalcemia, a high prevalence of pulmonary arterial hypertension and, in at least one subtype of disease, failure to reverse osteosclerosis despite successful donor cell engraftment (Steward 2010)

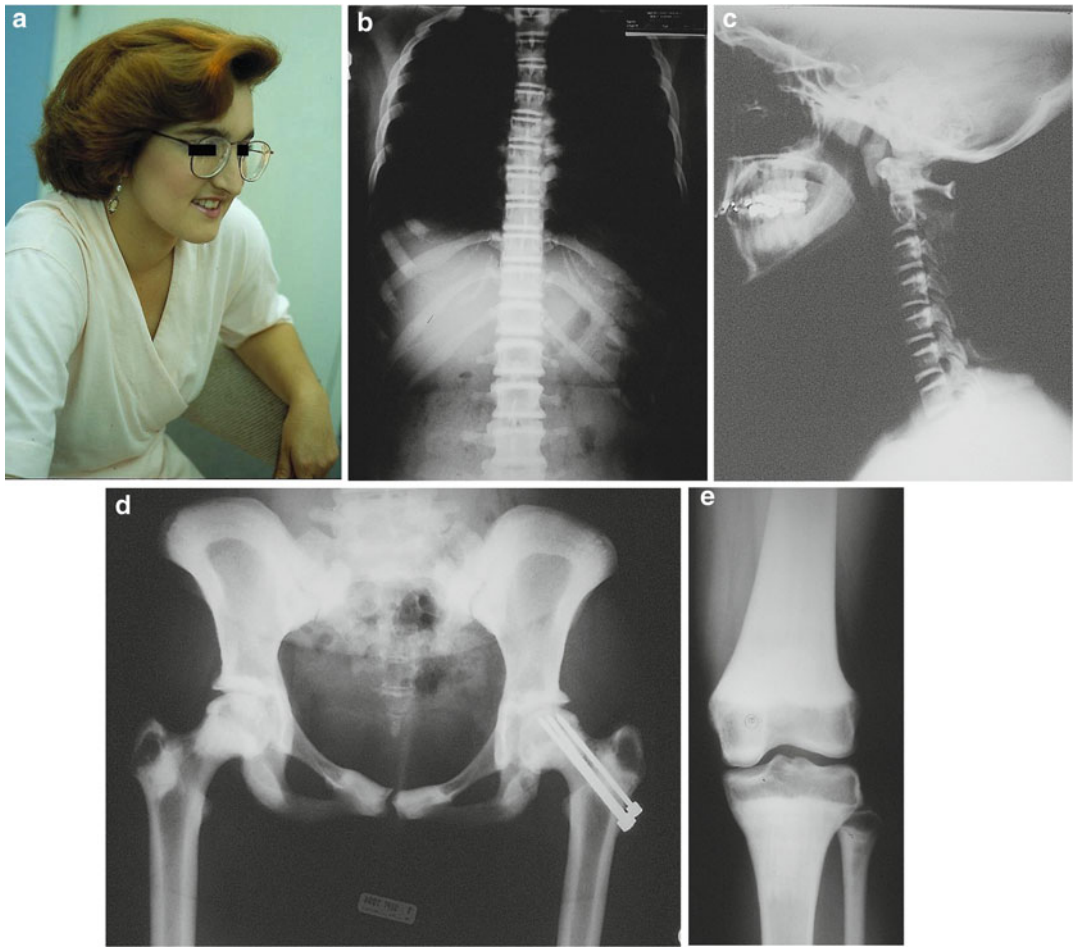

Fig. 3 (**a**–**e**) An adult female (**a**) with osteopetrosis showing generalized sclerotic bones with loss of corticomedullary differentiation including sandwich cervical vertebrae, illustrated by radiographs (**b**–**e**)

Osteopoikilosis

Contents

Osteopoikilosis was first described by Albers-Schönberg in 1915. It is a benign, usually asymptomatic condition diagnosed radiographically by the presence of multiple symmetrical circular/ovoid sclerotic opacities of the ischia, pubic bones, and the epimetaphyseal regions of the short tubular bones. The incidence is estimated as 1/50,000 (Cazzola et al. 1989).

Synonyms and Related Disorders

Buschke–Ollendorff syndrome (dermatofibrosis lenticularis disseminata); Melorheostosis; Mixed sclerosing bone dysplasia; Osteopathia condensans disseminata; Osteopathia striata (striped bone disease; Voorhoeve's disease); Osteosclerotic dysplasia; Spotted bone disease

Genetics/Basic Defects

1. Inherited in an autosomal dominant pattern (Korkmaz et al. 2015; Zhang et al. 2016).
2. Caused by loss of function mutation of LEM domain-containing three gene (*LEMD3*).
3. Usually occurs in isolation.
4. Osteopoikilosis in association with elastic or collagen connective tissue nevi of the skin: known as Buschke–Ollendorff syndrome (dermatofibrosis lenticularis disseminata).
5. In some families and individuals, osteopoikilosis can occur with other osteosclerotic skeletal disorders, such as melorheostosis and osteopathia striata.
6. Novel somatic mutation in *LEMD3* splice site results in Buschke–Ollendorff syndrome (BOS) with polyostotic melorheostosis and osteopoikilosis (Gutierrez et al. 2015).
7. The clinical overlap of BOS, osteopoikilosis, and melorheostosis is further supported by the involvement of *LEMD3* mutations in each diagnosis (Kadhim et al. 2015).
    1. *LEMD3* (LEM domain-containing 3) is a protein-coding gene that has been associated with hyperostotic bone disorders (BOS and osteopoikilosis).
    2. Mutations in this gene have been identified in families with osteopoikilosis, including some individuals, whose presentation is more consistent with melorheostosis, strongly suggesting a common genetic

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_187

cause (Hellemans et al. 2004; Couto et al. 2007; Mumm et al. 2007).
3. In addition, mutation of *LEMD3* gene has also been suspected to play a role in melorheostosis, although significant investigation to date has yet to identify *LEMD3* mutations in isolated melorheostosis. However, it is rare for sporadic individuals with melorheostosis to have mutations identified in the *LEMD3* gene (Hellemans et al. 2006). This is currently believed to likely be a result of somatic mosaic mutations that are present in the affected tissues, and not in blood, in a percentage lower than the current level of molecular detection (Zhang et al. 2009).

Clinical Features

1. Osteopoikilosis
    1. Presence of multiple osteosclerotic lesions in different parts of the skeleton (Lagier et al. 1984; Chigira et al. 1991; Carpintero et al. 2004).
        1. Epiphyses and metaphyses of long tubular bones
        2. Hands and wrists
            1. Phalanges
            2. Carpal bones
            3. Metacarpals
        3. Feet/ankles
            1. Phalanges
            2. Metatarsals
            3. Calcaneus
            4. Navicular bones
        4. Pelvis
        5. Scapulae
    2. An asymptomatic, uncommon osteosclerotic dysplasia: consists of multiple benign bone islands scattered throughout the axial and appendicular skeleton, typically clustered around the larger joints.
    3. A rare cause of bone pain (Mahbouba et al. 2015).
    4. Osteopoikilosis has been recognized as a condition associated with mixed sclerosing bone dysplasia.
        1. Mixed sclerosing bone dysplasia refers to when three relatively rare benign bone disorders occur in the same patient, occasionally all three at once.
        2. The bone disorders include:
            1. Osteopoikilosis
            2. Osteopathia striata (striped bone disease; Voorhoeve's disease)
            3. Melorheostosis (a condition typically involving one extremity with asymmetric marked cortical thickening that looks like dripping candle wax)
    5. Evident at any age (uncommon before the age of 3 years) and persists for life.
    6. Symmetric distribution.
    7. Generally asymptomatic.
    8. Joint inflammation and pain in about 15–20% of cases (Borman et al. 2002).
    9. Osteopoikilosis reported to coexist with other rheumatologic pathologies:
        1. Rheumatoid arthritis (Cazzola et al. 1989; Ureten 2007)
        2. Reactive arthritis (Mesci 2006)
        3. Discoid lupus erythematosus (Bicer et al. 2002)
        4. Familial Mediterranean fever (Kavukcu et al. 2003)
2. Melorheostosis (Butkus et al. 1997)
    1. A sporadic sclerosing bone condition.
    2. Melorheostosis can be present in a family with autosomal dominant osteopoikilosis (Nevin et al. 1999; Debeer et al. 2003).
    3. Manifesting in a sclerotomal distribution.
    4. Frequently affecting one limb.
    5. Usually asymptomatic.
    6. Pain, stiffness, leg-length discrepancy, and deformity in severe case.
    7. Radiographically, presence of cortical hyperostosis with thickening, resembling dripping candle wax.
3. Osteopathia striata
    1. Occurs in isolation or with cranial sclerosis
    2. A key radiographic feature: longitudinal striation of the metaphyses of the long bones
    3. Clinical features ranging from mild skeletal manifestation to multisystem organ involvement, even with the same family

1. Typical features
    1. Macrocephaly
    2. Cleft palate
    3. Hearing loss
2. Additional features
    1. Cardiac malformations
    2. Developmental delay
    3. Cranial nerve palsies
    4. Anal malformations
    5. Cataracts
    6. Nervous system malformations
    7. Cranial sclerosis (Savarirayan et al. 1997)

4. Buschke–Ollendorff syndrome (Pope et al. 2016)
    1. A rare, autosomal dominant disorder with high penetrance
    2. Caused by *LEMD3* gene mutation
    3. Typically a benign disorder that combines osteopoikilosis together with skin lesions consisting of connective tissue nevi (Buschke and Ollendorff 1928), juvenile elastomas (Uitto et al. 1981), or collagenous composition (dermatofibrosis lenticularis disseminata) (Foo and Kumarasinghe 2005)

Diagnostic Investigations

1. Radiographic features (Mclennan 1999).
    1. Often detected incidentally at radiographic examination: "pepper-pot/spotted bone" appearance (Hill and McKee 2015).
    2. Numerous, small, well-defined circular or ovoid sclerotic foci in a symmetric distribution.
        1. Usually seen in (Amezcua-Guerra et al. 2005):
            1. Epiphyses of short tubular bones
            2. Metaphyseal regions of long tubular bones
            3. Carpal bones
            4. Metacarpals
            5. Metatarsals
            6. Tarsal bones
            7. Sacrum
            8. Scapulae
            9. Iliac bones
        2. Rarely involved in (Mesci 2006):
            1. Skull
            2. Spine
            3. Ribs
            4. Clavicles
    3. The sclerotic lesions as described were in keeping with multiple benign bone islands (enostoses). When clustered around the joints and noted throughout the skeleton, the condition is known as osteopoikilosis (spotted bone disease) (Benli et al. 1992; Negi et al. 2013; Dasgupta and Thomas 2015; Perin et al. 2016).
    4. Differential diagnosis (Mclennan 1999).
        1. Sclerotic bone metastasis
            1. Nearly all tumors result in diffuse osteoblastic (sclerotic) bone metastases affect adults older than 40 years.
            2. The most common primary sites: the prostate (men) and breast (women).
            3. Other common primary sites in adults: the lungs, bladder (transitional cell carcinoma), bowel (malignant carcinoid tumor, mucinous adenocarcinoma), pancreas, and lymph system.
        2. Osteoma
            1. An osteoma is a benign localized mass of dense bone that develops in the periosteum of other bones.
            2. Osteomas typically appear as homogeneously dense foci of sclerosis along the outer cortex of both tubular and flat bones.
            3. Osteomas occur predominantly in the skull and facial bones, particularly in the paranasal sinuses.
        3. Hereditary multiple exostoses (also known as diaphyseal aclasis) (please see the chapter on "► Hereditary Multiple Exostoses")
            1. An autosomal dominant disorder resulting in numerous exophytic exostoses (osteochondromas) near the joints.

   2. The exostoses are usually palpable, but painless.
   3. These benign bony lesions develop in the distal diaphysis and metaphysis of long bones near the epiphyseal plate.
   4. They are most common around the knee and frequently occur around the elbow, scapula, pelvis, and ribs.
2. CT scan and MRI: used to support the diagnosis.
3. Whole-body bone scintigraphy.
   1. Typically normal (Tuncel and Caner 2012)
   2. Occasionally abnormal (Appenzeller et al. 2007), especially in younger patients (Borman et al. 2002; An et al. 2004)
4. SPECT (single-photon emission computerized tomography)/CT showed numerous sclerosing lesions devoid of significant Tc-99 m methylene diphosphonate (MDP) avid uptake (Tsai et al. 2016).
5. Bone biopsy: focal condensations of compact lamellar bone within the spongiosa (Benli et al. 1992).
6. In atypical cases of simultaneous occurrence of fibrotic skin lesions and "spotty bone" in the X-ray, genetic screening of the *LEMD3* gene is recommended (Brodbeck et al. 2016). A correct diagnosis of Buschke–Ollendorff syndrome is necessary to spare patients from expensive investigations and to provide reassurance about the benign nature of the disease (Surrenti et al. 2014).

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: a low recurrence risk if parents are not affected
   2. Patient's offspring: a 50% of risk of having an affected offspring if the spouse is normal
2. Prenatal diagnosis: has not been reported
3. Management
   1. Usually, no treatment is required for the condition.
   2. Supportive treatment for joint inflammation or joint pain.

Otopalatodigital Spectrum Disorders

Contents

Otopalatodigital spectrum disorders, a heterogeneous group of disorders characterized primarily by a skeletal dysplasia of variable severity, include otopalatodigital syndrome type I (OPD I), otopalatodigital syndrome type II (OPD II), frontometaphyseal dysplasia (FMD), and Melnick-Needles syndrome (MNS).

Dudding et al. (1967) in *1967* described three male sibs with conduction deafness, cleft palate, characteristic facies, and a generalized bone dysplasia. In retrospect, the male patient described by Taybi (1962) may have the same condition. The syndrome is now known as OPD I.

Fitch et al. (1976) in *1976* described a familial syndrome of cranial, facial, oral, and limb anomalies in which two male infants have microcephaly, abnormal ears, antimongoloid slant, small mouth, cleft palate, flexed overlapping fingers with syndactyly of the second to the fifth toes, and normal karyotype. The name OPD II was proposed for this syndrome by Fitch et al. (1983).

Gorlin and Cohen (1969) in *1969* described a male patient with extraordinarily marked frontal hyperostosis giving great prominence to the supraciliary ridges, underdeveloped mandible, cryptorchidism, subluxated radial heads, and metaphyseal dysplasia resembling that in Pyle disease (metaphyseal dysplasia).

Melnick and Needles (1966) in *1966* described families having multiple cases in multiple generations of a severe congenital bone disorder characterized by typical facies (exophthalmos, full cheeks, micrognathia, and malalignment of teeth), flaring of the metaphyses of long bones, S-like curvature of bones of legs, irregular constrictions in the ribs, and sclerosis of base of skull.

In *2000*, Verloes et al. (2000) presented clinical evidence for a single entity encompassing FMD, MNS, and OPD I and II. Later, mutations in *FLNA*, a gene encoding the cytoskeletal protein filamin A, were found to be associated with otopalatodigital spectrum disorders.

Filamin A mutations cause periventricular heterotopia with Ehlers-Danlos syndrome (Sheen et al. 2005).

Synonyms and Related Disorders

FG syndrome; Frontometaphyseal dysplasia; Melnick-needles syndrome; Otopalatodigital syndromes type I and type II; Terminal osseous dysplasia; X-linked periventricular nodular heterotopia

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_188

Genetics/Basic Defects

1. Inherited as X-linked disorders (André et al. 1981; Robertson 2013).
2. Mutations in *FLNA* (Filamin A), a gene encoding the cytoskeletal protein filamin A, mapped on Xq28 (Robertson et al. 2001).
    1. Gain-of-function mutations in FLNA were found to be associated with a group of X-linked dysplasias designed as otopalatodigital (OPD) spectrum disorders (Parrini et al. 2015).
    2. Loss-of-function mutations of the *FLNA* gene cause a neuronal migration disorder defined as X-linked periventricular nodular heterotopia (PNH) (Fox et al. 1998; Robertson et al. 2003; Parrini et al. 2015).
    3. Co-occurring gain-of-function and loss-of-function provide an exceptional model to explain pathogenetic mechanisms leading to otherwise mutually exclusive allelic phenotypes (Robertson 2005; Parrini et al. 2015).
    4. Different mechanisms contribute to the pathogenesis of these conditions based on the contrast in phenotypic consequences between loss-of-function mutation (leading to periventricular nodular heterotopia) and clustered missense mutations (leading to otopalatodigital spectrum disorders).
3. The four otopalatodigital spectrum disorders are likely allelic based on previous clinical observations, despite remarkably diverse phenotypic presentations.
    1. Mild end of the spectrum: Affected males with OPD I have cleft palate and mild skeletal anomalies with conductive deafness caused by ossicular anomalies.
    2. Intermediate end of the spectrum: Affected males with frontometaphyseal dysplasia (FMD) have a propensity to develop stenosis of the subglottic region, ureters, and urethra in addition to skeletal anomalies.
    3. Severe end of the spectrum.
        1. Affected males with OPD II have more marked skeletal anomalies, CNS anomalies, and other congenital malformations.
        2. OPD II: caused by a novel filamin a 629G > T mutation (Mariño-Enríquez et al. 2007; Sankararaman et al. 2013).
    4. Most severe end of the spectrum: Affected males with MNS also have severe skeletal anomalies and other congenital malformations similar to OPD II leading to prenatal and perinatal lethality.
4. Genetically related (allelic) disorders (Moutton et al. 2016).
    1. Frontometaphyseal dysplasia: X-linked inheritance (Gorlin and Winter 1980).
        1. Severe manifestations in males
        2. Extremely variable manifestations in females
    2. Melnick–Needles syndrome (MNS) (Robertson et al. 1997, 2003): report of a family in which a woman and her three daughters exhibited a complex phenotype combining PNH, epilepsy and Melnick–Needles syndrome (MNS), a skeletal disorder assigned to the OPD spectrum (Parrini et al. 2015). All four individuals harbored a novel nonconservative missense mutation in *FLNA* exon 3.
    3. X-linked periventricular nodular heterotopia
        1. Presence of uncalcified nodules of neurons ectopically situated along the surface of the lateral ventricles.
        2. Affected individuals: predominantly heterozygous females; males show early lethality.
        3. Affected females.
            1. Seizures on average at age 14–15 years.
            2. Intelligence ranging from normal to borderline functioning.
            3. Increased risk for stroke and other vascular problems or coagulopathies.
        4. Germline mutations of *FLNA* leading to null alleles are found almost exclusively in females, whereas missense mutations or mosaicism for truncating mutations

can account for affected males or a mild phenotype in females.

4. A variant of X-linked periventricular nodular heterotopia with marked connective tissue dysfunction (skin fragility, vascular dilatation) described in females has been associated with mutations in *FLNA*, predicted to lead to loss of function.
5. Gastrointestinal dysmotility associated with periventricular nodular heterotopia associated with *FLNA* mutations.
6. A dual phenotype of periventricular nodular heterotopia and FMD in a female caused by a mutation variably leading to either a substitution or a small deletion as a result of aberrant splicing.
7. Myxomatous cardiac valvular dystrophy associated with X-linked periventricular nodular heterotopia: caused by *FLNA* mutations.
8. Fronto-otopalatodigital osteodysplasia: clinical evidence for a single entity encompassing Melnick-Needles syndrome, otopalatodigital syndrome types 1 and 2, and frontometaphyseal dysplasia. (Verloes et al. 2000)
9. Other syndromes
    1. Osseous dysplasia with intellectual disability, such as terminal osseous dysplasia (Sun et al. 2010)
        1. An X-linked dominant male-lethal disease caused by a single recurrent mutation in the *FLNA* gene.
        2. Characterized by skeletal dysplasia of the limbs, pigmentary defects of the skin, and recurrent digital fibroma with onset in female infancy.
    2. FG syndrome (Unger et al. 2007)
        1. Originally described as a rare syndromic cause of X-linked mental retardation associated with congenital heart disease, anal atresia, inguinal hernia, cryptorchidism, and other anomalies.
        2. However, recent reports have highlighted the more common milder presentation which has for cardinal features: developmental delay, particularly in speech; neonatal hypotonia; relative macrocephaly; dysmorphic facial features; severe constipation; and few if any congenital malformations.
        3. Filamin A mutation is one cause of FG syndrome.

Clinical Features

1. Periventricular heterotopia (Parrini et al. 2006)
    1. Phenotypic heterogeneity and correlation with Filamin A mutations
    2. Clinical features
        1. Contiguous heterotopic nodules
        2. Mega cisterna magna
        3. Cardiovascular malformations
        4. Epilepsy
2. Males with OPD I
    1. Skeletal anomalies
        1. Digital anomalies
            1. Thumbs: short, often proximally placed
            2. Distal phalanges of other digits: hypoplastic with a squared (or "spatulate") disposition to the finger tips
            3. Characteristic toes: hypoplasia of the great toe, a long second toe, and a prominent sandal gap
    2. Limitation of joint movement (elbow extension, wrist abduction) in almost all affected individuals
    3. Mild limb bowing
    4. Characteristic facial features
        1. Prominent supraorbital ridges
        2. Downslanting palpebral fissures
        3. Ocular hypertelorism
        4. Broad nasal bridge and nasal tip
    5. Deafness: secondary either to ossicular malformation, neurosensory deficit, or a combination of both

6. Cleft palate
7. Oligohypodontia
8. Normal intelligence

3. Females with OPD I (Gorlin et al. 1973)
   1. Exhibit variable expressivity
   2. Some females can be affected to a similar degree as affected, related males.
4. Males with OPD II (Sankararaman et al. 2013)
   1. Skeletal anomalies
      1. Thoracic hypoplasia: thin clavicles and wavy, irregular ribs
      2. Limb bowing
      3. Absent or hypoplastic fibulae
      4. Digital anomalies
         1. Most commonly hypoplasia of the first digit of the hands and feet
         2. Camptodactyly
      5. Restricted joint movements: demonstrated in at least 50% of the cases
      6. Cranium: usually shows a sclerotic base
      7. Delayed closure of the fontanels
   2. Characteristic craniofacial features
      1. Large anterior fontanels, prominent forehead, hypertelorism, downslanting palpebral fissures, stubby nose with flat root, small mouth, micrognathia, cleft palate (Pierre-robin sequence), and malformed or low set ears
      2. More pronounced than those in OPD I
   3. Cardiac septal defects and obstructive lesions to the right ventricular outflow tract in some affected individuals
   4. Associated anomalies
      1. Omphalocele (Young et al. 1993)
      2. Hydronephrosis secondary to ureteric obstruction
      3. Hypospadias
   5. Central nervous system anomalies
      1. Associated with X-linked cerebellar hypoplasia/hydrocephalus (Stratton and Bluestone 1991)
      2. Cerebellar hypoplasia
      3. Rare encephalocele and meningomyelocele
      4. Dandy-Walker malformation, bifid tongue, and corneal clouding (Murphy-Ryan et al. 2011)
   6. Developmental delay: common
   7. Death commonly in the neonatal period secondary to respiratory insufficiency
   8. Survival into the third year of life has been described with intensive medical treatment.
5. Females with OPD II (Gorlin et al. 1973)
   1. Usually present with a subclinical phenotype
   2. Characteristic craniofacial features
      1. Prominent supraorbital ridges and a broad nasal root and tip: most common findings
      2. Occasional conductive hearing loss
   3. Occasional females manifest a phenotype similar in severity to that of males (craniofacial dysmorphism, cleft palate, conductive hearing loss, skeletal and digital anomalies)
6. Males with FMD (Kanemura et al. 1979)
   1. Skeletal anomalies
      1. Digital anomalies
         1. Distal phalangeal hypoplasia
         2. Progressive contractures of the hand over the first two decades resulting in marked limitation of movement at the interphalangeal and metacarpophalangeal joints
      2. Joint limitation at the wrists, elbows, knees, and ankles
      3. Scoliosis
      4. Limb bowing
   2. Characteristic craniofacial features
      1. Pronounced supraorbital hyperostosis
      2. Ocular hypertelorism
      3. Downslanting palpebral fissures
      4. Rare cleft palate
   3. Frequent oligohypodontia
   4. Conductive and sensorineural hearing loss in almost all affected individuals
   5. Common underdevelopment of the musculature, most notably around the shoulder

girdle and in the intrinsic muscles of the hands
6. Extraskeletal anomalies
1. Subglottic stenosis presenting as congenital stridor
2. Hydronephrosis
7. Normal intelligence

7. Females with FMD
1. Characteristic craniofacial features similar to those of affected males.
2. Digital, subglottic, and urologic anomalies observed in males with FMD either do not occur in females or are observed in markedly attenuated form.

8. Males with MNS
1. A lethal multiple congenital malformation syndrome (Donnenfeld et al. 1987)
2. Usually present with a phenotype indistinguishable from, or more severe than, that associated with OPD II
3. Affected male fetuses born to several women with classic MNS have presented with a lethal phenotype reminiscent of a severe form of OPD II.
4. Some mildly affected males have been born to clinically unaffected parents.

9. Females with MNS (Dereymaeker et al. 1986)
1. Skeletal anomalies (osteodysplasty)
1. Short stature
2. Digital anomalies
1. Typically long phalanges of both hands and feet
2. Mild distal phalangeal hypoplasia
3. Thoracic hypoplasia
4. Limb bowing
5. Joint subluxation
6. Scoliosis
2. Characteristic craniofacial features
1. Prominent lateral margins of the supraorbital ridges
2. Exorbitism
3. Micrognathia
3. Frequent oligohypodontia
4. Common sensorineural and conductive deafness
5. Common hydronephrosis secondary to ureteric obstruction
6. Normal intelligence
7. Normal pubertal development

Diagnostic Investigations

1. Diagnosis of the OPD spectrum disorders is made by a combination of clinical examination, radiologic studies, family history consistent with X-linked inheritance, and molecular genetic testing (Robertson 2013).
2. Audiometry for hearing loss.
3. Renal ultrasound for renal tract anomalies.
4. Radiographic studies
1. Males with OPD I
1. Skull
1. Sclerosis of the skull base
2. Thickening of the calvaria
3. Underdevelopment of the frontal sinuses
4. Typically underpneumatized mastoids
5. Increased mandibular angle
2. Spine: Failure of fusion of posterior vertebral or neural arches, particularly in the cervical spine
3. Long bones
1. Mildly bowed upper and lower limbs
2. Common dislocation of the radial heads
4. Hands and feet
1. Characteristic accessory proximal ossification center of the second metacarpal
2. Characteristic short, broad first metacarpal and distal phalangeal hypoplasia most marked in the thumb
3. Presence of accessory carpal bones and fusion of carpal and tarsal bones
5. Pelvis: typically contracted with a lack of normal flaring of the ilia

2. Males with OPD II
    1. Skull: findings similar to those in OPD I but delayed in ossification pattern, manifesting as large fontanels in infancy
    2. Cervical spine
        1. Failure of fusion of the posterior neural or vertebral arches
        2. Segmentation anomalies
    3. Long bones: bowed upper and lower limbs with splaying of the metaphyses
    4. Hands and feet
        1. Abnormal modeling of the metacarpals and phalanges, more prominently on the radial side
        2. Hypoplastic or absent great toe
        3. Broad and poorly modeled phalanges and metatarsals
        4. Pelvis: hypoplastic, with lack of normal flaring of the ilia
3. Females with OPD II
    1. Characteristic sclerosis of the skull base and odontoid process
    2. Flared metaphyses of the long bones
    3. Digital anomalies: either absent or presence of hypoplasia of the first metacarpal or metatarsal
4. Males with FMD
    1. Skull.
        1. Sclerosis of the skull base
        2. Marked thickened calvarium
        3. Craniosynostosis
        4. Underpneumatization of the mastoids
        5. Hypoplasia or aplasia of the paranasal sinuses
        6. A spur arising from the anteroinferior tip of the mandible
    2. Spine.
        1. Fusion of vertebral bodies (especially C2-3-4)
        2. Deficiency of the posterior vertebral arches
    3. Thorax: Ribs can adopt a distorted shape (coat-hanger configuration) even though the thoracic cage is not hypoplastic.
    4. Long bones: undermodeled and frequently mildly bowed.
    5. Hands and feet.
        1. Carpal and tarsal fusions: common
        2. Erosion of the carpal bones: observed in adolescence and adulthood
        3. Metacarpals, metatarsals, and phalanges: elongated and poorly modeled
        4. Distal phalanges of the thumb and great toes: hypoplastic
5. Females with FMD: exhibit the same cranial and long bone features as males, but to a lesser degree
6. Females with MNS
    1. Skull
        1. Sclerotic skull base
        2. Delayed closure of the fontanels
    2. Spine
        1. Vertebral bodies: increased in height, especially in the lumbar region
        2. Scoliosis: common
    3. Thorax
        1. Ribs: irregular in contour and form
        2. Clavicle: similarly wavy and irregular, with some expansion of its proximal end
    4. Long bones: bowed both limbs with marked cortical irregularity
    5. Hands and feet: elongated and undermodeled phalanges, metacarpals, and metatarsals
    6. Pelvis: exhibits a supra-acetabular constriction with flaring of the ilia
5. Molecular genetic testing
    1. *FLNA* is the only gene currently known to be associated with the otopalatodigital (OPD) spectrum disorders.
    2. Sequence analysis of entire coding region and of select exons: available clinically for confirmation of the diagnosis in the proband and carrier testing of the relatives.
    3. Both somatic and germline mosaicism in FLNA leading to periventricular nodular heterotopia (PVNH) have been observed and have been associated with modulation of the severity of the phenotype and survivorship in males (Guerrini et al. 2004; Parrini et al. 2004; Robertson 2007).
        1. Germline mosaicism has been observed in association with OPD I.
        2. Somatic mutation has been shown to have led to MNS, suggesting similar

processes may modulate the expression of OPD spectrum phenotypes (Robertson et al. 2006).

Genetic Counseling

1. Recurrence risk (Robertson 2013)
    1. Sibs of a male proband with OPD I, OPD II, or FMD: Risk depends on the genetic status of the parents.
        1. Mother is a carrier.
            1. A 50% risk to her son to receive the disease gene and express the disease.
            2. A 50% risk to her daughter to receive the disease gene and become a carrier with a range of possible phenotypic expression.
            3. Mother of an affected child, regardless of proven carrier status, has an increased risk of having an affected male fetus due to presence of maternal germinal mosaicism.
        2. Father has an *FLNA* mutation.
            1. All female sibs will inherit the mutation.
            2. Male sibs will not inherit the mutation.
    2. Sibs of a proband with MNS: Risk depends upon the genetic status of the mother.
        1. Mother has the gene mutation.
            1. A 50% chance of transmitting the *FLNA* mutation to each child.
            2. Male sibs who inherit the mutation will be affected and generally dies prenatally or perinatally.
            3. Female sibs who inherit the mutation will have a range of phenotypic expression.
        2. Mother is clinically unaffected: Risk to sibs appears to be low but greater than that of the general population due to possible parental germline mosaicism.
    3. Patient's offspring
        1. Males with OPD II do not reproduce.
        2. Males with OPD I or FMD transmit the disease-causing mutation to all of their daughters and none of their sons.
        3. Females with OPD I, OPD II, or FMD.
            1. A 50% chance of transmitting the disease-causing mutation to each child.
            2. Sons who inherit the mutation will be affected.
            3. Daughters will have a range of possible phenotypic expression.
        4. Males with MNS usually die prenatally or perinatally and do not reproduce.
        5. Females with MNS
            1. A 50% chance of transmitting the disease-causing mutation to each child.
            2. Sons who inherit the mutation will be affected and generally die prenatally.
            3. Daughters will have a range of possible phenotypic expression.
2. Prenatal diagnosis
    1. Prenatal ultrasonography: Prenatal ultrasound diagnoses of OPD II in a fetus of an affected mother and in a fetus of a normal mother (Eccles et al. 1994) have been reported.
    2. A report of a series of 10 fetuses and a neonatally deceased newborn displaying a multiple congenital anomalies syndrome suggestive of otopalatodigital spectrum disorders (OPDSD), in whom *FLNA* analysis was performed (Naudion et al. 2016).
        1. A global mutation rate of 44% was found.
        2. This series allows expanding the clinical and *FLNA* mutational spectrum in OPDSD. However, it was emphasized that difficulties to correctly discriminate OPDSD based on clinical criteria in fetuses are due to the major overlap between these conditions.
        3. Molecular analyses may help pathologists to refine clinical diagnosis according to the type and the location of *FLNA* mutations.
        4. Discriminating the type of OPDSD is of importance in order to improve the

genetic counseling to provide to families.

3. Fetal phenotype in OPDSD (Naudion et al. 2016).
    1. Hypertelorism, flat nose, microretrognathia, first ray hypoplasia, syndactyly, hydronephrosis/oligohydramnios due to urethral obstruction, and cerebellar hypoplasia are the strongest criteria to suggest OPD2 in fetuses.
    2. X-ray findings: uninformative (only splayed metaphyses in a single fetus) as they probably become progressively more obvious during development.
    3. Moreover, one fetus and the previously described fetus with the recurrent MNS mutation (infant 2 from Santos et al. 2010) confirm the neurological anomalies (white matter hemorrhage, leukomalacia, cerebellar neuronal heterotopias, Dandy–Walker malformation); cleft palate and eye anterior segment anomalies may also be observed in MNS.
    4. Sclerocornea has been described in at least two other males with lethal MNS (Santos et al. 2010) and one male patient who died at the age of 9 months (Verloes et al. 2000), while Peters anomaly was identified in a neonatally deceased male (Weh et al. 2014). These ocular anomalies are likely to be part of the phenotypic spectrum of severe OPDSD.
    4. Prenatal diagnosis and preimplantation genetic diagnosis (PGD) for at-risk pregnancies require prior identification of the disease-causing mutation in the family.
3. Management
    1. Hearing aids for deafness.
    2. Stridor in the neonatal period due to laryngeal stenosis rarely requires surgical intervention and is nonprogressive.
    3. Cosmetic surgery to correct the frontoorbital deformity attempted in some individuals with good results. Regrowth postsurgery does not seem to occur (Kung and Sloan 1998).
    4. Surgery to correct hand and foot malformations and scoliosis.
    5. Chest expansion surgery attempted in several individuals with Melnick-Needles syndrome, with only marginal clinical benefit.
    6. Continuous positive airway pressure (CPAP) for prevention of airway collapse and sleep apnea secondary to micrognathia and tracheobronchomalacia in severely affected individuals. Melnick-Needles syndrome with obstructive sleep apnea successfully treated with nasal continuous positive airway pressure ventilation (Lan et al. 2006).
    7. Anesthetists should be aware of the associated laryngeal stenosis, if intubation and ventilation are required (Leggett 1988; Mehta and Schou 1988).

Young, K., Barth, C. K., Moore, C., et al. (1993). Otopalatodigital syndrome type II associated with omphalocele: Report of three cases. *American Journal of Medical Genetics, 45*, 481–487.

Fig. 1 (**a**–**d**) A 2-month-old premature (33-week gestation) male infant has multiple congenital anomalies (**a**–**d**), consisting of marked brachycephaly (**b**), widely opened anterior fontanel, short neck with redundant nuchal skin, severe downslanting palpebral fissures, arched eyebrows, a small and flat nose, an extremely small mouth with posterior inverted U-shaped cleft palate (**d**), a groove present at philtrum site and lower lip areas (**c**), low-set, posteriorly rotated malformed ears (**b**), a short sternum, a large umbilical hernia, and hypoplastic scrotum with undescended testicles. Marked limb anomalies (**a**) are noted: mildly bowed upper arms and forearms, flexed hands with ulnar deviation and overlapping fingers, and duplicated fifth fingers with clinodactyly, bowing of upper and lower legs, and dorsiflexed feet with four toes each with medially deviated great toes and laterally deviated second through fourth toes. Clinical, postmortem, and radiological findings are consistent with otopalatodigital type II syndrome. DNA testing identified two hemizygous missense mutations: c.613 T > C (p.Cys-205-Arg) and c.5290 G > A (p. Ala-1764-Thr) in the *FLNA* gene (Sankararaman et al. 2013). The first sequence variation is previously reported to be associated with periventricular heterotropia. The significance of the second sequence variant is unknown. *FLNA* mutations with presumed gain of function are previously reported in association with four other disorders: otopalatodigital syndrome type I and II, frontometaphyseal dysplasia, and Melnick-Needles syndrome

Fig 2 (**a**–**l**) Radiographs show skull (**a**, **b**), hypoplastic scapulae, curved humeri, radii, and ulnae (**c**–**e**), duplicated fourth fingers with four unusually shaped metacarpals and phalanges (**f**, **g**), markedly bent femora (**h**–**j**), bent tibiae, unossified fibulae (**i**, **j**), and four toes in each foot (**k**, **l**) with unusually shaped metatarsals and phalanges

Pachyonychia Congenita

Contents

Pachyonychia congenita (PC) is a group of rare genetically inherited diseases characterized by nail dystrophy and by varying features of ectodermal dysplasias. There are two major clinical subtypes recognized: type I with oral leukokeratosis and type II with multiple pilosebaceous cysts (Çelebi et al. 1999).

Synonyms and Related Disorders

Pachyonychia congenita tarda; PC-1 (Jadassohn-Lewandowsky syndrome); PC-2 (Jackson-Lawler syndrome)

Genetics/Birth Defects

1. Inheritance (Çelebi et al. 1999; Conners et al. 2001):
    1. Type I pachyonychia congenita (Jadassohn-Lewandowsky type):
        1. Autosomal dominant inheritance
        2. Possible autosomal recessive inheritance (Haber and Rose 1986)
    2. Type II pachyonychia congenita (Jackson-Lawler type): autosomal dominant
2. Etiology (McLean et al. 1995; Munro 2001; Terrinoni et al. 2001; Eliason et al. 2012):
    1. Type I – caused by mutations in genes encoding one of the paired keratins of specialized epidermis, KRT6a (Smith et al. 1999a; Forrest et al. 2016) or KRT16 (Smith et al. 1999b), resulting in:
        1. Fragility of specific epithelia.
        2. Phenotypes of pachyonychia congenita I or focal nonepidermolytic palmoplantar keratoderma with insignificant nail changes.
        3. The novel mutation in the KRT6A confirms the role of this gene in causing early severe forms of PC and supports the adoption of a classification system based upon the mutant gene for a disease which may span from mild localized (focal) to extensive mucocutaneous manifestations (Cammarata-Scalisi et al. 2016).
    2. Type II – caused by mutations in genes encoding one of the paired keratins of specialized epidermis, KRT6b (Smith et al. 1998) or KRT17 (Feng et al. 2003):
        1. Linkage analysis mapped pachyonychia congenita type II phenotype within the

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_189

type I keratin gene cluster on chromosome 17q12-21 (Munro et al. 1994).
    2. A germline mutation has been identified in keratin 17 gene (K17).
    3. Colocalization of K17 with keratin 6b.
3. Genotype-phenotype correlation:
    1. Differences in type I and type II phenotypes: largely explainable by the difference in expression patterns between the K6a/K16 and K6b/K17 expression pairs
    2. K6b/K17 expresses at higher levels in the pilosebaceous unit than K6a/K16: responsible for the pilosebaceous cysts in type II
    3. Conversely, K6a/K16 more widely expressed in oral epithelia: responsible for the greater predominance of oral leukokeratosis in type I

Clinical Features

1. Presence of intra- and interfamilial phenotypic variation (Feinstein et al. 1988).
2. Pachyonychia congenita type I (56.2% of cases):
    1. The most common subtype
    2. Onset in infancy
    3. Severe nail dystrophy affecting all the nails symmetrically (Dogra et al. 2002):
        1. The best hallmark of the disease.
        2. Thickened wedge-shaped nails.
        3. Proximal portions of the nails: smooth and normally attached to the lateral nail folds.
        4. Distal portions of the nails: may increase to many times the normal thickness, producing a subungual keratinous mass that pushes the nail plate upward, arching it transversally, folding it longitudinally, and elevating it distally.
        5. Nails commonly shed and regrow with similar but more severe changes.
        6. Projections from the nail beds make the nails susceptible to trauma with consequent chronic paronychial infections.
    4. With or without following associated anomalies (Munro 2001):
        1. Focal nonepidermolytic palmoplantar keratoderma (predominantly a feature of type I)
        2. Follicular keratoses observed on:
            1. Temple
            2. Eyebrows
            3. Extensor aspect of the proximal parts of the extremities
        3. Hyperkeratosis of palms, soles, knees, and elbows
        4. Localized foot blistering
        5. Oral leukokeratosis: a prominent sign
        6. Neonatal teeth
        7. Blister formation on palms and soles
        8. Hoarse voice due to laryngeal involvement (leukokeratosis)
        9. Palmar and plantar hyperhidrosis
3. Pachyonychia congenita type II (24.9% of cases) (Munro 2001):
    1. Nail dystrophy
    2. Less pronounced or absent palmoplantar keratoderma and oral changes
    3. Follicular keratoses
    4. Oral leukokeratosis
    5. Multiple pilosebaceous cysts (most useful distinguishing feature for type II but usually occurring at puberty):
        1. Epidermoid or infundibular cysts (arising from the hair follicle infundibulum)
        2. Eruptive vellus hair cysts and multiple steatocystomas (characteristic of type II) (arising from the sebaceous duct epithelium) (Moon et al. 1994; Smith et al. 1997)
    6. Bullae of palms and soles
    7. Palmar and plantar hyperhidrosis
    8. Natal or neonatal teeth
    9. Pili torti in children
    10. Bushy eyebrows
    11. Hidradenitis suppurativa
4. Pachyonychia congenita type III (Schafer-Brunauer type) (11.7%):
    1. Features of type I and type II
    2. Angular cheilosis
    3. Leukokeratosis of the cornea
    4. Cataracts
5. Pachyonychia congenita tarda (type IV) (7.2%) (Lucker and Steijlen 1995; Mouaci-

Midoun et al. 1996; Hannaford and Stapleton 2000):
   1. A rare form of pachyonychia congenita
   2. Features of type I, type II, and type III
   3. Laryngeal lesions
   4. Hoarseness
   5. Mental retardation
   6. Hair anomalies
   7. Alopecia
   8. Nail changes occurring in the second or third decade
   9. Abnormal painful nails
   10. Palmoplantar keratoderma
6. Pachyonychia congenita with early-onset nail changes in the absence of other associated features.
7. Among patients with a detectable mutation, PC manifests with nail thickening and plantar keratoderma before school age in more than three-quarters of affected children, allowing early diagnosis. The highly visible nail changes and painful plantar thickening exert a psychosocial effect on most affected adolescents (Shah et al. 2014).
8. Differential diagnosis (Smith et al. 2014):
   1. Onychomycosis:
      1. Although the hyperkeratotic nail thickening seen in pachyonychia congenita may be mistaken for onychomycosis, dermatophytic infections do not affect all finger and toenails particularly at an early age.
      2. In the rare conditions of autoimmune endocrinopathy-candidiasis-ectodermal dystrophy and systemic mucocutaneous candidosis, all nails may be affected.
   2. Oral leukokeratosis together with nail dystrophy: often an indication of pachyonychia congenita and may be mistaken for *Candida albicans* (thrush), white sponge nevus, and/or leukoplakia.
   3. Epidermolysis bullosa simplex (please see the chapter "► Epidermolysis Bullosa") or other palmoplantar keratodermas can result in a similar pattern of plantar blister formation or hyperkeratosis, respectively; however, they do not share the characteristic nail changes of PC.
   4. Clouston syndrome, caused by mutation of *GJB6*, the gene encoding the gap junction protein connexin 30, can also mimic PC. Alopecia does not typically occur in PC but is a relatively common feature of Clouston syndrome.
   5. Nonsyndromic congenital nail disorder 10 without the associated palmoplantar keratoderma or other features of PC can be confused with PC. This is an autosomal recessive disorder caused by biallelic pathogenic variants in *FZD6*, encoding frizzled 6 (Wilson et al. 2013).
   6. Familial onychogryphosis without the associated palmoplantar keratoderma or other features of PC can be confused with PC. Individuals who have nail findings only are unlikely to demonstrate mutation in one of the PC keratins.
   7. Twenty-nail dystrophy may occur without keratoderma or other associated changes. Autosomal dominant inheritance has been described.
   8. Dyskeratosis congenita manifests with features overlapping with PC including nail dystrophy, palmoplantar keratoderma (PPK), hyperhidrosis, and oral leukoplakia. Distinctive features include reticulate hyperpigmentation, skin tumors, and hematologic manifestation.
   9. Palmoplantar keratoderma striata (PPKS1), caused by pathogenic variants in *DSG1*, can be confused with focal nonepidermolytic palmoplantar keratoderma (FNEPPK). However, pain is typically either absent or less significant in PPKS1 than in FNEPPK or PC.
   10. Punctate PPK type I, caused by pathogenic variants in *AAGAB*, can be painful and focal (due to coalescence of lesions) (Pohler et al. 2012).
   11. Olmsted syndrome is characterized by painful palmoplantar keratoderma that may occur with additional features including periorificial keratotic plaques and sometimes constricting digital bands on hands and feet that result in spontaneous amputation, mutilating PPK, alopecia, nail

dystrophy, and itching of lesions. It is caused by pathogenic variants in *TRPV3* (Lin et al. 2012).

9. Genodermatoses with nail involvement (Lawry and Ralph 2005; Tosti et al. 2006; Irvine and Mellerio 2010; Inamadar and Palit 2012):
    1. Genodermatoses with characteristic nail changes:
        1. Pachyonychia congenita:
            1. Thick, yellowish-brown-colored nails present at birth or developed during neonatal period with or without natal teeth are pointers to the diagnosis of PC.
            2. Dystrophy of all the twenty nails is a feature common to all the three variants of PC, but other features may be variable.
            3. Upward angulation of the distal free edge of the thickened nail plate (progressive distal thickening) is a distinct feature and helps to differentiate it from other disorders with thick nails.
            4. Recurrent painful paronychia may be associated.
        2. Nail-patella syndrome (please see the chapter "► Nail-Patella Syndrome"):
            1. Anonychia or nonprogressive micronychia (mostly involving thumb and index fingers) present since birth and triangular lunula with distal apex in the midline are highly predictive of nail-patella syndrome.
            2. Nail hypoplasia is more marked on the ulnar sides of the involved fingers.
        3. Yellow nail syndrome: Upper and lower respiratory tract illnesses (sinusitis/bronchitis/recurrent bilateral pleural effusion/bronchiectasis) and primary lymphedema (80%) (Hawsawi and Pope 2010) in combination with thickened, yellow nails are the clues for clinical diagnosis of yellow nail syndrome.
        4. Porphyrias (congenital erythropoietic porphyria, erythropoietic protoporphyria, porphyria cutanea tarda): Photo-onycholysis and marked koilonychia are the characteristic features of various hereditary porphyrias.
    5. Neurocutaneous syndromes:
        1. Tuberous sclerosis complex (please see the chapter "► Tuberous Sclerosis"): Garlic-clove fibromas (Koenen tumor) are multiple, elongated, pink- or flesh-colored tumors with hyperkeratotic tips, arising from beneath the proximal and lateral nail folds (periungual) producing longitudinal midline depression on nail plate. Such lesions appearing at puberty, along with facial angiofibromas and hypopigmented ash-leaf macules, are characteristic of tuberous sclerosis complex.
        2. Osler-Weber-Rendu syndrome: Telangiectasia of nail bed, visible as blanchable, punctate red dots, should prompt the clinician to screen the patient for Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia). These may bleed to give rise to splinter hemorrhage.
        3. Ataxia telangiectasia (please see the chapter "► Ataxia-Telangiectasia").
    6. Disorder of keratinization (Darier's disease): "V"-shaped notch on the free edge of the nail plate and alternate longitudinal red (erythronychia) and white (leukonychia) bands are the distinct features of Darier's disease. Splinter hemorrhages may be associated.
2. Genodermatoses with significant nail changes:
    1. Disorder of keratinization:
        1. Trichothiodystrophy: brittle nails, ridging and splitting of nail plate, nail dystrophy, yellow discoloration, onychogryphosis, and koilonychia. Diffuse alopecia, dental caries, and ichthyosis are the main clinical features.
        2. Bazex's syndrome: Psoriasiform nail changes (thickening and discoloration of nail plate, subungual hyperkeratosis, splinter hemorrhage) are

seen in all types of palmoplantar keratoderma and Bazex's syndrome but are not diagnostic of these disorders.
3. Marked nail changes are seen in transgradient keratodermas like Mal de Meleda, scleroatrophy of Huriez, and Olmsted syndrome.

2. Mechanobullous disorders:
1. Nail changes are milder in EB simplex, like nail dystrophy and onychomadesis. Onychogryphosis of great toenails may be a feature of EB (epidermolysis bullosa) simplex, Ogna variant (Tosti and Piraccini 2005).
2. Severe nail changes like onychodystrophy and anonychia are seen in junctional and dystrophic EB.

3. Poikilodermatous disorders:
1. Kindler syndrome: Gross nail dystrophy and pseudosyndactyly may be observed in patients with Kindler syndrome.
2. Dyskeratosis congenita: Nail dystrophy may be the initial presenting feature (evident by 5–13 years of age) of patients with dyskeratosis congenita.

4. Congenital immunodeficiency: Markedly dystrophic nail plate and recurrent tender paronychia in a child with associated oral thrush warrant screening for chronic mucocutaneous candidiasis.
5. Disorder of pigmentation (incontinentia pigmenti) (please see the chapter "► Incontinentia Pigmenti"): Periungual warty lesions with underlying osteolysis may appear in patients with incontinentia pigmenti during adolescence.

3. Genodermatoses with nonspecific nail changes:
1. Ectodermal dysplasia: Various hypoplastic nail changes (onychodystrophy, micronychia/anonychia) with variable combinations of hypotrichosis or alopecia, hypohidrosis, palmoplantar keratoderma, and dental anomalies are seen in patients with ectodermal dysplasia (Irvine and Mellerio 2010).
2. Disorders of pigmentation:
1. Cronkhite-Canada syndrome: characteristic nail dystrophy due to formation of ventral nail in the absence of normal nail production by the nail matrix
2. Peutz-Jeghers syndrome: punctate brown spots or longitudinal pigmented bands on nails
3. Laugier-Hunziker syndrome: longitudinal brownish bands on nails with adult-onset macular pigmentation of lips and buccal mucosa
4. LEOPARD syndrome (please see the chapter "► LEOPARD Syndrome"): koiloleukonychia

3. Poikilodermatous disorder (Rothmund-Thomson syndrome): Nails may be small and dystrophic.
4. Disorder of keratinization (KID syndrome): onychodystrophy.
5. Neurocutaneous disorders (neurofibromatosis type I) (please see the chapter "Neurofibromatosis Type 1"): "pterygium inversus unguium"-like changes.
6. Metabolic disorders:
1. Fucosidosis: onychogryphosis
2. Fabry disease: "turtle back configuration" of nails

7. Disorder with premature aging (progeria): onychodystrophy.

Diagnostic Investigations

1. Histology and ultrastructure of cutaneous and oral lesions: suggest a keratin disorder (Munro 2001)
2. Molecular analyses of mutations in KRT6A, KRT6B, KRT6C, KRT16, or KRT17 (Wilson et al. 2014): confirmed, at the molecular level, the clinical diagnosis of PC (Wilson et al. 2014)
3. Whole exome sequencing to establish the correct diagnosis (Almutawa et al. 2015)

Genetic Counseling

1. Recurrence risk:
   1. Patient's sib:
      1. Autosomal dominant inheritance: not increased unless a parent is affected
      2. Autosomal recessive inheritance: 25%
   2. Patient's offspring:
      1. Autosomal dominant inheritance: 50%
      2. Autosomal recessive inheritance: not increased unless the spouse is a carrier
   3. Counseling of unaffected parents with a first child diagnosed as having PC should entail a discussion of the possibility of germ cell mosaicism contributing to an increased risk of having subsequent affected children (Pho et al. 2011).
   4. Homozygous or compound heterozygous mutations should be especially sought in PC patients who present with alopecia (Irvine 2012). As four keratin genes are involved in dominant PC, bigenic inheritance is also a possibility (Wilson et al. 2012).
2. Prenatal diagnosis: genomic mutation detection possible in prenatal diagnosis of pachyonychia congenita type I (KRT6a/KRT16) or type II (KRT6b/KRT17) by CVS or amniocentesis.
3. Preimplantation genetic diagnosis may be available for families in which the disease-causing mutation has been identified.
4. Management (Dahl et al. 1995):
   1. No ideal treatment for the thickened nail plate available.
   2. Topical lubricants and keratolytics (Su et al. 1990): indicated to areas of palmar and plantar hyperkeratosis but usually produces only transient benefit. Squamous cell carcinoma developed in one of the patients over the site of chronic plantar ulcerations. Areas of chronic bullous formation or ulceration should be observed for possible skin malignancy.
   3. Antiseptic wet dressings for secondarily infected areas.
   4. Systemic treatment with acitretin producing variable and inconsistent results with caution of side effects (teratogenicity and hyperostosis).
   5. Two patients with genetically confirmed PC type I were treated with plantar injections of botulinum toxin type A. Both patients showed a marked improvement in pain and blistering with an average response time of 1 week, a 6-month mean duration of effectiveness, and a lack of any side effects or tachyphylaxis (González-Ramos et al. 2015).
   6. Gabapentin and plantar injections of botulinum toxin combined with psychological counseling, cognitive behavioral therapy, and physical therapy were all useful in alleviating chronic foot pain in a pediatric patient (Tariq et al. 2016).
   7. Custom-fitted footwear for protective support of painful fissures and blisters on the soles.
   8. Simple avulsion of the distorted nails is inadequate because the dystrophic nail regrows.
   9. Curettage and electrofulguration or surgical excision of the nail matrix and bed can improve function and appearance.
   10. Surgical excision of focal, hyperplastic epithelial mass results in improvement of hoarseness due to laryngeal obstruction by laryngeal lesions. Additional microsurgery may be necessary for the recurrence of the laryngeal lesions.
   11. Therapeutic small interfering RNAs (siRNAs) for pachyonychia congenita (Leachman et al. 2008):
      1. A new siRNA entering clinical trials in PC patients with the *KRT6A* N171K mutation, with a gene-specific *KRT6A* siRNA study possibly to follow.
      2. This is the first-in-man siRNA therapeutic trial for a skin indication and the first siRNA to target a gene mutation.

Fig. 1 (**a**–**d**) Characteristic nail changes in an 8-month-old girl with pachyonychia congenita type I showing smooth proximal ends and thick distal ends of the nails, producing a subungual keratinous mass that pushes the nail bed upward, arching it transversally, folding it longitudinally, and elevating it distally. The patient also has oral leukokeratosis

Pallister–Killian Syndrome

Contents

Pallister–Killian syndrome is a rare sporadic cytogenetic abnormality, caused by a tissue-specific mosaic distribution of an additional isochromosome 12p, first described in three adults by Pallister et al. in 1977 (Pallister et al. 1977) and followed by a report of a child by Teschler-Nicola and Killian in 1981 (Teschler-Nicola and Killian 1981). The syndrome is also known as Teschler-Nicola/Killian syndrome, Pallister mosaic aneuploidy syndrome, and isochromosome 12p mosaicism or mosaic tetrasomy 12p (Buyse and Korf 1983). It is the most frequent autosomal tetrasomy in humans (Bresson et al. 1991).

Synonyms and Related Disorders

Isochromosome 12p syndrome; Killian syndrome; Mosaic tetrasomy 12p syndrome; Pallister mosaic syndrome; Pallister–Killian mosaic aneuploidy syndrome

Genetics/Basic Defects

1. Genetics:
   1. Sporadic in mature (Srinivasan and Wright 2014)
   2. Appears to be associated with increased maternal age
2. Basic cytogenetic defect (Bresson et al. 1991; Yeung et al. 2009):
   1. Caused by tetrasomy 12p.
   2. Generally a mosaic.
   3. Frequently undetectable by standard cytogenetic analysis of peripheral blood.
   4. In the great majority of patients, the i(12p) is maternal in origin (maternal meiosis II nondisjunction), with the underlying mechanism thought to involve a combination of centromere misdivision and nondisjunction at meiosis. Although more rarely, paternal nondisjunction has also been reported (Izumi and Krantz 2014).
   5. As a result, the i(12p) is present at conception, and mosaicism results from postzygotic mitotic loss (Peltomaki et al. 1987).
   6. Chromosomally normal cell line in Pallister syndrome arises post-conception from a zygote already aneuploid consequent to meiotic nondisjunction (Wenger et al. 1988).
   7. There is no apparent correlation between the proportion of tetrasomic cells and the severity of clinical presentation (Schinzel 1991).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_190

Clinical Features

1. Wide spectrum of clinical manifestations (Genevieve et al. 2003; Wilkens et al. 2012).
2. Normal or large birth weight (Mathieu et al. 1997).
3. Craniofacial dysmorphism (Reynolds et al. 1987):
    1. Hypotonia
    2. Coarse face
    3. Brachycephaly
    4. High and broad forehead with frontal bossing
    5. Temporal alopecia
    6. Sparse eyebrows and eyelashes
    7. Hypertelorism
    8. Short nose with anteverted nares
    9. A thick philtrum
    10. A large mouth with down-slanting corners
    11. Full cheeks
    12. Cleft lip/palate
    13. High-arched palate
    14. Micrognathia
    15. Macroglossia
    16. Oral frenula
    17. Delayed dental eruption
    18. Dental anomalies
    19. Low-set and posteriorly rotated ears
    20. Hypertrophy of anthelix crux
    21. Thick earlobes
4. Oro-dental features (Bagattoni et al. 2016).
    1. Twelve probands (57%) showed an atypical dental pattern, with multiple missing teeth (primarily the first permanent molars) and two (10%) double teeth.
    2. The severity of gingivitis and dental caries increased with age, and gingival overgrowth was a common finding.
    3. A characteristic occlusive phenotype was found: a high-arched palate with mandibular prognathism associated with an anterior open bite and crossbite and with posterior crossbite (unilateral or bilateral).
    4. The prevalence of oral habits (nonnutritive sucking, mouth breathing, bruxism) was high, even in older probands.
5. Short neck.
6. Diaphragmatic hernia with or without lung hypoplasia.
7. Imperforate anus.
8. CNS/neurologic abnormalities:
    1. Severe hypotonia
    2. Mental retardation
    3. Dilated ventricles
    4. Bifrontal cortical atrophy
    5. Absent speech
    6. Poor vision
    7. Epilepsy
9. Developmental and behavioral characteristics (Kostanecka et al. 2012):
    1. Wide neurocognitive spectrum of PKS.
    2. Further studies are needed to investigate whether children with PKS are at increased risk for autism and to investigate the prevalence of neurosensory deficits, tactile defensiveness, and lethargy, especially as they may relate to developmental impairments in children with PKS.
10. Cardiac manifestations (Tilton et al. 2014):
    1. Atrial or ventricular septal defects: the most commonly seen congenital heart differences
    2. Occasional occurrence
        1. Bicuspid aortic valve
        2. Aortic dilatation
        3. Cardiac hypertrophy/cardiomyopathy
11. Limb defects:
    1. Talipes
    2. Broad and short hands and fingers
    3. Hypoplastic nails
    4. Abnormal palmar creases
    5. Lymphedema
12. Skin anomalies:
    1. Loose/excess skin
    2. Pigmentary dysplasia
    3. Mild hyperkeratosis
    4. Dry skin
    5. Sweating abnormalities
13. Occasional internal organ malformations:
    1. Umbilical hernia
    2. Malrotation of the gut
    3. Omphalocele

4. Abnormalities of urogenital tract including cystic or dysplastic kidneys
5. Genital anomalies in males
    1. Cryptorchidism
    2. Small scrotum
6. Occasional genital anomalies in females
    1. Ambiguous external genitalia
    2. Hypoplasia of the labia majora
    3. Absence of the upper vagina and uterus

14. Anhydrosis/hypohidrosis and episodic hyperventilation, suggesting involvement of the autonomic system (Blyth et al. 2015).
15. Lethal presentation of mosaic tetrasomy 12p (Pallister–Killian) syndrome in neonatal period: a consistent phenotype characterized by dysmorphic facies and large diaphragmatic hernia (Young et al. 1989).
16. Majority of patients die prenatally, perinatally, or early postnatally and may die even after 10 or 15 years.
17. Phenotype in older children and adults (Quarrell et al. 1988): marked phenotypic changes occurring during childhood and adolescence (Horneff et al. 1993):
    1. Coarse and flat facies
    2. Macroglossia
    3. Prognathia
    4. Everted lower lip
    5. Muscular hypertonia
    6. Contractures
    7. Severe psychomotor retardation

Diagnostic Investigations

1. Cytogenetic studies:
    1. Presence of an extra metacentric chromosome i(12p) mainly in skin fibroblasts (tissue-specific mosaic distribution of an additional isochromosome 12p) (Hunter et al. 1985; Genevieve et al. 2003), but rarely also in cultured peripheral blood lymphocytes (Wenger et al. 1988).
    2. Demonstration of a supernumerary isochromosome of 12p.
    3. Mosaic tetrasomy 21 is mosaic tetrasomy 12p some of the time (Hall 1985).
    4. Confirmation of the chromosomal origin of the supernumerary chromosome (mosaic tetrasomy 12p) in one of the original Pallister–Killian mosaic syndrome cases (Warburton et al. 1988).
    5. Confirmation of 12p tetrasomy by FISH techniques (Speleman et al. 1991; Butler and Dev 1995):
        1. Using centromere probe on chromosome 12
        2. Using whole chromosome 12 painting probe
    6. Cytogenetic studies of several tissues because of mosaicism (Mathieu et al. 1997): the mosaicism is usually detected in cultured skin fibroblasts or amniotic cells and rarely in phytohemagglutinin-stimulated lymphocytes, which suggests stimulation of T lymphocytes may distort the percentage of abnormal cells:
        1. Circulating lymphocytes: mosaicism as low as 1–3%.
        2. Amniocytes, chorionic cells, and skin fibroblasts: mosaicism ranging from 6% to 100%.
        3. Multiplex ligation-dependent probe amplification (MLPA) on buccal smears is a good and noninvasive method to detect extra copies of 12p and should be considered as the first exam, before a skin biopsy for a fibroblast karyotype is performed (Costa et al. 2015). A limitation of MLPA is that mosaicism in low level may not be detected, so a normal MLPA result cannot rule out PKS diagnosis (Van Opstal et al. 2011).
2. Demonstration of the utility of SNP (single nucleotide polymorphism) arrays in conjunction with traditional cytogenetic techniques for the evaluation of PKS. Given that the percentage of mosaic tetrasomic cells in peripheral blood decreases as the individual with PKS ages, SNP arrays should be performed as early as possible to avoid the

need for skin biopsy when possible (Conlin et al. 2012).
3. Array comparative genomic hybridization (aCGH) can detect partial tetrasomy of 12p in blood without invasive skin biopsy (Theisen et al. 2009). However, aCGH on unstimulated blood does not detect all cases of Pallister–Killian syndrome. A skin biopsy should remain the diagnostic gold standard (Hodge et al. 2012). Array CGH only suggested the diagnosis in 15.8%, but buccal FISH could have made the diagnosis in 75.0% (Blyth et al. 2015).
4. Droplet digital PCR (polymerase chain reaction) should be considered as an effective tool for both clinical and research analytics to precisely quantify mosaic genomic copy number alterations or mosaic mutations (Fujiki et al. 2016).
5. Radiography (Jamuar et al. 2012):
    1. A recurrent pattern:
        1. Delayed ossification of the vertebral bodies, pubic bones, triradiate cartilage, and sacroiliac junction, flaring of the anterior ends of the ribs, and metaphyseal broadening of the long bones.
        2. The absence of pubic ossification is particularly easy to recognize and thus may be a useful diagnostic marker.
        3. The delay of the endochondral ossification is apparently related to the feature of short limbs often reported in PKS. Moreover this slow endochondral bone formation is most evident in the axial skeleton.
    2. Additional dysostotic anomalies previously described (Schinzel 1991):
        1. Atlantooccipital fusion
        2. Absence of 12th ribs
        3. Radioulnar synostosis
        4. Absent thumbs
        5. Absence of the talus
        6. Duplication of halluces
6. Echocardiography for congenital heart defect.
7. EEG for seizure activities.
8. MRI of the brain (Saito et al. 2006):
    1. Normal MRI findings
    2. Abnormal MRI findings:
        1. Cortical atrophy with frontal predominance
        2. Ventricular dilatation
        3. Hydrocephalus
        4. Reduced white matter
        5. Thickened cortex
        6. Micropolygyria
        7. Heterotopic neurons
        8. Agenesis of corpus callosum
        9. Pineal gland tumor
        10. Multiple T2-high lesions
        11. T2 elongation in the white matter
9. Postmortem pathologic examinations (Mathieu et al. 1997):
    1. Malpositioned feet
    2. Diaphragmatic defect
    3. Hypoplastic nails
    4. Genital malformation
    5. Imperforate or anteriorly placed anus
    6. Supernumerary spleen
    7. Heart valvular dysplasia
    8. Hypoplasia of the fibula

Genetic Counseling

1. Recurrence risk:
    1. Patient's sib: low recurrence risk (all cases are sporadic with only one preliminary case report of recurrence.) (Mathieu et al. 1997)
    2. Patient's offspring: not surviving to reproductive age or severely handicapped by profound mental retardation
2. Prenatal diagnosis (Doray et al. 2002; Srinivasan and Wright 2014):
    1. Ultrasound anomalies (Liberati et al. 2008):
        1. Hydramnios (84%)
        2. Diaphragmatic hernia (16%)
        3. Short limbs, predominantly rhizomelic type of micromelia (10%)
        4. Hydrops fetalis (6%)
        5. Cystic hygroma (3%)
        6. Increased nuchal translucency (3%)
        7. Fetal overgrowth (3%)
        8. Flat fetal facial profile with a small nose and protruding lips (Liberati et al. 2008)
        9. Ventriculomegaly (3%)
        10. Dilatation of cavum pellucidum (3%)

11. Absence of visualization of the stomach (3%)
12. Presence of a sacral appendix (3%)
13. Cardiac malformation
14. Hypertelorism
15. Short neck
16. Other congenital anomalies

2. Cytogenetic studies on amniocytes (Shivashankar et al. 1988; Soukup and Neidich 1990), cells from CVS (Bernert et al. 1992), or fetal blood cells from cordocentesis (Chiesa et al. 1998):
    1. Conventional karyotyping
    2. FISH using chromosome 12 centromeric and whole chromosome painting probes:
        1. Interphase cells
        2. Metaphase cells

3. Management:
    1. Supportive treatment
    2. Surgical repair of diaphragmatic hernia or other congenital anomalies in nonlethal cases

Patellar Instability

Contents

Patellar or patellofemoral instability is a complex problem that is highly prevalent in the population (Gillespie 2012). It is a common cause of knee pain and disability (Minkowitz et al. 2007). Recurrent patellar instability can result from osseous abnormalities, such as patella alta, a distance of >20 mm between the tibial tubercle and the trochlear groove, and trochlear dysplasia, or it can result from soft tissue abnormalities, such as a torn medial patellofemoral ligament or a weakened vastus medialis obliquus (Colvin and West 2008).

Synonyms and Related Disorders

Patella alta; Patellar dislocation; Patellar subluxation; Patellofemoral instability; Slipping or recurrent patella dislocation

Genetics/Basic Defects

1. Definition of patellar instability (Grelsamer 1997; Minkowitz et al. 2007)
    1. A clinical entity or diagnosis of a traumatic dislocation
    2. A sign on physical examination, signifying the ability of the patella to be translated out of the trochlear groove of the femur in a passive manner
    3. A symptom, typically if the knee "gives away" as a result of the patella slipping out of the trochlear groove
2. Acute patellar dislocation
    1. Annual incidence of acute patellar dislocations in Finnish children <16 years of age: 43 per 100,000 children (Nietosvaara et al. 1994)
    2. Mechanisms of acute lateral patellar dislocations (Boden et al. 1997)
        1. An indirect injury
        2. A direct blow
3. Risk factors of recurrent patellofemoral instability (Boden et al. 1997)
    1. Typically an adolescent female
    2. Ligamentous laxity
    3. Multiple developmental anomalies
        1. Trochlear dysplasia
        2. Patella alta (high-standing patella)
        3. Rotational and angular bony alignment
4. Etiology of patellar instability: multifactorial (Redziniak et al. 2009)
    1. Patella alta

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_257

2. Trochlear dysplasia
3. Dysplasia of lateral trochlear margin
4. Shallow trochlear groove
5. Vastus medialis obliquus insufficiency
6. Joint laxity
7. Trauma
8. Previous surgery
9. Tight lateral structures (e.g., lateral retinaculum and iliotibial band)

Clinical Features

1. Acute patellar dislocation (Minkowitz et al. 2007).
    1. Rapid swelling associated with acute injury.
    2. A significant hemarthrosis frequently develops, especially if there is an associated osteochondral fracture.
    3. Loose chondral or bony fragments may be palpable in the joint.
    4. Attached osteochondral fragments may be felt in the medial parapatellar retinaculum.
    5. Focal areas of maximum tenderness suggest soft tissue injury.
    6. Tenderness at the medial femoral condyle may suggest an injury to the medial collateral ligament (MCL) of the knee.
    7. A palpable defect at the vastus medialis obliquus (VMO) distal insertion and a visible change in its symmetry suggest occurrence of significant disruption of the VMO insertion.
    8. A positive apprehension test at 30° of flexion: a classically described examination finding.
    9. Increased medial retinacular laxity not symmetrical with the contralateral knee with or without apprehension (DeLee et al. 2003).
2. Recurrent patellofemoral instability (Minkowitz et al. 2007)
    1. History
        1. A history of general ligamentous laxity or dislocation in the patient or family (Fig. 1) (Koh and Stewart 2014)
        2. Diffuse pain about the knee that is aggravated by going up and down the stairs or climbing hills
    2. Physical examination
        1. Patellar crepitation and swelling of the knee: common
        2. Patellofemoral crepitus: may be palpable
        3. Effusion: may be present
        4. The patellar grind test
            1. Done by applying pressure to the patella and manually displacing it medially, laterally, superiorly, and inferiorly in the trochlear groove.
            2. This test reproduces anterior knee pain when a patellofemoral pathological condition is present.
        5. Apprehension test
            1. The examiner holds the relaxed knee in 20–30° of flexion and manually subluxes the patella laterally.
            2. When the test is positive, the patient suddenly complains of pain and resists any further lateral motion of the patella.
        6. Patellar tilt test
            1. Done with the knee in extension.
            2. The examiner's fingers are placed along the medial side of the patella and the thumb on the lateral aspect.
            3. Inability to raise the lateral facet to the horizontal plane or slightly past indicates excessive lateral retinacular tightness.
        7. Dynamic patellar tracking
            1. Evaluated with the examiner standing in front of the seated patient while the patient slowly extends the knee.
            2. *A positive J sign*, lateral subluxation of the patella as the knee approaches full extension, indicates some degree of maltracking.
        8. Active patellar tracking
            1. Examined with the knee in the extended relaxed position.
            2. The quadriceps is tightened and motion of the patella is examined.
            3. Normally, the patella should move more superiorly than laterally.
        9. Tender patellar: indicates a pathological condition of the articular cartilage

3. Differential diagnosis: ► "Ehlers-Danlos Syndrome" (please see the chapter)

Diagnostic Investigations

1. Radiographic features associated with recurrent patellar instability (Colvin and West 2008; Gillespie 2012)
    1. Patella alta
    2. Patellar tilt
    3. Patellar subluxation
    4. Abnormally elevated distance between the tibial tubercle and trochlear groove (TT-TG distance)
    5. Trochlear dysplasia
        1. Crossing sign
        2. Supratrochlear spur
        3. Double contour (a hypoplastic medial facet)
2. Cross-sectional imaging with transverse computed tomography slices at different positions along the lower limb
    1. Provides a three-dimensional view of the patellofemoral joint and can be used to assess the lateral offset of the tibial tuberosity from the deepest point in the trochlear groove.
    2. A distance between the tibial tuberosity and the trochlear groove exceeding 20 mm is nearly always associated with patellar instability (Dejour et al. 1994).
3. Magnetic resonance imaging (Fig. 2) is better for assessing the integrity of the articular cartilage and soft tissue structures and has become the acceptable method to diagnose the medial patellofemoral ligament (MPFL) (Jain et al. 2011).
    1. Detects disruption of the MPFL (Sanders et al. 2001)
    2. Detects typical injuries seen after a patellar dislocation
        1. Cartilage damage or bone bruising of the medial patellar facet and the lateral femoral condyle (Kirsch et al. 1993)
        2. Injury to the vastus medialis obliquus: frequently presents as edema, hemorrhage, and/or elevation of the muscle away from the medial femoral condyle (Elias et al. 2002)
    3. Repair or reconstruction of the MPFL and distal realignment procedures: currently the most common surgical treatment options
4. Bone scan: can provide valuable functional information about the metabolic activity of the bone (Dye and chew 1994; Koh and Stewart 2014)
    1. A diffuse uptake pattern: seen in patients with patellofemoral pain
    2. A more localized pattern : seen in patients with specific areas of overload or a symptomatic chondral defect causing increased activity in the underlying bone

Genetic Counseling

1. Recurrence risk
    1. Risk to patient's sib: not increased unless in an autosomal dominant inheritance
    2. Patient's offspring: 50% in an autosomal dominant inheritance
2. Management (Colvin and West 2008; Gillespie 2012)
    1. Nonoperative treatment: generally recommended for primary patella dislocations
        1. Immobilization
        2. Physical therapy: mainstay therapy focusing on establishing optimal lower extremity balance, strength, and function
        3. Patellar taping or bracing
    2. Arthroscopic and minimally invasive techniques: typically limited to those patients with minimal amounts of bony malalignment or trochlear dysplasia or as an adjunct to provide additional soft tissue balancing in patients who undergo bony procedures (Koh and Stewart 2014)
        1. Arthroscopic medial plication techniques
        2. Miniopen medial reefing techniques
    3. Operative treatment
        1. For presence of osteochondral fracture fragment or retinacular injury

2. Reconstruction of the medial patellofemoral ligament with autograft or allograft in a patient with recurrent instability, with or without trochlear dysplasia, who has a normal tibial tubercle-trochlear groove distance and a normal patellar height
3. Distal realignment procedures
    1. Used in patients who have an increased tibial tubercle-trochlear groove distance or patella alta
    2. Contraindicated in patients with associated medial or proximal patellar chondrosis because of the potential to overload tissues that have already undergone degeneration
4. Tibial tubercle osteotomy
    1. Able to directly address some of the underlying biomechanical factors that predispose to patella instability with an increased anterior TT-TG distance or with patella alta.
    2. Anteromedial transfer can unload damaged articular cartilage (Fulkerson 2007).
5. Trochleoplasty for treatment of severe trochlear dysplasia in patients with instability

Fig. 1 (**a**–**d**) This 8-year-old Caucasian boy (**a**) was with his older brother and mother for evaluation of familial patellar instability leading to recurrent patellar subluxations and/or dislocations, shown by radiograph (**c**). Since 7 years of age, he repeatedly dislocated both patellae on normal walking or running. He could move the dislocated patellae back into normal places by his hands. His older brother and mother also have history of recurrent patellar dislocations. Patella operations were performed on both knees of the patient (**b**) and the *right* knee of the mother (**d**)

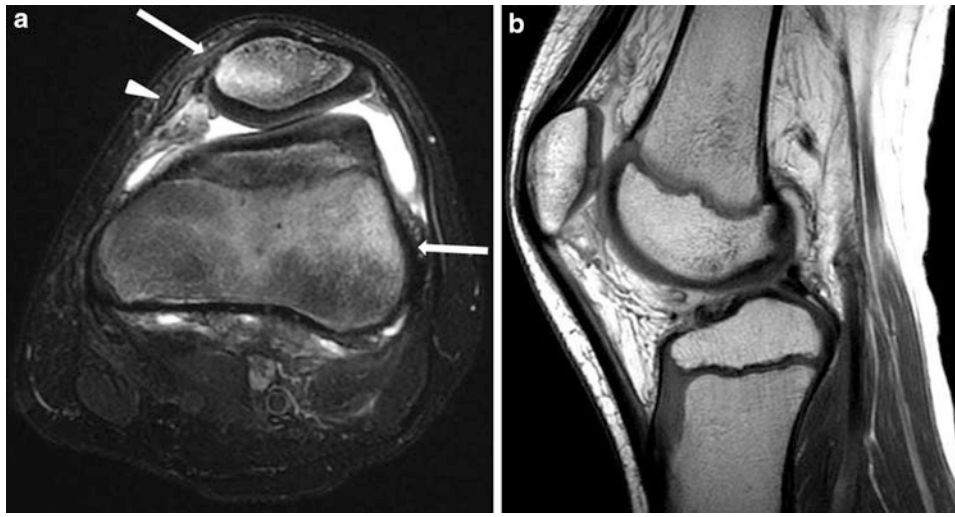

Fig. 2 (**a**, **b**) A 12-year-old boy with history of right transient patellar dislocation 2 years ago presented with *left* knee pain after an injury 4 weeks ago. MRI image (**a**) showed classic findings of transient patellar dislocation. There is subchondral marrow edema in the medial patella and lateral femoral condyle (*white arrows*). The medial patellofemoral ligament is torn (*white arrowhead*). A high riding patella, consistent with patella alta (**b**), is commonly associated with recurrent patellar instability (Courtesy of Dr. Grace Guo)

Peutz-Jeghers Syndrome

Contents

Peutz-Jeghers syndrome (PJS) was first described in 1921 by Peutz (Peutz 1921) and subsequently elaborated upon by Jeghers in 1949 (Jeghers et al. 1949) (Dong and Li 2004). The syndrome is characterized by gastrointestinal hamartomatous polyps and mucocutaneous hyperpigmentation of the lips, buccal mucosa, and digits. Incidence is estimated to be 1 in 50,000 to 1 in 200,000 live births (Giardiello and Trimbath 2006).

