Fig. 1 A healthy 9-year-old boy with ADA-deficient SCID who has been receiving biweekly Adagen (pegademase) injections since early infancy

Short-Rib Polydactyly Syndromes

Contents

Short-rib polydactyly syndromes (SRPSs) are a heterogeneous group of recessively inherited lethal skeletal dysplasia. There are four classic subtypes: type I (Saldino-Noonan) (SRPS I), type II (Majewski) (SRPS II), type III (Verma-Naumoff) (SRPS III), and type IV (Beemer-Langer) (SRPS IV).

Synonyms and Related Disorders

Lethal short-rib polydactyly syndromes (Martinez-Frias et al. 1993); SRPS I (Saldino-Noonan syndrome, polydactyly with neonatal chondrodystrophy type I); SRPS II (Majewski syndrome, polydactyly with neonatal chondrodystrophy type II); SRPS III (Verma-Naumoff syndrome, polydactyly with neonatal chondrodystrophy type III); SRPS IV (Beemer-Langer syndrome, short-rib syndrome, Beemer type)

Genetics/Basic Defects

1. Inheritance:
   1. Autosomal recessive in all four subtypes
   2. Saldino-Noonan syndrome: affected sibs (Richardson et al. 1977)
   3. Majewski syndrome: parental consanguinity (Black et al. 1982; Cooper and Hall 1982), affected siblings (Motegi et al. 1979)
   4. Beemer type: affected sibs (Hennekam 1991)
2. Different subtypes of SRPS (Elçioğlu and Hall 2002):
   1. A great overlap of anomalies present among different subtypes contributing to diagnostic dilemmas in the short-rib polydactyly syndrome group
   2. Possibly represent a continuous spectrum with variable expressivity, suggested by some reports
3. Ciliary abnormalities due to defects in the retrograde transport protein DYNC2H1 in short-rib polydactyly syndrome (Merrill et al. 2009):
   1. Homozygosity by descent mapping in a consanguineous SRPS family identified a genomic region that contained *DYNC2H1*, a cytoplasmic dynein involved in retrograde transport in the cilium. Affected individuals in the family were homozygous for an exon 12 missense mutation that predicted the amino acid substitution R587C.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_214

2. Compound heterozygosity for one missense and one null mutation were identified in two additional nonconsanguineous SRPS families.
3. Cultured chondrocytes from affected individuals showed morphologically abnormal, shortened cilia. In addition, the chondrocytes showed abnormal cytoskeletal microtubule architecture, implicating an altered microtubule network as part of the disease process.
4. These findings establish SRPS as a cilia disorder and demonstrate that *DYNC2H1* is essential for skeletogenesis and growth.
5. Mutations in *DYNC2LI1* disrupt cilia function and cause short-rib polydactyly syndrome (Taylor et al. 2015).
6. Identification of novel *DYNC2H1* mutations associated with short-rib polydactyly syndrome type III using next-generation panel sequencing (Chen et al. 2016).
7. *DYNC2H1* mutations also cause asphyxiating thoracic dystrophy: ATD and SRP type III are variants of a single disorder belonging to the ciliopathy group (Dagoneau et al. 2009).

4. *NEK1* mutations cause short-rib polydactyly syndrome type Majewski (Thiel et al. 2011).
5. *NEK1* and *DYNC2H1* are both involved in short-rib polydactyly Majewski type but not in Beemer Langer cases (Hokayem et al. 2012).
6. Short-rib polydactyly syndromes (SRPS) arise from mutations in genes involved in retrograde intraflagellar transport (IFT) and basal body homeostasis, which are critical for cilia assembly and function. Recently, mutations in *WDR34* or *WDR60* (candidate dynein intermediate chains) were identified in SRPS. Tctex1d2, which associates with Wdr34, Wdr60, and other dynein complex 1 and 2 subunits, has been identified and characterized (Gholkar et al. 2015). Tctex1d2 and Wdr60 localize to the base of the cilium and their depletion causes defects in ciliogenesis. *IFT52* mutations destabilize anterograde complex assembly, disrupt ciliogenesis, and result in short-rib polydactyly syndrome (Zhang et al. 2016).
7. Short-rib polydactyly and Jeune syndromes are caused by mutations in *WDR60* (McInerney-Leo et al. 2013).
8. Mutations in *KIAA0586* cause lethal ciliopathies ranging from a hydrolethalus phenotype to short-rib polydactyly syndrome (Alby et al. 2015).

Clinical Features

1. Variable expression of short-rib polydactyly syndrome (Sillence 1980; Sillence et al. 1987)
2. SRPS I (Saldino-Noonan)
   1. Constant findings:
      1. Severely shortened (flipper-like) limbs with postaxial polydactyly
      2. Small/narrow thorax with short ribs and hypoplastic lungs
      3. Protuberant abdomen
      4. Early neonatal death
   2. Common findings:
      1. Hydrops fetalis
      2. Gastrointestinal abnormalities:
         1. Esophageal atresia
         2. Short small intestine
         3. Malrotation of the bowel
         4. Imperforate anus
         5. Persistent cloaca
         6. Imperforate anus
         7. Pancreatic fibrosis and cysts
      3. Cardiac malformations:
         1. Transposition of the great vessels
         2. Coarctation of the aorta or hypoplastic aortic arch
         3. Ventricular septal defects
         4. Double-outlet left ventricle
   3. Occasional findings:
      1. Oligohydramnios
      2. Renal dysplasia/cystic disease
      3. Abnormal genitalia:
         1. Cryptorchidism
         2. Hypoplastic penis
      4. CNS malformations:
         1. Cerebellar hypoplasia
         2. Dandy-Walker malformation
      5. Bifid epiglottis

6. Bifid tongue
7. Cleft upper lip

3. SRPS II (Majewski) (Chen et al. 1980):
   1. Constant findings:
      1. Extremely short limbs with pre-/postaxial polydactyly of the hands and feet
      2. Small/narrow chest with short ribs and pulmonary hypoplasia
      3. Protuberant abdomen
      4. Median cleft lip or pseudocleft of the upper and lower lip or cleft palate
      5. Epiglottis and larynx hypoplasia
      6. Short/ovoid tibias with round ends
      7. Presence of premature ossification centers
      8. Early neonatal death
   2. Common findings:
      1. Polyhydramnios
      2. Hydrops fetalis
      3. Ocular hypertelorism
      4. Broad and flat nose
      5. Low-set ears
      6. Ambiguous genitalia
      7. Renal cystic disease
   3. Occasional findings:
      1. Short small intestine
      2. Malrotation of the bowel
      3. Cardiac malformations
      4. Dysplastic pancreas
4. SRPS III (Verma-Naumoff):
   1. Constant findings:
      1. Severely shortened limbs with postaxial polydactyly
      2. Small/narrow thorax with short ribs and hypoplastic lungs
      3. Early neonatal death
   2. Common findings:
      1. Hydrops fetalis
      2. Short cranial base
      3. Bulging forehead
      4. Depressed nasal bridge
      5. Flat occiput
      6. Renal cystic dysplasia
   3. Occasional findings:
      1. Congenital heart defects:
         1. Ventricular septal defect
         2. Situs inversus
      2. Epiglottic hypoplasia
      3. Intestinal malrotation
      4. Cloacal developmental abnormalities and ambiguous genitalia
5. SRPS IV (Beemer-Langer) (Beemer et al. 1983; Beemer 1987; Chen et al. 1994):
   1. Constant findings:
      1. Severely shortened limbs with (Yang et al. 1991; Elçioğlu et al. 1996) or without postaxial polydactyly
      2. Small/narrow thorax with short ribs and hypoplastic lungs
      3. Early neonatal death
   2. Common findings:
      1. Hydrops fetalis
      2. Macrocephaly with frontal bossing
      3. Ocular hypertelorism
      4. Flat nasal bridge
      5. Cleft lip and palate
      6. Protuberant abdomen
   3. Occasional findings:
      1. CNS abnormalities:
         1. Holoprosencephaly/absence of the corpus callosum/hydrocephalus
         2. Dandy-Walker cyst and/or arachnoid cyst
         3. Hypothalamic hamartomas
      2. Lobulated tongue with hamartomas
      3. Oral frenula
      4. Congenital heart defects
      5. Malrotation of the intestine
      6. Renal malformations:
         1. Renal cystic dysplasia
         2. Atresia of the ureter with hydronephrosis and hydroureter
      7. Omphalocele
      8. Inguinal hernia
6. SRPS-V (Schmidts 2014):
   1. SRPS-V was only recently described and the underlying genetic defect identified in two consecutively affected pregnancies of a mother from Maori descent from New Zealand.
   2. Hydrops, narrow chest, and severely shortened and bowed long bones displaying lack of ossification, hypoplastic scapulae, and peritoneal calcifications, postaxial polysyndactyly, and cleft palate were reported.

3. Extraskeletal findings include bilateral cystic hygroma, hypospadias, mainly glomerular kidney cysts, and intestinal malrotation.
4. Acromesomelic hypomineralization and campomelia distinguish SRPS-V from SRPS subtypes I–III (Kannu et al. 2007; Mill et al. 2011).

Diagnostic Investigations

1. Radiography:
   1. SRPS I (Saldino-Noonan):
      1. Extreme micromelia with severely dysplastic pointed (or ragged) metaphyses of the long tubular bones and absence of corticomedullary demarcation
      2. Narrow thorax with short/horizontal ribs
      3. Deficient ossification in calvarium, vertebrae, pelvis, and bones of the hands and feet
      4. Small iliac bones with horizontal acetabula
      5. Postaxial polydactyly
      6. Short tibiae
   2. SRPS II (Majewski):
      1. Extreme micromelia with smooth rounded metaphyses
      2. Extremely short horizontal ribs
      3. Normal pelvis and vertebrae
      4. Disproportionately shortened ovoid-shaped tibiae
      5. Pre- and postaxial polydactyly, syndactyly, and brachydactyly
      6. Advanced skeletal ossification maturation of the proximal femora and humeri
   3. SRPS III (Verma-Naumoff) (Naumoff et al. 1977):
      1. Extreme micromelia with severely dysplastic widened metaphyses (bones of the legs) and clear corticomedullary demarcation of the long tubular bones
      2. Extremely shortened and horizontal ribs
      3. Small and malformed vertebral bodies
      4. Shortened cranial base
      5. Short iliac bones with horizontal trident lower margin
      6. Polydactyly
   4. SRPS IV (Beemer-Langer):
      1. Extreme micromelia with smooth metaphyseal margins
      2. Extremely shortened and horizontal ribs
      3. Small, poorly ossified vertebrae and increased intervertebral spaces
      4. High clavicles and small scapulae
      5. Small iliac bones
      6. Bowed radii and ulnae
      7. Tibiae: well tabulated and longer than fibulae
      8. Postaxial polydactyly
   5. Examination of patients with the "Verma-Naumoff" short-rib polydactyly syndrome showed many radiologic and pathologic features similar to those of type 1 asphyxiating thoracic dysplasia (Yang et al. 1987).
2. Histopathology/necropsy:
   1. SRPS I (Saldino-Noonan):
      1. Markedly retarded and frequently deranged endochondral ossification. A large island of fibrous tissue may occupy the center of physeal growth zone. A premature ossification center may be seen in the epiphyseal resting cartilage.
      2. Lungs: hypoplasia which is easily assessed by abnormally small size and low weight.
      3. Identify associated multiple congenital anomalies listed in the clinical features.
   2. SRPS II (Majewski):
      1. Markedly retarded endochondral ossification. The chondrocytes in the physeal growth zones are markedly reduced in number and disorderly arranged
      2. Lungs: hypoplasia as in type I
      3. Identify associated multiple congenital anomalies listed in the clinical features.
   3. SRPS III (Verma-Naumoff):
      1. A "bajonet" deformity of the ribs for misalignment and overlap of cartilaginous and bony ends (Corsi et al. 2002). This deformity resulted from a "tandem" change in endochondral bone formation, that is, arrested orthotopic cartilage maturation and etherotopic perichondral

cartilage differentiation and ossification. At the cartilaginous end, cartilage maturation and vascular invasion were absent. At the bony end, longitudinal bone growth occurred by a perichondral ectopic growth plate.
2. Markedly retarded endochondral ossification as in type II.
3. A single patient showed chondrocytic inclusions which are PAS reactive and diastase resistant (Yang et al. 1980).
4. Lung: hypoplasia as in type I.
5. Identify associated multiple congenital anomalies which are less common in this type.

4. SRPS IV (Beemer-Langer):
   1. Physeal growth zones showing a prominent but disorganized zone of hypertrophy. The vascular penetration of physeal cartilage is irregular.
   2. Lungs: hypoplasia as in type I
   3. Identify associated multiple congenital anomalies listed in the clinical features.

Genetic Counseling

1. Recurrence risk:
   1. Patient's sib: 25%.
   2. Patient's offspring: The patients will not survive to reproductive age.
2. Prenatal diagnosis, not always possible to differentiate the subtypes:
   1. Ultrasonography for SRPS I (Saldino-Noonan) (Meizner and Bar-Ziv 1989):
      1. Short fetal limbs
      2. Narrow thorax
      3. Polydactyly
      4. Pointed metaphyses
      5. Dysplastic cystic kidneys
      6. Congenital heart defect
      7. Genital anomalies
   2. Ultrasonography for SRPS II (Majewski) (Benacerraf 1993):
      1. With a positive family history of Majewski syndrome:
         1. Presence of short fetal limbs
         2. Other skeletal findings
      2. Without a family history:
         1. Short fetal limbs
         2. Disproportionately short tibia
         3. Very narrow fetal chest
         4. Short ribs
         5. Bilateral postaxial polydactyly of the hands and feet
         6. Median cleft lip and palate
         7. Polyhydramnios
         8. Hydrops
         9. Marked shortened humerus and femur
         10. Severe bowing and deformity of the bones of the lower leg and forearm
         11. Hypoplastic lungs
         12. Congenital heart defect
         13. Enlarged echogenic kidneys
         14. Genital anomalies
   3. Ultrasonography for SRPS III (Verma-Naumoff) (Meizner and Bar-Ziv 1985; Meizner and Barnhard 1995; Golombeck et al. 2001):
      1. Short fetal limbs
      2. Small/narrow thorax
      3. Short thin ribs
      4. Polydactyly
      5. Widened metaphyses with marginal spurs
      6. Micromelia
   4. Ultrasonography for SRPS IV (Beemer-Langer):
      1. Short fetal bones
      2. Small/narrow thorax
      3. Short thin ribs
      4. Polydactyly
   5. Prenatal diagnosis of short-rib polydactyly syndrome type 3 (Verma-Naumoff type) by three-dimensional helical computed tomography (Yamada et al. 2011)
   6. Fetoscopy (Toftager-Larsen and Benzie 1984):
      1. To identify fetus with SRPS phenotype
      2. An invasive procedure currently replaced by ultrasonography
3. Management:
   1. Supportive therapy only for these lethal entities.

2. In cases with SRPS, persistent pulmonary hypertension of the newborn (PPHN) can develop dependent on the degree of thoracic narrowness and pulmonary hypoplasia and that PPHN can be resistant to therapy (Demir et al. 2015).

Fig. 1 (**a**, **b**) Radiograph of a neonate with Saldino-Noonan syndrome (SRPS I) showing extremely shortened horizontal ribs, very small and dysplastic vertebral bodies and iliac cones, and very short tubular bones with irregular metaphyses

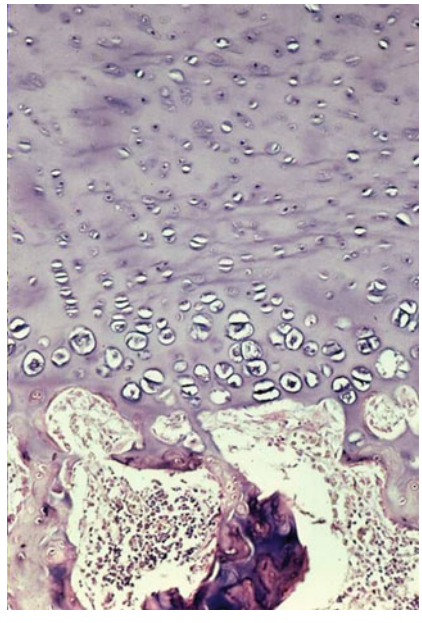

Fig. 2 Photomicrograph of femur (SRPS I) shows markedly retarded and disorganized physeal growth zone

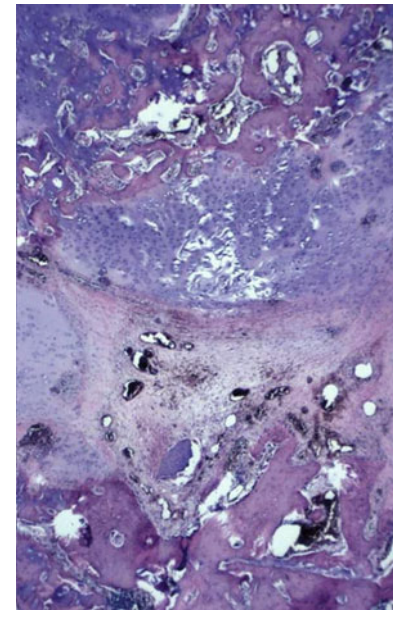

Fig. 3 Photomicrograph of humerus (SRPS I) shows markedly disrupted physeal growth zone by a large cartilage canal-like vascular fibrous tissue. In addition, there is a large premature ossification center (*upper* one third of the picture)

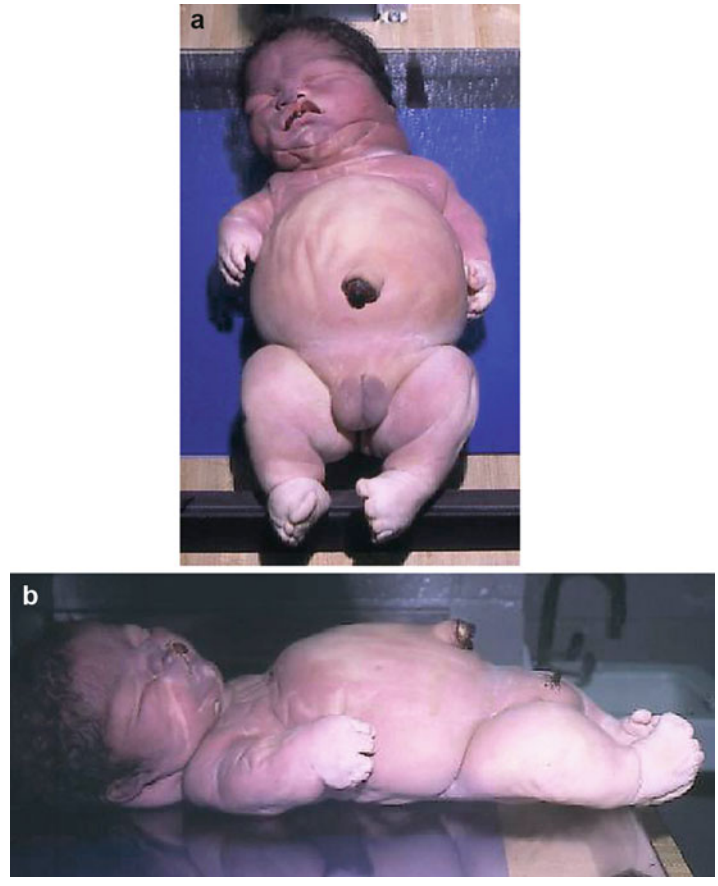

Fig. 4 (**a**, **b**) A neonate with Majewski syndrome (SRPS II) showed hydrops; a large head; hairy forehead; small, malformed, and low-set ears; telecanthus; short nose; a flat nasal bridge; a central cleft of upper and lower lips; short neck; short and narrow chest; markedly distended abdomen with ascites; and extremely short limbs with pre- and postaxial polydactyly, syndactyly, and brachydactyly

Fig. 5 Mouth of the neonate in Fig. 4 showing lobulated tongue and mucosal frenula

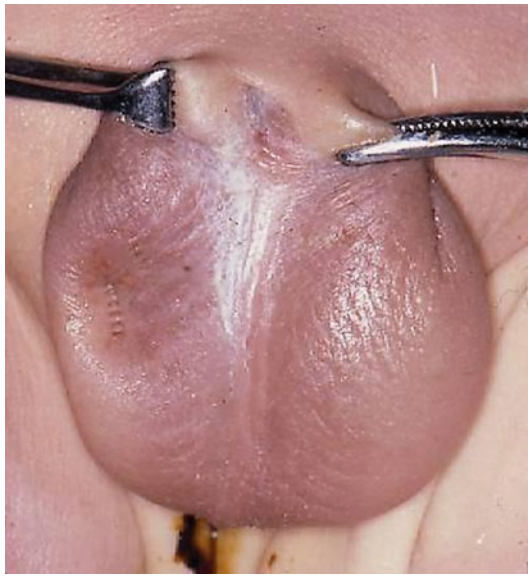

Fig. 6 Ambiguous genitalia with a barely visible micropenis (SRPS II)

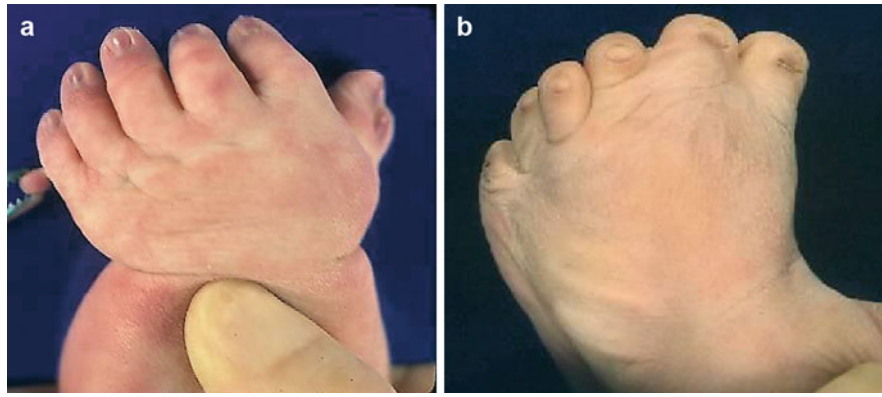

Fig. 7 (**a**, **b**) Hands and feet showed pre- and postaxial polydactyly, syndactyly, and brachydactyly (SRPS II)

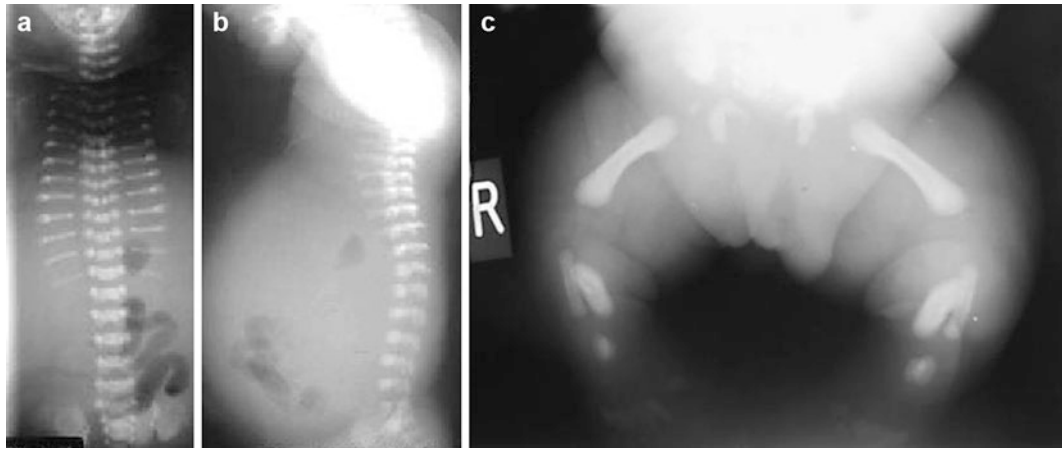

Fig. 8 (**a**–**c**) Radiographs (SRPS II) showing extremely short and horizontal ribs, high clavicles, unremarkable spine and pelvis, and premature ossification of the proximal epiphyses of the humeri, femora, and lateral cuboids. The tubular bones were extremely short, especially the mesomelic segments. The tibiae were disproportionately short and oval in shape

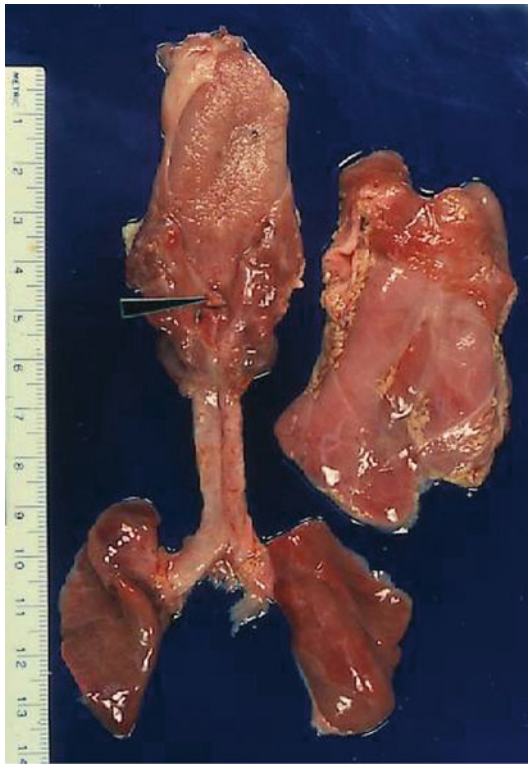

Fig. 9 Respiratory system (necropsy) (SRPS II) showing a small larynx with hypoplastic epiglottis (*arrow*) and remarkably small and hypoplastic lungs. The patient's thymus is juxtaposed for comparison

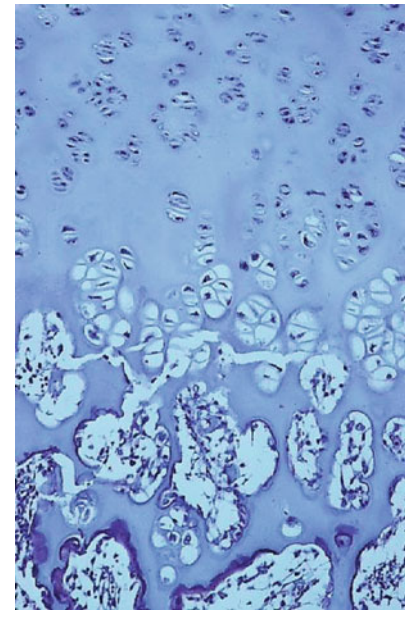

Fig. 10 Photomicrograph of tibia cartilage (SRPS II) (Hematoxylin-eosin, ×108) showing a markedly stunted and disorganized physeal growth zone

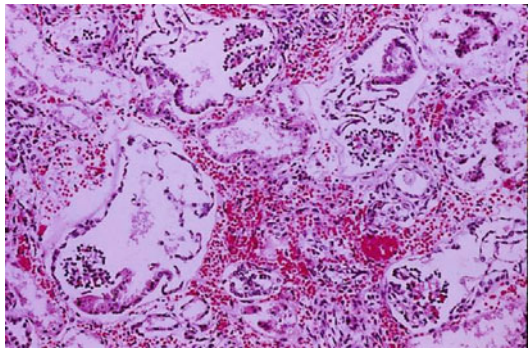

Fig. 11 Photomicrograph of renal cortex showing many dilated glomeruli and mildly cystic renal tubules (SRPS II)

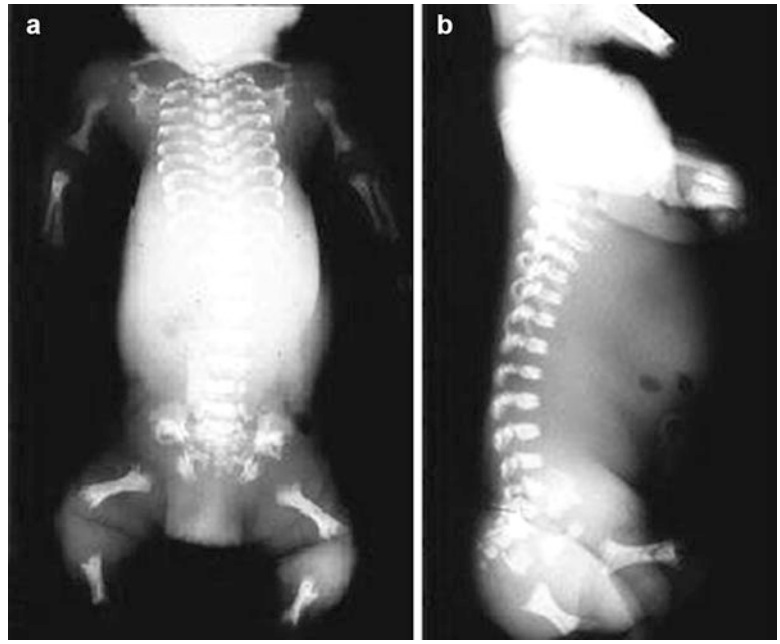

Fig. 12 (**a**, **b**) Radiographs of the skeletal system (SRPS III) showing extremely short and horizontal ribs, small dysplastic vertebral bodies and ilia, and short tubular bones with widened metaphyses with longitudinal spurs

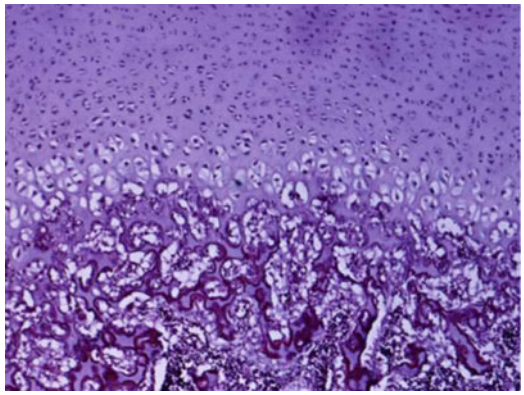

Fig. 13 Photomicrograph of the cartilage of the iliac crest (SRPS III) showing retardation and disorganization of physeal growth zone

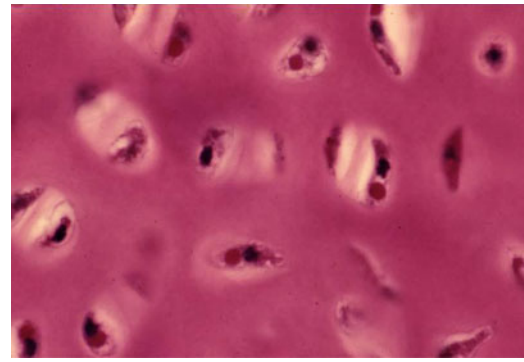

Fig. 14 Higher magnification of the chondrocytes in the resting cartilage and the physeal zone of proliferation frequently show cytoplasmic inclusions (PAS after diastase digestion) (SRPS III)

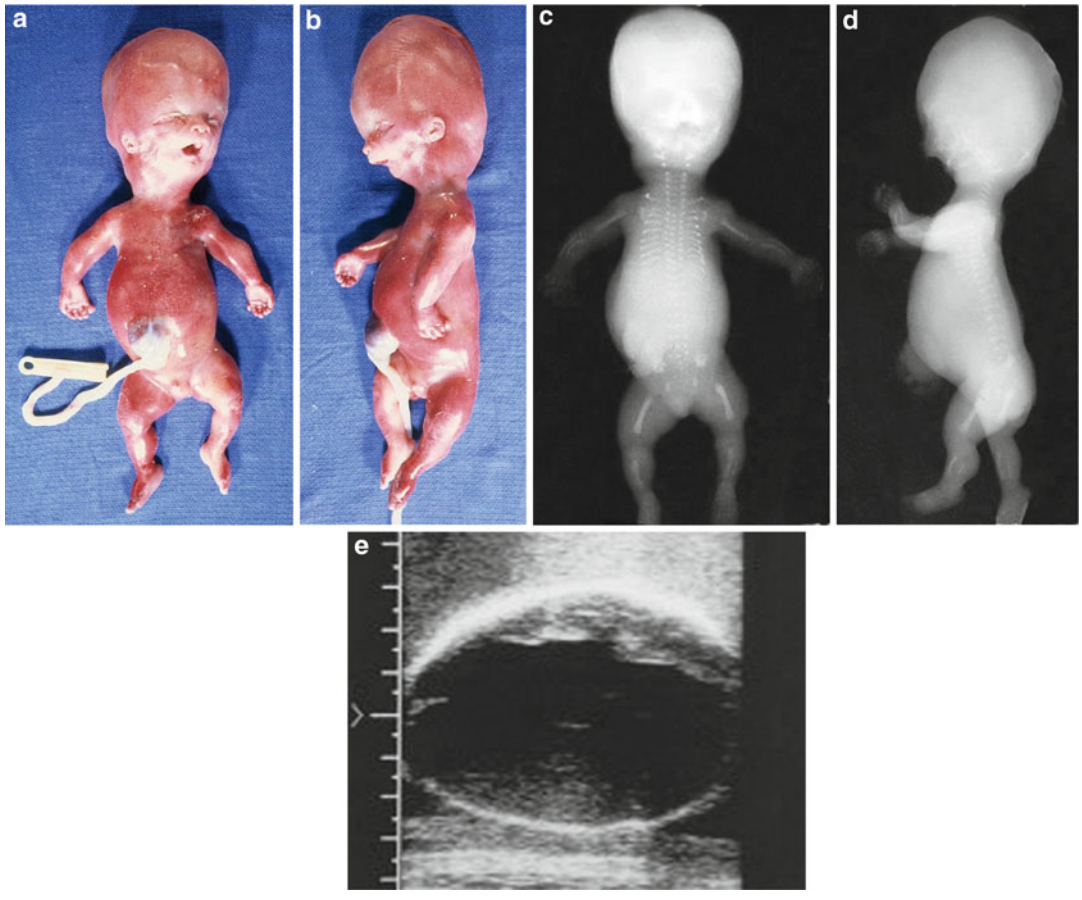

Fig. 15 (**a**–**e**) A fetus with Beemer-Langer syndrome showing macrocephaly, cystic hygroma, severe micro-/retrognathia with cleft palate, low-set and malformed ears, short limbs, narrow thorax, protuberant abdomen with an omphalocele, and polydactyly. The radiographs show short and horizontal ribs, small scapulae, relatively poorly ossified vertebral bodies, small ilia, short tubular bones with absence of metaphyseal spicules, bowed radii and ulnae, and postaxial polydactyly. The ultrasonography shows porencephalic cyst. The fetus also had a de novo paracentric inversion of chromosome 17q (q12;q25)

Fig. 16 Radiograph of another premature neonate (SRPS IV) showing extremely short and horizontal ribs, small dysplastic vertebral bodies, small iliac wings, and short tubular bone

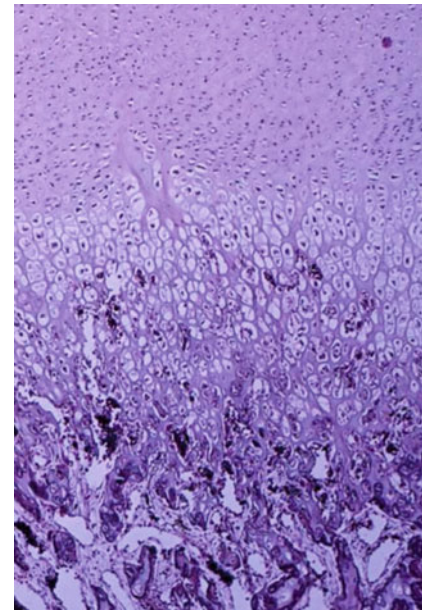

Fig. 17 Physeal growth zone of femur showing prominent but disorganized zone of hypertrophy (SRPS IV)

Sickle Cell Disease

Contents

Sickle cell disease (SCD) is the most common single gene disorder in Afro-Americans, affecting approximately 1 in 375 persons of African ancestry. The frequency of sickle cell trait is about 8% in the US blacks. Sickle blood cells have an increased resistance to malaria. Protection from malaria helps maintain the high prevalence of the sickle gene in areas where malaria is endemic (Fixler and Styles 2002).