Synonyms and Related Disorders

Hamartomatous intestinal polyposis; Periorificial lentiginosis; Polyps-and-spots syndrome

Genetics/Basic Defects

1. An autosomal dominant disorder.
2. Mutations in the serine-threonine kinase 11 (*STK11*, also known as *LKB1*) gene on chromosome 19p13.3, are considered the major cause of PJS (Jenne et al. 1998).
3. Germline mutations of *STK11* are documented in up to 70–80% of patients with PJS and up to 15% of cases have deletions of all or part of *STK11* (Hemminki et al. 1998).
4. Loss of heterozygosity at 19p13.3 seen in PJP polyps and malignancy suggests that STK11 acts as a tumor suppressor gene
5. Sporadic cases (up to 25% of documented cases): felt to be due to de novo mutations in *STK11* or low-penetrance variants (Giardiello et al. 2000).

Clinical Features

1. Hyperpigmentation (Schreibman et al. 2005; Giardiello and Trimbath 2006; Beggs et al. 2010).
    1. Melanotic pigmented macules
        1. Seen in around 95% of patients
        2. May be the first clue to an individual having PJS
        3. Dark brown or blue-brown in color (1–5 mm in size)
        4. Locations
            1. Vermilion border of the lips (94%)
            2. Buccal mucosal (66%)
            3. Hands/fingers (74%)
            4. Feet/toes (62%)
            5. Nostrils
            6. Perianal area

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_276

2. Usually occurring in infancy and fading in late adolescence but tend to persist in the buccal mucosa
3. Often precede the gastrointestinal manifestations

2. Gastrointestinal manifestations.
   1. Hamartomatous polyposis (Giardiello 1995)
      1. Occur most numerously in the small intestine but frequently in the colon and stomach.
      2. The polyps usually number between 1 and 20 per segment of the intestinal tract and vary in size from 0.1 to 5 cm in diameter.
      3. Polyps are seen at the following locations and frequency: small intestine (64%), colon (64%), stomach (49%), and rectum (32%) (Utsunomiya et al. 1975).
      4. They can also occur elsewhere (Sommerhaug and Mason 1970; Murday and Slack 1989; Vogel et al. 2000).
         1. Renal pelvis
         2. Urinary bladder/ureter
         3. Lungs/bronchi
         4. Gallbladder
         5. Nares
   2. Intussusception: most frequent complication in young age
      1. Occurring in 47% of patients
      2. Primarily in the small intestine (95% of cases)
   3. Chronic bleeding, anemia, and abdominal pain due to intussusception, obstruction, or infarction
3. Cancer risk (Su et al. 1999; Giardiello et al. 2000; Hearle et al. 2006).
   1. An increased risk of many cancers in PJS based on epidemiological and molecular genetic studies
   2. The most common cancers: luminal gastrointestinal cancers (colorectal cancer, most common; upper GI, less common) and breast cancer, followed by pancreatic cancer
   3. Other rare neoplasms (Harned et al. 1995)
      1. Adenoma malignum (a uterine cancer)
      2. Benign testicular neoplasms
      3. Malignant and benign neoplasms of the thyroid, gallbladder, ureter, and urinary bladder
   4. The risk increased rapidly after age of 50
4. Three diagnostic criteria for Peutz-Jeghers syndrome (Riegert-Johnson et al. 2011; Chae and Jeon 2014).
   1. Mayo clinic (2010)
      1. Without a family history of PJS: either of the following are present:
         1. Characteristic melanotic macules and one or more intestinal polyps with PJS-type histology
         2. Two intestinal polyps with PJS-type histology
      2. With family history of PJS in a sibling or child: if any of the following are present:
         1. Characteristic melanotic macules
         2. One or more intestinal polyps with PJS-type histology
         3. An *LKB1* mutation
   2. World Health Organization (2000)
      1. Without a family history of PJS – a diagnosis of PJS is made if there are:
         1. Three or more histologically confirmed PJS polyps
         2. Any number of PJS polyps and characteristic, prominent, PJS mucocutaneous pigmentation
      2. With family history of PJS in a sibling or child – if there are:
         1. Any number of PJS polyps
         2. Characteristic, prominent, PJS mucocutaneous pigmentation
   3. Tomlinson and Houlston (1997) – a diagnosis of PJS can be made if there are:
      1. Two or more intestinal polyps with PJS-type histology
      2. One intestinal polyp with PJS-type histology with either typical melanotic macules or a family history of PJS and characteristic melanotic macules
5. Correlation of *STK11* mutation detection rates with diagnostic criteria: over 95% of patients who meet the criteria for PJP had a mutation detected (64% point mutation, 30% deletions) (Aretz et al. 2005).

6. Differential diagnosis (Higham et al. 2010).
    1. Differential diagnosis of polyposis
        1. Familial juvenile polyposis (Zbuk and Eng 2007)
            1. Multiple juvenile polyps primarily in the colorectum
            2. Often symptomatic prior to age 20
            3. No mucocutaneous pigmentation
            4. Malignant predisposition: adenocarcinoma (colorectal, gastric, pancreas)
            5. Caused by *SMAD4* and *BMPR1A* gene mutations (van Hattem et al. 2008)
        2. Hereditary mixed polyposis syndrome: characterized by mixed hyperplastic, adenomatous, and juvenile polyps, associated with *BMPR1A* gene (Cao et al. 2006)
        3. Cronkhite-Canada syndrome (Daniel et al. 1982)
            1. Not familial: unlike most of the other polyposis syndromes
            2. Occurs in older adults
            3. Gastrointestinal polyps
            4. Abdominal pain, severe protein-losing diarrhea, weight loss, and anorexia: common
            5. Brown macules on the palmar and plantar skin surfaces of the hands and feet
            6. Nail loss secondary to dystrophic changes
            7. Rare gastric and colon adenocarcinomas
        4. Familial adenomatous polyposis (Gardner syndrome): please see the chapter of "Familial Adenomatous Polyposis"
        5. Bannayan-Ruvalcaba-Riley syndrome: please see the chapter of "Bannayan-Riley-Ruvalcaba Syndrome"
        6. Basal cell nevus syndrome (Gorlin syndrome): please see the chapter of "Gorlin Syndrome"
    2. Differential diagnosis of mucocutaneous pigmented lesions (Harned et al. 1995)
        1. Carney complex (McCarthy et al. 1986).
            1. Spotty skin pigmentation
            2. Lentigines
            3. Most commonly on the face, especially on the lips (freckling), eyelids, conjunctiva, and oral mucosa
        2. Cowden syndrome (multiple hamartoma syndrome).
            1. An autosomal dominant trait
            2. Primarily occurs in whites
            3. Characterized by hamartomas and neoplasms of ectodermal, mesodermal, and endodermal origin affecting multiple organ systems: thyroid goiters, adenomas, and follicular adenocarcinomas; female breast carcinoma; genitourinary lesions including uterine and cervical carcinomas and transitional cell carcinoma of the renal pelvis and urinary bladder; a variety of skeletal abnormalities and nervous system and solid visceral tumors
            4. Mucocutaneous lesions – present in all patients – the hallmark of the disease
            5. Facial papules, oral mucosal papillomatoses, acral keratosis, and multiple sclerotic fibromas: the most characteristic lesions
        3. Laugier-Hunziker syndrome: a rare acquired disorder characterized by diffuse macular hyperpigmentation of the oral mucosa and, at times, longitudinal melanonychia (Rangwala et al. 2010).
        4. LEOPARD syndrome: please see the chapter.

Diagnostic Investigations

1. Histology.
    1. Pigmented macules: increased melanin in basal cells, possibly due to an inflammatory block to melanin migration from melanocyte to keratinocyte (Beggs et al. 2010)
    2. Polyps: frond-like elongated epithelial component and cystic gland dilatation extending into the submucosa or muscularis propria, and arborizing smooth muscle extending into polyp fronds

2. Radiology: examine entire GI tract to document the location, size, and number of polyps (Godard et al. 1971).
    1. Abdominal plain films
        1. Most common abnormalities
            1. Reflect partial or complete intestinal obstruction
            2. Small bowel dilatation
            3. Multiple air-fluid levels
        2. Intussusception: occasionally seen as a soft tissue density
    2. Barium swallow required to demonstrate GI polyps
    3. Barium enema
    4. Pneumocolon examination
    5. Multidetector computed tomography: allows for the depiction of small bowel polyps and their complications (e.g., intussusceptions) (Tomas et al. 2014)
    6. MR enterography (Gupta et al. 2010)
        1. A promising alternative to capsule endoscopy for small bowel surveillance in adults with PJS
        2. Less prone to missing large polyps
        3. May be more reliable in polyp size assessment
    7. Molecular genetic analysis of *STK11* (www.ncbi.nlm.nih.gov/books/NBK1266/)
        1. Sequence analysis/mutation scanning to detect sequence variants
        2. Deletion/duplication analysis to detect (multi)exonic and whole-gene deletions

Genetic Counseling

1. Recurrence risk according to autosomal dominant inheritance
    1. Patient's sib
        1. A 50% risk if one parent is affected.
        2. A low risk if both parents are clinically unaffected.
        3. Two possible explanations (germline mosaicism in a parent or a den novo mutation in the proband) exist (Hernan et al. 2004). However, no instances of germline mosaicism have yet been reported.
    2. Patient's offspring: a 50% risk to the offspring of an affected individual with a positive family history and/or a pathogenic *STK11* mutation
2. Prenatal diagnosis: available through chorionic villus sampling and amniocentesis if a pathogenic mutation is confirmed
3. Management (Beggs et al. 2010)
    1. General
        1. Annual full blood count
        2. Liver function testing
        3. Annual clinical examination
    2. Gastrointestinal
        1. Baseline colonoscopy and upper gastrointestinal endoscopy at age 8
            1. Polyps detected: continue every 3 years until age 50
            2. No polyps detected: repeat age 18 years, then every 3 years until age 50
        2. Intraoperative enteroscopy and double-balloon enteroscopy (Kopacova et al. 2009)
        3. Colonoscopy: 1–2 yearly after age 50
        4. Video capsule endoscopy: every 3 years from age 8
    3. Breast
        1. Monthly self-examination from age 18
        2. Annual breast MRI from age 25–50
        3. Annual mammography thereafter
    4. Genital tract
        1. Annual examination and testicular examination from birth until age 20
        2. Testicular ultrasound if abnormalities detected at examination
        3. Cervical smear with liquid-based cytology: every 3 years from age 8

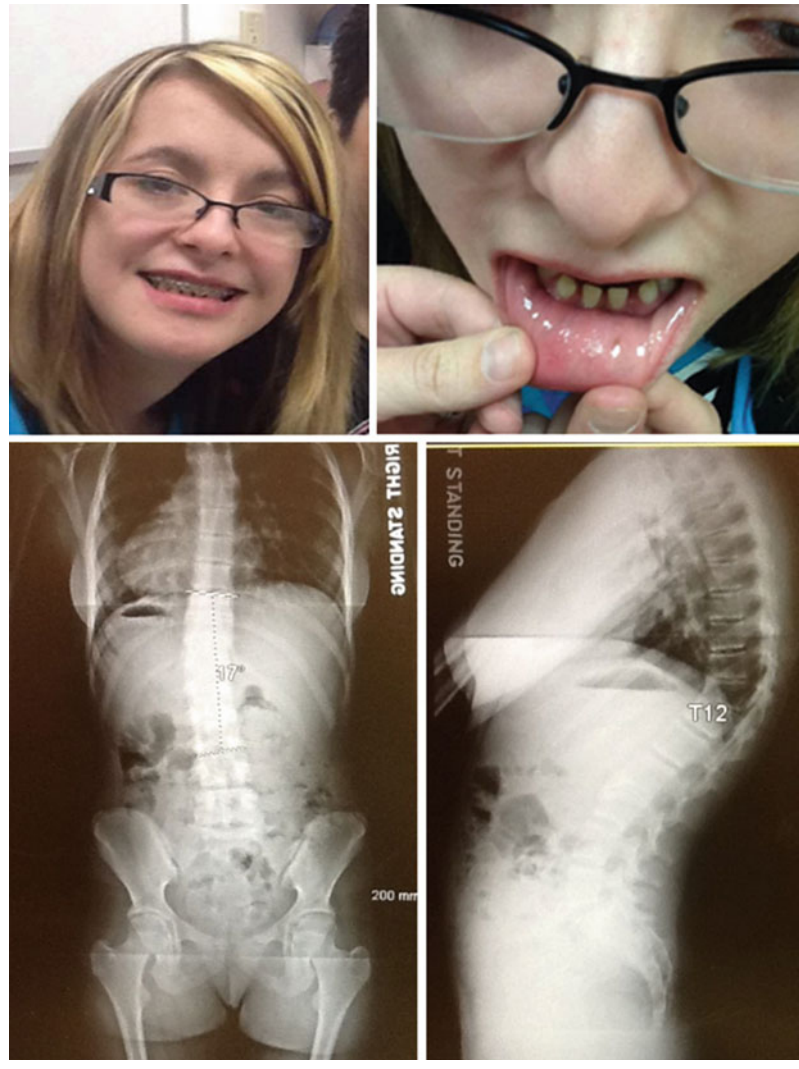

Fig. 1 (**a**, **b**) This 16-year-old Caucasian female (**a**) was seen initially for developmental delay with hearing and visual impairments, tetralogy of Fallot, and congenital spinal fusions (T11–T12 and L2–L3) contributing to accentuated kyphosis at this level (**c**, **d**). Chromosome analysis showed terminal deletion of 19pter-p13.2. Chromosome microarray analysis showed 1.261 MB terminal deletion of 19pter-p13.2 [arr 19p13.3 (41,981–1,136) × 1]. Because of the presence of hyperpigmented lesions on the oral mucosa (**b**), Peutz-Jeghers syndrome was suspected. DNA mutation study of *STK11* was positive. Recently, she had recurrent abdominal pains and was diagnosed to have intussusception twice. A large polyp was noted in the small intestine

Phenylketonuria

Contents

Classical phenylketonuria (PKU) is a rare metabolic disorder, resulting from a deficiency of a liver enzyme, phenylalanine hydroxylase. The deficiency of the enzyme leads to elevated phenylalanine (Phe) levels in the blood and various tissues including the brain. The incidence in Caucasians is approximately one in 10,000, giving a heterozygote frequency of one in 50 to one in 70. About one in 15,000 infants is born with PKU in the United States.

Synonyms and Related Disorders

Hyperphenylalaninemia; Maternal PKU; Phenylalanine hydroxylase deficiency; PKU

Genetics/Basic Defects

1. Inheritance
    1. Autosomal recessive
    2. Parents: obligatory carriers
2. Basic defect
    1. Deficient activity of the enzyme phenylalanine hydroxylase (PAH), resulting in hyperphenylalaninemia (HPA) (Scriver and Kaufman 2001). PAH, a liver-specific enzyme, catalyzes the conversion of phenylalanine to tyrosine, using tetrahydrobiopterin as a cofactor (Dyer 1999). Chromosomal locus of the *PAH* gene is on 12q24.1.
    2. Subclassification of PKU (Matalon and Michals 1991): defective activity of phenylalanine hydroxylase leads to a spectrum of clinical presentations.
        1. Classical PKU: blood phenylalanine greater than 1200 mumol/L usually indicates severe deficiency of phenylalanine hydroxylase.
        2. Atypical PKU: blood phenylalanine levels between 600 and 1200 mumol/L.
        3. Benign hyperphenylalaninemia: blood phenylalanine remains between 120 and 480 mumol/L on a normal diet.
        4. Malignant PKU: A deficiency of the cofactor tetrahydrobiopterin (BH4), which is required for phenylalanine hydroxylase activity, leads to hyperphenylalaninemia. This cofactor is also required for the enzymatic hydroxylation of tyrosine and tryptophan. Cofactor defects account for only 1–3% of hyperphenylalaninemia, which has been termed “malignant PKU,” but they must

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_191

be identified so that appropriate treatment can be established.

3. Tetrahydrobiopterin (BH4) deficiency (Al Hafid and Christodoulou 2015).
    1. In the 1970s it became apparent that there was a subset of patients with hyperphenylalaninemia who developed neurological complications despite prompt adherence to dietary therapy (Rey et al. 1976).
    2. This subgroup of patients (known to have atypical PKU) turned out to have mutations that cause defects in BH4 synthesis or recycling (Kaufman et al. 1978).
4. Identification of more than 400 different mutations in the *PAH* gene (National Institutes of Health Consensus Development Conference Statement 2001; Mitchell et al. 2011).
    1. Missense (62%)
    2. Deletion (mainly small) (13%)
    3. Splice (11%)
    4. Silent (6%)
    5. Nonsense (5%)
    6. Insertion (2%)
    7. Deletion or duplication of exon(s) or whole gene (<1%)
5. Compound heterozygotes in most PKU patients, contributing to the clinical heterogeneity and biochemical heterogeneity.
6. Strong correlations between PAH genotype and biochemical and clinical phenotypes in the heterogeneous American sample population, extending previous findings from relatively homogeneous European populations. These correlations further demonstrate the clinical utility of genotype analysis in the treatment of patients with PKU and HPA (Eisensmith et al. 1996).
7. Consequences of accumulation of phenylalanine (Phe) and other amino acids in the CNS.
    1. Irreversible brain damage from the first few weeks of life
    2. Severe learning disabilities and associated behavioral and psychological problems
3. Phenylketonuria pathophysiology (Schuck et al. 2015): Metabolic alterations include:
    1. Bioenergetic deficit
    2. Oxidative stress
    3. Impairment of lipid and protein metabolism
    4. Disruption of calcium homeostasis and neurotransmitter synthesis in the brain
    5. These metabolic disturbances might collaborate to the cognitive dysfunction and brain pathology of PKU.

Clinical Features

1. Treated patients
    1. Symptom-free on strict metabolic control using a low-phenylalanine diet for the infants detected by newborn screenings
    2. Normal development with a normal life span when diagnosed early in the newborn period and treated effectively with lifelong dietary control
2. Untreated patients
    1. Profound mental retardation
    2. Psychomotor handicaps
    3. Microcephaly
    4. Delayed speech
    5. Seizures
    6. Light hair and eyes and fair skin secondary to decreased formation of melanin pigment because of compromised tyrosine formation
    7. Musty body or urine odor secondary to excretion of phenylacetic acid into the sweat and the urine
    8. Vomiting
    9. Irritability
    10. Eczema
    11. Subtle neurologic findings, sometimes noted even in treated individuals
        1. Hypertonic reflexes
        2. Intention tremor
    12. Behavior problems
        1. Autistic-like behaviors
        2. Hyperactivity
        3. Agitation

4. Aggression

3. Maternal PKU: a metabolic teratogen (Levy and Ghavami 1996)
   1. Background information
      1. Loss of dietary compliance frequently starting during mid-childhood
      2. Noncompliance on special diet by many affected adolescent females, capable of reproduction, with blood phenylalanine levels above the current recommended therapeutic range
      3. Loss of follow-up of such females despite effort to identify them
      4. Teratogenic effect of elevated phenylalanine levels during pregnancy
      5. Fetal anomalies preventable by dietary therapy starting before conception and throughout pregnancy on women with PKU
   2. Abnormalities in the children of women with uncontrolled PKU during pregnancy (Rouse et al. 1997, 2000).
      1. Psychomotor retardation (92%)
      2. Intrauterine growth retardation (40%)
      3. Microcephaly
      4. Congenital heart defects (10%)
      5. Postnatal growth retardation
      6. Neurologic deficits
      7. Mild craniofacial dysmorphic features
      8. The frequency of abnormalities directly related to the degree of elevation of maternal phenylalanine levels during pregnancy
      9. Abnormalities more likely to occur if maternal phenylalanine levels are not controlled during critical periods of embryogenesis and organogenesis early in pregnancy
   3. Currently, the control of phenylalanine levels during pregnancy is recommended at 2–6 mg/dL or 1–4 mg/dL: at least as strict, if not more strict, as that currently recommended for PKU treatment during early childhood. Although tight control can improve pregnancy outcomes greatly, it is important to avoid phenylalanine deficiency because this can result in muscle breakdown, leading to paradoxic hyperphenylalaninemia, hypoglycemia, seizures, and death (Clarke 2003).
   4. Women with mild forms of PKU having relatively mild elevations of the phenylalanine are at risk of adversely affecting the fetuses if the mothers are unmonitored and untreated during pregnancies. Because placental gradient favors the fetus, the levels of Phe are higher in the fetus than in the mother.
   5. Effects of uncontrolled maternal PKU occur regardless of the genetic PKU status of the fetus.

Diagnostic Investigations

1. Universal newborn screening from a heel-stick blood spot for PKU (since the 1960s) for early detection and treatment of the disorder (Dougherty and Levy 1999; Hellekson 2001; Howell et al. 2001; Koch 1999; National Institutes of Health Consensus Development Conference Statement 2001; Mitchell 2013).
   1. Guthrie bacterial inhibition assay.
      1. Inexpensive
      2. Simple
      3. Reliable
   2. Fluorometric analysis.
      1. Quantitative and automated test
      2. Fewer false positive
   3. Tandem mass spectrometry: newborn screening for PAH deficiency in the United States is now primarily performed by tandem mass spectrometry (Vockley et al. 2014).
      1. Quantitative and automated test
      2. Fewer false positive
      3. Measurements of tyrosine
      4. Identification of other metabolic disorders on a single sample
2. Phenylketonuria screening: effect of early newborn discharge (Sinai et al. 1995).
   1. Twenty-four percent of term newborns in the United States are discharged by 24 h of life.
   2. Most hospitals screen all infants for PKU before discharge regardless of age.
   3. The majority of states do not mandate rescreening; rescreening policies among

pediatricians and institutions in those states vary widely.
4. A significant number of infants do not receive repeated screening and are therefore at risk for delayed or missed diagnosis of PKU because of insensitive initial screens.

3. About one percent of all babies tested from newborn screening prove to be "false positives" (Mabry 1990). Two-thirds of those with persistent hyperphenylalaninemia prove to have classical PKU. Nonclassical PKU with less intense, persistent hyperphenylalaninemia is due to different alterations in the enzyme, phenylalanine hydroxylase. Additionally, about one percent of the confirmed positive patients are due to either a defect in the synthesis or regeneration of the cofactor, tetrahydrobiopterin; these latter forms are not amenable to treatment with the low-phenylalanine diet. Screening programs have developed directives regarding the timing and conditions for obtaining the specimens for testing. Specific confirmatory tests of those with positive results must be performed. Even so, about one in 70 affected babies is "missed," resulting in mental retardation, seizures, and neurologic deficits.
4. Plasma quantitative amino acid analysis especially phenylalanine and tyrosine levels (National Institutes of Health Consensus Development Conference Statement 2001).
   1. Phe concentrations persistently >2 mg/dL in the untreated state
   2. Recommended blood Phe levels in US clinics
      1. 2–6 mg/dL for age <12 years
      2. 2–10 mg/dL for age >12 years
   3. Frequent monitoring of blood Phe levels
      1. During the first year: once a week to once a month
      2. After the first year: once a month to once every 3 months
   4. Recommended blood Phe levels in pregnant maternal PKU
      1. <6 mg/dL achieved at least 3 months before conception
      2. 2–6 mg/dL during pregnancy
5. MRI of the brain (Levy et al. 1996a).
   1. Hypoplasia of the corpus callosum: a marker for adverse brain development in maternal PKU
   2. Areas of demyelination
6. Molecular genetic testing.
   1. Primary purpose
      1. Confirmatory diagnostic testing.
      2. Determine carrier status of at-risk relatives.
      3. For prenatal diagnosis.
   2. Methodology (Mitchell et al. 2011)
      1. Targeted mutation analysis: 1–15 common mutations (alleles may be population related) (30–50%)
      2. Mutation scanning: common and private sequence variants (99%)
      3. Sequence analysis: common and private sequence variants (99%)
      4. Duplication/deletion analysis: exonic or whole-gene deletions/duplications (rare)
      5. Linkage analysis

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Twenty-five percent affected
      2. Fifty percent carrier
      3. Twenty-five percent normal
   2. Patient's offspring
      1. Not increased unless the spouse is also a carrier in which case there will be a 50% risk of having an affected offspring and a 50% of having a carrier offspring
      2. All offspring of PKU mothers
         1. Carry at least one abnormal gene at the PAH locus inherited from their homozygous-affected mothers (obligatory heterozygotes).
         2. Approximately, one in 120 (1/4 × 1/30) offspring will be affected by inheriting two abnormal *PAH* genes from both parents depending on the PKU carrier status of the father.

2. Prenatal diagnosis (Mitchell 2013)
    1. Fetal ultrasonography in noncompliant maternal PKU (Levy et al. 1996b)
        1. Intrauterine growth retardation
        2. Microcephaly
        3. Congenital heart disease
    2. DNA mutation analysis on fetal cells by amniocentesis or CVS
        1. Provided the disease-causing mutations in the *PAH* gene identified in an affected family member. Prenatal diagnosis for PAH deficiency is only available using DNA-based methodologies (Vockley et al. 2014).
        2. Informative markers available for linkage analysis.
    3. Preimplantation genetic diagnosis may be available for families in which the disease-causing mutations have been identified in an affected family member.
3. Management
    1. Maternal diet influences offspring outcome – before, during, and after pregnancy (Waisbren et al. 2015).
    2. Management during pregnancy (Singh et al. 2014; Vockley et al. 2014).
        1. Fetal development is optimal when maternal PHE levels are <360 μmol/l prior to conception.
        2. There is a linear relationship between maternal PHE levels >360 μmol/l throughout gestation and lower IQ of the developing fetus.
        3. Elevated blood PHE levels in the first 8–10 weeks of gestation are associated with an increased risk of CHD and poor fetal growth.
        4. Achievement of maternal PHE levels between 120 and 360 μmol/l prior to conception is recommended.
        5. Monitor dietary intake of pregnant women with PAH deficiency.
        6. Ensure nutrient adequacy.
        7. Consider sapropterin use on a case-by-case basis for pregnant women who have difficulty adhering to the diet.
        8. Large neutral amino acids (LNAAs) should not be used during pregnancy, as they do not consistently alter maternal blood PHE levels.
        9. Mothers with PAH deficiency may safely breastfeed.
    3. Dietary phenylalanine restriction: the only known strategy of preventing neurological impairment and mental retardation in patients with PKU.
        1. Natural history of the disease modified by a low-phenylalanine diet.
        2. Early strict restriction of phenylalanine intake resulting in normal intelligence.
        3. Phenylalanine-restricted diet for patients with PAH deficiency (Camp et al. 2014; Vockley et al. 2014).
            1. Treatment for PAH deficiency should be lifelong for patients with untreated PHE levels >360 μmol/l.
            2. Maintaining a treated PHE level of 120–360 μmol/l is recommended for all patients of all ages.
        4. Special medical foods devoid of or low in phenylalanine supplemented with tyrosine
        5. Tyrosine supplementation in the diet for PKU produces marked but nonsustained increases in plasma tyrosine levels, with calculated brain influx that often remains suboptimal. This could explain the lack of consistent neuropsychologic benefit with tyrosine supplementation (Kalsner et al. 2001).
        6. Restricted diet worth trying in most individuals with previously untreated PKU with possible benefits (Yannicelli and Ryan 1995) in the areas of concentration, alertness, mood, irritability, and adaptive behavior (Fitzgerald et al. 2000).
    4. Late-treated PKU: although the severe cognitive impairment associated with untreated PKU can in many cases be partially reversed with dietary treatment, prompt initiation of treatment following newborn metabolic screening is essential for optimal development and the prevention of disability (Grosse 2010).
    5. Adult complications in PKU (Hoeks et al. 2009): consisting of two

components, namely, high Phe levels (e.g., neurological and neuropsychological problems) and complications occur as a cause of dietary protein restriction (e.g., vitamin deficiencies and osteoporosis).

1. Adults with PKU who were treated from early infancy have normal intelligence, but their neuropsychological test scores are somewhat lower than those of the general population, their parents, and their unaffected siblings (Weglage et al. 1993).
2. Adults with PKU who were continuously treated but relaxed the diet have displayed white matter abnormalities on structural magnetic resonance imaging (Cleary et al. 1994; Sener 2003), which are considered to be indicative of a reduction in myelin (Dyer et al. 1996; Joseph and Dyer 2003). These abnormalities disappear after reintroducing a strict diet.
3. Neurological investigations in early-treated adults with PKU who discontinued the diet reveal a higher incidence of minor neurological signs including tremor, brisk deep tendon reflexes, or clumsy motor coordination (Thompson et al. 1990; Pietz et al. 1998). In rare cases, severe neurological deterioration may occur after cessation of dietary treatment.
4. Severe behavior and psychiatric problems are seen in profoundly retarded (untreated) adults with PKU in the third and fourth decade of life (Paine 1957). With introduction of a Phe-restricted diet, these symptoms are sometimes reversible (Baumeister and Baumeister 1998).
5. The risk for neurocognitive or psychological symptoms in PAH deficiency is related to age of onset of therapy, lifelong PHE levels, and adherence to treatment. Age-specific neuropsychiatric and cognitive testing is necessary to adequately assess clinical needs. Appropriate intellectual and mental health assessments are an important component of care for individuals affected with PKU (Vockley et al. 2014).
6. Vitamin B12 deficiency.
    1. Vitamin B12 is only found in animal protein, the sources being meat, fish, and poultry. Since the PKU diet is restricted in protein, vitamin B12 must be provided either combined with the amino acid supplement or from a separate supplement.
    2. Vitamin B12 deficiency can occur when PKU patients relax their diet in adolescence (Robinson et al. 2002). They tend to choose products that are low in animal protein, and amino acid supplements are not taken properly (Hvas et al. 2006).
7. Osteoporosis: possibly due to long-standing dietary deficiency in protein, calcium, vitamin D, or trace elements or a primary defect in bone turnover inherent to the disease itself (Modan-Moses et al. 2007).

6. Nutritional management of PKU (Feillet and Agostoni 2010).
    1. Becomes more complex with the multitude of amino acid substitutes available and with the different nutritional issues, such as polyunsaturated fatty acids, micronutrient deficiencies, bone disease, and antioxidant status, that have arisen.
    2. Long-term dietary guidance and monitoring of the nutritional status of patients with PKU should be part of a follow-up program that continues for life.
7. Sapropterin (Vockley et al. 2014).
    1. Currently, the only FDA-approved medication for the treatment of PAH deficiency and may be useful in reducing PHE levels in responsive patients.
    2. Reduction of blood PHE, increase in dietary PHE tolerance, or improvement

in clinical symptoms are all valid indications for continuation of therapy.

8. Tetrahydrobiopterin (BH4) therapy (Al Hafid and Christodoulou 2015).
    1. Synthetic biopterin compounds were made available in the late 1970s (Schircks et al. 1976), and the benefit of administering this preparation in patients with atypical PKU was first demonstrated by Schaub et al. (1978).
    2. These patients also require neurotransmitter precursors (L-dopa/carbidopa and 5-hydroxytryptophan) as part of their treatment and for dihydropteridine reductase deficiency, folinic acid supplementation (reviewed in Blau et al. (2011)).
9. Large neutral amino acids (LNAAs) (Al Hafid and Christodoulou 2015).
    1. The LNAAs, Phe, tyrosine, tryptophan, and the branched chain amino acids share the same amino acid transport system across the blood–brain barrier. Therefore, at high concentrations, phenylalanine in the blood will compete with other LNAAs for transport across the blood–brain barrier (Pietz et al. 1999).
    2. Large neutral amino acid supplementation has been shown to reduce cerebral Phe concentrations despite the observed increase in plasma Phe levels (Pietz et al. 1999). However, others have shown decreased blood Phe levels in PKU patients with LNAA supplementation (Sanjurjo et al. 2003; Schindeler et al. 2007; Matalon et al. 2006, 2007), suggesting that LNAAs not only compete with Phe for transport across the blood–brain barrier (Pietz et al. 1999) but may also exert its effect by competing with Phe for active transport across the intestinal mucosa (Koch et al. 2003b; Matalon et al. 2006, 2007).
10. Glycomacropeptides (GMP) (Al Hafid and Christodoulou 2015).
    1. GMP is a protein derived from cheese whey that is naturally low in Phe and is rich in valine, isoleucine, and threonine (Etzel 2004).
    2. GMP, manufactured to sufficient purity and supplemented with the essential amino acids tyrosine, tryptophan, arginine, cysteine, and histidine, can be a useful adjunct to the Phe-restricted diet (Ney et al. 2009; van Calcar et al. 2009).
    3. GMP may be used to replace 50% of the protein intake to improve the nutritive value and palatability of diet and to provide a more satisfactory diet (Zaki et al. 2016). No toxicity or side effects were reported in patients on that regimen.
    4. GMP-MFs (traditional amino acid medical foods) provide a safe and acceptable option for the nutritional management of phenylketonuria (Ney et al. 2016).
11. Alternative treatments (Al Hafid and Christodoulou 2015).
    1. Gene therapy.
        1. The use of self-complementary AAV vectors resulted in normalization of hyperphenylalaninemia for up to 80 weeks in both males and females (Yagi et al. 2011).
        2. The transfer of foreign genes using nonviral vectors into tissues or organs by direct injection of naked plasmid DNA has been achieved leading to transgene expression and therapeutic responses (Lechardeur and Lukacs 2002; Niidome and Huang 2002).
    2. Phenylalanine ammonia-lyase (PAL) (Strisciuglio and Concolino 2014).
        1. Enzyme therapy can be done either by enzyme replacement with PAH or by enzyme substitution with phenylalanine ammonia-lyase (Sarkissian et al. 1999).

2. The metabolism of Phe takes place for the most part in the liver, and orthotropic liver transplantation corrects the metabolic phenotype (Vajro et al. 1993).
3. Liver transplantation is not a treatment option except for unusual PKU patients who need a liver transplant for another disease such as cirrhosis, because of the burden of daily therapy in transplanted patients. In mice, enzyme replacement with PAH-fusion proteins is a promising approach (Eavri and Lorberboum-Galski 2007).
4. Enzyme substitution therapy with phenylalanine ammonia-lyase (PAL) appears more promising. It can act as a surrogate for the deficient PAH and converts the excess systemic Phe to trans-cinnamic acid and ammonia. Both pharmacological and physiological principles of therapy have been demonstrated following the use of PAL given orally or by injection in PKU mouse models (Gámez et al. 2004).

3. Cell-directed therapy (Strisciuglio and Concolino 2014): cell-based therapies using stem cells or more differentiated progenitor cells may represent the future of cell transplantation for treatment of metabolic liver diseases such as PKU.
4. Genetically modified (GM) probiotic for the production and delivery of metabolic enzymes.

4. Counseling for maternal PKU
   1. Genetic and nutritional evaluation and counseling, optimally before contemplating pregnancy.
   2. The achievement of pre- and periconceptional dietary control with a Phe-restricted diet significantly decreased morbidity in the offspring of women with HPA (Koch et al. 2003a).
   3. Benefits of dietary phenylalanine restriction in pregnant women with hyperphenylalaninemia decrease the incidence of following fetal effects (Hanley et al. 1999; Platt et al. 2000).
      1. Mental retardation
      2. Microcephaly
      3. Congenital heart disease
      4. Intrauterine growth retardation
   4. Quality of life and psychologic adjustment in children and adolescents with early-treated phenylketonuria can be normal (Landolt et al. 2002).
   5. The significant relationship among genotype, biochemical phenotype, and cognitive performance observed is of importance for the development of an optimal strategy for future treatment of females with PKU who plan pregnancy (Güttler et al. 1999).
   6. Female individuals with severe PKU should be offered a diet for a lifetime. If good metabolic control is established, then women with PKU will have children with IQ scores that are not influenced by their disease (Güttler et al. 2003).
   7. Long-term compliance with treatment remains a key challenge for the future, especially with respect to adolescents and young adults, those trying to become pregnant, and during pregnancy (Blau et al. 2010).
   8. Assistance of women with hyperphenylalaninemia, who are unable or unwilling to maintain blood phenylalanine levels in the range for optimum pregnancy outcome, to obtain adequate means for birth control, including tubal ligation if requested.
   9. Counseling of women with hyperphenylalaninemia who conceive with blood phenylalanine levels greater than 4–6 mg/dL concerning risks to the fetus offers detailed ultrasonography to detect fetal abnormalities such as growth retardation and congenital heart defects.
   10. Close monitoring of serum phenylalanine levels at 2–6 mg/dL during pregnancy of PKU mother and intake of vitamins (folic acid and vitamin B12, in particular) and other nutrients (National Institutes of Health

Consensus Development Conference Statement 2001).

11. Blood testing for hyperphenylalaninemia indicated to children born to women with features of maternal PKU fetal effects without a known cause.

Pierre Robin Sequence

Contents

Pierre Robin described a group of patients with cleft palate, micrognathia, and glossoptosis in *1923* (Robin 1923). The meticulous documentation of the triad of findings led to the recognition of the sequence that bears his name (Randall et al. 1965). Pierre Robin sequence is estimated to affect approximately 1 in 8,500 births (Bush and Williams 1983).

Synonyms and Related Disorders

Glossoptosis, micrognathia, and cleft palate; Pierre Robin syndrome (PRS); Robin anomalad

Genetics/Basic Defects

1. Inheritance
    1. Sporadic in most instances
    2. Rare occurrence of isolated robin sequence in siblings: rare (da Costa and Matias 2014)
    3. May be familial with autosomal dominant mode of inheritance (Sidhu and Deshmukh 1989)
    4. Robin anomalad: its nonspecificity and associated syndromes (Cohen 1976)
    5. Syndromic form: etiologically heterogeneous (Shprintzen 1988, 1992; Cohen 1999; Holder-Espinasse et al. 2001; Taylor 2001; Evans et al. 2011; Buchanan et al. 2014)
        1. Monogenic
            1. Stickler syndrome (common cause) (Sheffield et al. 1987; van den Elzen et al. 2001): associated with mutations in COL genes (*COL2A1*, *COL9A1*, *COL11A1*, and *COL11A2*) (Acke et al. 2012)
            2. Velocardiofacial syndrome (microdeletion of chromosome 22q11.2)
            3. Beckwith-Wiedemann syndrome
            4. Camptomelic syndrome
            5. Cerebrocostomandibular syndrome
            6. Congenital myotonic dystrophy
            7. Larsen syndrome
            8. Mandibulofacial dysostosis
            9. Miller-Dieker syndrome
            10. Nager syndrome (Rosa et al. 2015)
            11. Otopalatodigital syndrome II
            12. Popliteal pterygium syndrome
            13. Robin-oligodactyly syndrome
            14. Spondyloepiphyseal dysplasia
            15. Treacher Collins syndrome associated with mutations in the *TCOF1*,

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_192

PLORIC, and *POLRID* genes (Kadakia et al. 2014)
   2. Chromosomal
      1. Del(22q) velocardiofacial syndrome (common cause)
      2. Del(4q32-qter) syndrome
      3. Del(2q24-q22) syndrome
      4. Del(6q) syndrome
      5. Dup(11q21-q23) syndrome
      6. 17q21 deletion/translocation near SOX9
   3. Teratogenic
      1. Fetal alcohol syndrome
      2. Fetal hydantoin syndrome
      3. Fetal trimethadione syndrome
      4. Maternal diabetes
   4. Deformation
      1. Oligohydramnios
      2. Uterine structural anomalies
      3. Amniotic band syndrome
   5. Disruption: amniotic band disruption
   6. Unknown cause:
      1. CHARGE syndrome
      2. Femoral dysgenesis
      3. Moebius sequence
      4. Robin/amelia association
      5. Distal arthrogryposis-Robin syndrome
2. Pathogenetically and phenotypically variable (Robin sequences and complexes) (Carey et al. 1982)
   1. Malformation sequence based on intrinsic mandibular hypoplasia that prevents the normal descent of the tongue interfering with palatal fusion, for example:
      1. Treacher Collins syndrome
      2. Del(22q) syndrome
   2. Deformation sequence based on extrinsic mandibular hypoplasia caused by intrauterine constraint
      1. Oligohydramnios (reduced amniotic fluid results in compression of the chin against the sternum restricting mandibular growth and impacting the tongue between the palatal shelves)
      2. Mandibular catch-up growth expected after birth when intrauterine deforming forces are no longer acting since micrognathia is based upon intrauterine molding
      3. Neurogenic hypotonia leading to lack of mandibular exercise
      4. Connective tissue dysplasia: Stickler dysplasia complex
      5. Spondyloepiphyseal dysplasia congenita complex
3. Genetic basis of the Pierre Robin sequence (Jakobsen et al. 2006)
   1. A comparison among cases in the literature and cases in cytogenetic databases revealed consistency to a certain degree to loci 2q24.1-33.3, 4q32-qter, 11q21-23.1, and 17q21-24.3.
   2. No particular candidate genes can be identified for certain from the present study, but GAD67 on 2q31, PVRL1 on 11q23-q24, and the SOX9 gene on 17q24.3-q25.1 are suggested to be important.

Clinical Features

1. Classic triads
   1. Posterior, U-shaped cleft palate
   2. Micrognathia/retrognathia
   3. Glossoptosis (observed tendency of the tongue to move posteriorly obstructing the oropharynx)
2. Pierre Robin sequence using different criteria
   1. Mandibular deficiency
   2. Cleft palate (U-shaped) (Hanson and Smith 1975)
   3. Upper airway obstruction
3. Respiratory difficulty
   1. Often the first sign causing concern relating to feeding
   2. May not necessarily be present at birth
   3. Upper airway obstruction and apnea
      1. Glossoptosis associated with retrognathia
      2. Upper airway collapse secondary to:
         1. Hypotonic pharynx
         2. Laryngomalacia
         3. Laryngeal cleft
         4. Laryngeal web

4. Complications of continuing airway obstruction
    1. Failure to thrive
    2. Pectus excavatum
    3. Decreased pulmonary function
    4. Sudden death
4. Failure to thrive
5. Developmental delay
    1. Usually not present in isolated Robin sequence
    2. May be present depending on the underlying syndrome
6. Middle ear diseases associated with cleft palate
    1. Otitis media (80%)
    2. Auricular anomalies (75%)
    3. Hearing loss, mostly conductive (60%)
7. Cleft palate-associated problems (Williams et al. 1981)
    1. Speech defects (severe nasal escape of air)
    2. Abnormal articulation
    3. Velopharyngeal insufficiency
8. "Catch-up growth" of the mandible
    1. Normal mandibular growth in patients with Robin sequence secondary to mechanical constraint
    2. Deficient mandibular growth in patients with intrinsic mandibular anomalies
9. Other signs and symptoms and associated anomalies depending on the underlying conditions

Diagnostic Investigations

1. Assess respiratory sounds with stethoscope during feeding and at rest.
2. Monitor developmental milestone achievement.
3. Pulse oximetry monitoring to document drops in oxygen saturation.
4. Flexible fiber optic nasopharyngoscopy.
    1. To identify exact mechanism of upper airway obstruction.
    2. To assess pharyngeal, palatal, lingual, and laryngeal morphology and function during feeding and swallowing
5. Identify the underlying cause of the micrognathia.
6. Orthodontic assessment.
7. Hearing assessment.
8. Polysomnography, polygraphy, and oximetry (Breugem et al. 2016).
    1. Polysomnography or polygraphy can quantify airway obstruction and identify comorbidities, such as central apnea (DeHaan et al. 2015).
    2. Oximetry may be specific for detecting obstructive sleep apnea (OSA), but it is not sensitive for detecting airway obstruction and OSA (Marcus et al. 2012).
9. Cervical spine evaluation to rule out cervical instability, especially those with suspected abnormalities in bone or collagen formation (Barr et al. 2016).
10. Cephalometric radiographs
    1. Deformation sequence
        1. Mandible
            1. Short body
            2. Short ramus
            3. Increased gonial angle
            4. Incomplete catch-up growth
        2. Cranial base angle: decreased
    2. Treacher Collins syndrome
        1. Mandible
            1. Short body
            2. Short ramus
            3. Characteristic shape
            4. Severely affected growth
        2. Cranial base angle: decreased
    3. Del(22q11.2) syndrome
        1. Mandible
            1. Retrognathia
            2. Essentially normal in shape
        2. Cranial base angle: increased
    4. Stickler dysplasia complex
        1. Mandible
            1. Short ramus
            2. Antegonial notching of body
        2. Cranial base angle: decreased
    5. Spondyloepiphyseal dysplasia congenita complex: short body of mandible
11. Chromosome analysis: del(22q11.2) and others.
12. Molecular diagnosis (Cohen 1999).
    1. Treacher Collins syndrome: mutations in *TCOF1*

2. Stickler dysplasia complex
   1. Mutations in *COL2A1*
   2. Mutations in *COL11A1*
3. Spondyloepiphyseal dysplasia congenita complex: mutations in *COL2A1*

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: rare unless Pierre Robin sequence is a part of a syndrome
   2. Patient's offspring: rare unless Pierre Robin sequence is a part of a syndrome
2. Prenatal diagnosis (Hsieh et al. 1999)
   1. Ultrasonography (Pilu et al. 1986)
      1. Polyhydramnios
      2. Micrognathia/retrognathia and cleft palate
      3. Cardiac anomalies
   2. Chromosome analysis: occasional (trisomy 21, 18)
3. Management (Shprintzen 2001; Evans et al. 2011)
   1. Prone positioning of infants (Tewfik et al. 2015) believed to help prevent the tongue and mandible from obstructing the airway, leading to generally improved oxygen saturation
   2. Nasogastric tube placement for early feeding and ensuring adequate relief of the airway obstruction (Heaf et al. 1982)
   3. Occupational therapy directed toward management of the palatal abnormality
   4. Perioperative care of the neonate and infant with PRS (Cladis et al. 2014)
      1. The primary concern is upper airway obstruction with subsequent respiratory distress and feeding difficulty.
      2. The later may manifest as reflux and failure to thrive. PRS comprises a heterogeneous group of patients.
      3. Some may present with an isolated mandibular abnormality, while other patients with PRS have associated anomalies or syndromes.
      4. The patient with mild airway obstruction can be managed conservatively with nasopharyngeal airways, prone positioning, and mechanical feeders.
      5. Moderate or severe obstruction requires more invasive interventions such as gastrostomy tube placement, tongue-lip adhesion, mandibular distraction osteogenesis, and tracheostomy.
   5. Surgical intervention for upper airway obstruction (Bath and Bull 1997; Scott et al. 2012)
      1. Glossopexy/tongue-lip adhesion (Argamaso 1992) to bring tongue forward and attach it to an anterior structure to prevent the tongue from falling back into the airway
      2. Tracheotomy (Myer et al. 1998) needed only in cases where conservative treatments fail
      3. Mandibular distraction osteogenesis (surgical incision of the mandible followed by the application of traction to stimulate new bone growth): reduces cleft palate width and lengthens soft palate, influencing palatoplasty in patients with Pierre Robin sequence (Collares et al. 2016)
      4. Repair of cleft palate
   6. Treat middle ear infections
      1. Antibiotics
      2. Placement of tympanostomy tubes
   7. Speech therapy

Polycystic Kidney Disease: Autosomal Dominant Type

Contents

Autosomal dominant polycystic kidney disease (ADPKD) is the most common form of polycystic kidney disease with an estimated incidence of approximately 1/400–1/1,000 individuals worldwide. It roughly accounts for 10% of patients with chronic renal failure requiring hemodialysis or transplantation (Arnaout 2001).

Synonyms and Related disorders

Adult type; Polycystic kidney disease

Genetics/Basic Defects

1. Inheritance:
   1. Autosomal dominant with almost complete penetrance
   2. Negative family history in 40% of cases
2. Genetically heterogeneous with at least three different genes now known to cause ADPKD. All three types of ADPKD present with an identical profile of extrarenal manifestations (including liver cysts and aneurysms) (Wilson 2004):
   1. Type I (85–90% of cases): caused by mutations in *PKD1* gene, which is:
      1. Mapped on chromosome 16p13.3.
      2. The most severe form with a lower median survival and a higher risk of progressing to end-stage renal disease.
      3. Closely linked to TSC2, a gene responsible for a major form of tuberous sclerosis.
      4. ADPKD1 is an inherited disorder that has led to the discovery of a novel protein, polycystin. Polycystin, a 460 kd protein with a host of domains implicating a potential role in cell-cell and cell-matrix regulation, is encoded by a 52 kb gene with a 14 kb mRNA (Grantham 1996). ADPKD1 is caused by mutated DNA that encodes an abnormal form of polycystin.
      5. Highly variable severity of renal cystic disease (Rossetti et al. 2002a).
   2. Type II (most of the remaining cases): caused by mutations in *PKD2* gene, which is:
      1. Mapped on chromosome 4q13-q23 (Kimberling et al. 1993).
      2. Identified by positional cloning.
      3. Producing milder disease but otherwise phenotypically identical with the *PKD1* disease.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_193

4. PKD2 protein is also large (110 kd) and is thought to interact with polycystin (Grantham 1996).
5. Although PKD2 is clinically milder than PKD1, it has a deleterious impact on overall life expectancy and cannot be regarded as a benign disorder (Hateboer et al. 1999).

3. In the vast majority of cases, the disease is caused by mutations in *PKD1* or *PKD2* and appears to be recessive at the cellular level. Somatic second hits in the normal allele of cells containing the germline mutation initiate or accelerate formation of cysts. The intrinsically high frequency of somatic second hits in epithelia appears to be sufficient to explain the frequent occurrence of somatic second hits in the disease-causing genes (Arnaout 2001).
4. A small number of familial cases reported to be unlinked to both the *PKD1* and *PKD2* loci, suggesting the existence of at least one more proposed gene (*PKD3*) which has not been identified (Daoust et al. 1995; Ariza et al. 1997).
5. Patients with mutations in both the PKD1 and PKD2 genes (transheterozygotes) (Pei et al. 2001) have a more severe clinical course than those with mutations in only one of the genes.

3. Mechanism of cyst formation: somatic second-hit model (Wilson 2004):
   1. A germline mutation in one PKD allele in all cells in ADPKD
   2. A random somatic mutation (second hit) occurring in the normal allele causing increased cell proliferation, leading to cyst formation
4. Molecular basis of ADPKD (Rossetti et al. 2002b):
   1. Protein products of the disease gene forming a macromolecular signaling structure, the polycystin complex, that regulates fundamental aspects of renal epithelial development and cell biology
   2. Protein products of PKD1 and PKD2 (polycystin-1 and polycystin-2), respectively:
      1. Share sequence homology
      2. May form components of a receptor/channel complex
   3. Polycstin-1:
      1. Predicted to have a receptor-like structure
      2. May be involved in cell-cell/matrix interactions
      3. May have a regulatory role over a polycystin channel
   4. Polycystin-2:
      1. Similar to and functioning as an ion channel subunit
      2. Causes nonselective cation permeability
   5. Basic defect in ADPKD: could be in polycystin-regulated intracellular Ca^{++} levels
5. Molecular basis of other polycystic kidney disease (Wilson 2004):
   1. Autosomal recessive polycystic kidney disease (please see the chapter "▶ Polycystic Kidney Disease: Autosomal Recessive Type"):
      1. Caused by mutation in *PKHD1* loss of functional fibrocystin
      2. Fibrocystin: a receptor-like membrane protein with putative extracellular matrix interaction domains as well as intracellular signaling sites
   2. Juvenile nephronophthisis:
      1. Caused by mutation in *NPH1* loss of functional nephrocystin
      2. Nephrocystin: an intracellular protein that interacts with the focal adhesion complex, the cilium, and tyrosine signaling molecules
6. Disease characteristics:
   1. Principal ductal organs with cyst formation:
      1. Kidneys
      2. Liver
   2. Consequences of cyst enlargement:
      1. Progressive destruction of normal renal tissue
      2. End-stage renal failure in >50% of patients by age 60
   3. Systemic involvement:
      1. Arterial hypertension developing early and observed in >50% of patients

2. Vascular aneurysms
3. Cardiac valve defects
4. Colonic diverticula

Clinical Features

1. Autosomal dominant polycystic kidney disease:
    1. Presenting in the fetus or newborn is rare (Edwards and Baldinger 1989).
    2. First symptoms of the disease occur usually in the third or fourth decade of life (Wolyniec et al. 2008).
2. Intrafamilial and interfamilial variability in the onset, phenotype, and progression of the disease:
    1. Due to genetic heterogeneity:
        1. More common PKD1 (accounting for approximately 85% of cases associated with more severe disease)
        2. Evidence of significant intrafamilial phenotypic variation suggesting modifying factors (such as the angiotensin-converting enzyme insertion/deletion polymorphism) as well as environmental factors that influence the clinical course
        3. Association of the position of the *PKD1* mutation with earlier end-stage renal disease
    2. Age of onset:
        1. Presenting at any age
        2. Generally presenting in the fourth and fifth decades of life
        3. Occasionally presenting in the fetal or neonatal period
3. Onset of disease in the childhood in children who carry *PKD1* gene:
    1. Frequency of children with renal cysts detectable by ultrasound:
        1. Sixty percent by 5 years of age
        2. Seventy-five to eighty percent among children aged 5–18 years
    2. Number of renal cysts at 11 years:
        1. One to ten in 60% of children
        2. More than ten cysts in 40% of children
4. Age at the time of diagnosis and progression of the disease:
    1. Diagnosis in utero or in the first year of life (intrauterine or infantile onset)
        1. Manifesting unusually severe disease
        2. End-stage renal disease during childhood in 18% of cases
    2. Diagnosis after the first year of life:
        1. Increase in the number of cysts over a mean interval of 3.7 years
        2. Systolic hypertension in 9% of cases
        3. None with decreased renal function
5. Renal manifestations (Fick and Gabow 1994; Fick et al. 1994):
    1. Development of bilateral renal cysts:
        1. Primary renal manifestation
        2. Leading to functional changes (impaired renal concentrating capacity, hypertension)
        3. Leading to various clinical manifestations
    2. Flank or back pain (about 60%)
    3. Acute pain:
        1. Infected cyst
        2. Ruptured cyst (associated with gross hematuria)
        3. Nephrolithiasis (20–36%) (Torres et al. 1993)
    4. Urinary tract infection (40–68%)
    5. Hematuria
    6. Mild proteinuria
    7. End-stage renal disease
6. Extrarenal manifestations (Fick and Gabow 1994; Perrone 1997; Luciano and Dahl 2014):
    1. Liver involvement (Chauvear et al. 2000):
        1. Most common extrarenal manifestation
        2. Liver cysts uncommon before 16 years of age
        3. Liver cysts observed in about 75% of patients older than 60 years
        4. No liver symptoms in most patients with ADPKD
        5. Occasionally encountered liver changes:
            1. Congenital hepatic fibrosis
            2. Segmental dilation of the biliary tract

6. Liver cysts responsible for most of the hepatic complications
7. Acute complications (Chauvear et al. 2000):
    1. Cyst infection
    2. Cyst hemorrhage
    3. Cyst rupture
    4. Cyst torsion
8. Chronic complications related to progressive increase of the polycystic liver (Chauvear et al. 2000):
    1. Abdominal mass
    2. Ascites
    3. Hepatic venous outflow obstruction (Budd-Chiari syndrome)
    4. Portal hypertension with variceal bleeding
    5. Inferior vena cava compression
    6. Bile duct compression
    7. Jaundice
9. Intrahepatic biliary cysts:
    1. More common in women
    2. Exacerbated by pregnancy

2. Unrelated to liver cysts (Chauvear et al. 2000):
    1. Congenital hepatic fibrosis or biliary fibroadenomatosis, focal or diffuse
    2. Idiopathic dilation of the intra- or extrahepatic biliary tract (Caroli syndrome)
    3. Cholangiocarcinoma
3. Other rare cystic involvement (Fick et al. 1994):
    1. Pancreatic cysts (10%) (Kim et al. 2016)
    2. Arachnoid cysts (5%)
    3. Ovarian cysts
4. Cardiovascular manifestations not uncommon:
    1. Intracranial berry aneurysms (5–10%)
    2. Dolichoectatic arteries
    3. Aortic root dilatation
    4. Dissections of intracerebral, coronary, thoracic, iliac, aortic, and splenic arteries reported
    5. Cardiac valve defects
5. Other noncystic involvement (Mikolajczyk et al. 2016):
    1. Colonic diverticula (80% of patients with end-stage renal disease)
    2. Hernias (25%)
    3. Large bile duct abnormalities
7. Clinical course in children:
    1. Clinical spectrum ranging from severe neonatal manifestations mimicking autosomal recessive polycystic kidney disease to renal cysts noted on ultrasound in asymptomatic children
    2. Diagnosis made in utero by ultrasound: massively enlarged cystic kidneys
    3. Newborn presenting with Potter phenotype and death from pulmonary hypoplasia
    4. Newborn with large abdominal masses
    5. After neonatal period:
        1. Hypertension
        2. Abdominal pain
        3. Palpable abdominal mass
        4. Hematuria
        5. Renal insufficiency, only rarely
        6. Renal infections
    6. Rare extrarenal manifestations:
        1. Liver cysts
        2. Cerebral vessel aneurysms
    7. Prognosis:
        1. Severe symptoms in neonatal or infantile cases
        2. Milder symptoms in late childhood cases
8. The progression of ADPKD clearly occurs in childhood and manifests as an increase in cyst number and renal size (Fick-Brosnahan et al. 2001).
9. There was a significant relationship between the severity of the renal structural involvement and the frequency of flank and back pain, hypertension, and impaired renal concentrating capacity. There was progression of the disease, reflected by an increase in cyst number and an increase in the frequency of pain and hypertension. However, glomerular filtration rate (GFR) remained stable in all children (Fick et al. 1994).
10. Genotype-phenotype correlation in children with ADPKD (Fencl et al. 2009):

1. PKD1 children have more and larger renal cysts, larger kidneys, and higher ambulatory blood pressure than do PKD2 children.
2. Renal cysts and enlarged kidneys detected prenatally are highly specific for children with PKD1.

11. Reproductive issues for adults with ADPKD (Vora et al. 2008):
    1. Men with ADPKD:
        1. Necrospermia
        2. Immotile sperm
        3. Seminal vesicle cysts
        4. Ejaculatory duct cysts
    2. Female fertility is not affected:
        1. Affected women with ADPKD and normal renal function have a high rate of successful uncomplicated pregnancies.
        2. Pregnant women with ADPKD with compromised kidney function should be monitored carefully for the development of hypertension and preeclampsia.
12. Risk factors precipitating faster progression of the disease:
    1. The *PKD-1* gene
    2. Male gender
    3. Earlier onset of symptoms:
        1. Renal enlargement
        2. Hematuria
        3. Proteinuria
        4. Incipient renal failure
        5. Hypertension
    4. Having >10 renal cysts before age 12 years
    5. Having blood pressures above the 75th percentile for age, height, and gender
    6. Polycystic liver disease:
        1. Frequently associated with autosomal dominant polycystic kidney disease
        2. Develops later than renal cysts
        3. Develops earlier and more severe in women than in men
13. End-stage renal disease:
    1. The most feared renal complication of ADPKD
    2. Occurs in more than half of patients by the seventh decade of life
14. Differential diagnosis (Wolyniec et al. 2008):
    1. Autosomal recessive polycystic kidney disease: manifests advanced renal insufficiency present already in childhood or early youth (see the chapter "► Polycystic Kidney Disease: Autosomal Recessive Type")
    2. "► Tuberous Sclerosis" (see the chapter):
        1. Cysts in the kidneys observed in 20% of patients with tuberous sclerosis complex
        2. Associated with characteristic skin and neurological symptoms
    3. "► Von Hippel-Lindau Disease" (see the chapter)
    4. Medullary cystic kidney disease:
        1. Most commonly occurs as juvenile nephronophthisis
        2. Associated with chronic renal failure in childhood
    5. "► Oral-Facial-Digital Syndrome" (see the chapter)
    6. Multicystic renal dysplasia in adults:
        1. Usually a unilateral disorder
        2. Frequent presence of calcification in the cyst walls and abnormal structure of parenchyma between the cysts visible on ultrasound
    7. Medullary sponge kidney: lithiasis and nephrocalcinosis commonly observed in the course of the disease
    8. Acquired cystic kidney disease
15. Differential features of ARPKD and ADPKD (Verghese and Miyashita 2014):
    1. ARPKD:
        1. Mode of inheritance: autosomal recessive.
        2. Location of cysts: Cysts are dilation of renal collecting ducts.
        3. Gross appearance: reniform shape maintained; multiple minute cystic spaces throughout the capsular surfaces. Cut sections of the kidney show subcapsular extensions of radially oriented cylindrical or fusiform ectatic spaces from the medulla to the cortex.

4. Age of presentation: most often in the neonatal period or childhood.
5. Frequency: 1 in 20,000 live births.
6. Extrarenal features: can occur in neonates; congenital hepatic fibrosis in all patients; manifestations of oligohydramnios, such as pulmonary insufficiency; Potter facies, club foot, and so forth
7. Renal prognosis: Fetuses with severe renal failure, oligohydramnios, and pulmonary hypoplasia often die of pulmonary complications. Patients with less severe renal manifestations who survive the neonatal period have a 50% chance of developing end-stage renal disease (ESRD) by age 10 years.

2. ADPKD:
   1. Mode of inheritance: autosomal dominant
   2. Location of cysts: Cysts develop anywhere along the nephron.
   3. Gross appearance: loss of reniform shape of kidney; numerous, large, round nodules/cysts of varying sizes on the external surface of the kidney and randomly distributed through the entire parenchyma of the kidney.
   4. Age of presentation: Most often initially presents in adults aged 20–40 years, but increasingly there are reports of ADPKD presenting in childhood and even in utero.
   5. Frequency: one case in 400–1000 population.
   6. Extrarenal features: does not occur in neonates. Congenital hepatic fibrosis and portal hypertension are very rare. Manifestations of oligohydramnios are rare. Includes hepatic cysts, pancreatic cysts found exclusively in patients with PKD1, cerebral vessel aneurysms, mitral valve prolapse, endocardial fibroelastosis, increased left ventricular mass with diastolic dysfunction even in normotensive children, ovarian cysts.
   7. Renal prognosis: Chances of ESRD are 2% in those <40 years of age and increase to 50% by the seventh decade of life.

Diagnostic Investigations

1. Urinalysis:
   1. Hematuria
   2. Mild proteinuria
   3. Evidence of infection
2. Sonography:
   1. Prenatal presentation:
      1. Large hyperechogenic kidneys: the most consistent renal ultrasonographic findings in children (Fick et al. 1993)
      2. Variable size
      3. Mixtures of small and large cysts
      4. Exceptionally uncommon oligohydramnios
   2. Postnatal presentation: invariably large cysts
3. Renal ultrasound and IVP:
   1. Enlarged kidneys
   2. Macrocysts and distortion of the collecting system
4. Age at clinical onset and at ultrasonographic detection of adult polycystic kidney disease (Bear et al. 1984): The probability of ultrasonographic detection of asymptomatic APKD is estimated as 0.222, 0.657, and 0.855 at age 5, 15, and 25 years, respectively.
5. CT scan and/or MRI for renal, hepatic (Gupta et al. 1999), pancreatic, and ovarian cysts
6. CT scan and/or MRI angiography for intracranial aneurysm
7. Renal function tests
8. Renal ultrasound to assess carrier status:
   1. A painless and relatively noninvasive procedure
   2. Detection rate in asymptomatic subjects from families with known ADPKD:
      1. Twenty-two percent of cases in the first decade

2. Sixty-six percent of cases by the second decade
3. Eighty-six percent by age 25

9. Molecular diagnosis (Harris and Rossetti 2010):
   1. Diagnosis of ADPKD before the onset of symptoms is usually performed using renal imaging by either ultrasonography, CT, or MRI. In general, these modalities are reliable for the diagnosis of ADPKD in older individuals.
   2. However, molecular testing can be valuable when a definite diagnosis is required in young individuals, in individuals with a negative family history of ADPKD, and to facilitate preimplantation genetic diagnosis.
   3. Although linkage-based diagnostic approaches are feasible in large families, direct mutation screening is generally more applicable.
   4. Identification and characterization of *PKD1* and *PKD2* provided an opportunity for mutation-based molecular diagnostics to be used for ADPKD. Mutations in *PKD1* account for about 85% of cases and cause more severe disease than mutations in *PKD2*.
   5. As ADPKD displays a high level of allelic heterogeneity, complete screening of both genes is required.
   6. Consequently, such screening approaches are expensive. Screening of individuals with ADPKD detects mutations in up to 91% of cases.
   7. However, only about 65% of patients have definite mutations, with about 26% having nondefinite changes that require further evaluation.
   8. Collation of known variants in the ADPKD mutation database and systematic scoring of nondefinite variants is increasing the diagnostic value of molecular screening.
   9. Mutation analysis of the entire PKD1 gene (Rossetti et al. 2001): The majority of changes were predicted to truncate the protein through nonsense mutations (32%), insertions or deletions (29.6%), or splicing changes (6.2%) (Rossetti et al. 2001).
   10. A complete mutation screen of the ADPKD genes by denaturing high-performance liquid chromatography (DHPLC) (Rossetti et al. 2002b).
   11. Diagnosis of autosomal dominant polycystic kidney disease using efficient PKD1 and PKD2 targeted next-generation sequencing (Trujillano et al. 2014).
   12. Prenatal forms of autosomal dominant polycystic kidney disease (ADPKD) are rare but can be recurrent in some families, suggesting a common genetic modifying background. Few patients have been reported carrying, in addition to the familial mutation, variation(s) in polycystic kidney disease 1 (*PKD1*) or *HNF1* homeobox B (*HNF1B*), inherited from the unaffected parent, or biallelic polycystic kidney and hepatic disease 1 (*PKHD1*) mutations (Audrézet et al. 2016).

Genetic Counseling

1. Recurrence risk:
   1. Patient's sib:
      1. Not increased in de novo case
      2. Fifty percent if one of the parent is affected
   2. Patient's offspring:
      1. Fifty percent risk of acquiring the disease
      2. Both sexes of offspring affected equally
2. Carrier testing for family members at risk:
   1. Ultrasound and radiography
   2. Molecular mutation analysis of *PKD1* and *PKD2* genes
3. Prenatal diagnosis:
   1. Prenatal ultrasonography:
      1. Enlarged kidneys (hyperechogenic) with or without cysts: the most common fetal findings.
      2. Absence of urine in the bladder.
      3. May not be evident until the third trimester.

4. Evidence of uteroplacental insufficiency (Vora et al. 2008):
    1. Intrauterine growth restriction
    2. Oligohydramnios
5. Though a highly penetrant disease, due to varied clinical expression and the typical late onset of symptoms, reproductive-aged women may not know their carrier status. Fetal US findings of ADPKD prompted maternal diagnosis of ADPKD (Euser et al. 2015).

2. Molecular mutation analysis of *PKD1* and *PKD2* genes on fetal DNA obtained from amniocentesis or CVS, provided the mutation has been identified in the affected family members or linkage has been established in the family.
3. Preimplantation genetic diagnosis possible, provided the mutation has been identified previously (Harris and Torres 2015). Genetic testing offers the chance of performing prenatal or preimplantation testing of embryos in families with severe cases of the disease (Balcells and Criach 2011).

4. Management (Harris and Torres 2015):
    1. No treatment currently directed at the disease process.
    2. Monitoring of presymptomatic patients with ADPKD:
        1. Monitor blood pressure
        2. Test renal function
        3. Advantages:
            1. Prevent or control hypertension
            2. Prevent or control infection
            3. Identify potential kidney donors from among the family
            4. Offer advice on reproduction
            5. Provide prenatal diagnosis
    3. Identification of alterable factors such as hypertension, number of pregnancies, and recurrent urinary tract infections provides the clinician with the opportunity to modify these factors and improve the management of patients with autosomal dominant polycystic kidney disease (Gabow et al. 1992).
    4. In patients with ADPKD, an effort should be made to keep the arterial blood pressure below 120/80 mmHg. In patients at high risk of progression whose renal function is still intact (eGFR $>$ 60 mL/min), strict blood pressure control ($<$110/75 mmHg) is indicated and possibly V2R blockade with tolvaptan as well (Kühn and Walz 2015).
    5. Treatment of polycystic kidney disease:
        1. Narcotic analgesics for pain
        2. Antibiotics for infection
        3. Treatment of nephrolithiasis:
            1. Potassium citrate for uric acid lithiasis, hypocitric calcium oxalate nephrolithiasis, and distal acidification defects
            2. Extracorporeal shock wave lithotripsy
            3. Percutaneous nephrostolithotomy
        4. Needle aspiration of dominant cysts
        5. Laparoscopic management of renal cystic disease (Hemal 2001): a highly effective, safe, and minimally invasive alternative to open surgery and antegrade or retrograde endoscopic procedures
        6. Open renal cyst decortication
        7. Therapeutic intervention aimed at slowing the progression of renal failure:
            1. Control of hypertension
            2. Control of hyperlipidemia
            3. Dietary protein restriction
            4. Control of acidosis
            5. Prevention of hyperphosphatemia
        8. Renal dialysis
        9. Renal transplantation for end-stage renal disease
    6. Treatment of massive polycystic liver disease (Chauvear et al. 2000):
        1. Aspiration of cyst fluid.
        2. Stenting.
        3. Cyst fenestration.
        4. Liver resection.
        5. Liver transplantation.
        6. Selected patients with severe symptoms benefit from liver resection and extensive fenestration with acceptable morbidity and mortality. Total hepatectomy and orthotopic liver

transplantation may be considered for patients with severe adult polycystic liver disease (Chen 2000).

7. Treatment for nephrolithiasis: extracorporeal shock wave lithotripsy and percutaneous nephrostolithotomy (Torres et al. 1993).
8. Treatment of cerebral aneurysms (Pirson et al. 2002):
    1. Asymptomatic aneurysm:
        1. Observation and yearly follow-up
        2. Surgery for enlarging aneurysm
    2. Ruptured or symptomatic aneurysm: surgical clipping at its neck
9. Management of aortic dissection:
    1. Aortic root dilatation:
        1. Yearly follow-up
        2. Strict blood pressure control with β-blockade
    2. Surgery (replacement of the aorta) for aortic root greater than 55–60 mm
10. Multidrug approach in management of patients with ADPKD (Ecder 2016):
    1. A multidrug approach is needed in the management of patients with ADPKD, not only to slow the progression of renal disease but also to decrease the cardiovascular complications, the major cause of morbidity and mortality in these patients (Ecder 2013).
    2. Aggressive blood pressure control with an ACE inhibitor or an angiotensin receptor blocker forms the basis of this therapy.
    3. The addition of tolvaptan (Gansevoort et al. 2016) is expected to provide supplementary benefit in decreasing the decline of renal function in these patients.
    4. Statins would have beneficial effects on slowing the progression of ADPKD.

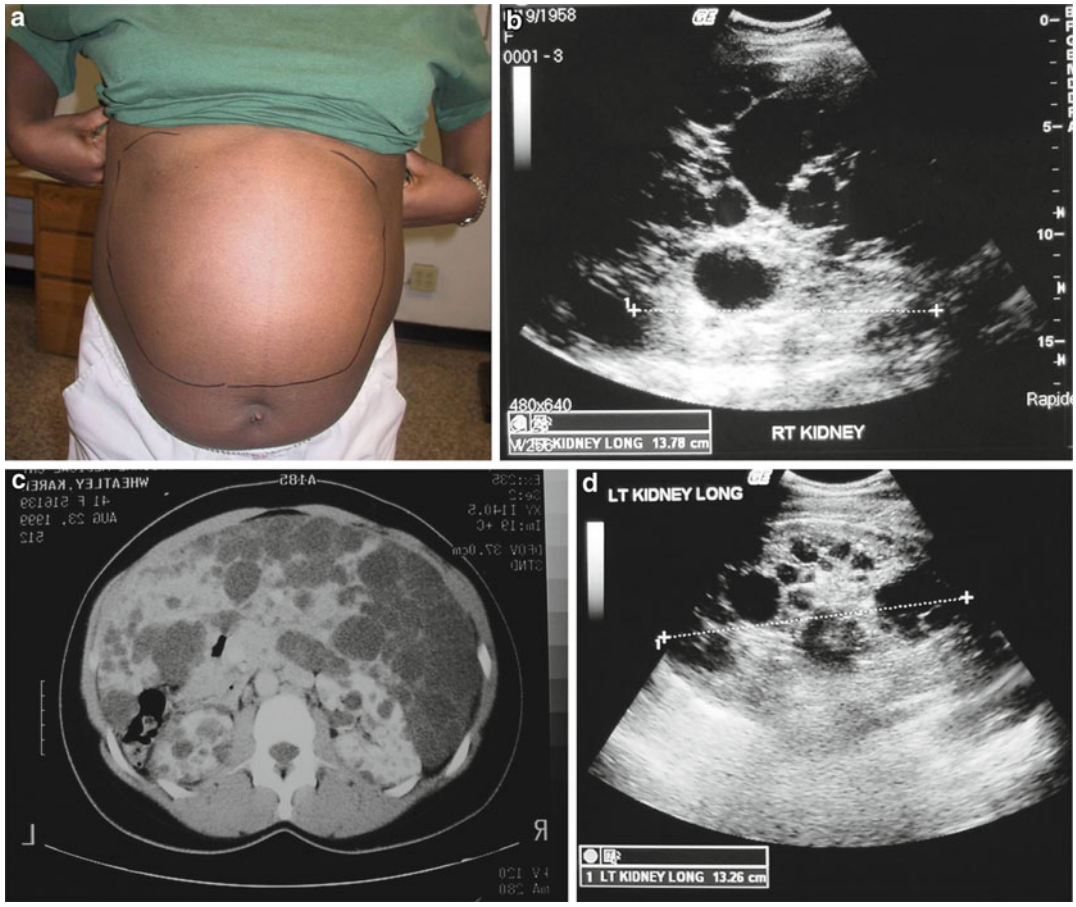

Fig. 1 (**a**–**d**) A lady (**a**) with autosomal dominant polycystic kidney disease and with family history of multiple affected family members. Her liver was markedly enlarged as shown by a *pencil mark* on the patient's photo. The ultrasonography of the kidneys showed numerous cysts with minimal residual normal appearing cortex. The *right* kidney (**b**) measured 11 cm, with the largest cyst measuring 2.9 cm. The *left* kidney measured 13.3 cm in length, with the largest cyst measuring 3.8 cm (image not shown). The abdominal CT scan (**c**) showed marked hepatomegaly which occupies the entire abdomen. Numerous hepatic cysts and renal cysts were evident. Numerous cysts of different sizes were also detected in her brother's enlarged kidneys by ultrasonography (the *left* kidney is shown here on image (**d**))

Polycystic Kidney Disease: Autosomal Recessive Type

Contents

Autosomal recessive polycystic kidney disease (ARPKD) or polycystic kidney and hepatic disease 1 (*PKHD1*) is an often devastating form of polycystic kidney disease. It is also known as infantile polycystic kidney disease. The incidence of ARPKD is estimated to be 1 in 20,000 live births, and the frequency of the heterozygous carrier state is 1 in 70 (Lonergan et al. 2000).