Synonyms and Related Disorders

Sickle cell anemia; Sickle cell trait; Sickle β^{+}-thalassemia; Sickle β-thalassemia (Sβ-thalassemia and $S\beta^{o}$ thalassemia); Sickle-hemoglobin C disease

Genetics/Basic Defects

1. Inheritance: autosomal recessive.
2. Caused by a point mutation at the second nucleotide of codon 6 of the β-globin gene. The base change of A to T causes the amino acid substitution of valine for glutamic acid (GAG to GTG):
    1. Immediate consequence of the mutation: Deoxygenated hemoglobin S polymerizes and distorts the shape of the red blood cell, causing vasoocclusion in the small vessels.
    2. Adverse effects of sickle hemoglobin on the red cell membrane:
        1. Oxidative damage
        2. Cellular dehydration
        3. Abnormal phospholipid asymmetry
        4. Increased adherence to endothelial cells
    3. Results of cellular abnormalities:
        1. Shortened red cell lifespan causing a lifelong hemolytic anemia
        2. Intermittent episodes of vascular occlusion causing tissue ischemia and acute and chronic organ dysfunction
3. Four genotypes: Sickle cell anemia (HbSS), sickle-hemoglobin C disease (HbSC), and 2 types of sickle β-thalassemia (Sβ-thalassemia and $S\beta^{o}$ thalassemia) account for most SCD in the USA (American Academy of Pediatrics 2002). Less common forms of SCD are caused by coinheritance of HbS with other hemoglobin variants, such as hemoglobin D-Punjab. Genes for SCD are common in persons of African, Mediterranean, Middle Eastern, and Indian ancestry and persons from the Caribbean and parts of Central and South America.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_215

4. Sickle cell disease (Lane 1996; Driscoll 2007):
    1. Sickle cell anemia (homozygous sickle cell disease, Hb SS):
        1. Accounts for 60–70% of sickle cell disease in the USA
        2. The most common form of sickle cell disease
        3. Caused by inheritance of hemoglobin S from both parents
    2. Other clinically significant sickle cell disorders caused by coinheritance of a sickle gene with a gene for:
        1. β-thalassemia:
            1. The β-thalassemias are divided into β^{+}-thalassemia (in which some β-globin chains are produced) and β^{o}-thalassemia (in which there is no β-chain synthesis).
            2. Clinical pictures of patients with hemoglobin S β^{+}-thalassemia and S β^{o}-thalassemia resemble sickle cell disease rather than thalassemia, because the sickle β-globin predominates in the presence of underproduction of normal β-globin.
        2. Hb C
        3. Hb $D_{Los\ Angels}$
        4. Hb E (HBB Glu25Lys) (Masiello et al. 2007):
            1. One of the world's most common hemoglobin variants.
            2. Found primarily in Sri Lanka, Eastern India, Southeast Asia, and Southwest China.
            3. Individuals homozygous for Hb E have mild anemia and microcytosis and are clinically asymptomatic.
            4. Compound heterozygotes for Hb S and Hb E are increasingly found throughout the world due to population migrations and racial intermarriages over the last century.
            5. Clinical course of adults with Hb SE disease resembles that of Hb S/β^{+}-thalassemia.
            6. Patients who are compound heterozygotes for Hb E and a β-thalassemia mutation have variable phenotypes from mild to severe; the latter is virtually indistinguishable from β-thalassemia major (Fucharoen and Winichagoon 2000).
            7. This is because the Hb E mutation creates a cryptic splice site and therefore manifests also as a mild β^{+}-thalassemia mutation (Orkin et al. 1982).
        5. Hb Lepore
        6. Hb O_{Arab}
        7. Hb C_{Harlem}
        8. Hb Quebec-CHORI
5. Pathophysiology of sickle cell disease (Bookchin and Lew 1996):
    1. Hemolysis: The shortened survival of SS red blood cells results from the following two apparently independent properties of Hb S:
        1. Propensity of the concentrated Hb to polymerization resulting in:
            1. Morphologic sickling
            2. RBC dehydration
            3. A marked decrease in RBC deformability
        2. Hemoglobin S instability
    2. Erythropoiesis:
        1. Submaximal erythropoietic response
        2. Abnormally low affinity for oxygen of SS cells
        3. Response of the red cells' glycolytic metabolism to hypoxia

Clinical Features

1. Infection:
    1. The most immediate risk for infants diagnosed with sickle cell disease
    2. Prone to many bacterial infections, especially from encapsulated organisms, because of lack of splenic function resulting from progressive infarction of the spleen due to sickling of the red cells
2. Hemolysis:
    1. Chronic anemia: Hemolytic anemia develops around 3 months of age.

2. Jaundice (indirect hyperbilirubinemia).
3. Aplastic crises (Rao et al. 1992):
    1. Erythrocyte production by the bone marrow may pause temporarily in children with sickle cell disease.
    2. Human parvovirus B19 infection responsible for 80% of aplastic crises
4. Cholelithiasis:
    1. Prone to develop pigmented gallstones due to large load of bilirubin from hemoglobin breakdown (chronic hemolysis)
    2. Presenting symptoms: severe recurrent right upper quadrant pain, episode of cholecystitis, common duct obstruction, or pancreatitis
5. Delayed growth and sexual maturation

3. Vasoocclusion due to occlusion of the microcirculation by rigid red cells and consequent tissue anoxia and infarction:
    1. Recurrent acute pain:
        1. Dactylitis (hand and foot syndrome) occurs in 25–45% of the patients and can be the earliest manifestation of sickle cell disease. The syndrome is rare after 4 years of age. It is believed to be due to infarction of the red marrow and associated periosteal inflammation. The clinical manifestations are fever and painful swelling of the hands or feet or both.
        2. Musculoskeletal pain
        3. Abdominal pain
    2. Functional asplenia (Lane 1996):
        1. The proportion of children with Hb SS who are functionally asplenic: 1 year (28%), 2 years (58%), 3 years (78%), and 5 years (94%)
        2. At risk for fulminant septicemia and meningitis with pneumococci and other encapsulated bacteria and death during the first 3 years of life in most patients with Hb SS
    3. Splenic sequestration (10–30% of children with Hb SS most commonly between 6 months and 3 years of life):
        1. Sudden massive collection of blood in the spleen due to sickle cells blocking outflow
        2. Rapid enlargement of the spleen causing acute fall of the hemoglobin level of more than 2 g/dL, despite a persistently elevated reticulocyte count
        3. Mild to moderate thrombocytopenia caused by sequestered platelets
        4. Symptoms:
            1. Acute pallor
            2. Lethargy
            3. Increased thirst
            4. Abdominal fullness
            5. Tachycardia
            6. Tachypnea
        5. May be associated with other complications of sickle cell disease, such as acute chest syndrome, vasoocclusive pain, bacterial infection, stroke, or aplastic crisis
        6. Increased tendency of recurrence (50%)
        7. High mortality (second leading cause of death in children with sickle cell anemia)
4. Head and neck manifestations: a significant component of the disease (Steven et al. 2016):
    1. Bony changes and lymphoid enlargement are characteristic.
    2. Orbital and inner ear crises may induce significant visual and hearing impairments.
5. Acute chest syndrome (Lane 1996; Quinn and Buchanan 1999):
    1. Appearance of a new pulmonary infiltrate on chest radiography
    2. Causes:
        1. Infection (bacterial pneumonia, atypical bacterial pneumonia by *Mycoplasma* or *Chlamydia*, viral pneumonia, parvovirus B19)
        2. Pulmonary vascular occlusion (in situ pulmonary thrombosis, fat embolism, peripheral thromboembolism)
        3. Hypoventilation/atelectasis (thoracic bony infarction, abdominal pain, opioids)

4. Pulmonary edema (intravenous fluids, opioids, pulmonary vascular injury)
5. Bronchospasm

3. The most frequent presenting symptoms:
   1. Varying degrees of fever
   2. Cough
   3. Tachypnea
   4. Shortness of breath
   5. Pleuritic chest pain
   6. Chills
   7. Wheezing
   8. Hemoptysis
   9. Hypoxemia
4. Occurs in more than 50% of pediatric patients with Hb SS
5. The second leading cause for hospitalization
6. Predispose to chronic restrictive lung disease with pulmonary hypertension (Gladwin et al. 2004) and cor pulmonale (important causes of morbidity and mortality in adulthood)

6. Stroke (Lane 1996):
   1. Caused by complete occlusion or severe narrowing of large cerebral vessels
   2. Occurs in 7–8% of children with Hb SS after the first year of life, less commonly in children with Hb SC and sickle β-thalassemia
   3. Presenting symptoms:
      1. Hemiparesis
      2. Monoparesis
      3. Aphasia
      4. Dysphasia
      5. Seizures
      6. Semicoma
      7. Coma
      8. Transient ischemic attack
   4. High rate of recurrence (60–90% have a second stroke within 3 years without transfusion therapy)
   5. Silent cerebral infarctions in 10–20% of children with Hb SS without clinically apparent neurologic event
7. Chronic nephropathy: an important cause of mortality in adult patients (Saborio and Scheinman 1999; Molitierno 2003; Gargiulo et al. 2014; Nath and Hebbel 2015):
   1. Hematuria:
      1. Persistent microscopic (asymptomatic) hematuria: one of the most prevalent features of the disease
      2. Gross hematuria
   2. Renal tubular acidosis
   3. Significant proteinuria (30%)
   4. Papillary necrosis
   5. Hyposthenuria and enuresis: inability to concentrate urine resulting in a high incidence of enuresis
   6. Nephrotic syndrome (40%)
   7. Renal infarction
   8. Pyelonephritis
   9. Renal medullary carcinoma
   10. Hypertension (2–6% in patients with Hb SS)
   11. Renal failure (5–18%)
8. Priapism (painful erection) (Powars and Johnson 1996):
   1. Affects about two thirds of male patients
   2. Recurrent attacks eventuate in impotence in 50% of the patients
9. Bone disorders (Smith 1996):
   1. Dactylitis (hand and foot syndrome).
   2. Bone infarction: Manifestations include pain, tenderness, and frequently swelling at the involved site(s).
   3. Aseptic necrosis of the long bones: Manifestations include pain or limitation of motion in the hip, shoulder, or other joints and during walking and climbing stairs.
10. Proliferative retinopathy
11. Leg ulcers (Eckman 1996):
    1. Most common cutaneous complication in sickle cell anemia
    2. Causing pain, physical disfigurement, social isolation, vocational adversity, and high utilization of health-care resources
    3. Most common in the ankle area over the medial or lateral malleoli and less

common over the dorsum of the foot and near the Achilles tendon
4. Universal secondary infections (*Staphylococcus aureus* and *Pseudomonas aeruginosa* most common pathogens)

12. Osteomyelitis (Burnett et al. 1998):
1. *Salmonella* (most common cause)
2. *Staphylococcus aureus*

13. Transfusional hemosiderosis

4. Prognosis:
1. Natural history of sickle cell anemia (Powars 1975) conducted before mandated newborn screening programs: 15% of children die from acute infections or acute anemic events in the first 5 years of life. The overall mortality rate for patients with sickle cell anemia diagnosed in the newborn period was 1.8% (Vichinsky et al. 1988).
2. Hb SC disease:
1. Clinical manifestations milder than Hb SS disease
2. Mild hemolytic anemia
3. Risk of overwhelming sepsis and death: less than that in Hb SS disease because of the later onset of splenic dysfunction
4. Risk of splenic sequestration up to young adulthood
5. Splenomegaly
6. Vasoocclusion
7. Proliferative retinopathy
8. Aseptic necrosis of femoral head

3. Early infectious morbidity and mortality (Vichinsky 1991) in Hb SS and sickle β^o-thalassemia preventable by:
1. Presymptomatic diagnosis by neonatal screening
2. Extensive parental education
3. Prophylactic penicillin for infants with Hb SS and Sβ^o-thalassemia (125 mg by mouth twice a day begun between 2 months and 3 years of age and 250 mg twice daily until at least 5 years of age)
4. Timely immunizations (all routine immunizations in a timely fashion; new heptavalent conjugated pneumococcal vaccine administered at 2 months of age; influenza virus vaccines yearly after 6 months of age; meningococcal vaccine for children with splenic dysfunction)
5. Prompt medical evaluation and management of febrile illness

4. Sickle cell disease and pregnancy (Sun et al. 2001). Affected pregnant women are at risk for:
1. Crisis.
2. Toxemia.
3. Pyelonephritis.
4. Thrombophlebitis.
5. Spontaneous abortion.
6. Intrauterine growth restriction.
7. Antepartum hospital admission.
8. Postpartum infection.
9. In addition, deliveries among women with Hb SS were more likely to be complicated by low birth weight, prematurity, and preterm labor or preterm premature rupture of membranes when compared with deliveries among women with hemoglobin AA.

5. Progress toward specific therapies:
1. Transfusion therapy
2. Bone marrow transplantation
3. Hydroxyurea

Diagnostic Investigations

1. Laboratory studies (Chen 1992; Lane 1996):
1. CBC and reticulocyte counts to document anemia and brisk marrow response
2. Peripheral blood smear to document presence of sickled erythrocytes, target cells, and Howell-Jolly body (indicating functional asplenism)
3. Differential white cell count
4. Arterial blood gases to reflect the severity of pulmonary crises
5. Hemoglobin electrophoresis to document Hb SS or Hb S with another mutant hemoglobin in compound heterozygotes
6. Liver function tests, BUN, creatinine, and serum electrolytes

7. Fetal hemoglobin

2. Imaging studies (Madani et al. 2007):
    1. Radiography:
        1. Performed in patients with respiratory symptoms:
            1. Pneumonia
            2. Acute chest syndrome: a new focus of opacity (which may be segmental, lobar, or multilobar) or collapse with or without a pleural effusion on a chest radiograph, associated with a variable combination of signs and symptoms including fever, leukocytosis, hypoxia, and chest pain (Charache et al. 1979)
        2. To detect areas of infarction for painful bones
    2. MRI:
        1. To detect areas of avascular necrosis for the femoral and humeral heads and to distinguish osteomyelitis from bony infarction.
        2. The majority of overt stroke and silent cerebral infarction occur from a distribution of the internal carotid artery, and pathologies are frequently observed in tissue within the anterior cerebral and middle cerebral arterial distribution (Zhang et al. 2016).
    3. MRI and MR angiography (MRA) of the brain:
        1. To detect infarction, ischemia and atrophy (44% prevalence), and vasculopathy (55% prevalence) in children with sickle cell disease (Steen et al. 2003)
        2. Moyamoya (Japanese for a "hazy puff of smoke"): an angiographic pattern of large vessel occlusion and telangiectatica collateral circulation, seen in patients with sickle cell disease (Dobson et al. 2002), as well as other conditions, such as tuberous sclerosis, neurofibromatosis, vasculitides, and infection
    4. Abdominal sonogram to document spleen size and the presence of biliary stones.
    5. Transcranial Doppler ultrasonography useful in selecting patients at risk for stroke.
    6. Cavernosonography and radionuclide scanning to assess penile hemodynamics are useful in determining whether priapism is of the low-flow type (Powars and Johnson 1996).
3. Sickle cell anemia (Hb SS) (Wethers 2000a):
    1. Relative clinical severity:
        1. Markedly severe hemolysis
        2. Markedly severe vasoocclusion
    2. Neonatal screening: hemoglobin FS
    3. Hemoglobin electrophoresis (Lane 1996):
        1. Hb A: 0%
        2. Hb S: 80–95%
        3. Hb F: 2–20%
        4. Hb A_2: <3.5%
        5. Hb C: 0%
    4. Thin layer isoelectric focusing:
        1. Gives better resolution of hemoglobins other than Hb A, Hb S, Hb C, and Hb F
        2. Less experience using this method for screening and more costly
    5. High-performance liquid chromatography:
        1. Differentiates many Hbs (Hbs F, A, S, C, D, E)
        2. Hb S + Hb F + Hb A_2 (probable sickle cell disease)
        3. Hb A + Hb S + Hb A_2 (Sickle cell trait)
        4. Hb A + Hb C (Hb C trait)
        5. Hb C (Hb C disease)
        6. Hb S + Hb C (sickle C disease)
        7. Is quantitative (can differentiate sickle trait from sickle β-thalassemia and identify β-thalassemia)
    6. Sickle prep:
        1. Does not distinguish between heterozygote and homozygote
        2. Easy for mass screening
        3. Inappropriate for newborn screening
    7. Solubility test:
        1. Hb S detected by precipitation/turbidity
        2. Does not distinguish sickle cell anemia from other sickle diseases
        3. May give false negative if Hb is low

4. May give false positive if lipidemia is present
5. Easy to use for mass screening if only the presence of Hb S is desired
6. Inappropriate for newborn screening

8. DNA diagnosis

4. Sickle β^o-thalassemia (Wethers 2000a)
   1. Relative clinical severity:
      1. Moderate severe hemolysis
      2. Moderate severe vasoocclusion
   2. Neonatal screening: hemoglobin FS
   3. Hemoglobin electrophoresis:
      1. Hb A: 0%
      2. Hb S: 80–92%
      3. Hb F: 2–15%
      4. Hb A_2: 3.5–7.0%
      5. Hb C: 0%
5. Sickle-hemoglobin C disease (Hb SC) (Wethers 2000a):
   1. Relative clinical severity:
      1. Mild hemolysis
      2. Mild vasoocclusion
   2. Neonatal screening: hemoglobin FSC
   3. Hemoglobin electrophoresis:
      1. Hb A: 0%.
      2. Hb S: 45–50%.
      3. Hb F: 1–5%.
      4. Hb A_2: Quantity of A_2 cannot be measured in the presence of Hb C.
      5. Hb C: 45–50%.
6. Sickle β^+-thalassemia (Wethers 2000a):
   1. Relative clinical severity:
      1. Mild to moderate hemolysis
      2. Mild to moderate vasoocclusion
   2. Neonatal screening: hemoglobins FSA and FS
   3. Hemoglobin electrophoresis:
      1. Hb A: 5–30%
      2. Hb S: 65–90%
      3. Hb F: 2–10%
      4. Hb A_2: 3.5–6.0%
      5. Hb C: 0%
7. Sickle cell trait:
   1. Relative clinical severity: normal phenotype
   2. Neonatal screening: hemoglobin FAS
   3. Hemoglobin electrophoresis:
      1. Hb A: 50–60%
      2. Hb S: 35–45%
      3. Hb F: <2%
      4. Hb A_2: <3.5%
      5. Hb C: 0%
8. Normal:
   1. Relative clinical severity: normal phenotype
   2. Neonatal screening: hemoglobin FA
   3. Hemoglobin electrophoresis:
      1. Hb A: 95–98%
      2. Hb S: 0%
      3. Hb F: <2%
      4. Hb A_2: <3.5%
      5. Hb C: 0%
9. Newborn hemoglobinopathy screening:
   1. Provided in all 50 states in the USA.
   2. The most commonly used screening method: electrophoresis and high-performance liquid chromatography.
   3. Fetal hemoglobin present predominantly in young infants.
   4. Positive results to be followed by fetal hemoglobin electrophoresis for confirmation.
   5. Results with only Hb F and S: suggest the infant has either sickle cell anemia or sickle β^o-thalassemia.
   6. Results with Hb F, S, and C: suggest the infant has hemoglobin SC disease.
   7. Results with Hb F, S, and A, and the infant has not been transfused:
      1. Hb S > Hb A: most likely sickle β^+-thalassemia
      2. Hb A > Hb S: presumed sickle cell trait
      3. Hb A ≈ Hb S:
         1. Study the parents to determine if one of them has the thalassemia trait
         2. Repeat Hb electrophoresis after several months
10. Molecular genetic testing:
    1. Carrier testing:
       1. Most commonly accomplished by high-performance liquid chromatography
       2. Isoelectric focusing
       3. DNA-based assays

2. Prenatal diagnosis: most commonly use DNA-based assays for the detection of the Hb S mutation
3. Testing methods
    1. Targeted mutation analysis:
        1. Hb S (E6V)
        2. Hb C (E6K)
        3. Hb D (E121Q)
        4. Hb O-Arab (E121K)
    2. Sequence analysis for Hb mutations

Genetic Counseling

1. Recurrence risk:
    1. Homozygous sickle cell disease (Hb SS). The child inherits a sickle (S) gene from each parent:
        1. Risk to patient's sibs: 25%
        2. Risk to patient's offspring: not increased unless the spouse is a carrier
    2. Sickle-hemoglobin C disease (Hb SC). The child inherits an S gene from one parent and a C gene from the other parent:
        1. Risk to patient's sibs: 25% if Hb AS in one parent and Hb AC in other parent
        2. Risk to patient's offspring: not increased unless the spouse is either Hb AS or Hb AC carrier
    3. Sickle β-thalassemias. The child inherits an S gene from one parent and a β-thalassemia gene from the other parent:
        1. Risk to patient's sibs: 25% if sickle cell carrier in one parent and β-thalassemia carrier in other parent
        2. Risk to patient's offspring: not increased unless the spouse is a carrier for either Hb S or β-thalassemia gene
2. Prenatal diagnosis:
    1. Possible by analysis of DNA extracted from fetal cells obtained by amniocentesis or CVS
    2. Both disease-causing hemoglobin alleles of the carrier parents must be identified before prenatal testing.
    3. Formal genetic counseling needed when the mother is a known carrier and the father is unknown and/or unavailable for testing.
3. Preimplantation genetic diagnosis (PGD) (El-Toukhy et al. 2010):
    1. PGD may be an option for some families in which the HBB (hemoglobin subunit beta, a protein coding gene) pathogenic variants have been identified (Bender and Hobbs 2014).
    2. PGD for SCD has been performed using PCR and RFLP for detection of the SCD mutation with linked markers (Kuliev et al. 1998, 2005; De Rycke et al. 2001).
    3. The A > T point mutation at codon 7 of the β-globin gene, responsible for SCA, can be easily identified by the *Ddel* or *MstII* restriction enzymes.
4. Management (Wethers 2000b; American Academy of Pediatrics 2002):
    1. Preventive care (health maintenance):
        1. Immunizations:
            1. *Haemophillus influenzae* type b (Hib) vaccine
            2. 7-valent pneumococcal conjugate vaccine
            3. 23-valent pneumococcal polysaccharide vaccine
            4. Consider quadrivalent meningococcal polysaccharide vaccine
            5. Influenza immunization recommended yearly
        2. Prophylactic medications:
            1. Penicillin prophylaxis: effective in preventing 80% of life-threatening episodes of childhood *Streptococcus pneumoniae* sepsis
            2. Erythromycin prophylaxis: an alternative for individuals allergic to penicillin
            3. Consider folic acid supplementation
        3. Other preventive strategies:
            1. Transcranial Doppler to screen the presence of abnormal velocity of arterial blood flow (at risk for stroke)
            2. Screening for pulmonary hypertension, proteinuria, retinopathy, osteonecrosis, neurocognitive dysfunction, liver disease, growth failure, nutritional deficiency, and gallbladder disease

2. Acute illness:
    1. Infection/fever:
        1. Broad-spectrum antibiotics (e.g., ceftriaxone) pending culture results
        2. Vancomycin only for proven or suspected meningitis or other severe illness
    2. Painful crisis:
        1. Oral hydration
        2. Oral analgesics including narcotics, acetaminophen, and ibuprofen
        3. Hospitalization for more severe pain episodes with parental analgesics and hydration
    3. Splenic sequestration:
        1. Emergency transfusion indicated when the signs of cardiovascular instability are present
        2. Splenectomy for multiple or severe episodes of splenic sequestration
    4. Acute chest syndrome:
        1. Treat aggressively with oxygen, analgesics, and antibiotics
        2. Simple transfusion
        3. Exchange transfusion
    5. Aplastic crisis:
        1. Characterized by an exacerbation of the patient's baseline anemia with a substantially decreased reticulocyte count, typically less than 1%.
        2. Most cases are caused by acute infection with human parvovirus B19, usually without the characteristic rash.
    6. Stroke:
        1. Monitor neurologic status.
        2. Aggressive treatment of increased intracranial pressure and seizures.
        3. Exchange transfusion generally indicated with the goal of decreasing Hb S percentage to $<30\%$ of the total hemoglobin.
        4. A preventive chronic transfusion protocol initiated after a CNS event to prevent a second stroke.
        5. Prophylactic transfusion with folic acid replacement shown to decrease the incidence of vasoocclusive crisis during pregnancy.
    7. Priapism:
        1. Hydration
        2. Analgesia administration
        3. Aspiration and irrigation by a urologist
3. Different nutritional approaches (Khan et al. 2016):
    1. Traditional herbal therapies.
    2. Antioxidants.
    3. Flavonoids.
    4. Vitamins.
    5. Minerals.
    6. Reducing oxidative stress.
    7. Blood aggregation.
    8. Nutritional therapies may also serve complementary to the newer therapies using ozone, hematopoietic stem-cell transplantation, antifungal medications, and erythropoietin.
4. Surgical care, limited to treat complications:
    1. Skin graft to help heal chronic leg ulcers
    2. Hip replacement or other orthopedic procedures to treat avascular necrosis
    3. Surgical draining of the penile corpora for resistant priapism
    4. Cholecystectomy for gallstones
5. Disease-modulating therapy:
    1. Hydroxyurea (Vichinsky 1997):
        1. Principle: The most prescribed therapy causes myelosuppressive-induced Hb F synthesis by decreasing terminal differentiation of erythroid stem cells, resulting in decreased sickling and improved red cell survival.
        2. Effects of therapy (Brawley et al. 2008): Patients treated have improved blood markers (increased hemoglobin level, fetal hemoglobin percentage, mean corpuscular volume, and leukocyte count), fewer acute episodes of pain crisis and acute chest syndrome, decreased need for transfusion, and improved survival.
        3. Not effective for cerebrovascular complications of sickle cell disease.
    2. Other medications that increase the percentage of Hb F, currently under investigation:

    1. Short-chain fatty acids, such as butyrate or valproic acid: Individual reports of response have been dramatic, with almost complete correction of anemia (Vichinsky 2002).
    2. 5-azacytidine.
3. Chronic red blood cell transfusion:
    1. To prevent stroke in patients with an abnormal transcranial Doppler and stroke recurrence
    2. To treat chronic debilitating pain and pulmonary hypertension
    3. Goal: to maintain the percentage of Hb S between 30% and 50%
    4. Complications: iron overload, alloimmunization, and infection
4. A major risk factor for development of chronic vasculopathy and pulmonary hypertension (PH) in patients with SCD is hemolytic anemia (37), caused by the pathological effects of plasma cell free hemoglobin and other erythrocyte damage-associated molecular pattern molecules (eDAMPs). Screening patients with SCD for PH for early diagnosis and disease modifying therapy is recommended (Potoka and Gladwin 2015).
5. Hydroxyurea and transfusion therapy are strongly recommended for many individuals with SCD (Yawn et al. 2014).
6. Psychological treatment (Anie and Green 2015):
    1. To help people cope with sickle cell disease might complement current medical treatment.
    2. Four types of treatment: patient education, cognitive therapy (to do with thoughts and feelings), behavioral therapy (to do with actions), and psychodynamic psychotherapy (talking to relieve emotional pain).
7. Bone marrow transplant (BMT): a curative option for patients with sickle cell disease and other hemoglobinopathies (Bolaños-Meade and Brodsky 2009):
    1. Bone marrow transplant from a nonaffected donor, usually a human lymphocyte antigen (HLA)-matched sibling, is the only known curative therapy (Walters et al. 1996, 2000; Vermylen et al. 1998; Bernaudin et al. 2007).
    2. The cure rate in children using an HLA-matched sibling donor following a myeloablative conditioning regimen is over 85%. Unfortunately, most sickle cell patients in need of a BMT are not eligible due to an inability to tolerate myeloablative conditioning and/or the lack of a matched sibling donor. Moreover, gonadal failure is a major drawback of myeloablative regimens (Bolaños-Meade and Brodsky 2014).
    3. Proposed selection criteria: Patients should be less than 16 years of age, have an HLA-identical related donor, and have at least one of the following signs or symptoms – stroke or central nervous system event lasting for more than 24 h, acute chest syndrome, recurrent severe pain episodes, impaired neuropsychological function with an abnormal MRI scan, stage I or II sickle lung disease, sickle nephropathy, bilateral proliferative retinopathy, osteonecrosis of multiple joints, or red blood cell alloimmunization during long-term transfusion therapy (Walters et al. 1996).
8. Allogeneic hematopoietic stem-cell transplantation (HSCT):
    1. The only curative treatment for sickle cell disease (SCD); nevertheless, its use has been limited by the risk of transplantation-related mortality (TRM). HLA-identical sibling HSCT after myeloablative conditioning with antithymocyte globulin (ATG) (Talano and Cairo 2015) should be considered as a standard

of care for SCD children who are at high risk for stroke (Bernaudin et al. 2007).
2. Although curative options with HSCT exist for SCD, they still remain limited due to a lack of appropriate donors and concerns with procedural toxicities (Kanter and Kruse-Jarres 2013).
3. Shown to reverse or at least halt the progression of end-organ damage secondary to SCD (Robinson and Fuchs 2016).
4. Today, almost all children treated by HLA-ID sibling bone marrow transplantation will survive free of SCD. The future of this treatment, however, hinges on the ability to broaden the availability of donors and to achieve success rates after alternate donor HCT that approach those observed after HLA-ID sibling HCT (Walters 2015).

9. Gene therapy:
   1. Principle: A single nucleotide substitution in the pathogenesis of sickle cell disease makes the presence of the sickle cell allele an ideal candidate for gene therapy.
   2. Question of the safety of this type of approach: development of leukemia in two patients participating in a clinical trial of gene therapy for X-linked severe combined immunodeficiency disease.
   3. There is a need for trials that assess the benefits or risks of gene therapy for sickle cell disease (Olowoyeye and Okwundu 2015).

Silver–Russell Syndrome

Contents

Silver–Russell syndrome (SRS) is a clinically and genetically heterogeneous disorder, characterized by severe prenatal/postnatal growth retardation, characteristic facies, skeletal asymmetry, and other congenital anomalies. The incidence is estimated as 1:50,000–1:100,000 live births.

Synonyms and Related Disorders

Primordial dwarfism; Russell–Silver syndrome; Silver–Russell dwarfism

Genetic/Basic Defects

1. Inheritance (Duncan et al. 1990; Preece 2002):
    1. Sporadic occurrence in majority of cases
    2. 19% of cases with more than one affected individuals in the family, providing evidence for a genetic cause
    3. A genetically (and clinically) heterogeneous disorder:
        1. Autosomal recessive (17.4%) (Fuleihan et al. 1971; Teebi 1992)
        2. Autosomal dominant (8.7%) (Al-Fifi et al. 1996)
        3. X-linked dominant (74%) (Partington 1986)
2. Chromosomal basis (Preece 2002):
    1. Small number of cases with Silver–Russell syndrome reported in association with numerous chromosomal abnormalities:
        1. R(15) and deletion of 15q (Wilson et al. 1985; Rogan et al. 1996)
        2. Diploid–triploid mixoploidy (Graham et al. 1981)
        3. 45,X/46,XY
        4. XXY (Bianchi et al. 1983)
        5. Trisomy 18 mosaicism
        6. Del(8)(q11-q13) (Schinzel et al. 1994)
        7. Del(18p) (Christensen and Nielson 1978)
        8. Dup(1)(q32.1-q42.1) (van Haelst et al. 2002)
        9. Dup(7p12.1-p13), including GRB10 and IGFBP1, in a mother and daughter with features of Silver–Russell syndrome (Joyce et al. 1999)
        10. One had a partial duplication [46, XX, dup(7)(p12 p14)] and the second contained a paracentric inversion [46, XY, inv(7)(p14 p21)] (Nakabayashi et al. 2002)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_216

11. Familial reciprocal translocation t(7;16) associated with maternal uniparental disomy 7 in a Silver–Russell patient (Dupont et al. 2002)
12. Distal chromosome 17q (Hitchins et al. 2002):
    1. Balanced translocation (17;20)(q25; q13) and severe Russell–Silver syndrome (Ramírez-Dueñas et al. 1992) inherited from clinically normal father.
    2. De novo translocation (1;17)(q31; q25) with breakpoint recently cloned and localized to 17q23.3-q24.
    3. Heterozygous deletion of the chorionic somatomammotropin hormone 1 (*CSH1*) gene located within the growth hormone and CSH gene cluster on 17q24.1 (Eggermann et al. 1998). The deletion was inherited from the father who appeared clinically normal but had short stature.