Synonyms and Related Disorders

Congenital hepatic fibrosis (Caroli disease); Infantile polycystic kidney disease; Polycystic kidney and hepatic disease

Genetics/Basic Defects

1. Inheritance: autosomal recessive.
2. No clear evidence of genetic heterogeneity.
3. ARPKD: a hepatorenal fibrocystic disorder with pleiotropic effects (Hartung and Guay-Woodford 2014).
4. Molecular cause (Harris and Rossetti 2004):
   1. Mutations in the *PKHD1* gene on chromosome 6p21.1-p12 (Zerres et al. 1994), encoding a putative receptor protein, fibrocystin (or polyductin)
   2. The ARPKD protein, fibrocystin, is predicted to be an integral membrane, receptor-like protein containing multiple copies of an Ig-like domain (TIG).
   3. Fibrocystin is localized to the branching ureteric bud, collecting and biliary ducts, consistent with the disease phenotype and often absent from ARPKD tissue.
   4. In common with other PKD-related proteins, fibrocystin is localized to the primary cilia of renal epithelial cells, reinforcing the link between ciliary dysfunction and cyst development.
   5. The majority of patients are compound heterozygotes, and preliminary genotype/phenotype studies associate two truncating mutations with severe disease.
   6. The complexities of *PKHD1*, marked allelic heterogeneity, and high level of missense changes complicate gene-based diagnostics.
5. Genotype-phenotype correlations (Denamur et al. 2010):
   1. All patients carrying two truncating mutations displayed a severe phenotype with

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_194

perinatal or neonatal demise (Bergmann et al. 2003; Dell and Avner 2011).
2. Patients who survive have at least one missense mutation.

6. The next challenges will be to determine how various factors, such as specific mutations in the *PKHD1* gene, variations in modifying gene loci, modulation by as yet unspecified environmental factors, or gene-environment interactions, contribute to the marked variability in survival and disease expression observed among ARPKD patients (Guay-Woodford and Desmond 2003).

Clinical Features

1. The most common heritable cystic renal disease manifesting in infancy and childhood (Lonergan et al. 2000).
2. A wide variable clinical spectrum (Zerres et al. 2003; Adeva et al. 2006), ranging from severe renal impairment, and a high mortality rate in infancy to older children and adolescents with minimal renal disease and complications of congenital hepatic fibrosis, cholangitis, and portal hypertension.
3. Principal manifestations:
   1. Fusiform dilatation of renal collecting ducts and distal tubuli
   2. Dysgenesis of the hepatic portal triad
4. Clinical characteristics at presentation: variable clinical spectrum:
   1. Zero to 1 month:
      1. Prenatal diagnosis made
      2. Positive family history
      3. Pneumothorax
      4. Flank mass
      5. Hypertension
      6. Renal insufficiency
   2. >1 month–1 year:
      1. Frank mass
      2. Hepatomegaly
      3. Hypertension
      4. Urinary tract infection
   3. >1–5 years:
      1. Hepatomegaly
      2. Portal hypertension
   4. >5 years:
      1. Hepatomegaly
      2. Hypertension
      3. Renal insufficiency
      4. Portal hypertension
   5. Predominance of renal abnormalities in younger children.
   6. Predominance of hepatic disease in older children and adolescents.
   7. Tendency of inverse relative degrees of kidney and liver involvement:
      1. Children with severe renal disease usually with milder hepatic disease
      2. Children with severe hepatic disease with milder renal impairment
   8. ARPKD may be underdiagnosed in adulthood because the sonographic data are not specific. Moreover, a correlation between age and hepatic involvement is not always seen, so this disease must be suspected when portal hypertension is present in a young adult with renal failure (Pérez et al. 1998).
5. "Potter" phenotype developed in affected fetuses:
   1. Pulmonary hypoplasia, often incompatible with life
   2. Characteristic face:
      1. Short and snubbed nose
      2. Deep eye creases
      3. Micrognathia
      4. Low-set flattened ears
   3. Deformities of the spine and limbs (clubfoot)
6. Renal manifestations:
   1. Frequent loss of concentrating ability of the kidney
   2. Common recurrent urinary tract infections
   3. Proteinuria
   4. Hematuria
   5. Creatinine clearance improving early but declining progressively during adolescence
   6. Hypertension early in life but usually regresses
   7. Enlarged kidneys
   8. End-stage renal disease

7. Hepatic manifestations:
    1. Congenital hepatic fibrosis (Lieberman et al. 1971):
        1. Invariably present but only occasionally do hepatic symptoms predominate.
        2. Two predominant features characterizing the liver in ARPKD:
            1. Bile ducts: abnormally/irregularly formed, often increased in number, and dilated intrahepatic bile ducts
            2. Portal tracts: enlarged and fibrotic
        3. Normal hepatic parenchyma.
        4. Hepatocellular function almost always normal in affected patients, even when they have relatively severe portal tract disease.
        5. Not by itself a diagnostic (not pathognomonic) sign. Congenital hepatic fibrosis has been observed in the following situations (Lonergan et al. 2000):
            1. Meckel-Gruber syndrome
            2. Vaginal atresia
            3. Tuberous sclerosis
            4. Juvenile nephronophthisis
            5. Rarely autosomal dominant polycystic kidney disease
    2. Caroli disease:
        1. Congenital hepatic fibrosis accompanied by a nonobstructive dilation of the intrahepatic bile ducts
        2. Clinical risk of secondary complications:
            1. Stone formation
            2. Recurrent cholangitis: may result from ectatic bile ducts
            3. Hepatic abscesses
            4. Rare cholangiocarcinoma
    3. Hepatomegaly
    4. Portal hypertension (Lonergan et al. 2000):
        1. The most common sequelae of congenital hepatic fibrosis
        2. Splenomegaly
        3. Variceal bleeding
        4. Hypersplenism:
            1. Leukopenia
            2. Thrombocytopenia
            3. Anemia
            4. Increased susceptibility to infections resulting from leukopenia associated with splenic sequestration
    5. Ascending cholangitis (Lonergan et al. 2000):
        1. Presumably caused by entry of nonsterile gastrointestinal contents into the dilated intrahepatic bile ducts
        2. Common in patients with macroscopically dilated bile ducts
        3. Clinical features:
            1. Abdominal pain
            2. Fever
            3. Elevation in levels of hepatic enzymes
        4. Tends to recur
        5. May lead to hepatic abscess formation, sepsis, and death
8. Cerebral aneurysm, a common feature of ADPKD, reported in an adult with ARPKD
9. Prognosis:
    1. Thirty to fifty percent of affected neonates die shortly after birth in respiratory insufficiency due to pulmonary hypoplasia.
    2. Most neonates without severe pulmonary hypoplasia will survive (Sumfest et al. 1993).
    3. Recent trend with improved prognosis.
    4. Sixty-seven percent of children who survive the newborn period with life-sustaining renal function at 15 years of age.

Diagnostic Investigations

1. Radiography in neonates and infants with moderate to severe renal disease:
    1. Smoothly enlarged kidneys because of the numerous dilated collecting ducts
    2. Abdominal distension
    3. Gas-filled bowel loops often deviated centrally
    4. Pulmonary hypoplasia and small thorax in the baby with severe kidney disease
    5. Pneumothorax common at birth following assisted ventilation
2. Ultrasonography:
    1. The absence of renal cysts in both parents as demonstrated by ultrasound examination

2. Neonatal ultrasonography with more marked renal cystic disease:
    1. Massive enlarged kidneys
    2. Increased echogenicity of the entire parenchyma
    3. Loss of corticomedullary differentiation
    4. Loss of central echo complex
    5. Small macrocysts (unusual focal rosettes consisting of a cluster of the radially oriented, dilated collecting tubules) (Stein-Wexler and Jain 2003)
    6. Usually small bladder
    7. Increased hepatic echogenicity, mainly in medulla
3. Ultrasonography in children with more prominent hepatic fibrosis:
    1. Massive kidney enlargement
    2. Increased hepatic echogenicity, mainly in medulla
    3. Macrocysts:
        1. Less than 2 cm in diameter
        2. Tend to become larger and more numerous over time
    4. Enlarged echogenic liver
    5. Hepatic cysts
    6. Pancreatic cysts
    7. Splenomegaly secondary to portal hypertension
    8. Hepatofugal-flow duplex and color-flow Doppler

3. CT scan:
    1. Nonenhanced CT: smooth, enlarged, and low-attenuating kidneys, likely the reflection of the large fluid volume in the dilated ducts
    2. CT with contrast:
        1. Kidneys with a striated pattern representing accumulation of contrast material in the dilated tubules
        2. Linear opacifications representing retention of contrast medium in dilated medullary collecting ducts
        3. Macrocysts appearing as well-circumscribed rounded lucent defects
        4. Time of delay in visualizing the contrast medium in the kidneys, proportionate to the severity of renal impairment
4. Ultrasonography and magnetic resonance cholangiography to investigate the presence of an extent of Caroli disease in children with autosomal recessive polycystic kidney disease
5. MRI of affected children (perinatal, neonatal, and infantile course) (Kern et al. 1999):
    1. Kidney appearance:
        1. Enlarged, humpy but still reniform in shape
        2. Homogeneously grainy parenchyma
    2. Signal intensity:
        1. Hypointense on T1-W spin-echo sequences
        2. Hyperintense on T2-W turbo spin-echo sequences
    3. Rapid acquisition with relaxation enhancement (RARE)-MR urography:
        1. Hyperintense, linear radial pattern seen in the cortex and medulla representing the characteristic microcystic dilatation of collecting ducts
        2. Possible few circumscribed small subcapsular cysts
    4. MR cholangiography: a valuable method to establish the diagnosis and demonstrate the extent of Caroli disease by showing the entire biliary free from different angles (Jung et al. 1999)
6. Histopathology of the kidney and liver (Sherwani et al. 2010):
    1. Kidneys: Grossly enlarged with multiple cysts on the external surface that involve the cortex and medulla and are located in collecting ducts and tubules, lined by cuboidal epithelium.
    2. Liver:
        1. Grossly, cysts are also present in an enlarged liver where they form due to enlarged portal areas forming anastomosing channels, with the biliary structures forming dilated sacs.
        2. Hepatic fibrosis is an essential diagnostic criterion for this autosomal recessive disease.
    3. The involvement of the renal collecting system and hepatic ductal plate malformation is due to the failure of terminal

differentiation of the collecting duct and biliary systems, causing oligohydramnios leading to pulmonary hypoplasia which is the cause of morbidity, in 30% of cases.

7. Molecular diagnosis:
    1. Linkage analysis of the affected family using 6p21 markers demonstrating linkage to the *ARPKD1* gene with the affected proband.
    2. 33 different mutations detected on 57 alleles (Rossetti et al. 2003):
        1. 51.1% in ARPKD
        2. 32.1% in congenital hepatic fibrosis/Caroli disease
        3. Two frequent truncating mutations:
            1. 9689delA (9 alleles)
            2. 589insA (8 alleles)
        4. Mutation detection rate:
            1. High in severely affected patients (85%)
            2. Lower in moderate severe ARPKD (41.9%)
            3. Low, but significant, in adults with congenital hepatic fibrosis/Caroli disease (323.1%)
        5. Complications for the prospects for gene-based diagnostics:
            1. Large gene size
            2. Marked allelic heterogeneity
            3. Clinical diversity of the ARPKD phenotype
    3. Direct DNA analysis – available clinically:
        1. Mutation scanning
        2. Sequence analysis
        3. Targeted mutation analysis
        4. Deletion/duplication analysis
        5. Linkage analysis
    4. Next-generation sequencing of the PKHD1 gene is a very useful method of molecular diagnosis in patients with a full clinical picture of ARPKD, and it has a high detection rate. Furthermore, its relatively low costs and rapidity allow the molecular genetic analysis of patients without the full clinical criteria of ARPKD, who might also have mutations in the PKHD1 gene (Obeidova et al. 2015). The estimated costs and the time invested for molecular screening of genes with large size and allelic heterogeneity such as PKHD1 demand the use of next-generation sequencing (NGS) technologies for a fast, accurate, and cost-effective molecular diagnostic tool for identifying mutations in targeted genes sequence analysis (Edrees et al. 2016; Melchionda et al. 2016).

Genetic Counseling

1. Recurrence risk:
    1. Patient's sib: 25%
    2. Patient's offspring: not increased (theoretical risk 0.7%)
2. Prenatal diagnosis:
    1. Ultrasonography in most severely affected fetuses:
        1. Enlarged, echogenic kidneys (main US signs of ARPKD) (Zerres et al. 1988)
        2. Dilated collecting ducts
        3. Characteristic hepatic ductal plate malformation
        4. A small or nonvisualized bladder
        5. Oligohydramnios attributable to poor fetal renal output
        6. Unreliable especially in early pregnancy
    2. Molecular genetic testing by mutation scanning of *PKHD1* is available clinically by analysis of fetal DNA obtained by amniocentesis or CVS. Both disease-causing alleles of an affected family member must be identified, or linkage has been established in the family before prenatal testing can be performed. The ARPKD locus mapped to proximal chromosome 6p allowing haplotype-based prenatal diagnosis in "at-risk" family with a previously affected child in whom prior family studies have identified informative linked markers (Zerres et al. 1998a). An absolute prerequisite for these studies is an accurate diagnosis of ARPKD in the previously affected sib (Zerres et al. 1998b; Dell 2011).
    3. Preimplantation genetic diagnosis may be available for families in which the disease-

causing mutations have been identified (Sweeney and Avner 2014).

3. Management (Dell 2011):
    1. Initial management of affected infants to focus on stabilization of respiratory function. Mechanical ventilation may be necessary to treat both pulmonary hypoplasia and respiratory compromise from massively enlarged kidneys.
    2. Water and electrolyte balance.
    3. Peritoneal dialysis may be required for neonates with oliguria or anuria within the first days of life.
    4. Vigorous treatment of systemic hypertension with antihypertensive agents:
        1. ACE inhibitors
        2. Calcium channel blockers
        3. Beta blockers
        4. Judicious use of diuretics (e.g., thiazides, loop diuretics)
    5. Importance of early detection and appropriate management of systemic and portal hypertension (Roy et al. 1997).
    6. Antibiotics for treatment of urinary tract infections.
    7. Management of renal osteodystrophy in children with ARPKD and chronic renal insufficiency:
        1. Calcium supplements
        2. Phosphate binders
        3. 1,25-Dihydroxyvitamin D3 to suppress parathyroid hormone (PTH)
        4. Erythropoietin (EPO):
            1. Increases hemoglobin levels
            2. Improves the overall well-being of the child
    8. Potential use of recombinant human growth hormone therapy to improve the growth of children with uremia (Lilova et al. 2003).
    9. Therapeutic options available for the treatment of portal hypertension in children (Lonergan et al. 2000):
        1. Conservative management
        2. Control of variceal bleeding:
            1. Sclerotherapy effective in controlling bleeding
            2. Banding of varices
            3. Placement of portosystemic shunts occasionally necessary to reduce bleeding and the formation of additional varices
        3. Prompt management with antibiotics and, when indicated, surgical drainage to help reduce morbidity and mortality associated with ascending cholangitis
        4. Splenectomy for hypersplenism
        5. Liver transplantation in patients with severe hepatic dysfunction or chronic cholangitis
    10. Replacement therapy for renal failure:
        1. Renal dialysis
        2. Renal transplant
    11. Kidney transplantation (Jamil et al. 1999):
        1. Liver disease did not progress rapidly after initiation of renal replacement therapy and did not subsequently present a clinical problem.
        2. When it occurs, recurrent bleeding appears to be controllable with sclerotherapy.
        3. Cholangitis is not a significant problem.
        4. Renal transplantation is appropriate for patients with ARPKD and that prophylactic portacaval shunting or combined liver/kidney transplantation is unnecessary.

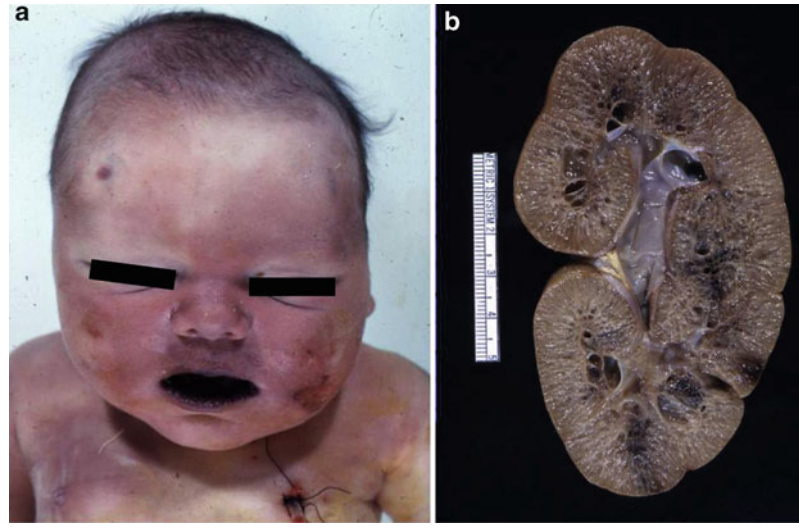

Fig. 1 A newborn with ARPKD showing Potter facies (**a**). The spongy appearing cut surface of a kidney from the same patient is due to generalized dilatation of the collecting ducts in both cortex and medulla (**b**)

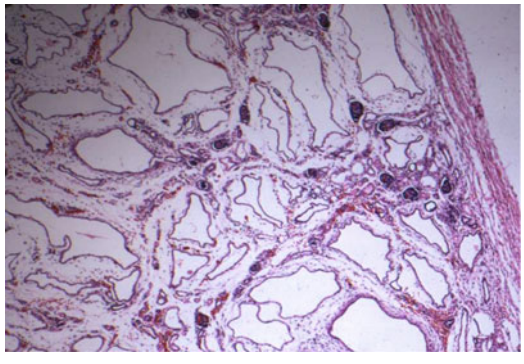

Fig. 2 Photomicrograph of a kidney of a neonate (37 weeks gestation) with ARPKD showing markedly dilated collecting ducts in the medulla (*top*) and the cortex (*bottom*). The infant also had intrahepatic bile duct proliferation and mild cystic changes and pulmonary hypoplasia

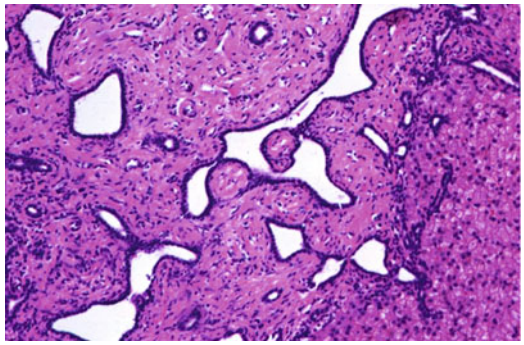

Fig. 3 Photomicrograph of the liver of a 2-year-old girl with congenital hepatic fibrosis, consistent with ARPKD. Note the irregularly dilated branching bile ducts. There is abundant fibrous connective tissue in this enlarged portal tract

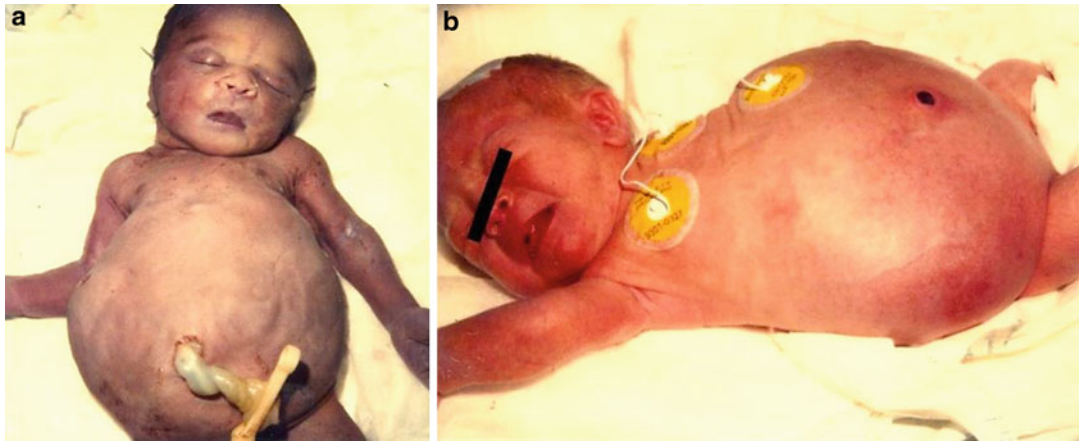

Fig. 4 Two neonates (**a**, **b**) with ARPKD showing markedly distended abdomen

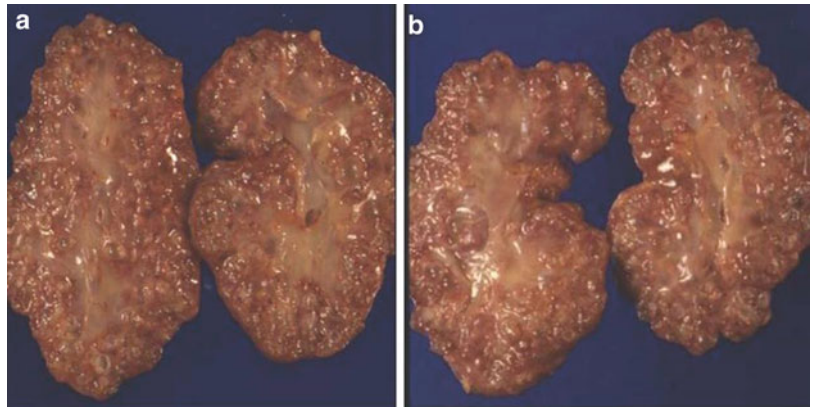

Fig. 5 (**a**, **b**) Kidneys in another neonates with ARPKD

Popliteal Pterygium Syndrome

Contents

In *1968*, Gorlin et al. (1968) described an autosomal dominant form of popliteal pterygium syndrome (PPS), a syndrome comprising cleft lip and palate, popliteal and intercrural pterygia, and digital and genital anomalies. Van der Woude syndrome (VWS) is one of the most common oral cleft syndromes. It accounts for about 2% of all cleft lip and palate cases. Both syndromes are caused by *IRF6* mutations.

In *1972*, Bartsocas and Papas (1972) reported on four sibs of third-cousin parents with a severe, presumably autosomal-recessive form of popliteal pterygium syndrome.

Synonyms and Related Disorders

Bartsocas-Papas syndrome; Cocoon syndrome; *IRF6*-Related Disorders including Van der Woude syndrome

Genetics/Basic Defects

1. Interferon regulatory factor 6 (*IRF6*) encodes a member of the IRF family of transcription factors (de Lima et al. 2009).
2. Mutations in *IRF6* cause popliteal pterygium syndrome and Van der Woude syndrome: interfamilial as well as intrafamilial variability has been described in IRF6-related disorders (Ferreira de Lima et al. 2009; Little et al. 2009; Durda and Schutte 2014; Busche et al. 2016).
3. Mutations in *RIPK4* gene on chromosome 21 cause the autosomal-recessive form of popliteal pterygium syndrome (Kalay et al. 2012).
4. Heterozygous mutations in *IRF6* cause popliteal pterygium syndrome (PPS), while homozygous mutations in *RIPK4* or *CHUK* (*IKKA*) cause the more severe Bartsocas-Papas syndrome (BPS) and Cocoon syndrome, respectively (Leslie et al. 2015). The most extreme end of this spectrum of disorders may be the lethal condition known as Cocoon syndrome (MIM 613630). This disorder, which has been described as an extreme form of Bartsocas-Papas syndrome, is caused by mutations in CHUK (also known as inhibitor of nuclear factor kappa-B kinase subunit alpha or IKKA) (Lahtela et al. 2010).
5. Popliteal pterygium syndrome (PPS)
   1. Inherited as an autosomal dominant trait.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_195

2. Exonic mutations in *IRF6* are found in nearly all families with PPS (De Lima et al. 2009).
3. First case of autosomal-recessive PPS reported (Leslie et al. 2015): Using a combination of Sanger and exome sequencing, the first case of an autosomal-recessive popliteal pterygium syndrome caused by homozygous mutation of *IRF6* and the first case of uniparental disomy of chromosome 21 leading to a recessive disorder.

6. Van der Woude syndrome (VWS)
   1. Inherited as an autosomal dominant trait with high penetrance (96.7%) but with variable expression.
   2. A nonsense mutation in the interferon regulatory factor 6 (*IRF6*) gene in the affected sib of two monozygotic twins discordant for VWS, suggesting *IRF6* as a candidate for VWS (Kondo et al. 2002).
   3. This hypothesis was confirmed in the same study by the detection of *IRF6* mutations in 45 additional unrelated families with VWS. In addition, a unique set of mutations in *IRF6* was discovered in 13 families with PPS, demonstrating that VWS and PPS as allelic, as previously suggested (Lees et al. 1999).
   4. Subsequently, mutations in *IRF6* were identified in 56 additional families with VWS and three with PPS (de Lima et al. 2009).
   5. Exonic mutations in *IRF6* are found in 68% of families with VWS.
7. Bartsocas-Papas syndrome (BPS)
   1. Inherited as an autosomal-recessive trait (Papadia and Zimbalatti 1984; Reich et al. 1984; Martinez-Frias et al. 1991; Massoud et al. 1998)
   2. Early lethality

Clinical Features

1. Autosomal dominant popliteal pterygium syndrome
   1. Cleft lip with or without cleft palate.
   2. Fistula of the lower lip.
   3. Filiform synechiae may connect the upper and lower jaws (syngnathia) or the upper and lower eyelids (ankyloblepharon).
   4. Syngnathia seen in nearly 40% of PPS patients are usually fibrous in type, limiting jaw excursion and creating difficulties in breathing and feeding (Froster-Iskenius 1990; Gahm et al. 2007).
   5. Webbing of the skin extending from the ischial tuberosities to the heels.
   6. Bifid scrotum and cryptorchidism in males.
   7. Hypoplasia of the labia majora in females.
   8. Syndactyly of fingers and/or toes.
   9. Anomalies of the skin around the nails: A characteristic pyramidal fold of the skin overlying the nail of the hallux is almost pathognomonic (Froster-Iskenius 1990; Mubungu et al. 2014).
   10. Normal growth and intelligence.
2. Autosomal-recessive popliteal pterygium syndrome (Kalay et al. 2012)
   1. Alopecia
   2. Ankyloblepharon filiforme adnatum
   3. Hypoplastic oral cavity and filiform bands between the jaws
   4. Limb abnormalities
      1. Digital hypoplasia
      2. Syndactyly
      3. Nail hypoplasia
      4. Arthrogryposis
      5. Clubfeet
      6. Popliteal, axillary, and inguinal pterygia
   5. Hypoplastic labia major
3. Van der Woude syndrome (Gorlin et al. 2001; Tripathi et al. 2014)
   1. Variable expressivity
   2. The most common oral cleft syndrome and accounts for 2% of complete cleft lip and palate cases (Katsube et al. 2015)
   3. Congenital lower-lip fistulae (pits)
      1. Usually bilateral and paramedian.
      2. The phenotype of the lower lip varies from a single barely evident depression to bilateral fistulae of the lower lip.
      3. Phenotypes of the orofacial cleft vary from a bifid uvula to a complete cleft lip and palate.

4. Cleft lip with or without cleft palate and cleft palate only
5. Hypodontia
6. Cleft or bifid uvula
7. Ankyloglossia
8. Less common features
    1. Syndactyly of the fingers
    2. Syngnathia
    3. Ankyloblepharon
9. Normal growth and intelligence

4. Autosomal-recessive Bartsocas-Papas syndrome (Hall et al. 1982; Erturan et al. 2016)
    1. Craniofacial
        1. Ankyloblepharon
        2. Facial cleft
        3. Hypotrichosis
        4. Microcephaly
        5. Filiform bands
        6. Hypoplastic nose
        7. Microphthalmia
        8. Eyelid colobomas
        9. Corneal opacities
        10. Salivary pits (with absent mouth)
    2. Musculoskeletal
        1. Synostosis of the hands and feet
        2. Talipes equinovarus
        3. Pelvic hypoplasia
        4. Popliteal and axillary webbing
        5. Single palmar crease
        6. Short sternum
        7. Syndactyly
        8. Laterally displaced nipples
        9. Diaphragmatic hypoplasia
    3. Genitourinary
        1. Ambiguous genitalia
        2. Renal agenesis (Hennekam et al. 1994)
        3. Penile shaft agenesis
        4. Urethral agenesis
        5. Dilated bladder
        6. Dysplastic kidneys
    4. Gastrointestinal
        1. Low-set umbilicus
        2. Stenotic anal orifice
        3. Esophageal atresia (Hennekam et al. 1994)
    5. Cardiothoracic: pulmonary stenosis.
    6. Developmental/cognitive: mental retardation.
    7. Early lethality is common, but about one-fourth of cases could survive (Giannotti et al. 1992).
    8. Causes of death
        1. Bronchopneumonia
        2. Respiratory distress
        3. Sepsis

5. VWS–PPS spectrum (Houweling et al. 2009)
    1. VWS and PPS may be regarded as mild and more severe manifestations of a single syndrome with intrafamilial and interfamilial variability.
    2. Instead of labeling VWS and PPS as separate syndromes, VWS–PPS spectrum, as recently published by De Medeiros et al. (2008), might prove to be more accurate.
    3. Lethal multiple pterygium syndrome (please see the chapter on "▶ Lethal Multiple Pterygium Syndrome").

Diagnostic Investigations

1. The role of MRI in evaluating the normal or abnormal position of the popliteal artery and peroneal nerve provides useful information for preoperative planning for surgical correction of the popliteal pterygium (Qasim and Shaukat 2012).
2. Histology of popliteal pterygium (Gorlin et al. 1968)
    1. Bilateral pterygium extending from the heel to the ischial tuberosity.
    2. Limiting extension and abduction as well as rotation of the leg.
    3. A hard, inelastic subcutaneous cord or fibrous band runs along the free edge of the pterygium.
    4. The sciatic nerve lies free within the pterygium deep to the fibrous band about halfway between the free edge and the apex being covered by fibromuscular septa.
    5. The popliteal vessels are normally situated deep in the popliteal space.
    6. Absence of muscle groups or abnormal muscle insertions in many cases.

3. Molecular genetic testing by sequence analysis of the *IRF6* coding region (exons 1–9) (Schutte 2014)
    1. Detects mutations in approximately 70% of individuals with the Van der Woude syndrome phenotype
    2. Detects mutations in approximately 97% of individuals with the popliteal pterygium syndrome phenotype
4. Exome Sequence Identifies RIPK4 as the Bartsocas-Papas Syndrome Locus (Mitchell et al. 2012).

Genetic Counseling

1. Recurrence risk for autosomal dominant *IRF6*-related disorders
    1. Patient's sib
        1. Appears to be low when parents are clinically unaffected, but the possibility of incomplete penetrance in a parent or of germline mosaicism need to be considered.
        2. Fifty percent of a parent of the proband is affected or has an *IRF6* mutations.
    2. Patient's offspring
        1. Each child of an individual with an *IRF6* mutation has a 50% chance of inheriting the mutation.
        2. The clinical manifestations of *IRF6*-related disorders are variable and cannot be predicted in the offspring.
2. Recurrence risk for autosomal-recessive PPS and BPS
    1. Patient's sib: 25%
    2. Patient's offspring: not increased unless the spouse is a carrier
3. Prenatal diagnosis
    1. Ultrasonography
        1. Oral cleft
        2. Popliteal pterygium
    2. Molecular genetic testing
        1. Prenatal diagnosis for pregnancies at increased risk is possible if the disease-causing allele of an affected family member is previously identified.
        2. Preimplantation genetic diagnosis (Durda and Schutte 2014): may be available for families in which the disease-causing mutation has been identified in an affected family member.
4. Management (Gahm et al. 2007)
    1. Early surgical treatment is of importance to enable and preserve oral feeding.
    2. Syngnathia in patients with PPS has raised concerns regarding oral feeds and airway compromise: need for thorough neonatal airway assessment (Posey et al. 2014).
    3. Intranasal flexible fiber intubation with the patient awake is a possible anesthetic strategy to secure the airway prior to surgery in patients with multiple or extensive interalveolar syngnathia.
    4. Surgical removal for synechiae.
    5. Cleft lip/cleft palate: surgical and orthodontic management.
    6. Speech therapy and audiologic evaluation for cleft palate.
    7. Surgery for lip pits for cosmetic purpose.
    8. Syndactyly may require surgery.
    9. To accomplish knee extension (Gardetto and Piza-Katzer 2003)
        1. Resect fibrous bands.
        2. Free the sciatic nerve.
        3. Z-lengthening of the Achilles tendon and multiple Z-plasties.
        4. Surgery result: 1 year after surgery, the patient can put his heel on the ground and has almost complete range of motion in the knee and ankle joints.
    10. Operations include excision of the fibrous band, mobilization of nerves and vessels and Z-plasty of the skin (Herold et al. 1986). Recurrence of flexion contracture is noted in some cases. Gradual soft tissue lengthening with an Ilizarov external fixator can be one of the optimal procedures when excision of a fibrous band and Z-plasty is not possible due to severe adhesion of the nerves and vessels into a fibrotic band (Kim et al. 2009).
    11. Excision of symptomatic accessory medial meniscus resulted in resolution of the symptoms (Funk et al. 2015).

12. Orthopedic care and physical therapy may be needed.

Fig. 1 (**a**–**c**) The newborn (**b**, **c**) was evaluated for multiple congenital anomalies, consisting of ankyloblepharon connecting upper and lower eyelids by fimbria (thin threadlike connective tissue); unilateral cleft lip and palate; thin strings of connective tissue connecting the upper and lower alveolar ridge on both sides; absence of labia majora, a clitoral hood, and a sacral dimple; hypoplastic labia minor; popliteal pterygium (webbing of the skin extending from the ischial tuberosities to the heels); skin over the nails of her great toes giving the nail a somewhat triangular shape with a flat base; and syndactyly over second to fifth toes bilaterally. The clinical diagnosis of popliteal pterygium syndrome (**a**) was confirmed by molecular genetic analysis of *IRF6* gene which showed a missense mutation of exon 4 [c252G > A or p. Arg841His (R84H)]

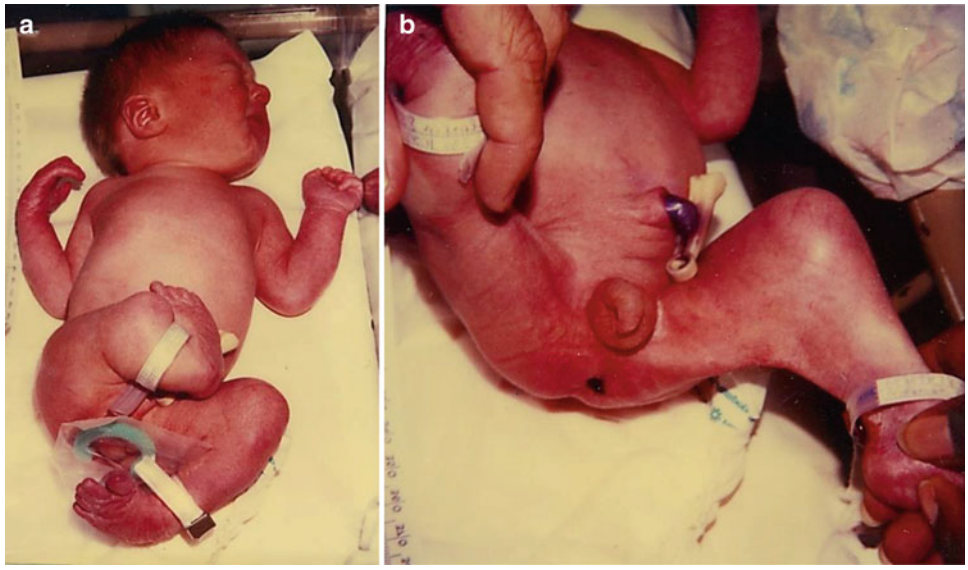

Fig. 2 (**a**, **b**) Another baby with popliteal pterygium syndrome

Prader-Willi Syndrome

Contents

Prader-Willi syndrome is a neurogenetic disorder characterized by hypotonia and feeding difficulties in infancy, followed by hyperphagia, hypogonadism, mental retardation, and short stature. It was the first recognized microdeletion syndrome identified with high-resolution chromosome analysis, the first recognized human genomic imprinting disorder, and the first recognized disorder resulting from uniparental disomy. The incidence of Prader-Willi syndrome is approximately 1/10,000–1/15,000 individuals.

Genetics/Basic Defects

1. Inheritance:
   1. Usually sporadic events (de novo deletions of 15q11-q13) (Ledbetter et al. 1981)
   2. Rare familial transmission (balanced translocations involving 15q11-q13) (<1%)
2. A contiguous gene syndrome involving multiple paternally expressed genes.
3. Caused by the lack of expression of normally active paternally inherited genes at chromosome 15q11-q13 because of a phenomenon called genomic imprinting (Horsthemke et al. 1997; Hanel and Wevrick 2001)
   1. The relevant region on chromosome 15q11-q13: normally expressed on the paternally derived chromosome and imprinted on maternally derived chromosome.
   2. The imprinted maternal allele is unable to produce functional protein since the normally expressed paternal copy is often deleted in Prader-Willi syndrome.
4. Prader-Willi syndrome can also be caused by disruption of the SNRPN gene (Ozçelik et al. 1992; Kuslich 1999).
5. Molecular subclassification of Prader-Willi syndrome: All involving loss of paternal gene expression from chromosome 15q11-q13 (Cassidy 1997; Buiting 2010):
   1. Paternal deletion 15q11-q13 (de novo) (70% of cases: microdeletion of the actively transcribed segment on the paternally derived chromosome 15q11-q13)
   2. Maternal uniparental disomy (UPD15) (inheritance of both copies of chromosome 15 from the mother) (Nicholls et al. 1989; Mascari et al. 1992) (25–30% of cases):
      1. Uniparental disomy (UPD) in humans is caused primarily by meiotic nondisjunction events, followed by trisomy or monosomy "rescue' (Ledbetter and Engel 1995).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_196

2. Inheritance of two copies of the maternal chromosome without paternal contribution.
3. In normal individuals, the paternally donated chromosome expresses multiple genes in the Prader-Willi syndrome region, while the maternal chromosome is largely silent.
4. In case of maternal uniparental disomy, without the presence of a chromosome donated from the father, normal imprinting on the two maternally donated chromosomes leads to the absence of gene expression in this region.

3. Mutation in the imprinting control center:
   1. Deletion of the imprinting center (1% of the cases) of the *s*mall *n*uclear *r*ibonucleoprotein *p*olypeptide *N* (SNRPN) gene causing inability to establish the normal methylation status
   2. Without imprinting center deletion (1% of cases)

6. Prader-Willi syndrome and Angelman syndrome: sister imprinted disorders (Nicholls 1993; Glenn et al. 1997; Cassidy and Schwartz 1998; Cassidy 2000; Buiting 2010):
   1. The most frequent genetic lesions in both disorders:
      1. A de novo deletion of the chromosomal region 15q11-q13
      2. A uniparental disomy 15 (Fridman 2000)
      3. An imprinting defect
      4. In the case of AS, a mutation of the UBE3A gene
   2. Angelman and Prader-Willi syndromes share a common chromosome 15 deletion but differ in parental origin of the deletion (Knoll et al. 1989): In contrast to the paternal inheritance of the deleted chromosome 15 observed in the majority of PWS patients, maternal inheritance of the deleted chromosome 15 was demonstrated in the AS patients by restriction fragment length polymorphisms (RFLPs).
   3. Imprinting in Prader-Willi and Angelman syndrome (Nicholls et al. 1998): PWS involves loss of function of multiple paternally expressed genes, while mutations in a single gene, UBE3A, which is subject to spatially restricted imprinting, occur in some AS patients.
   4. Genomic imprinting in an Angelman and Prader-Willi translocation family (Hultén et al. 1991):
      1. By genomic imprinting, we would expect to find translocation and inversion families with both AS and PWS children, dependent on transmitting parental sex.
      2. Such a translocation family have been reported. The index child with classic AS has a maternally derived unbalanced translocation, leading to a deletion 15pter- > q13 and a duplication 22pter- > q11. Another branch of this family has two children with PWS, having the same unbalanced translocation but of paternal derivation (Fernandez et al. 1987).
      3. This result has important clinical implications for genetic counseling. The carrier females are at high risk of having children with AS, while their brothers have a high risk of having PWS children.
   5. Prader-Willi syndrome and Angelman syndrome in cousins from a family with a translocation between chromosomes 6 and 15 (Smeets et al. 1992):
      1. One of the two female first cousins has PWS and the other has AS.
      2. Cytogenetic and molecular studies revealed that both syndromes resulted from a familial translocation between chromosomes 6 and 15, leading to a deletion in the paternally derived chromosome 15 in the patient with PWS and to the inheritance of two different copies of chromosome 15 from the father in the patient with AS.
   6. Microdeletions in a small number of patients with PWS and AS have led to the identification of the chromosome 15 imprinting center (IC). The IC consists of two critical elements, which act in cis to regulate imprinting in the whole chromosome 15q11-q13 imprinted domain.

7. The human small nuclear ribonucleoprotein polypeptide N (SNRPN) gene (Glenn et al. 1996):
    1. One of the gene families that encode proteins involved in pre-mRNA splicing and map to the smallest deletion region involved in the Prader-Willi syndrome (PWS) within chromosome 15q11-q13.
    2. Paternal only expression of SNRPN has previously been demonstrated by the use of cell lines from PWS patients (maternal allele only) and Angelman syndrome (AS) patients (paternal allele only).
8. Highly restricted deletion of the *SNORD116* region is implicated in Prader-Willi Syndrome (Bieth et al. 2015):
    1. A 23-year-old woman presented clinical criteria of PWS, including the behavioral and nutritional features, obesity, developmental delay, and endocrine dysfunctions with hyperghrelinemia.
    2. A paternally transmitted highly restricted deletion of the *SNORD116* gene cluster, the shortest described to date (118 kb), was found. This deletion was also present in the father.
    3. This finding strongly supports the current hypothesis that lack of the paternal *SNORD116* gene cluster has a determinant role in the pathogenesis of PWS.
    4. Moreover, targeted analysis of the SNORD116 gene cluster, complementary to SNRPN methylation analysis, should be carried out in subjects with a phenotype suggestive of PWS.
    5. The absence of a small nucleolar organizing RNA gene, *SNORD116*, seems to reproduce many of the clinical features. Sibling recurrence risk is typically $<1\%$, but higher risks may pertain in certain cases (Cassidy et al. 2012).

Clinical Features

1. Fetal presentation (McCandless and Committee on Genetics 2011):
    1. Breech presentation
    2. Reduced fetal activity
    3. Polyhydramnios
2. Growth:
    1. Short stature.
    2. Poor weight gain (failure to thrive) in infancy.
    3. Central obesity: PWS is the most common syndromal cause of obesity (Butler 1990).
3. Neonatal presentation:
    1. Central hypotonia in infancy (Miller et al. 1999)
    2. Poor feeding/sucking
    3. Genital hypoplasia/hypogonadism
    4. Diminished deep tendon reflexes
    5. Abnormal squeaky weak cry (Aughton and Cassidy 1990)
4. Developmental delay
5. Mild dysmorphic features:
    1. Almond-shaped eyes
    2. Dolichocephaly
    3. Narrow bifrontal diameter
    4. Narrow nasal bridge
    5. Small mandible
    6. Small mouth
    7. High-arched palate
    8. Down-turned lips
    9. Thick viscous saliva (Hart 1998)
6. Hyperphagia after the first–second postnatal years:
    1. Due to decreased satiation rather than increased hunger (Lindgren et al. 2000).
    2. Hyperghrelinemia (elevated circulating total ghrelin levels) in Prader-Willi syndrome begins in early infancy long before the onset of hyperphagia (Kweh et al. 2015).
7. Severe obesity without significant intervention
8. Retinal hypopigmentation
9. Small hands and feet (acromicria) (Bray et al. 1983)
10. Cryptorchidism
11. Mild to moderate mental retardation
12. Hypothalamic insufficiency suggested by several autonomic dysfunctions that affect appetite regulation, growth, pubertal development, control of breathing, and alertness

13. Behavioral (Curfs and Fryns 1992; Einfeld et al. 1999) and psychiatric difficulties:
    1. Excessive food-seeking behaviors
    2. Obsessions
    3. Compulsions
    4. Mood lability
    5. Depression
14. Other manifestations:
    1. Infantile lethargy
    2. Sleep disturbance and/or sleep apnea (Hertz et al. 1995)
    3. Hypopigmentation
    4. Skin sores from constant picking (Martin et al. 1998)
    5. Esotropia/myopia
    6. Speech articulation defects
    7. High pain threshold
    8. Ineffective thermoregulation
    9. Early adrenarche
    10. Osteoporosis
    11. Kyphoscoliosis
15. Adults with Prader-Willi syndrome (Greenswag 1987):
    1. Most were short, overweight, cognitively impaired, and emotionally labile, had poor gross motor skills, and were always hungry.
    2. Males were taller and heavier than females, and both sexes were far shorter and heavier than US norms.
    3. Micropenis and cryptorchidism in males and primary amenorrhea, late menarche, and irregular menstrual cycles in females indicated hypogenitalism in both sexes.
    4. Of 106 with chromosome analysis, 54 had an abnormality on chromosome 15, primarily a deletion.
16. Clinical features and common medical problems in adult PWS (Scheermeyer 2013; Ho-Ming 2016):
    1. Signs and symptoms that warrant referral to genetic service for genetic assessment of PWS in adult:
        1. History of hypotonia, poor sucking, and feeding problems during infancy
        2. Short stature
        3. Hypogenitalism
        4. Hyperphagia
        5. Obesity
        6. Small hands and feet
        7. Intellectual disability and/or behavioral problems
        8. Thick, viscous saliva
    2. Common medical problems in adult PWS:
        1. Cardiovascular: hypertension, hyperlipidemia
        2. Respiratory: breathing-related sleep disorder, infection like pneumonia
        3. Endocrine: type 2 diabetes mellitus, hypothyroidism, hypogonadism
        4. Psychological: psychosis, behavioral problems, sexuality, abuse
        5. Dermatological: skin picking, soft tissue infection like erysipelas
        6. Musculoskeletal: osteoporosis
        7. Iatrogenic: growth hormone-related side effects
17. Prognosis:
    1. Obesity: the major cause of morbidity and mortality
    2. Cardiopulmonary compromise (Pickwickian syndrome) resulting from excessive obesity: the presence of a primary disturbance of central respiratory control in patients with Prader-Willi syndrome which may be worsened by the development of obesity (Schlüter et al. 1997)
    3. Most common causes of death: respiratory insufficiency or infections (Tauber et al. 2008)
18. Clinical spectrum and molecular diagnosis of Angelman and Prader-Willi syndrome patients with an imprinting mutation (Saitoh et al. 1997):
    1. Detailed clinical findings of five AS imprinting mutation patients (three families) and two PWS imprinting mutation patients (one new family) were described.
    2. All these patients have essentially the classical clinical phenotype for the respective syndrome, except that the incidence of microcephaly is lower in imprinting mutation AS patients than in deletion AS patients.
    3. Furthermore, imprinting mutation AS and PWS patients do not typically have

hypopigmentation, which is commonly found in patients with the usual large deletion.

19. Diagnostic criteria (adapted from Holm et al. 1993; Scheimann 2015) – five points for children under 3 years (three from major criteria) and eight points for children above 3 years (four from major criteria):
    1. Major criteria (one point each):
        1. Infantile central hypotonia
        2. Infantile feeding problems/failure to thrive
        3. Rapid weight gain between 1 and 6 years
        4. Characteristic facial features
        5. Hypogonadism (genital hypoplasia, pubertal deficiency)
        6. Developmental delay/mental retardation
    2. Minor criteria (1/2 point each):
        1. Decreased fetal movement and infantile lethargy
        2. Typical behavioral problems
        3. Sleep disturbance/sleep apnea
        4. Short stature for the family by age 15 years
        5. Hypopigmentation
        6. Small hands and feet for height age
        7. Narrow hands with straight ulnar border
        8. Esotropia/myopia
        9. Thick viscous saliva
        10. Speech articulation defects
        11. Skin picking
    3. Supportive criteria (no points):
        1. High pain threshold
        2. Decreased vomiting
        3. Temperature control problems
        4. Scoliosis/kyphosis
        5. Early adrenarche
        6. Osteoporosis
        7. Unusual skill with jigsaw puzzles
        8. Normal neuromuscular studies
20. Genotype-phenotype correlations (Driscoll et al. 2016):
    1. UPD:
        1. Post-term delivery is more common with UPD (Butler et al. 2009).
        2. Individuals with UPD are less likely to have the typical facial appearance, hypopigmentation, or skill with jigsaw puzzles (Dykens 2002); they also have a somewhat higher verbal IQ and milder behavior problems (Dykens et al. 1999; Roof et al. 2000; Hartley et al. 2005).
        3. Individuals with UPD are more likely to have psychosis (Holland et al. 2003; Yang et al. 2013) and autism spectrum disorders (Veltman et al. 2004, 2005; Whittington et al. 2004; Descheemaeker et al. 2006). Studies suggest that as many as 62% of those with UPD develop atypical psychosis compared with 16% of those with a deletion (Soni et al. 2007).
    2. Deletion:
        1. Individuals with a deletion showed a higher frequency of need for special feeding techniques, sleep disturbance, hypopigmentation, and speech articulation defects in a recent study of 91 children (Torrado et al. 2007).
        2. Individuals with the slightly larger, type 1 deletions have been reported to have more compulsions and poorer adaptive behavior, intellectual ability, and academic achievement than those with type 2 deletions (Butler et al. 2004; Hartley et al. 2005).
        3. Two other studies found much less clinically significant differences between individuals with these two deletion types (Milner et al. 2005; Varela et al. 2005). Larger studies are needed to determine whether there are significant clinical differences between the two most frequent deletion classes.

Diagnostic Investigations

1. Cytogenetic studies:
    1. Diagnostic testing methods (Delach et al. 1994; ASHG/ACMG Test and Technology Transfer Committee 1996):

1. High-resolution chromosome analysis
2. FISH
3. PCR to detect UPD
4. Methylation analysis

2. Microscopic or submicroscopic del(15)(q11-q13) confirmed by fluorescence in situ hybridization (FISH probe for *SNRPN*) (60–80%)
3. Paternally derived chromosome 15 that is deleted
4. De novo events in most cases with cytogenetically normal father's chromosomes
5. Balanced chromosomal rearrangement with break in 15q11-q13 (<1%)

2. Molecular analyses:
   1. Uniparental disomy identified by using microsatellite repeat sequences of chromosome 15 in the patient and both parents:
      1. Maternal uniparental disomy for chromosome 15 in most of nondeletion cases (20–40%)
      2. Inheriting both copies of chromosome 15 from the mother
      3. The absence of the paternally inherited copy of chromosome 15q11-q13
   2. Rare Prader-Willi syndrome in a brother and sister without cytogenetic or detectable molecular genetic abnormality at chromosome 15q11q13: paternally inherited submicroscopic deletions are possible explanations for the sib occurrence in this family (Orstavik et al. 1992).
   3. Rare familial Prader-Willi syndrome: associated with very small mutations in 15q11-q13 region leading to the loss of expression of multiple genes from the paternal chromosome.
   4. DNA methylation analyses (Gillessen-Kaesbach et al. 1995) (by Southern blotting and PCR) of the *SNRPN* or PW71 (D15S63) (Gillessen-Kaesbach et al. 1995) loci to detect the absence of paternal methylation patterns on the basis of deletion, uniparental disomy, or defective methylation: detects over 99% of cases and is highly specific.
   5. Because methylation analysis can detect all three major classes of genetic defects associated with PWS (deletion, UPD, or imprinting mutations), methylation analysis with either PW71 or SNRPN is an efficient primary screening test to rule out a diagnosis of PWS. Only patients with an abnormal methylation result require further diagnostic investigation by FISH or DNA polymorphism analysis to distinguish among the three classes for accurate genetic counseling and recurrence-risk assessment (Kubota et al. 1996b).
   6. The SNRPN expression test is rapid and reliable in the molecular diagnosis of Prader-Willi syndrome (Wevrick and Francke 1996).
   7. Imprinting defect (Cassidy and Schwartz 2009):
      1. Presumed to be present in individuals with an abnormality in the parent-specific methylation imprint without evidence of a deletion of UPD (Driscoll et al. 1992; Ohta et al. 1999).
      2. Imprinting defects caused by microdeletions are detected using sequence analysis or MLPA of the PWS-SRO (smallest region of overlap).
      3. Most imprinting defects are epimutations (i.e., alterations in the imprint, not the DNA) and cannot be detected by sequence analysis (Buiting et al. 1998; Buiting et al. 2003; Horsthemke and Buiting 2006).
   8. As all typical PWS cases showed either a deletion or disomy of 15q11.2-q12, molecular examination should provide a reliable diagnostic tool (Robinson et al. 1991).
3. Polysomnography (Schlüter et al. 1997):
   1. An increased number of apneas per hour of sleep
   2. A decreased nadir of oxygen saturation
   3. An increased maximum of the instantaneous heart rate
   4. A decreased respiratory responses to hypercapnia during quiet sleep
4. Growth standard charts of infants with PWS available when examining infants with PWS and evaluating growth for comparison purposes, monitoring for growth patterns,

nutritional assessment, and recording responses to growth hormone therapy, commonly used in infants and children with PWS (Butler et al. 2011). Growth charts for nongrowth hormone-treated Prader-Willi syndrome are also available (Butler et al. 2015).

Genetic Counseling

1. Recurrence risks (Cassidy 1987; Cassidy and Schwartz 2009; Buiting 2010):
    1. Patient's sib:
        1. De novo deletion or maternal uniparental disomy in an affected child: a low recurrence risk ($\leq$1% due to possible paternal balanced insertion or gonadal mosaicism):
            1. Imprinting center mutation in an affected child
            2. No imprinting center deletion: $<$1%
        2. With imprinting center deletion: up to 50% recurrence risk
        3. Apparently de novo-balanced chromosome translocation breaking within the PWS/AS-critical region: $<$1%
        4. The presence of a parental balanced chromosomal rearrangement: up to 25% recurrence risk
        5. Two families with a microdeletion affecting the chromosome 15 imprinting center (IC) (Buiting et al. 2000):
            1. Carrier males have a 50% risk of having children with an imprinting defect leading to PWS, and in one of the two families, a father has two affected daughters.
            2. In the other family, diagnostic testing was confounded by the presence of a neutral microdeletion close to the IC. The silent transmission of PWS IC deletions through the female germline and the occurrence of neutral microdeletions close to the IC can impose considerable problems on diagnostic testing and genetic counseling in affected families.
    2. Patient's offspring (Cassidy and Schwartz 2009):
        1. With rare exception, individuals with PWS do not reproduce.
        2. The risk to the child of an affected individual depends on the etiology of the absence of the paternally derived PWS critical region and the sex of the affected individual.
        3. If the proband has PWS as the result of a deletion, the offspring have a 50% risk of having Angelman syndrome (AS) if the proband is female (reported once) and PWS if the proband is male (never reported).
        4. If the proband has UPD, there is a theoretical risk of the offspring inheriting two chromosomes 15 from the proband, which could lead to: (1) fetal demise if trisomy rescue does not occur, (2) PWS if the proband is female, and (3) AS if the proband is male. None of these possibilities have been reported. There is a single report of a female with PWS caused by UPD having a normal child (Schulze et al. 2001).
        5. If the proband has PWS as the result of an imprinting mutation, the offspring has a theoretical risk of $\leq$50% of having PWS (never reported).
        6. If the proband has a chromosomal translocation, there is a theoretical increased risk to offspring of having PWS or AS, depending on the sex of the proband (never reported).
        7. A pair of siblings affected by PWS was described. Neither demonstrates a microscopically visible deletion in 15q11q13 or maternal disomy. Methylation studies at D15S63 and at the SNRPN locus confirm the diagnosis of PWS. Molecular studies reveal biparental inheritance in both siblings with the exception of D15S128 and D15S63 where no paternal contribution is present indicating a deletion of the imprinting center. Family studies indicate that the father of the siblings carries the

deletion which he has inherited from his mother. The recurrence risk for PWS in his offspring is 50% (McEntagart et al. 2000).

3. Differentiated recurrence-risk estimations in the Prader-Willi syndrome (Kennerknecht 1992):
    1. A deletion at 15q has not been found in a familial case of PWS, except in those cases where del(15q) is due to familial structural chromosome rearrangements. Hence, with de novo deletion, the recurrence risk should be nearly zero.
    2. In cases with familial translocation, risk estimates depend on the variable nature of the familial chromosome mutation.
    3. If only one child is affected and has no deletion at 15q, this may be a sporadic or an isolated familial case. For this situation, an estimate of an overall recurrence risk of 0.4%.
    4. If two or more sibs are affected, consider a risk of 50% that the next sib may also be affected.
4. Fertility in Prader-Willi syndrome (Schulze et al. 2001):
    1. There is a variable degree of reduced fertility in untreated females with PWS of any molecular genetic etiology and that infertility may not be a consistent feature in females with this condition.
    2. There are no reports on fertility in PWS males.
    3. The risk for the offspring of an AS male of having PWS would be 1 in 2.

2. Molecular defects and recurrence risks in PWS (Ramsden et al. 2010):
    1. De novo deletion of 15q11-q13 on the paternal chromosome (75–80%): <1% recurrence risk
    2. Maternal uniparental disomy (UPD) of chromosome 15 (20–25%): <1% recurrence risk
    3. Imprinting defects (with an imprinting center deletion excluded) (about 1%): <1% recurrence risk
    4. Imprinting center deletion (about 10–15% of patients with an imprinting defect): up to 50% (if present in father) recurrence risk

3. Prenatal diagnosis:
    1. High-risk pregnancies:
        1. Parents who have had a previous child with Prader-Willi syndrome, caused by deletion or uniparental disomy, are not routinely offered prenatal testing in subsequent pregnancies but could be offered such testing for assurance.
        2. Parents who have had a previous child with Prader-Willi syndrome, caused by a defect in the imprinting control center, should be offered prenatal testing because of the high recurrence risk; methylation analysis can also be used in these cases.
        3. Prenatal testing for an inherited translocation involving chromosome 15 and resulting in a deletion is relevant because of the theoretical 25% risk of Prader-Willi syndrome in the offspring.
    2. PWS may be a possibility for low-risk pregnancies in which no family history of Prader-Willi syndrome exists – prenatal detection (ASHG/ACMG Test and Technology Transfer Committee 1996):
        1. Cytogenetic study to detect del(15q11-q13) from amniocytes, cordocentesis (Le Bris-Quillevere et al. 1990), or CVS cells performs FISH with SNRPN or other PWS/AS-critical region probes for confirmation. Parent-of-origin studies should be performed after confirmation of a deletion to determine if the deletion is paternally derived (fetus has PWS). (If the deletion is maternally derived, the fetus has Angelman syndrome.)
        2. If trisomy 15 or mosaic trisomy 15 (Christian et al. 1996) is detected on CVS and if subsequent amniocentesis reveals 46 chromosomes, the possibility of trisomy rescue (Roberts et al. 1997) leading to PWS (maternal UPD) through loss of a parental chromosome 15 [or leading to Angelman syndrome (maternal UPD) through loss of a maternal chromosome 15] can be considered. In this instance, parent-of-origin (UPD) studies or methylation analysis (Glenn

et al. 2000) on amniocytes or chorionic villus sampling should be considered (European Collaborative Research on Mosaicism in CVS 1999; Shaffer et al. 2001):
    1. If maternal UPD is present, PWS is confirmed.
    2. If paternal UPD is present, AS is confirmed.
    3. If an inherited or de novo translocation involving chromosome 15 is present or if a supernumerary chromosome derived from chromosome 15 is detected, FISH (to rule out a deletion) and parent-of-origin studies (to rule out the possibility of UPD) are indicated.
  3. Molecular studies of uniparental disomy 15 using microsatellite dinucleotide polymorphism analysis of amniocytes and parental DNA.
  4. DNA methylation analysis of amniocytes.
  5. SNRPN, but not PW71, methylation analysis may be useful for diagnosis of PWS/AS on lymphoblast cell lines, cultured amniotic fluid, or chorionic villus samples and will allow prenatal diagnosis for families known to carry imprinting center defects (Kubota et al. 1996a).
4. Preimplantation genetic diagnosis (PGD) (Driscoll et al. 2016):
  1. May be available for families in which a mutation in the imprinting control element has been identified
  2. Also can be used in cases of familial translocation to rule out UPD
5. Management (Greenswag and Alexander 1995; Cassidy 2001):
  1. Manage feeding problems with special nipples or gavage feeding if needed to assure adequate nutrition, to avoid failure to thrive, and to improve hypotonia.
  2. Early intervention programs with speech, physical, and occupational therapies after careful educational, behavioral, and psychological assessments.
  3. Dietary control (Holm and Pipes 1976):
    1. Monitoring of weight and nutritional counseling
    2. Low-calorie and well-balanced diet combined with a regular exercise program
    3. Limit access to food
    4. Close supervision to minimize food stealing
  4. Management of endocrine problems:
    1. Growth hormone treatment improves growth, physical phenotype, and body composition (Ritzen et al. 1999; Cassidy and Driscoll 2009; Wolfgram et al. 2013) and requires close monitoring for adverse events (Irizarry et al. 2016).
    2. Testosterone treatment in males to improve changes in voice and body hair, beard growth, genital size, body mass and strength, and self-image.
    3. Treatment with estrogen, cycling hormones, or birth control pills in females has resulted in increasing breast size and menstrual periods.
  5. Management of scoliosis as in the general population.
  6. Behavioral management (Dykens et al. 1996a):
    1. Firm limit setting and enforcement.
    2. Consult with a behavioral psychologist or other behavior specialist for behavioral management programs.
  7. Psychiatric management:
    1. Psychosis
    2. Manic-depressive illness
    3. Obsessive-compulsive disorder (Dykens et al. 1996b)
  8. Treatment of complications resulting from excessive obesity:
    1. Cardiopulmonary compromise
    2. Type II diabetes mellitus
    3. Thrombophlebitis
    4. Management of skin picking, chronic skin changes, and peripheral edema

Fig. 1 A 10-month-old girl with Prader-Willi syndrome showing severe hypotonia, strabismus, and small hands and feet. Parent-of-origin-specific DNA methylation studies at 15q11-q13 for Prader-Willi syndrome revealed the presence of maternal 4.2 kb hybridization band only but not paternal 0.9 kb band consistent with Prader-Willi syndrome. Uniparental disomy DNA analysis revealed that the patient has only maternal alleles based on the Mendelian inheritance of two informative markers (D15S205 and D15S1002) and two partial informative markers (D15S130 and D15S1007), indicative of uniparental disomy for chromosome 15

Fig. 2 A 17-month-old boy with Prader-Willi syndrome showing severe hypotonia. Methylation-specific PCR using SNRPN flanking primers revealed the absence of paternal SNRPN and presence of maternal SNRPN, confirming the diagnosis of Prader-Willi syndrome

Fig. 3 An infant with Prader-Willi syndrome [del(15)(q11-q13)] showing hypotonia and failure to thrive

Fig. 4 (**a**, **b**) A girl with Prader-Willi syndrome [del(15)(q11-q13)] showing obesity, short stature, almond-shaped eyes, and small hands and feet

Fig. 5 (**a**, **b**) A boy with Prader-Willi syndrome [del (15)(q11-q13)] showing obesity, almond-shaped eyes, and bitemporal narrowing

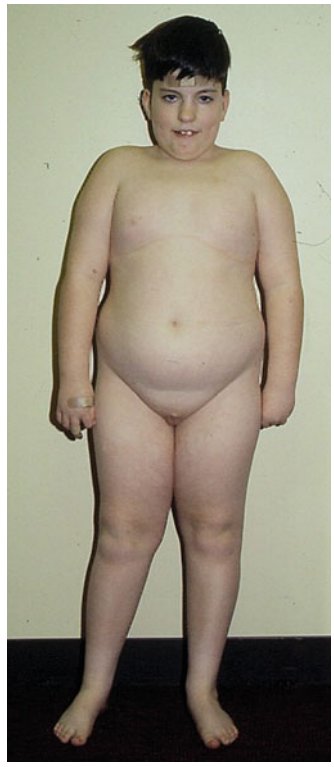

Fig. 6 A boy with Prader-Willi syndrome [del(15)(q11-q13)] showing almond-shaped eyes, bitemporal narrowing, obesity, hypogenitalism, and small hands and feet

Fig. 7 (**a**, **b**) A girl with Prader-Willi syndrome [del(15)(q11-q13)] showing extreme obesity, characteristic facial appearance, small hands and feet, and multiple skin sores from constant picking

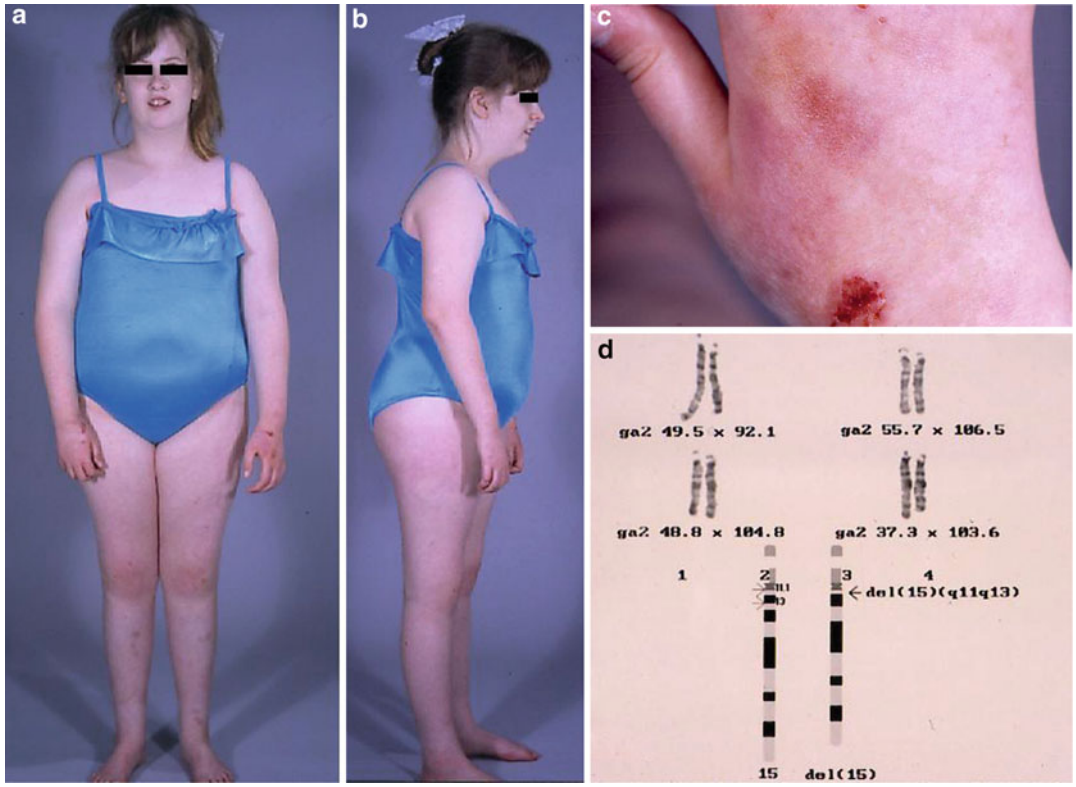

Fig. 8 (**a**–**d**) A patient with Prader-Willi syndrome [del(15)(q11-q13)] (shown by partial karyotypes and ideogram) and trimethylaminuria showing sores on the skin

Fig. 9 A woman with Prader-Willi syndrome [del(15)(q11-q13)] and neurofibromatosis 1 showing obesity and axillary freckles

Primary Microcephaly

Contents

Primary microcephaly (MCPH) is a rare autosomal recessive neurodevelopmental disorder characterized by two principal features, microcephaly present at birth and nonprogressive mental retardation (Woods et al. 2005). The incidence is about 1 in 10,000 in consanguineous populations (Thornton and Woods 2009), less in non-consanguineous populations (between 1 in 30,000 and 1 in 2 million).

Synonyms and Related Disorders

Autosomal recessive primary microcephaly; Premature chromosome condensation (PCC) syndrome; Premature chromosome condensation with microcephaly and mental retardation syndrome

Genetics/Basic Defects

1. Inheritance; autosomal recessive
2. Cytogenetic features (Neitzel et al. 2002)
   (a) Premature chromosome condensation in G2 phase associated with autosomal recessive microcephaly and mental retardation in two siblings from consanguineous parents
   (b) A high frequency of prophase-like cells (>10%) in lymphocytes, fibroblasts, and lymphoblast cell lines with an otherwise normal karyotype
3. Molecular genetics (Kaindl et al. 2010; Mahmood et al. 2011)
   (a) MCPH1
      (i) Chromosome: 8p23.1
      (ii) Gene: *MCPH1* (microcephalin)
      (iii) Cellular location: nucleus/chromatin
      (iv) Proposed function: DNA damage repair, chromosome condensation
   (b) MCPH2
      (i) Chromosome: 19q13.12-q13.2
      (ii) Gene: *WDR62* (WD repeat-containing protein 62)
      (iii) Cellular location: nucleus, centrosomal during mitosis
      (iv) Proposed function: not yet established (expression pattern resembles with *ASPM*)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_268

(c) MCPH3
  (i) Chromosome: 9q33.2
  (ii) Gene: *CDKSRAP2* (cyclin-dependent kinase 5 regulatory associated protein 2)
  (iii) Cellular location: centrosome/midbody
  (iv) Proposed function: regulation of microtubule function/centrosome maturation
(d) MCPH4
  (i) Chromosome: 15q15.1
  (ii) Gene: *CASC5* (cancer susceptibility candidate 5)
  (iii) Cellular location: kinetocore
  (iv) Proposed function: kinetochore integrity
(e) MCPH5
  (i) Chromosome: 1q31.3
  (ii) Gene: *ASPM* (abnormal spindle-like, microcephaly)
  (iii) Cellular location: pericentrosomal/midbody
  (iv) Proposed function: orientation of mitotic spindles during embryonic neurogenesis
(f) MCPH6
  (i) Chromosome: 13q12.12
  (ii) Gene: *CENPJ* (centromeric protein J)
  (iii) Cellular location: centrosome/midbody
  (iv) Proposed function: centriole length control/microtubule function
(g) MCPH7
  (i) Chromosome: 1p33
  (ii) Gene: *STIL* (SCL/TAL1-interrupting locus)
  (iii) Cellular location: pericentrosomal
  (iv) Proposed function: spindle organization/cell cycle progression
(h) MCPH8 (Hussain et al. 2012)
  (i) Chromosome: 4q12
  (ii) Gene: *CEP135*
  (iii) Cellular location: centrosome
  (iv) Proposed function: disorganized microtubule networks and mutant protein not localized to the centrosome
(i) MCPH9 (Genin et al. 2012)
  (i) Chromosome: 15q21.1
  (ii) Gene: *CEP152* (centrosomal protein 152)
  (iii) Cellular location: centrosome
  (iv) Proposed function: involved in centriole duplication
(j) MCPH10 (Yang et al. 2012)
  (i) Chromosome: 20q13.12
  (ii) Gene: *ZNF335* (zinc finger protein 335)
  (iii) Cellular location: neuronal cells
  (iv) Proposed function: disrupts the proliferation and proper differentiation of neuronal cells
(k) MCHP11 (Awad et al. 2013)
  (i) Chromosome: 12p13.31
  (ii) Gene: *PHC1* (polyhomeotic-like 1)
  (iii) Cellular location: chromatin
  (iv) Proposed function: abnormalities in chromatin regulation

Clinical Features

1. Main features (Woods et al. 2005; Mahmood et al. 2011)
  (a) Microcephaly (2 SD below the mean) at birth, further "relative" reduction of head circumference in the first years of life
  (b) Reduction in cerebral cortex volume
  (c) Simplification of gyral pattern
  (d) Mild to severe nonprogressive mental retardation (borderline IQ possible)
2. Inconsistent features
  (a) Neurological/neuropsychological
    (i) Seizures (tonic-clonic, focal, generalized): very rare but cannot exclude the diagnosis (*ASPM*)
    (ii) Delay in early motor milestone, especially speech delay
    (iii) Behavior pattern: sometimes aggressive but otherwise have a happy effect and easy to handle
    (iv) Sleep disorder
  (b) Other features
    (i) Sloping forehead common but is not always associated

(ii) Short stature in some cases (*MCHP1*)
(iii) Early puberty

3. Differential diagnosis
   (a) Nongenetic and genetic causes of "primary microcephaly with mental retardation," e.g.,
      (i) Congenital infection with toxoplasma
      (ii) Maternal alcohol overconsumption during pregnancy
      (iii) Rubinstein-Taybi syndrome
   (b) Secondary microcephaly: indicates a progressive neurodegenerative condition

Diagnostic Investigations

1. Plain X-ray films: microcephaly
2. MRI (Mahmood et al. 2011)
   (a) Reduction of cerebral cortical volume (neuronal proliferation defect) and simplification of gyral pattern in most cases
   (b) Pachygyria with cortical thickening as well as hypoplasia/agenesis of the corpus callosum (neuronal migration defect) in some cases (*ASPM*, *WER62*)
   (c) Lissencephaly, schizencephaly, polymicrogyria, and cerebellar hypoplasia in few cases (*WDR62*)
3. Abnormal cytogenetic findings: high proportion of prophase-like cells due to premature chromosome condensation reported in *MCPH1*-related MCPH (Jackson et al. 2002; Trimborn et al. 2004, 2005)
4. Molecular genetic analysis (clinical research laboratories listed in www.GeneTests.org)

Genetic Counseling

1. Recurrence risk
   (a) Autosomal recessive inheritance
      (i) Patient's sib: 25%
      (ii) Patient's offspring: not increased unless the spouse is also a carrier
   (b) The empiric recurrence risk for a non-consanguineous couple who have had one child with a diagnosis of MCPH: 1 in 5 if detailed chromosome studies and neuroimaging yield normal results (Tolmie et al. 1987)
   (c) There may be a phenotype in heterozygous carriers of MCPH mutations, because of an increased frequency of intellectual impairment in parents of individuals with recessive microcephaly (Kloepfer et al. 1964; Qazi and Reed 1975)
2. Prenatal diagnosis
   (a) Ultrasonography: microcephaly
   (b) Prenatal MRI studies of affected families: the frontal lobes of the cerebral cortex to be particularly affected (Desir et al. 2008; Saadi et al. 2008)
   (c) Molecular genetic analysis: currently available
3. Management: symptomatic
   (a) Early intervention
   (b) Speech therapy
   (c) Physical therapy
   (d) Occupational therapy
   (e) Behavior management
   (f) Seizure management

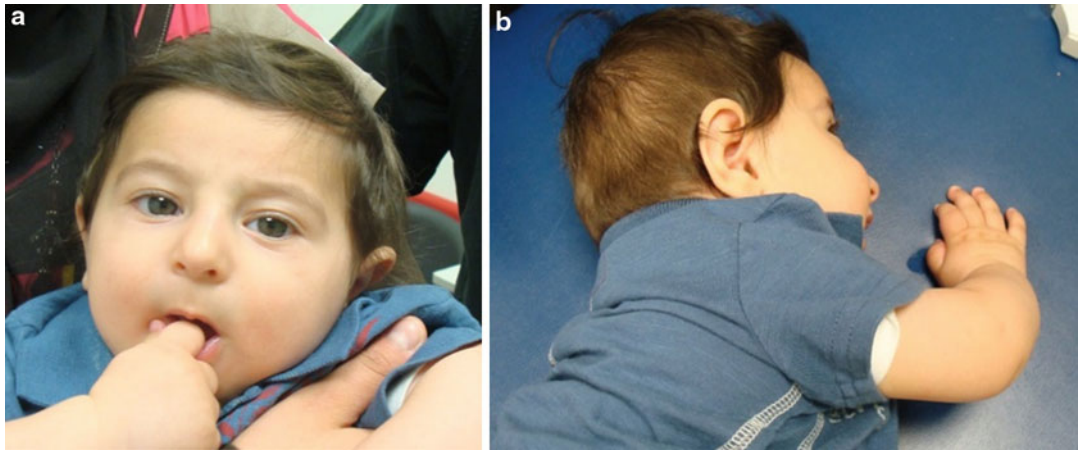

Fig. 1 (**a**, **b**) An 8-month-old Arabic boy was evaluated for developmental delay and microcephaly. Her older sister who expired at 15 months of age had microcephaly, developmental delay, and hypotonia. Normal laboratory tests include chromosome microarray analysis, chromosome analysis, plasma amino acids, urine organic acids, acylcarnitine profile, and VLCFA for peroxisomal disorders. Since two siblings are similarly affected in a family, the disorder most likely represents an autosomal recessive disorder of primary microcephaly

Fig. 2 (**a**, **b**) This 3-year-old Caucasian boy was evaluated for primary microcephaly. He had slightly sloping forehead with a very small cranial vault, slightly prominent ears, and mild retromicrognathia. He was born after 40 weeks gestation. It was a normal spontaneous delivery. The birth weight was 3,180 g, birth length 45.9 cm, and HC 29.5 cm (−3 standard deviations). TORCH titers were negative. He had unremarkable 3D CT. MRI of the brain showed a significantly decreased cranial to facial proportion with a sloping forehead and flattened occiput, abnormal cortical gyral/sulcal development with unusually broad and shallow gyri, and simplified sulcal pattern with generalized prominence of the extra-axial CSF space and thickening of the cortical mantle. The corpus callosum was small. The pituitary and midline structures were normal. This findings are compatible with group I primary microcephaly with an abnormal simplified gyral pattern, but with normal myelination. Craniosynostosis was not present. He has a history of seizures. Currently, he has developmental delay and receives speech and occupational therapy (Courtesy of Dr. Susanne Ursin)

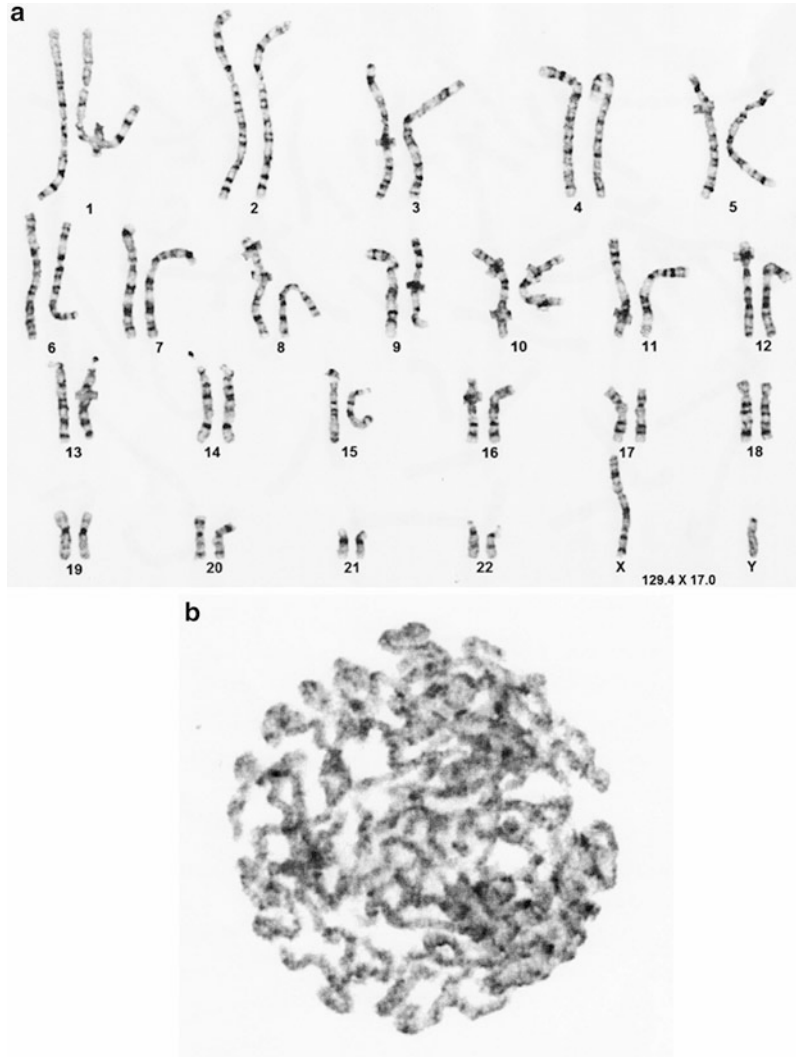

Fig. 3 (**a**, **b**) High-resolution cytogenetic analysis of metaphase cells from blood lymphocytes showed a cytogenetic male (**a**). However, approximately 14% of cells (normal reference range of <2% showed prophase-like cells) (**b**). Increased number of prophase-like cells has been reported in primary microcephaly in the literature. *MCPH1* gene sequencing did not identify any mutation in the *MCPH1* gene. However, the diagnosis cannot be completely ruled out due to mutations not detected by this assay or mutations in another gene. The frequency of mutations in the *MCPH1* gene ranges from 3.4% to 8.25% of the population affected with primary microcephaly (Courtesy of Dr. Leonard Prouty)

Progeria

Contents

In 1886, Hutchinson (1886) described a boy with congenital alopecia, wrinkled atrophic skin, an odd facies, joint contractures, and normal intelligence. Subsequently in 1904, Gilford (1904) reported a second patient with similar features and suggested the term progeria, from the Greek word *geras* meaning old age, to describe the premature senile characteristics of the patients. Thus, the syndrome is also known as Hutchinson-Gilford progeria syndrome (HGPS) (Thomson and Forfar 1950).