2. Maternal uniparental disomy (UPD) for chromosome 7 (about 7–10% of cases) (Preece et al. 1997; Bernard et al. 1999; Hannula et al. 2001b; Eggermann et al. 2001; Hitchins et al. 2001):
    1. Inheritance of both chromosome 7 from the mother: Maternal UPD7 was detected in several SRS patients, accounting for approximately 7-10% of the tested SRS patients (Eggermann et al. 1997; Preece et al. 1999).
    2. A possible novel imprinted region at 7p12-p14 (Monk et al. 2002), 7q32, and 7q31-ter: UPD can disrupt the balance between imprinted genes and thereby lead to phenotypic manifestations.
    3. Strong evidence of disruption of imprinted gene expression rather than mutation of a recessive gene underlying the Silver–Russell phenotype in these cases.
3. Genetic and epigenetic disturbances can meanwhile be detected in approximately 50% of patients with typical SRS features (Eggermann et al. 2010):
    1. Nearly one tenth of patients carry a maternal uniparental disomy of chromosome 7 (UPD(7)mat).
    2. More than 38% show a hypomethylation in the imprinting control region 1 in 11p15.
    3. More than 1% of patients show (sub) microscopic chromosomal aberrations.
    4. Interestingly, in 7% of 11p15 hypomethylation carriers, demethylation of other imprinted loci can be detected.
4. A splicing mutation of the *HMGA2* gene is associated with Silver–Russell syndrome phenotype (De Crescenzo et al. 2015).
5. Silver–Russell syndrome without body asymmetry in three patients with duplications of maternally derived chromosome 11p15 involving *CDKN1C* (Nakashima et al. 2015).
6. 14q32 disturbances significantly contribute to the mutation spectrum in this cohort. Furthermore, maternal uniparental disomy of chromosomes 6, 16, and 20 can be observed, but are rare. In case they occur, they can be regarded as causative for clinical features (Sachwitz et al. 2016b).

3. Clinical findings and molecular aberrations in the three congenital disorders associated with *CDKN1C* mutations (Eggermann et al. 2014):
    1. Silver–Russell syndrome:
        1. Frequency, 1:100,000
        2. Clinical findings (please see this chapter)
        3. Molecular aberrations:
            1. Aberrant *ICR1* (H19/IGF2) methylation: hypomethylation (40%)
            2. Large 11p15 duplications (including *ICR1* and *ICR2*): maternal (1%)
            3. Small *ICR2* duplications and deletions: single cases (the clinical outcome depends on the size and genomic content of the affected segment)
            4. Genomic imbalance in the centromeric 11p15 imprinting center in three families: further evidence of a role for *IC2* (or *ICR2*) as a cause of

Russell–Silver syndrome (Cytrynbaum et al. 2016)
5. UPD 11p15: upd(11p15)mat (single cases)
6. *CDKN1C* point mutations: gain-of-function mutations (sporadic cases, $n = 128$; familial cases, one case)

2. Beckwith–Wiedemann syndrome:
   1. Frequency: 1:13,700
   2. Clinical findings (please see the chapter on "► Beckwith-Wiedemann Syndrome")
   3. Molecular aberrations:
      1. Aberrant *ICR1* (H19/IGF2) methylation: hypermethylation (5–7%)
      2. Aberrant ICR2 (LIT1/KvDMR1) methylation: hypomethylation (50–60%)
      3. Large 11p15 duplications (including *ICR1* and *ICR2*): paternal (1%)
      4. Small *ICR2* duplications and deletions: single cases (the clinical outcome depends on the size and genomic content of the affected segment)
      5. UPD 11p15: upd(11p15)pat (20–25%)
      6. *CDKN1C* point mutations: loss-of-function mutations (sporadic cases, 5%; familial cases, 50%)
3. IMAGe syndrome: named for the acronym of its major features (intrauterine growth retardation (IUGR), metaphyseal dysplasia, adrenal hypoplasia congenita, and genital anomalies) (Bergadá et al. 2005; Bennett et al. 2014):
   1. Frequency, 25 patients reported worldwide
   2. Clinical findings:
      1. IUGR
      2. Skeletal abnormalities (most commonly delayed bone age and short stature; occasionally, metaphyseal and epiphyseal dysplasia of varying severity)
      3. Adrenal insufficiency presenting typically in the first month of life as an adrenal crisis or, rarely, later in childhood with failure to thrive and recurrent vomiting
      4. Genital abnormalities in males (cryptorchidism, micropenis, and hypospadias)
   3. Molecular aberrations: *CDKN1C* point mutations (gain-of-function mutations)
4. Epimutations of the IG-DMR and the MEG3-DMR at the 14q32.2 imprinted region in two patients with Silver–Russell Syndrome-compatible phenotype (Kagami et al. 2015)

Clinical Features

1. Existence of both the "Silver" (Silver et al. 1953; Silver 1964) and "Russell" (1954) variants in a nuclear family: provides additional evidence for considering SRS to be a single syndrome with a wide spectrum of clinical manifestations (Robichaux et al. 1981).
2. Diagnostic criteria: the presence of three major features plus one or more minor features is generally required for a positive diagnosis:
   1. Major criteria:
      1. Low birth weight (intrauterine growth retardation)
      2. Proportionate short stature (postnatal growth retardation): mature height about −3.6 standard deviation scores in both sexes (Tanner et al. 1975; Davies et al. 1988)
      3. Small triangular face
      4. Fifth finger clinodactyly
   2. Minor criteria:
      1. Relative macrocephaly due to sparing of cranial growth
      2. Ear anomalies
      3. Skeletal asymmetry (face, limb, or body)
      4. Brachydactyly of the fifth fingers
      5. Bilateral camptodactyly with terminal interphalangeal contractures
      6. Syndactyly
      7. Transverse palmar crease
      8. Downward-slanting corner of the mouth
      9. Muscular hypotrophy/hypotonia

10. Motor/neurological delay
11. Irregular spacing of the teeth
12. Café-au-lait spots
13. Precocious puberty
14. Squeaky voice
15. Genital abnormalities
16. Speech delay
17. Feeding difficulties (Blissett et al. 2001)

3. Other manifestations:
   1. Significant cognitive impairment (50%) (Lai et al. 1994)
   2. Gastrointestinal symptoms (77%):
      1. Gastroesophageal reflux disease (34%)
      2. Esophagitis (25%)
      3. Food aversion (32%)
      4. Failure to thrive (63%)
   3. Skeletal anomalies:
      1. Large anterior fontanelle (delayed closure)
      2. Absence of asymmetry (Gareis et al. 1971)
      3. Syndactyly of the toes
   4. Genitourinary anomalies:
      1. Hypospadias
      2. Posterior urethral valves
   5. Cardiac defects
   6. Various tumors:
      1. Craniopharyngioma
      2. Testicular seminoma (Funada et al. 2016)
      3. Hepatocellular carcinoma
      4. Wilms tumor
   7. Essentially normal pattern of puberty and adolescent growth (Davies et al. 1988)
   8. Fertility not necessarily impaired, at least in females (Abramowicz and Nitowsky 1977)
   9. Other features:
      1. Blue sclera
      2. Café-au-lait spots
      3. Excessive sweating
      4. Hypoglycemia
4. Silver–Russell syndrome should be considered in the differential diagnosis of children with severe pre- and postnatal growth deficiency (Donnai et al. 1989).
5. Netchine–Harbison clinical scoring system (Azzi et al. 2015): Patients with four or more items of the score are suspected to have Silver–Russell syndrome and should undergo molecular testing (Giabicani et al. 2016):
   1. Factor 1: Being born small-for-gestational-age: $\leq$2 (standard deviation score)* birth length and/or weight adjusted for gestational age (GA).
   2. Factor 2: Relative macrocephaly at birth: Head circumference at birth $\geq$1.5 SDS above birth weight and/or length adjusted for GA.
   3. Factor 3: Postnatal growth failure: Height $\leq$ 2 SDS at 24 months relative to mean or to midparental target height.
   4. Factor 4: Feeding difficulties and/or low BMI at 24 months: BMI $\leq$2 SDS at 24 months OR tube feeding OR cyproheptadine for appetite stimulation.
   5. Factor 5: Protruding forehead: The forehead protrudes from the facial plan (viewed laterally) between 1 and 3 years of age.
   6. Factor 6: Body asymmetry: Leg length discrepancy (LLD) of $\geq$ 0.5 cm OR arm asymmetry OR LLD $<$ 0.5 cm with at least two; other asymmetric body parts (with one being a nonface part).
6. A possible associations of Mayer–Rokitansky–Küster–Hauser syndrome and Silver–Russell syndrome (Abraham et al. 2016).
7. Clinical characterization (Hannula et al. 2001a; Binder et al. 2008; Bruce et al. 2009; Eggermann et al. 2010):
   1. Phenotype of maternal UPD7 carriers is generally milder.
   2. 11p15 epimutation (*H19* imprinting control region hypomethylation) carriers usually present the typical picture of SRS.
8. Differential diagnosis (Patton 1988):
   1. Intrauterine growth retardation owing to placental insufficiency:
      1. Chronic intrauterine growth retardation leads to a decrease in all growth parameters, that is, a "perfect miniature," and is

followed in most cases by catch-up growth in the first year of life.
    2. Late intrauterine growth retardation, especially in the postmature fetus, leads to a thin, low birth weight baby with normal length and head circumference
2. Chromosomal mosaicism:
    1. The phenotype has been reported in patients with mosaic trisomy 18 (Chauvel et al. 1975) a diploid–triploid mosaicism (Ferrier et al. 1964) and a 45,X/46,XY mosaicism. Consideration should be given to examining skin fibroblasts in addition to peripheral blood, especially where there is mental retardation or sexual ambiguity.
3. 3-M syndrome (Winter et al. 1984) This autosomal recessive syndrome has several features in common with the Russell–Silver syndrome, including intrauterine growth retardation, relatively large head, and short fifth fingers. It can be distinguished from the Russell–Silver syndrome by the presence of prominent heels, tall vertebral bodies, and facial features, which include a broad, fleshy nose and a hatchet-shaped profile.
4. X-linked short stature with skin pigmentation (Partington) (Partington 1986) This syndrome has been described as a variant of the Russell–Silver syndrome. There is a diffuse brown pigmentation with some achromic patches.
5. Neonatal progeroid (Rautenstrauch) (Wiedermann 1979) This syndrome has pseudohydrocephalus, generalized deficiency of subcutaneous fat, and natal teeth.

9. Subtypes existing in primordial dwarfism, their inheritance pattern, and distinguishing clinical features (Khetarpal et al. 2016):
    1. Seckel syndrome (please see the chapter on "► Seckel Syndrome")
        1. Autosomal recessive
        2. Microcephalic primordial dwarfism (brain size reduced to a third of normal volume)
        3. Extremely small head with narrow face, dental alterations, beak-like protrusion of nose, and receding mandible
    2. Majewski/microcephalic osteodysplastic primordial dwarfism (MOPD) types I/III
        1. Autosomal recessive
        2. Dry skin
        3. Sparsity of hairs and eyebrows
    3. MOPD type II
        1. Autosomal recessive
        2. Prominent nose and eyes
        3. Abnormally small or missing teeth
        4. A high squeaky voice
    4. Meier–Gorlin syndrome
        1. Autosomal recessive
        2. Underdeveloped ears
        3. Absent/hypoplastic patellae
    5. Silver–Russel syndrome
        1. Autosomal dominant or autosomal recessive and genomic imprinting
        2. Normal head size
        3. Small triangular face
        4. Micrognathia
        5. Dental anomalies

Diagnostic Investigations

1. Increased serum or urinary gonadotropin levels in the prepubertal age (Curi et al. 1967)
2. Hypoglycemia
3. Growth hormone studies
4. Metabolic acidosis due to renal tubular acidosis in a few patients
5. Radiography (Herman et al. 1987)
    1. Delayed bone age
    2. Limb asymmetry
    3. Ivory epiphyses of the distal phalanges
    4. Clinodactyly of the fifth fingers
    5. Fifth middle or distal phalangeal hypoplasia
    6. Pseudoepiphyses at the base of the second metacarpal
6. Chromosome analysis to define chromosome basis
    1. Mosaic trisomy 7 (Flori et al. 2005; Font-Montgomery et al. 2005)

2. Interstitial deletion of chromosome 7q [del (7)(q21.1q21.3)] (Courtens et al. 2005)
7. Molecular karyotyping in patients with SRS features: NSD1 duplication in Silver–Russell syndrome (Sachwitz et al. 2016a)
8. Molecular genetic testing (Eggermann et al. 2009; Saal 2007)
    1. Maternal uniparental disomy (UDP) of chromosome 7 (7–10%) clinically available: both maternal isodisomy and heterodisomy have been reported (Bernard et al. 1999; Price et al. 1999).
    2. Genetic or epigenetic mutations in the imprinted region on chromosome 11p15.5: methylation analysis of *H19* (35%) clinically available.
    3. 11p15 epimutation and UPD (7) mat carriers do not always show the unambiguous SRS phenotype.
    4. In addition to patients with the classical SRS phenotype fulfilling the SRS-specific scores, genetic testing for the 11p15 epimutation and/or UPD (7) mat should also be considered in case of SRS-like phenotypes, for example, mild IUGR and postnatal growth retardation (more than −2 SD) associated with a prominent forehead and triangular face or asymmetry as the only clinical sign.
    5. In particular, the lack of IUGR in patients with an SRS-like phenotype should not automatically result in exclusion from molecular testing.
    6. Silver–Russell syndrome in a patient with somatic mosaicism for upd(11)mat identified by buccal cell analysis (Luk et al. 2016).

Genetic Counseling

1. Recurrence risk (Saal 2007)
    1. Multiple etiologies of SRS
        1. Maternal uniparental disomy for chromosome 7: both parents are predicted to be unaffected.
        2. Possible mutations or epigenetic changes that modify expression of genes in the imprinted region of chromosome 11p15.5.
        3. Autosomal dominant inheritance.
        4. Autosomal recessive inheritance.
    2. Patient's sibs
        1. Not increased in a nongenetic sporadic case or as the result of maternal uniparental disomy for chromosome 7 (both parents are predicted to be unaffected)
        2. Increased depending on the inheritance pattern
    3. Patient's offspring
        1. Not increased in a nongenetic sporadic case and probably low in case of maternal uniparental disomy for chromosome 7
        2. Increased depending on the inheritance pattern
2. Recurrence risk estimation in SRS and Beckwith–Wiedemann syndrome (BWS) (Eggermann et al. 2016a)
    1. The majority of cases with SRS and BWS have been reported to occur sporadically. This is reflected by the type of (epi)mutations in both disorders (ICR1 hypomethylation in SRS as well as ICR2 hypomethylation and upd(11)pat in BWS) mainly occur as mosaicism and probably originate from postzygotic errors.
    2. In contrast, constitutional mutations (point mutations, duplications/deletions) are associated with a significantly increased recurrence risk of up to 50% depending from the affected paternal allele.
3. Molecular subtypes and recurrence risk (Eggermann et al. 2016b)
    1. 11p15.5
        1. *H19*/*IGF2*:IG-DMR hypomethylation: empirically low, only in rare cases increased due to genomic transacting mutations
        2. Duplications/deletions: Up to 50%, depending on the gene content of the aberration and the sex of the parent contributing the affected allele (in case of

duplication of the whole 11p15 region; in case of a maternal transmission)
3. UPD: empirically low
4. *CDKN1C* point mutation: 0% or 50%, depending on the sex of the parent contributing the affected allele
5. *IGF2* point mutation: 0 or 50%, depending on the sex of the parent contributing the affected allele

2. 7
1. upd(7)mat: empirically low, but some may be high because of familial translocations
2. upd(7q)mat: empirically low
3. Duplications/deletions/translocations affecting 7p13 and 7q32: up to 50%

3. 14q32
1. upd(14)mat, epimutation, duplications.
2. A number of SRS patients exhibiting (epi)mutations in 14q32 have recently been reported, and these molecular alterations correspond to findings in patients with Temple syndrome (Goto et al. 2016; TS14, OMIM616222).
3. TS14 is an ID with changes affecting the IG-DMR and/or MEG3-DMR in 14q32, and its phenotype (Ioannides et al. 2014) overlaps with SRS (for a review see Kagami et al. (2015)).
4. In single cases, maternal uniparental disomy of chromosomes 16 and 20 (upd(16)mat, upd(20)mat) has been reported (Azzi et al. 2015; Mulchandani et al. 2015) (for a review see Eggermann et al. (2015)).

4. Whole genome
1. (Mosaic) maternal unidiploidy: no
2. (Submicroscopic) chromosomal imbalances: up 50%, depending on the chromosome and type of rearrangement

4. Prenatal diagnosis
1. Ultrasonography of the fetus at risk by family history.
1. Delayed fetal skeletal growth may not be evident until the late second trimester.
2. Asymmetry of fetal limbs may not be evident until the third trimester.
2. Usually not possible because most occurrences are in a single individual in a family; therefore, most pregnancies are not identified to be at increased risk for recurrence (Saal 2007).
3. Russel–Silver syndrome should be considered in the differential diagnosis of fetal growth restriction with short, asymmetric, but morphologically normal limbs (Wax et al. 1996).
4. Molecular findings and interpretations in prenatal testing of SRS (and BWS) (Eggermann et al. 2016a).
1. Type of mutation: UPD, CNVs (copy number variations), epimutation, and point mutation.
2. Mosaicism: In case of a positive testing result, the suspected diagnosis can be confirmed, but a prediction of the phenotypic outcome is not possible but might be delineated from the ultrasound findings.
3. Mosaicism: In case of a negative testing result, the mosaic presence of UPD or epimutations can never be excluded. Mosaicism in case of constitutional mutations (CNVs, monogenic point mutations) can be neglected.
4. How to interpret the results in case of a twin pregnancy (the majority of monozygotic twins are clinically discordant)?

5. Management
1. Growth deficiency
1. Optimize caloric intake.
2. Consider nasogastric or gastrostomy feeding for severe gastroesophageal reflux and failure to thrive.
3. Consider growth hormone treatment in patients with documented growth hormone deficiency.
4. Growth hormone treatment of short children born small for gestational age or with Silver–Russell syndrome (Ranke and Lindberg 1996).
2. Dental cares for overcrowding of teeth
3. Orthopedic management for asymmetry of legs

4. Early intervention programs including physical therapy for developmental delay due to hypotonia
5. Special education for learning disabilities
6. Psychological counseling related to body image and peer relationship

Fig. 1 An infant with Silver–Russell syndrome showing prenatal and postnatal growth deficiency, triangular face, and asymmetry of legs

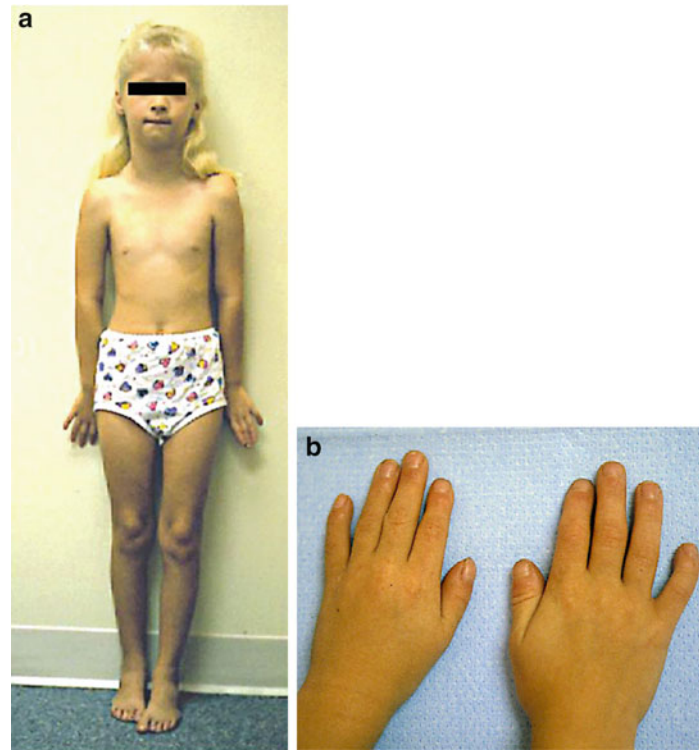

Fig. 2 (**a**, **b**) A girl (**a**) with Silver–Russell syndrome showing prenatal and postnatal growth deficiency, triangular face, and clinodactyly of the fifth fingers (**b**)

Fig. 3 (**a**, **b**) A girl (**a**) with Silver–Russell syndrome showing prenatal and postnatal growth deficiency with brachydactyly and clinodactyly of the fifth fingers (**b**)

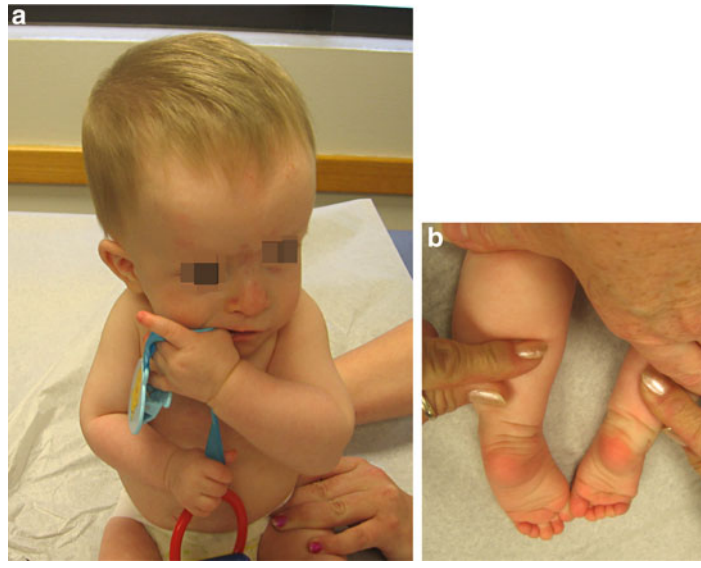

Fig. 4 (**a**, **b**) A 6-month-old male infant (**a**) was evaluated for intrauterine growth retardation, postnatal growth retardation, a relatively large head, a triangular face, and left side of the body larger than the right (**a**, **b**). Clinically, he was suspected to have Silver–Russell syndrome. Molecular genetic testing detected loss of methylation at differentially methylated region 1 (*DMR1*), upstream of the *H19* gene at 11p15. This result is consistent with a diagnosis of Silver–Russell syndrome due to hypomethylation of DMR1

Sirenomelia

Contents

Sirenomelia is a rare malformation sequence characterized by a partial or complete fusion of the lower limbs associated with urogenital, anal, lower spine, and other anomalies. The term sirenomelia comes from "siren" or "mermaid" because of the characteristic fusion of the lower extremities. Because of its physical resemblance to the mythical mermaid, the topic of sirenomelia has fascinated public for centuries. Sirenomelia occurs in approximately 1 in 60,000 births.

Synonyms and Related Disorders

Caudal regression syndrome; Mermaid syndrome; Sirenomelia mermaid syndrome; Sirenomelia sequence

Genetics/Basic Defects

1. Sporadic occurrence.
2. Familial occurrence of sirenomelia (Gerard et al. 2012):
    1. Only one family had true recurrence of sirenomelia, with four malformed siblings, two sirenomelic, one with renal agenesis, and one with imperforate anus (Rudd and Klimek 1990). The father had anomalies of the spine detected on radiographs, with narrow lumbosacral interpediculate distance, without sacral anomaly.
    2. In another family, there were four siblings, one sirenomelic, one with bilateral renal agenesis and tetralogy of Fallot, one with "posterior urethral valves," and the last with megacystis (Selig et al. 1993). The last family is the one reported by Castori et al. (2010) with an overweight diabetic mother giving birth to a first child with sirenomelia and another with bilateral renal agenesis, narrow pubic and ischial bones, atrial septal defect, and vertebral anomalies (T7 hemivertebrae and abnormal sacrum), in the VACTERL sequence, which is again a link to the embryological field of the malformations of VATER and sirenomelia.
3. Incidence of sirenomelia in monozygotic twins markedly increased over dizygotic twins or singletons.
4. Caudal regression syndrome (CRS) (a severe form of caudal regression syndrome) (Goodlaw et al. 1988) represents a continuum of congenital malformations ranging from

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_217

agenesis of the lumbosacral spine to the most severe cases of sirenomelia with lower extremities fusion and major visceral anomalies (Adra et al. 1994).

5. Cause obscure:
    1. Malformations as developmental field defects, probably arising during blastogenesis (Opitz et al. 2002). Previously considered a vascular disruption anomaly, sirenomelia is a quintessential primary defect of blastogenesis affecting multiple midline primordia during the final stages of granulation at the caudal eminence.
    2. The fusion theory: the lower extremities develop in lateral contact to each other and subsequently become fused.
    3. The classical theory: deficiency of the caudal axial area in the embryo allows the approximation of the side plates where the limbs develop.
    4. The single umbilical artery theory: resulting vascular insufficiency does not allow the normal process of lower limb development.
    5. The vascular steal theory: the sirenomelic malformations result from diversion of the blood flow from caudal structures of the embryo to the placenta. The tissues distal to the diversion receive diminished vascular supply; consequently, the development is arrested at some stage during fetal life.
    6. The extrinsic theory: any mechanical pressure on the caudal portion of the embryo may impede normal rotation of the limb buds as it has been observed in chick embryos exposed to such influences.
    7. The neural tube distention theory: overdistention of the neural tube in the caudal region expands the roof plate of the tube, displacing and laterally rotating the mesoderm, which allows the fusion of the limb buds.
    8. Caudal mesoderm pattern of anomalies: from renal agenesis to sirenomelia (Källén and Winberg 1974).
6. Sirenomelia and severe caudal regression syndrome: both cases of caudal regression syndrome (CRS) were infants of type II diabetic mother with poor control, supporting the strong correlation of CRS and maternal diabetes (Zeidahmed et al. 2014).
7. Exposure to methylergonovine maleate as a cause of sirenomelia (Cozzolino et al. 2016).

Clinical Features

1. Fusion of the lower limbs
    1. The most striking feature of the syndrome
    2. Fusion of the lower limbs and abnormalities of the feet creating the appearance of a mermaid
    3. Often with rotated feet
    4. Posteriorly located patella
2. Sirtori's classification into three types according to the number of the feet (Sepulveda et al. 1998; Heflin 2007)
    1. Sympus apus (absence of both feet)
        1. The most common form of sirenomelia.
        2. Characterized by a completely fused single lower extremity with one femur, no fibulae, and one or two tibiae.
        3. Both feet may be absent or rudimentary feet may be present.
    2. Sympus unipus or monopus (presence of only one foot)
        1. Characterized by a single fused lower extremity with two femora, two tibiae, and two fibulae.
        2. Only one foot is present with a varying number of toes (up to ten) on the single foot.
    3. Sympus dipus (presence of both feet)
        1. Characterized by a single fused lower extremity
        2. Presence of two distinct feet that appear like a fin or flipper
3. Stocker's more detailed classification into seven subtypes according to the fused bones (Stocker and Heifetz 1987)
    1. Type I: paired femora, tibiae, and fibulae (all thigh and leg bones are present)
    2. Type II: a single, fused fibula
    3. Type III: absent fibula
    4. Type IV: partially fused femora and a single fibula

5. Type V: partially fused femora and absent fibulae
6. Type VI: a single femur and tibia
7. Type VII: a single femur and absent tibiae and fibulae

4. Sirenomelia: a new type showing VACTERL association with Thomas syndrome (Lhuaire et al. 2013)
   1. Morphological appearance of the fetus
      1. Potter facies
      2. Bilateral labio-maxillary cleft
      3. Cleft hands
      4. Agenesis of right thumb
      5. Single inferior limb with anterior sole of the single foot
   2. 3D CT reconstructions
      1. Agenesis of right thumb
      2. Right radial hemimelia
      3. Cervical hemivertebrae
      4. Lumbar and sacral spine agenesis
   3. Thomas syndrome
      1. Thomas et al. (1993) reported a new syndrome that associated Potter sequence, cleft lip and palate, and cardiac abnormalities.
      2. The case by Lhuaire et al. (2013) presented a Thomas syndrome associated with a Potter sequence and a bilateral cleft lip and palate, agenesis of the right branch of the pulmonary artery, and agenesis of the right pulmonary veins and interatrial communication.
5. Oligohydramnios
6. Single umbilical artery (Perez-Aytes et al. 1997)
   1. With hypoplasia of the aorta below the origin of the umbilical artery
   2. Presents virtually in every case of sirenomelia
7. Vascular anomalies
   1. Single umbilical artery
   2. Persistent vitelline artery
   3. Hypoplastic distal aorta
   4. Aberrant femoral arteries
8. Urogenital anomalies
   1. Unilateral or bilateral renal agenesis (the most common finding)
   2. Renal cystic dysplasia
   3. Fusion of the renal pelvis
   4. Absent bladder
   5. Urethral atresia
   6. Ectopic urethra
   7. Posterior urethral valves
   8. Male
      1. Absent external genitalia
      2. Small/rudimentary phallus
      3. Absent testis
   9. Females
      1. Absent/ambiguous external genitalia
      2. Absent ovaries
      3. Anomalous/rudimentary uterus
      4. Anomalous vagina
9. Gastrointestinal anomalies
   1. Meckel's diverticulum
   2. Duodenal atresia
   3. Absent gallbladder
   4. Annular pancreas
   5. Omphalocele
   6. Intestinal malrotation
   7. Blind-end colon/rectum
   8. Colon duplication
   9. Absent spleen
   10. Imperforate anus
   11. Limb–body wall complex
10. Cardiac anomalies
    1. Tetralogy of Fallot
    2. Totally anomalous pulmonary venous return
    3. Ventricular septal defect
    4. Atrial septal defect
    5. Truncus arteriosus
    6. Hypoplastic ventricles
    7. Mitral atresia
    8. Transposition of the aorta
    9. Coarctation of the aorta
    10. Hypoplastic left heart
    11. Acardius amorphus
11. Pulmonary anomalies
    1. Pulmonary hypoplasia
    2. Tracheoesophageal fistula
    3. Laryngeal stenosis and tracheal atresia
    4. Cystic adenomatoid malformation
    5. Diaphragmatic hernia
    6. Abnormal lung lobation
    7. Pulmonary agenesis associated with acardius amorphus

12. CNS anomalies
    1. Craniorachischisis totalis (Rodriguez and Palacios 1992)
    2. Holoprosencephaly: report of cebocephaly, alobar holoprosencephaly, spina bifida, and sirenomelia in a stillbirth (Chen et al. 1997)
    3. Hydrocephalus
    4. Arnold–Chiari malformation
    5. Absent corpus callosum
    6. Meningomyelocele
13. Pelvis/sacral anomalies
    1. Dysplastic pelvis
    2. Sacral agenesis/dysplasia
14. Vertebral anomalies
    1. Hemivertebrae
    2. Spina bifida
    3. Kyphoscoliosis
15. Upper limb anomalies
    1. Absent radius.
    2. Abnormal thumb.
    3. Absent limb.
    4. Preaxial polydactyly.
    5. Rarer associated abnormalities, which include asymmetrical upper limb defects, not confined to the radial ray (Moosa et al. 2012). The clinical phenotypic overlap between caudal dysgenesis, VACTERL association, and sirenomelia in four patients lends support to the theory that these entities may be different manifestations of a single pathogenic process.
16. Face
    1. Potter facies
        1. Large, floppy low-set ears
        2. Flat nose
        3. Micrognathia
    2. Skin tags
17. Prognosis
    1. Generally lethal
        1. Stillborn in more than half of cases.
        2. Remainder of cases most likely die shortly after birth due to severe associated visceral anomalies, incompatible with life.
    2. Occasional long-term survival possible
        1. Reports of survival of infants with sirenomelia (associated with fused lower extremities, colon atresia, renal dysplasia, imperforate anus, pelvic and sacral "dysplasia," genital abnormalities, preauricular skin tag, and rib fusion) (Murphy et al. 1992; Clark et al. 1993).
        2. A report of a unique occurrence of sirenomelia in a healthy infant who exhibits the most significant external manifestations typical of the syndrome, but who has well-developed and functional kidneys and lungs. This resulted in a sirenomelus infant with an anatomy and physiology compatible with long-term survival (Savader et al. 1989).