Progeria is an extremely rare condition with characteristic clinical findings of premature and accelerated aging. Its incidence was estimated to be one per eight million live births in the United States. Male to female ratio is about 1.5:1. Most reported patients are Caucasians (Badame 1989).

Synonyms and Related Disorders

Hutchinson-Gilford progeria syndrome; Progeroid syndrome

Genetics/Basic Defects

1. Inheritance:
    1. Autosomal dominant inheritance (Khalifa 1989):
        1. Advanced paternal age effect observed
        2. Germinal mosaicism responsible for rare instances of affected sibs
    2. Possible autosomal recessive inheritance: affected siblings in a family (Monu et al. 1990; Parkash et al. 1990; Pollex and Hegele 2004)
2. Basic defects:
    1. Caused by mutations in lamin A (*LMNA*) gene (Cao and Hegele 2003; Pollex and Hegele 2004):
        1. *LMNA* gene encodes two protein products, lamins A and C, representing major constituent of the inner nuclear membrane lamina.
        2. Mutations in *LMNA*:
            1. About 90% of patients have an identifiable mutation.
            2. Most common mutation (Fukuchi et al. 2004): a de novo single-base substitution, G608G (GGC > GGT) in exon 11. G608G mutation responsible for the majority of progeria arises in the paternal germline (D'Apice et al. 2004).
            3. A second mutation in the same codon, G608S (GGC > AGC).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_197

4. E145K (exon 2) observed in a phenotypically unusual HGPS.

3. Mutations in *LMNA* also cause the following different recessive and dominant disorders (Eriksson et al. 2003):
   1. Emery-Dreifuss muscular dystrophy type 1 (EMD1) (autosomal dominant)
   2. Emery-Dreifuss muscular dystrophy type 2 (EMD2) (autosomal recessive)
   3. A familial dilated cardiomyopathy and conduction system defects (CMD1A) (autosomal dominant)
   4. Dunnigan-type familial partial lipodystrophy (FPLD) (autosomal dominant)
   5. Limb-girdle muscular dystrophy type 1B (LGMD1B) (autosomal dominant)
   6. Charcot-Marie-Tooth disorder type 2B1 (CMT2B1) (autosomal recessive axonal neuropathy)
   7. Mandibuloacral dysplasia (MAD) (autosomal recessive)

2. Del(1)(q23) reported in a patient with Hutchinson-Gilford progeria (Luengo et al. 2002).
3. Inv ins(1;1)(q32;q44q23) reported in the postmortem skin biopsy specimens from identical twins raising the possibility that a gene for progeria may be located at the breakpoint site of the inserted chromosome segment.
4. Hutchinson-Gilford progeria syndrome gene localized to chromosome 1q by observing two cases of uniparental isodisomy of 1q and one case with a 6-megabase paternal interstitial deletion (Eriksson et al. 2003).
5. Increased hyaluronic acid production by progeric fibroblasts postulated as the underlying metabolic abnormality in progeria:
   1. Urinary excretion of hyaluronic acid found to be increased in some patients.
   2. Elevated levels of hyaluronic acid may result in growth failure and accelerated senescence by inhibiting the growth of blood vessels.
6. Accumulation of type IV collagen due to an interaction between activated T lymphocytes and fibroblasts.
7. Current results of microarray analysis: further support the notion that patients with progeria experience an accelerated form of aging.
8. Reduced growth capacity in vitro in the skin fibroblasts from progeria patients with conflicting evidence on whether progeric cells can repair single-strand DNA breaks induced by X- or gamma irradiation.
9. Fibroblasts from progeric tissue (Ackerman and Gilbert-Barness 2002):
   1. Inability to subculture
   2. Having short telomeres
   3. Uncertain as to whether aging is the consequence of shortened telomeres with reduced cell replication, impaired telomerase activity, or the culmination of the effects of reactive oxygen species

3. Aging- and progeria-related disorders (Evangelisti et al. 2016):
   1. *LMNA*-linked progeroid syndromes
      1. Hutchinson-Gilford progeria syndrome (HGPS)
      2. Mandibuloacral dysplasia types A and B (MADA and MADB, respectively)
      3. Atypical Werner syndrome (A-WS)
   2. Nucleotide excision repair (NER)-linked progeroid syndromes
      1. Xeroderma pigmentosum (XP)
      2. Cockayne syndrome (CS)
      3. Trichothiodystrophy (TTD)
   3. RecQ-associated progeria-related syndromes
      1. Bloom syndrome (BS)
      2. Werner syndrome (WS)
      3. Rothmund-Thomson syndrome (RTS)
   4. DNA polymerase-linked progeroid syndromes:
      1. A variant form of XP (known as XP-V)
      2. A form of mandibuloacral dysplasia: the mandibular hypoplasia, deafness, progeroid features, and lipodystrophy syndrome (MDPL)

Clinical Features

1. General features (Ackerman and Gilbert-Barness 2002):
   1. Normal appearance at birth
   2. Normal intelligence and personality
   3. High-pitched voice
2. Growth (Cooke 1953):
   1. Profound growth failure/failure to thrive starting around 6 months to 1 year of age
   2. Extreme short stature
   3. No rapid growth during puberty
   4. Markedly diminished subcutaneous fat, especially on the face and limbs
   5. Absent sexual maturation
3. Skin:
   1. Unremarkable at birth
   2. Generalized nonpitting edema suggestive of scleroderma shortly after birth
   3. "Sclerodermatous" skin over the lower abdomen and proximal thighs, in which irregular bumps give appearance of lipodystrophy
   4. Becoming thin, dry, taut, and shiny in some areas, but lax and wrinkled in others, most commonly over the fingers and toes, by the second year
   5. Striking loss of subcutaneous tissue
   6. Prominent venous pattern
   7. Easy bruising
   8. Diminished eccrine sweating in some cases
   9. Progressive freckle-like hyperpigmentation (most evident in sun-exposed areas) and thickened sclerotic areas (usually on the lower parts of the trunk or thighs) after several years
4. Hair:
   1. Partial alopecia progressing to generalized alopecia often beginning at birth or in the first year and becoming prominent by the end of the second year
   2. Few remaining hairs: white or blond, fine, and fuzzy
   3. Body hair as well as scalp and facial hair: equally affected
5. Nails:
   1. Short, thin, and dystrophic fingernails and toenails
   2. Koilonychia (spoon nails)
   3. Onychogryposis (deformed overgrowth of the nails)
6. A striking facies after few months of life:
   1. Typical "plucked bird" appearance related to disproportionate craniofacial growth
   2. Disproportionately large cranium
   3. Relatively small face
   4. Prominent eyes
   5. Prominent scalp veins
   6. Sparse to absent scalp hair (alopecia, balding, hypotrichosis)
   7. Absent eyebrows and eyelashes
   8. Thin lips
   9. Circumoral cyanosis
   10. Protruded ears with absent earlobes
   11. "Beaked," pinched nose with sculptured tip
   12. Micrognathia
7. Teeth (Yu and Zeng 1991):
   1. Anodontia/hypodontia, especially permanent teeth
   2. Delayed and incomplete dentition
   3. Discoloration (yellowish brownish)
   4. Crowded, rotated, displaced, overlapped, and maloccluded, especially the anterior teeth
   5. High incidence of caries
   6. Poor oral hygiene/gingivitis
   7. Irregularity in size and shape of the odontoblasts
   8. Delayed in ossification of the crown of the permanent teeth
   9. Narrow pulp chambers and root canals
   10. Reticular atrophy of pulp
   11. Calcification along the nerve fibers and the vascular walls
   12. Irregular width of predentin, secondary dentin, and cementum
   13. Osteoclastic resorption at apical portion
   14. Incomplete formation of roots of deciduous molars
8. Endocrine manifestations:
   1. Incomplete sexual maturation
   2. Occasional hypoplastic nipples

9. Cardiovascular disease (Baker et al. 1981):
    1. Premature severe atherosclerotic heart disease and aortic stenosis (Makous et al. 1962).
    2. Calcification of the aortic and mitral valves, coronary arteries, and aorta.
    3. Premature coronary artery disease leads to ischemic changes in the myocardium, including well-defined infarcts.
    4. Death from coronary artery disease is frequent and may occur before 10 years of age.
    5. Angina pectoris.
    6. Myocardial infarction.
    7. Congestive heart failure.
    8. Epidural hematoma formation after a mild head injury possibly due to progressive atherosclerosis of intracranial vessels.
10. Musculoskeletal abnormalities (Moen 1982; Hamer et al. 1988):
    1. Generalized osteoporosis with pathologic fractures
    2. Osteolysis
    3. Marked delay in bone healing after fractures
    4. Skull: osteopenic and widened and unossified cranial sutures
    5. Short/dystrophic clavicles
    6. Hypoplasia of the mandible and maxilla
    7. Coxa plana and coxa valga
    8. Arthropathy
    9. Avascular necrosis of the femoral capital epiphysis
    10. Distal phalangeal osteolysis
    11. Delayed closure and persistently patent anterior fontanelle
    12. Joint contractures with contracted hands, elbows, and knees
    13. Dislocation of the hip
    14. Mild flexion of the knees resulting in a wide-gaited "horse-riding" stance and wide-based shuffling gait
    15. Short, tapered distal phalanges
    16. Thin limbs
    17. Muscle atrophy
11. Prognosis (Badame 1989):
    1. The absence of other factors associated with aging such as cancers, cataracts, and senility (not considered to be a phenocopy of normal aging)
    2. Death due to cardiovascular abnormalities in approximately 75% of patients
    3. Main cause of death due to cardiovascular complications:
        1. Myocardial infarction
        2. Congestive heart failure
    4. Other causes of death:
        1. Marasmus
        2. Inanition
        3. Convulsions
        4. Accidental head trauma due to thinned cortical bones
    5. Average life expectancy: 13 years (7–27 years)
12. Existence of a more severe prenatal form or "accelerated form" of progeria (Runge et al. 1978; Rodríguez and Pérez-Alonso 1999; Rodríguez et al. 1999):
    1. Intrauterine growth retardation
    2. Premature aging
    3. The absence of subcutaneous fat
    4. Brachydactyly
    5. Absent nipples
    6. Hypoplastic external genitalia
    7. Abnormal ear lobes
13. Progeroid syndromes:
    1. Acrogeria:
        1. Also known as Gottron syndrome (Gottron 1941)
        2. Characterized by premature aging, more specifically in the form of unusually fragile, thin skin on the hands and feet
    2. Werner syndrome (WS) (Muftuoglu et al. 2008; Goto et al. 2013):
        1. Characterized by premature aging which is clinically apparent during 20–30 years old.
        2. WS patients show abnormal physical development such as a birdlike face, short stature, and slender limbs.
        3. They also display a high-pitched voice, remarkable loss and graying of hair, and scleroderma-like skin changes. Other common clinical presentations include bilateral cataracts, type

2 diabetes mellitus, hypogonadism (with reduced fertility), skin ulcers, premature arteriosclerosis, osteoporosis, and cancer predisposition.
4. Many WS patients develop similar cardiovascular complications but also have an increased predisposition to developing multiple rare malignancies (Swahari and Nakamura 2016).
5. Ninety percent of WS is linked to mutations on WRN, a member of the RecQ family responsible for stable genome maintenance. Owing to autosomal recessive inheritance, biallelic mutation on WRN is pathogenic (Cheung et al. 2015).

3. Cockayne syndrome (CS) (Laugel 2012):
1. A rare autosomal recessive disorder: spans a phenotypic spectrum that includes CS type I (classic or moderate form), CS type II (more severe form), CS type III (a milder form), and xeroderma pigmentosum-Cockayne syndrome (XP-CS).
2. Characterized by dwarfism, progressive pigmentary retinopathy, birdlike facies, and photosensitivity.
3. The two genes in which mutations are known to cause Cockayne syndrome are ERCC6 (65% of individuals) and ERCC8 (35% of individuals).

4. Progeroid syndrome with characteristic facial appearance and hand anomalies in father and son: a new autosomal dominant disorder (Giannotti et al. 1997)

Diagnostic Investigations

1. Histopathology (Badame 1989):
1. Skin lesions indistinguishable from scleroderma:
1. Progressive hyalinization of dermal collagen (hyaline fibrosis)
2. Loss of subcutaneous tissue
3. Decreased sebaceous and sweat glands and hair follicles
4. Scleroderma-like skin lesions (Jansen and Romiti 2000)

2. Progeria is associated with hyperplastic scars or keloid-like lesions with an unusual accumulation of type IV collagen, which may be formed through interaction between activated T cells and fibroblasts after minor traumas (Jimbow et al. 1988).
3. Bone lesions:
1. Osteoporosis
2. Osteolysis prominent in distal phalanges and clavicles
3. Skeletal dysplasia manifesting as coxa plana, coxa valga, and attenuated diaphyses with dystrophic metaphyses
4. Avascular hip necrosis
5. Nonunion of fractures
6. Hip dislocations

4. Cardiovascular lesions:
1. Severe, progressive atherosclerosis with widely variable age of clinical manifestation
2. The presence of atherosclerotic plaques in the large and small arteries
3. Calcifications in the mitral and aortic valves as well as aorta, coronary, cerebral, subclavian, and axillary arteries
4. Myocardial ischemia and infarction resulting from the coronary artery disease
5. Diffuse interstitial myocardial fibrosis and lipofuscin pigment (Reichel and Garcia-Bunuel 1970)
6. Ventricular dilatation and hypertrophy

5. Increased lipofuscin in the brain, adrenal cortex, kidney, testis, liver, and heart.
6. Gonads:
1. Aspermatogenesis in males
2. The presence of primordial follicles and corpora albicans in females with evidence of ovulation

7. Arterial biopsy:
1. Premature atherosclerosis
2. Subintimal fibrosis

8. Abnormal mesangial collagen distribution in progeria kidney (Delahunt et al. 2000).

9. Autopsy findings of a case: scleroderma-like skin atrophy, elastotic degeneration of the skin, arteriosclerosis, and atrophy of the endocrine glands (Ishii 1976).

2. Radiography (Runge et al. 1978; Badame 1989; Gillar et al. 1991):
   1. Widespread degenerative changes of bone in the first or second year of life
   2. Skull and facial bones:
      1. Craniofacial disproportion
      2. Patent fontanelles
      3. Wormian bones with skull fractures
      4. Facial bone hypoplasia
      5. Mandibular hypoplasia with dental crowding
      6. Delayed and abnormal dentition
      7. Normal base of skull
   3. Thorax:
      1. Clavicular resorption: thinning and resorption of distal clavicles (a progressive process)
      2. Rib tapering: narrowing of ribs, particularly of posterior segments
   4. Long bones:
      1. Development of bizarre indentations with subsequent pathologic fractures
      2. Thinned cortices and poorly defined trabeculae
      3. Widened, poorly tubulated metaphyses
      4. Severe coxa valga
      5. Moderate genu valgum
      6. Normal capital femoral epiphyses
   5. Phalanges:
      1. Progressive resorption of the bone from distal phalanges of fingers and/or toes, one of the hallmarks of the disease
      2. Progressive osteolysis (Ozonoff and Clemett 1967)
      3. Radiolucent terminal phalanges (acroosteolysis) (Jansen and Romiti 2000)
   6. Others:
      1. Diffuse osteopenia/osteoporosis
      2. Ovoid and fish-mouth vertebral bodies
      3. Soft tissue loss
      4. Generally normal bone age
3. Blood chemistry for hyperlipidemia:
   1. Increased low-density lipoprotein levels
   2. Increased β-lipoprotein and pre–βlipoprotein levels of high-density lipoprotein
   3. Increased serum cholesterol levels
4. Metabolic workup – inconsistent results:
   1. Insulin resistance (Rosenbloom et al. 1983)
   2. Abnormal collagen formation
   3. Increased metabolic rate: could be the cause of the failure to thrive seen in progeria
   4. Elevated growth hormone levels
5. Urine test:
   1. Excessive excretion of glycosaminoglycans
   2. Excessive excretion of hyaluronic acid (unreliable)
6. Cultured skin fibroblasts:
   1. Exhibit 76.1% DNA repair capacity compared to normal (Sarkar and Shinton 2001).
   2. Decreased cell growth in culture.
   3. Short telomeres.
   4. Whether aging is the consequence of shortened telomeres with reduced cell replication, impaired telomerase activity, or the culmination of the effects of reactive oxygen species is uncertain.
   5. The cultured skin fibroblast from both the homozygous affected individual and the heterozygous parents can be distinguished from normals by decreased cell growth in culture (Danes 1971). Mitotic activity, DNA synthesis, and cloning efficiency are markedly reduced.
7. Immunofluorescence of cultured fibroblasts with antibodies directed against lamin A demonstrating visible abnormalities of the nuclear membrane in many cells
8. Molecular genetic analysis to detect *LMNA* p. gly608Gly point mutation – clinically available:
   1. Sequence analysis
   2. Targeted mutation analysis

Genetic Counseling

1. Recurrence risk:
   1. Patient's sib:
      1. The lamin A gene mutations not found in patient's parents suggesting that it occurs

spontaneously in each patient and does not pass from parent to child
    2. Recurrence risk very low, estimated at 1 in 500 with each subsequent pregnancy due to germline mutations (Wuyts et al. 2005)
    3. Rare reports of siblings with progeria from consanguineous or nonconsanguineous marriages
    4. Reported cases of monozygous twins with progeria
  2. Patient's offspring: inability of patients to reproduce
2. Prenatal diagnosis and preimplantation genetic diagnosis: possible in families in which the disease-causing mutation has been identified in a family member (Gordon et al. 2015)
3. Management (Gordon et al. 2015):
  1. Regular diet
  2. Combined nutritional treatment and growth hormone treatment:
    1. Improve growth.
    2. Increase the levels of growth factors.
    3. Paradoxically result in a decreased BMR.
    4. Response decreases over time.
    5. Do not prevent the progression of atherosclerotic disease (Abdenur et al. 1997).
  3. Early and definitive surgical intervention for symptomatic oral pathosis (Batstone and Macleod 2002):
    1. Abnormal facial morphology
    2. Dermal inelasticity
    3. Potential anesthetic difficulties
    4. Progressive ongoing deterioration in the medical condition
    5. Importance of special and early dental care by a dentist, oral surgeon, and orthodontist, leading to a reduction in oral pathologies and a higher quality of life (Reichert et al. 2014).
  4. Orthopedic cares for musculoskeletal abnormalities:
    1. Routine treatment of fractures.
    2. Conservative treatment for hip dislocation. Avoid surgery if possible.
    3. Routine physical therapy to maintain joint range of motion.
  5. Management of cardiovascular complications:
    1. Routine anticongestive therapy for congestive heart failure.
    2. Nitroglycerin for angina.
    3. Low doses of aspirin help delay heart attacks and strokes.
  6. Anesthesia in progeria: intubation difficulty (Liessmann 2001; Nguyen and Mayhew 2001).
  7. Farnesyltransferase inhibitors (FTIs) have been widely used in the treatment of progeria (Kieran et al. 2007). The results of the first clinical trials taught us that some improvements of the disease phenotypes can be achieved by FTI treatment, but they also made clear that we need a much better understanding of the underlying disease mechanisms to be able to tackle specific aspects of the disease in a more focused approach (Vidak and Foisner 2016).
  8. Potential therapeutic effects of mTOR inhibitors (Evangelisti et al. 2016):
    1. Rapamycin
    2. Rapalogs
    3. Resveratrol
    4. Metformin
  9. mTOR molecular pathways in aging (Evangelisti et al. 2016):
    1. Protein translation
    2. Autophagy
    3. Stem cell pool turnover
    4. Regulation of the inflammatory response
    5. Cellular senescence
  10. mTOR inhibitors and progeria-related disorders (Evangelisti et al. 2016):
    1. Regulation of autophagy and protein accumulation
    2. mTOR inhibitors and lamin A/C-dependent progeroid syndromes: HGPS and MADA
    3. mTOR inhibitors and other progeria-related disorders
    4. mTOR inhibitors and other aging-related diseases

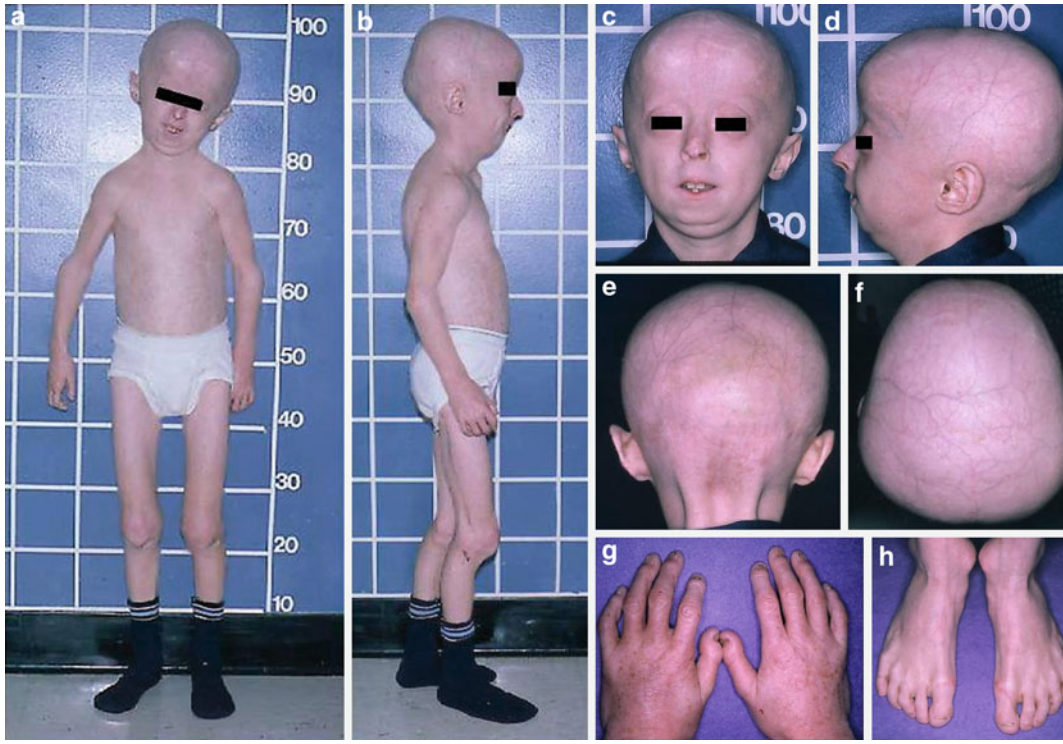

Fig. 1 (**a**–**h**) A boy with progeria (**a**, **b**) showing short stature; senile appearance; small face in comparison with large cranial vault (craniofacial disproportion); alopecia with prominent scalp veins; absent eyelashes and eyebrows; prominent eyes; beak-like nose; mandibular hypoplasia; absent earlobes (**c**–**f**); contracted hands, elbows, and knees (**a**, **b**); short, tapered terminal phalanges; enlarged joints; and dry, brittle, hypoplastic nails (**g**, **h**)

Prune Belly Syndrome

Contents

In 1895, Parker described the congenital triad of deficient abdominal musculature, cryptorchidism, and urinary tract abnormalities. Subsequently, the term "prune belly syndrome" was coined for this condition based on the characteristic wrinkled appearance of the abdomen. The incidence of the syndrome is estimated to be 1 in 35,000 to 1 in 50,000 live births.

Synonyms and Related Disorders

Absence of abdominal muscles with urinary tract abnormality and cryptorchidism; Eagle-Barrett syndrome; Potter sequence

Genetics/Basic Defects

1. Etiologies
    1. Questionable genetic inheritance.
    1. Questionable autosomal dominant inheritance
    2. Autosomal recessive inheritance suggested by some authors
2. Fetal abdominal distension caused by urinary tract obstruction (Burton and Dillerd 1984).
    1. The most common cause of prune belly syndrome
    2. Urethral obstruction causing dilatation of the fetal bladder and upper tracts, thereby attenuating the abdominal musculature
    3. Spontaneous relief of the urethral obstruction in some cases prenatally decompresses the abdomen, producing the shriveled, prune-like appearance of the baby's abdomen
    4. Persistent urethral obstruction causing huge distention of the urinary bladder, bilateral hydronephrosis, and hydroureter complicated by oligohydramnios in more severe cases
3. Fetal ascites from whatever cause: abdominal decompression during intrauterine life leading to prune belly appearance of the abdomen.
4. Prostatic hypoplasia resulting in a functional urethral obstruction leading to development of the prune belly syndrome (Hoagland et al. 1988).
5. Primary mesodermal defect simultaneously affecting the formation of abdominal

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_198

musculature and abnormalities in the lower urinary tract (Mouriquand et al. 2001).

6. Rare association of chromosome abnormalities.
   1. Trisomy 13
   2. Trisomy 18
   3. Turner syndrome with fetal ascites (pathogenetic mechanism thought to involve abdominal distention by ascites rather than by urinary obstruction)
   4. Ring X chromosome lacking *XIST* (Guillen et al. 1997)
   5. Cat eye syndrome
   6. Rarely with trisomy 21
   7. Mosaic unbalanced chromosome constitution of chromosome 16
   8. Presence of a small additional chromosome fragment
   9. Interstitial deletion of chromosome 1 [del(1)(q25q32)] (Scarbrough et al. 1988)
7. One genomic *HNF1β* mutation was detected in 3% of patients with prune belly syndrome but found to be functionally normal. Thus, functionally significant *HNF1β* mutations are uncommon in prune belly syndrome, despite case reports of *HNF1β* deletions (Granberg et al. 2012).
8. R179H mutation in *ACTA2* was reported in a child with prune belly sequence (Richer et al. 2012).

2. Pathogenesis (Pagon et al. 1979; Stranb and Spranger 1981): abdominal wall muscle deficiency (hypoplasia) as a nonspecific lesion resulting from fetal abdominal distension of various causes
3. Terminologies
   1. Prune belly: a descriptive term for a wrinkled and flaccid abdominal wall secondary to stretched skin, soft tissues, and muscles of the abdomen
   2. Prune belly syndrome generally used to indicate the condition having prune belly, cryptorchidism, and abnormalities of the urinary tract
4. Causes of urine flow impairment/obstruction (Mouriquand et al. 2001)
   1. Renal causes
      1. Pelviureteric junction anomaly
      2. Vesicoureteric junction anomaly
      3. Posterior urethral valves
      4. Duplex systems
      5. Ureterocele/ectopic ureter
      6. Urethral atresia
      7. Cloacal anomaly
      8. Vesicoureteric reflux
      9. Megaureter
      10. Megacystis microcolon
      11. Hypoperistalsis syndrome
   2. Extrarenal causes
      1. Sacrococcygeal teratoma
      2. Hydrometacolpos
      3. Other pelvic masses

Clinical Features

1. Broad spectrum in severity
2. Nearly 95% of cases occurring in males
3. Potter face
   1. Mandibular micrognathia
   2. Wide-set eyes
   3. Flattened palpebral fissures
   4. Prominent epicanthus
   5. Flattened nasal bridge
   6. Large, low-set ears with lacking cartilage
4. Abdomen (Nunn and Stephens 1961)
   1. Partial or complete absence of the abdominal musculature (Eagle and Berret 1950; Lattimer 1958; Ives 1974; Welch and kearney 1974)
   2. Thin/lax protruding abdominal wall
   3. Wrinkled abdominal skin
   4. Visible intra-abdominal intestinal patterns through thin abdominal wall
5. Pulmonary (58%): pulmonary hypoplasia (Hassett et al. 2012)
6. Other associated gastrointestinal abnormalities (Woods and Brandon 2007)

1. Malrotation: midgut anomaly, intestines abnormally rotated or become twisted during embryological development
2. Atresia: failure of the intestinal tract to completely form, causing absence of a normal opening
3. Stenosis: narrowing of the center passage within the intestines
4. Volvulus: intestines or stomach lack normal attachments of the body, causing the intestines to become twisted, resulting in a lack of blood supply
5. Clinical symptoms
    1. Bilious vomiting
    2. Abdominal distention
    3. Abdominal tenderness
    4. Failure to pass meconium
    5. Rectal bleeding
    6. Signs of shock and sepsis

7. Genitourinary anomalies (Harley et al. 1972; Rogers and Ostrow 1973; Pramanik et al. 1977; Tuch and Smith 1978; Woodhouse et al. 1982)
    1. Urethral obstruction
    2. Dilated/hypertrophic bladder
    3. Dilated urethra, particularly the prostatic urethra
    4. Dilated/tortuous ureters
    5. Renal dysplasia/hypoplasia with cystic changes
    6. Hydronephrosis
    7. Absence or hypoplasia of the prostate
    8. Ventral body wall defects
        1. Cloacal exstrophy
        2. Bladder exstrophy
        3. Hypo-/epispadias
    9. Genitalia
        1. Bilateral cryptorchidism in males
        2. Pseudohermaphroditism in females
    10. Potter sequence
        1. Oligohydramnios
        2. Potter face
        3. Pulmonary hypoplasia
        4. Other deformations

8. Secondary malformations
    1. Gastrointestinal (24%) (Hassett et al. 2012)
        1. Malrotation (40%)
        2. Atresia of small bowel and colon
        3. Splenic torsion
        4. Imperforate anus
        5. Anorectal agenesis
        6. Omphalocele
        7. Cloacal anomaly
    2. Limb (Genest et al. 1991) and other skeletal abnormalities believed to be the direct result of oligohydramnios with resultant fetal crowding (Green et al. 1993)
        1. Talipes equinovarus
        2. Metatarsus adductus
        3. Vertical talus
        4. Hip dislocation
        5. Arthrogryposis
        6. Pectus excavatum/carinatum
        7. Congenital muscular torticollis
        8. Bell shaped chest
        9. Infantile scoliosis
        10. Severe leg maldevelopment
            1. Generalized hypoplasia
            2. Complete absence
            3. Terminal defects
    3. Cardiacvascular (25%) (Hassett et al. 2012)
        1. Patent ductus arteriosus
        2. Tetralogy of Fallot
        3. Ventriculoseptal defect
        4. Atrioseptal defect
        5. Vascular anomalies
    4. Cleft lip
    5. Spina bifida
    6. Association with diverse chromosome syndromes (Qazi et al. 1978)
        1. Trisomy 13 (Beckman et al. 1984)
        2. Trisomy 18 (Frydman et al. 1983)
        3. Turner syndrome (Lubinsky et al. 1980)
        4. Cat-eye syndrome
        5. Trisomy 21 (Amacker et al. 1986)
        6. Others

9. Grading of patients according to severity of renal and pulmonary malformations (Herman and Siegel 2009)
    1. Grade 1: those with oligohydramnios-induced pulmonary hypoplasia and Potter's facies
    2. Grade 2: moderate-to-marked neonatal and infantile urinary tract involvement without pulmonary hypoplasia or Potter facies
    3. Grade 3: mild renal involvement
10. Prognosis
    1. High mortality although compatible with long-term survival
        1. Stillbirth or death by 1 month of age in 20% of cases
        2. Death by the second year for additional 30% of cases
    2. Causes of death (Christopher et al. 1982)
        1. Renal failure secondary to renal dysplasia present at birth
        2. Pulmonary complications including lung hypoplasia
        3. Infection associated with urinary stasis or operative interventions

Diagnostic Investigations

1. Renal and bladder ultrasound
2. Contrast voiding cystourethrogram
3. Radiography
    1. Hypoplastic lungs with flared lower ribs secondary to the distended abdomen
    2. Diffusely distended flanks
    3. Dilated/dysplastic calyces of the kidneys
    4. Markedly dilated/tortuous ureters
    5. Vertical and trabeculated bladder
    6. A wide and long posterior urethra
    7. Cryptorchidism
4. Histology of the abdominal wall (Moerman et al. 1984a, b)
    1. Muscle atrophy (degeneration of already formed muscle), not of primitive muscle.
    2. The finding supports the theory that the abdominal muscle hypoplasia is a nonspecific lesion, resulting from fetal abdominal distension of various causes.
5. Chromosome analysis for multiple congenital anomalies

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: not increased unless in autosomal recessive inheritance (which is still unclear)
    2. Patient's offspring: not increased
2. Prenatal diagnosis by 2D and 3D ultrasonography (Leeners et al. 2000; Chen et al. 2010)
    1. Signs of fetal abdominal laxity (characteristic abdominal appearance) associated with fetal urinary tract abnormalities
        1. Amniotic fluid wave produced by fetal movement
        2. Sinusoidal undulation of the fetal anterior abdominal wall produced by tapping the maternal abdomen
    2. A distended bladder (megacystis) (Cooperberg et al. 1979) and ureters
    3. Cryptorchidism
    4. Oligohydramnios
    5. Fetal ascites (Monie and Monie 1979; Stevenson et al. 1987)
    6. Lung hypoplasia
    7. Associated anomalies
        1. Other renal anomalies (25%)
        2. Extrarenal abnormalities (12%)
            1. Anorectal anomalies
            2. VATER syndrome
            3. Esophageal atresia
            4. Pattern compatible to specific chromosomal abnormality
3. Management
    1. Orchidopexy for cryptorchidism
    2. Treatment of vesicoureteral dysfunction
        1. Temporary diversion
        2. Ureteral reconstruction
    3. Treatment of vesicourethral dysfunction
        1. Reduction cystoplasty
        2. Internal urethrotomy
        3. Megalourethra repair

4. Abdominal wall reconstruction
5. Vesicoamniotic shunting with percutaneous-placed catheters: useful in some lower urinary tract obstructions such as those that occur with prune belly syndrome (Woods and Brandon 2007). However, vesicoamniotic shunt placement for suspected prenatal obstructive uropathy remains controversial (Freedman et al. 1996)
6. Urological surgical procedures (Seidel et al. 2015)
    1. Urethral surgery (13.0%): urethral dilation, urethrotomy
    2. Bladder surgery (47.8%): vesicostomy, appendicovesicostomy, reduction cystoplasty, tumor resection, Casale procedure, cystostomy, cystolithotomy
    3. Testicular surgery (93.2%)
    4. Renal surgery (23.9%): nephrectomy, transplant, nephrostomy
    5. Ureteral surgery (47.8%): reimplantation, ureterectomy, pyeloplasty
7. Renal transplantation (Hassett et al. 2012)
    1. Nearly a third of PBS patients outside the postnatal period will progress to renal failure requiring transplantation.
    2. Early identifiable risk factors are renal cystic disease and dysplasia reported in approximately 50% of infants with prune belly syndrome.
    3. The most accurate marker of significant renal dysplasia is nadir creatinine; that is the lowest consistent creatinine level in the first 12 months of life.
    4. The commonest indications for a renal transplant in prune belly syndrome patients are renal failure secondary to chronic pyelonephritis and renal dysplasia

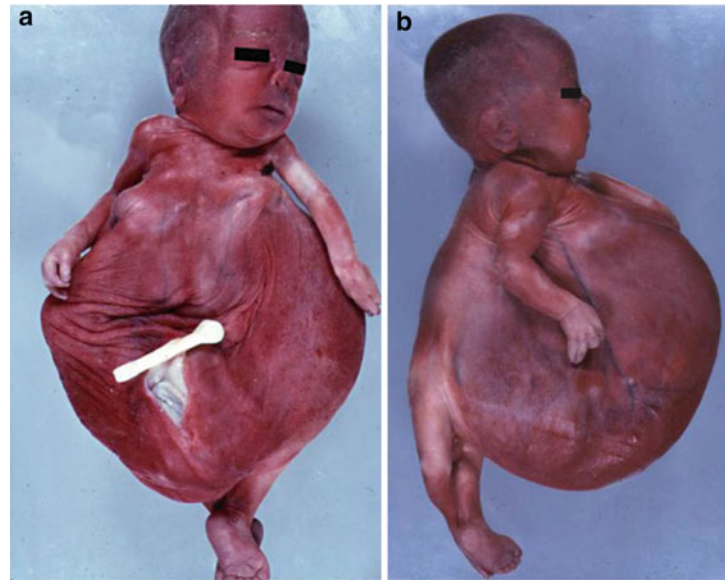

Fig. 1 (**a**, **b**) A premature male neonate with prune belly syndrome due to urethral atresia. He lived for 2 h. There was a massive dilation and hypertrophy of the urinary bladder. Mild hydronephrosis was seen in one kidney, but the second kidney was hypoplastic. The anterior abdominal wall showed muscle deficiency. Additional anomalies included imperforate anus with vesicorectal fistula, secundum-type atrial septal defect of the heart, mild coarctation of the aorta, and bilateral talipes equinovarus

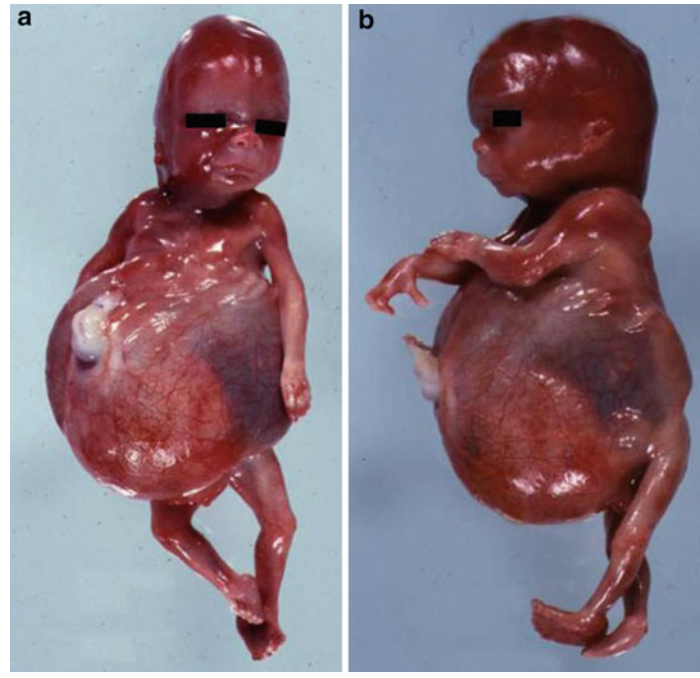

Fig. 2 (**a**, **b**) A male fetus with prune belly syndrome due to severe urethral stenosis. There were marked dilatations of the proximal urethra, bladder, and bilateral ureters. Mild hydronephrosis and cystic renal dysplasia were seen in both kidneys. There were no other anomalies

Fig. 3 An infant with prune belly syndrome showing thin, flaccid abdominal wall through which intra-abdominal intestinal patterns are visible

Fig. 4 A postmortem infant with prune belly syndrome showing flaccid and wrinkling abdominal wall with visible intestinal patterns

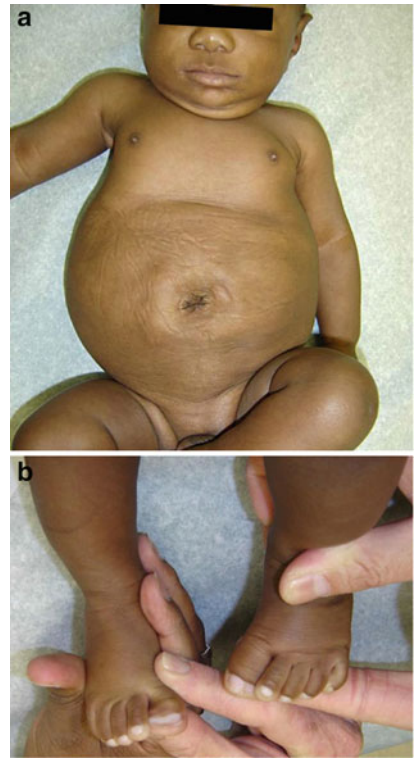

Fig. 5 (**a**, **b**) A neonate with prune belly syndrome showing wrinkling abdominal wall due to multicystic kidneys. The infant also has duplicated great toes

Fig. 6 This infant boy was evaluated for prune belly syndrome. Prenatal ultrasound showed oligohydramnios, bilateral hydronephrosis, and ascites. A wrinkled abdominal wall was noted at birth. The bladder was palpable up to the umbilicus. Bilateral kidneys were enlarged, left more than right. A clear fluid appeared oozing out from the umbilicus (patent urachus). He had a small penis with cryptorchidism. Also seen in the figure is a catheter in the urethra after ureterostomy and ligation of urachus (Courtesy of Dr. Barty Manchandia)

Pseudoachondroplasia

Contents

Pseudoachondroplasia (PSACH) is a type of short-limbed dwarfism, deriving its name from phenotypic similarity to achondroplasia. It is characterized by normal facies, short-limbed dwarfism, joint laxity, and epiphyseal and metaphyseal abnormalities in the growing child.

Synonyms and Related Disorders

Peudoachondroplastic spondyloepiphyseal dysplasia; Pseudoachondroplastic dysplasia

Genetics/Basic Defects

1. Inheritance
    1. Autosomal dominant with complete penetrance: multiple affected Ovitz family members (Muensterer et al. 2012)
    2. Autosomal recessive unlikely (Ferguson et al. 1997)
        1. Somatic mosaicism was demonstrated in two pseudoachondroplasia families that were originally considered to represent autosomal recessive inheritance.
        2. The results suggest that autosomal recessive inheritance is unlikely, and all cases of pseudoachondroplasia should be studied for mutations in *COMP*.
2. Cause
    1. Mutations in the gene encoding cartilage oligomeric matrix protein (*COMP*) on the centromeric region of 19p (19p13.1-p12) (Briggs et al. 1993; Hecht et al. 1995; Ikegawa et al. 1998).
        1. Deletions: Approximately 40–50% of cases of pseudoachondroplasia have deletion mutations in exon 13 of the *COMP* gene.
        2. Specific base substitutions
        3. Duplications
    2. The c. 1352_1353ins TGTCCCTGG is a novel mutation responsible for severe familial PSACH (Dai et al. 2011).
    3. The variant, c.1160_1162del of the COMP gene, was identified as a novel mutation responsible for the spontaneous form of PSACH (Luo et al. 2016).
    4. Can be caused by spontaneous or parental gonadal mosaicism in cases of unaffected parent and no COMP mutation identified in a child (Ferguson et al. 1997; Hall et al. 1987; Xie et al. 2013).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_199

5. Increase of the range of mutations in COMP that cause PSACH and provides additional evidence for the importance of the calcium-binding domains and the globular domain to the function of COMP (Deere et al. 1998).
6. Allelic to multiple epiphyseal dysplasia, which is also caused by *COMP* mutations (Song et al. 2003).
7. All mutations associated with pseudoachondroplasia and multiple epiphyseal dysplasia (MED): found in exons encoding the type III repeat region or C-terminal domain of *COMP*.
8. PSACH and MED (Briggs and Chapman 2002; Briggs et al. 1995, 1998; Jackson et al. 2012).
    1. Constitute a bone dysplasia family which is both genetically and phenotypically heterogeneous.
    2. The disease spectrum ranges from mild MED, which manifests with pain and stiffness in the joints and delayed and irregular ossification of the epiphyses, to the more severe PSACH, which is characterized by marked short stature, deformity of the legs, and ligamentous laxity.
    3. PSACH is almost exclusively caused by mutations in cartilage oligomeric matrix protein (COMP).
    4. AD-MED is genetically heterogenous and can also result from mutations in matrilin-3 (MATN3) and type IX collagen (*COL9A1*, *COL9A2*, and *COL9A3*).
    5. In contrast, autosomal recessive MED (rMED) appears to result exclusively from mutations in sulfate transporter solute carrier family 26 (*SLC26A2*).

Clinical Features

1. Variable clinical features (Hall 1975; Maroteaux et al. 1980)
2. Normal at birth
3. Normal intelligence
4. Normal craniofacial appearance
5. Waddling gait and diminished linear growth at about 2 years of age
6. Chronic pain in weight-bearing joints (Gamble et al. 2015)
    1. One of the earliest manifestations of PSACH
    2. Most frequently involves knees, hips, and back
    3. Significantly interferes with overall quality of life
7. Rhizomelic short-limbed dwarfism
    1. Body proportion resembling achondroplasia
    2. Usually detectable at age 2–4 years
8. Spine
    1. Accentuated lumbar lordosis
    2. Scoliosis
    3. Kyphosis
    4. Chronic compression myelopathy secondary to habitual atlantoaxial dislocation
9. Extremities
    1. Bowing of the long bones
    2. Deformities of the lower limbs
        1. Secondary to ligamentous laxity
        2. Ranging from genu varum (bowed legs), genu valgum (knock-knees), and genu recurvatum
        3. A "wind-swept deformity" (bowleg on one side and knock-knee on the other side)
    3. Markedly shortened hands (without trident configuration) and feet
    4. Ulnar deviation of the wrist
    5. Flexion contractures of the elbow and knees
    6. Brachydactyly
    7. "Telescoping" fingers
10. Joint
    1. Lax ligament
    2. Premature osteoarthritis
    3. Contractures of the hips
11. Prognosis
    1. Good survival.
    2. Early arthrosis, notably in the hip and knee joints.
    3. PSACH individuals are generally healthy but have problems associated with debilitating osteoarthritis (McKeand et al. 1996).

4. Possible myelopathy secondary to atlantoaxial dislocations.

12. Genotype-phenotype correlation (Briggs et al. 2014)
    1. Mutations in specific residues and/or regions of the type III repeats of COMP are significantly associated with either PSACH or MED.
    2. This newly derived genotype to phenotype correlation may aid in determining the prognosis of PSACH and MED, including the prediction of disease severity, and in the long term guide genetic counseling and contribute to the clinical management of patients with these diseases.
13. Differential diagnosis (Briggs and Wright 2015)
    1. Dominant multiple epiphyseal dysplasia (see the chapter of "▶ Multiple Epiphyseal Dysplasia"): Mutations in *COMP*, *COL9A1*, *COL9A2*, *COL9A3*, or *MATN3* genes can be demonstrated in about 50% of cases.
    2. Recessive multiple epiphyseal dysplasia (see the chapter).
        1. *SLC26A2* (*DTDST*) is the only gene known to be associated with recessive multiple epiphyseal dysplasia.
        2. Diagnosis can be confirmed by molecular genetic testing of the *SLC26A2* gene.
    3. Other forms of spondyloepimetaphyseal dysplasia: need complete skeletal survey for diagnosis.

Diagnostic Investigations

1. Radiography (Heselson et al. 1977)
    1. Tubular bones
        1. Irregularities and fragmentations of the developing epiphyses
        2. Shortened tubular bones
        3. Flaring of metaphyses
        4. Brachydactyly
        5. Delayed epiphyseal ossification (delayed bone age)
        6. Small phalangeal epiphyses (miniepiphyses)
        7. Small, irregular carpal bones
        8. Irregular, widened (frayed), mushroomed metaphyses
        9. Coxa vara
    2. Pelvis
        1. Delayed ossification of the capital femoral epiphyses, which become flattened and small when ossified
        2. Commonly observed sclerosis and irregularity of the acetabular roof
    3. Vertebrae
        1. Characteristic anterior beaking or tonguing (in lateral view of the lumbar spines)
            1. Due to delayed ossification of the annular epiphyses
            2. Vertebrae becoming more normal in appearance after puberty
        2. Some degree of vertebral end-plate malformation
        3. Characteristic platyspondyly in childhood
        4. Kyphoscoliosis
        5. Lumbar lordosis
        6. Odontoid hypoplasia
        7. Atlantoaxial dislocations
    4. Ribs: spatulate
    5. Radiographically, both PSACH and MED are characterized by abnormalities of the epiphyses of the hands, long bones, and hips (Cohn et al. 1996). PSACH also shows marked metaphyseal irregularities as well as characteristic anterior beaking of the vertebrae. The metaphyses and spine in MED are usually normal.
2. Histology of growth plates
    1. Irregular arrangement of chondrocytes without column formation
    2. Irregular provisional calcification
    3. Intracytoplasmic inclusions in chondrocytes
3. EM of chondrocytes (Cooper et al. 1973)
    1. Showing distinctive giant rough endoplasmic reticulum cisternae filled with punctuate material

2. The material composed of alternating electron-lucent and electron-dense layers in a unique lamellar appearance
4. Serum COMP concentration may be suggested as an additional diagnostic marker to aid clinical findings in suspected cases of Pseudoachondroplasia (Liu et al. 2010).
5. Molecular diagnosis
   1. Important to confirm suspected pseudoachondroplasia (Newman et al. 2000)
   2. Sequence analysis of selected exons or the entire coding region (Briggs and Wright 2015)
      1. Detect p.Asp473del (about 30%)
      2. Detect missense and small in-frame deletions (about 70%)
   3. Particularly useful in adult patients where radiological diagnosis can be difficult

Genetic Counseling

1. Recurrence risk: according to autosomal dominant inheritance (Briggs and Wright 2015)
   1. Patient's sib
      1. Fifty percent if one of the parent is affected.
      2. Not increased if parents are normal.
      3. If the disease-causing mutation identified in the proband cannot be detected in the DNA of either parent, two possible explanations are germ line mosaicism in a parent or a de novo mutation in the proband.
         1. The risk to the sibs of the proband depends on the probability of germ line mosaicism in a parent of the proband and the spontaneous mutation rate of *COMP*.
         2. Germ line mosaicism for a *COMP* mutation has been reported (Hall et al. 1987; Ferguson et al. 1997), but the frequency is unknown and the empiric risk to sibs of a proband has not been determined.
   2. Patient's offspring: 50%
2. Prenatal diagnosis
   1. Prenatal ultrasonography unlikely to detects the skeletal changes which will not manifest until about 2 years of age.
   2. Prenatal diagnosis and preimplantation genetic diagnosis: possible in the family at risk and the disease-causing *COMP* mutation has been characterized in an affected individual (Briggs and Wright 2015).
3. Management
   1. Supportive
   2. Surgical correction of the leg deformities
   3. Hip replacement for severe hip contractures
   4. Cervical stabilization procedures for cervical cord compression with progressive neurologic symptoms and signs

Fig. 1 (**a**–**d**) A girl with pseudoachondroplasia at 2½ years (**a**, **b**) with normal craniofacial appearance, mild short stature, and waddling gate and at 6 years (**c**, **d**) with short limbs, accentuated lumbar lordosis, and short stature

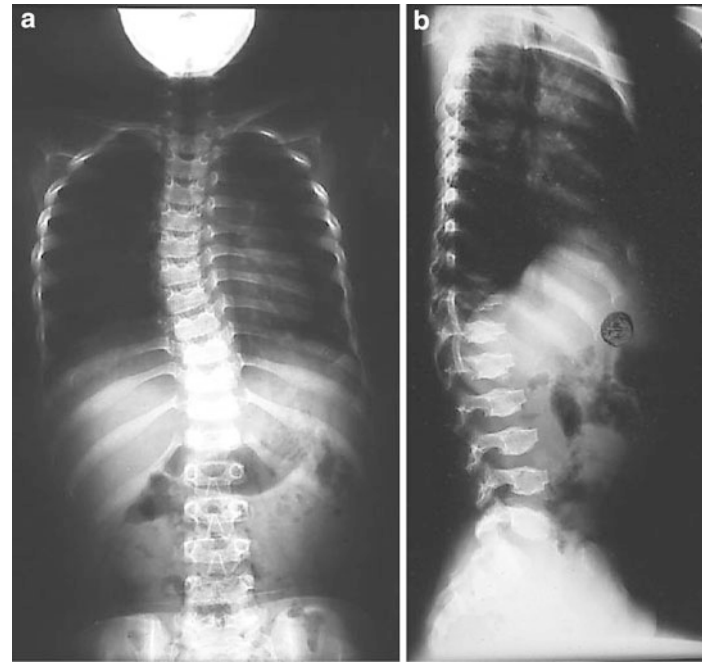

Fig. 2 (**a**, **b**) Radiographs of the spine show characteristic anterior beaking of the lumbar spine and mild scoliosis

Fig. 3 Radiographs of the pelvis and lower extremities showing irregular, horizontal acetabular roof, delayed epiphyseal ossification, and wide mushroom-shaped metaphyses

Fig. 4 Radiograph of the upper extremities showing markedly widened and defective metaphyseal and epiphyseal ossifications in the proximal humerus, distal radius, and ulna

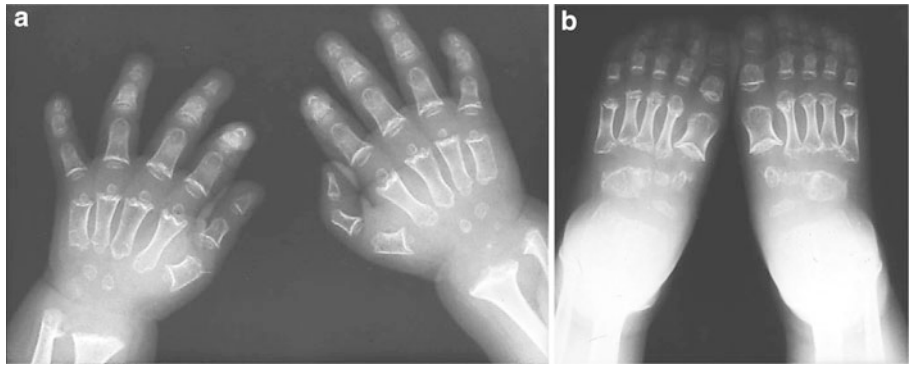

Fig. 5 (**a**, **b**) Radiographs of the hands (**a**) and feet (**b**) show grossly disturbed metaphyseal and epiphyseal ossification, short and stubby tubular bones, somewhat widened metacarpals and metatarsals, and small and markedly irregular carpal and tarsal bones

R(18) Syndrome

Contents

In 1962, Wang et al. (1962) reported the first observation of the ring chromosome 18. Ring chromosome 18 syndrome is a rare chromosome disorder resulting from loss (deletion) of genetic material from one or both ends of a chromosome 18 and joining of the chromosomal ends to form a ring.

Ring chromosome 18 has been reported in many cases of liveborns. The phenotype may vary greatly in range and severity from normal fertile persons in a majority of cases to those with severe malformations, depending upon the amount and location of lost genetic material. Ring chromosome 18 is usually caused by spontaneous (de novo) errors very early in the development of the embryo.

Synonyms and Related Disorders

Mosaic ring chromosome 18 syndrome; Ring chromosome 18 syndrome

Genetics/Basic Defects

1. Formation of a ring chromosome 18
    1. Ring chromosomes arise from chromosomal breakages occurring on either side of the centromere and subsequent rejoining of the segment containing the centromere.
    2. One of the breakpoints is generally at or adjacent to the centromere. Thus, two types of ring chromosomes may arise:
        1. One derived from the short arm
        2. One derived from the long arm
2. Supernumerary ring chromosome 18
    1. The r(18) was additional to the two existing chromosome 18 copies, leading to trisomy for the chromosome 18 segment carried on r(18).
    2. May show the characteristics of trisomy 18 or duplications of 18p or 18q.
3. Mosaic ring chromosome 18
    1. Ring chromosomes are known to be unstable and are often found in a mosaic state.
    2. Instability of a ring may lead to a monosomic cell line.
    3. A report of a deletion at 18pter and at 18qter and a mosaic partial trisomy of the pericentromeric region of chromosome 18 (Baumer et al. 2002).
4. Haploinsuficiency of several genes have been postulated to play a role in the 18q- and 18p- syndrome phenotypes:
    1. HPE4 (18p11.3): holoprosencephaly
    2. GALNR1 (18q23)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_200

3. Growth hormone deficiency (Aritaki et al. 1996)
4. MBP (18q23): hypomyelination

5. Phenotypic variability depends on the extent of the deleted chromosome 8 segments: most patients show the symptoms of 18q- syndrome, 10p- syndrome, or combination of these two.
6. Chromosome 18 replaced by two ring chromosomes of chromosome 18 origin (Miller et al. 2003): clinical findings partly overlap with observations in 18p- and 18q-syndrome and are similar to some cases of ring chromosome 18.
7. Rare occurrence of a ring chromosome 18 together with a duplication of a segment of chromosome 18 or with a marker chromosome.
8. Familial case of ring chromosome 18 and monosomy 18 mosaicism (Yardin et al. 2001).
9. Rare occurrence of a ring chromosome in mother and daughter (Christensen et al. 1970) and mother and son (Donlan and Dolan 1986; Fryns et al. 1992; Jenderny et al. 1993; Balci et al. 2014).

Clinical Features

1. Clinical features of r(18) syndrome (Wertelecki and Gerald 1971; Karda et al. 2001; Stankiewicz et al. 2001; Carter et al. 2015):
    1. Growth and development
        1. Mental retardation
        2. Hypotonia
        3. Short stature
    2. Head/brain
        1. Microcephaly
        2. Dolichocephaly
        3. Holoprosencephaly spectrum (cebocephaly, arhinencephaly)
        4. Abnormal white matter
    3. Midface: flat
    4. Ears
        1. Asymmetric
        2. Low set
        3. Atretic external ear canals
        4. Prominent antihelix
        5. Hearing loss
    5. Eyes
        1. Deep set
        2. Hypertelorism
        3. Down slanting palpebral fissures
        4. Epicanthal folds
        5. Hyperopia
        6. Amblyopia
        7. Nystagmus
        8. Strabismus
        9. Astigmatism
        10. Ptosis
        11. Optic nerve hypoplasia
        12. Coloboma
    6. Nose
        1. Broad base
        2. Depressed nasal bridge
        3. Broad tip
        4. Choanal atresia
    7. Mouth
        1. Micrognathia
        2. Carp-like down-turned corners
        3. Thin upper and lower lips
        4. High/narrow/cleft palate
        5. Bifid uvula
        6. Dental caries
    8. Throat
        1. Tracheomalacia
        2. Laryngomalacia
    9. Neck: short
    10. Chest
        1. Pectus excavatum
        2. Wide-spaced nipples
    11. Congenital heart defect
        1. PDA
        2. PS
        3. VSD
        4. AS
    12. Abdomen
        1. Umbilical hernia
        2. Inguinal hernia
    13. Gastrointestinal
        1. Reflux
        2. Neonatal feeding difficulties
        3. Constipation
        4. G or NG tube/dysphagia

14. Genitourinary
    1. Male genitalia
        1. Cryptorchidism
        2. Hypoplastic scrotum
        3. Micropenis
    2. Female genitalia: hypoplastic labia minora
15. Pulmonary
    1. Neonatal respiratory difficulties
    2. Asthma
16. Musculoskeletal
    1. Spine: scoliosis/kyphosis
    2. Hands
        1. Clinodactyly
        2. Camptodactyly
        3. Short fingers
        4. Long tapering fingers
        5. Proximally placed thumbs
        6. Single transverse palmar crease
    3. Legs/feet
        1. Club feet (varus)
        2. Vertical talus
        3. Metatarsus adductus
        4. Pectus cavus
        5. Overriding toes
        6. Long/broad toes
        7. Genu valgum
17. Other features
    1. Hypothyroidism.
    2. Autoimmune thyroiditis (Dacou-Voutetakis et al. 1999).
    3. Hypoparathyroidism.
    4. Growth hormone deficiency.
    5. Some of the anomalies overlap with the VACTERL association (van der Veken et al. 2010).
18. Atypical features
    1. Van der Woude syndrome
    2. Insulin-dependent diabetes mellitus (Dacou-Voutetakis et al. 1999)
    3. Agammaglobulinemia (Litzman et al. 1998)

2. Most patients share the features of del(18q) syndrome which are highly variable depending on the extent of the terminal or interstitial 18q deletion:
    1. Mental retardation
    2. Hypotonia
    3. Microcephaly
    4. Short stature
    5. Flat midface
    6. Carp-shaped mouth
    7. Prominent antihelix and antitragus
    8. Atretic/stenotic ear canals
    9. Proximally placed thumbs
    10. Long tapering digits
    11. Foot deformity
    12. Abnormal male genitalia
3. Monosomy 18/r(18) mosaicism fetus with complex malformations (Eiben et al. 1992)
    1. Cebocephaly
    2. Hypotelorism
    3. Microphthalmia
    4. Severe defects of brain development
    5. Arrest of placental maturation
4. Some patients share the features of del(18p) syndrome which are highly variable depending on the extent of the terminal or interstitial 18p deletion:
    1. Mental retardation
    2. Speech delay
    3. Hypotonia
    4. Short stature
    5. Midface defects including holoprosencephaly
    6. Ptosis of eyelids
    7. Small mandible
    8. Dental caries
    9. Short neck
    10. IgA deficiency
5. Some patients share the combined features of del(18p) syndrome and del(18q) syndrome.
6. Genotype–phenotype correlation (Spreiz et al. 2013)
    1. Revealed extensive clinical variability but no characteristic r(18) phenotype.
    2. Severity of clinical signs were generally correlated with the size of the deletion.
    3. Patients with large deletions in 18p and small deletions in 18q exhibited mainly symptoms related to 18p-, whereas those with large deletions in 18q and small deletions in 18p had symptoms of 18q-

Diagnostic Investigations

1. MRI of the brain: abnormal myelination (Nakayama et al. 1997)
2. Conventional cytogenetic studies
   1. Nonmosaic r(18)
   2. Mosaic r(18)
3. Molecular cytogenetic studies using fluorescence in situ hybridization (FISH) technique
   1. Ring chromosome positive for chromosome 18 centromeric probe
   2. Absence of 18q subtelomeric probe
4. Microdissection followed by FISH to determine the origin of the marker chromosome
5. Using a number of microsatellite markers to determine the parental origin and possible mode of formation of the r(18)
6. Single-nucleotide polymorphism array-based characterization of ring chromosome 18 (Spreiz et al. 2013)
7. Whole-genome low-coverage sequencing: would improve the detection and prediction of genotype and phenotypic outcomes to direct postnatal medical care. (Yao et al. 2016)
8. Absent/low IgA (Stewart et al. 1970)

Genetic Counseling

1. Recurrence risk
   1. Patient sibling
      1. A low recurrence risk if both parents are normal phenotypically and karyotypically (in cases of de novo instances in majority of cases).
      2. Careful chromosome analysis to rule out parental mosaicism which may contribute to a recurrent risk of giving birth to a child with either partial trisomy or monosomy of different regions of chromosome 18.
      3. A ring chromosome 18 can be transmitted from a phenotypically normal parent with 46,XX or XY/47,XX or XY,+r(18) karyotype to offspring with a 46,XX or XY,r(18) karyotype.
   2. Patient's offspring
      1. Patients with an r(18): 50%
      2. Patients with mosaic form of an r(18): lower than 50% depends on the percentage of the marker chromosomes
2. Prenatal diagnosis
   1. Prenatal ultrasonography for congenital anomalies including abnormal facial profiles (Los et al. 1996)
   2. Chromosome analysis by amniocentesis or CVS
      1. Presence of an r(18) chromosome
      2. Presence of monosomy 18/r(18) mosaicism (Eiben et al. 1992)
      3. FISH with a chromosome 18 probe to identify chromosome 18
3. Management
   1. Mainly supportive
   2. Multidisciplinary team approach with physical, occupational, and speech therapies
   3. Supportive treatment for chronic sinopulmonary infections associated with IgA deficiency
   4. Treat endocrine dysfunction if present
   5. Surgery for congenital anomalies

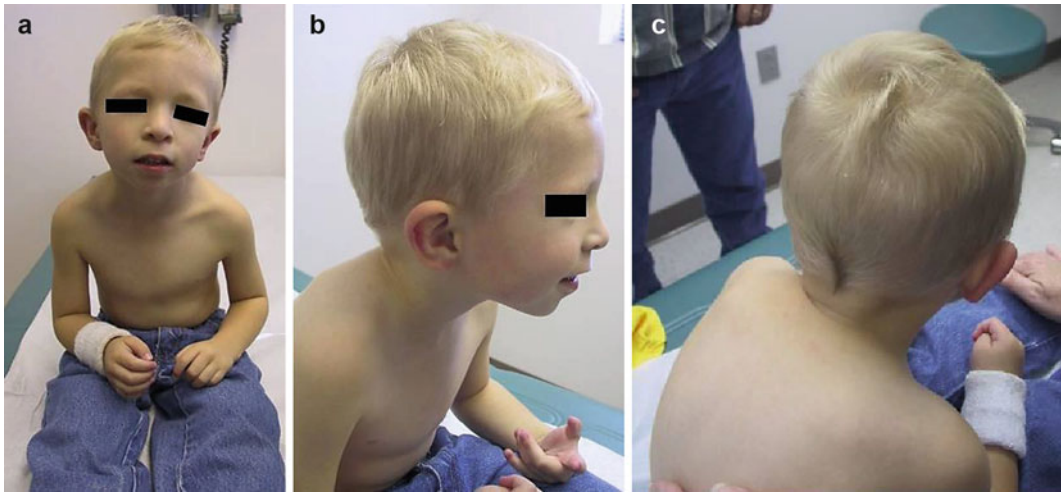

Fig. 1 (**a**–**c**) A 4-year-old boy with de novo r(18) syndrome showing growth deficiency (prenatal and postnatal), speech delay, hypertelorism, downward slanting of the palpebral fissures, strabismus, slightly low-set ears, mild pectus carinatum, clinodactyly of the 5th fingers, and syndactyly of toes. He also has IgA deficiency

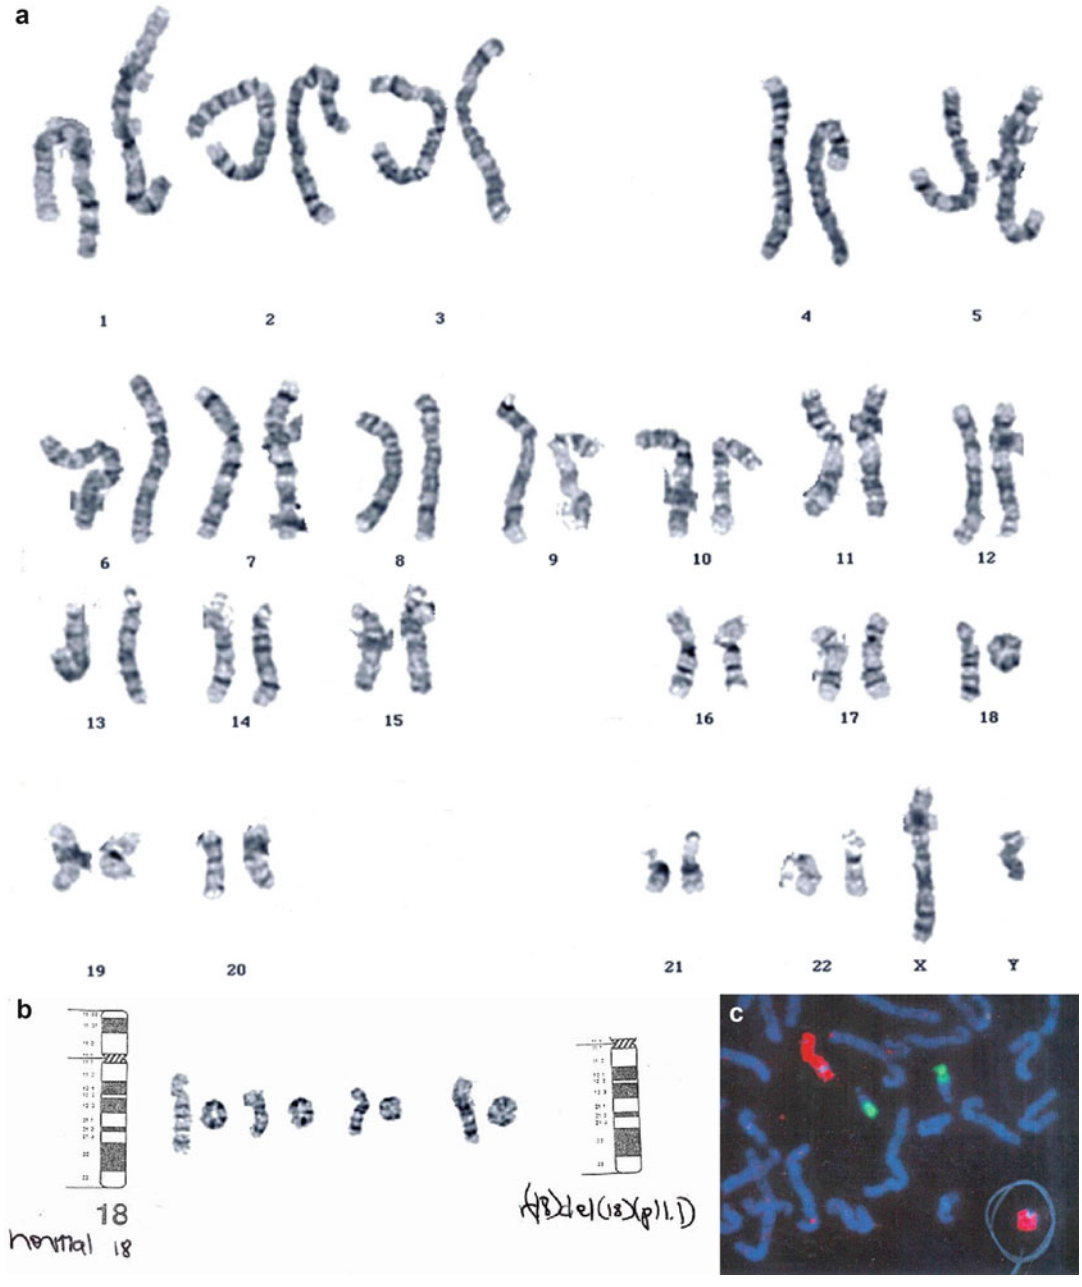

Fig. 2 (**a**–**c**) Chromosome analysis of the patient showed 46,XY,r(18), illustrated by a G-banded karyotype (**a**), a partial karyotype with idiograms (**b**), and FISH with whole chromosome 18 painting probe (**c**)

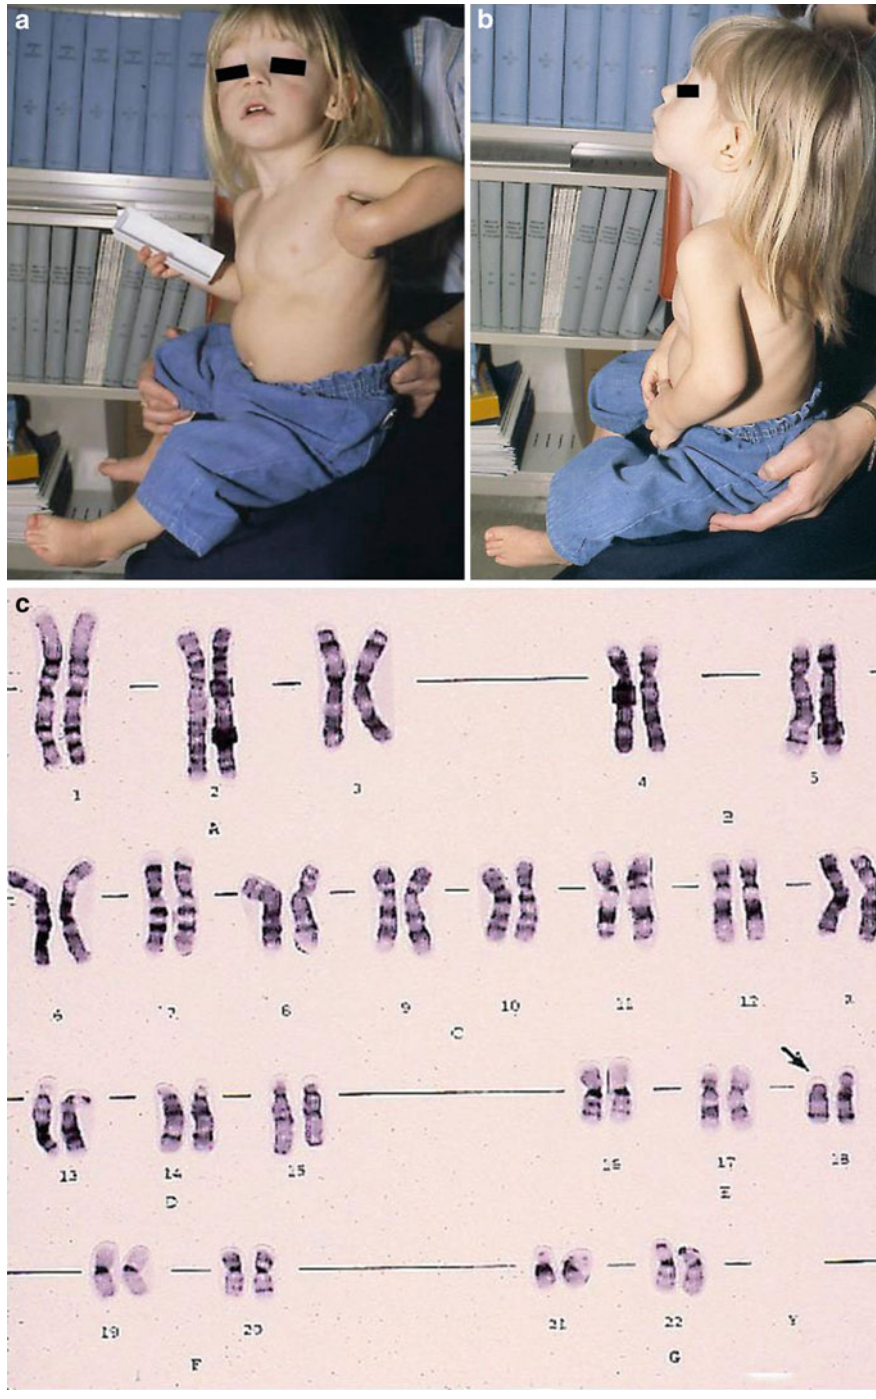

Fig. 3 (**a**–**c**) A girl (**a**, **b**) with del(18p) showing hypotonia, ptosis of the eyelids, and small mandible. The G-banded karyotype (**c**) shows deletion of the short arm of a chromosome 18 (*arrow*)

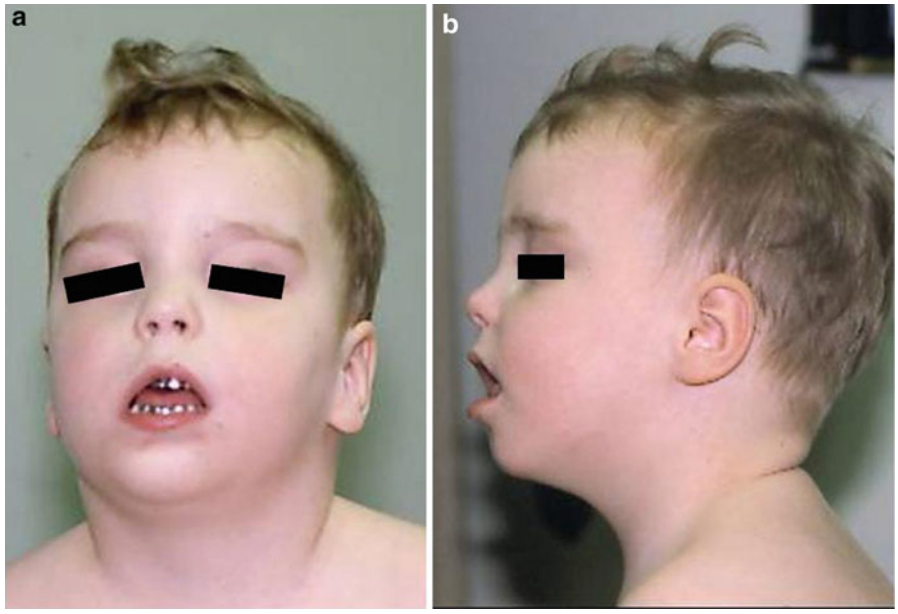

Fig. 4 (**a**, **b**) A boy with del(18q) showing hypotonia, ptosis of the eyelids, and carp-like mouth

Retinoid Embryopathy

Contents

Oral retinoids, isotretinoin (Accutane), and etretinate, uniquely effective in the treatment for severe cystic and keratinization disorders, are potent human teratogens.

Synonyms and Related Disorders

Isotretinoin embryopathy

Genetics/Basic Defects

1. Synthetic retinoids (isotretinoin, etretinate, acitretin)
    1. Closely resemble naturally occurring vitamin A, which is essential for the maintenance of visual and reproductive function and for proliferation and differentiation of epithelial tissues
    2. Isotretinoin and etretinate
        1. Released in the United States and Europe in 1982
        2. Isotretinoin (Brinker et al. 2002; Stashower 2003)
            1. Uniquely effective in severe cystic acne.
            2. Accutane is a powerfully effective therapy, but is not right for every patient.
            3. Estimate rate of pregnancy during Accutane therapy: Mitchell et al (1995) reported 402 pregnancies among 124,216 women completing follow-up for an incidence rate of 3.2 per 1000 women.
            4. From the rates of pregnancy documented during isotretinoin use, we can estimate an annual pregnancy rate during treatment of 16–24 per 1000 female users. Among the 118 live births were 11 (9.3%) cases of congenital malformation (Henry et al. 2016).
        3. Etretinate (and acitretin): uniquely effective in severe psoriasis and other keratinization disorders which proved recalcitrant to all other therapies, account for their availability on prescription despite their teratogenicity
    3. Acitretin released later to replace etretinate as it is more rapidly eliminated from the body

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_201

4. Adverse reactions (Rademaker 2010)
    1. Isotretinoin is a very effective medication with a low adverse effect profile when used at lower doses (Rademaker 2010).
    2. Commonly reported adverse reactions: largely dose-related, of early onset, and reversible on discontinuation.
        1. Cheilitis
        2. Dryness of the lips, mouth, and eyes
        3. Eczema
        4. Tiredness
        5. Mood change (mental depression)
        6. Skin fragility
        7. Nose bleeds
        8. Joint and muscle aches
        9. Eye problems (altered vision)
        10. Hair loss
        11. Pruitis
    3. Less common and more severe idiosyncratic reactions
        1. Headache
        2. Abnormally raised serum transaminase levels
        3. Serum lipid changes
        4. Increased serum triglyceride and cholesterol levels
        5. An increase in low-density/high-density lipoprotein ratio
    4. Rare reactions
        1. Infections
        2. Severe hepatitis
        3. Diffuse hyperostosis of the spine
        4. Benign intracranial hypertension
5. Teratogenicity of retinoids
    1. Foreshadowed by animal studies with strong warnings against exposure during pregnancy
    2. Believed to interfere with the activity and migration of cranial neural crest cells during development and thus cause craniofacial, thymic conotruncal heart, and CNS malformations
    3. Intellectual deficits

2. Teratogenicity (Chan et al. 1996)
    1. Isotretinoin (Lammer et al. 1988; Lancaster 1988; Strauss et al. 1988)
        1. Teratogenic during the first trimester fetal exposure within the therapeutic dose range
        2. Has a short elimination half-life of about 20 h
        3. Recommended contraception period after cessation of therapy: 1 month
        4. Labeling guidelines be followed in an effort to reduce the risk of pregnancy among women taking isotretinoin (Brinker et al. 2002; Mitchell and Van Bennekom 2003)
        5. Risk of teratogenicity for isotretinoin
            1. Exposure within first trimester: about 28%.
            2. Pregnancy occurring within 1 month after cessation of treatment: about 4%.
            3. Pregnancy occurring after 1 month: the risk of fetal malformations returns to baseline (isotretinoin is no longer detectable in the maternal circulation) (Ellis and Krach 2001).
    2. Etretinate
        1. Readily absorbed into adipose tissue and slowly released from it
        2. Has a long elimination half-life ($\geq$120 days)
        3. Recommended contraception period after therapy: 2 years
        4. Risk for teratogenicity for exposure to etretinate
            1. During pregnancy: about 26%
            2. Within 2 years of treatment cessation: about 2%
    3. Acitretin
        1. A shorter elimination half-life of 50 h.
        2. Recommendation of a 2-year contraception period after therapy for acitretin; as in some women, there is conversion of acitretin to etretinate during therapy.

Clinical Features

1. Isotretinoin embryopathy (Braun et al. 1984; de la Cruz et al. 1984; Chan et al. 1996)

1. Craniofacial abnormalities (Fernhoff and Lammer 1984)
    1. Major auricular malformations (Jahn and Ganti 1987)
        1. Microtia/anotia
        2. Agenesis or marked stenosis of external ear canals
    2. Hypertelorism
    3. Depressed nasal bridge
    4. Micrognathia
    5. Cleft palate
    6. Low-set ears
    7. Asymmetric crying facies (Sarici et al. 2012)
2. Central nervous system abnormalities
    1. Hydrocephalus
    2. Dandy-Walker malformation
    3. Microcephaly
    4. Microophthalmia
    5. Cerebellar defects
        1. Hypoplasia
        2. Microdysgenesis
    6. Cortical defects
    7. Cortical blindness
    8. Facial nerve palsy
    9. Optic nerve hypoplasia
    10. Retinal defects
    11. Spina bifida
    12. Mental retardation
3. Cardiovascular abnormalities
    1. Conotruncal malformations
        1. Transposition of the great vessels
        2. Tetralogy of Fallot
        3. Truncus arteriosus
        4. Double-outlet right ventricle
        5. Ventricular septal defect
        6. Atrial septal defect
    2. Coarctation of the aorta
    3. Interrupted aortic arch
    4. Hypoplastic left ventricle
    5. Retroesophageal right subclavian artery
4. Other abnormalities
    1. Thymic abnormalities
        1. Ectopia
        2. Hypoplasia
        3. Aplasia
    2. Nystagmus
    3. Decreased muscle tone
    4. Hepatic abnormality
    5. Hydroureter
    6. Simian crease
    7. Limb reduction defects (Rizzo et al. 1991)
    8. An increased risk of spontaneous abortions (about 15%) but no long-term effects on fertility
2. Retinate embryopathy
    1. Craniofacial abnormalities
        1. Microtia
        2. Micrognathia
        3. Low-set ears
    2. Central nervous system abnormalities
        1. Menigomyelocele
        2. Anophthalmia
        3. Brain defect
    3. Skeletal abnormalities
        1. Syndactyly
        2. Shortened or absent digits
        3. Club foot
        4. Multiple synostosis

Diagnostic Investigations

1. Sonogram/CT/MRI of the brain for CNS anomalies
2. Radiography/CT for auditory canal malformations
3. Echocardiography for congenital heart defects
4. Audiological assessment by brainstem auditory evoked response
5. Visual and somatosensory evoked potential to detect cortical response
6. Electroencephalography

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: not increased unless the mother exposes to retinoid again during the pregnancy
    2. Patient's offspring: not increased unless exposure to retinoid during pregnancy

2. Prenatal diagnosis
    1. History of maternal exposure to retinoid
    2. Prenatal ultrasonography
        1. Craniofacial anomalies
            1. Microtia/anotia
            2. Anophthalmia/microphthalmia
            3. Other facial abnormalities
        2. CNS anomalies
            1. Microcephaly
            2. Dandy-Walker malformation
            3. Hydrocephalus
        3. Cardiac defects by fetal echocardiography
        4. Skeletal abnormalities
3. Management (Dai et al. 1989; Atanackovic and Koren 1999a, b; Abroms et al. 2006)
    1. Pregnancy Prevention Program, developed by the manufacturer and the US Food and Drug Administration since 1988, to prevent fetal exposure to the drug Accutane (Pastuszak and Koren 1993; Pastuszak et al. 1994; Koren and Pastuszak 1997):
        1. Distribute printed material to prescribing physicians to be used in educating their female patients about the serious teratogenic effects.
        2. Instruct physicians to delay therapy until the second or third day of the patient's next normal menstrual period.
        3. Stress to patients the importance of using two forms of contraception concurrently.
        4. A consent form to be signed by female patients (Holmes et al. 1998):
            1. Acknowledging that they have been instructed through the program.
            2. Aware of the need to use two forms of contraception during isotretinoin therapy.
            3. Agree to undergo pregnancy testing before, during, and after the therapy.
        5. Still no full compliance to the isotretinoin pregnancy prevention program in many Western countries (Zomerdijk et al. 2014).
        6. Internet-based, performance-linked system called iPLEDGE (Abroms et al. 2006):
            1. The most recent and most stringent system
            2. To ensure that the drug is dispensed only when there is documentary proof that the patient is not pregnant and is using two forms of birth control
    2. Adhere to strict prescription guidelines, but exposure during pregnancy still occurs. The most common reasons for unwanted or mistimed pregnancies with isotretinoin therapy are (Perlman et al. 2001) as follows:
        1. Unsuccessful attempts at abstinence
        2. Use of ineffective contraception
        3. Inconsistent use of contraception
        4. Unexpected sexual activity
        5. Contraceptive failure
    3. Safe and optimal use of isotretinoin: summery and recommendations (Goldsmith et al. 2004).
    4. Currently, there appears to be no increased risk of retinoid embryopathy. However, according to current knowledge, topical retinoids cannot be advised for use during pregnancy because their risk/benefit ratio remains questionable (Panchaud et al. 2012).
    5. Physicians who cannot follow the program or are not experienced prescribers of oral isotretinoin should refer the patient to the most experienced practitioner available – to protect themselves and to serve their patients (Shear 1999).
    6. The need to improve pregnancy prevention programs (Crijns et al. 2011):
        1. Taking responsibility and enhancing the performance by health care professionals.
        2. Give explicit instructions.
        3. Monitor the performance and adjusting, if necessary.
    7. The medical community has a major role to play in ensuring that babies are not affected by prescription drugs taken during pregnancy. The continued occurrence of fetal exposure to isotretinoin highlights the need for improved practices. These

improvements will likely require intervention at multiple levels, including improved education for patients and healthcare providers, improved patient adherence with established safety protocols, and proper control of isotretinoin's distribution (Choi et al. 2013).

8. Encouraging the use of highly effective, patient-independent contraception and limiting abstinence to women who have never been sexually active may further reduce the rate of isotretinoin exposed pregnancies (Collins et al. 2014).
9. Increase adherence to contraceptive methods that will reduce and, hopefully, eliminate fetal exposure to isotretinoin (Altman 2014).
10. Since few clinicians provide women information on highly effective (i.e., intrauterine or subdermal) contraceptives, the iPLEDGE program increases anxiety about isotretinoin more than it helps women feel protected from the teratogenic risks of isotretinoin (Werner et al. 2014).
11. Surgical shunting for hydrocephalus.
12. Surgical repair of congenital heart defects.
13. Surgical reconstruction of the external ear canal and middle ear.
14. Orthopedic management of limb reduction.
15. Multidisciplinary approach to multiple handicapped conditions.

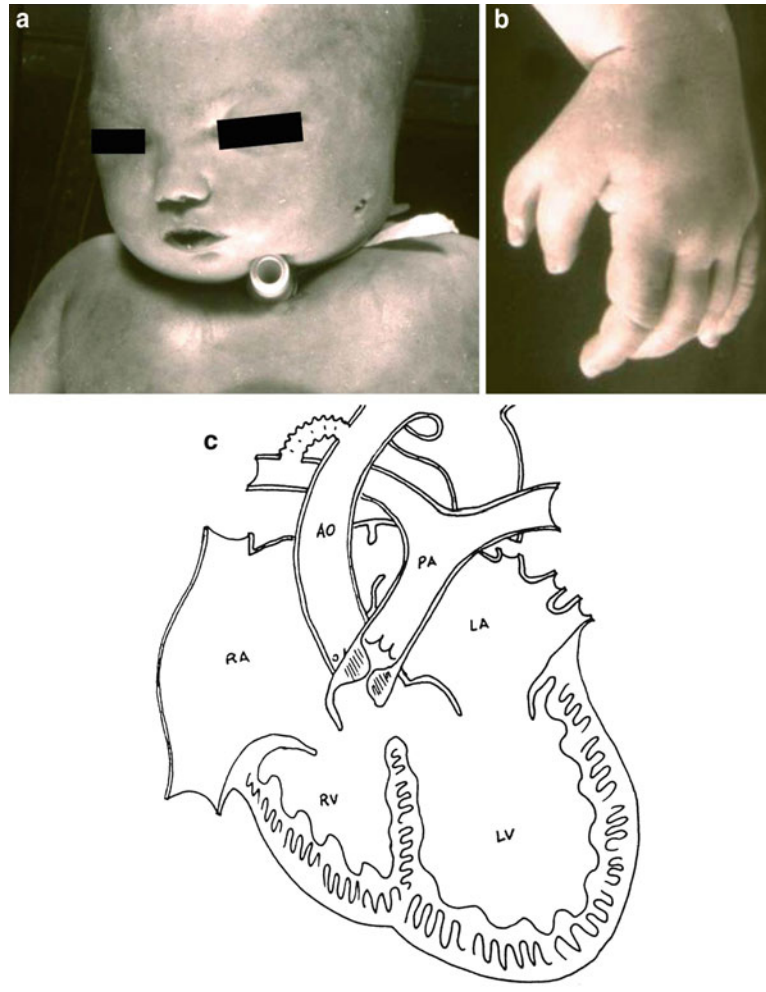

Fig. 1 (**a**–**c**) An infant with isotretinoin embryopathy (**a**, **b**). The mother took Accutane in the first trimester. Prenatal ultrasound examinations revealed intrauterine growth retardation, apparent ocular hypertelorism, flat nasal bridge, and tetralogy of Fallot. Parents elected to continue the pregnancy. The infant was born with dysmorphic craniofacial features (microcephaly, hypertelorism, flat nasal bridge, microretrognathia, cleft palate, absent ear canals and anotia, duplicated thumb on the left hand, anteriorly placed anus, and tetralogy of Fallot (illustrated in a drawing) (**c**))

Rett Syndrome

Contents

Rett syndrome (RTT), a neurodevelopmental disorder affecting girls almost exclusively, was first described by Rett (1966) in 1966. The disorder now bears his name and became widely known after a report of 35 cases by Hagberg et al. (1983). The prevalence is estimated to be 1/10,000–1/15,000 female births (Hagberg 1985); over 95% of cases arise de novo due to the fact that most females with Rett syndrome do not reproduce. Rett syndrome is considered to be one of the most common genetic causes of mental retardation in girls, second only to Down syndrome.

Synonyms and Related Disorders

Ataxia; Autism; Dementia; Loss of purposeful hand use

Genetics/Basic Defects

1. Inheritance:
    1. Sporadic cases (99.5%), occurring almost exclusively in females:
        1. A de novo mutation in the child with Rett syndrome
        2. Disease-causing mutation inherited from one parent who has somatic or germ line mosaicism
    2. Several reports of familial recurrence support X-linked dominant inheritance with lethality in hemizygous males.
2. The region of interest has been localized to Xq28 by linkage analysis from available familial cases (Sirianni et al. 1998; Webb et al. 1998).
3. Caused by mutations in the *MECP2* (methyl-CpG-binding protein 2) gene (Amir and Zoghbi 2000; Lombroso 2000) in Xq28:
    1. Caused by partial loss of *MECP2* function (Amir et al. 2000).
    2. Result in a loss of function by either disrupting the methylated DNA-binding properties of the protein or interfering with its association with transcriptional corepressors.
    3. *MECP2* mutations account for most cases of typical forms of Rett syndrome (Bienvenu et al. 2000).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_202

4. Detection of mutations and variants in the MeCP2 gene in Rett syndrome patients (Hampson et al. 2000):
    1. Missense
    2. Protein truncation (most mutations) (Huppke et al. 2000)
    3. Variants
5. *MECP2* mutations in sporadic or atypical cases (Webb and Latif 2001):
    1. Up to 80% of sporadic affected females.
    2. One third of the clinically atypical cases.
    3. MECP2 mutations in sporadic cases of Rett syndrome are almost exclusively of paternal origin (Trappe et al. 2001).
6. *MECP2* mutations in familial cases (lower incidence):
    1. Germ line mosaic mothers.
    2. Asymptomatic carrier mothers due to nonrandom patterns of X-inactivation. The pattern of X-inactivation most likely protects the mutation carriers from expression of the disease by preferential inactivation of the mutant *MECP2* allele.
7. Clinical spectrum of MECP2 mutations (Shahbazian and Zoghbi 2001):
    1. In classic Rett syndrome, genotype–-phenotype correlation studies suggest that X chromosome inactivation patterns have a more prominent effect on clinical severity than the type of mutation.
    2. When the full range of phenotypes associated with MECP2 mutations is considered, however, the mutation type strongly affects disease severity.
8. Deletion of MeCP2 results in a wide and temporally varied range of phenotypes (Feldman et al. 2016).

4. Rett syndrome targets synapses and synaptic plasticity and has been shown to disrupt the balance between glutamate excitatory synapses and GABAergic inhibitory synapses (Johnston et al. 2015). In fact, it can be argued that Rett syndrome is primarily a disorder of synaptic plasticity and that agents that can correct this imbalance may have beneficial effects on brain development.
5. MeCP2 is a multifunctional protein, with involvement in chromatin architecture, regulation of RNA splicing, and a role both as transcriptional repressor or activator (De Felice et al. 2016):
    1. The MeCP2 protein plays a critical role in the complex pathways linking innate and adaptive immune systems.
    2. MECP2 loss-of-function mutations elicit an inflammatory–autoinflammatory response in Rett syndrome patients.
6. Pathogenesis and clinical course of Rett syndrome: systemic subclinical inflammation and oxidative stress are crucial players of a detrimental vicious circle, driving the pathogenesis and clinical course of RTT (Pecorelli et al. 2016).
7. RTT gastrointestinal physiopathology (Strati et al. 2016):
    1. RTT is associated with a dysbiosis of both the bacterial and fungal component of the gut microbiota, suggesting that impairments of MeCP2 functioning favor the establishment of a microbial community adapted to the costive gastrointestinal niche of RTT patients.
    2. The altered production of short chain fatty acids associated with this microbiota might reinforce the constipation status of RTT patients and contribute to RTT gastrointestinal physiopathology.
8. Females with the *MECP2* mutations (Takahashi et al. 2008):
    1. High frequency of MeCP2 gene mutations causative of Rett syndrome in females and provides data concerning the molecular basis for clinical variability (mutation type and position and X-inactivation patterns) (Hoffbuhr et al. 2001).
    2. Regardless of the type of mutation, the XCI pattern is the major determinant of the phenotype in females (Wan et al. 1999).
    3. Exhibit a broad spectrum of clinical presentations ranging from classical Rett

syndrome to asymptomatic carriers due to differences in X chromosome inactivation (XCI) (Singer and Naidu 2001).
4. Correlation between the intrafamilial phenotypic differences observed in RTT families and their respective XCI pattern in blood (Ravin et al. 2011).
5. Mechanisms other than XCI may contribute to the phenotypic heterogeneity associated with *MECP2* mutations.

9. Males with the *MECP2* mutations:
1. MECP2 mutation causes X-linked mental retardation (Orrico et al. 2000) and progressive spasticity in male patients (Meloni et al. 2000).
2. May suffer from severe neonatal encephalopathy (Villard et al. 2000) and die from breathing difficulties before their second year.
3. The almost absence of men with classic Rett syndrome suggests a lethal effect of the *MECP2* mutation in hemizygous-affected men.
4. However, males with Rett syndrome are not always lethal although neurologic impairment is slowly progressive and much more severe in men than in women (Dotti et al. 2002).
5. Somatic mosaicism could explain the occurrence of other X-linked dominant disorders in males, when they would normally be lethal (Clayton-Smith et al. 2000).
6. Affected men have been reported in association with Klinefelter syndrome and somatic mosaicism.
7. Most *MECP2* mutations have originated in the paternal germ line. The paternal X *MECP2* never passed on from father to their sons.
8. The only way for a male to have Rett syndrome is a de novo mutation of a maternal X or inheritance of an *MECP2* gene mutation from his mother.
9. Some reported *MECP2* mutations may actually represent genetic variant rather than true pathogenetic novel mutations in the *MECP2* gene in males.

10. Genotype–phenotype correlations in males with MECP2 mutations (Moretti and Zoghbi 2006; Villard 2007):
1. The first group
1. Boys with Rett syndrome have XXY karyotype or somatic mosaic and carry the same *MECP2* mutations that cause classic Rett syndrome in girls.
2. The affected boys have severe neonatal encephalopathy and usually die in their first year of life.
3. These mutations can also lead to a milder phenotype when they are diluted among normally expressing cells.
2. The second group
1. Has mutations that are not found in females with Rett syndrome.
2. These mutations are usually compatible with life into adulthood.
3. The neurological presentation ranges from severe to mild nonspecific mental retardation.
3. The third group
1. Composed of males having a duplication of the whole *MECP2* gene (and sometimes genes in its vicinity)
2. The primary clinical features associated with this microduplication are nonspecific, but they comprise a severe phenotype.
3. Affected individuals experience infantile hypotonia (Heilstedt et al. 2002), recurrent respiratory infection, severe mental retardation, absence of speech development, seizures, and spasticity.

10. Clinical phenotypes of MeCP2 dysfunction in Rett syndrome and related disorders (Moretti and Zoghbi 2006; Chahrour and Zoghbi 2007):
1. Females (loss-of-function of MeCP2)
1. Classic Rett syndrome
2. Atypical Rett (preserved speech or normal hand use)
3. Infantile encephalopathy

4. Angelman syndrome phenotype
5. Mental retardation with seizures
6. Mild mental retardation
7. Learning disability
8. Autism
9. Normal

2. Males (loss-of-function of MeCP2)
   1. Infantile encephalopathy
   2. Classic Rett syndrome (47, XXY or somatic mosaics)
   3. Mental retardation with motor deficits
   4. Bipolar disorder, mental retardation, and tremors
   5. Juvenile-onset schizophrenia, mental retardation, and tremors
   6. Mental retardation, psychosis, pyramidal signs, and macroorchidism
3. MECP2 gene duplications (overexpression)
   1. Preserved speech variant of Rett syndrome (De Bona et al. 2000)
   2. Severe mental retardation and clinical features of Rett syndrome
   3. Nonspecific X-linked mental retardation

Clinical Features

1. Wide spectrum of clinical features associated with *MECP2* mutation (Auranen et al. 2001)
   1. Male patients with early-onset lethal encephalopathy to adult cases with severe mental retardation
   2. Female patients from asymptomatic or mildly mentally retarded to severe variant of Rett syndrome with congenital onset
2. Normal prenatal and perinatal history
3. Appropriate head circumference
4. Apparently normal psychomotor development until about 6–18 months of life in affected girls
5. Developmental milestones afterward beginning to slow down and regress with loss of skills already achieved
   1. Deterioration of communicative skills
   2. Social withdrawal
   3. Loss of purposeful hand movement
6. Continued deterioration over the next few years
   1. Loss of language
   2. Poor motor function (truncal and gait apraxia/ataxia)
   3. Stereotypic hand movements (hand wringing and flapping)
   4. Deceleration of head growth (acquired microcephaly)
   5. Autistic behavior
7. Period of stabilization
   1. Severe psychomotor dysfunction.
   2. Some patients may make small recoveries in contact and communication skills.
8. Breathing difficulties
   1. Periodic apnea
   2. Hyperventilation
   3. Breath holding
   4. Forced explosion of air/saliva
   5. Bruxism
9. Swallowing difficulties
10. Dystonia and hand and foot deformities as affected girls grow older
11. Later development of scoliosis
12. Osteoporosis at risk for fractures
13. Seizures (epilepsy) in 50% affected females
14. Possible survival into adulthood without further deterioration
15. An increased risk for sudden, unexplained death
    1. Longer corrected QT intervals
    2. T-wave abnormalities
    3. Reduced heart rate
16. Rett syndrome variants (Hagberg and Skjeldal 1994; Hagberg 1995) (<10% of cases)
    1. Patients with a milder clinical course ("forme fruste" phenotype): considered to be the most common variant of nonclassical Rett syndrome
       1. Less dramatic regression
       2. Mild learning disability
       3. Milder mental retardation
       4. Preserved speech
       5. Ability to walk
       6. Some hand use
       7. Usually without seizures

8. No apparent symptoms observed in a few women who demonstrate skewed X chromosome inactivation
2. Patients with a severe phenotype
   1. Lack of normal postnatal developmental period
   2. Congenital hypotonia
   3. Infantile spasms
3. Patients with late regression
4. Male patients with Rett syndrome
   1. Males with XXY (Klinefelter syndrome) (Schwartzman et al. 1998)
   2. Males with somatic mosaicism
   3. Males with XY (normal karyotype)
5. Male Rett syndrome variant: males with idiopathic developmental regression, autistic features, and loss of hand function (Jan et al. 1999)

17. Clinical stages in classic Rett syndrome (Percy 1995; Jedele 2007; Briggs 2013)
    1. Stagnation stage (early infancy to 18 months)
       1. Developmental arrest
       2. Deterioration of eye contact and possible loss of communication
    2. Rapid destructive stage (1–4 years): developmental regression
       1. Developmental deterioration
       2. Loss of acquired skills, including fine motor, babbling of words, and active playing
       3. Loss of purposeful hand use
       4. Stereotyped hand movements
       5. Apparent cognitive impairment
       6. Intermittently "in another world"
       7. Autistic features
       8. Gait ataxia and apraxia
       9. Irregular breathing (hyperventilation)
       10. Seizures in only 15%
    3. Pseudostationary stage (preschool–early school years)
       1. Some communication improvements
       2. "Wake-up" period
       3. Decreased autistic features
       4. Preserved ambulation (A few are never ambulant.)
       5. Prominent gait ataxia and hand apraxia
       6. Slow neuromotor regression
       7. Seizures most frequent and severe
    4. Late motor deterioration stage (5–25 years)
       1. Decreased mobility (loss of ambulation)
       2. Severe debilitation in patients who never walked
       3. Spasticity
       4. Improved emotional contact
       5. Scoliosis
       6. Severe wasting and debilitation leading to "frozen stiffness"
       7. Cachexia and growth retardation
       8. Staring, unfathomable gaze
       9. Complete wheelchair dependency
       10. Seizures may lessen or disappear
18. Wide spectrum of clinical features associated with an *MECP2* mutation
    1. Male patients with early-onset lethal encephalopathy
    2. Adult cases with severe mental retardation
    3. Female cases
       1. Asymptomatic
       2. Mildly mentally retarded
       3. Severe variant of Rett syndrome with congenital onset
19. Clinical findings in males with MECP2 mutation (Imessaoudene et al. 2001; Laccone et al. 2002)
    1. Normal pregnancy/delivery
    2. Developmental delay
    3. Severe mental retardation
    4. Acquired microcephaly
    5. Seizures
    6. Neurological findings
       1. Restless, uncoordinated movements
       2. Hypotonia
       3. Hyperlaxity
       4. Mild distal muscular atrophy
       5. Periodic breathing
       6. Dorsal extension of the hands
       7. Neurogenic muscular atrophy
    7. Purposeful hand skills
    8. Loss of skills
    9. Electroencephalogram: generalized slow waves
    10. Brain MRI: marked brain atrophy

20. Cardinal clinical features of Rett syndrome in relation to pathology (Julu et al. 2008; Smeets et al. 2011)
    1. Decreased dendritic arborization and smaller than normal brain (cortical); severe intellectual disability
    2. Epilepsy (cortical): seizures
    3. Monoaminergic dysfunction (extrapyramidal):
        1. Dystonia
        2. Incoordination of motor activities
        3. Secondary orthopedic deformities and muscle wasting with contractures
    4. Monoaminergic dysfunction (brainstem):
        1. Dyspraxia
        2. Agitation
        3. Sleep disturbances
    5. Immaturity with incompetence of inhibitory neuronal networks (brainstem): Abnormal breathing rhythms and lack of integrative inhibitions are likely causes of sudden deaths.
    6. Dysautonomia (brainstem):
        1. Cold and blue extremities
        2. Sympatho-vagal imbalance
21. Relatively restrictive international diagnostic criteria (The Rett syndrome Diagnostic Criteria Work Group 1988)
    1. Apparently normal prenatal and perinatal period*
    2. Normal head circumference at birth
    3. Apparently normal development through age 6 months*
    4. Deceleration of head growth occurring anytime between ages 3 months and 48 months
    5. Loss of acquired hand skills and purposeful hand use between ages 5 months and 30 months, with subsequent development of stereotyped hand movements
    6. Severe impairment of expressive and receptive language together with severe psychomotor retardation
    7. Development of gait apraxia and truncal ataxia between ages 12 months and 48 months

    * Clinical criteria "a" and "c" may not be applicable to severely affected females; other criteria will not apply to those who are mildly affected and are identified as having mutations in *MECP2*.
22. Modified diagnostic criteria (Percy 1995; Clarke in 1996)
    1. Necessary criteria
        1. Normal prenatal and perinatal development
        2. Loss of acquired skills such as communication and speech
        3. Normal head circumference at birth with acquired microcephaly
        4. Deceleration of head growth
        5. Marked developmental delay
        6. Loss of acquired hand skills
        7. Loss of communication skills (words and interpersonal)
        8. Autistic features
        9. Gait apraxia
        10. Stereotypic handwringing or handwashing
    2. Supportive criteria
        1. Seizures
        2. Abnormal EEG
        3. Awake breathing dysfunction
            1. Apnea
            2. Hyperventilation
            3. Forced air or saliva expulsion
            4. Air swallowing
            5. Breath holding
        4. Growth retardation
        5. Bruxism
        6. Cold feet
        7. Scoliosis
        8. Vasomotor instability
        9. Gait dyspraxia
        10. Spasticity with muscle wasting
        11. Unprovoked laughing or screaming
        12. Reduced or altered pain response
        13. "Eye pointing"
23. Revised diagnostic criteria for classical and variant Rett syndrome (Ellaway and Christodoulou 1999; Hagberg et al. 2002; Williamson and Christodoulou 2006)
    1. Classical Rett syndrome
        1. Necessary criteria
            1. Normal prenatal and perinatal history

2. Normal psychomotor development for the first 6 months
3. Normal head circumference at birth
4. Postnatal deceleration of head growth in most individuals
5. Loss of purposeful hand skills between 6 months and 2.5 years
6. Hand stereotypes
7. Evolving social withdrawal, communication dysfunction, loss of acquired speech, and cognitive impairment
8. Impairment or deterioration of locomotion

2. Supportive criteria
   1. Breathing disturbances during waking hours
   2. Bruxism
   3. Impairment of sleeping pattern from early infancy
   4. Abnormal muscle tone associated with muscle wasting and dystonia
   5. Peripheral vasomotor disturbances
   6. Progressive kyphosis or scoliosis
   7. Growth retardation
   8. Hypotrophic small and cold feet and/or hands
3. Exclusion criteria
   1. Evidence of a storage disorder including organomegaly
   2. Cataract, retinopathy, or optic atrophy
   3. History of perinatal or postnatal brain damage
   4. Confirmed inborn error of metabolism or neurodegenerative disorder
   5. Acquired neurological disorder due to severe head trauma or infection

3. Variant Rett syndrome
   1. Inclusion criteria
      1. At least three of the six main criteria
      2. At least 5 of the 11 supportive criteria
   2. Main criteria
      1. Reduction or absence of hand skills
      2. Loss or reduction of speech (including babble)
      3. Hand stereotypes
      4. Loss or reduction of communication skills
      5. Deceleration of head growth from early childhood
      6. Regression followed by recovery of interaction
   3. Supportive criteria
      1. Breathing irregularities
      2. Abdominal bloating or air swallowing
      3. Bruxism
      4. Abnormal locomotion
      5. Kyphosis or scoliosis
      6. Lower limb amyotrophy
      7. Cold, discolored, and usually hypotrophic feet
      8. Nighttime screaming and other sleep disturbances
      9. Inexplicable episodes of screaming or laughing
      10. Apparently diminished sensitivity to pain
      11. Intense eye contact and/or eye pointing

24. Differential diagnosis (Christodoulou and Ho 2012)
    1. Angelman syndrome (Please see the chapter on "► Angelman Syndrome")
    2. Pathogenic variants in *CDKL5*, a gene also located on the X chromosome and encoding cyclin-dependent-like kinase 5, have been identified in individuals with a Rett syndrome-like phenotype.
    3. Pathogenic variants in *FOXG1* are associated with the congenital form of Rett syndrome (Ariani et al. 2008; Bahi-Buisson et al. 2010; Mencarelli et al. 2010). The gene was first implicated in Rett syndrome by identification of microdeletions at its genetic locus on 14q12 (Papa et al. 2008; Jacob et al. 2009).
    4. Cerebral palsy (please see the chapter on "Cerebral Palsy")
    5. Autism (please see the chapter on "► Autism")

Diagnostic Investigations

1. Mutational analyses of *MECP2* gene (Buyse et al. 2000):
   1. Sequence analysis and mutation scanning.
   2. Mutations detected in 35–90% of patients (detected in almost every patient with classical Rett syndrome).
   3. Wide spectrum of mutations of the *MECP2* gene (Obata et al. 2000):
      1. Missense
      2. Nonsense
      3. Frameshift and stop
   4. Mutations extending to phenotypes that are not easily recognized as Rett syndrome.
   5. No significant correlation exists between the clinical course and mutation type.
   6. *MECP2* mutations have been identified in patients previously diagnosed with the following conditions:
      1. Autism
      2. Mild learning disability
      3. Clinically suspected but molecularly unconfirmed Angelman syndrome
      4. Mental retardation with spasticity or tremor
   7. Clinical predictors that facilitate a clinician's decision to order genetic testing for Rett syndrome (Knight et al. 2016):
      1. Loss of hand skills resulted in the highest odds of having a positive genetic test.
      2. Gait abnormalities and stereotypic hand movements were also strong predictors of MECP2þ testing.
      3. Many individuals with language delay had genetic testing; however, this is the least specific of the major criteria.
      4. These findings have implications for which patients should have genetic testing.
2. X chromosome inactivation pattern: not tested routinely
3. EEG: not specific
4. CT and MRI
   1. Cortical atrophy predominantly in the frontal area
   2. No abnormalities in the white matter, basal ganglia, thalamus, or hippocampus
   3. Narrowing of the brain stem in some patients
5. Photon emission CT
   1. Lower cerebral blood flow in the prefrontal and temporoparietal association regions with sparing of the sensorimotor regions
   2. The flow distribution in Rett patients
      1. Similar to that observed in infants of a few months of age
      2. Suggesting a neurodevelopmental abnormality rather than a neurodegenerative process

Genetic Counseling

1. Recurrence risk:
   1. Patient's sib
      1. 50% risk to sibs of inheriting *MECP2* allele from the carrier mother.
      2. Low risk to sibs (<1/300) (Killian 1986) when a mutation present in the proband is not identified in a parent, provided germ line mosaicism is not present in either parent (Amir et al. 1999; Mari et al. 2005).
   2. Patient's offspring
      1. Unlikely to have offspring due to mental retardation and other handicaps
      2. Reproduction reported in mildly affected females
         1. Each offspring of a carrier female with 50% risk of inheriting the disease-causing mutation.
         2. Daughters who inherit the mutation are at high risk of developing classic Rett syndrome although skewed X chromosome inactivation may result in a milder phenotype.
         3. Sons who inherit the mutation may suffer a severe neonatal encephalopathy or severe mental retardation in those who survive beyond the first year of age.
      3. Healthy sisters of a girl with Rett syndrome

1. Possibility of being carriers of the *MECP2* mutation but with little or no symptoms because of favorable skewed X chromosome inactivation
2. At risk of transmitting the disease-causing *MECP2* mutation to their own children

4. No male with an *MECP2* mutation known to reproduce

2. Prenatal diagnosis (Christodoulou and Ho 2012):
   1. Amniocentesis or chorionic villus sampling available to pregnancies at risk for women with a known *MECP2* mutation identified in a family member
   2. Appropriate to offer prenatal diagnosis to couples who have had a child with Rett syndrome or mental retardation due to an *MECP2* mutation, whether or not the disease-causing mutation has been identified in a parent since germ line mosaicism cannot be excluded in either parent
   3. A male fetus with the mutation
      1. May suffer from a severe neonatal encephalopathy
      2. May survive with a severe mental retardation syndrome
   4. A female fetus with the mutation
      1. Difficult to predict the phenotype in a female fetus with an *MECP2* mutation which can range from apparently normal to severely affected
      2. At high risk of developing classic Rett syndrome although skewed X chromosome inactivation may result in a milder phenotype
3. Preimplantation genetic diagnosis (PGD) may be an option for some families in which the pathogenic variant has been identified (Christodoulou and Ho 2012).
4. Management (Budden 1997; Naidu 1997):
   1. No treatment is known to improve the neurologic outcome of Rett patients.
   2. Supportive and symptomatic therapies:
      1. The most important aspects are high caloric intake to overcome the energy expenditure from increased motor activity (Naidu 1997).
      2. Feeding and swallowing difficulties may warrant a gastrostomy.
      3. Constipation beginning early in life is easily relieved with mineral oil and stool softeners.
      4. Anticonvulsants for seizures.
      5. Chloral hydrate for agitation.
      6. Carbidopa and levodopa for rigidity.
      7. Melatonin for sleep disturbances.
      8. Management of gastroesophageal reflux:
         1. Antireflux agents
         2. Smaller and thickened feedings
         3. Positioning
   3. Occupational and physical therapies:
      1. Maintain function
      2. Prevent scoliosis and deformities
   4. Augmentative communication.
   5. Facilitate communication.
   6. Maintain hand function and ambulation.
   7. Decreasing repetitive purposeless hand movements can be achieved by the use of various arm restraints, such as soft elbow splints, and are occasionally helpful in training specific hand skills such as self-feeding. These methods are also helpful in decreasing agitation and self-injurious behavior (Ellaway and Christodoulou 1999).
   8. Prevent deformities.
   9. Therapeutic horseback riding, swimming, and music therapy.
   10. During adulthood, continuation of multidisciplinary services and programs is necessary to optimize health and wellbeing (Anderson et al. 2014).
   11. Several clinical studies are under way to attempt to normalize synaptic abnormalities in Rett syndrome (RTT) (Johnston et al. 2015):
      1. Studies by Naidu et al. with dextromethorphan, a clinically approved competitive *N*-methyl-D-aspartate (NMDA) receptor blocker: A randomized unblinded trial of dextromethorphan showed improvement in receptive language in girls with RTT.
      2. Preclinical studies suggest that low-dose ketamine, a noncompetitive NMDA

blocker, might be useful for improving the connectivity of brain circuits affected in RTT and improving function.
3. Human recombinant IGF-1 has also shown benefit in mice with Mecp2 deficiency, and a preliminary study in girls with RTT showed that it was well tolerated and may have some benefits.

Fig. 1 A girl with Rett syndrome

Fig. 2 A girl with Rett syndrome who has *MECP2* mutation (R106W)

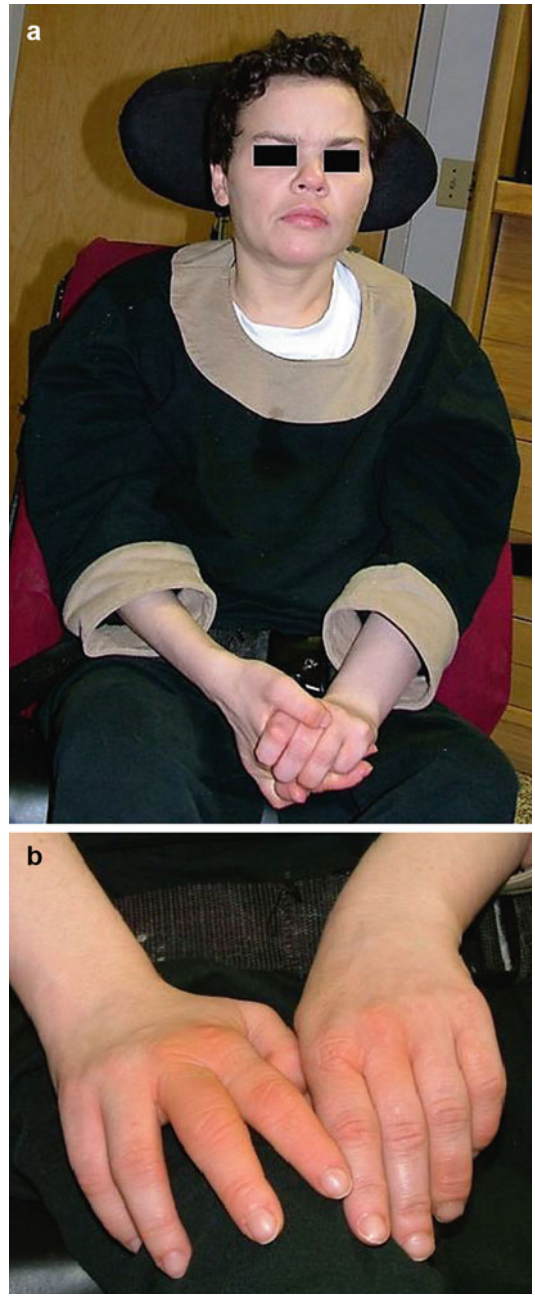

Fig. 3 (**a**, **b**) A 33-year-old female (**a**) with Rett syndrome showing severe psychomotor retardation and hand wringing so severe that the part of the hand and fingers are red, rough, and swollen from constant irritation by stereotypic hand movement (**b**). She was normal developmentally until about 18 months of age when she started to have handwashing/wringing, tiptoe walking, fell easily, and lost the skills she already attained. Shortly after, she started to lose eye contact with people and has seizures. DNA sequence analysis identify a nucleotide change of 763 C > T in one copy of the *MECP2* gene which predicts an amino acid change of arginine to a premature translation stop at codon 255 (R255X). This nonsense mutation was previously identified in multiple Rett syndrome patients as a disease-causing *MECP2* mutation

Rickets

Contents

Normal bone mineralization requires adequate supplies of calcium and phosphate and normal vitamin D metabolism (Norman 1982). Defective supply or function of any of these factors can cause rickets and osteomalacia (Pitt 1991). Nutritional rickets is a major public health problem in many countries of the world (Prentice 2013).

Synonyms and Related Disorders

Cutaneous skeletal hypophosphatemia syndrome; Familial hypophosphatemic rickets; Hereditary pseudo-vitamin D deficiency rickets; Nutritional rickets; Vitamin-deficiency rickets; Vitamin D-dependent rickets

Genetics/Basic Defects

1. Classification of rickets (Mughal 2011; Pai and Shaw 2011; Shore and Chesney 2013b)
    1. Calcipenic rickets
        1. Rickets due to dietary calcium deficiency or interruption in the supply, metabolism, or utilization of vitamin D
        2. Nutritional vitamin D deficiency
        3. Vitamin D deficiency due to:
            1. Malabsorption
            2. Liver disease
            3. Renal insufficiency
        4. Impaired hepatic 25-hydroxylation
        5. Impair renal 1α-hydroxylation of 25 (OH)D
        6. End-organ resistance to $1,25(OH)_2D$
    2. Phosphogenic (hypophosphatemic) rickets (DiMeglio and Econs 2001; Baroncelli et al. 2012)
        1. Primary
            1. X-dominant hypophosphatemic rickets (*PHEX* gene mutation)
            2. Autosomal dominant hypophosphatemic rickets (*FGF23* mutation)
            3. Autosomal recessive hypophosphatemic rickets type 1 (*DMP1* mutation)
            4. Autosomal recessive hypophosphatemic rickets type 2 (*ENPP1* mutation)
            5. Hereditary hypophosphatemic rickets with hypercalcinuria (*SLC34A3* gene mutation)
            6. X-linked recessive hypophosphatemic rickets (*CLCN5* mutation)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_203

7. Hypophosphatemic rickets and hyperparathyroidism (a translocation causing increased α-Klotho level) (Brownstein et al. 2008)
   2. Secondary
      1. Fibrous dysplasia: McCune-Albright syndrome
      2. Tumor-induced (oncogenic) osteomalacia
      3. Linear nevus sebaceous syndrome
      4. Ifosfamide nephrotoxicity
      5. Fanconi syndrome
      6. Low dietary phosphate intake
2. Major regulators of mineral homeostasis (Shore and Chesney 2013a)
   1. Parathyroid hormone (PTH) (Kruse 1995)
      1. Bone resorption to mobilize calcium and phosphate: increased by low Ca++ concentration via parathyroid calcium-sensing receptor
      2. Upregulates 1-OHase to promote calcitriol synthesis: decreased by calcitriol
      3. Increases calcium reabsorption in distal tubule decreased by FGF-23
      4. Decreases phosphate reabsorption in proximal tubule
   2. Calcitriol
      1. Increases gut absorption of Ca and phosphate: increased by PTH
      2. Permissive for PTH effect on bone resorption: decreased by FGF-23
   3. FGF-23
      1. Increases phosphate excretion by decreasing tubular reabsorption: increased by calcitriol
      2. Downregulates 1-OHase to decrease calcitriol synthesis: increased by high dietary or circulating phosphate, although no phosphate-sensing receptor found
3. Causes of rickets by age of onset
   1. Younger than 6 months of age
      1. The fetus is protected by the calcium trans-placental pump, but in severe maternal chronic osteomalacia such as with morbid exhaustion of calcium and in maternal malabsorption (Begum et al. 1968), neglected renal failure, prematurity, or inherited diseases, rickets might show up clinically at birth (Elidrissy 2016).
      2. Hypophosphatasia (Currarino et al. 1957).
      3. Prematurity.
      4. Primary hyperparathyroidism.
      5. Maternal factors.
         1. Vitamin D deficiency (Mancrieff and Fadahunsi 1974)
         2. Poorly controlled hyperparathyroidism
         3. Poorly controlled renal insufficiency (Levin et al. 1992)
   2. Older than 6 months of age
      1. Nutritional rickets in children (Felman et al. 1990)
         1. Inadequate levels (deficiency) of vitamin D due to either inadequate oral intake or insufficient exposure to sunlight (Bishop1999).
         2. With resultant decreased calcium absorption in the small intestine.
         3. Thereby decreasing the available calcium for epiphyseal cartilage and skeletal mineralization.
         4. Secondary hyperparathyroidism due to limited calcium availability and attendant renal phosphate losses contributes to the bone and growth plate pathophysiology that lead to the clinical manifestations of rickets.
      2. Liver disease (impaired 25-vitamin D formation)
         1. Chronic liver diseases (extrahepatic biliary atresia, total parenteral nutrition, tyrosinemia)
         2. Anticonvulsant therapy
      3. Malabsorption
         1. Celiac disease
         2. Inflammatory bowel disease
         3. Pancreatic insufficiency
      4. Renal tubular insufficiency (hypophosphatemia)
         1. Vitamin D-resistant rickets
         2. Vitamin D-dependent rickets
         3. Fanconi syndrome

4. Lowe syndrome
5. Cystine storage disease

5. Chronic renal disease (renal osteodystrophy)
1. Pyelonephritis
2. Polycystic kidney disease
3. Chronic glomerulonephritis
4. Renal tubular acidosis

4. Hypophosphatemic disorders (Goldsweig and Carpenter 2015)
1. Fibroblast growth factor-23 (FGF23) (Hardcastle and Dittmer 2015) regulates phosphate reabsorption in the kidney and therefore plays an essential role in phosphate balance in humans.
2. There is a host of defects that ultimately lead to excess FGF23 levels and thereby cause renal phosphate wasting and hypophosphatemic rickets:
1. X-linked hypophosphatemia (XLH), the best characterized of these abnormalities
2. Autosomal dominant hypophosphatemic rickets (ADHR)
3. Autosomal recessive hypophosphatemic rickets (ARHR)
4. Tumor-induced osteomalacia (TIO)
5. Other rarer FGF23-mediated conditions
1. Osteoglophonic dysplasia (OGD)
2. Epidermal nevus syndrome (ENS)
3. McCune-Albright syndrome (MAS) (please see the chapter on "McCune-Albright Syndrome")
4. Neurofibromatosis 1 (please see the chapter on "Neurofibromatosis 1")
5. A nonlethal variant of Raine syndrome:

5. Vitamin D deficiency rickets: caused by low endogenous vitamin D
1. Selected pediatric populations at high risk for vitamin D deficiency
1. Dietary factors (breast-fed infants with marginal calcium stores due to low levels of vitamin D in breast milk)
2. Skin pigmentation (African American children due to dark skin absorbing ultraviolet radiation less available for vitamin D production) (Kreiter et al. 2000)
3. Sunscreen application
4. Insufficient sun exposure (far northern latitudes, during the winter months, cultural traditions)
5. Latitude (Singleton et al. 2015)
2. Other predisposing factors
1. Severe liver failure
2. Nephrotic syndrome
3. Severe malnutrition
4. Gastrointestinal diseases leading to malabsorption, including impaired fat absorption or enterohepatic recirculation

6. Vitamin D-dependent rickets: caused by reduced activity of 25(OH)1-alphahydroxylase
1. Vitamin D-dependent rickets type I (1α-hydroxylase deficiency) (Miller 2016)
1. Autosomal recessive disorder.
2. Commonly found in the French Canadian population.
3. The gene locus mapped to chromosome 12q14.
4. Caused by mutation in the vitamin D 1-alpha-hydroxylase gene.
5. Impaired 1-alpha-hydroxylation in the renal proximal tubule that converts 25 (OH)D to $1,25(OH)_2D$.
6. Novel pathogenic mutations of the *CYP27B1* gene were reported patients with vitamin D-dependent rickets type 1A (Babiker et al. 2014; Demir et al. 2015).
7. Mutations in *CYP2R1* are responsible for an atypical form of vitamin D-deficiency rickets, which has been classified as vitamin D-dependent rickets type 1B (Thacher and Levine 2016).
8. The disease formerly known as "hereditary pseudo-vitamin D deficiency rickets" (PDDR), "vitamin D-dependent rickets," or "vitamin D-dependent rickets type I" is now more properly called vitamin D 1-alpha-hydroxylase deficiency, as it is known to be caused by mutations in CYP27B1, which converts 25OHD to $1,25(OH)_2D$ (Miller and Portale 2000).
2. Vitamin D-dependent rickets type II (receptor mutation): also known as hereditary

vitamin D-resistant rickets (Malloy et al. 1999)
1. Autosomal recessive inheritance
2. Caused by mutations in the vitamin D receptor (VDR) that result in end-organ resistance to active vitamin D (1,25-dihydroxyvitamin D) [1,25-$(OH)_2D_3$]
3. Major defect caused by the mutant VDR: a decrease of intestinal calcium and phosphate absorption which leads to decreased bone mineralization and rickets
4. The major biochemical distinction between type I and type II
    1. Low circulating 1,25-$(OH)_2D_3$ levels in patients with type I
    2. High circulating 1,25-$(OH)_2D_3$ levels in patients with type II

7. Familial hypophosphatemic rickets
    1. A heterogeneous disease with an incidence of 1 in 20,000 newborns
    2. Caused by defect in reabsorption of phosphate in the proximal tubule, resulting in hypophosphatemia, defective bone mineralization, normocalcemic rickets, and short stature
    3. Types of hypophosphatemia
        1. Dominant X-linked hypophosphatemic rickets (also called vitamin D-resistant rickets)
            1. The gene locus: mapped to Xp22.1.
            2. The gene responsible: phosphate-regulating (*PHEX*) gene with homologies to endopeptidases in the X chromosome (the HYP Consortium (1995; Chandran et al. 2010).
            3. Complete penetrance.
            4. This is the most common form of metabolic rickets.
        2. Autosomal dominant hypophosphatemic rickets
            1. The gene locus: mapped to 12p13
            2. Caused by mutations in *FGF23*
            3. Incomplete penetrance
        3. Autosomal recessive hypophosphatemic rickets (Farrow et al. 2009; Levy-Litan et al. 2010; Lorenz-Depiereux et al. 2010)
            1. Caused by mutations in dentin matrix protein-1 (*DMP1*) gene, which is associated with elevated fibroblast growth factor 23 (FGF23), or ectonucleotide pyrophosphatase/phosphodiesterase 1 (*ENPP1*) gene.
            2. Surprisingly, *ENPP1* loss-of-function mutations have previously been described in generalized arterial calcification of infancy, suggesting an as yet elusive mechanism that balances arterial calcification with bone mineralization.
        4. Hereditary hypophosphatemic rickets with hypercalcinuria (Pettifor 2008)
            1. Caused by *SLC34A3* mutations
            2. Gene product: inactivating mutation in NaPi-IIc (renal Na-P_i cotransporter)
            3. Elevated 1,25$(OH)_2D$

8. Cutaneous skeletal hypophosphatemia syndrome (CSHS) (Lim et al. 2016).
    1. A multilineage somatic mosaic *RAS*opathy.
    2. Identical RAS mutations in the affected skin and bone.
    3. Features epidermal or melanocytic nevi and hypophosphatemic rickets with elevated levels of a serum phosphatonin, fibroblast growth factor (FGF)-23 (Lim et al. 2014).
    4. Patients often require phosphate and calcitriol supplementation to maintain mineral homeostasis.

Clinical Features

1. Rickets versus osteomalacia
    1. Rickets: occurs only before fusion of the epiphyses.
    2. Osteomalacia: occurs in adults deficient in calcium, phosphate, or vitamin D.
2. Signs of rickets in osseous tissues (Wharton and Bishop 2003)
    1. Craniotabes in newborn baby and young infant
        1. Softening of skull bones
        2. May be present but not pathognomonic

2. Frontal bossing in early infancy
    1. Expansion of cranial bones relative to facial bones
    2. Also possibly due to hydrocephalus ("rickets hydrocephalus")
3. Fontanelle
    1. Delayed closure
    2. Occasional intracranial hypertension
4. Wrists: an apparent bracelet of the bone around the wrist (specificity 81%)
5. Rickety rosary: swollen costochondral junctions of ribs (specificity 64%)
6. Skeletal deformities
    1. Particularly, "bow legs" once the child is walking.
    2. Genu valgum generally not due to rickets.
    3. Spinal curvature most likely due to nonrickets cause.
    4. Narrowed pelvic outlet used to cause obstructed labor.
    5. The "double malleoli" sign (Kumar et al. 2015): The knobbed ankle of the rachitic child (anterior view) takes appearance of two distinct medial prominences resembling a second malleoli, one atop of the other.
7. Brown tumor: rare fibrous-cystic osteitis associated with the secondary hyperparathyroidism
8. Limb pain
    1. Bone pain and pseudoparalysis uncommon
    2. Osteomalacia and the subperiosteal hematoma of scurvy: more likely causes of pain
9. Teeth
    1. Delayed eruption of teeth
    2. Enamel hypoplasia: greater susceptibility to caries in the first dentition

3. Nonosseous effect of vitamin D deficiency (Wharton and Bishop 2003)
    1. Symptomatic hypocalcemia with convulsions: particularly in young infants less than 6 months of age born to mothers with untreated osteomalacia, many of whom are subclinical cases.
    2. Myopathy.
        1. Proximal myopathy in infants and adolescents
        2. Heart failure simulating cardiomyopathy with severe hypocalcemia
        3. Responding to treatment for rickets and inotropes
    3. Myelofibrosis.
        1. With pancytopenia or microcytic hypochromic anemia
        2. Returning to normal when treated with vitamin D
    4. Possible link between early vitamin D deficiency and other disorders in later life.
        1. Type I diabetes
        2. Multiple sclerosis
        3. Schizophrenia
        4. Hear disease
    5. Intrauterine and infant growth: vitamin D supplement in the last trimester of pregnancy improves growth in utero and during infancy in some studies.
4. Vitamin D deficiency rickets (Joiner et al. 2000; Elder and Bishop 2014)
    1. History
        1. Dark skin color
        2. Reduced skin exposure
        3. No vitamin D supplementation during pregnancy
        4. Prolonged exclusive breastfeeding
        5. No vitamin D supplementation of infant
        6. Use of foods high in phytates
        7. Iron deficiency
        8. Not clinically apparent before 6 months of age because of prenatal stores of vitamin D imparted by the mother
    2. Skeletal features
        1. Slowing linear growth
        2. Metaphyseal swelling at long-bone ends
        3. Rickety rosary
        4. Bowing deformity of long bones
        5. Frontal bossing
        6. Craniotabes
        7. Persistent anterior fontanelle
        8. Harrison's sulci
        9. Development of secondary hyperparathyroidism due to increasing severity of vitamin D deficiency, progressing to frank osteomalacia and fractures

3. Nonskeletal features
    1. Hypocalcemic convulsions
    2. Hypocalcemic cardiac failure
    3. Hypotonia
    4. Delayed motor milestones
    5. Carpopedal spasm
    6. Enamel hypoplasia
    7. Delayed dentition
    8. Failure to thrive
    9. Fractious, irritable child
    10. Bone pain
5. Vitamin D-dependent rickets
    1. Vitamin D-dependent rickets type I (hereditary pseudo-vitamin D deficiency rickets)
        1. Clinical presentation within the first few months of life
        2. First clinical sign: acute or chronic hypocalcemia because the major physiologic role of 1,25-dihydroxyvitamin D is to promote intestinal calcium absorption
        3. Hypocalcemic seizures as early as 4 weeks of age or usually before 2 years of age
        4. Growth retardation
        5. Bowing of the extremities
        6. Bone pain secondary to rickets and osteomalacia
        7. Enamel hypoplasia and oligodontia
        8. Hypocalcemia accompanied by secondary hyperparathyroidism resulting in hypophosphatemia and occasional aminoaciduria
    2. Vitamin D-dependent rickets type II (hereditary vitamin D-resistant rickets)
        1. Onset of disease: infancy or childhood.
        2. Major clinical findings: hypocalcemia and rickets due to defective intestinal calcium absorption lead to impaired mineralization of newly forming bone and preosseous cartilage.
        3. Rickets.
            1. Often severe
            2. Usually exhibits within months of birth
        4. Bone pain.
        5. Muscle weakness.
        6. Hypotonia.
        7. Occasional convulsions from hypocalcemia.
        8. Often growth retarded.
        9. Enamel hypoplasia, oligodontia, and severe dental caries.
        10. Hypocalcemia accompanied by secondary hyperparathyroidism results in hypophosphatemia and occasional aminoaciduria.
        11. Pneumonia secondary to severe rickets of the chest wall and poor respiratory effort causes death in some infants.
        12. Alopecia (Al-Khenaizan and Vitale 2003)
            1. Sparse body hair in many patients
            2. Alopecia totalis observed in some kindreds, including eyebrows and in some cases eyelashes
6. Hereditary hypophosphatemic rickets
    1. X-linked dominant hypophosphatemic rickets
        1. Characterized by renal phosphate wasting with hypophosphatemia.
        2. Disease severity is similar in males and females but differs among individuals (some patients with isolated hypophosphatemia; others with disabling severe bone disease).
        3. The disease may persist into adulthood.
        4. Short stature.
        5. Rickets with resultant lower-extremity deformities.
        6. Bone pain.
        7. Enthesopathy (calcification of tendons, ligaments, and joint capsules).
        8. Deficient calcification of teeth (Sarat et al. 2016).
            1. Delayed eruption
            2. Spontaneous periapical infections
            3. Exfoliation
            4. Dental abscesses
        9. Cranial abnormalities (e.g., craniosynostosis) (Murthy 2009) and spinal stenosis in some severely affected individuals.
        10. X-linked hypophosphatemic rickets has been associated with craniosynostosis, the sagittal suture being the most

commonly involved. Rachitic patients with scaphocephaly should be screened for craniosynostosis (Jaszczuk et al. 2016).

11. Secondary craniosynostosis develops postnatally due to metabolic or mechanical factors. The most common metabolic cause is hypophosphatemic rickets, which has a variety of etiologies. Head shape changes occur later and with a more heterogeneous presentation compared with that of primary craniosynostosis. Cranial vault remodeling (CVR) may be required to prevent or relieve elevated intracranial pressure and abnormalities of the cranial vault (Vega et al. 2016).

2. Autosomal dominant hypophosphatemic rickets
    1. Isolated renal phosphate wasting
    2. Short stature
    3. Impressive windswept deformity (valgus on one side and varus on the other side)
    4. Marked tendency for fracture with or without trauma
    5. Delayed onset of disease in some patients
    6. Patients who present as adults: osteomalacia with bone pain, weakness, and fractures
3. Autosomal recessive hypophosphatemic rickets: severe disease course (Stamp and Baker 1976; Farrow et al. 2009)
    1. Marked hypophosphatemia
    2. Persistent osteomalacia upon bone biopsy
    3. Increased bone density by dual-energy X-ray absorptiometry
    4. Stunted growth
    5. Nerve deafness
    6. Facial and dental abnormalities
    7. Learning disabilities

7. Cutis nevi in cutaneous skeletal hypophosphatemia syndrome (Ovejero et al. 2016)
    1. A giant congenital melanocytic nevus composed of nevomelanocytes (neural crest origin).
    2. Hair follicles may be enlarged and infiltrated by these cells, giving the observed hairy appearance.
    3. Phakomatosis pigmentokeratotica characterized by speckled lentiginous nevi, a subtype of melanocytic nevi (neural crest origin), and nevus sebaceous, a subtype of epidermal nevus (epidermal origin).
    4. Nevus sebaceous: seen as a round waxy alopecic scalp plaque containing small speckled lentiginous nevi.
    5. Epidermal nevus: characterized by hyperplasia of elements of epidermal origin, e.g., sebaceous glands or keratinocytes.
    6. Superimposed café au lait macules are frequently present in these patients.

Diagnostic Investigations

1. Classification of rickets by biochemical profile (Prentice 2013).
    1. Calciopenic: Typically, calciopenic rickets is associated with an elevated plasma parathyroid hormone concentration (PTH) in response to low plasma calcium, which results in internalization of phosphate transporters in the kidneys and decreased renal phosphate reabsorption.
    2. Phosphopenic
        1. Phosphopenic rickets is associated with a chronically low plasma phosphate with normal PTH and results from increased production or gain of function of FGF23, a phosphaturic hormone, or from renal disorders that compromise phosphate reabsorption.
        2. In both cases the result is urinary phosphate loss and hypophosphatemia, leading to reduced apoptosis of hypertrophic chondrocytes in the growth plate and rickets.
    3. Inhibited mineralization
        1. The third category, inhibition of mineralization, refers to rickets where the mineralization process in the growth plate is directly affected and typically the plasma

concentrations of calcium and phosphate are normal.
2. There are a variety of underlying causes responsible for the various forms of rickets, including genetic disorders, such as autosomal dominant hypophosphatemic rickets (ADHR) and X-linked hypophosphatemic rickets (XLH), tumors, organ malfunction, drugs, and exposure to toxic agents such as aluminum and fluoride.

2. A number of biochemical markers of deranged mineral or vitamin D metabolism have been considered as possible screening tools for nutritional rickets in communities (Pettifor 2015).
   1. 25(OH)D as a marker of vitamin D status
   2. Serum calcium, phosphorus, parathyroid hormone, and alkaline phosphatase as markers of bone mineral homeostasis
3. Vitamin D deficiency rickets.
   1. Decreased levels of 25-OH vitamin D (best screening test for vitamin D stores in otherwise healthy individuals)
   2. Normal or increased levels of 1,25 $(OH)_2$ vitamin D
   3. Increased levels of parathyroid hormone
   4. Decreased levels of calcium (hypocalcemia)
   5. Decreased levels of phosphate (hypophosphatemia)
4. Vitamin D-resistant rickets
   1. Renal tubular phosphate leakage and subsequent hypophosphatemia in all affected individuals
   2. Normal levels of 25-OH vitamin D
   3. Normal or decreased levels of 1,25 $(OH)_2$ vitamin D
   4. Normal or increased levels of parathyroid hormone
   5. Normal levels of calcium
   6. Decreased phosphate (hypophosphatemia)
5. Vitamin D-dependent rickets.
   1. Elevated or normal levels of 25-OH vitamin D
   2. Low levels of 1,25 $(OH)_2$ vitamin D in type I and elevated levels in type II
   3. Normal or increased levels of parathyroid hormone
   4. Normal or decreased levels of calcium
   5. Decreased levels of phosphorous (hypophosphatemia)
   6. Elevated serum alkaline phosphatase activity
6. Radiographic findings (Pitt 1981, 1991; Pai and Shaw 2011)
   1. Cupping, fraying, and widening of the metaphyses: a requirement for diagnosis of rickets
   2. Rachitic rosary (enlargement of the wrists, knees, and costochondral beadings)
   3. Flaring of ribs at diaphragm level (Harrison's groove)
   4. Bowing of the lower extremities in the newly ambulating child
   5. Widening and irregularity of all the physes
   6. Osteopenia (decreased mineralization of the bone matrix) (Schneider 1984) with blurred or nonapparent cortical outlines of the epiphyseal ossification centers
   7. Multiple fractures in various stages of healing
   8. Deformities caused by softening of the bone or poor muscle tone
      1. Femoral bowing
      2. Tibial bowing
      3. Genu valgum (knock knees)
   9. Genu valgum or varum
   10. Lordosis/kyphosis/scoliosis
   11. Pelvis
      1. Coxa valga
      2. Protrusio acetabuli
   12. Thorax: hourglass shape
   13. Skull
      1. Postural molding
      2. Frontal bossing
      3. Craniotabes
      4. Delayed closure of anterior fontanel
   14. Dental abnormalities
   15. The zone of provisional calcification appearing as a dense metaphyseal band due to calcium deposit in response to vitamin D therapy
      1. Seen as early as 2–3 weeks after initiation of therapy in children with nutritional rickets

2. Seen after 2–3 months in children with renal rickets
3. Persistence of deformities caused by bone softening despite successful treatment

16. X-linked dominant hypophosphatemia
    1. The rachitic changes, though less dramatic than in vitamin D deficiency rickets, are more severe in the knees than the wrists.
    2. The modeling defects manifest as short, squat long bones with coarse trabeculation of the axial skeleton.

7. Radiological features of cutaneous skeletal hypophosphatemia syndrome (Lim et al. 2016)
    1. Stretches of dysplastic bone with mixed sclerotic and lytic changes in the femurs
    2. Multiple transverse defects in the shaft of the humerus representing pseudofractures (Looser zones or Milkman lines), which is a sign of osteomalacic bone (arrows) in the setting of dysplastic bone, consistent with the mosaic nature of CSHS
8. Histological findings
    1. Primary metabolic abnormality at the zone of provisional calcification
    2. Diminished calcification of cartilage columns in the metaphysis
    3. Continued osteoid production by osteoblasts, but ossification of the osteoid tissue is impaired because of insufficient calcium deposition
    4. Widened, irregularly calcified physis resulting from resorption of osteoid and calcium because of impaired osteoclast function
    5. Metaphyseal broadening or "cupping" likely caused by stress at sites of ligament attachment
    6. Splaying of cartilage cells peripherally
    7. Microfractures of the primary spongiosa by herniation of cartilage into this area
    8. Tumor-associated FGF-23-induced hypophosphatemic rickets in children: In contrast to biochemical screening for increased circulating FGF-23 levels, immunohistochemical confirmation of FGF-23 production in resected tumor tissue can be regarded as being well established (Burckhardt et al. 2015)
9. Molecular genetic diagnosis
    1. X-linked dominant hypophosphatemic rickets (*PHEX* gene mutations)
        1. Sequencing of entire coding region
        2. Deletion/duplication analysis
    2. Autosomal dominant hypophosphatemic rickets (*FGF23* gene mutations)
        1. Sequencing of entire coding region
        2. Mutation scanning
        3. Targeted mutation analysis
        4. Deletion/duplication analysis
    3. Hypophosphatemic rickets, autosomal recessive 1 (*DMP1* gene mutations)
        1. Sequencing of the entire coding region
        2. Deletion/duplication analysis
    4. Hypophosphatemic rickets, autosomal recessive 2 (*ENPP1* gene mutations): sequencing of the entire coding region
    5. Vitamin D-dependent rickets, type I (*CYP27B1* gene mutations)
        1. Sequencing of the entire coding region
        2. Targeted mutation analysis
        3. Deletion/duplication analysis
    6. Vitamin D-dependent rickets, type II (VDR gene mutations): sequencing of the entire coding region
    7. Hereditary hypophosphatemic rickets with hypercalcinuria (*SLC34A3* gene mutations): sequencing of the entire coding region

Genetic Counseling

1. Recurrence risk: depends on the etiology
    1. Vitamin D deficiency rickets: recurrence risk high if conditions leading to vitamin D deficiency exist
    2. Autosomal recessive inheritance
        1. Patient's sib: 25%
        2. Patient's offspring: not increased unless the spouse is a carrier or affected
    3. Autosomal dominant inheritance
        1. Patient's sib: not increased unless a parent is affected

2. Patient's offspring: 50%
4. X-linked dominant inheritance
   1. Patient's sib: not increased unless a parent is affected
   2. Patient's offspring
      1. Affected female: 50% of daughters and 50% of sons will be affected.
      2. Affected male: All daughters will be affected and all sons normal.

2. Prenatal diagnosis
   1. Fetal radiography, particularly in mothers with osteomalacia
      1. Poorly mineralized fetal bones
      2. Thin cortices of the limb bones and penciled outlines of the vertebral bodies
      3. Cupped tibial/radial metaphysis with indistinct border to the epiphyseal aspect
   2. Fetal echocardiography
      1. Atrial flutter with heart failure reported in a fetus affected with X-linked dominant hypophosphatemic rickets (Vintzileos et al. 1985).
      2. Causal relationship in this case remained unknown.
   3. Amniotic fluid cells from a mother of a child with vitamin D-dependent rickets, type II (VDDR-II), were unable to bind [3H]1,25-(OH)2D3, and the hormone failed to stimulate 24-hydroxylase activity. VDDR-II in this fetus was confirmed after termination of pregnancy by the total inability of 1,25-(OH)2D3 to stimulate 24-hydroxylase activity in tissue explants and cell cultures prepared from the fetus's kidney and skin (Weisman et al. 1990).
   4. Prenatal diagnosis by molecular analysis of cultured fetal cells obtained from CVS and amniocentesis in pregnant women from high-risk families to look for disease-causing mutation, previously identified in an affected individual
      1. X-linked dominant hypophosphatemic rickets
      2. Autosomal dominant hypophosphatemic rickets
      3. Autosomal recessive hypophosphatemic rickets, I
      4. Vitamin D-dependent rickets type I and type II
      5. Hereditary hypophosphatemic rickets with hypercalcinuria

3. Management (Smith 1972; Carpenter 1997)
   1. Hypocalcemia and "simple rickets" (Wharton and Bishop 2003)
      1. Hypocalcemia (early infancy)
         1. IV calcium gluconate to control continuing seizures.
         2. Oral calcium daily.
         3. Oral calciferol daily.
         4. Look for evidence of rickets in the baby (radiographs of the knees and wrists).
         5. Look for maternal osteomalacia (elevated maternal alkaline phosphatase).
         6. Slowly withdraw treatment when the plasma calcium is normal.
         7. Continue prophylactic vitamin D thereafter.
      2. Rickets without hypocalcemia (early infancy): oral calciferol daily for 2–4 months
      3. Older infants, toddlers, and adolescents
         1. Oral calciferol.
         2. Add oral calcium if dietary deficiency may be a factor.
         3. Phosphorus not needed in simple rickets since phosphorus is abundant in the diet.
         4. Necessary to supplement phosphorus for very preterm babies and in the phosphate-wasting causes of rickets.
   2. Prevention and treatment of nutritional rickets (Shaw 2015)
      1. Traditionally with vitamin D2 or D3, often given as a daily oral dose for several weeks until biochemical and radiological evidence of healing.
      2. However, other treatment regimens with single or intermittent high doses have also proved to be effective.
      3. It is now recognized that oral calcium either as dietary intake or supplements should be routinely used in conjunction with vitamin D for treatment.