Diagnostic Investigations

1. Radiography
    1. Classification based on osseous findings:
        1. Type I (all bones of the thigh and lower leg present and unfused)
        2. Type II (fused fibulae)
        3. Type III (absent fibulae)
        4. Type IV (partially fused femora and fused fibulae)
        5. Type V (partially fused femora)
        6. Type VI (fused femora and fused tibiae)
        7. Type VII (fused femora and absent tibiae)
    2. Rotation of the legs and feet.
    3. Abnormalities of the vertebrae, especially sacral bones.
    4. Deficient bony pelvis.
    5. A fetus with a single lower extremity and a single foot with four toes: radiograph showed a single femur with broad metaphyses, paired tibiae, scoliosis with hemivertebrae, and minimal ossification of the lumbosacral spine (Van Zalen-Sprock et al. 1995).
2. Angiography for vascular anomalies (Talamo et al. 1982)
3. Chromosome analysis: normal in most cases

Genetic Counseling

1. Recurrence risk
    1. Patient's sibs: negligible.
    2. Patient's offspring: affected individuals do not expect to survive to reproduce.
2. Prenatal diagnosis
    1. Ultrasonography (Sirtori et al. 1989; Van Zalen-Sprock et al. 1995; Nori et al. 2016)
        1. Three major US findings suggesting the diagnosis of "mermaid syndrome" (Raabe et al. 1983):
            1. Oligohydramnios
            2. Bilateral renal agenesis
            3. Most importantly lower extremity fusion
        2. Inability to demonstrate separate lower limbs.
        3. Identification of varying degree of a single or "fused" lower limb.
        4. Lower spine agenesis/dysgenesis.
        5. CNS, cardiac, GI, and other abnormalities.
        6. A single umbilical artery.
        7. Oligohydramnios associated with urogenital anomalies, especially renal agenesis/dysgenesis.
        8. Prenatal diagnosis of sirenomelia difficult to make because of the associated anhydramnios.
        9. The additional information obtained from the 3D images was the overall view, the confirmation of 2D findings, and especially the observation of abnormal fetal movements due to conjoined fetal legs (Blaicher et al. 2001).
        10. US findings of caudal regression versus sirenomelia (Twickler et al. 1993):
            1. Normal or increased amniotic fluid
            2. Mild dilation or normal urinary systems
            3. Nonfused extremities
            4. Sacral agenesis
        11. 3D-SUIS seems to be a useful complementary method to 2D-US and may improve the accuracy of identifying prenatal skeletal abnormalities related to sirenomelia (Liu et al. 2015).
    2. Color Doppler imaging (Sepulveda et al. 1994, 1998)
        1. A simple, noninvasive method to detect vascular abnormalities associated with sirenomelia
        2. Two vascular hallmarks of the syndrome in utero
            1. Persistence of the vitelline artery: a single large artery arising from the high abdominal aorta to become the single umbilical artery, leaving an atretic or absent distal aorta. Such a vascular abnormality is thought to be responsible for a vascular steal phenomenon and poor perfusion distal to the anomalous artery, leading to the sirenomelia sequence (Stevenson et al. 1986).
            2. Absence of renal vessels.
    3. Prenatal diagnosis by ultrasonography of fetus made as early as first trimester (Monteagudo et al. 2002; Schiesser et al. 2003; van Keirsbilck et al. 2006; Contu et al. 2009; Cuillier et al. 2013; Singh et al. 2014)
    4. Three-dimensional ultrasound imaging and first trimester diagnosis in a case of mosaic 69,XXX/46,XX fetus (Gabriele and Gianpaolo 2013)
    5. MRI of aberrant lower extremity and the spine compared with normal age-matched fetus (Nori et al. 2016): fused lower extremities, hyperextension at the knee, absence of the soft tissue cleft/separation between the thighs, and absent sacral tapering with prominent gluteal concavity
3. Management (Guidera et al. 1991)
    1. Orthopedic treatment of patients with less severe spectrum of caudal regression
        1. Soft tissue release.
        2. Osteotomies.
        3. Separation of the lower limbs. Long-term functional results of the separation are unknown.
        4. Orthotics.
    2. Anticipate extensive reconstruction in the event of survival

3. Goal of orthopedic intervention: proper seating and standing, achievable without amputation
4. Severe form of sirenomelia: a lethal condition

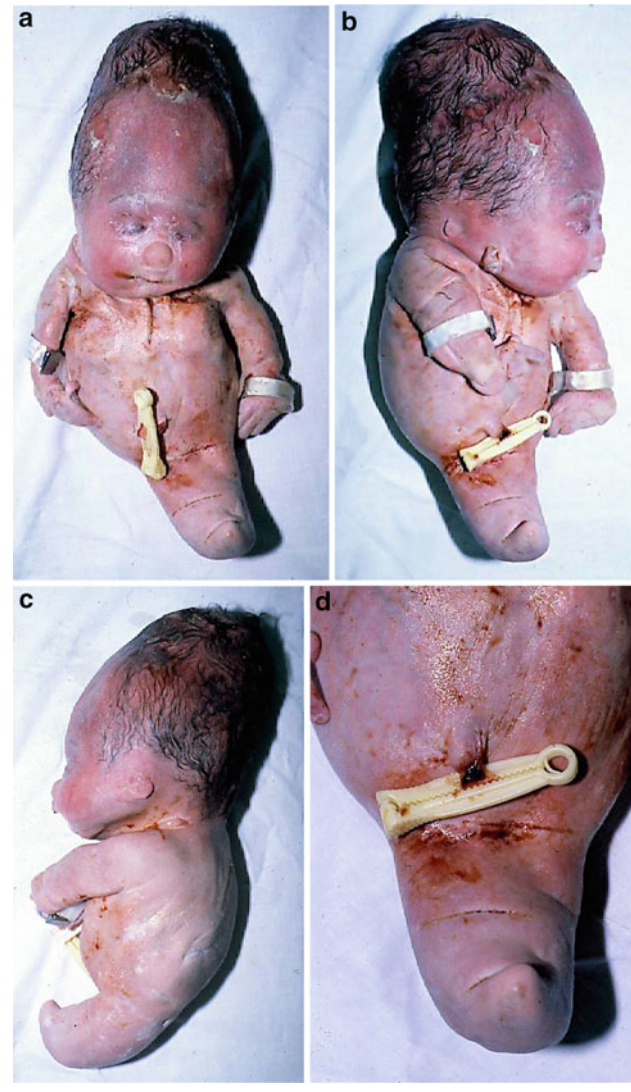

Fig. 1 (**a**–**d**) A stillborn with sirenomelia showing Potter facies, short neck, absent external genitalia, and fused single lower limb with absent feet. This infant also had holoprosencephaly

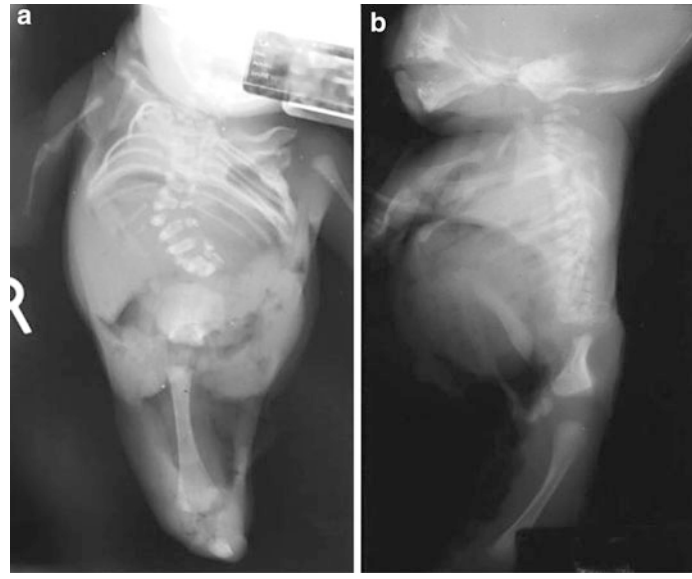

Fig. 2 (**a**, **b**) Radiographs of the previous infant showed vertebral segmentation defects, malformed ribs, absent sacrum, dysplastic pelvic bones, single femur, and absent tibiae/fibulae/tarsal/metatarsals/phalanges

Fig. 3 A female stillborn (35 weeks gestation) with sirenomelia (monomelia). The infant had a single femur with one bone below knee; agenesis of urinary system (ureters, bladder, and urethra); ectopic rudimentary renal tissue; absence of uterus, vagina, and external genitalia; and imperforate anus

Fig. 4 A male premature neonate with sirenomelia showing fused lower extremities and posterior alignment of the knees and feet. The *left* foot was malformed. Other major anomalies included absence of external genitalia; bilateral renal agenesis; agenesis of the ureters, bladder, urethra, and prostate; esophageal atresia with TE fistula; imperforate anus with absence of the rectum; intestinal malrotation; persistent *left* superior vena cava; bifid cardiac apex; and scoliosis with two hemivertebrae

Smith–Lemli–Opitz Syndrome

Contents

In 1964, Smith et al. (1964) reported three patients with a common distinctive facial appearance, microcephaly, broad alveolar ridges, hypospadias, a characteristic dermatoglyphics pattern, severe feeding disorder, and global developmental delay. The incidence of the Smith–Lemli–Opitz syndrome is estimated to be approximately 1 in 10,000 to 1 in 40,000 births based on clinical diagnosis and 1 in 60,000 to 1 in 100,000 births based on biochemical testing. There appears to be strikingly different incidences among various ethnic groups.

Synonyms and Related Disorders

RSH syndrome; Rutledge multiple congenital anomaly syndrome; SLO syndrome; SLOS

Genetics/Basic Defects

1. Inheritance: autosomal recessive.
2. Basic defect.
   1. Caused by a defect of cholesterol biosynthesis.
   2. Underlying biochemical defect: deficiency of 7-dehydrocholesterol reductase (DHCR7), an enzyme catalyzing the last step of the Kandutsch–Russell cholesterol biosynthesis pathway, resulting in generalized cholesterol deficiency.
   3. Mutations of *DHCR7* gene (Waterham et al. 1998) lead to deficient activity of 7-dehydrocholesterol reductase (DHCR7), the final enzyme of the cholesterol biosynthesis pathway. Functional null alleles of the *DHCR7* locus result in lethal form of Smith–Lemli–Opitz (SLO) syndrome.
   4. Human *DHCR7* gene has been cloned and localized to 11q12-13.
   5. An example of metabolic deficiency as a cause of a dysmorphic syndrome.
   6. First-trimester exposure to DHCR7 inhibitors resulted in outcomes similar to those of known teratogens (50 vs. 48% born healthy) (Boland and Tatonetti 2016). DHCR7 activity should be considered during drug development and prenatal toxicity assessment.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_218

3. Clues pointing to an underlying biochemical defect of cholesterol metabolism.
    1. Holoprosencephaly, microcephaly, pituitary agenesis, limb defects, and genital anomalies produced by in utero exposure of rat and mouse pups to chemical inhibitors of the cholesterol biosynthetic pathway
    2. Large adrenal glands with complete absence of lipid in adrenal cortex of patients with Smith–Lemli–Opitz syndrome (SLOS)
    3. Abnormalities of the pituitary–adrenal axis
    4. Suppressed fetal estriol production in pregnancies affected with Smith–Lemli–Opitz syndrome
    5. Neonatal liver disease in severe Smith–Lemli–Opitz syndrome associated with low serum cholesterol level
    6. Male pseudohermaphroditism not caused by dihydrotestosterone receptor defects
    7. Observation of two patients with Smith–Lemli–Opitz syndrome with low plasma cholesterol and elevated levels of 7-dehydrocholesterol (7DHC), the immediate precursor of cholesterol in the Kandutsch–Russell biosynthetic pathway, suggesting that this multiple malformation was caused by a simple Garrodian enzymatic defect
4. The apparent 7-DHC reductase deficiency makes the RSH (Smith–Lemli–Opitz) syndrome the first true metabolic malformation syndrome (Tint et al. 1994; Opitz and de la Cruz 1994).
5. The RSH syndrome has been identified as another metabolic multiple congenital anomalies/mental retardation (MCA/MR) syndrome (prototype Zellweger syndrome) in which deficient cholesterol synthesis must be held responsible for all parts of the syndrome, including blastogenetic and organogenetic malformations, minor anomalies, more or less severe abnormalities of CNS and PNS structure and function, postnatal failure to thrive, and, in some cases, stillbirth or infancy/childhood death (Opitz 1994).
6. The RSH (so-called Smith–Lemli–Opitz) syndrome has become a paradigmatic metabolic malformation syndrome in a pathway that also involves cause and pathogenesis of desmosterolosis, two forms of the Conradi–Hünermann–Happle-type chondrodysplasia punctata and its mouse homologues and the Greenberg "moth-eaten" skeletal dysplasia and the CHILD syndrome. Many other defects in this pathway remain to be discovered (Opitz 1999).
7. Rutledge multiple congenital anomaly syndrome (Rakheja et al. 2003).
    1. A "new" lethal multiple congenital anomaly syndrome: joint contractures, cerebellar hypoplasia, renal hypoplasia, urogenital anomalies, tongue cysts, shortness of limbs, eye abnormalities, defects of the heart, gallbladder agenesis, and ear malformations (Rutledge et al. 1984)
    2. Considered a variant of Smith–Lemli–Opitz syndrome
    3. Biochemical abnormality of excess 7-dehydrocholesterol and low cholesterol identified in the liver tissue
8. Homozygosity for the W151X stop mutation in the delta7-sterol reductase gene (DHCR7) causing a lethal form of Smith–Lemli–Opitz syndrome (Löffler et al. 2000).
9. Maternal *ABCA1* genotype is associated with severity of Smith–Lemli–Opitz syndrome and with viability of patients homozygous for null mutations (Lanthaler et al. 2013).
10. The p.Phe174Ser mutation is associated with mild forms of Smith–Lemli–Opitz syndrome (Tucci et al. 2016).
11. Correlation between the 7DHC levels and the clinical severity of patients compared the plasma 7DHC levels to the severity score in the 165 patients in whom both values were available (Waterham and Hennekam 2012): Severity score and 7DHC levels correlated with one another, but this was less pronounced in patients who had a combination of a nonsense mutation and missense mutation compared to patients who had two missense mutations.

12. Genotype–phenotype correlations (Witsch-Baumgartner et al. 2000).
    1. Four classes of mutations: nonsense and splice-site mutations resulting in putative null alleles, missense mutations in the transmembrane domains (TM), mutations in the fourth cytoplasmic loop (4 L), and mutations in the C-terminal ER domain (CT).
    2. All but one of the tested missense mutations reduced protein stability. Concentrations of the cholesterol precursor 7-dehydrocholesterol and clinical severity scores correlated with mutation classes.
    3. The mildest clinical phenotypes were associated with TM and CT mutations, and the most severe types were associated with 0 and 4 L mutations.
    4. Most homozygotes for null alleles had severe SLOS; one patient had a moderate phenotype.
    5. Homozygosity for 0 mutations in DHCR7 appears compatible with life, suggesting that cholesterol may be synthesized in the absence of this enzyme or that exogenous sources of cholesterol can be used.
13. Additional related human syndromes resulting from impaired cholesterol synthesis (Kelly 2000; Porter 2002; Herman and Kratz 2012; Kanungo et al. 2013).
    1. Desmosterolosis
        1. Autosomal recessive inheritance.
        2. Caused by mutations in 24-dehydrocholesterol reductase (*DHCR24*) gene (1p31.1-p33).
        3. Elevated plasma desmosterol.
        4. Report of a female infant with a lethal syndrome of macrocephaly, thick alveolar ridges, gingival nodules, cleft palate, total anomalous pulmonary venous drainage, ambiguous genitalia, short limbs, and generalized osteosclerosis was found to have markedly increased tissue levels of desmosterol.
        5. Another report of a child with microcephaly, short stature, and delays in speech and psychomotor development was found to have an increased plasma level of desmosterol and markedly increased levels of desmosterol in cultured lymphoblasts.
        6. Intellectual disability.
        7. Midline facial defects.
        8. Relative macrocephaly.
        9. Microcephaly.
        10. Hypoplastic to agenesis of corpus callosum.
        11. Spastic contractures.
        12. Hydrocephalus.
        13. Dilated ventricles.
        14. Absent septum pellucidum.
        15. Mildly effaced gyral pattern and incomplete opercularization.
        16. Failure to thrive.
    2. Lathosterolosis
        1. Autosomal recessive
        2. Caused by mutations in *SC5DL* gene (11q23.3)
        3. Microcephaly
        4. Bitemporal narrowing
        5. Neural tube defects
        6. Congenital cataracts
        7. Intrauterine and postnatal growth retardation
        8. Seizures
        9. Intellectual disability
    3. X-linked dominant chondrodysplasia punctata type 2 (CDPX2) (Conradi–Hünermann syndrome)
        1. Caused mutations in *EBP* gene (Xp11.22-11.23)
        2. Typically in females with a variable combination of bilateral and asymmetric shortening of long bones; punctate calcification of epiphyses, trachea, and larynx; segmental cataracts; and patches of ichthyotic skin that typically follow the lines of Blaschko
        3. Lethal to males early in gestation
        4. Characteristic craniofacial appearance with frontal bossing, midface hypoplasia, flat nasal bridge, and midline orofacial defects

5. Agenesis or hypoplasia of corpus callosum
6. Congenital cataracts, microphthalmia, and microcornea
7. Sensorineural hearing loss
8. Tethered cord
9. Dandy–Walker malformation
10. Cervical myelopathy
11. Normal intelligence in females

4. CHILD syndrome (*c*ongenital *h* emidysplasia with *i* chthyosiform erythroderma/nevus and *l*imb *d* efects)
   1. X-linked dominant inheritance
   2. Caused by mutations in *NSDHL* gene (Xq28)
   3. Cutaneous and bony abnormalities similar to CDPX2
   4. Report of a patient with classic CHILD syndrome
      1. Manifests the characteristic sterol abnormality of CDPX2
      2. Carries a mutation creating a stop codon in the same sterol-Δ^8-isomerase associated with CDPX2
   5. Sensorineural hearing loss
   6. Normal intelligence in females
   7. One-sided cerebral hypoplasia with cortical polymicrogyria, ventriculomegaly, absent corpus callosum, and ipsilateral cerebellar dysplasia with completely normal contralateral side of the brain
5. Greenberg dysplasia (hydrops-ectopic calcification-moth-eaten skeletal dysplasia)
   1. Autosomal recessive inheritance
   2. A lethal skeletal dysplasia characterized by hydrops fetalis, short-limbed dwarfism, postaxial polydactyly, and abnormal chondro-osseous mineralization
   3. Radiologic abnormalities
      1. Moth-eaten-appearing long bones
      2. Ectopic epiphyseal calcification
      3. Laryngeal and tracheal calcification
      4. Platyspondyly
   4. Steroid-Δ^{14}-reductase deficiency
6. Antley–Bixler syndrome (Opitz et al. 2002)
   1. Autosomal recessive
   2. Caused by mutations in *POR* gene (1q11.2)
   3. A skeletal abnormality syndrome primarily affecting head and limbs
   4. Also known as multisynostotic osteodysgenesis with long bone fractures
   5. A high incidence of genital ambiguity, an anomaly unlikely due to the *FGFR2* mutation, suggesting possible disordered steroidogenesis in early pregnancy
   6. Elevated two primary precursors of steroid hormones, pregnenolone, and progesterone, as are the classical diagnostic metabolites for 17- and 21-hydroxylase deficiencies, suggesting attenuated steroid hydroxylation (including 17,20-lyase activity) at least in the form not associated with *FGFR2* mutations (Shackleton et al. 2004)
   7. Severe craniosynostosis
   8. Brachycephaly with high broad forehead and midface hypoplasia/choanal atresia
   9. Hydrocephalus
   10. Arnold–Chiari malformation
   11. Intellectual disability
7. CK syndrome
   1. X-linked intellectual disability
   2. Caused by mutations in *NSDHL* gene (Xq28)
   3. Mild to severe intellectual disability in males
   4. Microcephaly
   5. CNS malformation
   6. Seizures
   7. Hypotonia
   8. Dysphasia/speech delay
   9. Behavioral problems
   10. Possible psychopathology in carrier females
8. Mevalonic aciduria
   1. Autosomal recessive

2. Caused by mutations in *MVK* gene (12q24)
3. Severe failure to thrive
4. Developmental delay
5. Mild to severe intellectual disability
6. Progressive cerebellar atrophy
7. Growth retardation
8. Persistence of open fontanelle including third fontanelle
9. Cerebellar ataxia
10. Hypotonia/myopathy
11. Cataracts
12. Shortened lifespan

9. Sterol C4 methyl oxidase deficiency
   1. Autosomal recessive
   2. Caused by mutations in *SC4MOL* gene (4q32-q34)
   3. Developmental delay
   4. Microcephaly
   5. Congenital cataracts
   6. Possible psychopathology (as a result of skin findings)

Clinical Features

1. Variable clinical and biochemical phenotype (Ryan et al. 1998).
2. General.
   1. Postnatal growth retardation
   2. Failure to thrive
   3. Feeding difficulties requiring gavage feeding in many cases
   4. Abnormal intestinal motility
      1. Pyloric stenosis
      2. Vomiting
      3. Gastroesophageal reflux
   5. Feeding intolerance
   6. Gastrointestinal irritability
   7. Allergy
   8. Initial hypotonia/later hypertonia
   9. Recurrent otitis media and pneumonias
   10. Photosensitivity
   11. Adrenal insufficiency uncommon
3. Craniofacial features.
   1. Congenital microcephaly: very common
   2. Metopic prominence and bitemporal narrowing
   3. Capillary hemangioma over the glabella
   4. Eyes
      1. Epicanthal folds
      2. Ptosis (more than 50% of patients, often with asymmetrical or unilateral ptosis)
      3. Congenital cataracts
      4. Optic nerve hypoplasia
   5. Broad nasal bridge and short nasal root with anteverted nares
   6. Micrognathia
   7. Oral
      1. Cleft lip/palate
      2. High-arched/narrow hard palate
      3. Broad/ridged alveolar ridges
      4. Redundant sublingual tissues
      5. Long philtrum
   8. Low-set and posteriorly rotated ears
4. CNS anomalies.
   1. Global psychomotor retardation
   2. Microcephaly (almost universal finding)
   3. Agenesis/hypoplasia of corpus callosum
   4. Cerebellar hypoplasia
   5. Enlarged ventricles
   6. Decreased size of frontal lobes
   7. Pituitary lipoma
   8. Cerebellar hypoplasia with hypoplasia or aplasia of the vermis
   9. Holoprosencephaly sequence (5% of cases)
   10. Seizures
5. Limb anomalies.
   1. Bilateral or unilateral postaxial polydactyly in the hands or feet
   2. Short/proximally placed thumb
   3. Short first metacarpals
   4. Hypoplastic thenar eminences
   5. Subtle "zigzag" alignment of the phalanges of the index finger
   6. Characteristic Y-shaped cutaneous syndactyly of the second-third toes
6. Genital anomalies.
   1. Male (range from normal to the appearance of complete sex reversal) (Nowaczyk and Irons 2012)
      1. External genitalia: normal, hypospadias, female appearing, or ambiguous.

2. Internal genitalia: gonads varying from normal testes to ovotestes to normal ovaries or missing gonads; sex reversal including blind vaginal pouch and rudimentary or bicornuate uterus.
3. Up to 25% of individuals with SLOS have a 46,XY karyotype with a female genital phenotype.
4. Hypospadias or bilateral cryptorchidism occurs in 50% of males with SLOS.

2. Female
1. Hypoplasia of labia minora
2. Hypoplasia of labia majora

7. Congenital heart defects (about 50% of cases) (Lin et al. 1997).
1. Endocardial cushion defect (AV canal)
2. Septal defect
3. Hypoplastic left heart syndrome
4. Patent ductus arteriosus
5. Aortic coarctation
6. Anomalous pulmonary venous return
7. Hypertrophic cardiomyopathy
8. Hypertension

8. Renal anomalies (about 25% of cases).
1. Renal hypoplasia/aplasia with oligohydramnios sequence
2. Horseshoe kidney
3. Renal cortical cysts
4. Hydronephrosis
5. Renal ectopia
6. Ureteral duplication
7. Fetal lobation
8. Hypoplastic bladder and ureters

9. Adrenal anomalies.
1. Adrenal hyperplasia
2. Adrenal hypoplasia

10. Respiratory tract anomalies.
1. Laryngomalacia
2. Tracheomalacia
3. Sleep apnea
4. Abnormal pulmonary lobation
5. Pulmonary hypoplasia

11. Gastrointestinal/hepatic anomalies.
1. Pyloric stenosis (prominent clinical problem)
2. Poor feeding/sucking
3. Gastroesophageal reflux
4. Constipation
5. Malrotation
6. Hirschsprung disease
7. Cholestatic liver disease

12. Skin.
1. Photosensitivity
2. Cutis marmorata
3. Dry skin/eczema

13. Behavioral disorders.
1. Hypersensitivity with tactile defensiveness (oral, hands, and feet)
2. Unusual hyperresponsivity to auditory and visual stimuli
3. Aggressiveness and self-injury
4. Severe sleep disturbance
5. Autistic behavior

14. Prognosis.
1. Many survive to adulthood.
2. Many affected children died in the first year from failure to thrive and infections.

15. So-called Smith–Lemli–Opitz syndrome type II (Curry et al. 1987), a lethal syndrome resembling the original Smith–Lemli–Opitz syndrome.
1. Autosomal recessive disorder
2. Multiple congenital anomalies with male pseudohermaphroditism and frequent early lethality
3. Lethal in the newborn period from internal malformations
4. Most 46,XY "males" with severe hypogenitalism or female-appearing external genitalia
5. Same sterol pattern in most patients
6. Differences in severity between type I and type II Smit–Lemli–Opitz syndrome: due to severity of the mutations according to subsequent molecular genetic studies
7. Possibility of genetic heterogeneity of the Smith–Lemli–Opitz syndrome

16. A lethal multiple congenital anomaly syndrome of polydactyly, sex reversal, renal hypoplasia, and unilobular lungs described in three cases (Donnai et al. 1986).
17. Clinical criteria for the revised severity score (revised Bialer score) by Kelly and Hennekam (2000). The severity score is obtained based on categories of cerebral,

ocular, oral, skeletal, and genital defects identified. Based on the severity score, Smith–Lemli–Opitz syndrome phenotype can be divided into three categories: mild (<20), classical (20–50), and severe (>50). Severity score can be correlated with biochemical parameters and provides a basis for establishing a genotype–phenotype correlation.

1. Brain
    1. Score 1: seizures; qualitative MRI abnormality
    2. Score 2: major CNS malformations; gyral defects
2. Oral
    1. Score 1: bifid uvula or submucous cleft
    2. Score 2: cleft hard palate or median cleft lip
3. Acral
    1. Score 0: non-Y-shaped minimal toe syndactyly
    2. Score 1: Y-shaped 2–3 toe syndactyly; clubfoot; upper or lower polydactyly; other syndactyly
    3. Score 2: any two of the above
4. Eye
    1. Score 2: cataract; frank microphthalmia
5. Heart
    1. Score 0: functional defects
    2. Score 1: single-chamber or vessel defects
    3. Score 2: complex cardiac malformation
6. Kidney
    1. Score 0: functional defect
    2. Score 1: simple cystic kidney disease
    3. Score 2: renal agenesis; clinically important cystic disease
7. Liver
    1. Score 0: induced hepatic abnormality
    2. Score 1: simple structural abnormality
    3. Score 2: progressive liver disease
8. Lung
    1. Score 0: functional pulmonary disease
    2. Score 1: abnormal lobation; pulmonary hypoplasia
    3. Score 2: pulmonary cysts; other major malformations
9. Bowel
    1. Score 0: functional GI disease
    2. Score 1: pyloric stenosis
    3. Hirschsprung disease
10. Genitalia
    1. Score 1: simple hypospadias
    2. Score 2: ambiguous or female genitalia in a 46,XY; frank genital malformation in a 46,XX

Diagnostic Investigations

1. Diagnostic biochemical hallmarks of the syndrome
    1. Low serum cholesterol levels (10% of patients with DHCR7 deficiency have normal levels of cholesterol).
    2. Markedly elevated serum levels of 7-dehydrocholesterol (cholesta-5,7-dien-3beta-ol; 7DHC), precursor of cholesterol. However, up to 25% of reports of RSH/SLO in the literature may describe genetic conditions other than RSH/SLO with 7-DHC-emia (Cunniff et al. 1997).
    3. Cholesterol precursors 7-DHC and 8-DHC are important biomarkers of the level of functioning in SLOS, especially regarding cognitive abilities (Thurm et al. 2016).
2. DHCR7 enzyme assay
3. Analysis of sterol biosynthesis in cultured cells
4. Use of patient-derived iPSCs (induced pluripotent stem cells), a new discovery, to model neural deficits in SLOS, a rare autosomal recessive, multiple malformations, and intellectual disability syndrome (Francis et al. 2016; Wen et al. 2016)
5. Aberrant MRI findings (Lee et al. 2013)
    1. Observed in 96% SLOS patients, with abnormalities of the septum pellucidum the most frequent (76%) finding.
    2. Abnormalities of the corpus callosum were found in 69% patients.
    3. Other findings
        1. Cerebral atrophy
        2. Cerebellar atrophy
        3. Colpocephaly
        4. White matter lesions
        5. Arachnoid cysts

6. Dandy–Walker variant
7. Type I Chiari malformation

6. *DHCR7* mutation testing
   1. Sequence analysis.
   2. Targeted mutation analysis.
   3. Seven most frequent mutations described to date, representing two-thirds of the mutation in analyzed alleles (Jira et al. 2003).
      1. IVS8-1 G > C (31.5%)
      2. T93M (11.2%)
      3. R404C (10.7%)
      4. W151X (6.4%)
      5. V326L (6.3%)
      6. R352W (3.2%)
      7. E448K (3.2%)
   4. SLOS patients who are heterozygous/homozygous for one pathogenic mutation and only one parent carrying that mutation are candidates for DHCR7 gene (partial) deletions (Lanthaler et al. 2015).

Genetic Counseling

1. Recurrence risk: carrier frequency (2%, a reasonable estimate for risk assessment) is relatively high (Porter 2008).
   1. Patient's sibs: 25%
   2. Patient's offspring: not increased
2. Prenatal diagnosis.
   1. Prenatal screening as part of routine triple-marker screen for Down syndrome and neural tube defects: abnormally low maternal serum level of unconjugated estriol observed in pregnancies affected with Smith–Lemli–Opitz syndrome (Bradley et al. 1999; Schoen et al. 2003).
   2. Second trimester ultrasonography (Goldenberg et al. 2004).
      1. Nuchal edema
      2. Renal malformation
      3. Polydactyly
      4. Ambiguous genitalia
      5. Cerebral malformation
      6. Cardiac malformation
      7. Intrauterine growth retardation
   3. A successful first-trimester prenatal diagnosis of SLO by showing elevated levels of 7-DHC in direct analysis of a chorionic villus biopsy (Sharp et al. 1997). The result was confirmed by demonstration of 7-DHC accumulation in cultured cells (skin fibroblasts, CV cells) under modified growth conditions and by the biochemical examination of fetal brain.
   4. Prenatal diagnosis (Jezela-Stanek et al. 2006) can be established by:
      1. Detection of elevated 7-dehydrocholesterol concentrations (Abuelo et al. 1995) or SLOS-causing mutations in the DHCR7 gene by analysis in chorionic villus samples or amniocytes.
      2. Amniotic fluid sterol analysis: accurate prenatal diagnosis of RSH/SLOS is possible by sterol analysis of AF and CV specimens (Kratz and Kelley 1999; Haas et al. 2013).
      3. Serial measurements of estriol, pregnanetriol, 7-dehydropregnanetriol, and 8-dehydroestriol concentrations in maternal urine samples obtained between 9 and 20 weeks of gestation.
   5. Preimplantation genetic diagnosis has been made for SLOS with successful blastomere diagnosis with mutations in the *DHCR7* gene, allowing transfer of mutation-free embryos and successful pregnancies (Liss et al. 2008).
   6. Prenatal diagnosis and preimplantation genetic diagnosis (PGD) for at-risk pregnancies require molecular genetic testing; prior identification of the disease-causing mutations in the family is necessary (Nowaczyk 2013).
3. Management (Porter 2000; Jira et al. 2003; Svoboda et al. 2012).
   1. The mainstay of SLOS treatment (Kelly et al. 2015).
      1. Adequate dietary cholesterol intake.
      2. Cholesterol supplementation increases plasma and tissue cholesterol levels and often decreases 7DHC and 8DHC levels via feedback inhibition of the 3-hydroxy-3-methylglutaryl-coenzyme

A (HMG-CoA) reductase (Svoboda et al. 2012).
3. Patients are encouraged to consume high-cholesterol foods (e.g., egg yolks, whipped cream, and butter fat) or take pharmaceutical-grade cholesterol, administered at a dose of 20–300 mg/kg/day (Svoboda et al. 2012).
4. Educational interventions.
5. Behavioral management.

2. Therapeutic trials using dietary supplementation of cholesterol (Irons et al. 1997).
   1. Used to treat complications related to the biochemical disturbance. Clinical benefits of this therapy are limited by the presence of developmental problems.
   2. Currently, most patients being treated with pharmaceutical-grade cholesterol suspended in either soybean oil or Ora-Plus syrup or alternatively with egg yolks (Linck et al. 2000): increases plasma cholesterol and decreases plasma 7-dehydrocholesterol in Smith–Lemli–Opitz syndrome.
   3. Multiple benefits of dietary cholesterol supplementation (Elias et al. 1997).
      1. Improved nutrition and growth
      2. Decreased irritability
      3. Increased alertness
      4. Increased sociability
      5. Decreased self-abusive and aggressive behavior
      6. Decreased tactile defensiveness
      7. Decreased photosensitivity
      8. Decreased infections
      9. Improved hearing
      10. Improved muscle tone and strength
   4. Use of bile acids shown to have no clear benefit.
3. An alternative therapeutic strategy of treating with simvastatin (an oral HMG-CoA reductase inhibitor) (Jira et al. 2000) for a median period of 2 years with impressive overall biochemical effect.
   1. A decrease of 7DHC and 8DHC
   2. An increase of cholesterol
   3. Promising clinical improvement
4. A placebo-controlled trial of simvastatin therapy in Smith–Lemli–Opitz syndrome (Wassif et al. 2016).
   1. Relatively safe in patients with SLOS
   2. Improves the serum dehydrocholesterol-to-total sterol ratio and significantly improves irritability symptoms in patients with mild to classic SLOS
5. Fresh frozen plasma, which contains cholesterol-rich lipoproteins, used to provide cholesterol supplementation in very sick patients and the fetuses (Porter 2000).
6. Antenatal treatment of SLOS by cholesterol supplementation is feasible and results in improvement in fetal plasma cholesterol levels and fetal red cell volume. SLOS may be added to the growing list of human genetic disorders for which prenatal diagnosis is available and therapeutic intervention may be possible (Irons et al. 1999).
7. Management of SLOS during pregnancy (Ellingson et al. 2014).
   1. Serial monitoring of cholesterol and 7DHC levels with dietary intervention to increase exogenous cholesterol and decrease the accumulation of potentially toxic cholesterol precursors.
   2. A cholesterol-loading diet, including lean meats, cheese, and eggs, was recommended beginning at approximately 29 weeks of gestation.
   3. Serial fetal ultrasounds were performed due to concern for intrauterine growth restriction, heart defects, or other anomalies associated with either SLOS or toxicity due to cholesterol precursors crossing the placenta.

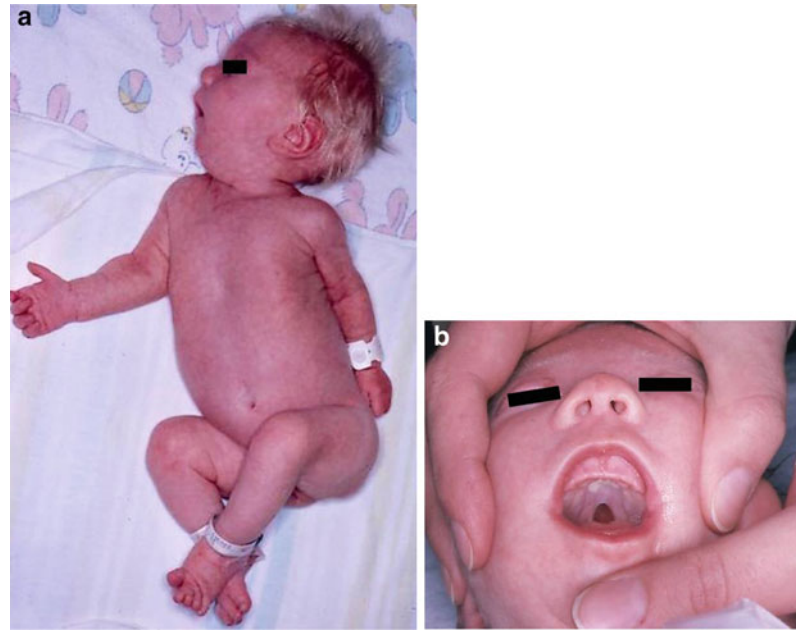

Fig. 1 (**a**, **b**) An infant (**a**) with Smith–Lemli–Opitz syndrome showing failure to thrive, ptosis, cleft palate (**b**), thick alveolar ridge, upturned nares, micrognathia, transverse palmar crease, and syndactyly between the second and third toes

Fig. 2 (**a**–**f**) A boy (**a**, **b**) with Smith–Lemli–Opitz syndrome showing characteristic facial features (epicanthal folds, ptosis of the eyelids, broad nose with upturned nares, and thick alveolar ridges), ambiguous genitalia (hypospadias) (**c**), umbilical hernia (**d**), transverse palmar crease (**e**), and talipes equinovarus (**f**)

Smith-Magenis Syndrome

Contents

Smith-Magenis syndrome (SMS) is a complex multiple congenital anomaly and mental retardation syndrome caused by an interstitial deletion of chromosome 17p11.2.

Synonyms and Related Disorders

Chromosome 17p11.2 deletion syndrome

Genetics/Basic Defects

1. Inheritance
    1. Autosomal dominant inheritance in virtually all cases of SMS occurring de novo
    2. Rare familial chromosome complex rearrangements leading to deletion (17)(p11.2) and SMS
2. Caused by an interstitial deletion of 17p11.2 in the majority of cases (Smith et al. 1986; Straton et al. 1986; Elsea et al. 1997; Potocki et al. 2003)
    1. A common deletion size observed in the majority of patients, derived from nonallelic homologous recombination between low-copy repeat gene clusters during either maternal or paternal gametogenesis
    2. Either smaller- or larger-sized deletions in about 20–25% of patients
3. Considered a contiguous gene syndrome (Greenberg et al. 1991)
    1. Haploinsufficiency of multiple functionally unrelated genes located in close proximity is responsible for the phenotype (Juyal et al. 1996).
    2. Deletion of a common interval spanning an estimated 4–5 Mb in majority of patients.
4. Sterol regulatory element-binding protein 1 (SREBF1) has been mapped to 17p11.2 within the SMS critical region (Chen et al. 1996). Therefore, the patients are hemizygous for the gene encoding SREBP1 leading to hypercholesterolemia.
5. Rare nondeletion cases (Potocki et al. 2003; Truong et al. 2010)
    1. Report of additional patients without a microdeletion, each harboring a mutation in *retinoic acid-induced 1* gene (*RAI1*), which maps within the SMS critical region (Slager et al. 2003).
    2. *RAI1* mutations: the second most frequent molecular etiology with this gene being located in the SMS locus at 17p11.2 (Dubourg et al. 2014).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_219

3. Haploinsufficiency of *RAI1* results in developmental delay, mental retardation, sleep disturbance, self-abusive behaviors, and most features commonly seen in SMS (Seranski et al. 2001).
4. Although *RAI1* is the primary gene responsible for most features of SMS, other genes within 17p11.2 contribute to the variable features and overall severity of the syndrome (Girirajan et al. 2006).
5. *MYO15* clearly associated with a specific phenotypic feature (sensorineural hearing impairment) in a patient with SMS who harbored a recessive mutation on the nondeleted allele (Liburd et al. 2001).

Clinical Features

1. Infantile hypotonia (Smith et al. 2010)
2. Feeding difficulties
3. Failure to thrive
4. Developmental delay
5. Distinctive craniofacial features (Chen et al. 1996; Allanson et al. 1999)
    1. Brachycephaly
    2. Broad square-shaped face
    3. Prominent forehead
    4. Synophrys
    5. Epicanthal folds
    6. Upslanted palpebral fissures
    7. Deep-set eyes
    8. Broad nasal bridge
    9. Marked midfacial hypoplasia
    10. Short full-tipped nose with reduced nasal height
    11. Micrognathia in infancy changing to relative prognathia with age
    12. Distinctive appearance of the mouth, with fleshy everted upper lip with a "tented" appearance
6. Otolaryngologic anomalies
    1. Speech delay
    2. Hoarse voice
    3. Velophalangeal insufficiency
    4. Tracheobronchial problems
7. Ocular anomalies
    1. Iris anomalies
    2. Microcornea
    3. Retinal detachment
8. Skeletal abnormalities (Spilsbury and Mohanty 2003)
    1. Short stature
    2. Scoliosis
    3. Brachydactyly
    4. Flat feet
9. Dermatological features (Guérin-Moreau et al. 2015)
    1. Skin features secondary to self-injurious behavior, such as bites, abrasions, dystrophic scars, limited spots of hyperkeratosis, anomalies of the nails, and whitlows, were found in the majority of patients.
    2. Acral pachydermia and fissured plantar keratoderma: common.
    3. Xerosis: constant and associated with extensive keratosis pilaris in the majority of patients.
    4. Dermatofibromas: frequent in older patients.
    5. Dense and shiny hair with an unusual hairline.
    6. Eyelash trichomegaly and heavy brows as well as folliculitis on the back: common.
10. Immune complex-mediated autoimmunity: adult onset of multiple autoimmune disorders (Yang et al. 2014)
    1. Systemic lupus erythematosus
    2. Antiphospholipid antibody syndrome
    3. Autoimmune hepatitis
11. Characteristic neurobehavioral phenotype (Dykens et al. 1997; Smith et al. 1998a, b; Willekens et al. 2000; Boddaert et al. 2004)
    1. Mental retardation (most patients in moderate range)
    2. Speech delay
    3. Signs of peripheral neuropathy
    4. Inattention
    5. Hyperactivity
    6. Maladaptive behaviors including frequent outbursts and temper tantrums
    7. Attention seeking
    8. Mimics attention deficit hyperactivity disorder (Gnanavel 2014)
    9. Impulsivity

10. Distractibility
11. Disobedience
12. Aggression
13. Toileting difficulties
14. Decreased sensitivity to pain
15. Self-injurious behaviors
    1. Self-hitting
    2. Self-biting
    3. Skin picking
    4. Inserting foreign objects into body orifices
    5. Yanking fingernails and/or toenails (onychotillomania)
16. Stereotypic behaviors (Dykens and Smith 1998)
    1. Specific to SMS
       1. Spasmodic upper-body squeeze or "self-hug"
       2. Hand licking and page flipping ("lick and flip")
    2. Additional stereotypes
       1. Mouthing objects or insertion of hand in mouth
       2. Teeth grinding
       3. Body rocking
       4. Spinning or twirling objects
17. Significant sleep disturbance (Smith et al. 1998b) potentially due to circadian rhythm abnormalities of melatonin (Potocki et al. 2000, 2003; De Leersnyder et al. 2001a)

12. Other features (Greenberg et al. 1996)
    1. Cardiac defects
    2. Renal and urinary tract abnormalities
    3. Thyroid function abnormalities
    4. Cleft lip/palate
    5. Hearing loss
    6. Seizures
    7. Immune function abnormalities, especially low IgA

Diagnostic Investigations

1. Cytogenetic studies for detection of an interstitial deletion of 17p11.2
    1. G-banded karyotype: may not detect small deletion especially when the indication of cytogenetic study is other than SMS
    2. Molecular cytogenetic analysis by FISH using a DNA probe specific for the SMS critical region
2. Molecular genetic testing of RAI1, the only gene known to account for the majority of features in SMS: available only on a clinical basis
3. Blood chemistry
    1. Hypercholesterolemia (Smith et al. 2002)
    2. Hypertriglyceridemia
    3. Qualitative immunoglobulins
    4. Thyroid function tests
4. Molecular analysis using single-nucleotide polymorphism array (Yang et al. 2014)
    1. A de novo 3.8-Mb deletion (breakpoints, chr17:16,660,721-20,417,975), resulting in haploinsufficiency for TACI (transmembrane activator and CAML interactor).
    2. The data are consistent with potential loss of function for the BAFF (B-cell-activating factor) receptor TACI as a contributing factor to human autoimmune phenomena.
5. Renal ultrasound for possible renal and urologic anomalies
6. Echocardiogram for possible cardiac defects
7. Radiography of the spine for scoliosis and other vertebral anomalies
8. EEG for clinical seizures
9. MRI (Maya et al. 2014) and PET imaging (Boddaert et al. 2004)
    1. Periventricular heterotopia
    2. Ventriculomegaly
    3. Hypoplasia of the cerebellar vermis
    4. Thin corpus callosum
    5. Thin brain stem
    6. A significant decrease of gray matter concentration in the insula and lenticular nuclei
    7. A significant hypoperfusion in the same regions
10. Diagnostic strategies (Elsea and Girirajan 2008)
    1. Fluorescent in situ hybridization (FISH): classical methods used to detect the SMS 17p11.2 microdeletion (90% of cases).

2. Molecular identification (sequence analysis) of a mutation in *RAI1* (remaining 10% of cases).
3. Whole genome chromosome microarray studies (CGH) will also identify 17p11.2 deletion involving *RAI1*.
4. Multiplex ligation-dependent probe amplification (MLPA) and real-time quantitative PCR are the newer cost-effective and high-throughput technologies.

Genetic Counseling

1. Recurrence risk (Smith et al. 2010).
   1. Patient's sib (Elsea and Girirajan 2008)
      1. Less than one percentage if parental chromosome analysis is normal, taking account of possible presence of parental germ line mosaicism
      2. An increased risk, provided a parent carries a chromosome rearrangement and dependent upon the specific chromosome rearrangement or if mosaicism for either a deletion (Zori et al. 1993) or *RAI1* mutation is present in either parent (mosaicism in a parent of an affected child is estimated at 3–5%)
   2. Patient's offspring
      1. Unlikely to have offspring due to severe phenotype
      2. Theoretically, a 50% risk of having offspring with SMS
2. Prenatal diagnosis: available for pregnancies at risk using a combination of routine cytogenetic studies and FISH.
   1. Amniocentesis
   2. CVS
3. Preimplantation genetic diagnosis may be available for families in which the disease-causing deletion or mutation has been identified.
4. Management.
   1. Early childhood intervention programs
   2. Special education
      1. Speech and language
      2. Physical and occupational
      3. Sensory integration
   3. Vocational training in later years.
   4. Psychotropic medications to increase attention and decrease hyperactivity.
   5. Behavioral modification.
   6. Administration of β_1-adrenergic antagonist and melatonin helps to manage hyperactivity, enhances cognitive performance, and reduces sleep disorders (de Leersnyder 2001b).
   7. Psychosocial support for the family.

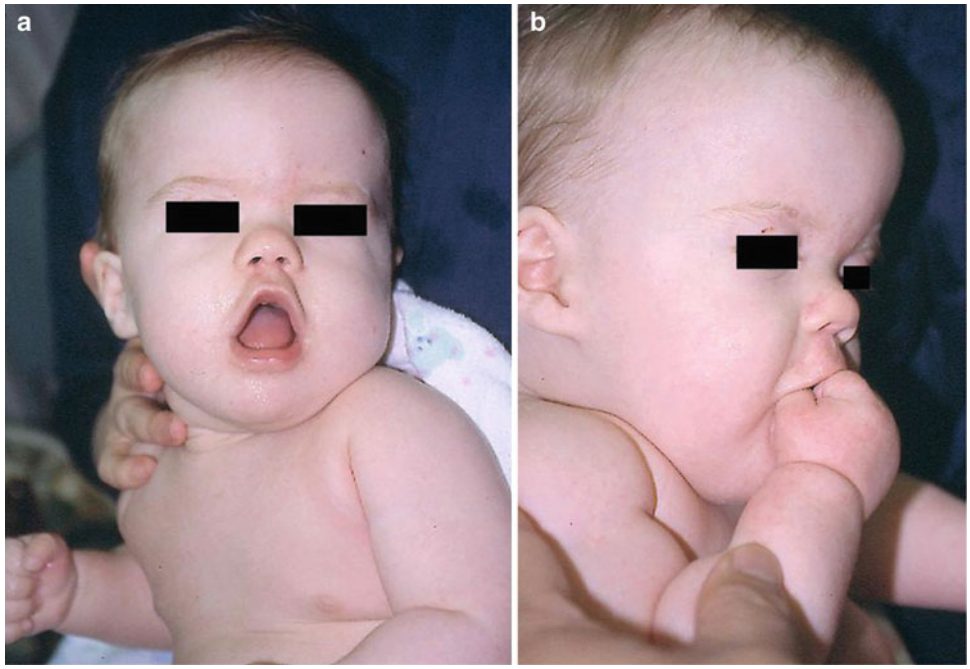

Fig. 1 (**a**, **b**) An infant with Smith-Magenis syndrome (**a**, **b**) showing prominent forehead, broad square-shaped face, synophrys, short full-tipped nose, and fleshy everted upper lip with a "tented" appearance. Chromosome analysis showed an interstitial deletion of 17p11.2

Fig. 2 Previous infant, now 16-year-old, was 4′10″ and ambulatory. She loves computer (changes pictures and knows command, search, and test-out with simple letters). However, she has behavior problems (difficult to handle, outburst, impulsive, anger, bite people, and seek attention) (Courtesy of Dr. Gerald Whitton)

Sotos Syndrome

Contents

Sotos syndrome was described by Sotos et al. (1964) in 1964 and is relatively common among overgrowth syndromes. It is also known as cerebral gigantism (Abraham and Snodgrass 1969).

Synonyms and Related Disorders

Cerebral gigantism; Malan syndrome (Sotos syndrome 2)

Genetics/Basic Defects

1. Inheritance: genetically heterogeneous (Boman and Nilsson 1980; Visser and Matsumoto 2003).
    1. Sporadic in majority of cases (>98%)
    2. Autosomal dominant inheritance reported in a few families (Hansen and Friis 1976; Winship 1985; Scarpa et al. 1994; Donnelly et al. 2011)
        1. Full penetrance
        2. Extremely variable phenotype
    3. Autosomal recessive inheritances postulated in some families
2. Discovery of human *n*uclear receptor *S*ET *d*omain-containing protein 1 (*NSD1*) gene (Hőglund et al. 2003).
    1. Report of a patient with Sotos syndrome who had t(5;8)(q35;q24.1) (Imaizumi et al. 2002).
    2. Discovery of a partial genomic sequence homologous to mouse *NSD1* near the breakpoint by constructing a BAC/PAC/cosmid contig covering the breakpoint.
    3. Human *NSD1* gene was subsequently isolated and characterized.
3. Molecular defect.
    1. A report of a child with Sotos phenotype and a de novo balanced translocation [46, XX,t(5;15)(q35;q22)] suggests a relationship between genetic material at 5q35 or 15q22 and the expression of an autosomal dominant gene (Maroun et al. 1994).
    2. The major cause of Sotos syndrome: haploinsufficiency of the *NSD1* gene (Kurotaki et al. 2002) at 5q35, because the majority of patients had either a common microdeletion including *NSD1* or a truncated type of point mutation in *NSD1*.
    3. *NSD1* gene mutations and deletions (Kamimura et al. 2003; Rio et al. 2003).
        1. Japanese patients (66%)
            1. Point mutations (48.5%)
            2. Deletions (18.2%)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_220

2. British patients (78%)
    1. Point mutations (70%)
    2. Large deletions (8%)
4. Size of the deletion correlates with severity of the phenotype.
5. Preferential paternal origin of microdeletions caused by prezygotic chromosome or chromatid rearrangements in Sotos syndrome (Miyake et al. 2003).
6. Mutations in *NSD1* are responsible for Sotos syndrome, but are not a frequent finding in other overgrowth phenotypes (Türkmen et al. 2003).
7. At least 10% of patients with clinical features of Sotos syndrome do not carry abnormalities in *NSD1* (Tatton-Brown and Rahman 2007).
    1. To date, 26 patients with Sotos-like overgrowth features have been described with either microdeletions encompassing the Nuclear Factor I-X gene (NFIX) at 19p13.2, point mutations, or small intragenic deletions (Malan et al. 2010; Yoneda et al. 2012; Priolo et al. 2012; Klaassens et al. 2014).
    2. *NFIX* mutations affecting the DNA-binding domain cause a peculiar overgrowth syndrome (Malan syndrome) (Gurrieri et al. 2015).
    3. Novel mutations of *NFIX* gene causing Marshall–Smith syndrome or Sotos-like syndrome (Martinez et al. 2015).
    4. Malan syndrome (Sotos syndrome 2) in two patients with 19p13.2 deletion encompassing NFIX gene and novel NFIX sequence variant (Jezela-Stanek et al. 2016).
8. Two siblings with Sotos features without mutations in NSD1 and detected a homozygous frameshift mutation in the *APC2* gene by whole-exome sequencing, which resulted in the loss of function of cytoskeletal regulation in neurons (Almuriekhi et al. 2015).

4. Patient with Dup(5)(q35.2-q35.3) reciprocal to the common Sotos syndrome deletion (Žilina et al. 2013).
    1. Some reciprocal genomic events, such as dup(5q35.2-q35.3), can result in opposite phenotypic outcome.
        1. Deletions in this locus lead to Sotos syndrome characterized by childhood overgrowth with advanced bone age, craniofacial dysmorphic features including macrocephaly, and learning difficulties, while duplications have been proposed to manifest in opposite phenotype related to growth.
        2. 5q35.2-q35.3 duplication phenotype: short stature since the birth, microcephaly, brachydactyly, delayed bone age, mild to moderate intellectual disability, and mild facial dysmorphism.
    2. Clinical presentation of three new cases with 5q35 microduplication, encompassing *NSD1* gene, outlining a novel syndrome characterized by microcephaly, short stature, developmental delay, and in some cases delayed bone maturation, without any typical facial or osseous anomalies (Novara et al. 2014).
5. No satisfactory explanation for the overgrowth.

Clinical Features

1. Prenatal and postnatal overgrowth (major clinical features)
    1. Large for gestational age at birth
    2. Excessive growth velocity, particularly in the first 3–4 years
    3. Advanced bone age by 2–4 years over chronological age during childhood
    4. Large hands and feet
    5. Excessive heights in some adult patients
2. Performance
    1. Developmental retardation
    2. Mental deficiency of varying degree
    3. Lack of fine motor control
    4. Difficulties in neonatal adaptation and/or feeding
3. Characteristic craniofacial appearance (Cole and Hughes 1990; Allanson and Cole 1996)
    1. Dolichocephalic large head
    2. Prominent forehead

3. Ocular hypertelorism
4. Downslanting of the palpebral fissures
5. High-arched palate
6. Premature teeth eruptions
7. Pointed chin (prominent mandible)

4. CNS manifestations
   1. Hypotonia
   2. Seizures
   3. Clumsy gait
   4. Mildly enlarged ventricles
   5. Increased subarachnoid spaces
   6. Agenesis/hypoplasia of the corpus callosum
   7. Agenesis of the septal pellucidum
   8. Hypoplasia/atrophy of the cerebellar vermis
   9. Large cisternal magna
   10. Abnormal Sylvian fissure
5. Neoplasms (3.9%) (Cohen 1999)
   1. Benign tumors
      1. Multiple hemangiomas
      2. Osteochondroma
      3. Large hairy nevus
      4. Giant-cell granulomas of the mandible
   2. Malignant tumors
      1. Wilms tumor
      2. Neuroblastoma
      3. Hepatocellular carcinoma
      4. Epidermoid carcinoma of the vagina
      5. Small-cell carcinoma of the lung
6. Other features
   1. Severe connective tissue laxity, manifesting as redundant skin, joint hypermobility, vesicoureteric reflux, and aortic dilatation in four patients with novel truncating mutations in *NSD1* (Hood et al. 2016)
   2. Strabismus
   3. Pes planus
   4. Kyphoscoliosis
   5. Asymmetric leg length
   6. Syndactyly
   7. Congenital heart defects (Noreau et al. 1998)
      1. Septal defects
      2. Persistent ductus arteriosus
      3. Ebstein malformation
   8. Functional megacolon
   9. Urinary anomalies
      1. Hypoplastic kidney
      2. Hydronephrosis
      3. Vesicoureteric reflux
   10. Recurrent hernias
   11. Abnormal dermatoglyphics
7. Social difficulties and neuropsychiatric disorders (Sarimski 2003)
   1. Social difficulties
      1. Emotional immaturity
      2. Poor motor control
      3. Temper tantrums
      4. Good social skills in some patients
   2. Neuropsychiatric disorders (Mouridsen and Hansen 2002)
      1. Intellectual impairment
      2. Learning disabilities
      3. Language impairments
      4. Behavioral disorders
8. Differential diagnosis (Tatton-Brown et al. 2015): classified into two groups (Cole and Hughes 1994)
   1. Group 1: relatively easy to distinguish because of other specific associated features.
      1. Constitutional gigantism (alone)
      2. Marfan syndrome (please see the chapter on "▶ Marfan Syndrome")
      3. Neurofibomatosis (please see the chapter on "▶ Neurofibromatosis 1")
      4. Beckwith–Wiedemann syndrome (please see the chapter on "▶ Beckwith-Wiedemann Syndrome")
      5. Marshall–Smith syndrome
      6. Adrenogenital and gonadal secreting tumors
      7. Klinefelter syndrome (please see the chapter on "▶ Klinefelter Syndrome")
      8. Acromegaly
   2. Group 2: the syndromes in this group cause more difficulties.
      1. Ruvalcaba–Myhre–Smith (Bannayan–Riley–Ruvalcaba) syndrome: characterized by macrocephaly, vascular malformations, hamartomatous polyps of the distal ileum and colon, pigmented macules on the shaft of the penis, lipomas, and increased risk of

thyroid and breast cancer. Pathogenic variants in PTEN have been found in about 65% of cases. A somewhat similar facial gestalt in combination with overgrowth may lead to confusion with Sotos syndrome, but a detailed clinical examination and molecular genetic testing should differentiate the two conditions (please see the chapter on "▶ Bannayan-Riley-Ruvalcaba Syndrome)."

2. EZH2-related Weaver syndrome (also known as Weaver–Smith syndrome): please see the description below.
3. Simpson–Golabi–Behmel syndrome type 1 (SGBS1): this X-linked condition is also associated with pre- and postnatal overgrowth in males. However, other features of SGBS not typically found in Sotos syndrome include polydactyly, supernumerary nipples, diastasis recti, and pectus excavatum. The facial gestalt also differs between the two disorders. Mutation of GPC3 is causative.
4. Fragile X syndrome (please see the chapter on "▶ Fragile X Syndrome").
5. Benign familial macrocephaly: this autosomal dominant condition is characterized by dolicho- and/or macrocephaly in an individual who is otherwise neurologically normal. It is likely a heterogeneous condition and is usually a diagnosis of exclusion.
6. Nevoid basal cell carcinoma syndrome (NBCCS or Gorlin syndrome): characterized by the development of multiple jaw keratocysts, frequently beginning in the second decade of life, and/or basal cell carcinomas usually from the third decade onward. Most individuals have skeletal anomalies such as bifid ribs or wedge-shaped vertebrae. About 60% of individuals have a recognizable appearance with macrocephaly, bossing of the forehead, and coarse facial features. Head circumference increases above the 98th centile until age 10–18 months, but is not usually associated with global developmental delay. NBCCS is caused by germ line pathogenic variants in *PTCH* and is inherited in an autosomal dominant manner.
7. Chromosome abnormalities: a Sotos syndrome-like phenotype has been associated with 4p duplications, 19p13.2 microduplication (Lehman et al. 2012), mosaic 20p trisomy (Faivre et al. 2000), and 22q13.3 deletion syndrome.
8. Nonspecific overgrowth: many individuals with overgrowth do not fulfill the diagnostic criteria for any of the above conditions but nevertheless have other features (e.g., learning difficulties, distinctive facial features) that suggest an underlying genetic cause. Nonspecific overgrowth is likely to be a heterogeneous group of conditions with multiple causes.

9. Weaver syndrome: the major differential diagnosis (Opitz et al. 1998; Douglas et al. 2003)
    1. Seen less commonly than Sotos syndrome
    2. Caused by *NSD1* mutations in a significant number of patients
    3. Cardinal features
        1. Accelerated growth
        2. Distinctive facies with micrognathia and a deep horizontal chin crease
        3. Advanced bone age
        4. Developmental delay
    4. Additional features
        1. A hoarse low-pitched cry
        2. Metaphyseal flaring of the femurs
        3. Deep-set nails
        4. Prominent finger pads
        5. Camptodactyly

Diagnostic Investigations

1. Glucose intolerance (14%).
2. Radiography.
    1. Advanced bone age.
    2. Cephalometric radiographs: steepness of the anterior cranial base angle and

protrusion of the middle and lower face, shown in all three patients from a family (Bale et al. 1985).
3. Metacarpophalangeal pattern profile analysis (Butler et al. 1988): the mean hand profile contained a major peak in the proximal phalangeal area and a smaller peak in the metacarpal area, while the distal hand bones were relatively short.

3. CNS lesions by CAT scan and/or MRI of the brain (Schaefer et al. 1997; Gusmão Melo et al. 2000).
   1. Ventricles
      1. Ventriculomegaly
      2. Prominent trigone of the lateral ventricles
      3. Prominent occipital horn
   2. Extracerebral fluid
      1. Increased supratentorial space
      2. Increased posterior fossa space
   3. Midline anomalies
      1. Persistent cavum septum pellucidum
      2. Persistent cavum vergae
      3. Cavum velum interpositum
      4. Macrocisterna magna
      5. Agenesis of corpus callosum
      6. Hypoplasia (thinning) of corpus callosum
   4. Migration abnormalities
   5. Periventricular leukomalacia
   6. Macrocerebellum
   7. Open operculum
4. Cytogenetic testing.
   1. Most affected individuals do not have a cytogenetic abnormality.
   2. Rare cytogenetic abnormality such as a translocation involving 5q35 results in Sotos syndrome (Kurotaki et al. 2003).
5. DNA analysis: NSD1 abnormalities, such as truncating mutations, missense mutations in functional domains, partial gene deletions, and 5q35 microdeletions encompassing NSD1, are identifiable in the majority (49%) of Sotos syndrome cases (Tatton-Brown and Rahman 2007).
   1. Intragenic sequence analysis/mutation scanning
   2. Deletion/duplication analysis
      1. 5q35 microdeletion analysis/*NSD1* whole gene deletion analysis
      2. *NSD1* exonic/multiexonic gene deletions

Genetic Counseling

1. Recurrence risk (Tatton-Brown and Rahman 2007)
   1. Patient's sib
      1. Most individuals with Sotos syndrome are the result of de novo mutations.
      2. No affected siblings of unaffected parents have been reported, indicating that the incidence of germ line mosaicism must be low.
      3. Therefore, the recurrence risk of unaffected parents approximates to the population risk, which is estimated to be about 1:15,000.
   2. Patient's offspring: a 50% risk as for other autosomal dominant conditions
2. Prenatal testing and preimplantation genetic diagnosis of Sotos syndrome (Tatton-Brown et al. 2015)
   1. Ultrasonography in the third trimester (Chen et al. 2002; Chen 2012).
      1. Macrocephaly
      2. Ventriculomegaly
      3. Hypoplasia of the corpus callosum
      4. An enlarged cisterna magna
      5. Overgrowth
      6. Unilateral hydronephrosis
      7. Polyhydramnios
   2. Prenatal diagnosis possible by molecular mutation analysis of fetal DNA obtained from amniocytes or CVS of previously identified disease-causing *NSD1* gene: available on a clinical basis.
   3. Preimplantation genetic diagnosis may be available for families in which the disease-causing mutation has been identified.
3. Prenatal findings and the genetic diagnosis of fetal overgrowth disorders (Chen 2012)

1. Simpson–Golabi–Behmel syndrome
    1. Macrosomia
    2. Polyhydramnios
    3. Elevated maternal serum α-fetoprotein (MSAFP)
    4. Cystic hygroma
    5. Hydrops fetalis
    6. Increased nuchal translucency
    7. Craniofacial abnormalities
    8. Visceromegaly
    9. Renal anomalies
    10. Congenital diaphragmatic hernia
    11. Polydactyly
    12. A single umbilical artery
2. Beckwith–Wiedemann syndrome
    1. Macrosomia
    2. Polyhydramnios
    3. Macroglossia
    4. Omphalocele
    5. Placentomegaly
    6. A long umbilical cord
    7. Echogenic kidneys
    8. Pancreatic cystic dysplasia
4. Management:
    1. No specific therapy exists.
    2. Supportive management for cardiac abnormalities, seizures, renal problems, and scoliosis
    3. Referral to appropriate specialist for learning/behavior/speech difficulties.

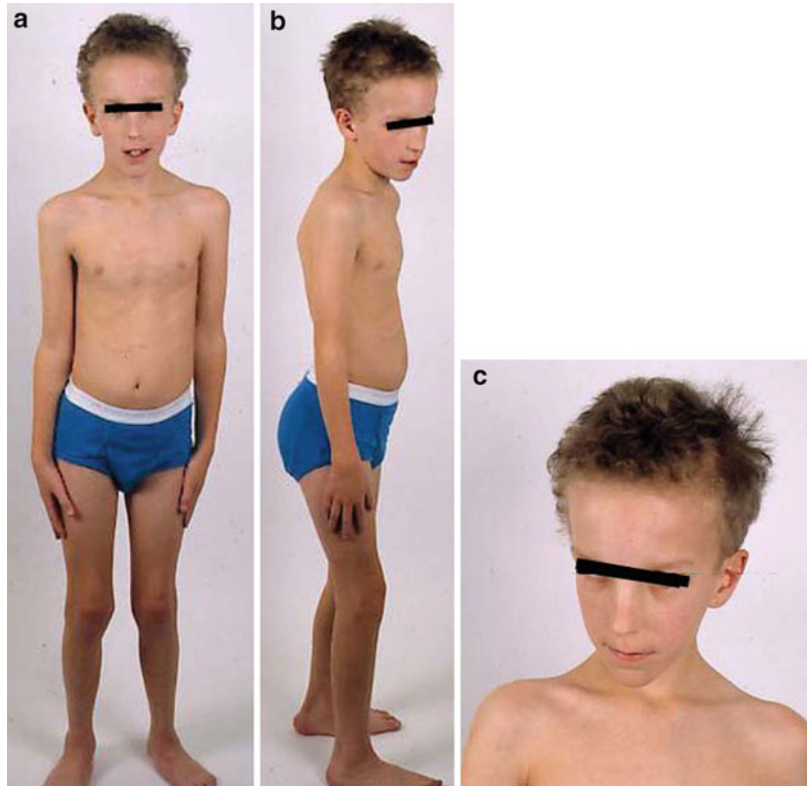

Fig. 1 (**a**–**c**) A child with Sotos syndrome showing excessive growth, a large dolichocephalic head, prominent forehead, downslanting palpebral fissures, and a pointed chin

Fig. 2 The radiograph of the hand from a 20-month-old, showing advanced bone age (3 years)

Fig. 3 (**a**–**c**) A 5-year-old girl (**a**) with Sotos syndrome showing gigantism, large head, prominent forehead, large hands and feet, and MRI findings of enlarged subarachnoid spaces, mild ventriculomegaly, thinning of the corpus callosum, and mild polymicrogyria (**b**, **c**)

Fig. 4 (**a**–**c**) An adult with Sotos syndrome showing excessive height (compared with other family members) (**a**); prominent forehead, hypertelorism, and a pointed chin (**b**); and large hands and feet (**c**) (compared to normal adult). Chromosome analysis by FISH showed duplicated 4p15.2 and deleted 4q32. Both parents have normal chromosomes

Fig. 5 (**a**–**c**) A 2-year-old girl with Sotos syndrome has excessive height, weight, and head circumference, advanced bone age, and delayed development. The skull is characterized by dolichocephaly, frontal bossing, and deep-set eyes. Molecular study showed two variants of unknown significance: c.1515 T > C (p.N505N) and c.1515 T > C (p.L1956P). There were no apparent deletions or duplications within the coding region of NSD1

Spinal Muscular Atrophy

Contents

Spinal muscular atrophy (SMA) is a disorder characterized by degeneration of lower motor neurons and occasionally bulbar motor neurons, leading to progressive limb and trunk paralysis as well as muscular atrophy. It is a clinically and genetically heterogeneous group of neuromuscular diseases. It is the second most common lethal autosomal recessive disorder after cystic fibrosis in Caucasian populations with an overall incidence of 1 in 10,000 live births and a carrier frequency of approximately 1 in 50 (Biros and Forrest 1999).

Synonyms and Related Disorders

Adult SMA; Arthrogryposis multiplex congenita-SMA; Congenital axonal neuropathy; Dubowitz disease; Kugelberg-Welander disease; Werdnig-Hoffman disease

Genetics/Basic Defects

1. Inheritance
    1. Autosomal recessive in most cases (SMA1, SMA2, SMA3) (Crawford and Pardo 1996)
    2. Autosomal dominant in both juvenile and adult form, representing 2% of infantile and about 30% of adult SMA (Pearn 1978)
    3. X-linked infantile spinal muscular atrophy (Xp11.3-q11.2) (Dressman et al. 2007)
2. Caused by mutation or deletion of *survival motor neuron-1* (*SMN1*) (Lefebvre et al. 1995)
3. Mutation in all three forms (SMA1, SMA2, and SMA3) mapped to chromosome 5q13 (SMA critical region) (Roy et al. 1995; Brahe and Bertini 1996)
4. SMN deletions
    1. High frequency of *SMN* deletions in SMA patients (92.8%) provides a direct and accurate genetic test for:
        1. Diagnostic confirmation of SMA
        2. Prenatal prediction of SMA
    2. Homozygous deletion of *SMN* observed in:
        1. Atypical forms of SMA associated with congenital heart defects
        2. Arthrogryposis
        3. Some cases of congenital axonal neuropathy
        4. Some patients affected with adult form of SMA
    3. Rare cases of homozygous *SMN* exon 7 deletion or conversion reported in

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_221

asymptomatic relatives of haploidentical type II or III SMA patients
4. Absence of deletion of the *SMN* gene or linkage to chromosome 5q in (Zerres et al. 1997):
    1. SMA associated with diaphragmatic involvement
    2. SMA with olivopontocerebellar atrophy
    3. Autosomal dominant form of SMA
    4. Amyotrophic lateral sclerosis
    5. Post-polio syndrome
5. Molecular-phenotype correlation (Lorson et al. 2010; MacKenzie 2010)
    1. Phenotype of SMA associated with disease-causing mutations of the *SMN* gene spans a continuum without a clear delineation of subtypes.
    2. The severity of the SMA phenotype inversely correlated with:
        1. *SMN2* copy number: The greater the *SMN2* copy number (both in infants and children with spinal muscular atrophy and in mouse models), the milder the disease.
        2. The level of full-length SMN protein produced by *SMN2* (~10–15% compared with *SMN1*).