3. Vitamin D deficiency rickets
    1. Increase dietary intake of vitamin D
        1. The new recommended adequate intake of vitamin D by the National Academy of Sciences to prevent vitamin D deficiency in normal infants, children, and adolescents is 200 IU per day (Gartner and Greer 2003).
        2. An intake of at least 200 IU per day of vitamin D will prevent physical signs of vitamin D deficiency and maintain serum 25-hydroxy-vitamin D at or above 27.5 nmol/L.
    2. Increased sun exposure
    3. Prevent other predisposing factors
4. Vitamin D-resistant rickets
    1. Increase dietary intake of vitamin D
    2. Increased sun exposure
    3. Prevent other predisposing factors
5. Vitamin D-dependent rickets: lifelong treatment with 1-alpha-hydroxyvitamin D or 1,25-dihydroxyvitamin D
6. Dominant X-linked hypophosphatemic rickets: treat bone lesions and impaired longitudinal growth
    1. Without treatment, clinical manifestations begin in the first year of life, and affected children suffer progressive growth failure and bony deformities, such as tibial bowing and frontal bossing (Quinlan et al. 2012).
    2. However, treatment with vitamin D and phosphate resulted in only a partial growth improvement in most cases and was frequently complicated by hypercalcinuria, hypercalcemia, nephrocalcinosis, or hyperparathyroidism (Cho et al. 2005).
    3. Early initiated vitamin D and phosphate treatment are not sufficient to correct hypophosphatemic rickets caused by severe loss-of-function mutations (Cheon et al. 2014).
    4. Medical treatment remains the main pillar of therapy in affected children (Glorieux et al. 1972).
        1. Vitamin D supplement
        2. Oral phosphate supplement: risks of stimulating secondary hyperparathyroidism (Schmitt and Mehls 2004)
5. Dental treatment options (Sabandal et al. 2015).
    1. Frequent dental examination
    2. Besides vitamin D analogs and phosphate supplements that improve tooth mineralization, rigorous oral hygiene, active endodontic treatment of root abscesses, and preventive protection of teeth surfaces are recommended (Linglart et al. 2014).
    3. Application of topical fluoride varnish and sealing of pits and fissures to prevent microbial invasion that may result in pulpitis and further endodontic complications.
6. Surgery can be safely performed in XL vitamin D-resistant hypophosphatemic rickets, independent of age or bone maturation (Fucentese et al. 2008).
7. Cranial vault expansion for craniostenosis in XL hypophosphatemic rickets patients (Jaszczuk et al. 2016).
8. Contemporary medical and surgical management of X-linked hypophosphatemic rickets (Sharkey et al. 2015).
    1. Despite medical management, progressive bone deformities develop in some children.
    2. Surgical treatment of these deformities can be done before or after skeletal maturity, although growth plate-respecting surgery is necessary in the presence of open growth plates.
    3. In younger children, milder deformities may correct with guided-growth treatment.
    4. Skeletally mature persons may benefit from the placement of intramedullary rods for osteotomy fixation because the rods can span the bone and provide long-term support.

9. Surgical measures are usually reserved for the treatment of severe bowing, tibial torsion, or pathological fractures. Osteotomy with plating and multiple osteotomies and intramedullary fixation are standard methods for operative management (Pavone et al. 2015).
10. CSHS: Oral phosphate and calcitriol can improve rachitic symptoms and help heal dysplastic bone by enhancing mineralization (Lim et al. 2016).

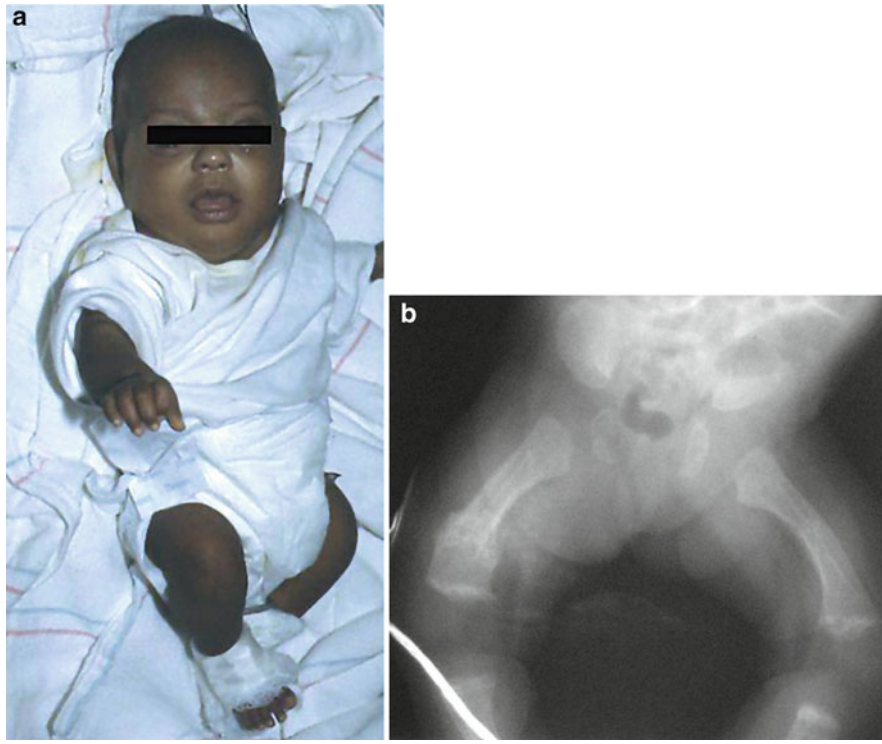

Fig. 1 (**a**, **b**) An infant with healing nutritional rickets (**a**). The radiograph (**b**) shows femoral bowing and a healing fracture with callus formation in the right femur

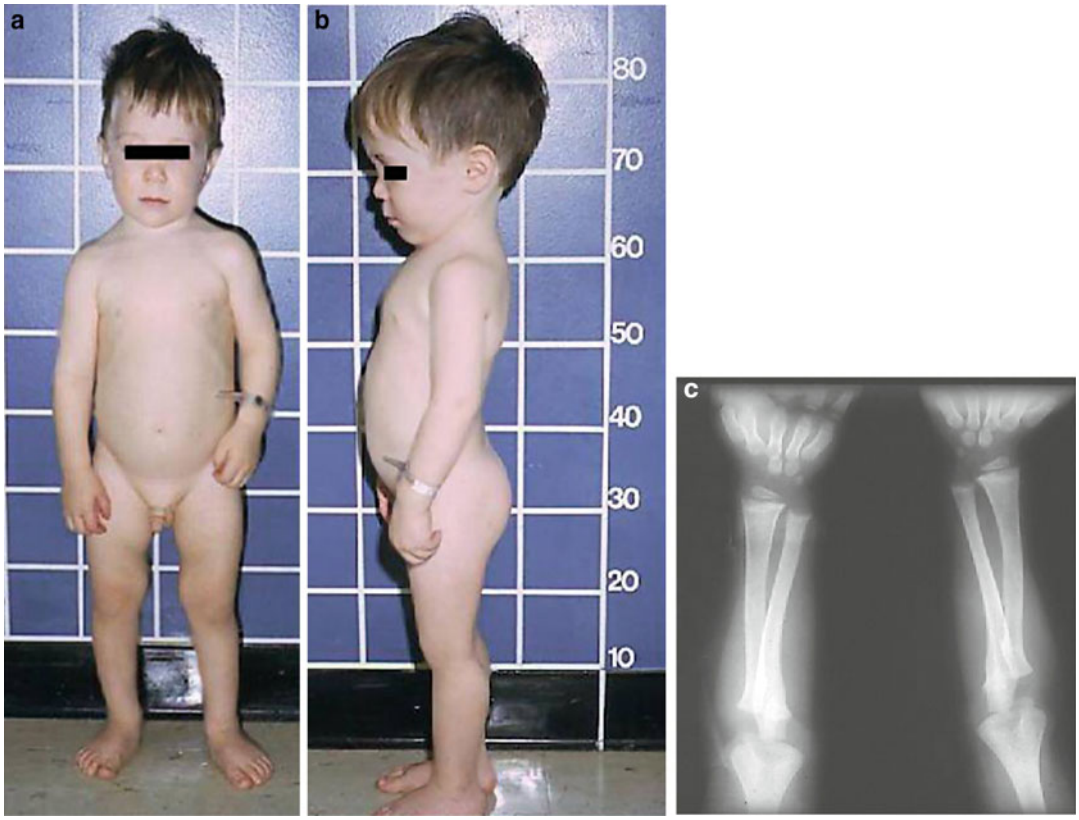

Fig. 2 (**a**–**c**) A boy with vitamin D-resistant rickets showing short stature (**a**, **b**). The radiograph (**c**) shows widening, cupping, and fraying of the distal radius and ulna

Fig. 3 (**a**, **b**) Another boy with vitamin D-resistant rickets

Fig. 4 (**a**, **b**) Radiograph from a patient with renal rickets shows widening, cupping, and fraying of the distal radius and ulna

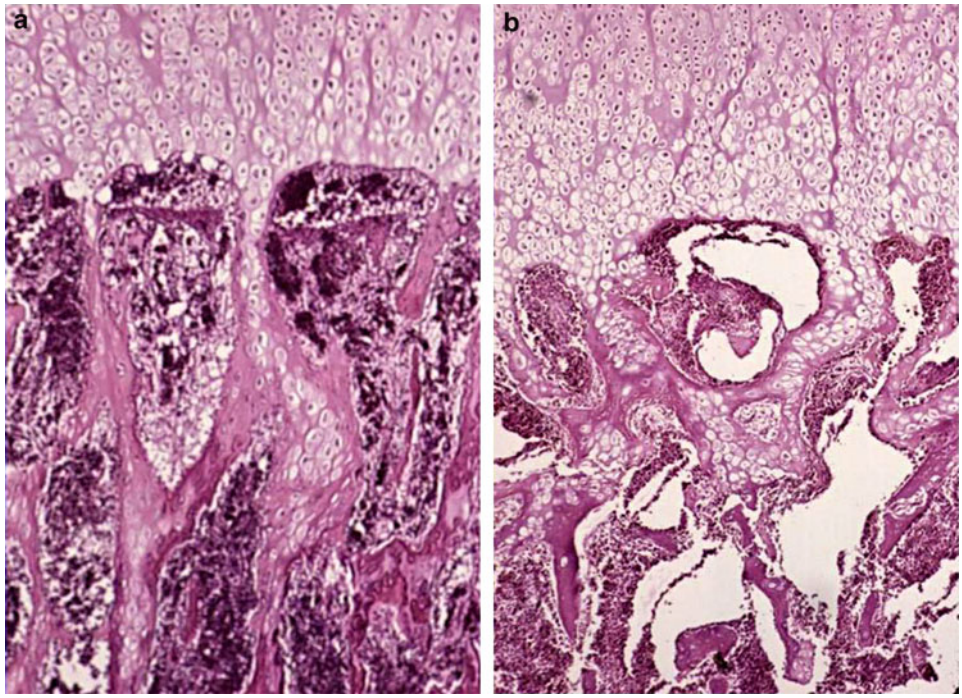

Fig. 5 (**a**, **b**) Photomicrograph of the humerus (*left*) and the rib (*right*) of a female neonate who lived 43 min. Broad cartilage columns with many large chondrocytes are present in the metaphysis. They have broad osteoid seams and are poorly ossified. The abnormal area corresponds to the radiographic metaphyseal irregular lucency. The findings are similar to those of hypophosphatasia, though the changes are milder. The cause of congenital rickets in this case is unknown. The mother did not have history of malabsorption, vitamin D intake deficiency, renal failure, or preeclampsia

Fig. 6 Three sisters with hypophosphatemic rickets showing short stature and bowed legs. They have an affected father

Fig. 7 Two sisters and a brother with hypophosphatemic rickets showing short stature. The brother had severe short stature and bowed legs. The oldest sister had surgeries on her legs to correct the lower leg deformities. The middle sister was mildly affected. Their mother was affected

Rigid Spine Syndrome

Contents

The peculiar phenotype caused by the combination of muscle wasting and prominent spinal rigidity was first proposed by Dubowitz (1965, 1973) and termed "rigid spine syndrome." Rigid spine syndrome (RSS) is also a heterogenous disease with a broad spectrum of skeletal and muscular disorders and a prominent feature in the X-linked, autosomal dominant, and/or autosomal recessive forms of Emery–Dreifuss muscular dystrophy (Emery 1987), nemaline (Topaloglu et al. 1994), and other congenital myopathies (Reichmann et al. 1997).

Synonyms and Related Disorders

Congenital muscular dystrophy with spinal rigidity; Emery–Dreifuss muscular dystrophy, nemaline and other congenital myopathies; Selenoprotein N1-related myopathy

Genetics/Basic Defects

1. *SEPN1* gene mutations resulting in rigid spine congenital muscular dystrophy were first identified by Moghadaszadeh et al. in (Moghadaszadeh et al. 2001).
2. Several different forms of autosomal recessive muscle disorders caused by mutations in the *SEPN1* gene (Rederstorff et al. 2007).
    1. Different forms.
        1. Congenital muscular dystrophy with spinal rigidity (RSMD1) (Moghadaszadeh et al. 2001; Okamoto et al. 2006; Flanigan et al. 2000)
        2. Multiminicore myopathy (MmD) (Ferreiro et al. 2002)
        3. Desmin-related myopathy with Mallory body-like inclusions (MB-DRM) (Ferreiro et al. 2004)
        4. Congenital fiber-type disproportion myopathy (CFTD) (Clarke et al. 2006)
    2. Share identical clinical features, despite distinctly different histopathological descriptions of these different disorders.
        1. Early weakness of axial muscles
        2. Development of spinal rigidity and scoliosis
        3. Severe respiratory insufficiency
3. These phenotypes are now grouped under the generic term of *SEPN1*-related myopathy (Ferreiro et al. 2002).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_204

3. *SEPN1* gene mutations.
    1. *SEPN1* gene, mapped on chromosome 1p35-36 (Moghadaszadeh et al. 1998), codes for selenoprotein N, an endoplasmic reticulum glycoprotein.
    2. Numerous mutations scattered all over the *SEPN1* gene (Deniziak et al. 2007).
    3. Most mutations are nonsense mutations and deletions, likely to induce a loss of function.
4. Aggresome–autophagy involvement in a sarcopenic patient with rigid spine syndrome and a p.C150R mutation in four-and-a-half LIM domain 1 (*FHL1*) gene (Shalaby et al. 2008; Sabatelli et al. 2015).
5. Recessive skeletal muscle α-actin gene (*ACTA1*) variant causes congenital muscular dystrophy with rigid spine (O'Grady et al. 2015).

Clinical Features

1. SEPN1-related myopathies.
    1. Mutations in *SEPN1* have been associated with three autosomal recessive congenital myopathies, including rigid spine muscular dystrophy, multiminicore disease, and desmin-related myopathy with Mallory body-like inclusions. These disorders constitute the SEPN1-related myopathies (SEPN-RM) (Tajsharghi et al. 2005).
    2. Characterized by an early onset of hypotonia and weakness, with predominant axial muscle impairment leading to life-threatening respiratory failure and scoliosis. A variable degree of spinal rigidity was observed in most of the patients (Petit et al. 2003).
2. Early spine rigidity: a predominant feature (limitation in flexion of dorsolumbar and cervical spine due to contracture of spinal extensors) (Van Munster et al. 1986).
3. The origin of spine stiffness in rigid spine syndrome is not well understood (Sastre-Garriga et al. 2001).
    1. Shortening of paraspinal ligaments or shortening of muscle fibers due to myofibrillar disorganization has been invoked as possible origins of stiffness (Lotz and Stübgen 1993).
    2. Weakness of neck flexors can make this group of muscles incapable of counteracting extensor strength, finally causing spinal rigidity and cervical lordosis.
4. Diffuse and mild to severe muscle wasting with failure to thrive.
5. Muscle weakness/axial hypotonia.
    1. Diffuse, more prominent in the neck and trunk
    2. Facial weakness
    3. Finger extensors and trunk flexors weakness
6. Contractures.
    1. Limitation in mouth opening
    2. Joint contractures (knees, ankles, elbows, and/or hips)
7. Lumbar scoliosis.
8. Delay of gross motor milestones evident, though ambulation is eventually achieved and preserved in most patients.
9. Nasal speech common due to palatal weakness.
10. Impaired respiratory function.
    1. Respiratory failure due to skeletal abnormalities and diaphragmatic weakness.
    2. Nocturnal hypoventilation may be an early feature and a cause of mortality (Morita et al. 1990; Ras et al. 1994).
    3. May require mechanical ventilation by teens.
11. Rare reports of various cardiac involvement (Stübgen 2008a).
    1. Complete heart block.
    2. Interventricular septum hypertrophy.
    3. Left atrial and ventricular hypertrophy.
    4. Cardiomyopathy may occur concomitantly.
12. Differentiating features between myopathic rigid spine and rigid spinal muscular dystrophy (Koul et al. 2014).
    1. Myopathic rigid spine
        1. Neck stiffness (rigidity): part of myopathy and late onset
        2. Muscle weakness: proximal
        3. Respiratory involvement: late

4. Muscle contractures: peripheral and common
5. Imaging of spine: negative
6. Creatine kinase: high
7. Muscle biopsy: typical of underlying disease
8. Cardiac involvement: early
9. Electromyogram: typical and more proximal
10. Genetics: underlying disease
11. Inheritance: autosomal dominant, autosomal recessive, X-linked recessive

2. Rigid spinal muscular dystrophy
    1. Neck stiffness (rigidity): early onset and severe
    2. Muscle weakness: axial
    3. Respiratory involvement: early
    4. Muscle contractures: minimal and mainly spine
    5. Imaging of spine: positive and typical
    6. Creatine kinase: normal
    7. Muscle biopsy: nonspecific
    8. Cardiac involvement: late
    9. Electromyogram: axial muscles
    10. Genetics: *SEPN1* gene
    11. Inheritance: autosomal recessive

13. Differential diagnosis of spine rigidity associated with various neuromuscular and movement disorders (Sponholz et al. 2006).
    1. Classic form of multiminicore disease
    2. Desmin-related myopathy with Mallory body-like inclusions
    3. Emery–Dreifuss muscular dystrophy
    4. Bethlem myopathy
    5. Ullrich congenital muscular dystrophy
    6. Dysferlinopathy: an autosomal recessive neuromuscular disorder caused by a deficiency of functional dysferlin protein due to mutations in the dysferlin gene (Bashir et al. 1998; Liu et al. 1998; Nagashima et al. 2004)
    7. Other congenital myopathies
    8. Mitochondrial myopathies
    9. Metabolic diseases (e.g., lysosomal storage disorders)
    10. Dystonias
    11. Ankylosing spondylitis

Diagnostic Investigations

1. CK serum levels: normal or only mildly elevated (Lisi and Cohn 2007).
2. Muscle biopsy/histology (Lotz and Stübgen 1993): nonspecific myopathic changes.
    1. Autophagic vacuoles: a salient histological feature.
    2. Vacuoles containing capillaries.
    3. Muscle spindle swelling.
    4. Type I fiber predominance.
    5. Fiber diameter variability.
    6. Atrophy and internalization of nuclei.
    7. Marked fibrosis.
    8. Some specimen contains minicores typical of classical minicore myopathies (Ferreiro et al. 2002).
    9. Consistent with nemaline myopathy in two siblings with familial rigid spine syndrome (Topaloglu et al. 1994).
3. Electromyogram: myopathic pattern in spinal muscles.
4. There was evidence of minor upper alimentary tract dysfunction in patients with the "vacuolar variant" of RSS. The myopathy that underlies this syndrome likely caused dysfunction of striated muscle of the pharyngeal constrictors and upper esophageal sphincter (Stübgen 2008b).
5. Computed tomography of the muscles: severe involvement of the paraspinal musculature (Vanneste et al. 1988).
6. MRI imaging of muscles: range from mild isolated involvement of the sartorius muscle to a more striking involvement of the sartorius compared with the other thigh muscles in patients with an overall more diffuse involvement. No involvement or only minimal nonselective involvement of calf muscles (Mercuri et al. 2010).

7. MRI of the brain: normal
8. Antibodies directed against the 70-kDa SEPN1 show the absence of the protein in fibroblasts of patients with nonsense mutations.
9. Screening for mutations in the *SEPN1* gene is required to establish the diagnosis of rigid spine muscular dystrophy.

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: 25% affected, given the parents are carriers
    2. Patient's offspring
        1. When the spouse is not a carrier, all offspring obligate heterozygotes.
        2. When the spouse is a carrier, 50% of offspring affected and 50% of offspring carriers.
2. Prenatal diagnosis
    1. Not reported to date.
    2. Possible for pregnancies at increased risk if the disease-causing gene mutation has been identified in the family.
3. Management (Jungbluth 2007).
    1. No curative treatment currently available.
    2. Regular physiotherapy.
        1. Promote endurance
        2. Preserve muscle function
        3. Prevention of contractures, especially Achilles tendon
    3. Swimming and riding for promoting truncal stability.
    4. Management of scoliosis.
        1. Conservative approaches often unsuccessful due to the progressive nature of the deformity
        2. Eventually need to be managed surgically
    5. Mobilization following surgery ought to be early in order to avoid the detrimental effects of prolonged immobilization on muscle strength.
    6. Appropriate rehabilitative measures to promote independent ambulation.
    7. Management of severe respiratory impairment; mechanical ventilation may eventually be needed.
    8. Botulinum toxin may have an important part to play in preventing development of contractures and avoiding stiffness, not only in a symptomatic way but also in a curative manner (Sastre-Garriga et al. 2001).
    9. Echocardiography for cardiomyopathy.
    10. Therapeutic perspectives (Reed 2009).
        1. Recently, Rederstorff et al. (2007) reported a patient with a homozygous point mutation at the selenocysteine (Sec) codon (c.G1385A) that converted the normal codon UGA to UAA, therefore preventing synthesis of a full-length active SePN protein.
        2. Lescure et al. (2008) subsequently "engineered a mutant tRNASec gene carrying a point mutation in the anticodon, thereby restoring the base complementarity with the SEPN1-mutated codon; in patient-derived primary fibroblasts, the corrector tRNASec gene allowed read through of the UAA stop codon, thus enabling synthesis of the full-length SePN protein" (Rederstorff et al. 2007).
        3. This is the first attempt of a therapeutic strategy for rigid spine CMD and other SEPN-related disorders, using a mutation-specific approach.

Fig. 1 This 8-year-and-6-month-old boy was evaluated for poor weight gain, hypotonia, and muscle weakness. On examination, he was noted to be very hypotonic with poor head control, inability to flex the spine or the neck and limited rotation of the neck, mild scoliosis, and chest wall asymmetry. Metabolic panel revealed a minimally elevated AST (40 μ/L), a minimally elevated CPK (362 μ/L), and a mildly elevated aldolase (7.8 μ/L). The radiographs of the spine showed straight lateral view of the spine without normal cervical and thoracic curvatures with minimal scoliosis. Because of the radiographs, rigid spine muscular dystrophy, a selenoprotein N1-related myopathy, was suspected. The *SEPN1* mutation analysis revealed that the patient is heterozygous for a mutation in exon 1 of the *SEPN1* (c.1A > G) and a mutation in exon 7 of the *SEPN1* gene (c.943 G > A) which are both known to be pathogenic. The results are consistent with a diagnosis of SEPN1-related myopathy, an autosomal recessive myopathy. Note the myopathic face

Fig. 2 Note the stiff neck and spine with minimal scoliosis

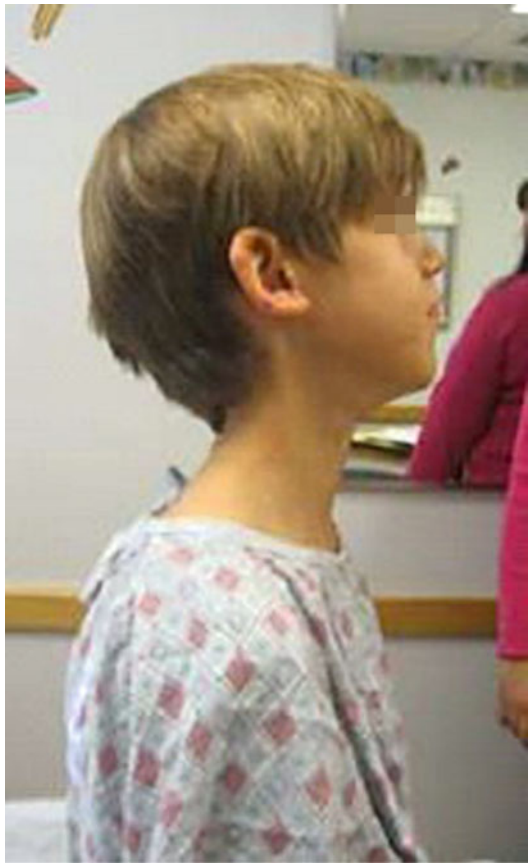

Fig. 3 Note his rigid neck that cannot bend

Fig. 4 Note difficulty in bending his neck and spine

Fig. 5 (**a**–**c**) Radiographs of the spine showed stiff spinal column (lateral views) (**a**, **b**) and mild scoliosis (AP view) (**c**)

Roberts Syndrome

Contents

Roberts syndrome is a rare hereditary disorder characterized by symmetrical reduction of all limbs and a unique cytogenetic abnormality of premature centromere separation, which disrupts the process of chromatid pairing.

Synonyms and Related Disorders

Cohesinopathies (Barbero 2013); Roberts-SC phocomelia syndrome; Roberts tetraphocomelia syndrome; Tetraphocomelia syndromes (Roberts syndrome and SC phocomelia (Herrmann and Opitz 1977)/pseudothalidomide syndrome (Lenz et al. 1974))

Genetics/Basic Defects

1. Autosomal recessive disorder: affected siblings with the Roberts tetraphocomelia syndrome (Qazi et al. 1979; Fryns et al. 1987; Holmes-Siedle et al. 1990).
2. Associated with unique cytogenetic abnormality: premature centromere separation:
   1. Disrupts the process of chromatid pairing and disjoining of sister chromatids (German 1979)
   2. Responsible for the development of multiple structural anomalies observed in Roberts syndrome
3. Caused by mutations in *establishment of cohesion 1 homologue 2* (*ESCO2*) on 8p21.1, a human homologue of yeast *ECO1* that is essential for the establishment of sister chromatid cohesion (Vega et al. 2005).
4. Loss of ESCO2 acetyltransferase activity was recently implicated in the molecular mechanism of Roberts syndrome (Gordillo et al. 2008; Vega et al. 2010).
5. Roberts syndrome and SC phocomelia: a single genetic entity (Römke et al. 1987).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_205

6. Roberts syndrome and pseudothalidomide syndrome are the same condition and emphasize that normal intelligence and positive social-personal adjustment are possible, even with all of the stigmata of Roberts syndrome (Holden et al. 1992; Hwang et al. 2002).
7. A deficit in acetylated cohesin leads to nucleolar dysfunction in Roberts syndrome (Xu et al. 2014).

Clinical Features

1. Highly variable clinical features (Sinha et al. 1994)
2. Craniofacial malformations: marked variability (Vega et al. 2010; Afifi et al. 2016):
    1. Bilateral cleft lip and cleft palate in severe cases (Roberts 1919)
    2. No clefting of the lip or palate in some cases
    3. Hypertelorism secondary to widely spaced orbits
    4. Ophthalmic manifestations:
        1. Exophthalmos due to shallow orbits
        2. Microphthalmia
        3. Peter anomaly
        4. Cloudy cornea
        5. Cataracts
    5. Wide nasal bridge
    6. Hypoplastic nasal alae
    7. Hemangiomata of the lip, nose, face, or forehead
    8. Micrognathia
    9. Dark scalp hair that becomes thin and silvery blond
3. Limb defects:
    1. Phenotype varies from a complete absence of arms and legs with rudimentary digits to mild growth reduction in the limbs.
    2. Limb reduction defects tend to be symmetric and more severely involved in the upper extremities than the lower extremities.
    3. The presence of phocomelia:
        1. Tetraphocomelia: a prominent characteristic of the syndrome
        2. Two deficient limbs in 11% of cases
        3. No phocomelia in 2% of cases
    4. Often reduced number of fingers (oligodactyly)
    5. Radial aplasia or dysplasia common
    6. Lack of first metacarpal, thumb, or first phalanx
    7. Report of a mild form of this syndrome, who presented with an asymmetrical reduction of the right upper limb (Concolino et al. 1996)
    8. Tetra-amelia with lung hypoplasia and facial clefts (Roberts-SC syndrome) (Ragavan et al. 2010)
4. Other associated anomalies:
    1. CNS anomalies:
        1. Mental retardation
        2. Microcephaly
        3. Hydrocephalus
        4. Absent olfactory lobes
        5. Calcification of the basal ganglia
        6. Encephalocele
        7. Cranial nerve paralysis (Parry et al. 1986)
        8. Seizures
    2. Congenital heart defects:
        1. Atrial septal defect
        2. Patent ductus arteriosus
        3. Pulmonic stenosis
        4. Valvular aortic stenosis (Dogan et al. 2014)
        5. AV canal defect
    3. Renal anomalies:
        1. Polycystic kidneys
        2. Dysplastic kidneys
        3. Horseshoe kidney
        4. Hydronephrosis
        5. Renal agenesis
    4. Gastrointestinal obstruction
    5. Splenogonadal fusion
    6. Cryptorchidism
    7. Enlarged phallus
    8. Failure to thrive
    9. Neoplasms:
        1. Sarcoma botryoides
        2. Malignant melanoma
5. Adult patients (Goh et al. 2010):
    1. The characteristic clinical features of RBS/SC phocomelia were present in the majority of adult patients:

1. Limb anomalies (9/10)
2. Craniofacial anomalies (8/10)
3. Growth retardation (10/10)
4. Mental retardation/learning difficulties (7/10)

2. Clinically apparent limb anomaly may not be an obligate feature for the diagnosis of this condition and that careful measurements may be required to detect subclinical limb shortening.

6. Prognosis:
   1. Severe cases:
      1. Often resulting in spontaneous abortions or stillbirths.
      2. Few cases survive past one month of life.
   2. Phenotypically milder cases:
      1. Requiring minimal to full time care depending on the degree of mental retardation
      2. May require surgical interventions to correct craniofacial and limb anomalies
7. Differential diagnosis (Gordillo et al. 2013):
   1. SC phocomelia (Herrmann et al. 1969):
      1. Clinical characteristics:
         1. Tetraphocomelia
         2. Scanty silvery blond hair
         3. Microcephaly
         4. Mild mental retardation
         5. Facial hemangioma
         6. Cloudy cornea
         7. Hypoplastic nasal alae and ears
      2. Originally thought to differ from Roberts syndrome by:
         1. Usual absence of midfacial clefting
         2. Prolonged survival
         3. Lesser degree of mental and physical retardation
         4. Relatively milder degree of phocomelia
      3. Now considered to be the same entity as Roberts syndrome (Roberts-SC phocomelia syndrome) based on the following observations (Schüle et al. 2005):
         1. The presence of severely and mildly affected individuals in the same sibship raised the suspicion that the two disorders are allelic, representing spectrum of severity.
         2. Furthermore, both are characterized by heterochromatin repulsion (HR) or premature centromere separation in mitotic cells (Judge 1973; Freeman et al. 1974a, b; Tomkins et al. 1979).
         3. Somatic cell complementation studies revealed that cells positive for HR (HR+) from individuals with Roberts syndrome and from those with SC do not complement each other, further supporting the notion that the same gene is affected in the two disorders (McDaniel et al. 2000).
   2. Thrombocytopenia-absent radius (TAR) syndrome (Urban et al. 1998) (see the chapter on "Thrombocytopenia-Absent Radius Syndrome"):
      1. Absent radii with thumbs present
      2. Hypomegakaryocytic thrombocytopenia
      3. Absent cleft palate
   3. Baller-Gerold syndrome:
      1. Autosomal recessive disorder
      2. Craniosynostosis (brachycephaly)
      3. Ocular proptosis
      4. Bulging forehead
      5. Radial ray defect (oligodactyly)
      6. Aplasia or hypoplasia of the thumb and/or aplasia or hypoplasia of the radius
      7. Growth retardation
      8. Poikiloderma
      9. Caused by mutations in *RECQL4*
   4. Fanconi anemia (see the chapter on "Thrombocytopenia-Absent Radius Syndrome")
   5. Tetra-amelia, X-linked (Zimmer tetraphocomelia):
      1. Tetra-amelia
      2. Facial clefts
      3. Absence of ears and nose
      4. Anal atresia
      5. Absence of frontal bones
      6. Pulmonary hypoplasia with adenomatoid malformation
      7. Absence of thyroid

8. Dysplastic kidneys, gallbladder, spleen, uterus, and ovaries
9. Imperforate vagina

6. Tetra-amelia, autosomal recessive:
   1. Caused by mutations in the WNT3
   2. Amelia
   3. Severe lung hypoplasia and aplasia of the peripheral pulmonary vessels
   4. Cleft lip/palate
   5. Hypoplasia of the pelvis
   6. Malformed uterus
   7. Atresia of the urethra, vagina, and anus
   8. Diaphragmatic defect
   9. Agenesis of the kidney, spleen, and adrenal glands
7. Splenogonadal fusion with limb defects and micrognathia (de Ravel et al. 1997):
   1. Autosomal recessive inheritance
   2. Abnormal fusion between the spleen and the gonad or the remnants of the mesonephros
   3. Tetramelia
   4. Mild mandibular and oral abnormalities (micrognathia, multiple unerupted teeth, crowding of the upper incisors, and deep, narrow, V-shaped palate without cleft)
8. DK phocomelia syndrome:
   1. Autosomal recessive inheritance
   2. Phocomelia
   3. Absence of radius and digits
   4. Thrombocytopenia
   5. Encephalocele
   6. Cleft palate and absence of radius and digits
   7. Anal atresia
   8. Abnormal lobation of the lungs
   9. Diaphragmatic agenesis
9. Holt-Oram syndrome (see the chapter)
10. Thalidomide embryopathy (see the chapter on "Dysmelia"):
    1. Abnormalities of the long bones of the extremities:
       1. Upper limb bones are affected in an order of frequency starting with the thumb, followed by the radius, the humerus, the ulna, and finally the fingers on the ulnar side of the hand.
       2. In extreme cases, the radius, ulna, and humerus are lacking; the hand bud arises from the shoulders.
       3. Legs may be affected but less severely.
    2. The second major group of defects involves the ears (anotia, microtia, accessory auricles) and the eyes (coloboma of the iris, anophthalmia, microphthalmia).
    3. Internal defects commonly involve the heart, kidneys, and urinary, alimentary, and genital tracts.
11. Cornelia de Lange syndrome (Skibbens et al. 2013) (please see the chapter on "De Lange Syndrome"):
    1. Roberts syndrome (RBS) and Cornelia de Lange syndrome (CdLS) are severe developmental maladies that present with nearly an identical suite of multi-spectrum birth defects.
    2. Not surprisingly, RBS and CdLS arise from mutations within a single pathway involving cohesion.
    3. Sister chromatid tethering reactions that comprise cohesion are required for high-fidelity chromosome segregation, but cohesin tethers also regulate gene transcription, promote DNA repair, and impact DNA replication.
    4. Currently, RBS is thought to arise from elevated levels of apoptosis, mitotic failure, and limited progenitor cell proliferation, while CdLS is thought to arise, instead, from transcription dysregulation.
    5. RBS cells, like CdLS cells, show hypersensitivity to DNA-damaging agents such as mitomycin C, camptothecin, and etoposide, suggesting a role of *ESCO2* in cohesin-mediated DNA repair and genome stability maintenance (van der Lelij et al. 2009; Cucco and Musio 2016).
12. Mosaic variegated aneuploidy syndrome:
    1. Autosomal recessive inheritance.
    2. Caused by mutations in *BUB1B* which encodes BUBR1, a key protein in the

mitotic spindle checkpoint, which have been found in individuals with this disease.
3. Severe microcephaly.
4. Growth deficiency.
5. Mental retardation.
6. Childhood cancer predisposition.
7. Associated with constitutional mosaicism for chromosomal gains and losses.
8. Cytogenetic findings include premature centromere division, in which mitotic cells show split centromeres and splayed chromatids in all or most chromosomes (Plaja et al. 2001).

Diagnostic Investigations

1. Cytogenetics:
    1. Distinctive abnormality of the constitutive heterochromatin (the RS effect): premature centromere separation (PCS):
        1. Detected in:
            1. Fibroblasts and lymphocytes in neonates
            2. Chorionic villi and amniocytes in the fetus
        2. Consists of "puffing" or "repulsion" of the constitutive heterochromatin:
            1. Chromosome puffing most obvious at the large heterochromatic regions of chromosomes 1, 9, and 16
            2. Chromosome repulsion most evident at the short arms of the acrocentrics and the distal long arm of the Y chromosome (Louie and German 1981; Mann et al. 1982)
        3. A "railroad-track" or "tram-track" appearance of the sister chromatids due to the absence of a constriction at the centromere in several other chromosomes (Van Den Berg and Francke 1993; Lopez-Allen et al. 1996):
            1. This phenomenon, called heterochromatin repulsion, is observed in cells of different tissue origin with several chromosomes in each metaphase showing a visible abnormality.
            2. Most evident in chromosomes containing the largest amount of heterochromatin.
    2. There are other cytogenetic features that are equally characteristic of Roberts syndrome (Jabs et al. 1989, 1991):
        1. Aneuploidy with random chromosome loss
        2. Micronuclei and/or nuclear lobulations of 8–24% of interphase cells
    3. Sporadic aneuploidy was noted with the pattern of aneuploidy different in each patient. The possible relationship between centromere "splaying" and aneuploidy is yet to be determined.
    4. Normal karyotypes lacking any microdeletion or chromosomal rearrangement from either leukocytes or fibroblasts in about a fifth of all cases.
    5. Roberts syndrome variant with normal cell division (Keppen et al. 1991).
    6. Phenomenon of centromeric heterochromatin separation (as occasionally revealed by C-bands in normal subjects) in obligate heterozygotes and possible heterozygotes for RS: indicative of the possibility to screen for heterozygotes (Maserati et al. 1991).
2. Radiography for phocomelia evaluation:
    1. Absence of the radius and fibula: the most common skeletal abnormalities in the upper and lower limbs
    2. Absent, short, deformed, and/or hypoplastic ulna and tibia: the second most common bone defects
    3. Absent, short, deformed, or hypoplastic humerus and femur: the third and least common abnormalities
3. Echocardiography for congenital heart defect.
4. Renal ultrasound for renal anomalies.
5. MRI of the brain for CNS anomalies.
6. In situ hybridization on human embryos showed ESCO2 expression in the brain, face, limb, kidney and gonads, which corresponds to the structures affected in Roberts syndrome (Vega et al. 2010).
7. Molecular genetic testing: sequence analysis of the *ESCO2* gene available clinically.

Genetic Counseling

1. Recurrence risk according to autosomal recessive inheritance (Gordillo et al. 2013):
   1. Patient's sib: 25%
   2. Patient's offspring:
      1. Not increased (not surviving to reproduction in severe cases).
      2. The offspring of an individual with RBS are obligate heterozygotes (carriers) for a disease-causing mutation in *ESCO2*.
2. Prenatal diagnosis (Schulz et al. 2008):
   1. First trimester prenatal evaluation for RS in an at-risk pregnancy: cytogenetic analysis and transvaginal ultrasound (Otaño et al. 1996)
   2. Ultrasonography (Paladini et al. 1996):
      1. Intrauterine growth retardation
      2. Bilateral phocomelia (tetraphocomelia in majority of cases) of varying degree (Robins et al. 1989)
      3. Cleft lip and palate
      4. Associate anomalies:
         1. Hydrocephalus
         2. Congenital heart defects
         3. Renal anomalies
         4. Pulmonary hypoplasia (Sherer et al. 1991)
   3. Three-dimensional (3D) sonography (Dulnuan et al. 2011): can reveal additional abnormalities such as:
      1. Bilateral hypoplastic and proximal implantation of the thumb
      2. Exophthalmic eyes
      3. Suspected cleft lip
      4. Shortened upper extremities
      5. Contracted legs
   4. DNA from fetal cells obtained from amniocentesis or CVS:
      1. Confirmed by characteristic disjunction of centromeres (premature centromere separation in metaphases) (Tomkins 1989; Stioui et al. 1992; Benzacken et al. 1996)
      2. Molecular diagnosis of *ESCO2* gene mutations (Gordillo et al. 2013)
3. Preimplantation genetic diagnosis (PGD) may be an option for some families in which the disease-causing mutations have been identified (Gordillo et al. 2013).
4. Management:
   1. Aggressive medical intervention for those with normal intelligence and no internal anomaly (Karabulut et al. 2001)
   2. Special education
   3. Cornea grafting
   4. Corrective surgery:
      1. Cleft lip/palate
      2. Limb defects
   5. Prosthetic devices:
      1. For underdeveloped or missing limbs
      2. Used to increase independence

Fig. 1 The G-banded metaphase spread from fibroblast culture of a male infant with Roberts syndrome showing characteristic heterochromatin separation: puffing of the centromeric heterochromatin of some chromosomes and splaying of the Yqh region (arrows). The patient had profound psychomotor retardation, corneal clouding, and tetraphocomelia

Fig. 2 A newborn with Roberts syndrome variant showing bilateral cleft lip and cleft palate, phocomelia, and club hands with an appendage-like thumb on the right and a missing thumb on the left. The infant also had intrauterine growth retardation, hydrocephalus, cloudy cornea, AV canal heart defect, and normal lower extremities. Cytogenetic studies revealed no premature centromere separation. The mother took Diflucan during pregnancy and the teratogenic etiology was a possibility

Robinow Syndrome

Contents

In *1969*, Robinow et al. (1969) described a new dwarfing syndrome characterized by mesomelic shortening of extremities, hemivertebrae, genital hypoplasia, and "fetal facies" (Wadlington et al. 1973). The incidence is estimated to be approximately 1 in 500,000.

Synonyms and Related Disorders

Acral dysostosis with facial and genital abnormalities; Costovertebral segmentation defect with mesomelia; Fetal face syndrome; Robinow dwarfism

Genetics/Basic Defects

1. Genetic heterogeneity (Robinow 1993)
2. Autosomal recessive (AR) form
    1. Affected siblings from consanguineous parents (Teebi 1990; Schorderet et al. 1992).
    2. Phenotype tends to be more severe than the autosomal dominant form.
    3. Caused by different homozygous (and compound heterozygous) missense, nonsense, and frameshift mutations of the *ROR2* gene (Tufan et al. 2005).
    4. *ROR2* gene:
        1. Mapped to chromosome 9q22 (Afzal et al. 2000a).
        2. Encoding an orphan receptor tyrosine kinase 2 with orthologues in mouse and other species.
        3. Mutation of the gene encoding the ROR2 tyrosine kinase causes autosomal recessive Robinow syndrome (van Bokhoven et al. 2000).
        4. Allelic to dominant brachydactyly type B (characterized by terminal deficiency of fingers and toes) (Afzal et al. 2000b; Patton and Afzal 2002; Afzal and Jeffery 2003).
3. Autosomal dominant (AD) form (Person et al. 2010):
    1. Caused by missense mutations in *WNT5A*, which result in amino acid substitutions of highly conserved cysteines and are associated with autosomal dominant Robinow syndrome.
    2. One mutation has been found in all living affected members of the original family described by Meinhard Robinow and another in a second unrelated patient.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_206

3. Targeted sequencing identified five unrelated individuals harboring heterozygous, de novo frameshift variants in *DVL3*, including two splice acceptor mutations and three 1 bp deletions. Similar to the variants observed in *DVL1*-mediated Robinow syndrome, all variants in *DVL3* result in a −1 frameshift, indicating that these highly specific alterations might be a common cause of dominant Robinow syndrome (White et al. 2016).
4. Mutations in *DVL1* cause an osteosclerotic form of Robinow syndrome (Bunn et al. 2015).

Clinical Features

1. Characteristic craniofacial appearance (Butler and Wadlington 1987)
    1. Early childhood
        1. Frontal bossing
        2. Midfacial hypoplasia
        3. Occasional midline capillary hemangioma
        4. Eyes
            1. Marked hypertelorism
            2. Prominent eyes giving the appearance of exophthalmos (pseudoexophthalmos)
        5. A short upturned nose with anteverted nares
        6. Mouth (Soman and Lingappa 2015)
            1. Long philtrum.
            2. Small chin.
            3. "Tented" upper lip having an inverted-V appearance with tethering in the center.
            4. Midline clefting of the lower lip.
            5. Gum hypertrophy at birth.
            6. Dental crowding/irregular teeth.
            7. "Tongue tie" (ankyloglossia) resembling a bifid tongue when the tongue tie is marked.
            8. Malocclusion in the form of crowding and irregular teeth may be seen in primary and secondary dentition.
        7. Ears
            1. Low set
            2. Simple
            3. Deformed pinna
        8. Resemblance to a fetal face
            1. Relatively small face.
            2. Laterally displaced eyes.
            3. Forward-pointing alae nasi.
            4. "Fetal facies" becomes less prominent over time.
            5. Facial features of autosomal dominant RS (with WNT5A mutation) in Chinese ethnic background are not different from those in other ethnicities (Xiong et al. 2016).
    2. Adulthood
        1. Loss of fetal facial proportions
        2. Absent midfacial hypoplasia
        3. Persistent hypertelorism with a broad nasal root and broad forehead
2. Short stature
    1. Reduced birth length
    2. Not a universal finding with some reports of normal growth
3. Limb abnormalities
    1. Mesomelic or acromesomelic limb shortening
    2. Shortening of the forearms more striking than the shortening of the legs
    3. Occasional Madelung deformity
    4. Hands/feet
        1. Brachydactyly with shortening of the distal phalanx and nail hypoplasia or dystrophy
        2. Thumbs
            1. Displaced
            2. Occasionally bifid
            3. Partial cutaneous syndactyly
            4. Ectrodactyly (especially patients reported from Turkey)
4. Other skeletal abnormalities
    1. Chest deformities
    2. Kyphoscoliosis
    3. Vertebral anomalies
    4. Rib defects
    5. Pectus excavatum

6. Acrodysostosis
7. Delayed bone age

5. Genital hypoplasia
    1. Genital abnormalities: may be present at birth causing concern regarding gender assignment
        1. Males
            1. Micropenis
            2. Normal scrotum and testes
        2. Females
            1. Reduced clitoral size
            2. Hypoplasia of the labia minor
            3. Associated vaginal atresia and hematocolpos
        3. Onset of puberty normal in both sexes
        4. Several reports of both male and female patients having normal children
6. Congenital heart defects (15%) (Webber et al. 1990; Atalay et al. 1993; Al-Ata et al. 1998)
    1. Severe pulmonary stenosis or atresia (the most common cardiac abnormalities)
    2. Atrial septal defect
    3. Ventricular septal defect
    4. Coarctation of the aorta
    5. Bicuspid aortic valve
    6. Tetralogy of Fallot
    7. Tricuspid atresia
    8. Double-outlet right ventricle
    9. Patent ductus arteriosus
7. Renal abnormalities
    1. Hydronephrosis (relatively common)
    2. Cystic dysplasia of the kidney (Wiens et al. 1990)
8. Developmental delay but intelligence is usually normal
9. Dermatoglyphics
    1. Absent interphalangeal creases
    2. Bilateral transverse creases
    3. Hypothenar whorl pattern
10. Clinical characteristics of recessive Robinow syndrome: Tend to be more severe with fusions of vertebrae and ribs, hemivertebrae, radial head dislocation, severe mesomelic brachymelia than the dominant form (Patton and Afzal 2002). Parental consanguinity, multiple affected sibs, or other similarly affected family members in addition to increased mortality rate among affected patients favored the AR inheritance pattern of RS (Aglan et al. 2015).
    1. Short stature
    2. Mesomelic and acromelic brachymelia
    3. Thick abnormally modeled radius and ulna
    4. Characteristic face
        1. Hypertelorism
        2. Wide palpebral fissures
        3. Broad-based nose with everted nares
        4. Large mouth
        5. Gum hypertrophy
        6. Irregular and crowded teeth
    5. Costovertebral anomalies
    6. Endocrine dysfunction
        1. Empty sella
        2. Partial insensitivity of Leydig cells to HCG
        3. Low basal testosterone in prepubertal boys
        4. Defective sex-steroid feedback mechanism
    7. Micropenis in males
11. Clinical characterization of autosomal dominant and recessive variants of Robinow syndrome, based on inheritance pattern in familial cases and presence of rib fusions as diagnostic of the recessive variant (Mazzeu et al. 2007):
    1. Clinical signs present in more than 75% of patients with either form and therefore the most important for the characterization of this syndrome:
        1. Hypertelorism
        2. Nasal features (large nasal bridge, short upturned nose, and anteverted nares)
        3. Midfacial hypoplasia
        4. Mesomelic limb shortening
        5. Brachydactyly
        6. Clinodactyly
        7. Micropenis
        8. Short stature
    2. The craniofacial dysmorphology of RS was more severe in ARRS (Beiraghi et al. 2011).
        1. Nasal anomalies were the most frequent craniofacial features in both ADRS and ARRS.

2. In contrast, intraoral features such as wide retromolar ridge, alveolar ridge deformation, malocclusion, dental crowding, and hypodontia were more severe in patients with ADRS.
3. Overall, facial characteristics appeared less pronounced in adult subjects compared to younger subjects.
4. Craniofacial and intraoral findings are highly variable in RS, with abnormalities of the intraoral structures being more prominent in the ADRS form.
5. The difference in the alveolar ridge deformation pattern and severity of other intraoral characteristics could enhance the differential diagnosis of the two forms of this syndrome.
    1. Hemivertebrae and scoliosis were present in more than 75% of patients with the recessive form but in less than 25% of patients with the dominant form.
    2. Umbilical hernia (32.3%) and supernumerary teeth (10.3%) were found exclusively in patients with the dominant form.
2. Differential diagnosis of mesomelic dwarfism (Giedion et al. 1976)
    1. With Madelung deformity: dyschondrosteosis (please see the chapter on "► Dyschondrosteosis")
    2. With malformations of long bones depending on various distribution/severity patterns and types of transmission
        1. Ulnofibular
            1. With mild triangular deformity
            2. With extreme variety: boomerang bone disease
        2. Radiotibial with "normal" fibula
        3. Ulno-fibular-mandibular (Langer type, homozygous dyschondrosteosis)
        4. Ulno-radio-fibular-tarsal with square, triangular, or rhomboid tibia
        5. Ulno-radio-tibial with absent fibula
    3. With associated malformations of spine
        1. Robinow syndrome
        2. Wegmann syndrome
        3. Campallia and Martinelli syndrome
        4. "Spondylo-epiphyso-metaphyseal" dysplasia
    4. With acrodysplasia
        1. Acromesomelic dwarfism
        2. Ellis-van Creveld syndrome (please see the chapter on "► Ellis-van Creveld Syndrome")
        3. Grebe achondrogenesis

Diagnostic Investigations

1. Partial primary hypogonadism in pubertal boys, with persistence of micropenis (Lee et al. 1982)
    1. Normal pubertal virilization with persistence of micropenis
    2. Elevated basal serum follicle-stimulating hormone levels and a hyperresponse of serum-luteinizing hormone to gonadorelin hydrochloride (Factrel) stimulation among postpubertal male patients, suggesting partial primary hypogonadism
    3. Normal 5 alpha-reductase and androgen receptor activity in genital skin fibroblasts
    4. Normal to borderline adult height.
2. Radiography
    1. Skull
        1. Macrocephaly
        2. Prominent forehead
        3. Hypertelorism
        4. Hypoplastic mandible
        5. Dental anomalies
    2. Spine/ribs: widespread fusion of thoracic vertebrae with frequent hemivertebrae and fusion of the ribs, resembling Jarcho-Levin syndrome (spondylocostal dysostosis) in severe cases (autosomal recessive form)

1. Hemivertebrae and vertebral fusions
2. Fusion of ribs
3. Shortened interpeduncular distance

3. Extremities (long bones): mesomelic shortening
   1. Upper extremities
   2. Lower extremities
   3. Ulna shorter than radius
   4. Luxation of the radius
4. Hands and feet
   1. Brachymesophalangism of fifth digits
   2. Clinodactyly of the fifth digits
   3. Shortening of other phalanges
   4. Brachymetacarpism
   5. Fusion of carpal bones
   6. Bifid terminal phalanges (splitting of one or more distal phalanges)
   7. Fusion of phalanges
   8. Retarded bone age
5. Axial and appendicular osteosclerosis: may represent a distinctive sub-phenotype of Robinow syndrome (Bunn et al. 2014)
   1. Marked generalized osteosclerosis affecting the skull, axial and appendicular skeleton.
   2. The calvaria were thickened and sclerotic with the skull base most affected.
   3. The frontal sinuses were hypoplastic.
   4. There was undertubulation of the long bones with pronounced cortical thickening.
   5. The ulnae were bowed bilaterally.

3. Computed tomography scan and magnetic resonance imaging (Altunkas et al. 2016)
   1. Rib fusions
   2. Multilevel block vertebrae
   3. Butterfly vertebra
   4. Posterior fusion defects in vertebrae
   5. Diastematomyelia in the spinal cord
4. A single butterfly vertebra is more frequent in the dominant form, whereas hemivertebrae, vertebral fusions, and narrow interpedicular distance are more frequent in the recessive form (Kanatupra et al. 1999).
5. Spondylothoracic dysplasia is formed as a result of posterior fusion of cervical-thoracic-lumbar vertebrae with hypoplastic-dysplastic asymmetric rib changes (Bain et al. 1986).
6. Renal ultrasound for renal anomalies.
7. Echocardiography for congenital heart disease.
8. Growth hormone assay for possible growth hormone deficiency.
9. DNA mutation analysis: available on clinical basis.
   1. *ROR2* gene is the gene responsible for autosomal recessive *ROR2*-related Robinow syndrome.
   2. Sequence analysis of *ROR2* gene detects 65–100% of affected individuals.

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Autosomal dominant inheritance: not increased unless a parent is affected
      2. Autosomal recessive inheritance: 25%
   2. Patient's offspring
      1. Autosomal dominant inheritance: 50%
      2. Autosomal recessive inheritance: not increased unless the spouse is a carrier
2. Prenatal diagnosis
   1. Ultrasonography
      1. First-trimester ultrasonography: shortening of extremities and increased nuchal translucency thickness in a family at risk (Percin et al. 2001)
      2. Possible by measuring the length of the long bones and the ulna/humerus ratio for the fetus at risk (Loverro et al. 1990)
      3. Characteristic US craniofacial findings: hypertelorism with prominent eyes that give the impression of exophthalmos, low-set ears, micrognathia, and cleft palate (Castro et al. 2014)
   2. Prenatal diagnosis: also possible for pregnancies at increased risk for ROR2-related Robinow syndrome by sequencing of entire coding region of *ROR2* gene on fetal DNA obtained by amniocentesis or CVS, provided the disease-causing alleles have been previously identified in the proband.

3. Prenatal diagnosis and preimplantation genetic diagnosis (PGD) for at-risk pregnancies require prior identification of the pathogenic variants in the family (Bacino 2011; Roifman et al. 2015).

3. Management
   1. Anticipate difficult intubation because of midfacial hypoplasia.
   2. Orthopedic care for vertebral anomalies and hip dislocation.
   3. Orthodontics for dental malalignment.
   4. Surgery for cleft lip and palate, inguinal hernia, and undescended testes.
   5. Growth hormone therapy if associated with growth hormone deficiency (Kawai et al. 1997; Castells et al. 1999).
   6. HCG and/or testosterone therapy during infancy may improve the severe micropenis in these patients (Soliman et al. 1998).
   7. Psychologic support.

Rubinstein-Taybi Syndrome

Contents

In *1963*, Rubinstein and Taybi (1963) described a new syndrome characterized by broad thumbs and toes, facial abnormalities, and mental retardation. The prevalence of Rubinstein-Taybi syndrome (RTS) is estimated to be 1 in 100,000–1 in 125,000 live births in the Netherlands.

Synonyms and Related Disorders

Broad thumb-hallux syndrome (Rubinstein 1990); broad thumbs and great toes, characteristic facies, and mental retardation; Rubinstein syndrome

Genetics/Basic Defects

1. Inheritance: autosomal dominant.
2. Most cases are sporadic (~99%); familial cases are extremely rare (Hennekam et al. 1989; Bartsch et al. 2010).
3. Caused by deletions or heteroallelic mutations of *CREBBP*, the gene for cAMP-responsive element-binding (CREB) protein, which resides on chromosome 16p13.3 (Lacombe et al. 1992; Hennekam et al. 1993; Giles et al. 1997). CREBBP is a large nuclear protein involved in transcription regulation, chromatin remodeling, and the integration of several different signal transduction pathways. The following mutations of *CREBBP* were reported in patients with Rubinstein-Taybi syndrome (Bartsch et al. 2002; Coupry et al. 2002):
    1. Chromosomal translocations (t(2;16)(p13.3;p13.3)) (Imaizumi and Kuroki 1991)/inversions
    2. Deletions at the microscopic and submicroscopic levels (Masuno et al. 1994; Wallerstein et al. 1997; Taine et al. 1998)
    3. Molecular mutations
4. Mutations in the *CREBBP* gene are responsible for:
    1. Rubinstein-Taybi syndrome (Petrij et al. 1995)
    2. t(8;16)-associated acute myeloid leukemia
5. Also rarely caused by mutations in *EP300* gene (located on 22q13.2)
    1. Individuals reported with mutations in *EP300* have a milder skeletal phenotype, lacking typical broadening and angulation of the thumb and hallux (Bartholdi et al. 2007).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_207

2. As more of the EP300 protein is preserved, particularly the HAT domain, the milder the phenotype (Sellars et al. 2016).
3. EP300 mutations might account for a higher frequency of RTS patients than previously thought. The clinical presentation of EP300-mutated patients is milder than that of CREBB-mutated patients (Negri et al. 2015).

6. RTS caused by mutations in *CREBBP* has been referred to as RTS type 1 (RTS1), whereas mutations in *EP300* cause RTS type 2 (RTS2) (Hamilton et al. 2016).
7. No clear phenotypic differences are observed between patients in whom microdeletions or truncating mutations were found.
8. Variable expression and somatic mosaicism contribute to the phenotypic variability of RTS. Somatic mosaicism may be more frequent in RTS than previously assumed (Bartsch et al. 2010).
9. Different chromosomal anomalies have been identified in some patients with this syndrome (Imaizumi et al. 1993; Cantani and Gagliesi 1998).

Clinical Features

1. Characteristic craniofacial features.
    1. Typical facial phenotype may not be obvious until late childhood (Allanson 1990; Hennekam 1993).
    2. Microcephaly (35–94%).
    3. Prominent forehead.
    4. Down-slanting palpebral fissures.
    5. Apparent ocular hypertelorism.
    6. High-arched or heavy eyebrows.
    7. Long eyelashes.
    8. Epicanthal folds.
    9. Prominent nose with columella (lower margin of the nasal septum) below the alae nasi.
    10. Malpositioned ears with dysplastic helices.
    11. Grimacing smile.
    12. Hypoplastic maxilla.
    13. Oral features (Hennekam and Van Doorne 1990)
        1. Thin upper lip
        2. Small oral opening
        3. Pouting lower lip
        4. Retro/micrognathia
        5. Apparently higher arched, narrow palate
        6. Cleft uvula
        7. Cleft palate
        8. Rarely, cleft upper lip
2. Skeletal abnormalities.
    1. Broad thumbs and broad hallux: the hallmarks for the Rubinstein-Taybi syndrome (da Silva et al. 2014)
    2. Thumbs
        1. Broad terminal phalanges
        2. Severe radial angulation deformity ("hitchhiker thumbs") with abnormal shape of the proximal phalanx, which prevents opposition and functional gripping strength (Wood and Rubinstein 1987)
    3. Great toes
        1. Broad terminal phalanges
        2. Angulation deformity with abnormal shape of the proximal phalanx or first metatarsal
        3. Duplicated proximal phalanx
        4. Duplicated distal phalanx
    4. Short stature (78%)
    5. Fifth finger clinodactyly
    6. Overlapping toes
    7. Broad terminal phalanges of other fingers
    8. Pelvic anomalies
        1. Flat acetabular angles
        2. Flaring of the ilia
        3. Notch in the ischia
    9. Stiff gait
    10. Lax ligaments
    11. Hyperextensible joints
    12. Vertebral anomalies
        1. Spina bifida
        2. Kyphosis
        3. Lordosis
        4. Scoliosis
    13. Sternal or rib anomalies
        1. Premature fusion

2. Simian sternum
3. Pectus excavatum or carinatum
4. Forked ribs
5. Cervical ribs
6. Fusion of the first and second ribs

3. History of maternal polyhydramnios (30%) (Hennekam 2006).
4. Hypotonia.
5. Growth retardation.
6. Developmental delay.
7. Variable mental retardation.
   1. Severe in some patients
   2. Moderate degree in many patients
   3. Mild in some patients
8. Behavioral/psychiatric disorders (Levitas and Reid 1998; Hellings et al. 2002).
   1. Childhood (Gotts and Liemohn 1977)
      1. More emotional and excitable
      2. Nightmares and engaged in self-stimulation
      3. Greater difficulty getting over anger (pouted)
      4. Friendly and more readily accepted social contacts
      5. Short attention span
      6. Experience more difficulty in planning motor acts and in executing locomotor and oculomotor skills
      7. Impulsiveness
      8. Clinically nonsignificant stereotype
      9. Withdrawal
      10. Expressive speech skill difficulty and "maladaptive behavior" (Stevens et al. 1990)
      11. Repetitive motions
      12. Resistance to change
      13. Distractibility
      14. Aggressive outbursts
      15. Difficulty in sleeping
   2. Adulthood
      1. Mood disorders
      2. Chronic motor tic disorder
      3. Obsessive compulsive disorder
      4. Depressive disorder
      5. Bipolar disorder
      6. Tourette disorder
      7. Trichotillomania
      8. Pervasive developmental disorder
      9. Self-injurious behaviors
      10. Autistic features
      11. Preference of being alone (between manic episodes)
9. Seizures (27–28%).
10. Ophthalmologic problems: very frequent in RST, ~80% of cases having extraocular or intraocular features (Brei et al. 1995; Van Genderen et al. 2000).
    1. Strabismus (60–71%) with subsequent risk of amblyopia.
    2. Refractive errors (41–56%).
    3. Lacrimal duct obstructions (38–47%).
    4. Ptosis (29–32%).
    5. Coloboma (9–11%).
    6. Duane retraction syndrome (8%).
    7. Ghost vessels.
    8. Peters anomaly.
    9. Optic nerve hypoplasia.
    10. Cataracts.
    11. Corneal opacities.
    12. Congenital glaucoma: the most serious one that requires early diagnosis and treatment is glaucoma.
    13. Retinal abnormalities.
11. Dental manifestations (67%).
    1. Talon cusps of secondary dentition
    2. Crowding and malpositioned teeth
    3. Anterior and posterior crossbites secondary to a narrow palate or jaw size discrepancy
    4. Natal teeth
    5. Gingivitis
    6. Hypodontia/hyperdontia
    7. Increased rate of carries
12. Hearing loss.
13. Respiratory problems.
    1. Neonatal respiratory problems
    2. Upper airway infections
14. Upper airway obstruction during sleep due to:
    1. Hypotonia
    2. Anatomy of the oropharynx and airway
       1. Small nasal passages
       2. Retrognathia
       3. Micrognathia
       4. Hypertrophy of the tonsils and adenoids
       5. Obesity

15. Gastrointestinal problems.
    1. Significant gastroesophageal reflux
    2. Feeding difficulties
    3. Constipation
16. Congenital heart disease (24–38%) (Stevens and Bhakta 1995).
    1. ASD
    2. VSD
    3. PDA
    4. Coarctation of the aorta
    5. Pulmonary stenosis
    6. Bicuspid aortic valve
    7. Pseudotruncus
    8. Aortic stenosis
    9. Hypoplastic left heart syndrome (Bartsch et al. 1999)
    10. Complex congenital heart defects
    11. Dextrocardia
    12. Vascular rings
    13. Conduction problems
17. Renal anomalies (52%).
    1. Hydronephrosis
    2. Duplications
    3. Vesicoureteral reflux
    4. Urinary tract infections
    5. Renal stones
    6. Nephrotic syndrome
    7. Neurogenic bladder
18. Cutaneous manifestations (Selmanowitz and Stiller 1981).
    1. Tendency of keloid and hypertrophic scar formation
    2. Ingrown toenails
    3. Toenail paronychia (44%)
    4. Fingernail paronychia (9%)
    5. Pilomatrixomas
    6. Capillary hemangioma
        1. Forehead
        2. Nape of the neck
        3. Back
    7. Supernumerary nipples
    8. Hirsutism
    9. Transverse palmar creases
    10. Deep plantar crease between the first and second toes
19. Orthopedic problems.
    1. Hypotonia
    2. Lax ligaments
    3. Tight heel cords
    4. Elbow abnormalities
    5. Legg-Perthes disease (3%)
    6. Dislocated patella (2.5%)
    7. Congenital hip dislocation (1.4%)
    8. Slipped capital femoral epiphysis (0.6%)
    9. Congenital or acquired scoliosis, kyphosis, and lordosis
    10. An increased risk of associated thickened filum terminale, tethering of the cord, and lipoma
    11. An increased risk of fractures
20. Polysplenia (Bartsch et al. 1999).
21. A germ cell tumor occurring in a pediatric patient with RTS (Butler et al. 2016): a palpable right-sided abdominal mass and an elevated alpha-fetoprotein. Histology revealed a malignant germ cell neoplasm arising within the undescended testis.
22. An increased risk of having benign and malignant tumors as well as leukemia and lymphoma (Miller and Rubinstein 1995).
    1. Oligodendroglioma
    2. Medulloblastoma
    3. Neuroblastoma
    4. Meningioma
    5. Pheochromocytoma
    6. Nasopharyngeal rhabdomyosarcoma
    7. Leiomyosarcoma
    8. Seminoma
    9. Embryonal carcinoma
    10. Odontoma
    11. Choristoma
    12. Dermoid cyst
    13. Pilomatrixomas (Rokunohe et al. 2016)

Diagnostic Investigations

1. Developmental evaluation
2. Echocardiography for cardiac defects
3. Ophthalmologic examination
4. Renal ultrasound
5. Voiding cystourethrogram
6. Hearing evaluation
7. EEG (Giacobbe et al. 2016)
    1. Normal (24%)
    2. Interictal abnormalities (76%)

1. Spikewave and polyspikewave generalized and spike
2. Spikewave in fronto-central and/or temporal regions
3. Monomorphic activity (33%)

8. Radiography
   1. Hands
      1. Broad thumbs (Hennekam et al. 1990b)
      2. Broad first distal phalanx
      3. Broad first ray
      4. Duplicated first distal phalanx
      5. Delta-shaped proximal phalanges of the thumbs
      6. Mushroom-shaped distal phalanges
      7. Angulation of the distal phalanges
      8. Thin tubular bones
      9. Delayed bone age (74%)
   2. Feet
      1. Broad halluces (Hennekam et al. 1990b).
      2. Broad first distal phalanx.
      3. Broad first ray.
      4. Duplicated first distal phalanx.
      5. Duplicated first proximal and distal phalanges.
      6. Delta-shaped first proximal phalanx. A duplicated longitudinal bracketed epiphysis ("kissing delta" phalanx) always involves the proximal phalanx of the great toe (Wood and Rubinstein 1999).
      7. Angulation deformity of the hallux.
      8. Mushroom-shaped distal phalanges.
      9. Very small distal phalanges.
      10. Thin tubular bones.
      11. Protruding calcaneus.
      12. Synostosis of cuneiform ossicles.
      13. Proximally split fifth metatarsal bone.
   3. Limbs
      1. Thin tubular bones
      2. Fractures
      3. Patella luxations
   4. Spine
      1. Cervical hyperkyphosis
      2. Lumbar hyperlordosis
      3. Scoliosis
      4. Spina bifida occulta: cervical or lumbosacral
      5. Spondylolisthesis
      6. Irregular thoracic endplates
   5. Skull
      1. Microcephaly
      2. Absent sinus frontalis
      3. Deviated nasal septum
      4. Steep skull base
      5. Abnormally shaped sella turcica
      6. Foramina parietal permagna
      7. Prominent digital marking
   6. Thorax
      1. Narrow thoracic aperture
      2. 11 ribs
      3. Fusion of ribs
      4. High diaphragm
   7. Pelvis
      1. Small iliac wings
      2. Flaring iliac wings
      3. Irregularly formed acetabulum
      4. Symphysiolysis
9. MRI (Giacobbe et al. 2016)
   1. Corpus callosum dysmorphism (from mild to severe) (74%)
   2. White matter hyperintensity (63%)
10. Diagnosis of Rubinstein-Taybi syndrome
    1. Made primarily by clinical examination
    2. Confirmed by the presence of microdeletion
11. Cytogenetic analysis: chromosome abnormalities observed in about 10% of patients (Breuning et al. 1993; Blough et al. 2000; Petrij et al. 2000b)
    1. FISH analysis with RT1 probe (McGaughran et al. 1996) and cosmids from the *CBP* region to detect chromosome 16p13.3 microdeletion (Petrij et al. 2000a)
    2. Chromosome abnormalities
       1. t(2;16)(p13.3;p13.3)
       2. t(7;16)(q34;p13.3) (Tommerup et al. 1992)
       3. Inv(16)(p13.3q13)
12. Clinical testing of *CREBBP* gene: available clinically
    1. Fluorescent in situ hybridization (FISH) probes.
       1. Specific for chromosome region 16p13.3

2. Containing regions of the cyclic AMP-responsive element-binding protein gene (*CBP* gene)
3. Microdeletions identified in approximately 10% of patients by five cosmid probes containing almost the entire gene

2. Sequence analysis/mutation scanning available clinically detects *CREBBP* mutation in another 30–50% of affected individuals.
3. Deletion/duplication analysis using array CGH or quantitative multiplex fluorescent-PVR.
4. Whole exome sequencing can be successfully applied as a tool for clinical differentiation of overlapping RST phenotypes (Kamenarova et al. 2016).

13. Clinical testing of *EP300* gene: available clinically
    1. *EP300* mutations available clinically can identify approximately 3% of affected individuals.
    2. Deletion/duplication analysis.

Genetic Counseling

1. Recurrence risk (Berry 1987; Hennekam et al. 1990a; Baxter and Beer 1992).
    1. Patient's sib: Accumulating data suggest a recurrence risk of approximately 0.5–1.0% for parents of a child with RTS due to gonadal mosaicism, exceeding the so far empiric estimated risk of 0.1% for siblings (Chiang et al. 2009; Bartsch et al. 2010)
    2. Patient's offspring: as high as 50%, particularly in individuals with deletions.
    3. Germline mosaicism (Tajir et al. 2013).
        1. Chiang et al. reported a family with two affected siblings with the same CREBBP mutation. This mutation was not found in the blood and saliva DNA samples from the parents, suggesting the mechanism of germline mosaicism (Chiang et al. 2009).
        2. The second report of the recurrence of RSTS with CREBBP mutation in non-twin siblings whose parents are unaffected. It confirms that germ cell mosaicism is a cause of familial recurrence of RSTS with impact on genetic counseling.
        3. Many clinical geneticists and genetic counselors give a recurrence risk of about 1% for RSTS in a family with an obvious sporadic case of RSTS in a child (similar to the situation in many other diseases that occur mostly or exclusively as a consequence of de novo mutation events) (van Belzen et al. 2011).
2. Prenatal diagnosis.
    1. 3D ultrasonography (Bedeschi et al. 2014)
        1. Broad thumb
        2. Facial anomalies: broad nasal bridge and tip with columella extending below the nasal alae, long philtrum
    2. Possible for fetuses at risk on fetal cells obtained by amniocentesis or chorionic villus sampling, provided the disease-causing *CREBBP* or *EP300* mutation or deletion in an affected family member is known (Stevens 2014)
3. Preimplantation genetic diagnosis for at-risk pregnancies requires prior identification of the disease-causing mutation in the family (Stevens 2014).
4. Management (Wiley et al. 2003).
    1. Early intervention programs
        1. Physical therapy
        2. Occupational therapy
        3. Speech therapy
    2. Management of gastroesophageal reflux
    3. Prophylaxis for subacute bacterial endocarditis for patients at risk
    4. Requires assistance and training in self-help skills but can become self-sufficient in most self-help areas such as feeding, dressing, and toileting
    5. Special education
    6. Behavioral modification
    7. Syndrome-specific growth charts can be used in managing problems related to growth in RTS individuals (Beets et al. 2014)

8. Surgery to correct a delta phalanx deformity (Wood and Rubinstein 1987)
9. Caution with general anesthesia in children (Stirt 1981; Karahan et al. 2016)
    1. Challenging to intubate due to airway anomalies.
        1. Relatively anterior position of the larynx
        2. Easily collapsible laryngeal wall
    2. Important to intubate due to the high risk of aspiration during induction and emergence.
    3. Presence of skeletal anomalies.
    4. Cardiac arrhythmia may result from use of cardioactive drugs.
        1. Atropine
        2. Neostigmine
        3. Succinylcholine
        4. Suxamethonium
    5. Control of a difficult airway and difficult intubation in terms of anesthesia management is the most important problem in patients with RTS because of their abnormal anatomical structures. Therefore, it is necessary to prepare for difficult ventilation and intubation prior to anesthesia. Because succinylcholine, neostigmine and atropine will increase the risk of arrhythmia, particularly in patients with heart defects, the use of a rocuronium-sugammadex combination may be a good alternative.