Clinical Features

1. Variability of clinical features and severity (Arnold et al. 2015):
    1. The predominant clinical features of SMA: muscle weakness and atrophy attributed to motor neuron dysfunction and loss.
    2. Weakness: usually symmetric and proximally predominant.
    3. The spectrum of severity: ranges from mild proximal limb weakness noticed in adulthood to severe generalized weakness with respiratory failure in the neonatal period.
    4. Lower limbs: more involved than upper limbs, and bulbar and respiratory weakness usually occurs in patients with more severe limb weakness.
    5. Onset and progression of weakness: distinct from many other motor neuron disorders in that there is usually a presymptomatic period in all but the most severe cases (type 0), followed by rapidly progressive functional loss and a later relatively static phase with slow progression.
2. Existing classification system based on age of onset of symptoms, useful for prognosis and management (Tsao 2013):
    1. Congenital axonal neuropathy (Korinthenberg et al. 1997)
        1. Prenatal onset of SMA
        2. Decreased fetal movement
        3. Maternal polyhydramnios
        4. Severe muscle weakness (hypotonia)
        5. Absence of movement
        6. Joint contractures
        7. Facial diplegia
        8. Ophthalmoplegia
        9. Respiratory failure requiring immediate endotracheal intubation and ventilation
        10. Death from respiratory failure within days
    2. Arthrogryposis multiplex congenita-SMA (Burglen et al. 1996)
        1. Prenatal onset of SMA
        2. Decreased fetal movement
        3. Maternal polyhydramnios
        4. Breech presentation
        5. Severe muscular weakness (hypotonia)
        6. Arthrogryposis multiplex congenita
        7. Absence of movement except for extraocular and facial movement
        8. Death from respiratory failure before 1 month of age
    3. SMA1 (acute spinal muscular atrophy, Werdnig-Hoffman disease) (Byers and Banker 1961; Thomas and Dubowitz 1994)
        1. Represents about 30% of all SMA cases
        2. Onset before 6 months of age
        3. The most severe form with fatal outcome
        4. Severe generalized muscular weakness (hypotonia)
        5. Lack of motor development

6. Mild joint contractures at the knees and rarely at the elbows
7. Most severely affected neonates:
    1. Difficulty in sucking and swallowing
    2. Abdominal breathing
8. Facial muscles spared completely with a bright, normal expression
9. Ocular muscles and the diaphragm not involved until late in the course of the disease
10. Fasciculation of the tongue seen in most but not all cases
11. Intercostal paralysis with severe collapse of the chest: the rule
12. Affected children unable to sit without support
13. Absence of tendon reflexes (areflexia)
14. Normal intelligence
15. Usually die within 2 years due to the following:
    1. Feeding difficulty
    2. Breathing difficulty

4. SMA2 (chronic infantile spinal muscular atrophy, Dubowitz disease)
    1. Represent about 45% of SMA cases
    2. Onset between 6 and 12 months
    3. The intermediate form (a more slowly progressive generalized disease with a variable prognosis)
    4. Poor muscle tone at birth or within first 2 months of life
    5. Slow attainment of motor milestones
        1. Not sitting independently by age 9–12 months
        2. Not standing by 1 year of age
    6. Frequent tongue fasciculation and atrophy
    7. Common finger trembling and general flaccidity
    8. Diminished or absent deep tendon reflexes
    9. Intact sensation
    10. Loss of the ability to sit independently by the mid-teens
    11. Slow or arrest of clinical progression
    12. Severe scoliosis if untreated
    13. Defect in respiratory ventilation
    14. Highly variable life expectancy, ranging up to adult life in some cases
5. SMA3 (juvenile spinal muscular atrophy, Kugelberg-Welander disease) (Kugelberg and Welander 1956)
    1. Represents about 8% of all SMA cases
    2. Childhood onset after 12 months (usually after 18 months to 30 years of life)
    3. The mild chronic form
    4. Motor milestones
        1. Ability to walk but frequent fall on walking
        2. Trouble walking upstairs and downstairs at age 2–3 years
    5. Muscle weakness
        1. Proximal muscle weakness associated with muscle atrophy
        2. Legs more severely affected than the arms
    6. Normal sensation
    7. No evidence of upper motor neuron involvement
    8. Hypertrophy of the calves in about 25% of cases
    9. Prognosis generally correlates with the maximum motor function attained.
    6. SMA4 (adult SMA)
        1. Adult onset (after 20 or 30 years of age)
        2. Muscle weakness (after 30 years of age)
        3. Clinical features similar to those described for SMA3 with evidence of lower motor neuron involvement
            1. Tongue fasciculations
            2. Muscle atrophy
            3. Depressed deep tendon reflexes
            4. Normal sensation

3. Dubowitz classification of childhood SMA (Dubowitz 1995):
    1. Type 1: severe (variable)
    2. Type 2: intermediate (variable)
    3. Type 3: mild (variable)
    4. Type 4.0: normal
4. Subtypes of childhood SMA (Munsat 1991; Nicole et al. 2002; Carre and Empey 2015):
    1. Type 0
        1. Age of onset: prenatal

2. Clinical presentations
    1. Most severe
    2. Lack of fetal movement
    3. Arthrogryposis
    4. Joint contractures
    5. Fatal at birth unless respiratory/medical support is available.
2. Type I
    1. Age of onset: birth to 6 months
    2. Clinical presentations
        1. Severe generalized muscle weakness and hypotonia at birth
        2. Motor milestones: never sit alone
        3. Death from respiratory failure in less than 2 years
3. Type II
    1. Age of onset: 6–12 months
    2. Clinical presentations
        1. Motor milestones: able to sit, unable to walk or stand without aid
        2. Death: >2 years
4. Type III
    1. Age of onset: after 18 months
    2. Clinical presentations
        1. Milder form
        2. Motor milestones: can stand and walk unaided but lose ambulation as disease progresses
        3. Death: adult
5. Type IV
    1. Age of onset: adolescence to adulthood
    2. Clinical presentations: like type III, but rarely diagnosed

5. Consider diagnosis of SMA in infants presenting with the following clinical features:
    1. During neonatal period
        1. Severe hypotonia
        2. Absent movement
        3. Contractures, usually of a mild degree
        4. Evidence of anterior horn cell (i.e., lower motor neuron) involvement
            1. Tongue fasciculations
            2. Absence of deep tendon reflexes
        5. Respiratory failure
        6. Variable cranial nerve involvement usually apparent late in the course
            1. Ophthalmoplegia
            2. Facial diplegia
    2. After neonatal period
        1. Poor muscle tone
        2. Symmetric muscle weakness
            1. Sparing the ocular muscles
            2. Involving the facial muscles and diaphragm late in the course of the disease
        3. Delayed acquisition of motor skills
        4. Evidence of anterior horn (i.e., lower motor neuron) involvement
            1. Tongue fasciculations (seen in only 65% of patients)
            2. Absence of deep tendon reflexes
        5. Normal reaction to sensory stimuli
        6. Normal intelligence
6. Natural history (Lorson et al. 2010; MacKenzie 2010):
    1. Clinical features of the disease are caused by specific degeneration of α-motor neurons in the spinal cord, leading to muscle weakness, atrophy, and, in the majority of cases, premature death.
    2. Most afflicted infants and children, while largely neurologically and completely cognitively intact, grow progressively weaker over time, with many ultimately succumbing to respiratory failure at a young age.
    3. The natural history of SMA has been altered over the past several decades, primarily through supportive care measures, but an effective treatment does not presently exist.
7. Spinal muscular atrophy not linked to *SMN* gene (Wang et al. 2007; Savas et al. 2014):
    1. Scapuloperoneal spinal muscular atrophy
        1. Inheritance (gene locus): autosomal dominant (gene mapped on 12q24.1–q24.31)
        2. Clinical presentations
            1. Congenital absence of muscles
            2. Progressive weakness of scapuloperoneal and laryngeal muscles
    2. Pontocerebellar hypoplasia with spinal muscular atrophy (Barth 1993)
        1. Inheritance (gene locus): autosomal recessive (*VRK1*)
        2. Clinical presentations
            1. Onset at 0–6 months
            2. Cerebellar and brainstem hypoplasia

3. Absent dentate nucleus
4. Neuronal loss in basal ganglia
5. Cortical atrophy

3. X-linked infantile spinal muscular atrophy with arthrogryposis
   1. Inheritance (gene locus): X-linked (gene mapped on Xp11.3–q11.2)
   2. Clinical presentations
      1. Onset at birth or infancy
      2. Contractures
      3. Death before 2 years of age
4. Spinal muscular atrophy with respiratory distress type 1 (Grohmann et al. 2003)
   1. Inheritance (gene locus): autosomal recessive (gene mapped on 11q13.2–q13.4)
   2. Clinical presentations
      1. Onset within the first 3 months of age
      2. Eventuation of the right or both hemidiaphragms
      3. Finger contractures
      4. Pes equinus foot deformities
5. Congenital SMA with predominant lower limb involvement (Fleury and Hageman 1985)
   1. Inheritance (gene locus): autosomal dominant or sporadic (*DYNC1H1*)
   2. Clinical presentations
      1. Arthrogryposis
      2. Weakness, especially distal lower limbs early
      3. Nonprogressive but severe disability
6. Congenital SMA with predominant upper limb involvement (Darwish et al. 1981; Hageman et al. 1993)
   1. Inheritance (gene locus): unknown
   2. Clinical presentations
      1. Arthrogryposis
      2. Weakness, especially distal upper limbs early
      3. Nonprogressive

Diagnostic Investigations

1. Increased serum creatine phosphokinase (CK) activity in about half of the patients with type III SMA
2. Electromyography (EMG)
   1. During voluntary effort
      1. Spontaneous discharge activity in resting muscle
      2. Increased amplitude
      3. Prolonged duration of motor unit potentials
   2. Severe denervation commonly found in older patients
   3. Nerve conduction velocity
      1. Generally considered normal (Emery 1971)
      2. Some decrease in velocity in severe case
3. Muscle histology (Emery 1971)
   1. Denervation changes with small groups of atrophic muscle fibers associated with markedly hypertrophied fibers.
   2. Small angular fibers randomly intermixed with normal-sized fibers.
   3. Atrophic fibers arranged in groups
      1. Usually of uniform fiber type based on the myosin ATPase reaction
      2. Considered as an extensive collateral reinnervation of previously denervated muscle fibers by sprouts from surviving motor neurons
   4. In SMA type III, but not in infantile SMA (type I or II)
      1. Markedly hypertrophic fibers
      2. Excessive variation in fiber size
      3. Internal nuclei
      4. Observation of degenerative changes with necrosis and regenerative fibers associated with proliferative interstitial connective tissue
         1. Interpreted as “pseudomyopathic” changes.
         2. Usually found in patients with high serum levels of CK activity suggesting the presence of a myopathic process secondary to neurogenic process.
         3. These pseudomyopathic changes not observed in other human neurogenic diseases suggest that they can be specific to the molecular mechanism resulting in or associated with juvenile SMA.

4. Neuropathologic features found at autopsy of SMA patients
    1. Loss of the large anterior horn cells of the spinal cord (most striking feature)
    2. Severe degree of central chromatolysis in the remaining surviving motor neurons, appearing as large ballooned cells without stored substances
    3. Other anterior horn cells
        1. Pyknotic
        2. Presence of occasional figures of neuronophagia associated with astrogliosis
        3. Small anterior roots
5. Algorithm of diagnostic tests for a patient suspected to have SMA (D'Amico et al. 2011)
    1. Homozygous SMN1 deletion detected: confirm 5q SMA diagnosis
    2. Homozygous SMN1 deletion not detected
        1. Creatine kinases dosage and electrophysiological tests such as electromyography (EMG), and nerve conduction study, should be performed. If EMG suggests a motor neuron disease, then further testing for SMN mutations should be pursued.
        2. SMN1 gene copy number testing using multiplex ligation-dependent probe amplification (MLPA) or real-time PCR.
        3. If the patient has a single *SMN1* copy, it is mandatory to sequence the coding region of the undeleted allele to identify the second causative mutation, generally subtle sequence variations, including point mutations, insertions, and deletions.
        4. However, in about one third of patients with a typical clinical picture and a single SMN1 copy, the second mutation is not found in *SMN1*/*SMN2* coding region. This finding is more common in type III SMA and might be due to the presence of deep intronic mutations, unidentified so far. Finally, sequence analysis of SMN1 gene is suggested also in those patients who have a typical clinical picture, two *SMN1* copies, and are born to consanguineous parents or originate from genetic isolates. Indeed, rare patients homozygous for *SMN1* subtle mutations have been occasionally reported.
        5. Conversely, in a patient with two *SMN1* copies, SMA diagnosis, related to SMN1 mutations, is virtually excluded, and other motor neuron disorders such as spinal muscular atrophy with respiratory distress (SMARD1), X-linked spinal muscular atrophy, distal SMA, and juvenile amyotrophic lateral sclerosis should be considered.
        6. If the electrophysiological examination excludes a motor neuron disease, the child should be reexamined and must receive additional diagnostic testing considering other disorders.
6. Molecular diagnosis of SMA (Prior and Russman 2011)
    1. Molecular testing for homozygous deletion or mutation of the *SMN1* gene allows efficient and specific diagnosis. In combination with loss of *SMN1*, patients retain variable numbers of copies of a second similar gene, *SMN2*, which produces reduced levels of the survival motor neuron (SMN) protein that are insufficient for normal motor neuron function (Arnold et al. 2015).
    2. The following relatively simple DNA tests enable confirmation of a suspected clinical diagnosis of SMA or prediction of the outcome of a pregnancy in families with a history of SMA (Biros and Forrest 1999).
        1. SSCP analysis
        2. PCR followed by restriction enzyme digestion
    3. Mutation analysis of *SMN1* available on clinical basis.
        1. Used to detect deletion of exons 7 and 8 of *SMN1*
        2. Homologous deletions of exon 7 of *SMN1* in 95% of cases with clinical diagnosis of SMA (Ogino et al. 2002)
        3. Compound heterozygotes for deletion of *SMN1* exon 7 and an intragenic mutation of *SMN1* in 2–5% of patients with a clinical diagnosis of SMA
    4. Sequence analysis of all *SMN1* exons and intron/exon borders available on clinical basis.

1. Used to identify the intragenic *SMN1* mutations present in the 2–5% of patients who are compound heterozygotes
2. Limitations
    1. Cannot determine whether the point mutation is in the SMN1 gene or the SMN2 gene, unless one of these genes is absent
    2. Does not detect exonic duplications
    3. Cannot detect deletions of whole exons if more than one SMN gene copy is present

5. Duplication analysis to determine *SMN2* copy number.
    1. *SMN2* copy number ranges from 0 to 5
    2. Quantitative PCR: currently used for accurate determination of *SMN2* copy number
6. SMA carrier testing (gene dosage analysis) available clinically.
    1. Mutation analysis not reliable for carrier detection since it does not quantitate the number of *SMN1* gene copies.
    2. A PCR-based dosage assay (called SMA carrier testing or *SMN* gene dosage analysis) allows for the determination of the number of *SMN1* gene copies, thus permitting highly accurate carrier detection.
    3. Dosage analysis to differentiate carriers from non-carriers (Zeesman et al. 2002).
7. Linkage analysis available on clinical basis.
    1. Available to families in which direct DNA testing is not informative
    2. May be used for confirmation of carrier testing results and prenatal testing results
8. UBA1 sequence analysis for X-linked infantile spinal muscular atrophy (Baumbach-Reardon et al. 2012)

7. Newborn screening: An effective technology exists for newborn screening of SMA (Prior et al. 2010).

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. Autosomal recessive inheritance: 25%
        2. Autosomal dominant inheritance: not increased unless a parent is affected
        3. X-linked recessive inheritance (Baumbach-Reardon et al. 2012): If the mother of the proband has a disease-causing mutation, the chance of transmitting it in each pregnancy is 50%. Male sibs who inherit the mutation will be affected; female sibs who inherit the mutation will be carriers and will usually not be affected.
    2. Patient's offspring: only milder forms of SMA likely to reproduce
        1. Autosomal recessive inheritance
            1. All offspring: carriers
            2. Recurrence risk not increased unless the spouse is affected or a carrier (Carre and Empey 2015)
        2. Autosomal dominant inheritance: 50%
        3. X-linked recessive inheritance (Baumbach-Reardon et al. 2012): Males with a severe phenotype do not generally survive; males with milder phenotypes will pass the disease-causing mutation to all of their daughters and none of their sons.
2. Prenatal diagnosis (Matthijs et al. 1998; Stewart et al. 1998; Baumbach-Reardon et al. 2012; Carre and Empey 2015)
    1. Possible to detect fetuses at 25% risk when the disease-causing *SMN* mutations in both parents are known
    2. Mutation analysis on fetal DNA obtained from CVS or amniocentesis
    3. Prenatal diagnosis cannot predict the clinical outcome in terms of severity, because the number of copies of *SMN2* is not specific to each SMA subtype: two copies of *SMN2* can be present in either SMA type 1 or type 2 (Feldkötter et al. 2002)
    4. Linkage analysis
        1. Many diagnostic laboratories still perform linkage analysis in addition to direct SMN^T mutation analysis in families where the previously affected child lacks both copies of SMN^T, since there are people in the normal population who lack both copies of SMN^T but not clinically affected.

2. The only option available to the families where no deletion has been observed but the clinical findings are consistent with 5q SMA.
5. Preimplantation genetic diagnosis: available clinically for families in which the disease-causing mutations have been identified in an affected family member

3. Management (Iannaccone 2007; Sendtner 2010)
   1. Treat and prevent complications of weakness and maintain quality of life.
   2. Several organ systems affected by weakness.
      1. Respiratory (restrictive lung disease)
         1. Noninvasive ventilation support using new technology for patients with sufficient orofacial muscle strength. Long-term ventilatory support is not usually considered.
         2. A new awareness of the importance of identifying sleep-disordered breathing.
         3. A new multidisciplinary approach to standard of care.
      2. Gastrointestinal (dysphagia): feeding gastrostomy for children with difficulty in sucking and swallowing
      3. Orthopedic (progressive deformities)
         1. Orthosis to allow to sit upright rather than be bedridden
         2. Option of surgical repair for the severe scoliosis
   3. Therapy development.
      1. Previous therapy approaches have focused on upregulation of SMN expression from a second SMN (*SMN2*) gene that gives rise to low amounts of functional SMN protein.
      2. Drug development to target disease-specific mechanisms at cellular and physiological levels is in its early stages, as the pathophysiological processes that underlie the main disease symptoms are still not fully understood.
      3. Human-induced pluripotent stem cell technology for generation of large numbers of human motor neurons could help to fill this gap and advance the power of drug screening.
      4. In parallel, advances in oligonucleotide technologies for engineering *SMN2* pre-mRNA splicing are approaching their first clinical trials, whose success depends on improved technologies for drug delivery to motor neurons.
      5. If this obstacle can be overcome, this could boost therapy development, not only for SMA but also for other neurodegenerative disorders.
   4. Future treatment approaches (Tisdale and Pellizzoni 2015).
      1. Results from ongoing clinical trials are eagerly awaited, and evidence of therapeutic benefit would favor the implementation of universal newborn screening, in turn allowing both earlier diagnosis and therapeutic intervention and possibly improved clinical outcome.
      2. It is anticipated that continuing progress in SMA research will strongly affect not only this devastating disease of childhood, but also other neurodegenerative conditions of the motor system.

Fig. 1 A 2 1/2-week-old white male died of respiratory failure associated with congenital spinal muscular atrophy (Werdnig-Hoffman disease). There was generalized muscle atrophy including respiratory muscle

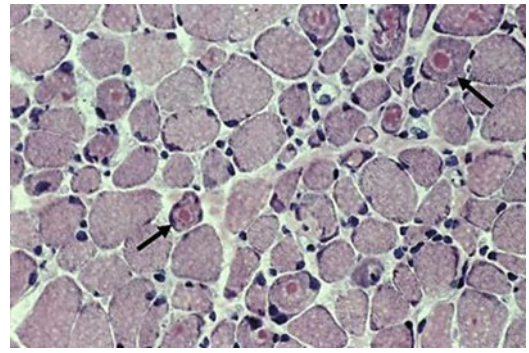

Fig. 3 Residual muscle seen in a 14-year-old female with spinal muscular atrophy showed chronic denervative change with presence of scattered target fibers (*arrows*) (H & E ×400)

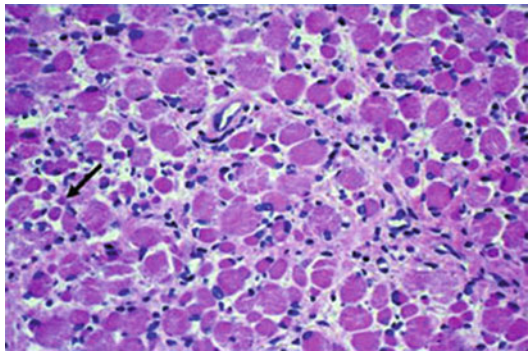

Fig. 2 Quadriceps muscle showed many exceedingly atrophic muscle fibers which tend to be in groups (*arrow*). No degenerative muscle fibers were present (H & E, ×100)

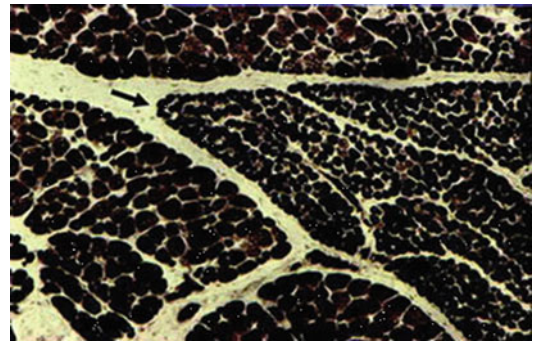

Fig. 4 Biopsy of quadriceps muscle from a 10-month-old girl with spinal muscular atrophy showed a group atrophy involving several entire fascicles (*arrow*). Both type I (*light-stained*) and type II (*dark-stained*) fibers were affected. This was accompanied by an enervative phenomenon (the large muscle fibers all stain pale) (Myosin ATPase, at 9.4, ×50)

Fig. 5 A 3-month-old infant boy with Werdnig-Hoffman disease showing generalized hypotonia (**a**). He had a small chest with diaphragmatic breathing (**b**), fasciculation of the tongue, and absence of deep tendon reflexes. Molecular genetic analysis revealed homozygous exon 7 deletion and homozygous exon 8 deletion for the survival motor neuron genes (*SMN*)

Fig. 6 A 27-month-old girl with SMA1. She could not stand holding or independently and had foot drops, absence of deep tendon reflexes, and muscle weakness. She was confined to a wheelchair. Molecular genetic analysis revealed homozygous exon 7 deletion and homozygous exon 8 deletion for the *SMN* gene

Fig. 7 A 5-year-old girl with SMA showing tongue fasciculation

Fig. 8 A 30-year-old man with Kugelberg-Welander disease showing muscle weakness and had been confined to a wheelchair for some time. He had trouble standing and began to walk at 6 years of age. Molecular genetic diagnosis revealed homozygous exon 7 deletion and homozygous exon 8 deletion

Fig. 9 This 22-month-old boy was evaluated for spinal muscular atrophy. He never pulls himself up and stands alone. He used his hands to move his legs. Physical examination showed slightly atrophic lower leg muscles and absent knee jerks. Molecular genetic analysis (Athena Diagnostics) identified zero copy of the survival motor neuron gene 1 (*SMA1*), confirming the clinical diagnosis of spinal muscular atrophy in this patient, and three copies of *SMN2*. An increased number ($\geq$3 copies) of *SMN2* gene copies may be associated with a less severe phenotype of SMA. Conversely, fewer ($\leq$2) *SMN2* gene copies may be associated with a severe phenotype of SMA. *SMA2* genes are able to produce a protein identical to that of the *SMN1* gene but at a reduced (10–20 %) capacity

Spondyloepiphyseal Dysplasia

Contents

Spondyloepiphyseal dysplasia (SED) refers to a group of disorders with primary involvement of the vertebrae and epiphyseal centers resulting in a short-trunk disproportionate dwarfism. Two major types (congenita and tarda) will be discussed here.

Synonyms and Related Disorders

SED congenita; SED tarda

Genetics/Basic Defects

1. Genetic basis of SED
    1. SED congenita
        1. Autosomal dominant inheritance (Diamond 1970)
        2. Spondyloepiphyseal dysplasia congenita gene mapped to chromosome 12q13
        3. Gonadal mosaicism reported
        4. Advanced paternal age recognized as a risk factor
    2. SED tarda
        1. X-linked recessive inheritance (Bannerman et al. 1971; Heuertz et al. 1995)
            1. Most common
            2. The gene mapped to Xp22.12-p22.31
        2. Autosomal recessive inheritance
        3. Autosomal dominant inheritance
2. Molecular basis of SED (Lee et al. 1989; Cole et al. 1993; Chan et al. 1995)
    1. SED congenita
        1. Caused by mutations in *COL2A1* gene, which encodes the α1(II) chain of type II collagen. The gene was mapped on chromosome 12.
        2. The mutations result in abnormal type II collagen, which is the major collagen of nucleus pulposus of the spine, hyaline cartilages, fibrocartilages, and vitreous humor of the eyes.
        3. Other skeletal dysplasias affected by collagen II abnormalities.
            1. Autosomal forms of SED tarda
            2. Achondrogenesis type II
            3. Hypochondrogenesis
            4. Kniest dysplasia
            5. Stickler dysplasia
            6. Spondylometaepiphyseal (Strudwick) dysplasia
    2. SED tarda, X-linked form (Gedeon et al. 1999, 2001; Christie et al. 2001;

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_222

Grunebaum et al. 2001; Savarirayan et al. 2003; Choi et al. 2009)

1. Caused by mutations in *SEDL* (SED late) gene (designated "sedlin"), now called *TRAPPC2* (trafficking protein particle complex 2) gene, mapped on Xp22.12-p22.31.
2. *SEDL* gene encodes a protein of 140 amino acids with a role in vesicular transport.
3. Over 30 novel mutations affecting the *SEDL* gene recognized: the most common type of *SEDL*-gene disruption being deletion, representing 50% of identified mutations (Savarirayan et al. 2003).

Clinical Features

1. SED congenita
    1. Clinical features present at birth.
    2. Short newborn with disproportionately shortened trunk.
    3. Delayed motor development.
    4. Short neck.
    5. Cervical myelopathy resulting from atlantoaxial instability (Reardon et al. 1994), odontoid hypoplasia, and spinal cord compression, often presenting at age 5–10 years.
        1. Delayed motor development
        2. Decreased endurance
        3. Progressive motor weakness
        4. Hypotonia
        5. Sleep apnea
        6. Alterations in respiration
        7. Pyramidal tract signs (spasticity, hyperreflexia, Babinski sign, and clonus)
    6. Respiratory insufficiency may develop secondary to thoracic dysplasia (Naumoff 1977).
    7. Barrel-shaped chest with pectus carinatum deformity.
    8. Protuberant abdomen.
    9. Spine abnormalities.
        1. Lumbar lordosis
        2. Thoracic kyphoscoliosis evident in adolescence
    10. Hip abnormalities.
        1. Hip flexion contractures
        2. Coxa vara
            1. An almost universal finding
            2. Varying severity
            3. Progressive
            4. Associated progressive hip dislocation if ligamentous laxity present
        3. The delayed ossification of the capital femoral epiphysis predisposing the hip to deformation with flattening, lateral extrusion, hinge abduction, and premature osteoarthritis
    11. Knee abnormalities.
        1. Valgus alignment of the knees often associated with overgrowth of the medial femoral condyle
        2. Rare genu varum
    12. Other clinical features.
        1. Gait problems often attributed to hip and knee deformities
        2. Clubfeet (talipes equinovarus) present in some patients
        3. Ocular anomalies
            1. Myopia and retinal detachment (>50%): important clinical findings in many patients
            2. Cataracts
            3. Buphthalmos secondary glaucoma and strabismus
            4. Clear corneas
        4. Deafness
        5. Cleft palate
        6. Abdominal or inguinal hernias
    13. A cause of lethal neonatal dwarfism (Macpherson and Wood 1980)
2. SED tarda
    1. X-linked recessive form
        1. Normal appearance at birth
        2. Variable age of onset
            1. Hip and trunk features appearing around 4 years of age.
            2. Diagnosis not recognized until the adolescent years in some patients.
        3. Only males are affected.
        4. Mild disproportionate trunk shortening.

5. Barrel-shaped chest.
6. Atlantoaxial instability secondary to odontoid hypoplasia.
7. Progressive joint and back pain with osteoarthritis commonly involving hip, knee, elbows, and shoulder joints.
8. Hip involvement.
    1. Hip pain or stiffness presenting around the first or second decade of life.
    2. Changes mimic bilateral Legg-Calve-Perthes disease.
    3. Varying degrees of coxa magna, flattening, extrusion, and subluxation.
    4. Osteoarthritis of the hip, a common sequela.
9. Kyphoscoliosis.
10. Lumbar lordosis.
11. Epiphyseal involvement.
    1. Primarily in the shoulders, hips, and knees
    2. Symmetrical and bilateral
12. Rare association with nephrotic syndrome.
13. Craniofacial appearance, vision, and hearing not affected in X-linked SED tarda.
14. Normal intelligence.
15. Normal life span.

2. Autosomal recessive form
    1. Onset between the ages of 4 and 10 years.
    2. Short stature.
    3. Waddling gait.
    4. Disproportionately short trunk.
    5. Accentuated spinal curvatures.
    6. Restricted mobility of the hip joints.
    7. Hip pain becomes worse with increasing age.
3. Autosomal dominant form
    1. Clinical features identical to those in the recessive form of SED tarda
    2. Hip pain and waddling gait noted after the fourth year of life
    3. Mild shortness of the trunk
    4. Progressive hip changes causing considerable discomfort

Diagnostic Investigations

1. Radiography
    1. SED congenita (Spranger and Langer 1970, 1974; Kozlowski et al. 1977)
        1. A generalized delay in the development of ossification centers
            1. Absent epiphyseal centers of the distal femur and proximal tibia, os pubis, calcaneus, and talus, which are usually present at birth
            2. Femoral heads usually not visible on radiographs until patients are aged 5 years
            3. Femoral capital epiphyses: flattened and irregular in shape when they appear on radiographs
        2. Vertebral abnormalities
            1. Varying degrees of platyspondyly
            2. Oval, trapezoid, or pear-shaped vertebrae resulting from posterior wedging of vertebral bodies.
            3. Incompletely fused ossification centers of the vertebral bodies.
            4. End-plate irregularities and intervertebral disk space narrowing become obvious with an increased anteroposterior diameter of the vertebral bodies in adolescents and young adults.
            5. Exaggerated lumbar lordosis.
            6. Progressive kyphoscoliosis developing in late childhood.
            7. Odontoid hypoplasia or os odontoideum leading to atlantoaxial instability: common.
        3. Pelvic abnormalities
            1. Short and small iliac crests with horizontal acetabular roofs and delayed ossification of the pubis
            2. Small iliac bones with lack of normal flaring of the iliac wings
            3. Deep acetabular fossae appearing empty due to the severely retarded ossification of femoral heads
            4. Varying severity of coxa vara
            5. Delayed ossification of the femoral head predisposing hip to deformation

with flattening, lateral extrusion, hinge abduction, and premature osteoarthritis

4. Tubular bone abnormalities
    1. Delayed ossification centers of the distal femur and proximal tibia leading to flattening and irregularity
    2. Genu valgum usually present with overgrowth of the medial femoral condyle
    3. Relatively short and broad long tubular bones
    4. Presence of some metaphyseal flaring especially in the region of the distal femur and proximal and distal humerus
    5. Delayed or disorganized ossification of carpal and tarsal centers with occasional extra epiphyses

2. SED tarda, X-linked recessive form (Langer 1964; MacKenzie et al. 1996)
    1. Radiographic changes usually apparent in children older than 4–6 years (not evident at birth).
    2. Changes suggestive of atlantoaxial instability, platyspondyly, kyphoscoliosis, and epiphyseal involvement similar to those seen in patients with SED congenita.
    3. Predominantly affecting the spinal vertebral bodies and epiphyses during skeletal growth.
    4. A mound of bone ("donkey hump") typically present in the central and posterior portions of the superior and inferior end plates on lateral radiographs in patients with X-linked recessive type of SED tarda (not features of the autosomal dominant or recessive types of SED tarda). However, absence of ossification at the upper and lower anterior margins of the vertebral bodies is considered to be the distinctive radiographic feature.
    5. Symmetric epiphyseal involvement primarily in the shoulders, hips, and knees.
    6. Delayed ossification predisposing the weight-bearing joints of the lower extremities to deformation and premature osteoarthritis.
    7. Changes in the hip (dysplastic changes of femoral heads and neck) mimic bilateral Legg-Calve-Perthes disease.
    8. Presence of varying degrees of coxa magna, flattening, extrusion, and subluxation.
    9. Minor skeletal changes in carrier women with X-linked recessive SED tarda in a six-generation kindred from Arkansas (Whyte et al. 1999).
        1. Subtle abnormal shape of the pelvis and knees
        2. Premature occurrence of degenerative changes in the spine leading to frequent complaint of arthralgia in the middle age

3. SED tarda, autosomal recessive form
    1. Irregular upper and lower plates of the vertebral bodies
    2. Anteriosuperior ossification defects of some vertebrae
    3. Less frequent findings
        1. Additional ossification defects of the anterioinferior edges of the vertebral bodies
        2. Anterior protrusion of central portions of the vertebral bodies
    4. Femoral heads
        1. Well-developed capital femoral epiphyses in the younger child
        2. Progressive flattening and destruction of the femoral heads with advancing age
        3. Milder abnormalities in the knee joints
        4. Small and irregular carpal bones
        5. Slightly short and irregular metacarpals and phalanges in some patients

4. SED tarda, autosomal dominant form
    1. Accentuated dorsal flattening of the vertebral bodies in the younger patient
    2. Platyspondyly with a rectangular shape of the vertebral bodies in the older patient
    3. Mild and slowly progressive deformities of capital femoral epiphyses and knee epiphyses

4. Slightly short phalanges and metacarpals with narrowing of the joint spaces
2. MRI (Parikh 2013)
   1. To delineate cord compression due to C1-C2 instability
   2. To evaluate severe spinal deformities prior to surgical intervention
   3. To evaluate the condition of the epiphyseal centers prior to reconstructive procedures
3. CT scan (Parikh 2013)
   1. To assess the configuration of bones and joints prior to surgical intervention
   2. To reconstruct three-dimensional images for help in surgical planning of severe cases
4. Hip arthrography (Parikh 2013)
   1. To document congruity of the femoral head or hinged abduction
   2. To evaluate severe varus deformity of the femoral neck
5. Laboratory features of SED congenita
   1. Fine metachromatic inclusions in the peripheral lymphocytes
   2. Normal urinary excretion of acid mucopolysaccharides including keratosulfate
   3. Histopathology (Yang et al. 1980)
      1. Mildly disorganized physis (epiphyseal growth plate).
      2. Chondrocytes containing PAS-positive cytoplasmic inclusions.
      3. Ultrastructurally, the inclusions correspond to the accumulations of finely granular material in dilated cisterns of rough endoplasmic reticulum.
6. Molecular genetic analysis
   1. Mutations in *COL2A1* gene in SED congenita
   2. Mutation in *SEDL* gene in X-linked recessive SED tarda (Tiller and Hannig 2011)
      1. Sequence analysis clinically available
      2. Mutation types
         1. Deletions
         2. Splice mutations
         3. Missense mutations
         4. Nonsense mutations
      3. Detected in >80% of affected males with X-linked spondyloepiphyseal dysplasia tarda
      4. Molecular genetic testing in new patients relied largely on mutation screening by sequencing the entire coding region.
      5. Carrier testing of at-risk female relatives available once the mutation has been identified in the proband

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Spondyloepiphyseal dysplasia congenita (autosomal dominant): recurrence risk low unless presence of parental gonadal mosaicism
      2. Spondyloepiphyseal dysplasia tarda, X-linked
         1. The risk to sibs depends on the carrier status of the mother.
         2. When the mother is a carrier: a 25% risk of having an affected brother; a 25% risk of having an unaffected brother; a 25% risk of having a carrier sister; a 25% risk of having a non-carrier sister.
         3. When the mother is not a carrier: The risk to sibs is low (the risk of gonadal mosaicism in mothers not yet known).
      3. Spondyloepiphyseal dysplasia tarda, autosomal recessive: 25%
      4. Spondyloepiphyseal dysplasia tarda, autosomal dominant: low unless a parent is affected
   2. Patient's offspring
      1. Spondyloepiphyseal dysplasia congenita, autosomal dominant
         1. When the spouse is not affected: 50% of offspring will be affected.
         2. When the spouse is also affected with spondyloepiphyseal dysplasia congenita: 50% of offspring are heterozygous and affected; 25% are homozygous, which is ordinarily fatal in the first few months of life, and 25% are unaffected.

2. Spondyloepiphyseal dysplasia tarda
    1. Autosomal recessive form: recurrence risk to offspring low unless the spouse is a carrier
    2. Autosomal dominant form: 50%
3. Spondyloepiphyseal dysplasia tarda, X-linked recessive
    1. None of the sons of an affected male will be affected.
    2. All daughters of an affected male are carriers.

2. Prenatal diagnosis
    1. Prenatal ultrasound at 20 weeks of gestation (Turner et al. 2010): shortening of all fetal long bones, bowing of femora and humeri, clubfeet, and small thoracic cage.
    2. Molecular genetic diagnosis on fetal DNA from amniocytes or CVS available in families at risk for SED congenita, provided the disease-causing mutation (*COL2A1*) is identified in the proband.
    3. Molecular genetic diagnosis on fetal DNA from amniocytes or CVS possible in families at risk for X-linked SED tarda, provided the disease-causing mutation (*SEDL*) is identified in the proband.
    4. Preimplantation genetic diagnosis may be available for families in which the disease-causing mutation has been identified in an affected family member.
3. Management (Parikh 2013)
    1. SED congenita
        1. Supportive care including psychosocial support
        2. Tracheostomy/ventilator support for severe respiratory difficulties to maintain adequate ventilation (Harding et al. 1990; Augenstein et al. 1996)
        3. Posterior atlantoaxial fusion for patients with signs and symptoms of atlantoaxial instability measuring 8 mm or more or myelopathy
        4. Brace for scoliosis initially
        5. Posterior spinal fusion for severe scoliosis or for patients resistant to bracing
        6. Surgical correction for hip and knee abnormalities
        7. Surgical correction of equinovarus deformities unmanageable by physical therapy or serial casting
    2. SED tarda, X-linked type
        1. Supportive care
            1. Avoid activities and occupations that place undue stress on the spine and weight-bearing joints to prevent premature arthritis.
            2. Chronic pain management.
            3. Psychosocial support for the patient and family.
        2. Bracing for scoliosis
        3. Posterior spinal fusion for severe scoliosis
        4. Posterior stabilization for atlantoaxial instability
        5. Valgus or valgus-extension intertrochanteric osteotomy to improve hip congruity
        6. Total joint arthroplasty for osteoarthritis in adulthood
        7. Management of hip dysplasia
            1. Acetabular augmentation if the acetabulum is insufficient to contain the enlarged femoral head (coxa magna)
            2. May require hip replacement

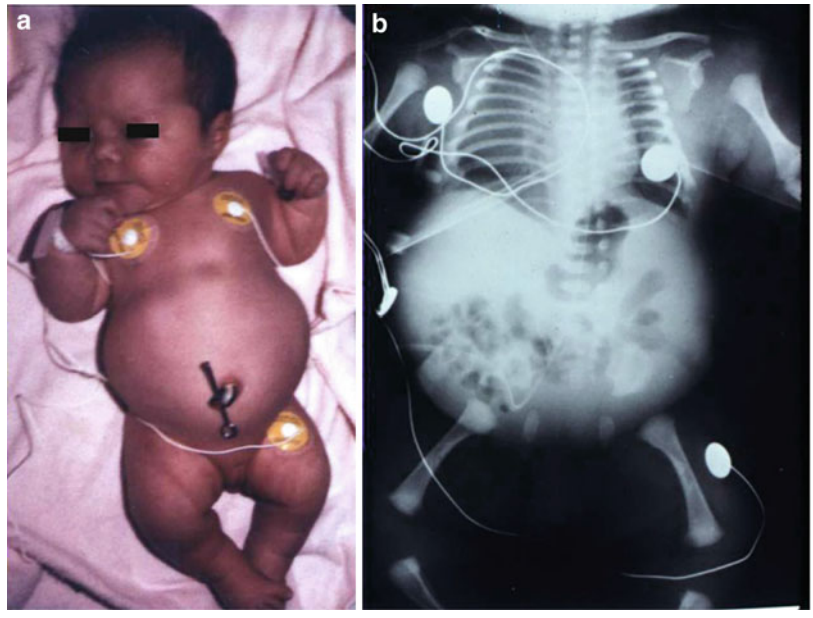

Fig. 1 (**a**, **b**) A neonate with SED congenita showing moderately shortened limbs, short trunk, and large head. Radiograph shows small oval vertebral bodies, reniform ilia, and moderately shortened limb bones

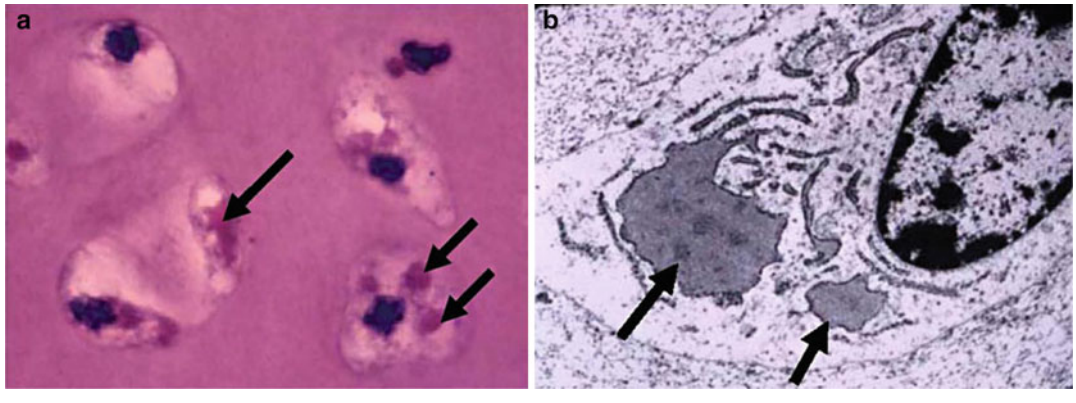

Fig. 2 (**a**, **b**) Photomicrograph of a neonate with SED congenita shows frequent presence of cytoplasmic inclusions in the chondrocytes of resting cartilage and the zone of proliferation. The cytoplasmic inclusion is a dilated rough endoplasmic reticulum containing finely granular material

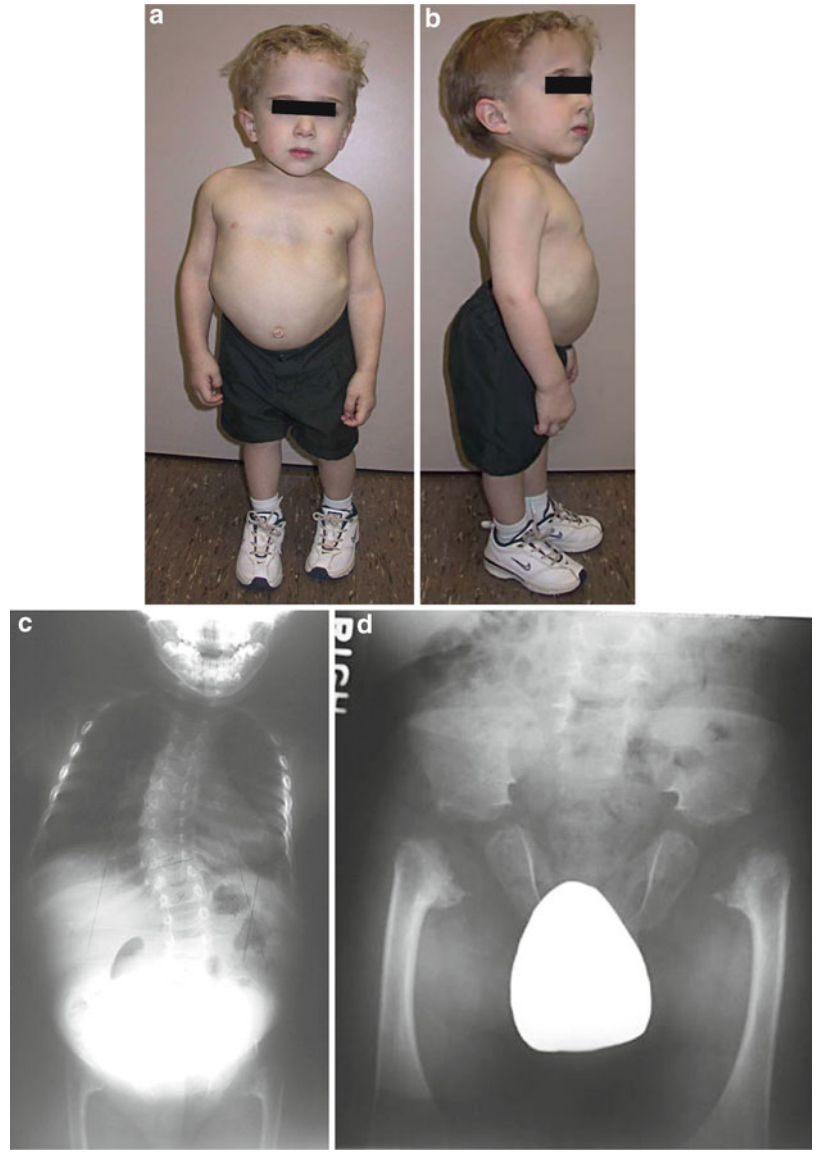

Fig. 3 (**a**–**d**) A boy with SED congenita showing short trunk, short, broad chest with pectus excavatum, globoid abdomen, and hyperlordosis. Radiographs showed lack of ossification of the femoral epiphysis, short femoral neck, generalized platyspondyly, and thoracolumbar scoliosis

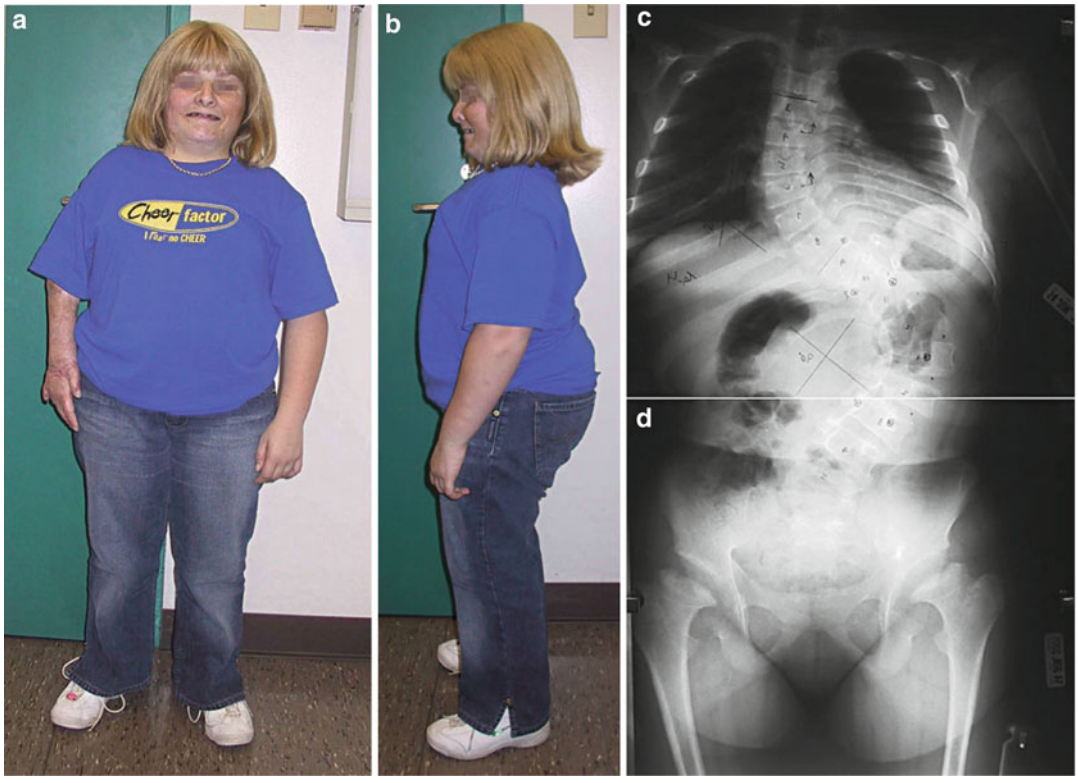

Fig. 4 (**a**–**d**) An adult with SED showing short-trunk dwarfism. Radiographs showed flat vertebral bodies, severe scoliosis, and retarded ossification of femoral head and neck

Fig. 5 (**a–d**) A 9-year-old boy with spondyloepiphyseal dysplasia tarda showing kyphosis. The spinal radiographs showed anterior body projection, widening of vertebral body spaces, and lumbar kyphosis. Femoral epiphysis was poorly developed (flat epiphyses) and acetabular sockets were not well formed

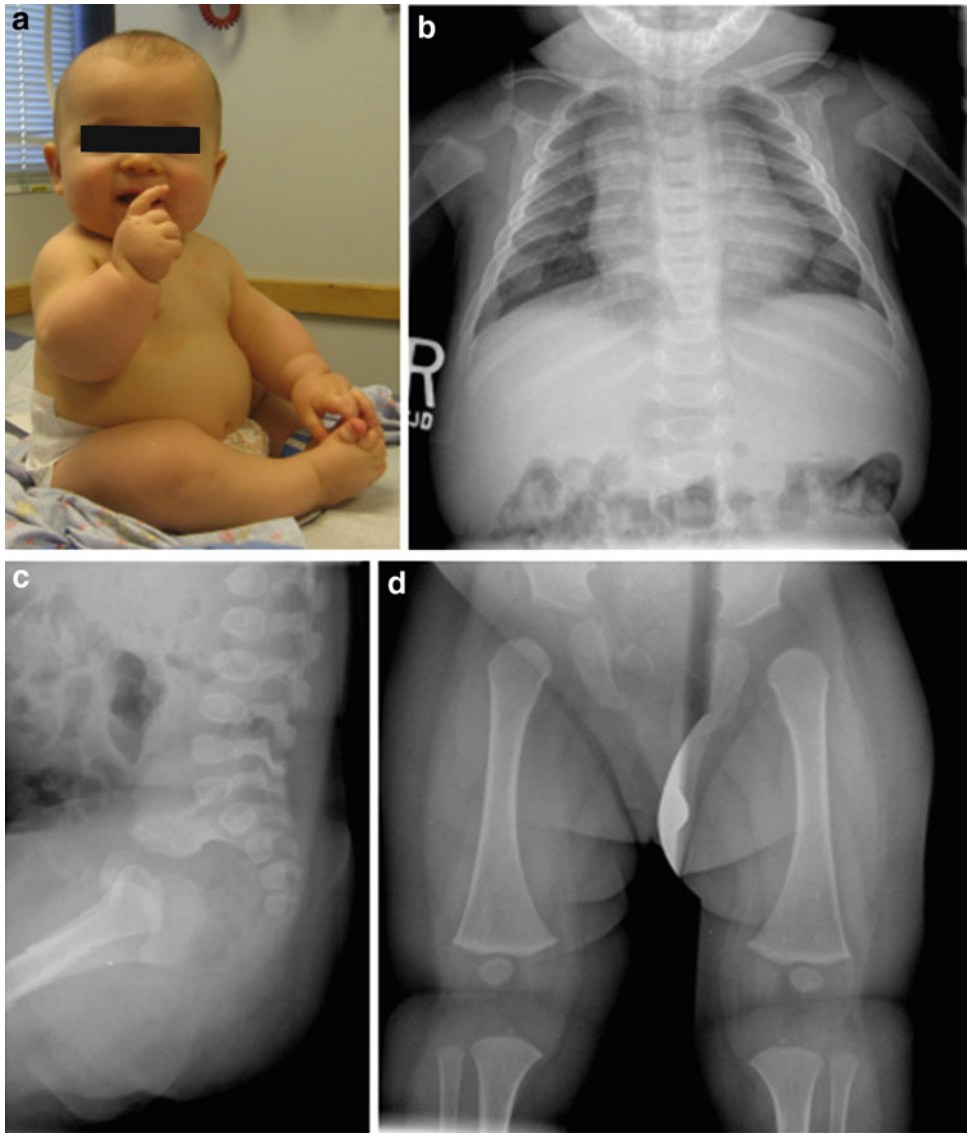

Fig. 6 (**a**–**d**) This 9-month old boy (**a**) was evaluated for short stature (height age of approximately 4 months). Skeletal survey (**b**–**d**) showed markedly delay epiphyseal development and ovoid appearance of the thoracic and lumbar vertebrae with anterior tonguing of L1, suggesting spondyloepiphyseal dysplasia congenita. DNA sequencing revealed a c.2965C>T transition in exon 43 of the *COL2A1* gene. This change converts a codon for arginine (CGT) to a codon for cysteine (TGT). The patient is heterozygous for this mutation. This exact change has previously been reported as a *COL2A1* mutation in a patient with spondyloepiphyseal dysplasia (Chan et al. 1993) (Courtesy of Dr. Susonne Ursin)

Stickler Syndrome

Contents

In 1965, Stickler et al. (1965) described a family with progressive myopia, retinal detachment and blindness, and premature degenerative changes in various joints. The disorder was subsequently termed "hereditary arthroophthalmopathy" (Herrmann et al. 1975a, b) or "hereditary progressive arhroophthalmopathy" (Popkin and Polomeno 1974). The incidence is estimated to be about 1 in 10,000 (Admiraal et al. 2002).

Synonyms and Related Disorders

Hereditary arhroophthalmopathy; Hereditary progressive arhroophthalmopathy; Wagner-Stickler syndrome

Genetics/Basic Defects

1. Inheritance (Robin et al. 2014)
    1. Autosomal dominant.
        1. Stickler syndrome caused by heterozygous mutation of COL2A1, COL11A1, or COL11A2 is inherited in an autosomal dominant manner.
        2. Autosomal dominant (Hall 1974) with wide variation in expression and virtually complete penetrance (Popkin and Polomeno 1974).
        3. Wagner-Stickler syndrome: a hereditary progressive arthroophthalmopathy with an autosomal dominant pattern of inheritance (Liberfarb et al. 1981).
    2. Autosomal recessive: Stickler syndrome caused by biallelic mutation of COL9A1, COL9A2, or COL9A3 is inherited in an autosomal recessive manner.
2. Association of the Stickler syndrome with following collagen gene mutations (Richards et al. 2013):
    1. Stickler syndrome type 1: *COL2A1* gene mutations (Hoornaert et al. 2010).
        1. Observed in membranous or type 1 vitreous phenotype (afibrillar phenotype).
        2. The presence of vitreous anomalies, retinal tears or detachments, cleft palate, and a positive family history were shown to be good indicators for a COL2A1 defect.
        3. Stickler syndrome type 1 is predominantly caused by loss-of-function mutations in the COL2A1 gene as >90% of the mutations were predicted to result in nonsense-mediated decay.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_223

4. A report on a familial apparently balanced reciprocal translocation t(12;15)(q13;q22.2) which disrupts *COL2A1* and causes type 1 Stickler syndrome, in a mother and two of her children (Dupont et al. 2013).
5. Different mutations of the *COL2A1* gene were associated with similar phenotypes, but with different degrees of expressivity. Retinal detachment was the most serious complication (Kondo et al. 2016).

2. Stickler syndrome type 2: *COL11A1* gene mutations (Richards et al. 2010).
   1. Observed in beaded or type 2 vitreous phenotype.
   2. Stickler syndrome type 2 (Marshall syndrome).
      1. Marshall syndrome associated with a splicing defect at the COL11A1 locus (Griffith et al. 1998)
      2. More severe facial features (short nose, midfacial flattening)
      3. High myopia
      4. Less risk of retinal detachment
      5. Moderate hearing impairment
   3. Some mutations in *COL11A1* have been classified as Marshall syndrome, but as demonstrated by Annunen et al. (1999), the short nose, anteverted nares, midfacial hypoplasia, and flat nasal bridge that are common in cases of Marshall syndrome with *COL11A1* mutations are also often present in young individuals with mutations in *COL2A1*, making differential diagnosis based on facial phenotypes difficult (Marjava et al. 2007).
   4. Recently, recessive mutations in the *COL11A1* gene have been demonstrated to result in fibrochondrogenesis, a much more severe skeletal dysplasia, which is often lethal.
   5. Some mutations in *COL11A1* are recessive (associated with unusually profound hearing loss), modified by alternative splicing and result in type 2 Stickler syndrome rather than fibrochondrogenesis.
3. Stickler syndrome type 3: *COL11A2* gene mutations.
   1. *COL11A2* gene has been localized to 6p22 to 6p21.3 (Brunner et al. 1994)
   2. Cause nonocular Stickler syndrome type 3 (Iwasa et al. 2015).
      1. Stickler-like facial features
      2. Mild-to-moderate deafness
      3. Normal eyes (Sirko-Osadsa et al. 1998)
   3. Also found in patients with a recessively inherited variant denoted as otospondylomegaepiphyseal dysplasia (OSMED)
   4. Also cause autosomal dominant nonsyndromic deafness (DFNA13) (McGuirt et al. 1999)
4. Rare recessive forms of Stickler syndrome exist that are due to mutations in genes encoding type 9 collagen.
   1. Stickler syndrome type 4: *COL9A1* mutations – vitreous syneresis with an optically empty vitreous due to progressive gel liquefaction (Van Camp et al. 2006)
   2. Stickler syndrome type 5: *COL9A2* mutations
   3. Autosomal recessive Stickler syndrome due to a loss-of-function mutation in the *COL9A3* gene (Faletra et al. 2014)
5. *LOXL3*, encoding lysyl oxidase-like 3, is mutated in a family with autosomal recessive Stickler syndrome (Alzahrani et al. 2015).

3. Stickler syndrome has been subclassified on the basis of vitreoretinal phenotype (Snead 1996).
   1. Type 1 families with a characteristic congenital vitreous anomaly show linkage without recombination to markers at the *COL2A1* locus.
   2. Type 2 families with different congenital vitreoretinal phenotypes are not linked to *COL2A1*.
4. Type 11 collagenopathies (Spranger 1998):
   1. On the basis of molecular studies, three type 11 collagenopathies have been defined: Stickler syndrome type 2 and dominant

and recessive otospondylomegaepiphyseal dysplasia (OSMED) (Vikkula et al. 1995; Van Steensel et al. 1997).
2. Stickler syndrome 1 and Kniest dysplasia are type 2 collagenopathies with considerable clinical and radiographic overlap.
3. Inborn errors of cartilage collagen formation lead to a family of genetically heterogeneous but pathogenetically related and hence phenotypically similar disorders. The type 11 collagenopathies are part of this family.

5. Genotype-phenotype correlations: difficult to predict the severity of the phenotype on the basis of genotype (Liberfarb et al. 2003).
   1. Type 1 Stickler syndrome.
      1. Ocular Stickler syndrome with mutations in *COL2A1* (chromosome locus: 12q13.11-q13.2).
      2. Families with Sticklers syndrome type 1 have a characteristic congenital vitreous anomaly and are linked without recombination to markers at the COL2A1 locus (Richards et al. 1996).
      3. The presence of vitreous anomalies, retinal tears or detachments, cleft palate, and a positive family history were shown to be good indicators for a *COL2A1* defect (Hoornaert et al. 2010).
   2. Type 2 Stickler syndrome.
      1. Ocular Stickler syndrome with mutations in *COL11A1* (chromosome locus: 1p21).
      2. Families with the type 2 variety have a different vitreoretinal phenotype and are not linked to the *COL2A1* gene (Richards et al. 1996).
   3. Type 3 Stickler syndrome: nonocular Stickler syndrome with mutations in *COL11A2* (chromosome locus: 6p21.3).
   4. Early onset of high myopia with vitreous abnormalities may serve as a key indicator of Stickler syndrome, while the existence of mandibular protrusion in pediatric patients may be an efficient indicator for the absence of mutations in *COL2A1* and *COL11A1* (Wang et al. 2016).

Clinical Features

1. Considerable clinical variability within families and between families (Zlotogora et al. 1992; Stickler et al. 2001), explainable in part by locus and allelic heterogeneity
2. Ocular features (Spallone 1987)
   1. Myopia.
      1. Congenital
      2. Nonprogressive
      3. Of high degree
   2. Abnormalities of vitreous formation and gel architecture.
      1. Pathognomonic of Stickler syndrome
      2. A prerequisite for diagnosis
      3. Vitreous anomalies
         1. Characteristic congenital "membranous" vitreous anomaly (type 1 phenotype) in type 1 Stickler syndromes
         2. Sparse and irregularly thickened bundles of fibers throughout the vitreous cavity (type 2 phenotype) in type 2 Stickler syndrome
   3. Retinal detachment.
      1. The most serious ophthalmologic complication
      2. Mainly occurs in the second decade of life (Vilaplana et al. 2015)
   4. Cataracts: mainly developing in the fourth decade of life (Vilaplana et al. 2015). However, congenital glaucoma has been reported in a 1-month-old boy (Shenoy and Mandal 2013).
   5. Ectopia lentis.
   6. Strabismus.
   7. Open-angle glaucoma.
   8. No ocular abnormalities in Stickler syndrome type 3.
3. Hearing impairment (Nowak 1998; Admiraal et al. 2002; Acke et al. 2012)
   1. Considerable variability (Jacobson et al. 1990).
   2. Common occurrence.
   3. Sensorineural hearing loss predominates, but also conductive hearing loss, especially in children and patients with a palatal defect, may occur.

4. The distinct disease-causing collagen genes are associated with a different prevalence of hearing impairment, but still large phenotypic variation exists.
5. Conductive hearing impairment.
    1. Resulting from recurrent otitis media
    2. Secondary to cleft palate
6. Sensorineural hearing impairment.
    1. Type 1 Stickler syndrome with mutations in the *COL2A1* gene
        1. Occurring in 50–60%
        2. Typically mild-to-moderate degrees
        3. Predominantly affecting higher frequencies
        4. No tangible progression beyond presbycusis
    2. Type 2 Stickler syndrome (Marshall syndrome) with the mutations in the *COL11A1* gene
        1. Occurring in 80–100%
        2. More severely affected
        3. Starting at a younger age or congenital in origin
        4. Showing progression
    3. Type 3 Stickler syndrome with mutations in the *COL11A2* gene
        1. A typical feature
        2. Hundred percent penetrance
        3. Mild-to-moderate impairment
        4. Nonprogressive when accounted for presbycusis
        5. Showing different audiometric configurations
4. Associated anomalies
    1. Orofacial anomalies
        1. Facial bone hypoplasia
            1. Flat midface.
            2. Depressed nasal bridge.
            3. Maxillary hypoplasia.
            4. Mandibular hypoplasia (Pierre-Robin anomaly/sequence): 51% of the patients presenting with Robin sequence features had been diagnosed with the Stickler syndrome (Antunes et al. 2012).
        2. High arched/cleft palate
        3. Bifid uvula
        4. Abnormal teeth
        5. Malocclusion
    2. Generalized musculoskeletal abnormalities
        1. Arthropathy (Lewkonia 1992)
            1. Joint hyperextensibility
            2. Enlarged joints
            3. Premature osteoarthritis
            4. Progressive joint degeneration (85%) (Popkin and Polomeno 1974)
        2. Slender extremities
        3. Long fingers
        4. Hypotonia
        5. Relative muscle hypoplasia
        6. Kyphosis
        7. Scoliosis
        8. Pectus carinatum
        9. Accessory carpal ossicles
        10. Hip dislocation
        11. Coxa valga
        12. Genu valga
        13. Talipes equinovarus
    3. Mitral valve prolapse (Liberfarb and Goldblatt 1986)
5. Intelligence: normal
6. Clinical features seen in different types of Stickler syndrome (Li and Thorne 2010)
    1. Type 1
        1. Ocular
            1. Myopia
            2. Vitreoretinal degeneration
            3. Cataracts
            4. Retinal detachment
        2. Musculoskeletal
            1. Mild degenerative changes
            2. Hypermobility
        3. Auditory: Normal to slight hearing impairment
        4. Craniofacial: cleft palate
        5. Possibility of a potential occurrence of seizures among the clinical manifestations of Stickler syndrome type 1, suggesting the presence of a continuous neurological spectrum in some individuals harboring heterozygous mutations in *COL2A1* (Savasta et al. 2015)
    2. Type 2
        1. Ocular

1. Congenital nonprogressive myopia
2. Cataracts

2. Musculoskeletal
1. Mild degenerative changes
2. Hypermobility

3. Auditory: early-onset sensorineural hearing loss
4. Craniofacial: cleft palate

3. Type 3
1. Ocular: none
2. Musculoskeletal: early-onset osteoarthritis
3. Auditory: high-tone sensorineural hearing loss
4. Craniofacial: Pierre-Robin sequence

7. Differential diagnosis (Snead and Yates 1999; Bowling et al. 2000)
1. Wagner hereditary vitreoretinal degeneration
1. Consisting solely of ocular abnormalities
1. Myopia
2. Vitreous degeneration
3. Preretinal avascular membranes
4. Retinal degeneration and thinning

2. No increased risk of retinal detachment or systemic abnormalities

2. Weissenbacher-Zweymüller syndrome and otospondylomegaepiphyseal dysplasia (OSMED)
1. Pierre-Robin sequence
2. Snub nose
3. Proximal limb shortening resolved by adulthood
4. Dumbbell-shaped femora and humeri
5. Coronal vertebral clefts
6. Sensorineural hearing loss
7. No eye abnormalities
8. *COL11A2* mutations
9. Appears to represent the same entity as nonocular Stickler syndrome

3. Erosive vitreoretinopathy (Brown et al. 1994)
1. Autosomal dominant eye disorder
2. Phenotype resembling Wagner syndrome but lacking any systemic abnormalities
3. Condition mapped to 5q13-q14 suggesting it may be an allelic variant of Wagner syndrome (Brown et al. 1995)

4. Marshall syndrome (Marshall 1958)
1. Autosomal dominant disorder
2. Clinical phenotype
1. Cataracts
2. Myopia
3. Abnormal vitreous
4. Midfacial hypoplasia
5. Congenital deafness

3. Associated with *COL11A1* mutation in a family affected with Marshall syndrome

5. Kniest dysplasia
1. Ocular abnormalities
1. Severe myopia
2. Vitreous veils
3. Perivascular lattice
4. Retinal detachment
5. Cataracts

2. Systemic findings
1. Short trunk dwarfism
2. Kyphoscoliosis
3. Deafness
4. Depressed nasal bridge
5. Cleft palate

6. Spondyloepiphyseal dysplasia
7. Marfan syndrome
8. Goldmann-Farve syndrome
1. A rare recessively inherited condition
2. Ocular abnormalities
1. Night blindness
2. Retinal detachment
3. Pigmentary chorioretinal degeneration
4. Vascular sheathing in the fundus

9. Jansen syndrome
1. Ocular abnormalities similar to Wagner syndrome
2. Absent systemic abnormalities

10. Congenital retinoschisis
1. A sex-linked recessive trait
2. Usually occurring in emmetropic or hyperopic patients
3. Membrane-like structures in midvitreous