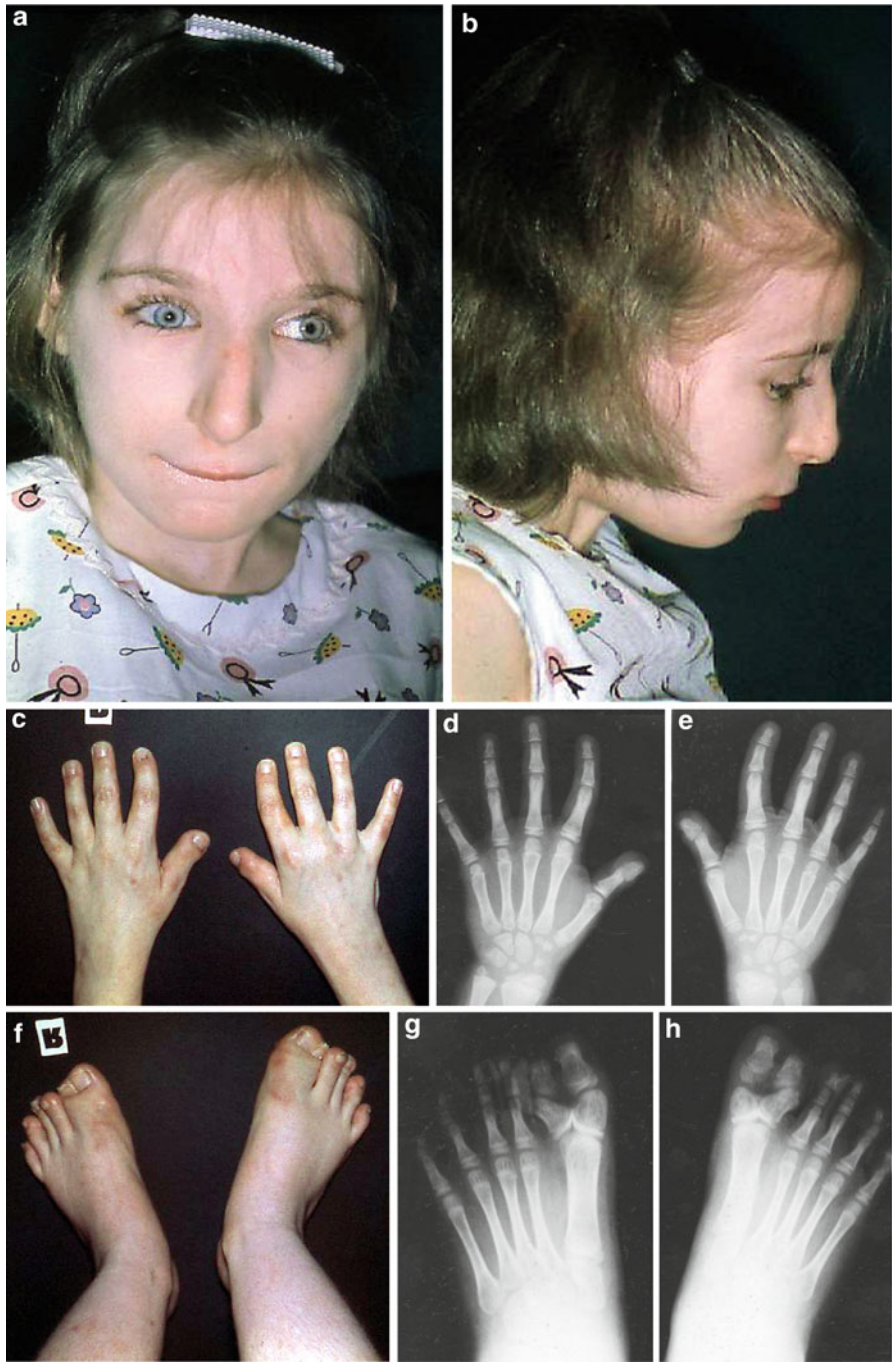

Fig. 1 (continued)

Fig. 1 (**a**–**l**) A patient with Rubinstein-Taybi syndrome at different ages (childhood (**a**–**h**) and adulthood (**i**–**l**)) showing typical facial appearance (prominent beaked nose with the columella below the alae nasi) (**a**, **b**, **i**, **j**), broad thumbs (**c**, **k**), and broad/bifid great toes (**f**, **l**), which are illustrated by radiographs (**d**, **e**, **g**, **h**)

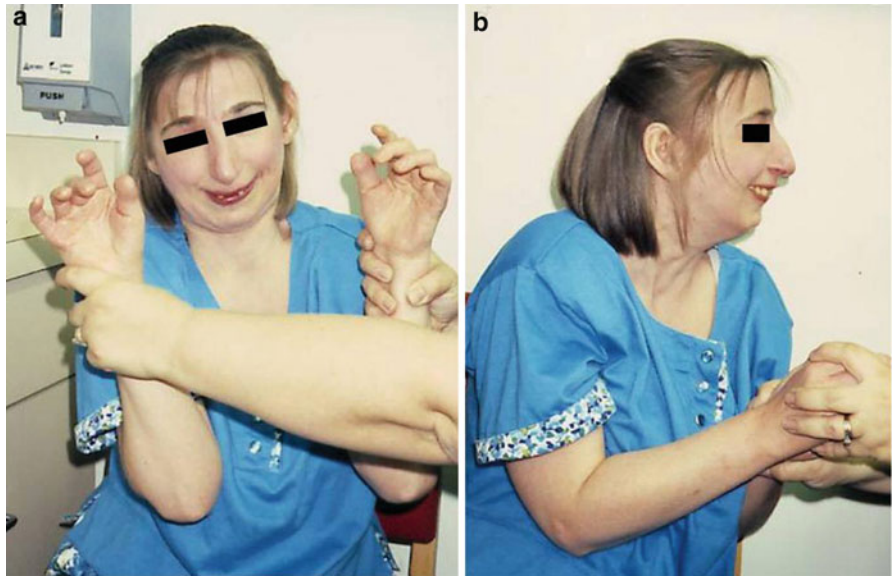

Fig. 2 (**a**, **b**) An adult with Rubinstein-Taybi syndrome showing the characteristic facies and broad thumbs

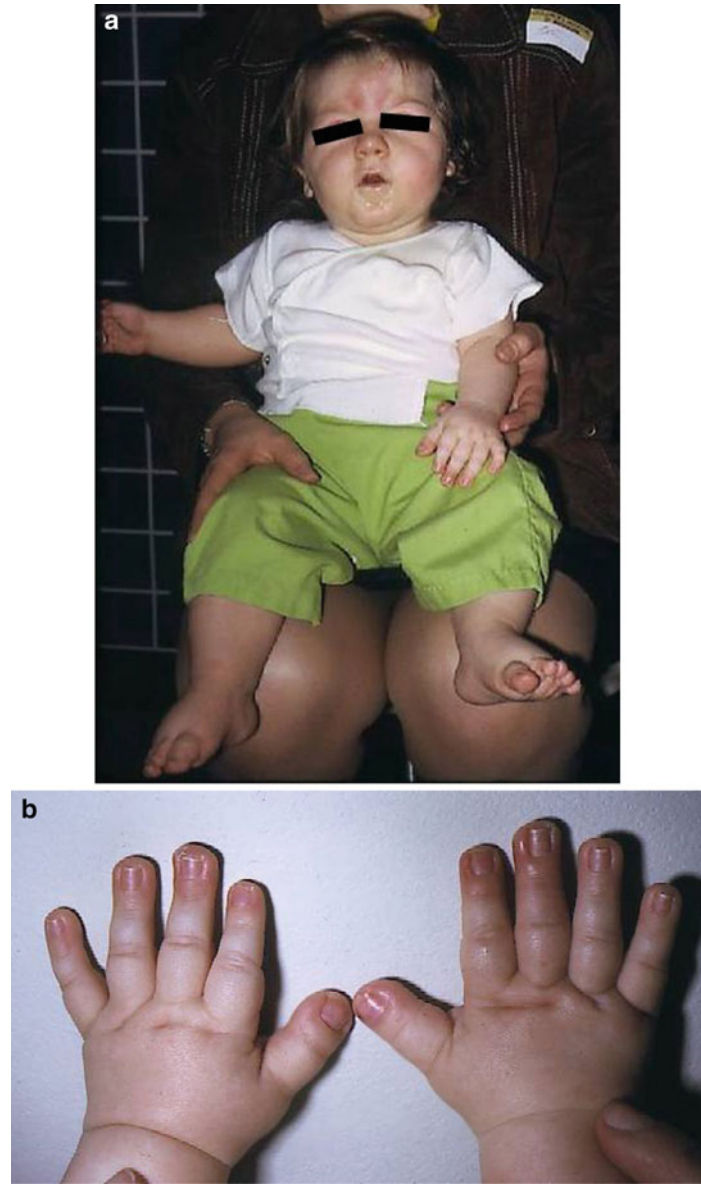

Fig. 3 (**a**, **b**) A young patient with Rubinstein-Taybi syndrome showing characteristic facies (**a**), broad thumbs (**b**), and great toes

Saethre-Chotzen Syndrome

Contents

Saethre (1931) in *1931* and Chotzen (1932) in *1932* separately described a group of patients with cranial vault dysmorphology ("acrocephaly"), skull asymmetry, and incomplete simple syndactyly of the index and middle fingers and the third and fourth toes.

Saethre-Chotzen syndrome (SCS) is one of the more common forms of syndromic craniosynostosis. Its prevalence was estimated to range from 1:25,000 to 1:50,000, approximately the same prevalence as Crouzon syndrome.

Synonyms and Related Disorders

Acrocephalosyndactyly, Type III; Acrocephaly, skull asymmetry, and mild syndactyly; Chotzen syndrome

Genetics/Basic Defects

1. An autosomal dominant disorder with high penetrance and wide variable expressivity (Foo et al. 2009). TWIST1 deletions and intragenic mutations manifest as either mild or severe craniofacial deformities.
2. A variety of mutations, including missense and nonsense mutations (el Ghouzzi et al. 1997), small insertions, duplications, and deletions (Gripp et al. 2000; Chun et al. 2002) on the *TWIST* gene, which was mapped at 7p21, lead to heterogeneous symptoms of the syndrome.
3. Increased risk for developmental delay in Saethre-Chotzen syndrome (SCS) is associated with TWIST deletions (Cai et al. 2003).
4. Strikingly, it was found that all Saethre-Chotzen syndrome patients with large genetic deletions, encompassing the *TWIST* gene and extending onto chromosome 7p, had mental retardation, a rare feature in the syndrome (Johnson et al. 1998; Zackai and Stolle 1998; Chun et al. 2002).
5. A patient with SCS, a large TWIST/7p deletion, and postnatal onset of craniosynostosis (de Heer et al. 2004).
6. A new stop codon mutation in the TWIST1 gene in SCS associated with renal cell carcinoma in childhood (Seifert et al. 2006).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_208

7. Notable intrafamilial phenotypic variability in a large family with Q28X TWIST mutation (Dollfus et al. 2002).
8. Patients with characteristics of Saethre-Chotzen syndrome but without *TWIST* mutations have been described (de Heer et al. 2005):
    1. Some of these patients harbored the *FGFR3* P250R mutation, nowadays considered to cause a distinct and unique craniosynostosis syndrome, Muenke syndrome (Muenke et al. 1997; Graham et al. 1998).
    2. Germline mutation in the FGFR3 gene in a TWIST1-negative family with Saethre-Chotzen syndrome and breast cancer (Sahlin et al. 2009).

Clinical Features

1. Widely variable phenotype
2. Craniosynostosis (premature fusion of one or more sutures of calvarium) (Paznekas et al. 1998):
    1. Coronal suture (unilateral or bilateral): most commonly affected:
        1. Bilateral (59% of cases)
        2. Unilateral (23% of cases)
    2. Other cranial sutures (21% of cases), such as sagittal, lambdoid, and metopic and even pansynostosis, may be involved:
        1. Can undergo premature fusion
        2. Reports of affected individuals with no evidence of pathologic suture
    3. Often presents with an abnormal skull shape:
        1. Brachycephaly (short, broad skull)
        2. Acrocephaly (tall skull)
    4. A new and unique pattern of sutural fusion "peace sign synostosis" characterized by synostosis of the metopic, bicoronal, and sagittal sutures and associated with abnormalities of the TWIST1 gene known to be associated with Saethre-Chotzen syndrome (Tahiri et al. 2015)
3. Other craniofacial features:
    1. Facial asymmetry (the most conspicuous facial feature), particularly in individuals with unicoronal synostosis
    2. Low frontal hairline
    3. Ptosis of the eyelids: often results from a defective functioning or agenesis of the levator palpebrae muscle
    4. Downslanting of the palpebral fissures
    5. Epicanthal folds
    6. Strabismus
    7. Amblyopia
    8. Midface hypoplasia
    9. A broad nose with depressed nasal bridge
    10. Characteristic appearance of the ears: low-set and rotated ears with small pinna with a prominent superior and/or inferior crus
4. Limb anomalies:
    1. Brachydactyly: most frequent finding
    2. Cutaneous syndactyly of the second and third digits of the hands and feet: highly variable degree but nearly diagnostic in the presence of limb anomalies
    3. Clinodactyly of the fifth fingers
    4. Transverse palmar creases often present
    5. Broad digit I of the feet
    6. Hallux valgus
    7. Duplicated distal phalanx of the hallux
    8. Triangular epiphyses of the hallux
5. Other variable clinical features:
    1. Short stature.
    2. Presence of foramina parietalia permagna (bony defects on both sides of the parietal suture exceeding 1 cm in diameter).
    3. Impressiones digitatae, considered to be an indicator of raised intracranial pressure, often recorded without the presence of increased intracranial pressure.
    4. Conductive, mixed, and profound sensorineural hearing loss (Lee et al. 2002).
    5. Most patients with Saethre-Chotzen syndrome had hearing loss at some point during childhood. This was typically mild and correlated with middle ear abnormality and eustachian tube dysfunction. Usually, the hearing deficit resolved. Early mischaracterization of mixed hearing loss or conductive hearing loss as sensorineural hearing loss was common (Rosen et al. 2011).
    6. Ocular hypertelorism.

7. Occasional blepharophimosis.
8. Lacrimal duct stenosis.
9. Maxillary hypoplasia.
10. High-arched and/or cleft palate.
11. Congenital heart defects.
12. Vertebral fusion.
13. Radioulnar synostosis.
14. Increased risk of cancers (breast (Sahlin et al. 2007), kidney).

6. Intelligence:
   1. More commonly normal intelligence
   2. Significant learning disability usually noted in affected individuals with microdeletion in 7p21 but severe delay or mental retardation is not typical
7. Family history of abnormal skull shape and/or a combination of other physical findings, usually present in SCS; however, craniosynostosis is not an obligatory finding (some affected relatives may not have been diagnosed with a craniosynostosis syndrome).
8. Differential diagnosis (Gallagher et al. 2012):
   1. Muenke syndrome (Kress et al. 2006):
      1. Characterized by "nonsyndromic" coronal craniosynostosis caused by the specific point mutation p.Pro250Arg in *FGFR3* (encoding fibroblast growth factor receptor-3)
      2. Shares features with Saethre-Chotzen syndrome (SCS)
      3. Individuals with *TWIST1* mutations distinguished from those with the *FGFR3* p.Pro250Arg mutations from a recent study of 39 pedigrees (71 affected individuals) ascertained on the basis of coronal synostosis with the following clinical features:
         1. A low frontal hairline
         2. Ptosis
         3. Small ears
         4. Parietal foramina
         5. Interdigital webbing
         6. Hallux valgus or broad great toe with bifid distal phalanx
   2. Isolated unilateral coronal synostosis:
      1. Represents coronal suture fusion with no evidence of other malformations.
      2. Approximately ten times more common than SCS. Coronal synostosis is the second most common form of single-suture fusion after sagittal synostosis.
      3. Facial asymmetry resembling SCS can result from untreated or incompletely treated isolated unilateral coronal synostosis.
   3. Baller-Gerold syndrome (BGS):
      1. Characteristic clinical features:
         1. Coronal craniosynostosis manifesting as abnormal shape of the skull (brachycephaly) with ocular proptosis and bulging forehead
         2. Radial ray defect manifesting as oligodactyly (reduction in number of digits), aplasia or hypoplasia of the thumb, and/or aplasia or hypoplasia of the radius
         3. Growth retardation
         4. Poikiloderma
      2. *RECQL4*: the only gene currently known to be associated with BGS.
      3. Clinical findings overlap with those of Rothmund-Thomson syndrome and Rapadilino syndrome, also caused by mutations in *RECQL4*.

Diagnostic Investigations

1. Diagnosis primarily based on clinical findings
2. Radiographic abnormalities:
   1. Pathognomonic signs for SCS are the triangular shape of the epiphysis and duplicated distal phalanx of the hallux. Calcaneocuboid fusion was detected in Muenke-type mutation (MTM) only. These signs may be helpful in the differentiation of SCS from Muenke-type MTM (Trusen et al. 2003).
   2. Vertebral fusion was present in 9 of the 20 patients (Anderson et al. 1997).
   3. Fusion of both the vertebral bodies and the posterior elements.
   4. C2–3 was the level most commonly involved.

5. Progressive vertebral fusions during childhood.

3. Molecular genetic testing:
   1. Identification of *TWIST* microdeletion by array CGH (Cho et al. 2013).
   2. *TWIST1* mutations: identified in 46–80% of affected individuals using a combination of deletion/duplication analysis and sequence analysis (positive in 46–80% of cases).
   3. Consider testing for *FGFR3* (p. Pro250Arg) mutation if no *TWIST1* mutation is identified in an individual with a presumed diagnosis of Saethre-Chotzen syndrome since clinical findings of Muenke syndrome overlap with Saethre-Chotzen syndrome.
4. Cytogenetic analysis:
   1. A diagnostic approach to identifying submicroscopic 7p21 deletions in Saethre-Chotzen syndrome: Fluorescence in situ hybridization and dosage-sensitive Southern blot analysis (Gripp et al. 2001)
   2. A chromosome translocation or inversion involving 7p21 or ring chromosome 7 reported in occasional patients with atypical findings, including developmental delay

Genetic Counseling

1. Recurrence risk:
   1. Patient's sib:
      1. A 50% risk if a parent is also affected
      2. An apparently low risk if the parents are clinically unaffected and do not have a *TWIST1* mutation:
         1. Spontaneous mutation rate if the proband represents de novo mutation.
         2. Possible parental germ line mosaicism exists although no instances of germ line mosaicism have been reported.
   2. Patient's offspring: a 50% recurrence risk for an affected individual to have an affected offspring
2. Prenatal diagnosis:
   1. Possible for pregnancies at increased risk if the disease-causing mutation has been identified in the family
   2. Prenatal diagnosis of a 7p15-p21 deletion encompassing the TWIST1 gene involved in Saethre-Chotzen syndrome (Spaggiari et al. 2012)
3. Preimplantation genetic diagnosis (PGD) may be an option for some families in which the disease-causing mutation has been identified (Gallagher et al. 2012).
4. Management:
   1. Cranioplasty in the first year of life:
      1. To prevent progressive facial asymmetry in those with asymmetric coronal fusion
      2. To prevent increased intracranial pressure (ICP) in those with multiple sutural synostosis
      3. To prevent developmental delay and impaired vision secondary to increased intracranial pressure
   2. Reoperation for high rate of recurrent elevated intracranial hypertension in TWIST1-confirmed Saethre-Chotzen syndrome (Bartlett and Foo 2009)
   3. Patients with TWIST1-confirmed Saethre-Chotzen syndrome had a reoperation rate of 65% for Whitaker class III and IV surgical outcome, and 59% of these patients required a secondary intracranial procedure for recurrent supraorbital retrusion (Foo et al. 2009).
   4. Midfacial surgery needed for dental malocclusion, swallowing difficulties, and respiratory problems.
   5. Cleft palate surgery usually follows cranioplasty.
   6. Orthodontic treatment and/or orthognathic surgery as needed near the completion of facial growth; developmental intervention.
   7. Routine treatment of hearing loss.
   8. Prevention of secondary complications:
      1. Attention to possible cervical vertebral instability secondary to vertebral anomalies
      2. Periodic ophthalmologic evaluation for chronic papilledema

3. Brain imaging in later life for evidence of increased intracranial pressure
4. Routine evaluation for facial asymmetry, psychomotor development, and hearing loss

9. Variability of the clinical spectrum of craniofacial disorders associated with TWIST1 abnormalities. It is important to note that the Saethre-Chotzen syndrome caused by microdeletion is generally characterized by a mental disability. However, the postoperative psychomotor development of the child considered was within the normal limits (di Rocco et al. 2015).

Fig. 1 (**a**, **b**) A 2-month-old boy was evaluated for trigonocephaly (metopic suture premature synostosis)

Fig. 2 His mother was diagnosed to have Saethre-Chotzen syndrome clinically. Preoperatively, she was noted to have marked forehead asymmetry, retrusion of the right side of the supraorbital region, disproportion of the orbits with the right orbit higher, and temporal fossa hollowness. The diagnosis was confirmed molecularly by detection of a *TWIST* gene mutation (c.396-416 dup mutation, i.e., c.417ins21) which has been previously detected in other Saethre-Chotzen syndrome patients

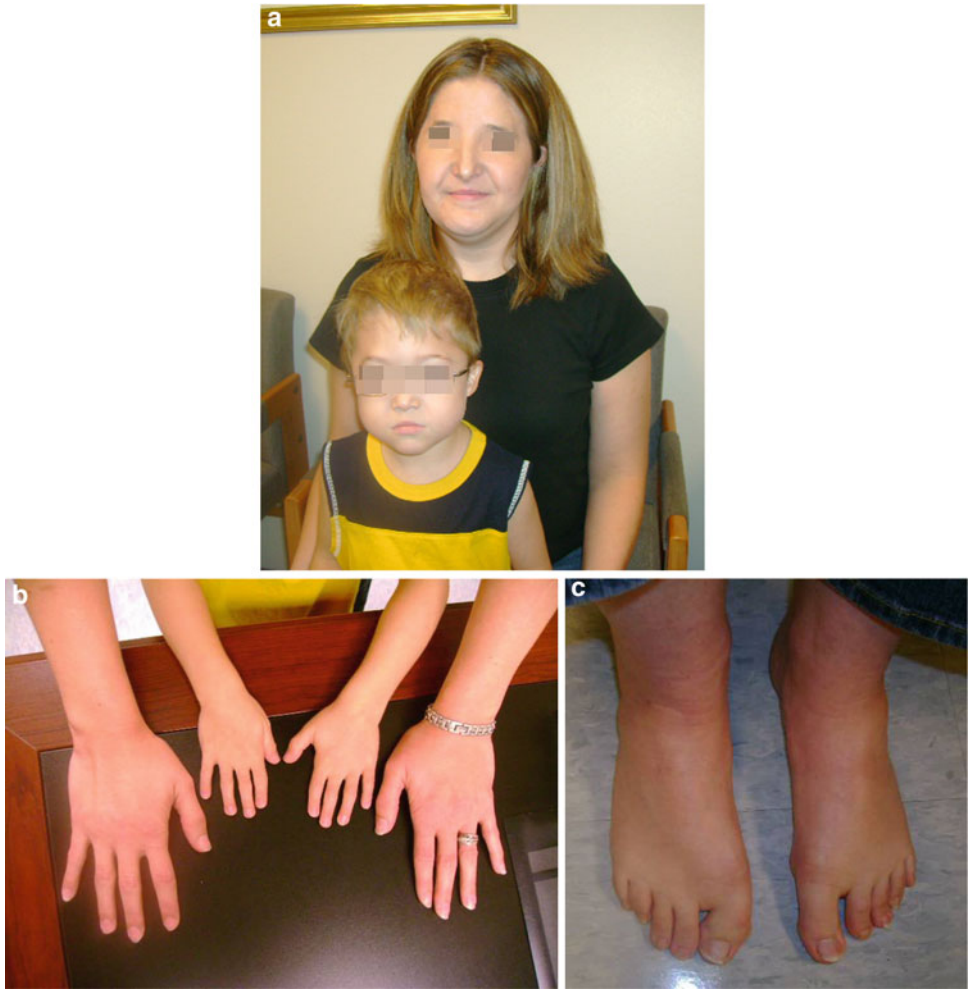

Fig. 3 (**a**–**c**) Follow-up visit of the child and the mother

Fig. 4 (**a**–**f**) A 42-year-old man (**a**, **b**) was diagnosed to have Saethre-Chotzen since childhood. He was noted to have a brachycephalic skull with midfacial hypoplasia, a high forehead with a low hairline, a small cranial vault, asymmetric face with a curved nose, marked ptosis, down turned upper lip, underbite, repaired cleft palate, an underbite, low-set ears with prominent crus, cutaneous syndactyly, and contractures at the proximal interphalangeal joints in the second and fifth digits bilaterally (**c**–**f**), a single flexion crease in the fifth digit of both hands with unusual palmar creases, short toes with broad great toes bilaterally, minimal cutaneous syndactyly of toes 2–3 bilaterally, and bilateral hearing aids in place. In addition, he had developmental delay, seizures, heart murmur, and toeing-in requiring braces in childhood, keratoconus requiring corneal transplants, hypertension, and colon polyps and spastic colon. Southern blot analysis of genomic DNA showed complete deletion of one allele of the *TWIST* gene. Such mutations are diagnostic for Saethre-Chotzen syndrome

Sagittal Craniosynostosis Associated with Chromosome Abnormalities with a Brief Review on Craniosynostosis

Contents

Craniosynostosis, defined as the premature closure of >1 cranial suture with an estimated prevalence of 1 in 2,000–3,000 births (Cohen 2000), comprises a heterogeneous group of birth defects, including isolated forms and syndromic cases.

Sagittal craniosynostosis (or synostosis), usually an isolated congenital abnormality in otherwise normal infants, is characterized by scaphocephaly. It is characterized by a scaphocephalic appearance of the cranial vault, with a long, narrow head, widest in the temporal regions and narrowing toward the top of the head, with associated ridging over the fused sagittal suture, giving the appearance of an inverted boat keel (Agrawal et al. 2006). It is the most common form of craniosynostosis with prevalence of 1 in 5,000 children, comprising approximately 50% of all craniosynostosis cases (Lajeunie et al. 1996, 2005). Rarely, when sagittal synostosis is a part of a syndrome, it can be due to a chromosome abnormality associated with multiple congenital abnormalities or due to a single-gene abnormality such as Crouzon or Carpenter syndrome, invariably associated with obvious facial or digital anomalies, with clinically evident closure of multiple sutures.

Genetics/Basic Defects

1. Classification of craniosynostosis based on suture involvement (Kimonis et al. 2007):
    1. Simple (involving one suture) or complex (involving two or more sutures)
    2. Primary (caused by an intrinsic defect in the suture) or secondary (premature closure of normal sutures because of another medical condition such as deficient brain growth)
    3. Isolated (occurring without other anomalies) or syndromic (accompanied by other dysmorphic features or developmental defects)
    4. Frequencies of the various sutures involved:
        1. Sagittal: 40–58%, etiology unknown
        2. Coronal: 20–29%, estimated one-third caused by single-gene mutations
        3. Metopic: 4–10%, etiology unknown
        4. Lambdoidal: 2–4%, etiology unknown
2. Nonsyndromic craniosynostosis (Passos-Bueno et al. 2008; Lattanzi et al. 2012):
    1. Nonsyndromic craniosynostoses are the most frequent craniofacial malformations worldwide. They represent a wide and heterogeneous group of entities, in which the dysmorphism may occur in a single (simple

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_209

forms) or in multiple sutures (complex forms).
2. Simple forms present a higher birth prevalence and are classified according to the involved suture and to the corresponding abnormal cranial shape:
    1. Scaphocephaly (sagittal suture)
    2. Trigonocephaly (metopic suture)
    3. Anterior plagiocephaly (unilateral coronal suture)
    4. Posterior plagiocephaly (unilateral lambdoid suture)
3. Familial recurrence (Hennekam and Van den Boogaard 1990; Lajeunie et al. 1996, 1998, 2005; Cohen and McLean 2000):
    1. Nonsyndromic coronal synostosis (14%)
    2. Nonsyndromic sagittal synostosis (6%)
    3. Nonsyndromic metopic synostosis (3–9%) versus 22% in syndromic metopic synostosis
    4. Pedigrees from familial recurrence: compatible with:
        1. Autosomal dominant inheritance
        2. Autosomal recessive inheritance
        3. X-linked inheritance
4. Genetic etiology:
    1. Poorly understood
    2. *EFNA4*: The only gene that when mutated causes only nonsyndromic craniosynostosis (Merrill et al. 2006)

3. Etiologies of isolated (nonsyndromic) sagittal synostosis:
    1. Suggestions of possible genetic and environmental factors (Johnson et al. 2000; Zeiger et al. 2002; Lajeunie et al. 2005)
    2. Possible intrauterine pressure on the neurocranium on the etiology of craniosynostosis (Johnson et al. 2000; Kirschner et al. 2002)
    3. Preference for (Butzelaar et al. 2009):
        1. Male sex
        2. Twinning
        3. Prematurity
4. Etiologies of syndromic craniosynostosis (Passos-Bueno et al. 2008; Jehee et al. 2008):
    1. To date, well over 180 syndromes are associated with craniosynostosis as a major clinical feature. Mendelian and chromosomal alterations are important causative mechanisms.
    2. Mutations associated with syndromic craniosynostosis:
        1. Mutations in seven genes (*FGFR1*, *FGFR2*, *FGFR3*, *TWIST1*, *EFNB1*, *MSX2*, and *RAB23*): unequivocally associated with Mendelian forms of syndromic craniosynostosis and explain the etiology of about 30% of syndromic cases (Wilkie et al. 2007)
        2. Mutations in four other genes, *FBN1*, *POR*, *TGFBR1*, and *TGFBR2*: also associated with craniosynostosis, but not causing the major clinical feature of the phenotype and/or with an apparently low penetrance (Sood et al. 1996; Flück et al. 2004; Loeys et al. 2005)
5. Chromosome alterations in the etiology of craniosynostosis (Passos-Bueno et al. 2008):
    1. All types of chromosomal abnormalities have already been described in patients with craniosynostosis, including deletions and duplications in almost all human chromosomes.
    2. Approximately 16% of syndromic cases have been associated with chromosomal abnormalities in conventional cytogenetic studies (Cohen 2000):
        1. A high association of craniosynostosis with duplication 13q21-q34
        2. A high association of craniosynostosis with deletion 7p15-p21, 9p21-p24, and 11q23-q25 (Brewer et al. 1998, 1999)
        3. Deletion and/or duplication 1p36 (Gajecka et al. 2005; McDonald-McGinn et al. 2005)
    3. Jehee et al. (2008) screened 45 patients with craniosynostotic disorders with a variety of methods including conventional karyotype, microsatellite segregation analysis, subtelomeric multiplex ligation-dependent probe amplification, and array-based comparative genome hybridization with the following results:
        1. Causative abnormalities were present in 42.2% (19/45) of the samples.

2. 27.8% (10/36) of the patients with normal conventional karyotype carried submicroscopic imbalances.
3. Sagittal synostosis:
    1. Del(1p)
    2. Dup(5)(p15.1-p14.1)
    3. Dup17q
    4. Dup(X)(p11.23)
    5. Association of specific chromosomal 19p microdeletions (19p13.12–13.2) and cranial suture dysmorphology: sagittal craniosynostosis, micrognathia, seizure disorder, hypotonia, and developmental delay (Lyon et al. 2015)
4. Metopic synostosis:
    1. Del(1q)
    2. Del(1q)/dup(15q)
    3. Del(9)(p22.3p24.2)
    4. Del(9q)/dup(17q)
    5. Del(11)(q23.3)
    6. Del(X)(p11.3)
    7. Del(Y)(q11)
    8. Der(9)t(9;4)(p22.3;q34)
    9. Der(9)t(9;?)(p21.3;?)
    10. Dup(3)(p25.2)
    11. Dup(6)(q27)
    12. Dup(15)(q13.2)
    13. Dup(22)(q11.23)
    14. Dup(X)(p22.3)
5. Bilateral coronal synostosis: Dup(3)(q26.33)
6. Bilateral coronal and metopic synostosis: Dup(X)(q22.2)

6. Chromosome abnormalities in children with craniosynostosis (Wilkie et al. 2010):
    1. 47,XX,+mar.ish der(2)(wcp2+)[4]/46,XX[30] (metopic suture)
    2. 46,XY,der(12)t(3;12)(p26.3;p13.33)mat (metopic suture)
    3. 46,XY,der(10)t(3;10)(q2?7;q2?6.1) (R + L squamotemporal sutures)
    4. 46,XY,del(4)(q25q28.2) (sagittal → multiple sutures)
    5. 46,XY,add(4)(q32.3q33) (sagittal suture)
    6. 46,XX,der(7),t(6;7)(p21;q36) (multiple sutures)
    7. 46,XY,t(7;8)(p21;q13) L (coronal suture)
    8. 46,XX,del(9)(p22.1) (metopic suture)
    9. 46,XY,del(11)(q23.3) (metopic suture)
    10. 46,XX,del(17)(q21.31) (sagittal suture)
    11. 47,XX,+21 (sagittal, R coronal sutures)
    12. 46,XX,dup(22)(q11.21q11.23) (sagittal, R coronal sutures)
    13. 46,XY,inv(22)(p1?1.2q13?.1) (metopic, bicoronal sutures)
7. Selected chromosomal aberrations observed in simple craniosynostosis patients (Lattanzi et al. 2012):
    1. 7p21 μdel (karyotype analysis + FISH): coronal suture
    2. 46,XX,del15q15-22.1 (46,XX,del15q15-22.1): (coronal suture)
    3. 47,XY,+mar[14]/46,XY[6] (karyotype analysis + FISH): coronal suture
    4. 46,XY,t(7;8)(p21;q13) (karyotype analysis): coronal suture
    5. 22q11.2 deletion (karyotype analysis) coronal/metopic sutures
    6. 1p36 μdup (FISH + CGH): metopic suture
    7. 46,XY,der(9)t(9;4)(p22.3;q34) (FISH): metopic suture
    8. 11q23.3-qter μdel (FISH): metopic suture
    9. 6p12.3-p21.1 μdup (CGH): metopic
    10. 46,XX, t(5;13)(q33.3;q34) (karyotype analysis + FISH): metopic suture
    11. 46,XX,der(17)t(5;17)(q35.1;p13.3) (karyotype analysis + CGH): metopic suture
    12. 46,XY,inv(22)(p1?1.2q13?.1) (karyotype analysis): metopic/coronal sutures
    13. 46,X,der(Y)t(Y:1)(q12;p36.3) (karyotype analysis + FISH): metopic/sagittal sutures
    14. 46,XX,der(1)t(Y;1)(q12;p36.3) (karyotype analysis + FISH): metopic/sagittal sutures
    15. 7p21.1 μdel (FISH): metopic/sagittal sutures
    16. 46,XX,del(17)(q21.31) (CGH): sagittal suture
    17. 46,XX,dup(22)(q11.21q11.23) (CGH): sagittal/coronal sutures
8. Sagittal synostosis associated with chromosome abnormalities (Figs. 1–5):
    1. Our patient 1: del(4)(q26 → q28.3ter) and del(13)(q21.2 → q21.31) (Fig. 1)

2. Our patient 2: del(13)(q33.1 → qter) and dup(17)(q25.3 → qter) [der(13)(13)(t13;17)(q33.1;q25.3)] (Figs. 3–4)
3. Our patient3: t(4;18)(p12p11.2) (Fig. 5)

9. Multiple craniosynostosis involving sagittal and other sutures associated with chromosome abnormalities:
   1. Sagittal and metopic synostosis (Hiraki et al. 2006): 46,X,der(Y)(t(Y;1)(q12;p36.3) inherited from father [46,X,t(Y;1)(q12;p36.3)]
   2. Sagittal and bilateral lambdoid synostosis (called craniofacial dyssynostosis, "Mercedes Benz" syndrome, or nonsyndromic multisutural synostosis) (Hing et al. 2009):
      1. Case reported by Shiihara et al. (2004), sagittal and metopic suture synostosis:
         1. An unbalanced translocation, 46,XX, der(13)t(5;13)(q33.3;q34)mat resulting in monosomy 13 q34-qter and trisomy 5q33.3-qter.
         2. FISH analysis showed three MSX2 signals indicating the presence of three copies of the MSX2 gene.
      2. Case reported by Cohen (2000): complex rearrangement of chromosome 5, resulting in three paracentric inversions/two insertions and a duplication of 5q35 inclusive of the MSX2 gene region
      3. Case reported by Tagariello et al. (2006):
         1. A de novo-balanced translocation, t(9;11)(q33;p15).
         2. Both breakpoint regions were cloned, and the chromosome 11p15 breakpoint was noted to disrupt the *SOX6* gene between exons 6 and 7. However, the potential role of the *SOX6* gene disruption in BLSS remains undetermined.
      4. Case reported by Hing et al. (2009): an Xp11.2 deletion
   3. Sagittal, metopic, and coronary synostosis (Hiraki et al. 2008): 46,XX,der(15)(q15.2q22.1).
   4. Sagittal, metopic, lambdoid, temporal, and squamosal synostosis (Jehee et al. 2007): De novo interstitial 11q duplication [46,XY,dup(11)(q11-q13.3)(/46,XY] included the duplication of genes FGF3 and FGF4.

Clinical Features

1. Natural history of sagittal synostosis (Chatterjee et al. 2007):
   1. As the condition occurs in utero, diagnosis should be possible at birth with careful attention to the sagittal suture and the deformity that is created.
   2. If uncorrected, sagittal synostosis leads to progression of the scaphocephalic deformity which can be an esthetic problem as well as raised intracranial pressure and speech and language impairment in almost 40% of patients.
2. Clinical features of sagittal synostosis:
   1. Scaphocephaly or dolichocephaly due to growth restriction transverse to the sagittal suture resulting in a biparietally narrowed skull and continuing growth of the calvaria in the ventral-dorsal direction resulting in the elongation of the skull
   2. Variable appearance of the elongation of the skull depending on which portion of the sagittal suture is fused
   3. Ridging of the sagittal suture
   4. Frontal bossing: resulting from premature closure of the anterior portion of the sagittal suture (Jane et al. 2000)
   5. Variants of posterior sagittal synostosis (Jane et al. 2000): Closure of the posterior portion of the sagittal sutures occurs less commonly than anterior closure:
      1. Occipital knob: The occipital bone becomes the site of compensatory overgrowth because it is located distal and perpendicular to the fused suture.
      2. "Golf tee" deformity:
         1. An exaggerated form of the occipital knob, simulating a golf tee
         2. The skull is narrower posteriorly and protrudes more prominently. In addition, the unfused anterior portion of

the sagittal suture may widen the parietal bone anteriorly, accentuating the occipital narrowing.
3. Bathrocephalic deformities: an extreme consequence of premature posterior closure of the sagittal suture:
1. Characterized by the appearance of a podium in the occipital region
2. The posterior portion of the parietal bone slants inferiorly while the occipital bone juts superiorly.
6. Complete sagittal synostosis: the most extreme form of the sagittal synostosis, resulting in both anterior and posterior deformity

3. Sagittal synostosis associated with chromosome abnormalities (our cases):
1. Patient 1 (monosomies 4q and 13q):
1. Sagittal suture synostosis (palpable bonny ridge along the sagittal suture)
2. Ocular hypertelorism
3. Proptotic eyes
4. Micrognathia
2. Patient 2 (translocation 4p and 18p):
1. Sagittal synostosis (scaphocephaly)
2. Tetralogy of Fallot

4. Multiple suture synostoses (including sagittal synostosis) associated with chromosome abnormalities: wide variation of clinical features depending on the gain or loss of the chromosome(s) and chromosome segments involved. Following are some of the examples:
1. Multiple craniosynostoses involving the sagittal and metopic sutures with 1p36.3-pter trisomy (Hiraki et al. 2006):
1. Borderline mental retardation
2. Bitemporal narrowing
3. Sloping forehead
4. Blepharophimosis
5. Blepharoptosis
2. Multiple craniosynostoses involving sagittal and bilateral lambdoid sutures: Premature fusion of the sagittal and both lambdoid sutures results in a characteristic head shape with frontal bossing, turribrachycephaly, biparietal narrowing, occipital concavity, inferior displacement of the ears, and ridging of the sagittal and lambdoid sutures (Hing et al. 2009):
1. Case reported by Shiihara et al. (2004):
1. Sagittal and bilateral lambdoid sutures
2. Developmental delay
3. Atrial septal defect
4. Patent ductus arteriosus
5. Unbalanced translocation, 46,XX,der(13)t(5;13)(q33.3;q34)mat resulting in monosomy 13 q34-qter and trisomy 5q33.3-qter
6. FISH analysis demonstrated three copies of the *MSX2* gene.
2. Case reported by Cohen (2000):
1. Sagittal and bilateral lambdoid sutures.
2. Hypotonia.
3. Ventricular septal defect.
4. Coarctation of the aorta.
5. A complex rearrangement of chromosome 5 resulting in three paracentric inversions/two insertions and a duplication of 5q35 inclusive of the *MSX2* gene region.
6. MSX2 is known to play an important role in cranial bone formation as haploinsufficiency of MSX2 results in parietal skull defects and overexpression causes craniosynostosis.
3. Case reported by Tagariello et al. (2006):
1. Sagittal and bilateral lambdoid sutures.
2. Mild speech delay.
3. A de novo-balanced translocation, t(9;11)(q33;p15).
4. Both breakpoint regions were cloned, and the chromosome 11p15 breakpoint was noted to disrupt the *SOX6* gene between exons 6 and 7.
4. Case reported by Hing et al. (2009):
1. Sagittal and bilateral lambdoid sutures: frontal bossing, brachycephaly, and narrow occiput
2. Hypotonia at birth
3. Progressive apnea
4. Seizures

5. Expired at 4 months of age
6. Xp11.22 deletion: clinical significance unknown

3. Multiple craniosynostoses involving the sagittal, metopic, and coronary sutures:
   1. Cases reported by Hiraki et al. (2008) with a de novo 15q15q22 deletion:
      1. Hypotonia
      2. Profound growth and psychomotor retardation
      3. Craniofacial dysmorphic features (bow-shaped eyebrows, downslanting palpebral fissures, mild blepharophimosis, strabismus, nystagmus, optic nerve atrophy, low-set ears with stenotic bilateral ear canals, bulbous nasal tip, hypoplastic alae nasi, upturned nostrils, high-arched palate, bifid uvula, epiglottic hypoplasia, a thin upper lip, and tucked-in lower lip)
      4. Other anomalies (pectus excavatum, accessory nipples, small hands and feet, long fingers, abducted and proximally placed thumbs, clinodactyly of the fifth fingers, four finger creases, overlapping third and fifth over fourth toes, metatarsus adductus)
4. Sagittal, metopic, lambdoid, temporal, and squamosal synostosis (Jehee et al. 2007): de novo interstitial 11q duplication:
   1. Developmental delay
   2. Marked trigonocephalic, turricephalic, and scaphocephalic-shaped skull
   3. Blue sclerae
   4. Nystagmus
   5. Strabismus
   6. Short neck
   7. Short philtrum
   8. Supernumerary maxillary lateral incisor
   9. PDA
   10. Patent foramen ovale
   11. Seizures
   12. Recurrent infections
   13. Mild brachydactyly of the finger
   14. Clinodactyly of the fifth fingers
   15. Slightly broad thumbs
   16. Shortened distal phalanges
   17. Hypoplastic nails

Diagnostic Investigations

1. Radiographic study to demonstrate sagittal synostosis
2. Three-dimensional computed tomographies to discern the characteristics of sagittal synostosis (David et al. 2009):
   1. Anterior type: characterized by a transverse retrocoronal band.
   2. Central type: Prematurely fused sagittal suture is marked by a prominent heaped-up appearance.
   3. Posterior type: a significantly elongated occiput as the most striking radiographic feature.
   4. Complex type: combined characteristics of anterior, central, and posterior types.
3. Conventional karyotype
4. Microsatellite segregation analysis
5. Subtelomeric multiplex ligation-dependent probe amplification
6. Array-based comparative genome hybridization

Genetic Counseling

1. Recurrence risk (Kimonis et al. 2007; Wilkie et al. 2007):
   1. Patient's sib
      1. "Truly nonsyndromic craniosynostosis": thought to be a multifactorial trait with recurrent risk around 5% for coronal and around 1% for sagittal suture fusion
      2. Autosomal dominant craniosynostosis:
         1. Common in craniosynostosis syndromes with a relatively high proportion of new mutations
         2. Genetic counseling for the parents of a child with an apparently new mutation: difficult by uncertainties over the recurrence risk attributable to occult germ line mosaicism in a parent

3. Negative parental mutation testing: still leaves a small (<1%) risk of recurrence because of potential gonadal mosaicism
3. Craniosynostosis associated with chromosome abnormality: recurrent risk depends on whether a de novo event or a parent is a carrier of the abnormality.

2. Patient's offspring:
1. "Truly nonsyndromic craniosynostosis": thought to be a multifactorial trait with recurrent risk around 5% for coronal and around 1% for sagittal suture fusion.
2. Autosomal dominant craniosynostosis: Mutation carriers have a 50% risk of passing the affected gene to their offspring.
3. Chromosome aneuploidy: depends on the type and complexity of the chromosome rearrangement.

2. Prenatal diagnosis. Craniosynostoses are rarely detected in utero (Fjortoft et al. 2007):
1. Prenatal ultrasonography of the cranial suture:
1. Most craniosynostoses are missed during routine US screening examination.
2. Most of the prenatal diagnoses made have been severe syndromic synostosis elide mainly on cranial deformity and associated abnormalities, in particular limb malformations. Examples include:
1. Pfeiffer syndrome
2. Apert syndrome
3. Saethre-Chotzen syndrome
2. Prenatal MRI imaging of the cranial suture:
1. MRI cannot directly visualize calvarial sutures.
2. Diagnostic when craniosynostosis is suspected by prenatal ultrasound examination.
3. Advantage of MRI: allows detection and provides better assessment of brain abnormalities which may be associated with craniosynostosis.
3. Prenatal 3-dimensional CT: useful as it allows direct visualization of the cranial vault sutures, which is not possible with MRI
4. Prenatal testing strategies:
1. Chorionic villus sampling (typically at 10–14 weeks gestation)
2. Amniocentesis (typically at 16–18 weeks gestation)
3. Prenatal chromosome testing for syndromic craniosynostosis due to chromosome abnormality
4. Molecular genetic testing of syndromic craniosynostosis due to single-gene mutation
5. Preimplantation genetic diagnosis:
1. A valuable option available for those who have been identified as carriers of the mutation but are interested in ensuring that their children are unaffected without making the decision to terminate a pregnancy in the event of a positive prenatal diagnosis.
2. Molecular testing enables the selection of only genetically normal embryos for use in in vitro fertilization.

3. Management (Adamo and Pollack 2009; Jimenez et al. 2008):
1. Goals of surgery in sagittal synostosis:
1. Eliminate the biparietal constriction caused by the fused sagittal suture.
2. Increase the width of the skull.
3. Decrease the anterior-posterior (AP) length of the skull.
2. In cases of mild scaphocephaly:
1. Perform strip or extended craniectomies to remove the sagittal suture using either open or endoscopic techniques
2. Then rely on future cranial vault remodeling with brain growth
3. In cases of more marked scaphocephaly:
1. Extend the craniectomy to follow along the lambdoid sutures.
2. Add bilateral parietal bone wedge osteotomies.
4. The Pi technique (Jane et al. 1978), also widely used:
1. Bilateral parasagittal strip craniectomies with outfracturing of the temporal bones
2. Removal of the vertex bone
3. AP shortening of the calvarial vault, in some instances with bifrontal osteotomies

5. In older children: The bone is more difficult to reshape:
    1. A more extensive calvarial reconstructive procedure is performed with bifrontal, biparietal, and occipital bone removal and reconstruction.
    2. The bones are then angulated to reduce frontal bossing, and the grafts are shortened to reduce the AP dimension of the skull.
6. Surgical procedures used for the treatment of sagittal synostosis:
    1. Strip craniectomy procedure
    2. Total vertex craniectomy
    3. Peninsula craniectomy
    4. Pi procedure
    5. Modified Pi procedure
    6. Clamshell procedure
    7. Distraction-contraction procedure
    8. Foreshortening and lateral expansion
    9. Spiral osteotomy technique
    10. Parietal bone fixation technique
    11. Reversal exchange technique
    12. Sprint-assisted cranioplasty
    13. Marchac transposition
    14. Modified Marchac transposition
    15. Endoscopic craniectomy
    16. Microscopic craniectomies
7. Cranial reconstruction for nonsyndromic sagittal craniosynostosis improved cranial index equally in all patients but increased head circumference and intracranial volume significantly more in patients who underwent surgical reconstruction at age 6 months or older (Bergquist et al. 2016).

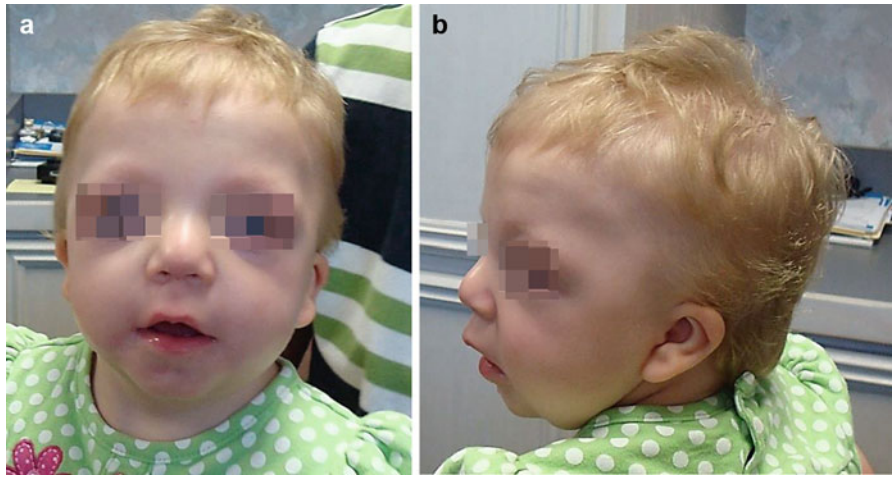

Fig. 1 (**a**, **b**) An 8-month-old infant was evaluated for sagittal suture synostosis. Her craniofacial features were characterized by palpable bonny ridge along the sagittal suture, ocular hypertelorism with proptotic eyes, and mild retrognathia. Conventional cytogenetics showed a complex chromosomal rearrangement involving chromosomes 2, 4, and 13 and deletions in chromosomes 4 and 13 [46,XX,ins (2;4)(p21;q31.2q33),del(4)(q26q28.3),t(4;13)(q31.3;q21.32), del(13)(q21.2q21.31)]. Oligonucleotide array CGH analysis showed a 22-Mb deletion in bands 4q26 to 4q28.3 and a 3.5-Mb deletion in 13q21.2 to13q21.31. The karyotype is therefore monosomic for genes in these regions

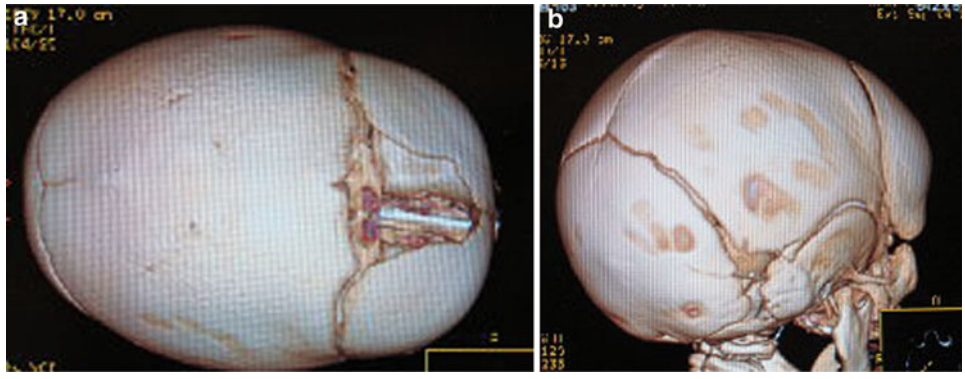

Fig. 2 (**a**, **b**) Three-dimensional CT reconstructions from the same patient shows dolichocephalic skull resulting from premature fusion of the sagittal suture (**a**) and sagittal ridge (**b**)

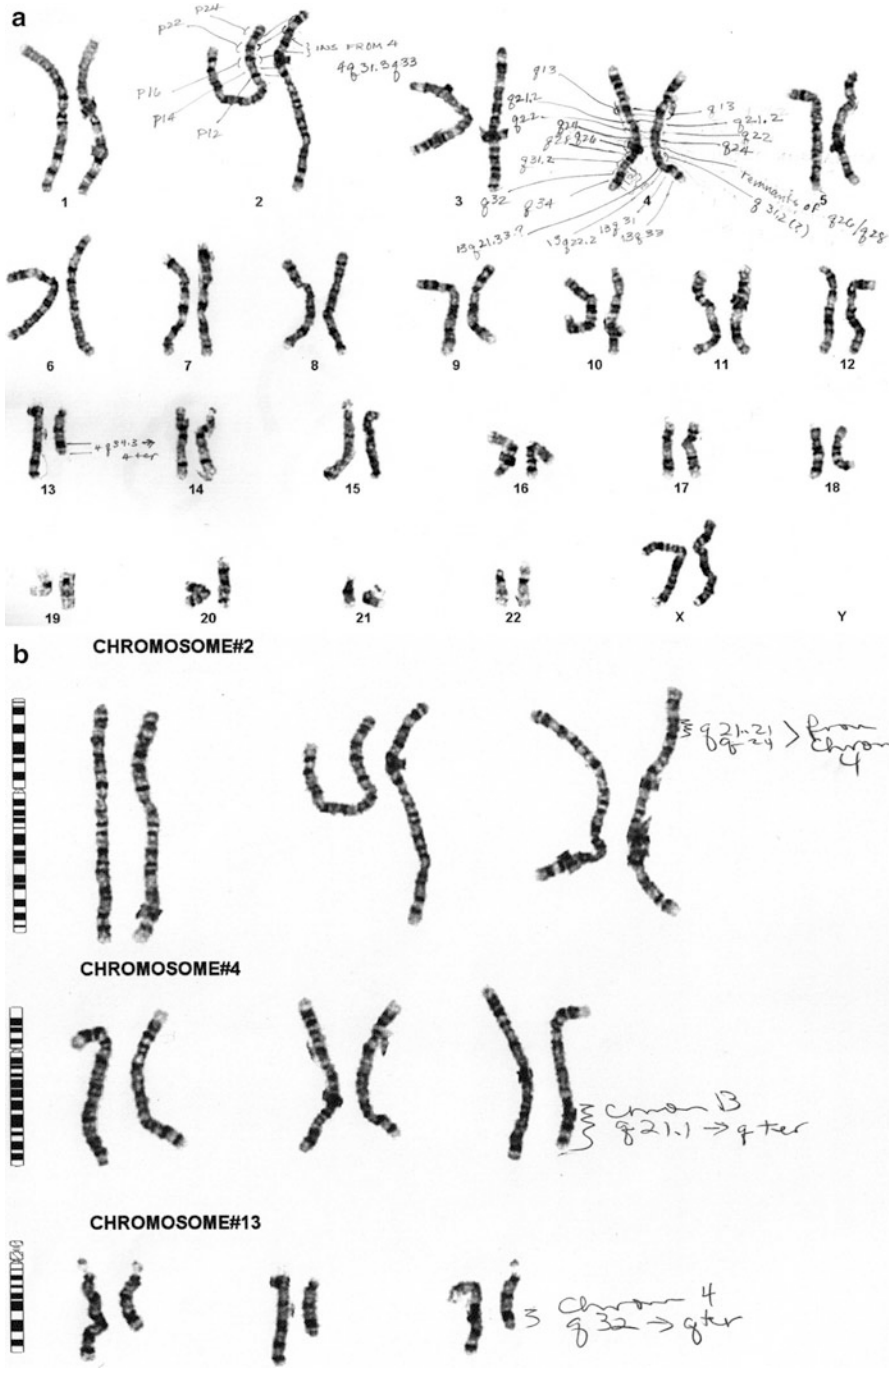

Fig. 3 (**a**, **b**) Her karyotype showed del(4)(q26 → q28.3ter) and del(13)(13q21.2 → q21.31) (pencil marks are intentionally left here to show the complex chromosome rearrangements)

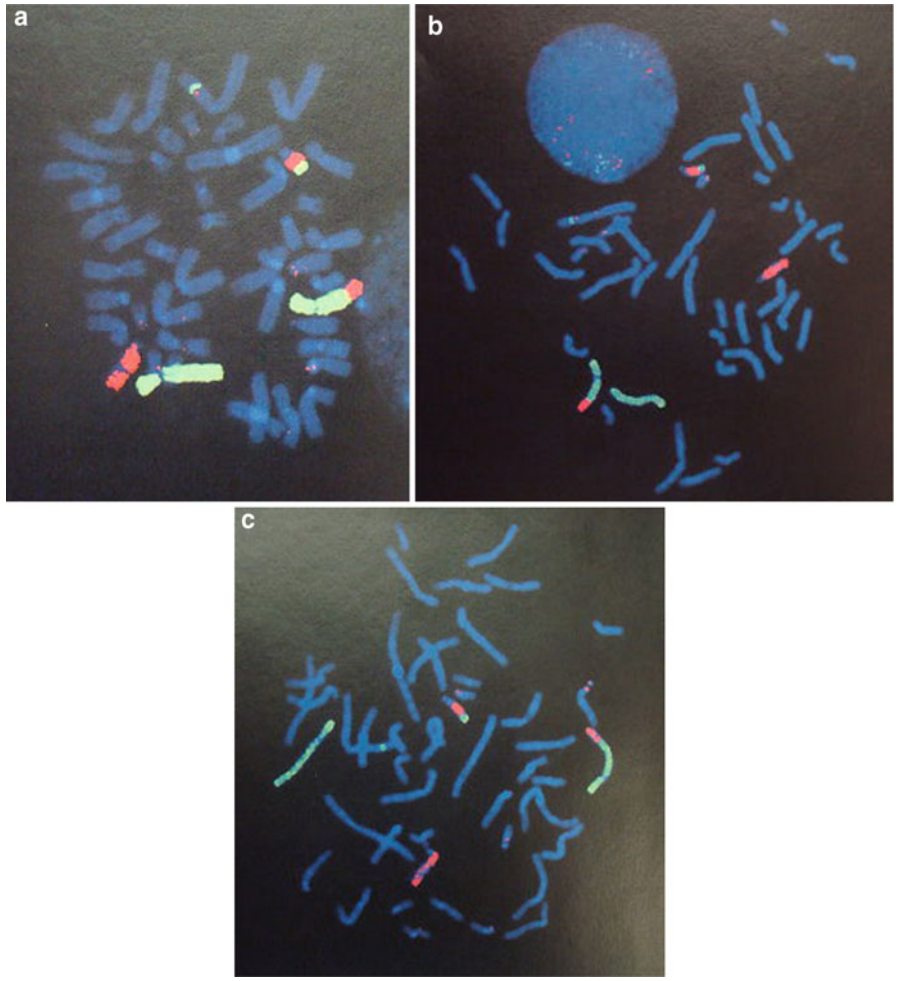

Fig. 4 (**a**–**c**) FISH with wcp2 and wcp4 confirmed an insertion of chromosome 4 material (4q31.2-33) into the short arm of 4q31.1 to 4qter. This translocation was confirmed with FISH subtelomeric probes, showing the qter of the translocation positive for the 13q subtelomere sequences, and the qter of the translocation 13 positive for 4q subtelomere

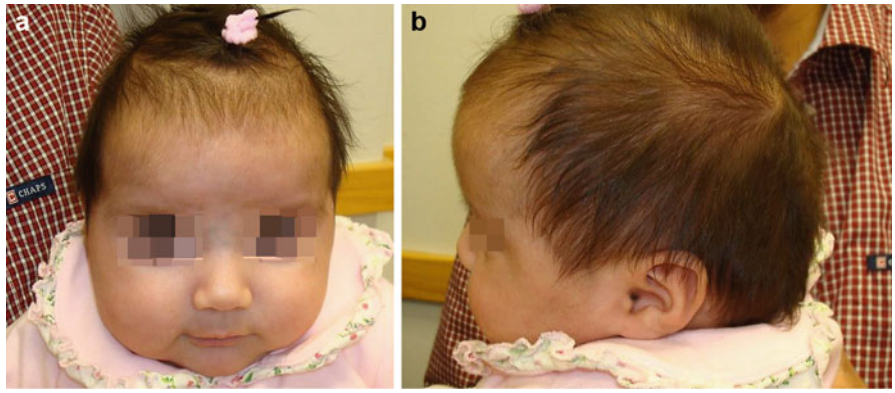

Fig. 5 (**a**, **b**) A 2-month-old infant was evaluated for scaphocephaly (sagittal suture ridge palpable) with tetralogy of Fallot

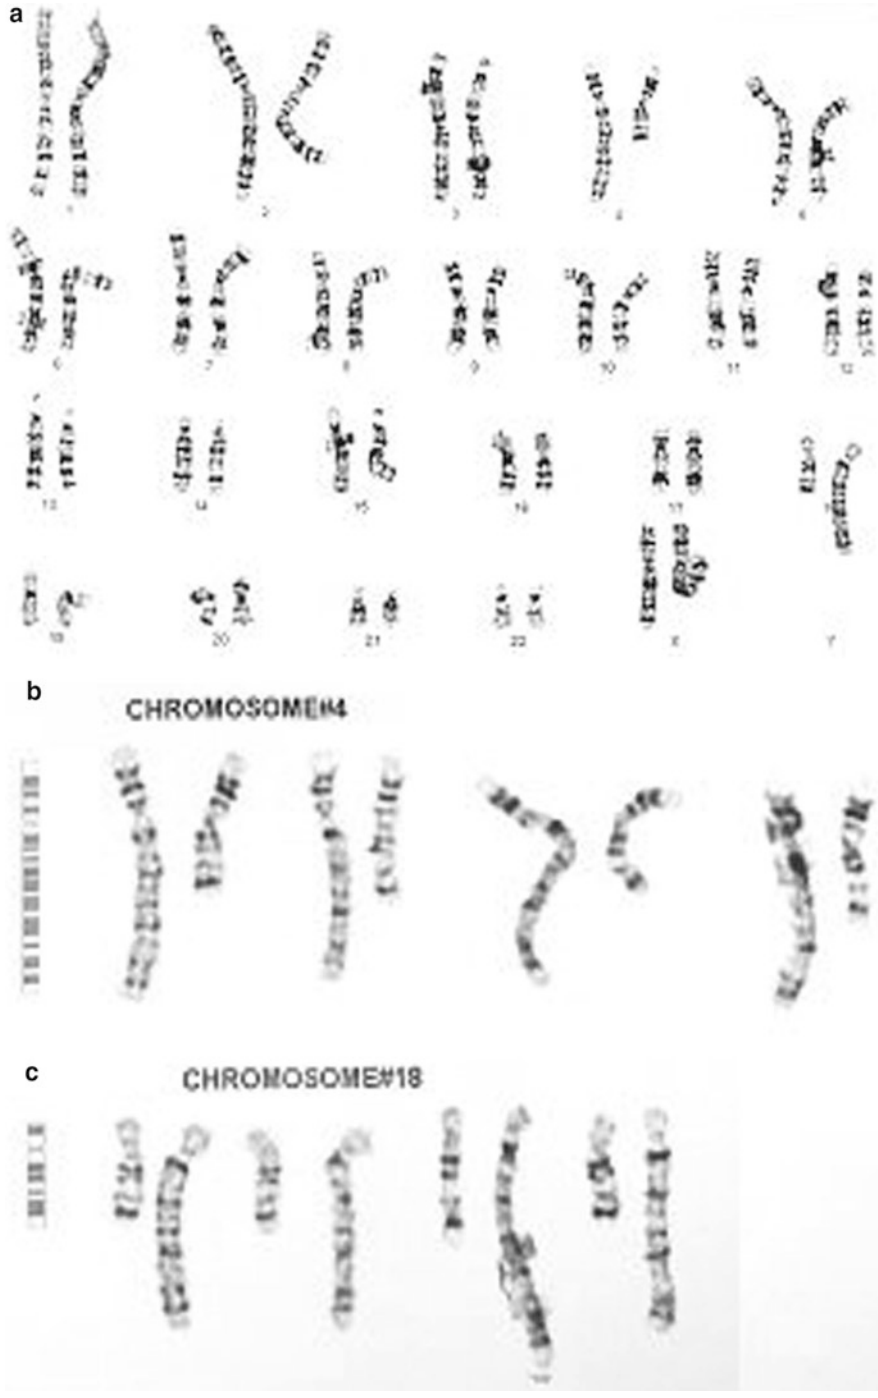

Fig. 6 (**a**–**c**) Her karyotype (**a**) and ideogram with partial karyotypes (**b**) showed a balanced translocation t(4;18)(p12; p11.2)

Schizencephaly

Contents

Schizencephaly is a rare congenital brain malformation characterized by deep clefts of the cerebral mantle that extend from the cortical surface to the lateral ventricles. Large portions of the cerebral hemispheres may be missing and are replaced by cerebrospinal fluid (Capra et al. 1996). The walls of the clefts are lined by polymicrogyric grey matter and are covered by the so-called pialependymal seam. The cleft may be unilateral or bilateral and if bilateral are fairly symmetrical. Their dimensions can be small or large. The clinical features may vary from a normal to a severe development delay. The conditions are often associated with convolutional anomalies such as polymicrogyria or nodular subependymal heterotopias.

Genetics/Birth Defects

1. Inheritance
   1. Isolated schizencephaly: mainly sporadic
   2. Rare reports of familial schizencephaly (Robinson 1991; Hosley et al. 1992; Hilburger et al. 1993; Haverkamp et al. 1995) associated with EMX2 mutation (Granata et al. 1997)
2. Etiology
   1. A developmental defect in the blood vessels supplying the cerebral cortex.
      1. Resulting in tissue death and cleft formation due to lack of oxygen (in utero vascular insufficiency)
      2. With preferential location in the parasylvian regions following the frontoparietal distribution of the middle cerebral artery
   2. Progressive destruction of brain tissue in utero: consistent with a vascular cause rather than a failure of formation of portions of the cerebral mantle (Klingensmith and Cioffi-Ragan 1986).
   3. A developmental vasculopathy could be the cause for some cases of schizencephaly and could be life-threatening until the postnatal life (Landrieu and Lacroix 1994).
   4. Mutations in the homeodomain gene *EMX2* as a possible cause of some cases of schizencephaly.
      1. At least some schizencephaly cases result from germline mutations.
      2. *EMX2*: expressed in restricted areas of the developing mammalian forebrain, including areas that develop into the cerebral cortex.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_210

3. Discovery of *EMX2* mutations in both sporadic and familial cases of schizencephaly marking an important advance in establishing genetic causes for brain malformations.
4. Germline mutations in the homeobox gene EMX2 in patients with schizencephaly (Brunelli et al. 1996; Faiella et al. 1997).
5. Lack of *EMX2* mutations in most schizencephaly patients has increased the likelihood of other genes being involved.
6. *EMX2* mutations were not confirmed from recent studies on large schizencephaly case series (Tietjen et al. 2007; Merello et al. 2008; Hehr et al. 2010).

5. Heterozygous mutations in *SIX3* and *SHH* are associated with schizencephaly: a subset of patients with schizencephaly may develop as one aspect of a more complex malformation of the ventral forebrain, directly result from mutations in the *SHH* pathway, and hence be considered as yet another feature of the broad phenotypic spectrum of holoprosencephaly (Hehr et al. 2010).
6. *COL4A1* mutation.
    1. Schizencephaly-associated *COL4A1* mutation (Matsumoto et al. 2015)
    2. Novel *COL4A1* mutation in an infant with severe dysmorphic syndrome with schizencephaly, periventricular calcifications, and cataract resembling congenital infection (Smigiel et al. 2016)
    3. Phenotypic spectrum of *COL4A1* mutations: porencephaly to schizencephaly (Yoneda et al. 2012)
7. Contactin-associated protein-like (CNTNAP) 2 gene mutation in a patient with bilateral schizencephaly (Samanta 2016).

3. Schizencephaly
    1. Refers to gray matter-lined clefts that extend through the entire hemisphere from the ependymal lining of the lateral ventricles to the pial covering of the cortex.
    2. Cleft.
        1. A cleft in the cerebral mantle which communicates between the subarachnoid space laterally and ventricular system medially
            1. Unilateral or bilateral cleft
            2. Symmetric or asymmetric cleft
        2. The sides of clefts generally lined with heterotopic gray matter (an abnormal accumulation of neurons)
    3. Two types of schizencephaly depending on the size of the area involved and the separation of the cleft lips (Yakovlev and Wadsworth 1946a, b).
        1. Type I (closed-lip schizencephaly).
            1. Consisting of a fused cleft.
            2. This fused pial-ependymal seam forms a furrow in the developing brain and is lined by polymicrogyric gray matter.
        2. Type II (open-lip schizencephaly) (Sharma et al. 2014): presence of a large defect, a holohemispheric cleft in the cerebral cortex filled with cerebral spinal fluid and lined by polymicrogyric gray matter.
    4. Associated malformations commonly accompanying schizencephaly. (Panda 2016)
        1. Mild hypoplasia of the corpus callosum.
        2. Total or nearly total absence of cavum septum pellucidum in 70–90% of patients with schizencephaly. 30–50% of patients show associated optic nerve hypoplasia on clinical examination (septo-optic dysplasia with schizencephaly).
        3. Focal cortical dysplasia.
        4. Coloboma of the retina.
        5. Hydrocephalus.
        6. Subependymal nodules.
        7. Microcephaly.
    4. Syndromes associated with schizencephaly
        1. Septo-optic dysplasia-schizencephaly syndrome (Barkovich et al. 1989; Kuban et al. 1989)
            1. Clinical features distinct from isolated septo-optic dysplasia

2. Frequently associated with endocrinologic, ophthalmologic, and neurologic symptoms and signs
3. Significant global developmental delay and spastic motor deficits
4. Seizures and visual symptoms rather than with endocrine abnormalities

2. Other rare schizencephaly syndromes
   1. Prenatal cytomegalovirus infection
   2. Vascular disruption related to twinning
3. Schizencephaly (plus polymicrogyria) as part of multiple congenital anomaly/mental retardation syndromes
   1. Adam-Oliver syndrome
   2. Aicardi syndrome
   3. Arima syndrome
   4. Delleman (oculocerebrocutaneous) syndrome
   5. Galloway-Mowat syndrome
   6. Micro syndrome

Clinical Features

1. Clinical manifestations depend on the size and location of involved brain.
   1. A narrow, small unilateral cleft
      1. Usually present with seizures and mild focal neurological deficits
      2. A good developmental prognosis (Barkovich and Kjos 1992)
   2. Bilateral clefts
      1. Severe developmental delay.
      2. Early intractable epilepsy.
      3. Severe motor dysfunction.
      4. Correlations between bilateral schizencephaly and presence of seizures also showed that atypical absence, generalized tonic-clonic jerks, and especially myoclonic jerks in the follow-up are more characteristic of bilateral schizencephaly (Kopyta et al. 2014).
2. Clinical features
   1. Most frequent neurological symptoms in children with schizencephaly (Stopa et al. 2014).
      1. Psychomotor retardation (varying degree).
      2. Seizures (epilepsy).
      3. Hemiparesis or quadriparesis (tetraparesis): Bilateral clefts were significantly associated with tetraparesis, whereas unilateral clefts were associated with hemiparesis (Granata et al. 1996; Denis et al. 2000).
      4. Hydrocephalus.
      5. Microcephaly (varying degree).
   2. Developmental delay: moderate to severe if the defects are large.
   3. Hypotonia in the postnatal period.
   4. Motor difficulties.
   5. All patients presented with a seizure disorder and manifest left handedness, but there was no history of familial sinistrality in first-degree relatives. This constellation of symptoms suggestive of the pathologic left handedness (PLH) syndrome described by Orsini and Satz (1986) (Aniskiewicz et al. 1990).
   6. Generalized spasticity.
   7. Blindness secondary to optic nerve hypoplasia.
   8. Unilateral homonymous hemianopia (Neves et al. 2016).
   9. Prognosis depending on the size of the clefts and the degree of neurological deficits.
      1. Patients with type I abnormalities.
         1. Almost normal
         2. May have seizures and spasticity
      2. Patients with smaller, unilateral clefts (clefts in only one hemisphere).
         1. Often paralyzed on one side of the body
         2. May have normal intelligence
      3. Patients with type II abnormalities.
         1. Mental retardation
         2. Seizures
         3. Hypotonia
         4. Spasticity
         5. Inability to walk or speak
         6. Blindness
      4. Patients with bilateral open-lip schizencephaly generally with the worst clinical symptoms.
      5. The presentation and outcome of children with schizencephaly are quite

variable but are related to the extent of cortex involved in the schizencephalic defect (Packard et al. 1997).

Diagnostic Investigations

1. Ultrasonography of the brain (Ceccherini et al. 1999) to demonstrate closed-lip or open-lip brain cleft communicating with lateral ventricle(s).
2. Magnetic resonance imaging (MRI) or computed tomography (CT) of the brain.
    1. Open-lip or closed-lip schizencephaly
    2. Associated absence of the septum pellucidum and hypoplasia of the optic chiasm
3. Common findings in US, CT, and MRI (Chamberlain et al. 1990).
    1. Bilateral cerebral clefts by CT (Komarniski et al. 1990).
    2. Parasylvian and midline clefts.
    3. Size asymmetries of the basal ganglia and thalamus.
    4. Cerebral parenchymal volume loss.
    5. Ventriculomegaly.
    6. Ventricular diverticula.
    7. Absence of the septum pellucidum.
    8. MRI and CT were superior to US in detecting calcification, gyral and sulcal abnormalities, and parasylvian clefts.
    9. MRI alone demonstrated homolateral absence of the sylvian vasculature, small medullary pyramids, low position of the fornix, and the thinning of the corpus callosum.
4. CT images (Miller et al. 1984)
    1. Cerebral clefts
    2. Infolding of cortical gray matter along the clefts
    3. An abnormal ventricular system
    4. Other associated cerebral anomalies
5. MR images (Hayashi et al. 2002)
    1. The clefts were unilateral in 51% of patients and bilateral in 49% of patients.
    2. 17% had fused lips (Yakovlev and Wadsworth 1946a) and 83% had separated-lip clefts (Yakovlev and Wadsworth 1946b).
    3. Recurrent seizures associated with unilateral opened lip schizencephaly. (Ugboma and Agi 2016)
    4. Polymicrogyria was present inside 43% clefts, while subependymal heterotopias were present at the cleft orifice in 50% clefts.
    5. Polymicrogyria was identified outside the cleft, both adjacent to and remote from the cleft, in 66% of patients.
    6. Abnormal cerebral white-matter signal intensity was present in 20% of patients, while white-matter volume diminution was noted in all patients.
    7. Neuronal migration disorders such as heterotopias and, more frequently, cortical dysplasias were observed in several patients (Pascual-Castroviejo et al. 2012)
    8. Nearly half of prenatally open schizencephaly defects had closed on postnatal imaging (Nabavizadeh et al. 2014).
6. Potential role of diffusion tensor imaging with tractography in providing insights into the evaluation of white matter tracts in patients with schizencephaly (Sarikaya 2009)
7. Angiography and pneumography (Page et al. 1975)
    1. Differentiated from the porencephalies that follow destructive lesions
    2. Differentiated from the prognostically more favorable subdural hematomas and effusions
8. Pathology
    1. Clefts most commonly in the Rolandic fissures
    2. Frequently associated with pachygyria, polymicrogyria, or lissencephaly
9. Molecular genetic testing of *EMX2* mutation for familial schizencephaly: not considered to be appropriate (Merello et al. 2008) and not available clinically

Genetic Counseling

1. Recurrence risk: low unless germline mutation is present in one of the parent
2. Prenatal diagnosis
    1. Ultrasonography, CT, and/or fetal MRI of the brain (Lituania et al. 1989; Denis et al. 2001) to demonstrate brain clefts connecting to the lateral ventricles.
    2. Intracranial sonographic features demonstrating in utero development of hemorrhagic brain damage leading to schizencephaly-associated *COL4A1* mutation (Matsumoto et al. 2015).
    3. Differential diagnosis of CSF-containing abnormalities in the fetal brain (Oh et al. 2005).
        1. Developmental lesions
            1. Arachnoid cyst
            2. Ventriculomegaly
            3. Monoventricle in holoprosencephaly
            4. Agenesis of the corpus callosum with an interhemispheric cyst
            5. Schizencephaly
        2. Destructive lesions
            1. Porencephalic cyst
            2. Ventriculomegaly (infection or bleeding)
            3. Hydranencephaly
    4. *EMX2* mutation analysis on amniocytes or CVS: not considered to be appropriate and not available clinically.
    5. Prenatal diagnosis of chromosome 8p23.1 microdeletion by array comparative genomic hybridization using uncultured amniocytes in a pregnancy associated with fetal partial corpus callosum agenesis and schizencephaly (Chen et al. 2015).
3. Management
    1. Physical therapy.
    2. Seizure control: Accurate localization of the epileptogenic zones using intracranial EEG and electrical stimulation can lead to a seizure-free outcome in patients with refractory epilepsy associated with schizencephaly (Zhang et al. 2016).
    3. Resection or multilobe disconnection for intractable epilepsy with open-lip schizencephaly (Cui et al. 2013).
    4. VP shunt for hydrocephalus.

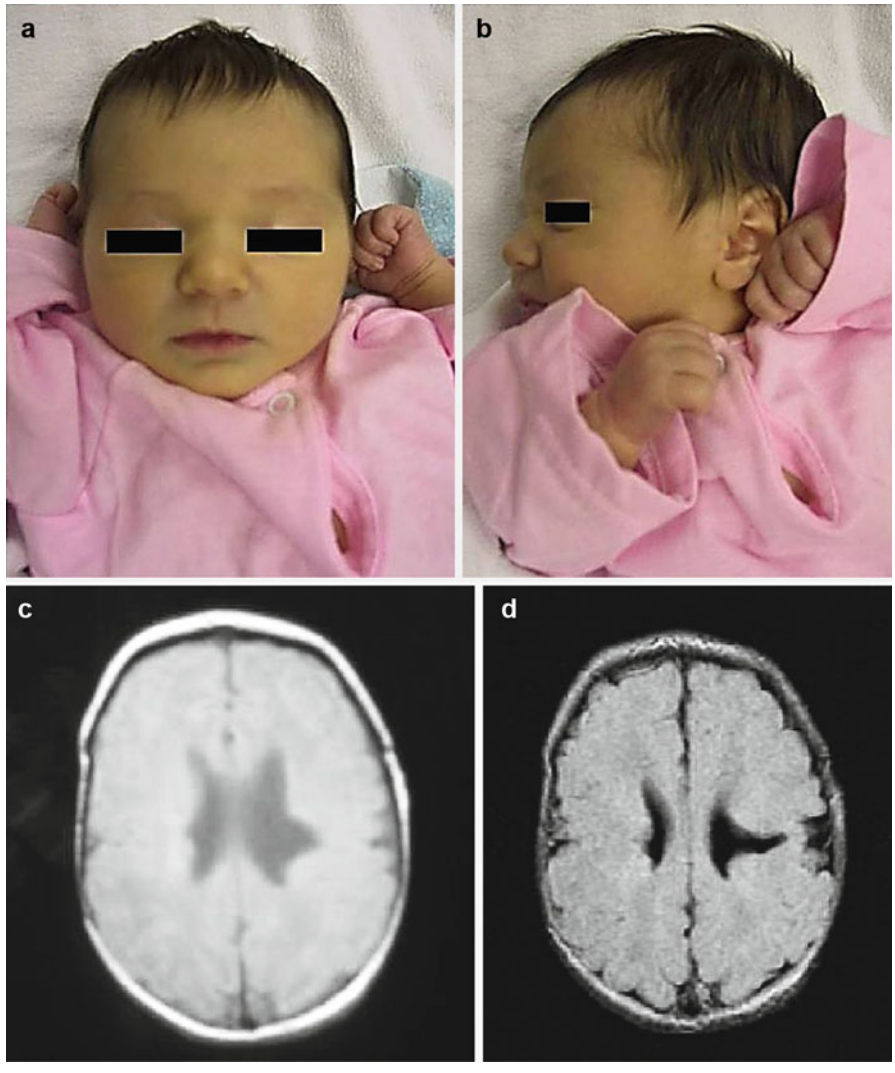

Fig. 1 (**a**-**d**) An infant (**a**, **b**) with asymmetric open-lip parietal schizencephaly, illustrated by MRI (**c**, **d**)

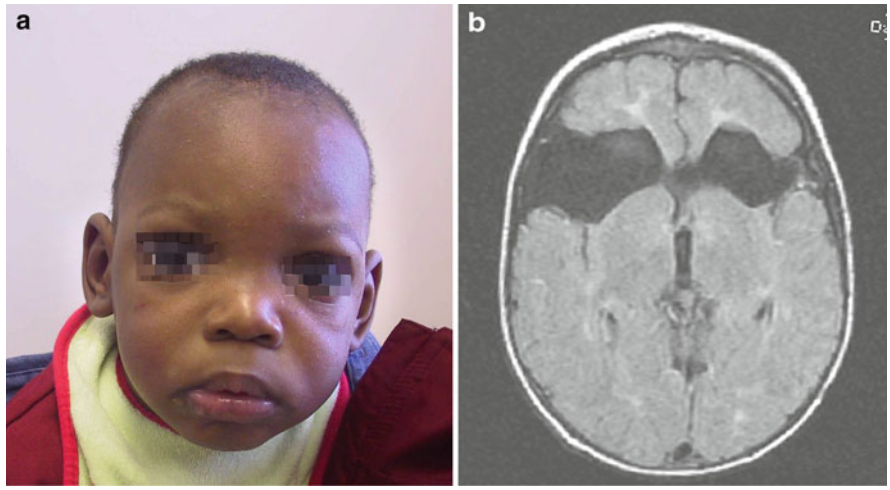

Fig. 2 (**a**, **b**) An infant (**a**) with schizencephaly, global delay and spastic quadriplegia. His MRI of the brain showed bilateral large open-lip schizencephaly in frontotemporal regions (**b**)

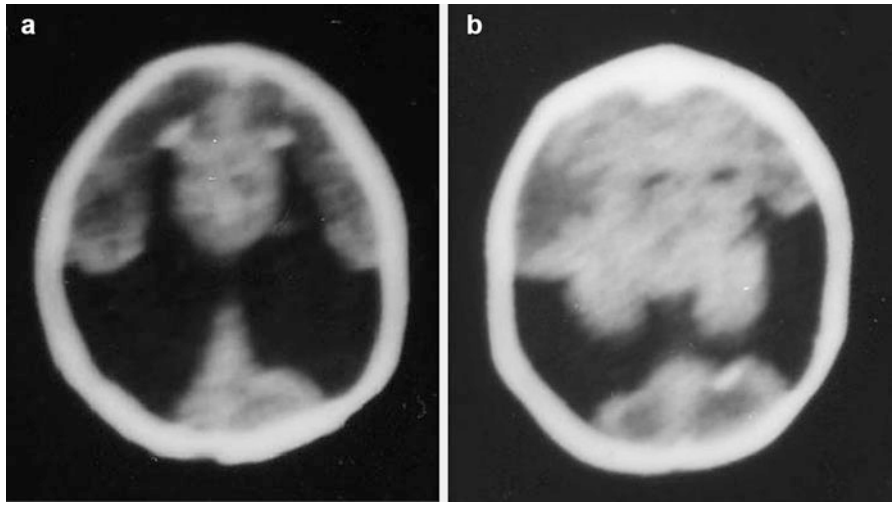

Fig. 3 (**a**, **b**) MRI of the brain of another patient showing bilateral open-lip schizencephaly in the parietal regions in communication with a large cavity filled by cerebrospinal fluid

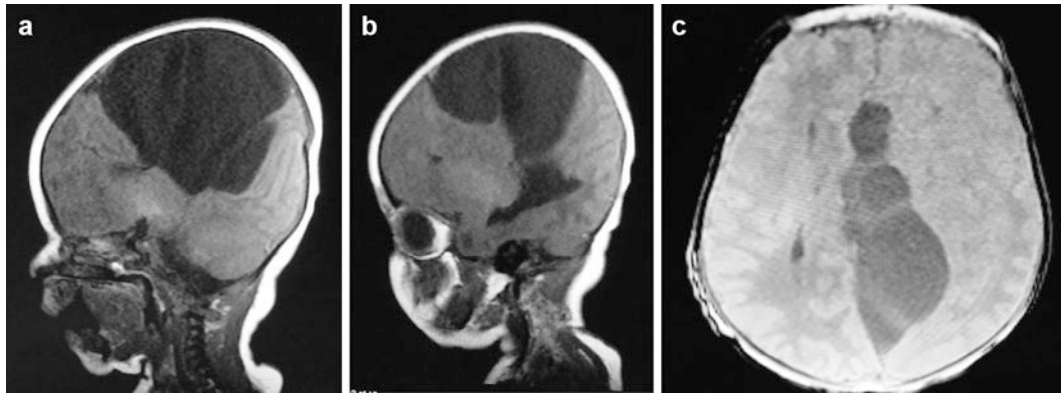

Fig. 4 (**a**–**c**) MRI of the brain of a neonate showed a large open-lip schizencephaly extending to the *right* convexity causing a large gap in the *right* cerebellar hemisphere. There is also absence of the corpus callosum

Schmid Metaphyseal Chondrodysplasia

Contents

Schmid metaphyseal chondrodysplasia (SMCD) is a mild hereditary chondrodysplasia resulting from growth plate cartilage abnormalities (Chan et al. 1998).

Genetics/Basic Defects

1. Inheritance
   1. Autosomal dominant
   2. Variable expression
2. Molecular pathogenesis
   1. Caused by heterozygous mutations in the gene *COL10A1* (Warman et al. 1993; Wallis et al. 1996; Mäkitie et al. 2005) (mapped to chromosome 6q21-q22), the gene which encodes α1(X) chains of type X collagen, a short-chain collagen whose expression is largely restricted to the hypertrophic chondrocytes of growth plate cartilage (Bateman et al. 2003).
   2. Each α1(X) chain contains a core triple helical domain, composed of uninterrupted repeats of the Gly-Xaa-Yaa tripeptide, flanked by two globular domains (NC2 and NC1) at both the amino and carboxyl-terminal ends (Bateman et al. 2005).
   3. Most mutations reside in the noncollagenous carboxyl terminal globular domain (CN1) which contains motifs that promote trimerization of α1(X) chains and subsequent formation of the triple helix to yield stable collagen X molecules (Bonaventure et al. 1995; Sawai et al. 1998; Ridanpää et al. 2003; Higuchi et al. 2016).
   4. Two mutations observed in a putative signal peptide cleavage site (Chan and Jacenko 1998; Chan et al. 1998, 2001).
   5. A novel mutation leading to elongation of the deduced α1(X) chain results in metaphyseal chondrodysplasia type Schmid (Zhu et al. 2011).
   6. Identification of a mutation in type X collagen (COL10A1) in families with Schmid metaphyseal chondrodysplasia (Dharmavaram et al. 1994; Wallis et al. 1994; Higuchi et al. 2016).
   7. The novel type X collagen gene mutation (G595R) identified supports the concept of type X collagenopathy (Matsui et al. 2000).
   8. Growth plate abnormalities of SMCD: resulting from collagen X

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_211

haploinsufficiency, a reduction by 50% in collagen X (Bateman et al. 2003).

9. Early-onset metaphyseal chondrodysplasia type Schmid associated with a COL10A1 frame-shift mutation and impaired trimerization of wild-type α1 (X) chains (Mäkitie et al. 2010).
10. The novel sequence variation involving an unusual mutational site of the COL10A1 gene can cause mild SMCD (Park et al. 2015).

Clinical Features

1. Mild to moderate short-limbed dwarfism (Beluffi et al. 1982)
2. Bowed legs
3. Waddling gait, often a presenting sign at second year
4. Coxa vara
5. Genu varum
6. Exaggerated lumbar lordosis
7. Flared anterior rib cage
8. Leg pain during childhood
9. Prognosis
    1. Radiological changes appearing early with a tendency to heal and change slowly with time, giving rise to mildly dwarfed patients.
    2. Normal intelligence.

Diagnostic Investigations

1. Radiography (Beluffi et al. 1983; Lachman et al. 1988)
    1. Hip
        1. Abnormal acetabular roofs
        2. Enlarged capital femoral epiphyses
        3. Coxa vara
        4. Coxa magna
        5. Femoral bowing
        6. Abnormal proximal femoral metaphyses
    2. Knee
        1. Abnormal distal femoral metaphyses
        2. Abnormal proximal tibial metaphyses
        3. Abnormal proximal fibular metaphyses
    3. Ankle
        1. Abnormal distal tibial metaphyses
        2. Abnormal distal fibular metaphyses
    4. Wrist
        1. Abnormal distal radial metaphyses
        2. Abnormal distal ulnar metaphyses
    5. Ribs: anterior cupping, splaying, and sclerosis
    6. Wide metaphyses with cupping and fraying
    7. Short and stubby long bones
    8. Mild hand involvement: a common feature (Elliott et al. 2005)
        1. Shortening of the tubular bones
        2. Metaphyseal cupping of the proximal phalanges and metacarpals
    9. Normal spine
2. Histology: variable bone changes (Dimson 1968)
    1. Mild sharp serrations of the metaphyses with increased density of the provisional zone of calcification
    2. Irregularity with flaring and fragmentation and widening of the growth plate
3. Molecular genetic analysis of *COL10A1* mutation (Milunsky et al. 1998)
    1. Mutation analysis
    2. Mutation scanning

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: low recurrence risk unless a parent is affected
    2. Patient's offspring: 50%
2. Prenatal diagnosis by amniocentesis or CVS: can be offered to families at-risk for DMCD with a previously characterized disease-causing *COL10A1* mutation
3. Management
    1. Supportive
    2. Orthopedic management of bowed legs: generally does not require orthopedic surgery

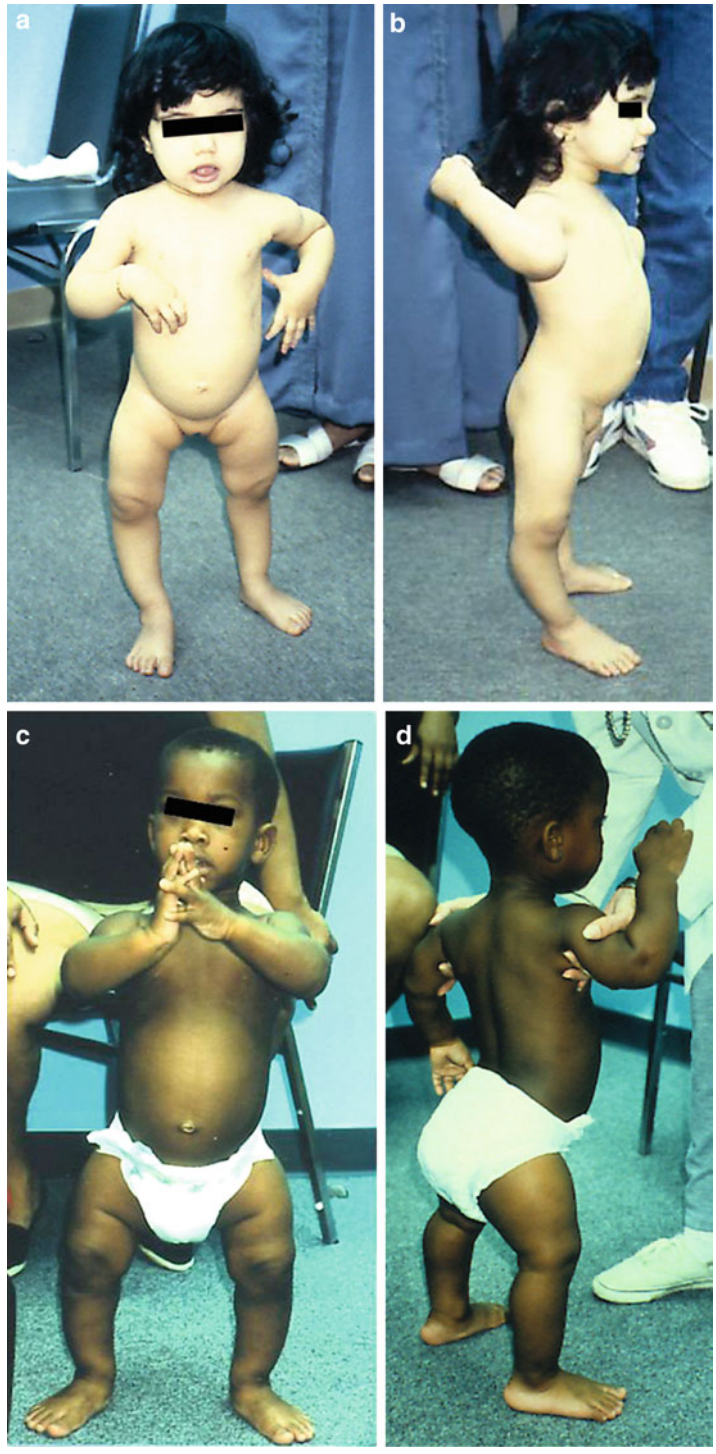

Fig. 1 (continued)

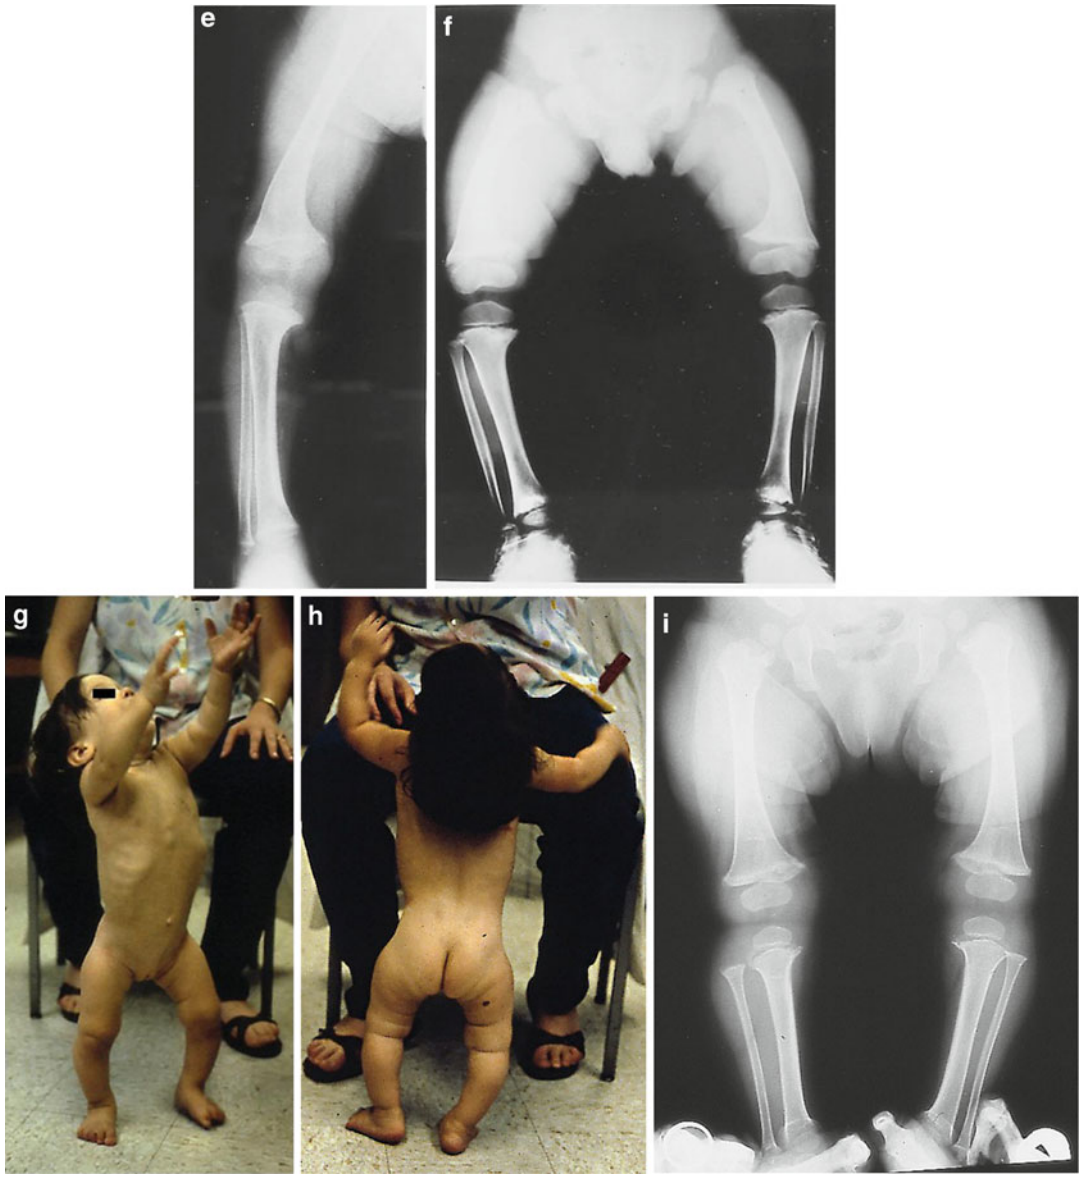

Fig. 1 (**a**–**i**) Three young children (**a**, **b**; **c**, **d**; **g**, **h**) with Schmid metaphyseal chondrodysplasia showing short stature, lumbar lordosis, and bowing of the legs. Radiographs (**e**, **f**, **i**) showed genu varum and metaphyseal widening with fraying and cupping. Epiphyses are normal

Schwartz-Jampel Syndrome

Contents

In 1962, Schwartz and Jampel (Schwartz and Jampel 1962) described the first case of Schwartz-Jampel syndrome (SJS) or chondrodystrophic myotonia.

Synonyms and Related Disorders

Chondrodysplasia myotonia; Schwartz-Jampel-Aberfeld syndrome; Stuve-Wiedemann syndrome

Genetics/Basic Defects

1. Inheritance
   1. Autosomal dominant (Ferrannini et al. 1982)
   2. Autosomal recessive: Two sisters born to consanguineous parents (Pavone et al. 1976)
2. Genetics of SJS type I (Schwartz-Jampel syndrome)
   1. Caused by partial loss-of-function mutations in *HSPG2* encoding perlecan (Iwata et al. 2015).
   2. Localization of the Schwartz-Jampel syndrome (SJS) locus to chromosome 1p34-p36.1 by homozygosity mapping (Nicole et al. 1995).
   3. Specific gene affected: the gene for perlecan (a heparan sulfate proteoglycan), the major proteoglycan of basement membranes (Nicole et al. 2000).
   4. Partial endplate acetylcholinesterase (AChE) deficiency may contribute to muscle stiffness (Stum et al. 2006).
   5. Peripheral nerve hyperexcitability with preterminal nerve and neuromuscular junction remodeling is a hallmark of Schwartz-Jampel syndrome (Bauche et al. 2013).
3. Genetics of SJS type II (Stuve-Wiedemann syndrome) (Knipe et al. 2015)
   1. Autosomal recessive bent bone skeletal dysplasia with associated autonomic involvement.
   2. The diseased gene leukemia inhibitory factor receptor (LIFR) in type II has been mapped to band 5p13.1, at locus D5S418 (Dagoneau et al. 2004).
   3. Autonomic dysfunction.
      1. Dysphagia.
      2. Respiratory failure.
      3. Pulmonary hypertension.
      4. Delayed growth.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_284

5. Hyperthermic episodes associated with excessive and paradoxical sweating are seen; these can be life-threatening.
6. Long-term complications: corneal opacities, along with osteopenia, pathological fractures, and progressive bone deformities.
7. Intellect: usually preserved.
8. Prognosis: poor with most sufferers dying in the first few months of life due to respiratory distress or hyperthermia.

4. Dyssegmental dysplasia of the Silverman-Handmaker type (DDSH): also caused by a recessive mutation of the perlecan gene (Arikawa-Hirasawa et al. 2001).

Clinical Features

1. Typical phenotypic features (Pascuzzi et al. 1990; Ault 2014)
   1. Short stature (90%)
   2. Characteristic facial features
      1. Fixed facies (55%)
      2. Pinched face
      3. Blepharophimosis (narrow palpebral fissures) and blepharospasm (32.5%)
      4. Epicanthal fold
      5. Puckered-small mouth (80%)
      6. Long philtrum
      7. Large ears
      8. High arched palate
   3. Musculoskeletal features
      1. Clinical myotonia (85%)
      2. Muscle hypertrophy (70%): stiff muscles (either hypertrophic or reduced in mass)
      3. Short neck
      4. Pectus carinatum
      5. Kyphosis
      6. Joint deformities and limitations of joint motion
      7. Coxa valga
      8. Irregularity of capital femoral epiphysis
      9. Delayed bone age (Kulkarni and Pillai 2004)
   4. High-pitched voice (Pfeiffer et al. 1977)
   5. Bilateral carpal tunnel syndromes (Van Meir and De Smet 2003)
   6. Malignant hyperthermia (Oue et al. 2004)
2. SJS type I (Schwartz-Jampel syndrome) (Giedion et al. 1997)
   1. Type IA: most commonly recognized
      1. Classic type described by Schwartz and Jampel.
      2. Myotonia: early childhood.
      3. Bone dysplasia: childhood.
      4. Muscle weakness: mild and largely nonprogressive.
   2. Type IB
      1. Clinically more severe than type IA
      2. Myotonia: infancy or childhood
      3. Infancy: short-limbed dysplasia with dumbbell-shaped femora (Kniest dysplasia-like)
      4. Childhood: spondylo-epi-metaphyseal dysplasia
      5. Long-term survival possible
3. SJS type II (Stuve-Wiedemann syndrome) (Giedion et al. 1997)
   1. Apparent immediately at birth
   2. Known as Stuve-Wiedemann syndrome
   3. Cardinal features
      1. Myotonia: birth
      2. Bone dysplasia: birth
      3. Severe respiratory difficulties and feeding problems
      4. Joint contractures
      5. Short stature
   4. Caused by the leukemia inhibitory factor receptor (LIFR) mutation
4. Differential diagnosis (Basiri et al. 2015)
   1. Stiff-person syndrome (Baizabal-Carvallo and Jankovic 2015).
      1. Generalized stiffness with attacks of muscle contraction.
      2. Progressive rigidity and muscle spasms affecting the axial and limb muscles.
      3. Electrodiagnostic findings: continuously firing motor unit action potentials, but no myokymic or neuromyotonic discharges.
   2. Isaacs syndrome (Ahmed and Simmons 2015)
      1. A peripheral nerve hyperexcitability syndrome that presents as continuous motor activity.

2. Clinical features (cramps, fasciculations, and myokymia).
3. Myotonic disorders
   1. Congenital myotonic dystrophy
   2. Myotonic dystrophy
   3. Myotonia congenita
   4. Paramyotonia congenita
4. Muscular dystrophies
   1. Becker muscular dystrophy
   2. Duchenne muscular dystrophy (please see the chapter of "▶ Dystrophinopathies")
   3. "▶ Congenital Muscular Dystrophy" (please see the chapter)
5. Congenital myopathies
6. Channelopathies
7. "▶ Mucopolysaccharidosis 4" (Morquio's syndrome) (please see the chapter)
8. "▶ Ehlers-Danlos Syndrome" (please see the chapter)
9. Malignant hyperthermia
10. Blepharospasm

Diagnostic Investigations

1. Serum creatine kinase or aldolase: normal or slight elevations
2. Radiological findings (Giedion et al. 1997)
   1. Type IA
      1. Mild epi-metaphyseal dysplasia with enlarged epiphyses at knees
      2. Spine: mild platyspondyly
      3. Pelvis: narrow sciatic notch
      4. Epiphyses: moderately enlarged at knees and other long bones
   2. Type IB
      1. Short-limbed dysplasia with dumbbell-shaped femora (Kniest dysplasia-like)
      2. Spondylo-epi-metaphyseal dysplasia
      3. Spine: moderate platyspondyly and coronal clefts
      4. Pelvis: some flaring of iliac wings; presence of supra-acetabular notch
      5. Epiphyses: moderately enlarged at knees
   3. Type II
      1. Short-limbed dysplasia with bowing of legs in infancy
      2. Pyle disease-like undertubulation of long bones in childhood
      3. Spine: not characteristic
      4. Pelvis: not characteristic
      5. Epiphyses: flattened at knees
3. Muscle biopsy: consistent with myopathy
4. Ultrastructural investigation of muscle: nonspecific
   1. Clusters of enlarged mitochondria and swelling of sarcoplasmic reticulum, giving the impression of a fine vacuolation of muscle fibers (Pavone et al. 1976).
   2. Swelling of sarcotubular system has been observed in myopathies characterized by an alteration of muscle contraction.
      1. Periodic paralysis
      2. Dystrophia myotonica
5. Electromyography (EMG) and nerve conduction studies
   1. EMG
      1. Showing continuous discharges, frequently with individual appearance of positive sharp waves or fibrillations, but may occur in runs of many discharges.
      2. Myotonic in some cases suggesting a waxing and waning character.
   2. Nerve conduction findings: typically normal (Regalo et al. 2005)

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Autosomal recessive inheritance (25%)
      2. Autosomal dominant inheritance: not increased unless a parent is affected
   2. Patient's offspring
      1. Autosomal recessive inheritance: not increased unless the spouse is affected or a carrier
      2. Autosomal dominant inheritance (50%)

2. Prenatal diagnosis
    1. Ultrasonography at 17–19th week of pregnancy (Hunziker et al. 1989): possible for a family at risk
        1. Decreased fetal motor activity
        2. Constant flexion of the fingers
        3. Mild bowing and shortening of the femora
    2. Possible to detect fetuses at 25% risk when the disease-causing *HSPG2* (perlecan) mutation in both parents are known, by mutation analysis on fetal DNA obtained from chorionic villus sampling or amniocentesis
    3. Preimplantation genetic diagnosis: not clinically available for families in which the disease-causing mutations have been identified in an affected family member
3. Management
    1. Pharmaceutical treatment: limited usage and effective only in early diagnosed less severe cases (Ho et al. 2003; Nessler et al. 2011)
        1. Muscle relaxants: limited use
        2. Antiepileptic drugs, especially carbamazepine, give satisfactory action (Topaloglu et al. 1993; Squires and Prangley 1996)
    2. Botox injection
        1. Into the orbicularis oculi: usually helpful (Vargel et al. 2006).
        2. Into the lower eyelid (Flynn et al. 2001).
        3. Local injections of botulinum toxin A have transitional effect of relieving symptoms in mimic muscles (Vargel et al. 2006).
        4. Unresponsiveness of blepharospasm in most reported cases (Kashkouli et al. 2015), since muscle spasm in SJS is a myogenic rather than neurogenic activity (Lehmann-Horn et al. 1990).
    3. Rae surgical intervention of orbicularis oculi myectomy or levator aponeurosis resection after failure with botulinum toxin A injection (Morrison et al. 2006)

Fig. 1 (**a**, **b**) This 23-year-old white female was referred for genetic evaluation of Schwartz-Jampel syndrome. She showed fixed facial expression, bushy eyebrows, blepharophimosis, and difficulty in opening her jaw completely (**a**, **b**). She had a history of trouble swallowing and reflux. She was not able to rollover. When she was older she would fall easily and had a stiff gait. At 2 ½ years of age, she was admitted to the hospital with difficulty swallowing and overall motor difficulty. Muscle biopsy revealed possible myopathic change. At 4 years of age, she was diagnosed to have Schwartz-Jampel syndrome by Dr. Victor Ionasescu, a medical geneticist, who observed blepharophimosis, small mouth with incomplete opening, micrognathia, and high arched palate, long eyelashes in irregular rows, stiff legs, externally rotated outward legs, and percussion of thenar muscle (myotonia)

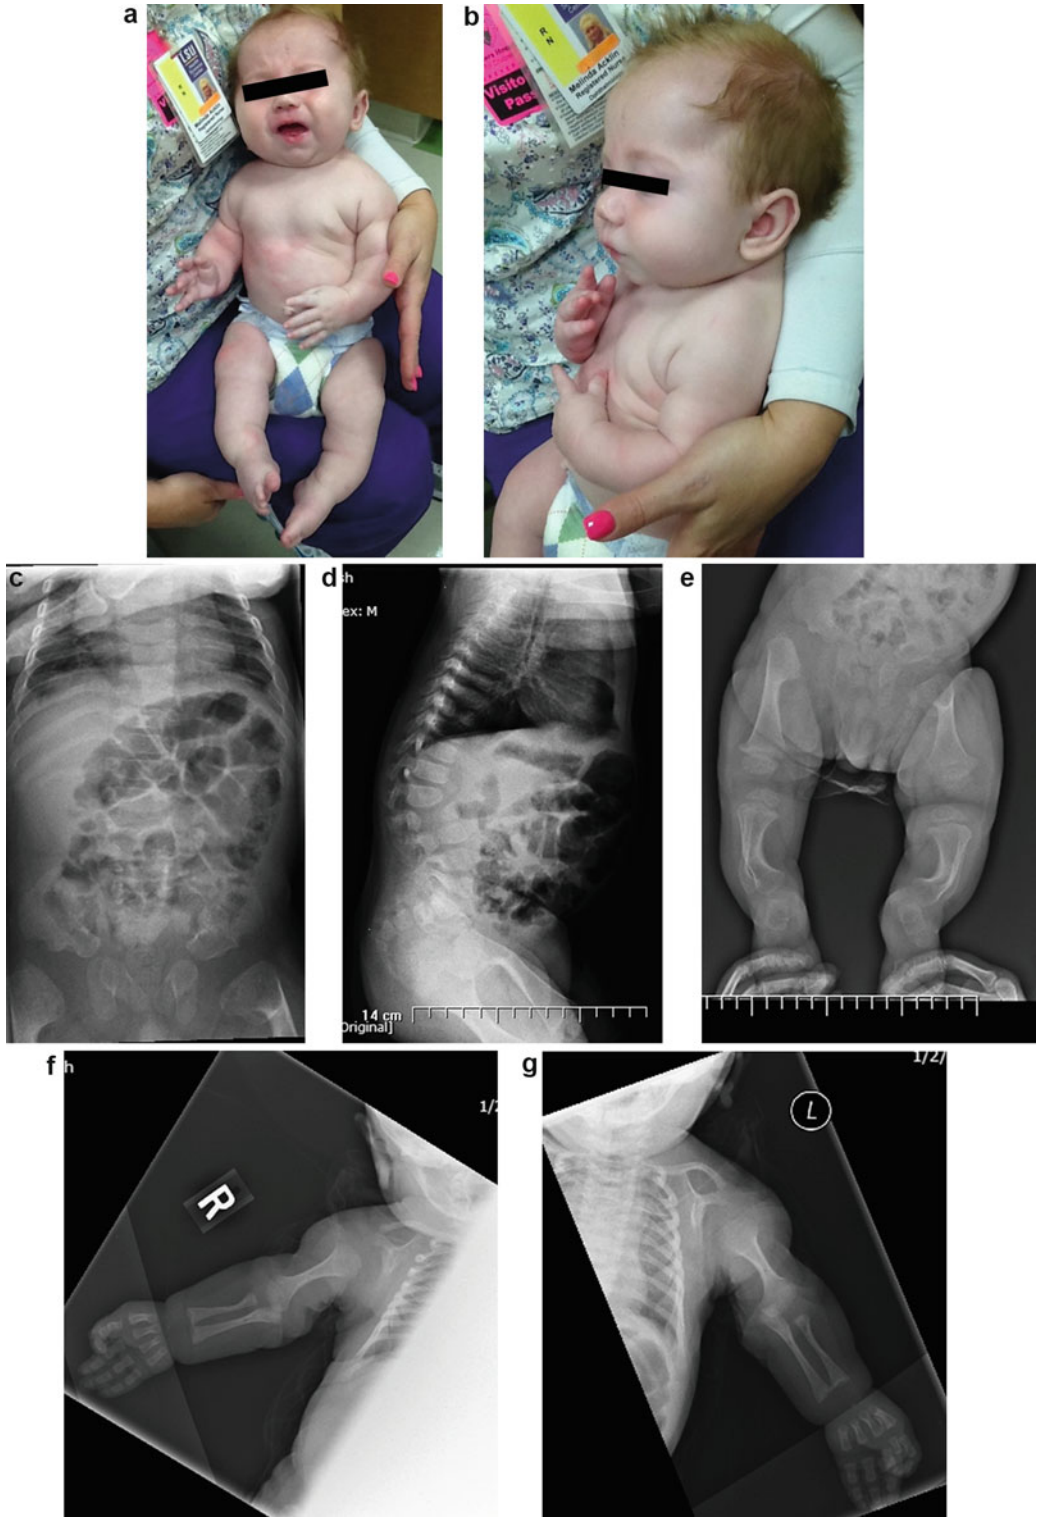

Fig. 2 (continued)

Fig. 2 (**a**–**g**) This 2-month-old infant boy was evaluated for short-limbed dwarfism. Prenatal ultrasound at 20 weeks of gestation showed the fetus with short extremities. After birth, the baby was noted to have prolonged jaundice, poor feeding, sleepiness, and sluggish. Chromosome analysis and thyroid function were normal. He was noted to have hemangiomas on the head, nose, and midface, round face, slightly receding chin, neck short, shored limbs, and curved extremities (**a**, **b**). Radiographs showed short limbs with dumbbell-shaped long bones due to splaying of the metaphyses (**c**, **e**, **f**), bowed tibiae and fibulae (**e**), dysplasia of the pelvic bones with dislocation of both hips (**c**, **e**), and lumbar coronal clefts on the lateral view on L4 and L5 (**d**). Molecular studies of *COL2A1* for Kniest dysplasia and *COL11A2* for Weissenbacher-Zweymuller syndrome were negative

Fig. 3 (**a**–**c**) The previous boy, now 2-year-10-month old, showed a significant hypertonia, disproportionate short stature, fixed face with pursed lips, low-set ears (**a**, **b**), flexion contracture of the elbows and the knees, and bowed tubular bones (**c**). The diagnosis was made by Dr. Michael Bober of Nemours Children's Clinic with skeletal features (short stature of short-limb type, pectus carinatum with the rib flaring, flexion contractures of the elbows and the knees, and features of skeletal dysplasias consisting of absence of capital femoral epiphysis indicating a delay in bone age at his age, relatively large epiphyses at the knees, mottled and widened metaphyses throughout, bilateral bowing of the tibia and fibula, coronal cleft in the lumbar vertebrae, and some platyspondyly, indicating some type of spondylo-epi-metaphyseal dysplasia), a significant hypertonia, and questionable double row of eyelashes. Molecular testing revealed two distinct changes in *HSPG2* gene. The first change, c.10355G > A transition in exon 75 converts codon for arginine (CGA) to codon for glutamine (CAA) (performed by Connective Tissue Gene Tests Diagnosis Laboratory). The change has been previously reported as *HSPG2* mutation associated with Schwartz-Jampel syndrome type I (Stum et al. 2006 Human Mutation 27:1082). This change is consistent

Fig. 3 (continued) with disease-causing mutation. The patient is heterozygous for this mutation. The second change, c.11208-19G > A transition in IVS81, occurs in the intervening sequences. This change has the potential to create a new acceptor splice site and result in aberrant mRNA processing. To the best of their knowledge, this change has not been previously reported in either mutation or polymorphism. Additionally, this change is not listed in either the Single Nucleotide Polymorphism database (dbSNP) or the Exome Sequencing Project (ESP) database. These findings suggest that this change may be pathogenic

Fig. 4 (**a**–**e**) The radiographs of the extremities (**a**–**c**) at 14 months of age showed shortened and bowed long bones, broadening of the metaphyses, unossified femoral heads, and mild broadening of the tubular bones of the hands. The ribs are downward sloping bilaterally with mild broad deformity. The pelvic bones are thickened with irregular contours and with flattened acetabula (**d**). There were platyspondyly with flattening of the thoracic and lumbar vertebral bodies, dysplastic L1-3 with mild kyphosis (**e**) (Courtesy of Dr. Grace Guo)

Seckel Syndrome

Contents

In 1960, Seckel (1960) reported 2 personal cases and 13 cases from the literature of a clinical condition characterized by severe intrauterine and postnatal proportionate dwarfism, severe microcephaly, "bird-headed" profile with receding forehead and chin, large and beaked nose, severe mental retardation, and other anomalies (Majewski and Goecke 1982). Seckel syndrome (SCKL) is a rare heterogeneous type of primordial dwarfism with frequency of less than 1 in 10,000 live births.

Synonyms and Related Disorders

Bird-headed dwarfism; Familial bird-headed dwarfism; Microcephalic primordial dwarfism; Nanocephalic dwarfism; Osteodysplastic primordial dwarfism; Seckel-type dwarfism

Genetics/Basic Defects

1. Inheritance: autosomal recessive (familial occurrence) (Sauk et al. 1973; Syrrou et al. 1995)
2. Genetic heterogeneity (Abou-Zahr et al. 1999; Faivre et al. 2002)
    1. SCKL1: A gene for Seckel syndrome was mapped to human chromosome 3q22.1-q24 in two inbred Pakistani families originating from the same village (Goodship et al. 2000).
        1. The gene encoding ataxia-telangiectasia and Rad3-related (ATR) protein maps to the critical region to an interval of 5Mbp between markers D3S1316 and D3S1557.
        2. A splicing mutation affecting expression of ataxia-telangiectasia and Rad3-related protein (ATRP) results in Seckel syndrome (O'Driscoll et al. 2003).
        3. A synonymous mutation in affected individuals was identified that alters *ATR* splicing.
        4. The mutation confers a phenotype including marked microcephaly and dwarfism.
        5. Identification of the first ATRIP-deficient patient and novel mutations in ATR define a clinical spectrum for

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_212

ATR–ATRIP Seckel syndrome (Ogi et al. 2012).

2. SCKL2: Another gene locus was mapped to chromosome 18p11.31-q11.2 in one inbred Iraqi family (Børglum et al. 2001).
3. SCKL3: A novel locus at 14q23 by linkage analysis in 13 Turkish families. The novel gene locus SCKL3 is 1.18 cM and harbors ménage a trois 1, a gene with a role in DNA repair (Kilinç et al. 2003).
4. Caused by mutations of the pericentrin gene (*PCNT*) (mapped to 21q22.3) (Griffith et al. 2008; Rauch et al. 2008; Willems et al. 2009).
    1. The gene encodes centrosomal protein which plays a key role in the organization of mitotic spindles.
    2. The mutations also can cause microcephalic osteodysplastic primordial dwarfism type II (Rauch 2011).
5. Mutations in *CENPJ*, a gene that has hitherto been linked to primary microcephaly only (Bond et al. 2005; Gul et al. 2006), also can cause Seckel syndrome (Al-Dosari et al. 2009).
6. Mutations in CDK5RAP2 cause Seckel syndrome (Yigit et al. 2015).
7. Mutations in the NHEJ component *XRCC4* cause primordial dwarfism (Murray et al. 2015).
8. Interstitial deletion 2q33.3-q34 in a boy with a phenotype resembling the Seckel syndrome (Courtens et al. 1997).

Clinical Features

1. Broad interfamilial clinical heterogeneity (Arnold et al. 1999)
2. Growth
    1. Severe proportionate short stature of prenatal onset
    2. Severe postnatal growth deficiency
    3. Intrauterine growth retardation
    4. Low-birth-weight dwarfism
3. Mental retardation
4. Characteristic craniofacial features
    1. Bird-headed dwarfs (Harper et al. 1967; McKusick et al. 1967)
    2. Cranial manifestations
        1. Severe microcephaly
        2. Premature closure of cranial sutures
    3. Receding forehead
    4. "Birdlike" face
    5. Antimongoloid slant of palpebral fissures
    6. Large eyes
    7. Beaklike protrusion of the nose
    8. Narrow face
    9. Receding lower jaw (retrognathia)
    10. Micrognathia
    11. High-arched or cleft palate
    12. Ears
        1. Low set
        2. Hypoplastic lobules
    13. Dental abnormalities
        1. Enamel hypoplasia
        2. Missing permanent teeth
        3. Precocious eruption of teeth
        4. Microdontia
        5. Malocclusion
        6. Taurodontism
    14. "Dysplastic" ears
5. Associated anomalies
    1. Ocular manifestations (Guirgis et al. 2001)
        1. Severe myopia and astigmatism
        2. Severe, early onset, bilateral retinal degeneration
        3. Hypotelorism
        4. Bilateral ptosis
        5. Microphthalmos
        6. Megacornea
        7. Glaucoma
        8. Retrolental membrane
        9. Macular coloboma
        10. Optic hypoplasia
        11. Strabismus
        12. Lens dislocation
        13. Ocular changes in two female siblings with Seckel syndrome, including cataract, lens subluxation, and chorioretinal degenerations, as well as retinal detachment (Krzyżanowska-Berkowska et al. 2014)
    2. Skeletal defects
        1. Premature closure of cranial sutures

2. Dislocation of the radial head
3. Clinodactyly of the fifth fingers
4. Hip "dysplasia"/dislocation
5. Retardation of ossification
6. Clubfoot
7. Hypoplastic patella
8. Scoliosis

3. CNS anomalies (Shanske et al. 1997)
   1. Small cerebrum with simplified, ape-like convolutional pattern (pongidoid micrencephaly)
   2. Dysgenesis of cerebral cortex
   3. Agenesis of corpus callosum
   4. Cerebellar vermis hypoplasia
   5. Dorsal cerebral cyst
   6. Arachnoid cyst
   7. Dilated ventricles
   8. Pachygyria
   9. Agyria
   10. Intracranial aneurysms (D'Angelo et al. 1998)
4. Endocrine abnormalities
   1. Pituitary gland abnormalities
      1. Delayed development
      2. Decreased adrenocorticotropic hormone production
      3. Decreased growth hormone production
      4. Absence of adenohypophysis
      5. Hypophyseal hypoplasia
      6. Precocious puberty
   2. Adrenal hypoplasia
   3. Hirsutism
5. Hematopoietic abnormalities
   1. Acute myelogenous leukemia
   2. Refractory anemia with excess blasts
   3. Pancytopenia
   4. Fanconi anemia
6. Urogenital abnormalities
   1. Males
      1. Cryptorchidism
      2. Hypoplasia of the testis
   2. Females
      1. Clitoromegaly
      2. Hypoplasia of the labia majora
7. Features of premature senility
   1. Receding hair
   2. Redundant wrinkled skin on the palms
8. Miscellaneous findings
   1. Congenital heart defects
      1. Patent ductus arteriosus
      2. Atrial septal defect
      3. Ventricular septal defects
      4. Atrioventricular canal defect
   2. Multiple intestinal atresia

6. Seckel-like syndromes (Majewski and Goecke 1982; Arnold et al. 1999)
   1. Microcephalic osteodysplastic primordial dwarfism type I.
      1. Distinguished from Seckel syndrome by:
         1. Broad, low "dysplastic" pelvis with poor development of the acetabula.
         2. Disproportionately short, broad bowing of humeri and femora with rather unremarkable metaphysis.
         3. Agenesis of the corpus callosum and lissencephaly have also been noted.
      2. Classified as Seckel syndrome by Majewski and Goecke (1982)
   2. Microcephalic osteodysplastic primordial dwarfism type II (Majewski et al. 1982a; Majewski and Goecke 1998): differences from the Seckel syndrome include the following (mainly based on X-ray features):
      1. Short limbs with preferential distal involvement (disproportionate shortness of forearms and legs) in the first years of life
      2. Brachymesophalangy
      3. Brachymetacarpy I
      4. Coxa vara
      5. Epiphysiolysis
      6. Metaphyseal flaring with V-shaped distal femoral metaphyses
   3. Microcephalic osteodysplastic primordial dwarfism type III (Majewski et al. 1982b; Majewski 1992).
      1. Alopecia
      2. Seckel-like features
         1. Intrauterine growth retardation
         2. Microcephaly
         3. Receding forehead and chin
         4. Large ears
         5. Large prominent nose
         6. Platyspondyly
         7. Long dysplastic clavicles

8. Hypoplasia of iliac wing and acetabula
9. Broad femora

3. Currently considered to be the same entity as type I (Meinecke and Passarge 1991; Meinecke et al. 1991)

4. A variant of osteodysplastic bird-headed dwarfism described by Bangstad et al. (1989).
   1. Progressive ataxia
   2. Primary gonadal insufficiency
   3. Endocrine abnormalities
      1. Insulin-resistant diabetes mellitus
      2. Goiter
5. Chromosome abnormalities.
   1. Chromosome instability/breakage (Butler et al. 1987; Bobabilla-Morales et al. 2003)
   2. Deletion 1q22-q24.3
   3. Interstitial deletion 2q33.3-q34 (Courtens et al. 1997)
   4. Ring chromosome 4 mosaicism (Anderson et al. 1997)

Diagnostic Investigations

1. Hematological workup indicated in selected patients
   1. Anemia
   2. Pancytopenia
   3. Acute myeloid leukemia
2. Endocrine workup for pituitary and adrenal dysfunction
3. Radiography
   1. Microcephaly with a rather steeply sloping base of the skull
   2. Premature closure of the cranial sutures
   3. Delayed bone age
   4. Hip dysplasia
   5. Elbow dislocation
   6. Dislocation of the radial head
   7. Ivory epiphyses (dense sclerotic areas in the phalanges)
   8. Cone-shaped epiphyses
   9. Disharmonic bone development
      1. Hypoplasia of proximal radii and fibulae
      2. Absence of epiphyseal ossification centers in fingers and toes
4. Neuropathology and CT/MRI of the brain
   1. Microcephaly
   2. Neuroglial ectopia
   3. Agenesis of the corpus callosum
   4. Micropolygyria
   5. Disproportion of the cerebrum and cerebellum
   6. Dysgenetic cerebral cortex
   7. Hypoplasia of the cerebellar vermis
   8. Dorsal cerebral cyst
5. Growth plate histology
   1. Normal column formation
   2. No structural abnormality of chondrocytes
   3. Decrease in cellularity of chondrocytes

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: 25%
   2. Patient's offspring: not likely to have offspring due to severe mental retardation
2. Prenatal diagnosis possible by serial ultrasonography for families at risk for Seckel syndrome (Nadjari et al. 2000)
   1. Severe intrauterine growth retardation
   2. Craniofacial abnormalities
      1. Microcephaly
      2. Receding forehead
      3. A prominent nose
      4. Severe micrognathia
   3. Short limbs
3. Prenatal ultrasound and MR imaging in a family without a previous child with the disorder (Featherstone et al. 1996)
   1. Intrauterine growth retardation
   2. Disproportionately large fetal nose with a beaklike appearance
   3. Facial dysmorphism (beaked nose with hypotelorism with mild proptosis with micrognathia) (Gupta et al. 2014)
   4. Microcephaly
   5. A posterior fossa cyst
4. Prenatal ultrasound diagnosis of a Seckel-like syndrome (Majoor-Krakauer et al. 1987)

1. Microcephaly
2. Intrauterine growth retardation
3. A Hellenic nose
4. Severe micrognathia

5. Management
   1. Symptomatic.
   2. Psychosocial support for mental retardation.
   3. Dental cares.
   4. Orthopedic cares.
   5. Treatments for hematological abnormalities.
   6. Successful outcome of allogeneic stem cell transplantation in Seckel syndrome: bone marrow transplantation is an acceptable therapeutic option for Seckel syndrome complicated by hematological alterations (Darrigo et al. 2014).

Severe Combined Immune Deficiency

Contents

Severe combined immune deficiency (SCID) is a fatal, heterogeneous group of immune disorder, characterized by T-cell lymphopenia, a profound lack of cellular (T-cell) and humoral (B-cell) immunity, and, in some cases, decreased NK-cell number and function. All infants with SCID develop infections from both common and opportunistic pathogens because protection from maternal antibodies wanes early in life (Buckley et al. 1997; Friedrich et al. 2007). The incidence of SCID is estimated to be 1/100,000 live births, but this may be an underestimate due to some children dying before diagnosis or having unrecognized less severe disease (Stephan et al. 1993; Chan and Puck 2005; McGhee et al. 2005).

Synonyms and Related Disorders

Autosomal recessive SCID (Swiss-type agammaglobulinemia); Bare lymphocyte syndrome; Interleukin (IL)-2 deficient SCID; Janus-associated kinase 3 (JAK3) deficient SCID; Omenn syndrome; Purine nucleoside phosphorylase (PNP) deficient SCID; Reticular dysgenesis; SCID; X-linked SCID; ZAP-70 protein tyrosine kinase (PTK) deficient SCID

Genetics/Basic Defects

1. A heterogeneous syndrome of varied genetic origins (Secord 2009):
    1. X-linked type SCID (X-SCID):
        1. The most common type (50% of all patients with SCIDs), characterized by the absence of the cytokine receptor common γ chain.
        2. A combined cellular and humoral immunodeficiency resulting from lack of T and natural killer (NK) lymphocytes and nonfunctional B lymphocytes.
        3. Caused by a mutation in the X-linked gene *IL2RG*, which encodes the common γ chain, γc (mapped on Xq13), of the leukocyte receptors for interleukin-2 and multiple other cytokines (Fanos et al. 2001):
            1. Significant frequency of de novo mutations accounting for one third of the cases
            2. Occurrence of maternal germ line mosaicism
        4. A novel intronic splice site deletion of the IL-2 receptor common gamma chain

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_213

results in expression of a dysfunctional protein and T-cell-positive X-linked severe combined immunodeficiency (Gray et al. 2015).
5. Atypical X-SCID: less frequently seen in patients with mutations that result in production of a small amount of gene product or a protein with residual activity.

2. Autosomal recessive type SCID:
1. Formerly known as Swiss-type agammaglobulinemia
2. Causes:
1. Adenosine deaminase deficiency (10–20% of all cases of SCID): the *ADA* gene mapped on chromosome 20q13.11 (Arredondo-Vega et al. 1998)
2. Purine nucleoside phosphorylase (PNP) deficiency: the *PNP* gene mapped on 14q13
3. Janus-associated kinase 3 (JAK3) deficiency causing autosomal recessive T-B + SCID: the JAK3 gene mapped on 19p13
4. Interleukin (IL)-2 deficiency
5. ZAP-70 protein tyrosine kinase (PTK) deficiency: ZAP-70 mapped on 2q12
6. Bare lymphocyte syndrome
7. Reticular dysgenesis
8. Omenn syndrome

2. Mutations in any of eight known genes, *IL2RG*, *ARTEMIS*, *RAG1*, *RAG2*, *ADA*, *CD45*, *JAK3*, and *IL7R,* cause SCID (Kalman et al. 2004).
3. Pathophysiology:
1. Varies among various forms of SCID
2. Common end point in all forms of SCID:
1. Lack of T-cell function
2. Lack of B-cell function
3. Cellular hallmarks differentiating various forms of SCID:
1. X-linked SCID:
1. Absence or near absence of T cells ($CD3^+$) and natural killer (NK) cells leading to lymphopenia
2. Variable levels of B cells that produce no functional antibodies
2. JAK3 deficiency:
1. Absence or near absence of T cells ($CD3^+$) and natural killer (NK) cells leading to lymphopenia
2. Normal or high levels of B cells that produce no functional antibodies
3. ADA deficiency:
1. Death of T and B cells secondary to the accumulation of toxic metabolites in the purine salvage pathway leading to lymphopenia
2. Decreased or absence of functional antibodies
4. PNP deficiency:
1. Death of T cells secondary to the accumulation of toxic metabolites in the purine salvage pathway leading to lymphopenia
2. Normal number of circulating B cells with poor B-cell function, evidenced by the lack of antibody formation
5. IL-2 deficiency:
1. Normal or near normal numbers of T cells (both $CD4^+$ and $CD8^+$)
2. Decreased production of functional antibody
6. ZAP-70 PTK deficiency:
1. Absence of $CD8^+$ T cells leading to lymphopenia
2. No antibody formation
7. Bare lymphocyte syndrome:
1. Normal or mildly reduced lymphocyte count
2. Decreased $CD4^+$ T cells
3. Normal or mildly increased $CD8^+$ T-cell numbers
4. Normal or mildly decreased B-cell numbers with decreased antibody production
8. Reticular dysgenesis:
1. Absence of myeloid cells in the bone marrow leading to lymphopenia
2. Presence of functioning red blood cells and platelets

9. Omenn syndrome:
    1. A variant of SCID: believed to be caused by a mutation impairing the function of immunoglobulin and TCR recombinase genes, such as *RAG1* and *RAG2* genes
    2. Presence of normal or elevated T-cell numbers of maternal origin
    3. Usually undetectable B cells
    4. Presence of NK cells
    5. Markedly low total immunoglobulin level with poor antibody production
    6. Elevated eosinophils and total serum immunoglobulin E (IgE) level
    7. Characterized by erythrodermic rash, lymphadenopathy, hepatosplenomegaly, and diarrhea

4. Molecular defects of major types of SCID (Gaspar et al. 2001):
    1. X-linked SCID:
        1. Mutation of the common gamma chain of the IL receptors (IL-2R, IL-4R, IL-7R, IL-9R, IL-15R) resulting in loss of cytokine function (Cavazzana-Calvo et al. 2000)
        2. Loss of IL-2R function leading to the loss of a lymphocyte proliferation signal
        3. Loss of IL-4R function leading to the inability of B cells to class switch
        4. Loss of IL-7R function leading to the loss of an antiapoptotic signal resulting in a loss of T-cell selection in the thymus and also associated with the loss of a T-cell receptor
        5. Loss of IL-15R function leading to the ablation of NK cell development
    2. JAK3 deficiency:
        1. JAK, a protein tyrosine kinase that associates with the common gamma chain of the IL receptors
        2. Deficiency of JAK3 resulting in the same clinical manifestations as those of X-linked SCID
    3. ADA and PNP deficiencies:
        1. Associated with enzyme deficiencies in the purine salvage pathway
        2. Toxic metabolites responsible for the destruction of lymphocytes that cause the immune deficiency
    4. IL-2 deficiency:
        1. Molecular defect unknown
        2. Often associated with other cytokine production defects
    5. ZAP-70 PTK deficiency: caused by a mutation in the gene coding for this tyrosine kinase, which is important in T-cell signaling and is critical in positive and negative selection of T cells in the thymus
    6. Bare lymphocyte syndrome:
        1. Deficiency of major histocompatibility complex (MHC)
        2. Absent or decreased MHC type I levels
        3. Decreased MHC type II levels on mononuclear cells

Clinical Features

1. Age of onset: 3–6 months of life
2. A pediatric emergency (Rosen 1997)
3. Usual presentation with infections due to lack of T-cell function:
    1. Opportunistic organisms:
        1. *Pneumocystis carinii* pneumonia
        2. Systemic candidiasis
        3. Atypical mycobacterium
        4. Cryptosporidium
        5. Pneumococcus
    2. Recurrent infections
    3. Persistence of infections despite conventional treatment
4. Failure to thrive
5. Oral or diaper candidiasis (persistent oral thrush)
6. Dehydration from chronic diarrhea
7. Fevers
8. Erythrodermic rashes
9. Cough and congestion
10. Increased respiratory rate and effort
11. Absence of tonsils and lymph nodes
12. Absence of lymphadenopathy or increased tonsillar tissue despite serious infections

13. Pneumonias
14. Sepsis
15. Disseminated infections:
    1. Salmonella
    2. Varicella
    3. Cytomegalovirus
    4. Epstein–Barr virus
    5. Herpes simplex virus
    6. BCG
    7. Vaccine strain (live) polio virus
16. Recurrent sinopulmonary infections
17. Recurrent skin infections
18. Abscesses
19. Poor wound healing
20. Lymphadenopathy
21. Hepatosplenomegaly
22. Lymphopenia
23. Transplacental transfer of maternal lymphocytes to the infant prenatally or during parturition causing graft-versus-host disease (GVHD), characterized by:
    1. Erythematous skin rashes
    2. Hepatomegaly
    3. Lymphadenopathy
24. ADA deficiency and PNP deficiency with later onset and milder or atypical clinical presentation:
    1. Diagnosis suspected in patients with:
        1. Unexplained T-cell lymphopenia
        2. Late manifestations of immunodeficiency:
            1. Chronic pulmonary insufficiency
            2. History of autoimmunity and neurologic abnormalities
            3. Onset during the first two decades of life and even later
    2. Diagnosis confirmed by finding absent or very low enzyme activity in erythrocytes or in nucleated blood cells
25. Lymphadenopathy or hepatosplenomegaly in Omenn syndrome or bare lymphocyte syndrome
26. Prognosis:
    1. Fatal if untreated
    2. Bone marrow transplantation or enzyme replacement to reconstitute the immune system compatible with long survival

Diagnostic Investigations

1. Newborn screening (Adeli and Buckley 2010; Lipstein et al. 2010; Secord 2009; Kwan and Puck 2015):
    1. Newborn screening would not only make the diagnosis at birth but would lead to measures to protect infants from becoming infected before they could receive a transplant.
    2. Newborn screening would also reveal the true incidence of SCID and define the range of conditions characterized by severely impaired T-cell development.
    3. Evidence indicates the benefits of early treatment of SCID and the possibility of population-based newborn screening.
    4. Better information on optimal treatment and the costs of treatment and screening would benefit policy makers deciding among competing health-care priorities.
    5. Newborn screening for SCID using the T-cell receptor excision circle assay has revolutionized early identification of infants with SCID or severe T-cell lymphopenia (Kelly et al. 2013).
2. Laboratory workup:
    1. X-SCID (Allenspach et al. 2016):
        1. Lymphocyte count:
            1. Usually very low number of T cells
            2. B cells generally present, but nonfunctional
            3. Low or absent number of NK cells
            4. Typical X-SCID designated as $T^{-}B^{+}NK^{-}$
        2. Lymphocyte functional tests:
            1. Absent antibody responses to vaccines and infection agents
            2. Lacking T-cell responses to mitogens
        3. Immunoglobulin concentrations:
            1. Low serum concentrations of IgA and IgM
            2. IgG generally normal at birth but declines as maternally transferred IgG disappears by 3 months of age
        4. Thymus: absent thymic shadow on chest radiogram.

5. Carrier detection in X-linked severe combined immunodeficiency based on patterns of X-chromosome inactivation (Puck et al. 1987): In the T cells of three carriers, the X chromosome bearing the X-SCID mutation was consistently inactive. Nonrandom X inactivation was also found in the T cells of one at-risk female, while two others had normal, random X inactivation.
6. Identification of X-linked severe combined immunodeficiency by mutation analysis of blood and hair roots (Ting et al. 1999): The strategy of using DNA from hair roots was particularly valuable where no pre-transplant blood was stored.
7. Molecular genetic testing clinically available: *IL2RF* is the only gene known to be associated with X-SCID:
    1. Sequence analysis
    2. Targeted mutation analysis

2. Adenosine deaminase deficiency (Hershfield 2014):
    1. Immune function:
        1. Lymphopenia, the laboratory hallmark of ADA-deficient SCID, is present at birth. The total blood lymphocyte count is usually lower than 500/μL (normal for neonates: 2,000 to >5,000).
        2. All lymphoid lineages (T, B, and NK cells) are depleted as demonstrated by flow cytometry.
        3. Lower or absent in vitro lymphocyte function, as measured by proliferative response to mitogens and antigens.
        4. Low serum immunoglobulins and absence of specific antibody response to infections and immunizations.
    2. Adenosine deaminase (ADA) catalytic activity:
        1. Affected individuals who have not been transfused have less than 1% of normal ADA catalytic activity in erythrocyte hemolysates.
        2. Affected individuals who have been recently transfused may require testing of another cell type, such as fibroblasts or leukocytes.
    3. Biochemical markers of ADA deficiency:
        1. Elevated erythrocyte deaminate 2′-deoxyadenosine (dAdo) nucleotides (dAXP): pathognomonic
        2. Reduced erythrocyte S-adenosylhomocysteine hydrolase (AdoHcyase, SAHase) activity (<5% of normal)
        3. Markedly elevated urinary excretion of dAdo
    4. Molecular genetic testing; *ADA* is the only gene associated with ADA deficiency:
        1. Sequence analysis
        2. Deletion/duplication analysis
3. ZAP70-related SCID (Rosenberg and Larkin 2014):
    1. Lymphocyte counts:
        1. T-cell counts: absent or very low CD8+ cells, normal or elevated CD4+ cells, and normal CD3+ cells
        2. B-cell counts: normal B cells and NK cells
    2. Lymphocyte function:
        1. Absence of proliferation of CD4+ cells in response to mitogens (e.g., PHA).
        2. Absence of proliferation of CD4+ cells in response to antigens (e.g., ConA).
        3. Defective $CD4^{+}$ cell-cell activation manifests as impaired Ca^{2+} flux in response to CD3 (OKT3) stimulation.
    3. ZAP-70 protein expression: absence of ZAP-70 protein in most cases by immunocytochemistry testing of CD4+ T cells.
    4. Immunoglobulin concentrations and function:
        1. Severe hypogammaglobulinemia in a majority of affected individuals but normal immunoglobulin levels have been seen

2. Although functional antibody responses to immunization are present in a few persons, this finding does not indicate that all specific antigenic responses are intact.
5. Molecular genetic testing: Sequence analysis of the *ZAP70* coding region detects missense and nonsense mutations, splice and regulatory region mutations, and insertion mutations.

4. Autosomal recessive SCID (T-B-NK+. *RAG1*/*RAG2*-related): molecular genetic testing of *RAG1*/*RAG2* gene available clinically by sequence analysis or deletion/duplication analysis

3. Chest X-ray:
   1. Absent to small thymus shadow
   2. Pneumonia
   3. Typical cupping and flaring of the costochondral junction in patients with ADA deficiency
4. Lymph node biopsy:
   1. Paucity of T and B cells
   2. Lack of germinal centers
5. Consider X-SCID in male infants with:
   1. Severe recurrent or persistent infections
   2. Infections not responding to ordinary treatment
   3. Infections caused by opportunistic pathogens
   4. Failure to thrive
6. A correct diagnosis for SCID and related disorders cannot be overstated, from T-cell receptor excision testing to targeted mutation analysis to whole exome/whole genome sequencing (Shearer et al. 2014). Genotype information provides substantial and accurate information regarding current eligibility of patients for study databanks and stratum assignment (Manolio et al. 2013). However, maternal chimerism and lymphocyte function (proliferation to phytohemagglutinin) tests in addition to the absolute numbers of T, B, and NK cells, remain essential.
7. Carrier testing of X-SCID:
   1. Testing for known family-specific *IL2RG* mutations.
   2. Sequence analysis of the *IL2RG* coding region and splice regions.
   3. Southern blot analysis is used to detect large deletions and complex mutations if the family-specific mutation is not known and sequence analysis is uninformative.
   4. X-chromosome inactivation studies on lymphocytes for at-risk females in whom sequence analysis and/or mutation analysis are not an option for carrier testing or are not informative, provided presence of the following two conditions:
      1. Skewed X-chromosome inactivation in lymphocytes
      2. Non-skewed X-chromosome inactivation in another blood lineage such as granulocytes
8. The remarkable advances in gene sequencing technology now allow the simultaneous sequencing of large number of genes or indeed whole exome or genome sequencing (Rivers and Gaspar 2015). Some studies show that targeted next-generation sequencing has sensitivity and specificity of >99% in detecting point mutations and 100% sensitivity and specificity of exonic deletions (Nijman et al. 2014). In this particular approach, accurate simultaneous detection of mutations in 161 of 170 known primary immunodeficiency (PID)-related genes was possible, meaning that screening for genetic mutations can be rapidly carried out where such conditions are suspected.

Genetic Counseling

1. Recurrence risk:
   1. X-SCID:
      1. Female germ line mosaicism present if a woman has more than one affected son and the disease-causing mutation in the *IL2RG* gene cannot be detected in her leukocytes.
      2. Over 50% of affected males do not have family history of early deaths in maternal male relatives.

3. Patient's sib if the mother is a carrier:
    1. Fifty percent of male sibs affected
    2. Fifty percent of female sib carriers
4. Patient's sib is still at increased risk even if the disease-causing mutation has not been identified in the mother's leukocytes since germ line mosaicism has been demonstrated in this condition.
5. Patient's offspring (offspring of affected males):
    1. Hundred percent of daughter carriers
    2. None of sons affected

2. Autosomal recessive SCID:
    1. Patient's sib: 25%
    2. Patient's offspring: not increased unless the spouse is a carrier in which case 25% of the offspring will be affected

2. Prenatal diagnosis:
    1. X-SCID:
        1. Determination on fetal cells obtained by CVS or amniocentesis
        2. Analysis of DNA from fetal cells for the known disease-causing mutation, provided:
            1. Karyotype revealing 46,XY.
            2. The disease-causing *IL2RG* mutation has been identified in a family member.
        3. Fetal blood sampling for immunological evaluation when the family-specific mutation is not known:
            1. Lymphocytopenia
            2. Low numbers of T cells
            3. Poor T-cell blastogenic responses to mitogens
    2. Autosomal recessive SCID:
        1. JAK3-deficient SCID (Schumacher et al. 1999):
            1. Immunophenotypic evaluation of cord blood cells at 18–20 weeks of gestation
            2. Direct gene analysis using chorionic villus sampling derived DNA in the first trimester
        2. ADA deficiency:
            1. Prenatal diagnosis established by measuring ADA enzyme activity in amniotic cells or chorionic villi (Aitken et al. 1986).
            2. Prenatal diagnosis and preimplantation genetic diagnosis for at-risk pregnancies require prior identification of the disease-causing mutations in the family (Hershfield 2014).

3. Management (Secord 2009):
    1. General principles (Rivers and Gaspar 2015):
        1. Isolation of SCID infants: important to keep affected infants away from other children, infected individuals, large groups of individuals, and closed environments including public transport, in order to reduce exposure to pathogens.
        2. Vaccinations:
            1. Live vaccines must be avoided, and those who have already received *Bacillus* Calmette–Guérin vaccine (BCG) prior to diagnosis will need to start antituberculosis treatment.
            2. It is recommended that siblings of those with SCID should also not receive the rotavirus vaccine (Buckley 2004)
            3. Although routine vaccinations are unlikely to cause harm, they are unlikely to confer any additional benefit as they will not be effective.
        3. Nutrition: Nasogastric tube feeding or parenteral nutrition may be required in order to optimize nutrition.
        4. Prophylaxis: *Pneumocystis jirovecii* pneumonia prophylaxis should start with co-trimoxazole and additional antiviral and antifungal cover given depending on local guidelines and clinical circumstances.
        5. Immunoglobulin replacement: Replacement immunoglobulins should be given intravenously or subcutaneously every two to three weeks depending on response.
        6. Organism surveillance:

    1. Some centers conduct weekly screening of infants for herpes viruses (adenovirus, Epstein–Barr virus, and cytomegalovirus) as well as for respiratory and stool organisms.
    2. Early detection allows for intervention prior to end-organ damage and improved outcomes(Hiwarkar et al. 2012).
7. Breast feeding: Due to the increased risk of cytomegalovirus (CMV) transmission through breast milk, breast feeding is discouraged until the mother and infant's CMV status is known (Gaspar et al. 2013)).
8. Chicken pox: Early intervention with use of varicella zoster-specific immunoglobulin in those who have been in contact with the virus and treatment with Aciclovir in those with suspected infection are essential to avoid disseminated infection.
9. Blood products: All blood products will need to be CMV negative, irradiated, and leukocyte depleted in order to prevent donor T cells from attacking the infant and to prevent interference with future hematopoietic stem-cell transplant (HSCT).
10. Immunosuppression: Infants with Omenn's syndrome or maternal engraftment (see above) are likely to require immunosuppressive treatment such as systemic steroids and possibly cyclosporine in order to control the inflammatory reaction.
11. Enzyme replacement:
    1. In ADA-SCID, enzyme replacement therapy (ERT) can provide initial benefit in reducing the toxic accumulation of metabolites.
    2. Unfortunately, there are no equivalent agents to aid other forms of SCID.

2. X-linked SCID and JAK3 PTK deficiency:
    1. Fatal disease unless cured by bone marrow transplantation (BMT):
        1. The best results achieved by using an HLA-matched sibling as a donor (success rates of 97%)
        2. Using haploidentical T-cell-depleted BMT from a parent (haploidentical family donors resulting in lower success rates of 52%): lifesaving for the majority of X-SCID patients who lack matched sibling
    2. Monthly intravenous immunoglobulin replacement therapy is required if B cells do not engraft.
    3. Report of in utero transplantation of hematopoietic progenitor cells allowing immune reconstitution in a fetus (Wengler et al. 1996).
    4. Accurate prenatal diagnosis-assisted decision making and expanded treatment options for families at risk for having infants with a severe but treatable genetic disorder that presents early in life (Puck et al. 1997).
    5. Gene therapy (Hacein-Bey-Abina et al. 2010):
        1. Using autologous bone marrow stem/progenitor cells retrovirally transduced with a therapeutic gene.
        2. Successful in reconstituting the immune system in patients with X-SCID.
        3. Youngest two of the first ten infants treated in a French study developed leukemia due to retroviral insertional mutagenesis.
        4. After nearly 10 years of follow-up, gene therapy was shown to have corrected the immunodeficiency associated with SCID-X1. Gene therapy may be an option for patients who do not have an HLA-identical donor for hematopoietic stem-cell transplantation and for whom the risks are deemed acceptable (Hacein-Bey-Abina et al. 2010). This treatment is associated with a risk of acute leukemia.

3. ADA deficiency:
    1. Usually fatal unless:
        1. Keeping affected children in protective isolation.
        2. Allogeneic bone marrow transplantation (BMT) is the treatment of choice if an HLA-identical sibling bone marrow donor is available, resulting in almost 100% cure rate (Hoogerbrugge et al. 1996). BMT-related mortality is high in patients lacking such a donor.
        3. Reconstituting the immune system by bone marrow transplantation from a human leukocyte antigen (HLA)-identical sibling donor (therapy of choice but only available for a minority of patients).
    2. Exogenous enzyme replacement primarily with polyethylene glycol-conjugated ADA (PEG-ADA) replacement therapy (Hershfield 1993, 1995a, b; Blaese et al. 1995):
        1. Providing noncurative, lifesaving treatment for ADA-SCID patients
        2. Increased peripheral T-cell counts providing a source of T cells for gene correction not available without enzyme therapy
        3. Weight gain and decreased opportunistic infections in most patients
        4. Improved T-cell function as measured by in vitro mitogen responses in most patients
        5. Recovery of consistent immune responses to specific antigens in fewer patients
        6. An alternative to haploidentical bone marrow transplantation and an adjunct to gene therapy for adenosine deaminase deficiency
    3. The first genetic disorder treated by gene therapy: a clinical trial using retroviral-mediated transfer of the adenosine deaminase (*ADA*) gene into the T cells of children with ADA-SCID:
        1. Normalization of the number of blood T cells as well as many cellular and humoral immune responses
        2. Successful gene transfer into long-lasting progenitor cells, producing a functional multilineage progeny (Bordignon et al. 1995)
        3. Safe and effective addition to treatment for some patients
    4. Combined treatment with PEG-ADA and gene therapy
4. PNP deficiency and bare lymphocyte syndrome: primarily with bone marrow transplantation when an appropriate donor is available.
5. IL-2 production defects:
    1. Primarily with intravenous IL-2 replacement
    2. Alternatively with bone marrow transplantation when an appropriate donor is available
6. Omenn syndrome:
    1. Primarily with bone marrow transplantation when an appropriate donor is available
    2. Pretreatment ablative chemotherapy necessary because of maternal cell engraftment
7. SCID patients were the first to be successfully transplanted with nonsibling-related bone marrow, unrelated bone marrow, T-cell-depleted allogeneic hematopoietic stem-cell transplantation, and genetically corrected (gene transfer) autologous hematopoietic stem cells (Copenhagen Study Group of Immunodeficiency 1973; O'Reilly et al. 1977; Reisner et al. 1983; Bordignon et al. 1995; Rappeport et al. 2010).
8. Bone marrow transplantation from a related donor: a lifesaving and life-sustaining treatment for patients with any type of severe combined immune deficiency, even when there is no HLA-identical donor (Buckley et al. 1999).
9. While symptomatic and prophylactic treatment is available, hematopoietic

stem-cell transplantation is an option for many primary immunodeficiencies, leading to cure of the immunodeficiency and establishing normal physical and psychological health (Gennery 2015).

10. Hematopoietic stem-cell transplantation for severe combined immunodeficiency in the neonatal period leads to superior thymic output and improved survival (Myers et al. 2002).
11. Two fetuses successfully treated with gene therapy in utero by an injection of haploidentical $CD34^{+}$ cells for the γ chain deficiency.
12. In the recent past, the gene therapy field has witnessed a remarkable series of successes, many of which have involved primary immunodeficiency diseases, such as X-linked severe combined immunodeficiency, adenosine deaminase deficiency, chronic granulomatous disease, and Wiskott–Aldrich syndrome (Candotti 2016).
13. Psychosocial support for the affected family.
14. Avoid live vaccines.