Diagnostic Investigations

1. Audiologic and otologic testing for hearing loss (Jacobson et al. 1990)
2. Audiometric analysis (Acke et al. 2012, 2016)
    1. Regular auditory follow-up is strongly advised, particularly because many Stickler patients are visually impaired.
    2. A mild and predominantly high-frequency sensorineural hearing loss (SNHL) in type 1 Stickler patients, which is characterized by an early onset and is nonprogressive compared with normal age-specific hearing thresholds. The absence of otoacoustic emissions is a frequent finding and is probably inherent to the impact of a *COL2A1* mutation in the inner ear.
    3. In type 2 patients, the audiogram demonstrates mild-to-moderate low- and mid-frequency SNHL and moderate-to-severe high-frequency SNHL. This hearing loss has an early onset as well, and seems to be nonprogressive in adult age.
3. Vitreous slit-lamp biomicroscopy can distinguish between patients with *COL2A1* mutations and those with dominant negative mutations in *COL11A1*, who produce a different "beaded" vitreous phenotype (Richards et al. 2000)
4. Radiographic features
    1. The most common specific roentgenographic findings (Bennett and McMurray 1990)
        1. Coxa valga
        2. Widening of femoral neck
        3. Acetabular protrusio
        4. Chondrolysis
        5. Avascular necrosis
        6. Premature arthritic changes
    2. Generalized spondyloepiphyseal dysplasia
    3. Flattening of the epiphyses
    4. Narrowing of the diaphyses
    5. Flaring or widening of the metaphyses
    6. Wedging of the tubular bones
    7. Anterior maxillary and mandibular underdevelopment
5. CT scan studies in type 1 Stickler syndrome (Kaissi et al. 2013)
    1. Anterolateral ossification of the anterior longitudinal spinal (Forestier disease)
    2. Platyspondyly
    3. Extensive endplate sclerosis and anterior spurring associated with giant osteophytes formation
    4. Schmorl's nodes associated with narrowing of the intervertebral disc spaces
    5. Development of vertebral scalloping along the lower lumbar vertebrae
    6. Extensive hyperostosis of the anterior longitudinal spinal ligaments, resulting in the characteristic radiographic finding of a Bamboo-like spine resembling ankylosing spondylitis
    7. The overall spine pathology is compatible with severe premature spine degeneration overwhelmed by diffuse hyperostosis
    8. Femoral anteversion of the hips secondary to significant acetabulo-femoral dysplasia
    9. Internal rotation of both knees
    10. Epiphyseal fragmentations associated with trochlear dysplasia
6. Ocular histopathologic findings (Blair et al. 1979)
    1. Total retinal detachment with marked folding
    2. Disorganization of the retina
    3. A preretinal membrane
7. A novel strategy for screening families with type 1 Stickler syndrome due to *COL2A1* nonsense mutations, using a modified RNA-based protein truncation test (Freddi et al. 2000)
8. Rapid determination of *COL2A1* mutations in individuals with Stickler syndrome: Analysis of potential premature termination codons (Wilkin et al. 2000)
9. Nonocular Stickler syndrome with a novel mutation in *COL11A2* diagnosed by massively parallel sequencing in Japanese hearing loss patients (Iwasa et al. 2015)

10. Clinically available molecular genetic testing for mutations affecting different genes (*COL2A1*, *COL11A1*, *COL11A2*, *COL9A1*, *COL9A2*, *COL9A3*) (Robin et al. 2014)
    1. Sequence analysis
    2. Deletion/duplication analysis
11. Targeted next-generation sequencing is an efficient and cost-effective molecular tool in the genetic diagnosis of Stickler syndrome, whereas the more standardized whole-exome sequencing might be an alternative approach (Acke et al. 2014)

Genetic Counseling

1. Recurrence risk (Robin et al. 2014)
    1. Variable clinical expression of Stickler syndrome may complicate the genetic counseling (Faber et al. 2000).
        1. Exercise caution on assuming a de novo mutation: radiographic studies and clinical examination of the parents including formal testing of hearing and vision
        2. Mutation search whenever possible
        3. Uncertainty in predicting clinical consequences of inheriting a mutation
    2. Patient's sib
        1. Autosomal dominant inheritance (COL2A1, COL11A1, COL11A2-related Stickler syndrome)
            1. A 50% risk if a parent has Stickler syndrome
            2. A low recurrence risk if the parents are clinically affected and the disease-causing mutation not identified
        2. Autosomal recessive inheritance (*COL9A1*): a 25% risk
    3. Patient's offspring
        1. Autosomal dominant: a 50% risk
        2. Autosomal recessive: risk not increased unless the spouse is a carrier
    4. Mosaicism in Stickler syndrome (Stevenson et al. 2012)
        1. A family with two clinically affected sibs with Stickler syndrome who have clinically unaffected parents.
        2. Both sibs have a novel heterozygous mutation in exon 26 of *COL2A1* (c.1525delT); this results in a premature termination codon downstream of the mutation site.
        3. One parent was found to have low level mosaicism in DNA extracted from whole blood.
        4. This scenario encourages consideration of molecular testing in seemingly unaffected parents for recurrence risks and potential screening for mild age-related manifestations.
2. Prenatal diagnosis (Robin et al. 2014)
    1. Ultrasonographic demonstration of Pierre-Robin sequence as a part of Stickler syndrome (Soulier et al. 2002)
    2. Mutation analysis on amniocytes or CVS cells in at-risk families with known mutations
    3. Linkage analysis of the 3′VNTR polymorphism on the involved gene (*COL2A1*) using amniocytic DNA (Lisi et al. 2002)
    4. Preimplantation genetic diagnosis for at-risk pregnancies require prior identification of the disease-causing mutations in the family
3. Management (Bowling et al. 2000; Wilkin et al. 2001)
    1. Early evaluation of at-risk patients for the development of the following complications
        1. Retinal tears
        2. Retinal detachment
        3. Cataracts
        4. Glaucoma
    2. Long-term monitoring
    3. Cleft palate repair with appropriate feeding techniques
    4. Corrective lenses for myopia
    5. Avoid contact sports which may lead to retinal detachment
    6. Laser photocoagulation of vitreoretinopathy as preventive treatment for retinal detachment (Leiba et al. 1996)
    7. Surgical repair of retinal detachments and remove cataracts with possible lens implantation

8. The primary surgery should be vitrectomy combined with scleral buckling and silicone oil tamponade (Alshahrani et al. 2015)
9. Glaucoma management
10. Corrective treatment for strabismus
11. Hearing aids for hearing loss
12. Speech therapy
13. Symptomatic treatment for arthropathy
    1. Joint pain management
    2. Appropriate splints for strengthening and stabilizing lax joints
    3. Braces or aids to assist daily activities
    4. Hydrotherapy or other physical therapy modalities to increase range of motion, endurance, and strength
    5. Low-dose steroids along with methotrexate and hydroxychloroquine: The patients responded to treatment and there was significant improvement in their joint symptoms (Dhaon et al. 2015)
14. Management for mitral valve prolapse
    1. Antibiotics prophylaxis
    2. Beta-blocker for symptomatic patients
15. Use of external distractors and the role of imaging prior to mandibular distraction in infants with isolated Pierre-Robin sequence and Stickler syndrome (Mingo et al. 2016)

Sturge-Weber Syndrome

Contents

Sturge-Weber syndrome (SWS) comprises of vascular malformations of the central nervous system and the port-wine stain or nevus flammeus of the face in a trigeminal nerve distribution. The syndrome is also known as encephalotrigeminal angiomatosis (King and Schwarz 1954). The incidence is estimated to be approximately 1 in 50,000 (Sturge 1879; Parkes Weber 1922; Thomas-Sohl et al. 2004).

Synonyms and Related Disorders

Encephalofacial or encephalotrigeminal angiomatosis; Leptomeningeal vascular malformation (angioma); Port-wine stains

Genetics/Basic Defects

1. Genetics:
   1. A sporadic, nonfamilial disease
   2. Uncertain inheritance: only a few familial clusters of the syndrome reported; most of these have not exhibited the clear-cut autosomal dominant inheritance pattern.
   3. Proposed to represent a genetically mosaic condition. Lesions in the Sturge-Weber syndrome result from somatic mutations in affected areas, such as the port-wine stain or leptomeningeal angioma, but not in blood or normal skin (Huq et al. 2002).
   4. A potential role of fibronectin in the pathogenesis of Sturge-Weber syndrome. The gene expression findings in fibroblast (Comi et al. 2003) supported the hypothesis of a somatic mutation underlying the disorder.
   5. A novel synonymous mutation (c.1229G > A) (p.K420K) of RASA1 was identified in a Chinese patient with sporadic Sturge-Weber syndrome (Zhou et al. 2011): Further study is needed.
2. Basic defect: caused by residual embryonal blood vessels and their secondary effects on surrounding brain tissue.
3. Sturge-Weber syndrome and port-wine stains caused by somatic mutation in *GNAQ* (Shirley et al. 2013; Nakashima et al. 2014).
4. Angiomas are well documented in SWS and are thought to arise from a mutation in the guanine nucleotide-binding protein G (q) subunit alpha (GNAQ) which mediates signals between G-protein coupled receptors and

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_224

downstream processes. The finding of an angiomatous meningioma in SWS suggests a common pathway may be involved in the aberrant vascular proliferation of both conditions (Ahmed and Prayson 2015).

5. Pathophysiology: Neurologic dysfunction of the syndrome results from secondary effects of residual embryonal blood vessels on surrounding brain tissue:
   1. Hypoxia
   2. Ischemia
   3. Venous occlusion
   4. Thrombosis
   5. Infarction
   6. Vasomotor phenomenon
   7. Seizures
6. Factors contributing to epileptogenesis (Pinto et al. 2016):
   1. Decreased brain tissue perfusion due to abnormal venous drainage
   2. Anoxic injury contributing to cerebral calcification
   3. Breakdown of the blood–brain barrier
   4. Presence of developmental cortical malformations

Clinical Features

1. Variable natural history of the disease (Oakes 1992; Mirowski et al. 1999)
2. Three cardinal features (Comi 2003):
   1. Capillary malformation (port-wine stain, cutaneous angioma) in the upper trigeminal neural distribution
      1. Involves the ophthalmic branch of the trigeminal nerve, in particular, the upper eyelid and supraorbital region
      2. May extend into the maxillary and mandibular regions
      3. May be associated with soft tissue and bony overgrowth
      4. May be hidden in scalp or mouth
      5. May be absent in the forme fruste of Sturge-Weber syndrome
   2. Ocular abnormalities (Celebi et al. 2000; Mantelli et al. 2016):
      1. Usually ipsilateral to the port-wine stain, involving the eyelid, anterior chamber, cornea, choroid, and retina
      2. Glaucoma (60%) (Cibis et al. 1984): unilateral and is associated with the presence of an ipsilateral port-wine stain
      3. Buphthalmos
      4. Vascular malformations of the conjunctiva, episclera, choroids, and retina
      5. Rare choroidal hemangioma and nevus of Ota (Celebi et al. 2000)
   3. Leptomeningeal vascular malformation (angioma):
      1. May be unilateral (more common) or bilateral
      2. Usually ipsilateral to port-wine stain
      3. Capillary and venous anomalies of leptomeninges
      4. No correlation between the size of facial and CNS malformations
      5. Encephalotrigeminal angiomatosis with intracranial calcification (Alonso et al. 1979)
3. CNS manifestations:
   1. Seizure/epilepsy (75–90% of cases) (Arzimanoglou and Aicardi 1992)
   2. Bilateral intracranial calcification (15%) (Boltshauser et al. 1976)
   3. Mental retardation present in approximately 50% of cases
   4. Contralateral hemiplegia or hemisensory deficits
   5. Contralateral homonymous hemianopsia (impaired vision in half of the visual field)
   6. Headaches
   7. Developmental delay
   8. Learning disorders
   9. Attention deficit hyperactivity disorder
   10. Predictors of cognitive functions in children with Sturge-Weber syndrome (Bosnyák et al. 2016):
      1. The early trajectory of cognitive changes in children with unilateral Sturge-Weber syndrome is highly variable.
      2. Children with improving IQ likely undergo effective unimpeded functional reorganization.

3. Early onset, frequent seizures, and interictal epileptiform abnormalities on EEG likely interfere with this process resulting in poor cognitive functions.

11. Uncontrolled seizures, mental subnormality, visual handicap, and cosmetic disfiguration were the major impediments in life (Jagtap et al. 2012).

4. In a child with developmental delay presenting with seizures, macrocephaly, presence of port-wine stains on the body and imaging features of subcortical "tram-track"-like pattern of calcifications, parenchymal volume loss, enlarged choroid plexus, and calvarial hyperostosis are diagnostic of Sturge-Weber syndrome (Ragupathi et al. 2014).
5. Soft tissue and skeletal overgrowth (60–83%) (Greene et al. 2009):
   1. Often exhibit localized cutaneous growths, either pyogenic granuloma or fibrovascular nodules
   2. Do not combine venous, lymphatic, or arterial anomalies in an extremity, although simple diffuse venous varicosities have been seen
   3. Often erroneously diagnosed as having either Klippel-Trenaunay syndrome (extremity capillary-lymphatico-venous malformation with overgrowth)
   4. Parkes Weber syndrome (extremity capillary-arteriovenous malformation with overgrowth): Right-sided hemihypertrophy resulting from right-sided congenital spastic hemiplegia with a morbid condition of the left side of the brain revealed by radiogram (Parkes Weber 1922)
6. Long-term outcome in adults (Sujansky and Conradi 1995a, b; Arzimanoglou et al. 2000):
   1. Distribution of port-wine stain
      1. Cranial: 98%
      2. Extracranial: 52%
   2. Glaucoma (60%)
   3. Seizures (83%)
   4. Neurologic deficit (65%)
   5. Developmental delay usually associated with seizures
      1. With seizures: 43%
      2. Without seizures: 0%
   6. Presence of behavior and emotional problems
      1. With seizures: 85%
      2. Without seizures: 58%
   7. Require special education
      1. With seizures: 71%
      2. Without seizures: 0%
   8. Employability
      1. With seizures: 46%
      2. Without seizures: 78%
   9. Normal fertility
   10. Indications of progressive nature
      1. Increasing duration of seizures and postictal deficits
      2. Increase in atrophy or of calcified lesions or both
7. Classification of encephalofacial angiomatosis of Sturge-Weber syndrome (Roach 1992; Sudarsanam and Ardern-Holmes 2014; Mukherjee et al. 2015):
   1. Type I (both facial and leptomeningeal angioma, possible glaucoma) (classic Sturge-Weber syndrome).
   2. Type II (facial angioma alone, without evident endocranial involvement); may have glaucoma.
   3. Type III (isolated leptomeningeal-brain angioma): usually no glaucoma. Very few cases of Sturge-Weber syndrome type III have been reported (Pascual-Castroviejo et al. 1993).
8. Neurocutaneous syndromes (Chao 1959; Figueiredo et al. 2016):
   1. Autosomal dominant:
      1. NF1 (please see the chapter on "► Neurofibromatosis 1")
      2. NF2 (please see the chapter on "► Neurofibromatosis 2").
      3. Hereditary hemorrhagic telangiectasia: an inherited systemic vascular dysplastic disorder correlated with multiple mucocutaneous telangiectasias, recurrent nasal and gastrointestinal bleeding episodes, and large arteriovenous malformations of the lungs, liver, and/or brain.
      4. Tuberous sclerosis complex (please see the chapter on "► Tuberous Sclerosis").

5. Von Hippel-Lindau disease (please see the chapter on "► Von Hippel-Lindau Disease").
6. Hypomelanosis of Ito (please see the chapter on "► Hypomelanosis of Ito").

2. Autosomal recessive:
   1. Pseudoxanthoma elasticum: a connective tissue disorder that causes mineralization of elastic skin fibers, eyes, cardiovascular system, and digestive system.
   2. Xeroderma pigmentosum (XP): a disorder identified by photosensitivity, pigmentary transformation, premature aging of the skin, and development of malignant tumors as a result of cellular hypersensitivity to ultraviolet (UV) radiation due to an error in DNA repair. Patients with XP have been divided into eight complementation groups.
   3. Ataxia telangiectasia (please see the chapter on "► Ataxia-Telangiectasia").
3. X-linked:
   1. Fabry disease (deficiency of α-galactosidase A (a-Gal A) activity): Early manifestations include corneal and lenticular opacities, skin lesions, acroparesthesias, hypohidrosis, and gastrointestinal symptoms.
   2. Incontinentia pigmenti (please see the chapter on "► Incontinentia Pigmenti").
4. Sporadic:
   1. Sturge-Weber syndrome
   2. Wyburn-Mason Syndrome (retinoencephalofacial angiomatosis): characterized by arteriovenous malformations that affect the retina, visual pathways, midbrain, and facial structures

Diagnostic Investigations

1. Radiography:
   1. Asymmetric skull
   2. Double contour curvilinear following "gyriform" patterns of intracranial calcifications: Pathognomonic for Sturge-Weber syndrome (Boltshauser et al. 1976):
      1. Classic "tram-line," "tram-track," or "trolley-track" intracranial calcifications:
         1. Considered pathognomonic prior to modern neuroimaging
         2. Often a late finding
         3. May not be present initially
      2. Distribution:
         1. In the subcortical region, primarily in the parietal and occipital regions
         2. Unilateral (80%) or bilateral (20%)
2. EEG to evaluate seizure activities: The most consistent EEG finding was a unilateral reduction of background amplitude in the waking record (Brenner and Sharbrough 1976).
3. Angiographic findings:
   1. Lack of superficial cortical veins
   2. Nonfilling dural sinuses
   3. Abnormal, tortuous vessels
4. Ultra-widefield fluorescein angiography: first documentation of retinal vein-to-vein anastomoses in Sturge-Weber syndrome (Quan et al. 2015).
5. CT scan findings (Chamberlain et al. 1989; Di Rocco and Tamburrini 2006):
   1. Intracranial dense gyriform or "tram-track" calcifications which more commonly affect the parieto-occipital cortical area and/or the choroid plexus and are usually absent in early infancy.
   2. Diffuse high attenuation of the superficial and deep white matter, presumably due to microcalcifications.
   3. Gyriform enhancement after iodinated contrast enhancement, expression of the pial angiomatosis.
   4. Brain atrophy, consequence of vascular steal phenomenon (Limotai et al. 2015) of the pial angioma on the surrounding cortical structures.
   5. Thickening of the calvarium, more frequently observed in patients with early onset symptoms as an indirect feature of loss of the brain substance.
   6. Abnormal draining veins.
   7. Enlarged ipsilateral choroid plexus.

8. Blood–brain barrier breakdown during seizures.

6. MRI findings: the gold standard imaging modality for the identification of structural brain abnormalities (Di Rocco and Tamburrini 2006):
   1. Leptomeningeal enhancement with Gd-diethyltriaminepentaacetic acid on T1-weighted images is considered one of the most important signs that help define the extent of the vascular malformation; however, its absence does not exclude the diagnosis (Elster and Chen 1990).
   2. Enlarged choroid plexus.
   3. Sinovenous occlusion.
   4. Cortical atrophy.
   5. Accelerated myelination.
7. MRI with contrast for any parturient with a port-wine nevus of the face in the ocular (trigeminal nerve) region have to rule out an intracranial vascular malformation, especially if a related seizure disorder is present (Dolkart and Bhat 1995).
8. Even though computed tomography and T1- and T2-weighted magnetic resonance imaging have great diagnostic value, magnetic resonance imaging enhanced with gadolinium-DTPA discloses the cerebral, leptomeningeal, and ocular lesions before the first evidence of neurologic abnormality (Pascual-Castroviejo et al. 1993).
9. Single-photon emission computed tomography to measure cerebral blood flow (Griffiths 1996; Pinton et al. 1997):
   1. Hyperperfusion early (before 1 year)
   2. Hypoperfusion late (after 1 year)
10. Positron emission tomography (PET) for hypometabolism.
11. Histology:
    1. Thickened and discolored leptomeninges
    2. Abnormal venous structures
    3. Calcifications (Di Trapani et al. 1982):
       1. Cerebral vessel walls
       2. Perivascular tissue
       3. Rarely within neurons

Genetic Counseling

1. Recurrence risk:
   1. Patient's sib: low
   2. Patient's offspring: low
2. Prenatal diagnosis: not been reported
3. Management (Thomas-Sohl et al. 2004; Comi 2015; Sudarsanam and Ardern-Holmes 2014; Takeoka 2015):
   1. Medical care:
      1. Medications for recurrent headaches/migraine
         1. Ibuprofen: first choice
         2. Abortive therapy with sumatriptan
         3. Preventive therapy with propranolol or nortriptyline
      2. Stimulant medication may be a safe and effective intervention for SWS children with attention issues/attention deficit hyperactivity disorder (ADHD) (Lance et al. 2014).
      3. Management of glaucoma to control the intraocular pressure and prevent progressive visual loss and blindness:
         1. Beta-blocker drops: first choice
         2. Adrenergic drops or carbonic anhydrase inhibitor drops: second choice
      4. Anticonvulsants for seizure (partial epilepsy most prevalent in children) control:
         1. Carbamazepine and oxcarbazepine: first choice (Kaplan et al. 2016)
         2. Valproate, topiramate, phenobarbital, phenytoin
      5. Strokelike episodes: aspirin
      6. Neurobehavioral problems:
         1. Methylphenidate: first choice
         2. Clonidine: second choice
         3. Dextroamphetamine or risperidone
      7. Dermatologic laser therapy for port-wine stain: Treatment of the cutaneous PWS with dye laser photocoagulation has been helpful in reducing the cosmetic blemish from the cutaneous vascular dilatation.

8. Port-wine birthmark (Comi 2015):
    1. Laser therapy of port-wine stains: a method of selection (Kowalska-Brocka et al. 2015).
    2. Treated with laser procedures beginning in infancy when the flat, pink birthmark responds best and the birthmark is smaller (Chapas et al. 2007).
    3. Early laser treatment may lessen later progression of the birthmark, which can consist of tissue hypertrophy, blebs, and complications affecting vision, airway, and swallowing.
9. Successful treatment with photodynamic therapy for Sturge-Weber syndrome-associated diffuse choroidal hemangioma (Nugent et al. 2015).

2. Anesthetic management of pediatric patients with Sturge-Weber syndrome (Khanna et al. 2015):
    1. Avoiding a rise in intracranial and intraocular pressures, vigilant intraoperative monitoring, and postoperative care are the key for conducting safe anesthesia in these children.
    2. Sevoflurane was safely used in children with seizures.
    3. For ophthalmic procedures, laryngeal mask airway can be used for airway maintenance with minimal complications in children with SWS.
3. Surgical care:
    1. Surgery (trabeculectomy) for glaucoma if medications fail to lower intraocular pressure.
    2. Drainage valve implantation, with an anterior chamber maintainer, is a good choice for treatment when surgery is done in cases with glaucoma. This method may reduce the risk of intraoperative suprachoroidal effusion and expulsive hemorrhage by stabilizing intraocular pressure within normal limits during the surgery (Celebi et al. 2000).
    3. Option of early surgery for patients with Sturge-Weber syndrome with drug-resistant epilepsy:
        1. Focal cortical resection
        2. Hemispherectomy
        3. Corpus callosotomy
        4. Vagal nerve stimulation
    4. Lesionectomy provided that the pial angioma is unilateral and the resection can be complete.
    5. Hemispherectomy:
        1. For treatment of encephalotrigeminal angiomatosis (Falconer and Rushworth 1960): All exhibited epilepsy and/or a behavioral disturbance occurring in association with an infantile hemiplegia and their epilepsy and personality conditions were improved by excision of the affected cerebral hemisphere (hemispherectomy), but not their infantile hemiplegia. All remained mentally backward, but the four who were operated on during childhood proved to be educable.
        2. One can expect excellent results if the indications for surgery are carefully analyzed and hemispherectomy is performed on an individual basis (Ito et al. 1990).
        3. Children undergoing hemispherectomy presented at a young age and had frequent seizures for approximately 1 year but are now mostly seizure-free (Kossoff et al. 2002).

Symphalangism

Contents

Symphalangism is a rare congenital condition characterized by stiffness of the digits caused by ankylosis of the interphalangeal joints of the fingers and toes. Symphalangism was first described by Harvey Cushing in 1916 (Fig. 1).

Synonyms and Related Disorders

Cushing proximal symphalangism; Proximal symphalangism with conductive hearing loss; Multiple synostosis syndrome; Symbrachydactyly

Genetics/Basic Defects

1. Symphalangism was initially used to describe an autosomal dominant disorder affecting PIP joints of the fingers (Cushing 1919; Strasburger et al. 1965; Elkington and Huntsman 1967; Gaal et al. 1988; Castle et al. 1993)
2. Caused by mutations of the nogin (*NOG*) gene (on chromosome 17q22) in most cases of symphalangism (Polymeropoulos et al. 1995; Takahashi et al. 2001)
3. Identical mutations in *NOG* can cause either tarsal/carpal coalition syndrome or proximal symphalangism (Dixon et al. 2001)
4. Mutations in another protein, growth and differentiation factor 5 (*GDF5*): recently found to be associated with symphalangism (Seemann et al. 2005)
5. *NOG* and *CDF5* genes have been identified to be the disease-causing genes of proximal symphalangism (SYM1) (Gong et al. 1999; Seemann et al. 2005)
6. Nonhereditary symphalangism, often seen with symbrachydactyly, is reported as sporadic (Upton 2005)

Clinical Features

1. Symphalangism may involve proximal or distal interphalangeal joints, although proximal interphalangeal joint involvement is more common (Borah et al. 2006).
2. The fused phalanges cause disability or loss of hand function, including the inability to make a fist or perform activities that require fine manual dexterity (Durmus et al. 2012).
3. The diagnosis is currently applied most often to congenital stiffness of the finger joints with absence of transverse volar skin creases over

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_270

those joints that are fused (Flatt and Wood 1975)

4. Proximal symphalangism (Plett et al. 2008; Potti et al. 2011; Liu et al. 2014)
    1. Also called Cushing proximal symphalangism
    2. An autosomal dominant disorder
    3. Ankylosis of the PIP joints of the fingers and toes: generally affect the PIP joints of digits from the ulnar side to the radial side and finally to the thumbs
    4. Frequently associated with other bony fusions
        1. Talonavicular synostosis in the feet (Geelhoed et al. 1969)
        2. Ear ossicle (stapes) fusion leading to conductive deafness
    5. When the abnormality is more extensive, it is termed multiple synostosis syndrome (Maroteaux et al. 1972)
    6. Other clinical features
        1. Hyperopia
        2. Characteristic facies: a broad hemicylindrical nose with a lack of alar flare and a thin upper vermilion (Herrmann 1974)
        3. Absent flexion creases of the digits
        4. Shortened metacarpals and hypoplasia or aplasia of the distal phalanges in the hands and feet
5. Distal symphalangism
    1. Ankylosis or rigidity of the distal interphalangeal joints of the hands and/or feet (Poush 1991)
    2. Inheritance consistent with autosomal dominant inheritance
6. Classification of symphalangism by Flatt and Wood (1975)
    1. True symphalangism: involved digit with normal length
    2. Symbrachydactylism: short and stiff digits
    3. Symphalangism with associated anomalies
7. Associated syndromes, e.g.,
    1. Apert syndrome
    2. Poland syndrome
    3. Wassel type III polydactyly with symphalangism: thumb duplication with symphalangism (Wassel 1969; Boutros et al. 1998; Al-Aithan et al. 2005; Takagi et al. 2009; Al-Qattan 2010; Ciloglu et al. 2014)

Diagnostic Investigations

1. Radiography
1. Hallmark feature: longitudinal bony fusion across the joint
2. Involvement sites
    1. Symphalangism of the distal interphalangeal (DIP) can be seen in patients with symbrachydactyly
    2. Involvement of the metacarpophalangeal (MP) joint: extremely rare (Flatt and Wood 1975; Upton 2005)
2. Molecular genetic analysis for NOG and CDF5 genes: currently not available clinically

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. Autosomal dominant inheritance: not increased unless a parent is affected
        2. Sporadic: apparently not significantly increased
    2. Patient's offspring
        1. Autosomal dominant inheritance: a 50 % risk
        2. Sporadic: apparently not significantly increased
2. Prenatal diagnosis: has not been reported
3. Management
    1. Treatment of symphalangism in adults: uniformly unsuccessful
    2. Manipulations and various arthroplasties can be applied to the fusions, but patient satisfaction is poor (Flatt and Wood 1975)
    3. Surgical intervention is rarely indicated, and physical, occupational, and exercise therapies are usually beneficial (Joshi et al. 2008)
    4. Physical therapy: considered before surgical intervention (Durmus et al. 2012)

5. Symphalangism of the hand in children: can be restored into a mobile joint by release of the collateral ligament, a dorsal capsulotomy, and postoperative physical therapy (Baek and Lee (2012)

Fig. 1 (**a**–**c**) The patient was evaluated for congenital stiffness of finger joints and inability to make fists. The knuckles were smooth over the proximal interphalangeal (*PIP*) joints of the 2nd to 5th fingers of both hands. The distal phalanx motions were normal (**a**, **b**). The hand radiograph showed PIP joint ankylosis of the 3rd–5th fingers and severely reduced PIP joint space of the 2nd fingers of both hands (only the right hand is shown here) (**c**)

Tay-Sachs Disease

Contents

Tay-Sachs disease is a hereditary neurodegenerative disorder resulting from excess storage of GM2 ganglioside within the lysosomes of cells, caused by deficiency of hexosaminidase A. The incidence of the disease is estimated to be 1 in 3,600 in Ashkenazi Jews (AJ) with carrier frequency of 1 in 30 and 1 in 360,000 in other population with carrier frequency of 1 in 300. Tay-Sachs disease is the most frequently occurring sphingolipidoses.

Synonyms and Related Disorders

GM1-gangliosidosis; GM2 activator protein deficiency (GM2-gangliosidosis-AB variants); GM2-gangliosidosis; Hexosaminidase A deficiency; Sandhoff disease

Genetics/Basic Defects

1. Inheritance: autosomal recessive.
2. Biochemical defect (Brady 2001): deficiency of the isoenzyme β-hexosaminidase A (Hex A).
3. Genetic basis.
    1. Mutations in the hexosaminidase A (*HEXA*) gene (on chromosome 15q23-q24) that codes for the subunit of the β-hexosaminidases result in the deficiency of Hex A (αβ) that results in Tay-Sachs disease.
    2. A high heterogeneity of HEXA lesions in Tay-Sachs disease (Akli et al. 1993).
    3. Over 100 different mutations have been identified in the *HEXA* gene to date.
    4. Presence of a small number of common mutations in populations where the carrier frequency is high (Sutton 2002).
        1. Ashkenazi Jews (Bach et al. 2001).
            1. Two common mutations associated with Tay-Sachs disease [a four base-pair insertion into exon 11 of the *HEXA* gene (1278insTATC) accounting for 75–80% of all mutations in this population; a splice site mutation in intron 12 (1421 + 1G → C) accounting for 15% of mutations]

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_225

2. One mutation associated with a late-onset form of the disease (G269S in 3% of carriers)
3. The high incidence of the disease in Ashkenazi Jews is attributed predominantly to three mutations present in high frequency, while in non-Jews some two dozen mutations have been identified thus far (Gravel et al. 1991)
4. Pseudodeficiency polymorphism (R247W in 2% of carriers)

2. Pennsylvania Dutch.
   1. An intron 9 splice site mutation (1,073 + 1G → A)
   2. Pseudodeficiency allele (R247W)
3. Cajuns in Southern Louisiana: A genealogy could well trace to a single ancestral couple (Thurmon 1993).
   1. An intron 9 splice site mutations (1,073 + 1G → A)
   2. Four base-pair insertion in exon 11 (1278insTATC)
4. French Canadians in Eastern Quebec.
   1. A large (7.6 kb) deletion at the 5′ end of the gene
   2. A splice site mutation in intron 7 (805 + 1G → A)
   3. Common 4 base-pair insertion in exon 11 seen in Ashkenazi Jews (1278insTATC)

4. GM2-gangliosidosis-AB variants (Sheth et al. 2016).
   1. A rare autosomal recessive neurodegenerative disorder occurring due to deficiency of GM2 activator protein resulting from the mutation in *GM2A* gene.
   2. Children with phenotypic presentation as GM2-gangliosidosis (Tay-Sachs or Sandhoff disease) and normal enzyme activity of β-hexosaminidase A and β-hexosaminidase B in leucocytes need to be investigated for GM2 activator protein deficiency.
5. The concept of Tay-Sachs disease as the only ganglioside storage disease has expanded to two forms of gangliosidoses, GM1-gangliosidoses and GM2-gangliosidoses, and the latter into three distinct genetic disorders, Tay-Sachs disease, Sandhoff disease, and the GM2 activator protein deficiency. More recently, all three genes coding for the three proteins each responsible for distinct genetic forms of GM2-gangliosidosis – beta-hexosaminidase alpha and beta subunits and the GM2 activator protein – have been cloned, and many disease-causing mutations have been identified (Suzuki 1994).
6. Sphingolipidoses or gangliosidoses (Chen et al. 2014).
   1. Include GM1-gangliosidoses and GM2 (Tay-Sachs)-gangliosidoses, Niemann-Pick disease, Gaucher disease, Farber disease, Krabbe disease, Fabry disease, and metachromatic leukodystrophy.
   2. Each disease includes several types that are named for the lipid substrate that accumulate in each case.
   3. With the exception of X-linked recessive Fabry disease, they share a common autosomal recessive inheritance pattern and have a collective frequency of 1 in 8,000 live births.
   4. Multiple-organ dysfunction (liver, lung, spleen, heart, and lungs) is common.
   5. Since gangliosides are abundantly expressed in the central nervous system, the diseases share clinical findings, including a spectrum of early onset progressive neurodegeneration and a "cherry-red macula" from accumulation of various sphingolipid precursors or by-products within cells of the retina.

Clinical Features

1. Classic infantile acute-onset Tay-Sachs disease
   1. Natural history (Sutton 2002)
      1. Appears normal at birth
      2. Normal motor development in the first few months of life
      3. Progressive weakness and loss of motor skills beginning around 2–6 months of life

4. Followed by decreased social interaction, increased sensitivity to noise (hyperacusis), and an increased startle response to noise
5. Progressive neurodegeneration
6. Uniformly fatal: death from pneumonia usually occurring between 2 and 5 years of age

2. Clinical features
    1. Delayed development
    2. Poor feeding
    3. Lethargy
    4. Hypotonia
    5. Hyperreflexia
    6. Opisthotonos
    7. Hyperacusis
    8. A cherry-red spot on the fovea centralis of the macula, representing loss of ganglion cells in the foveal area with the remaining ones filled with the ganglioside
    9. The disappearance of the cherry-red spot in an otherwise typical patient with Tay-Sachs disease: consistent with the pathological finding of loss of retinal ganglion cells (Kivlin et al. 1985)
    10. Progressive neurodegeneration
        1. Developmental regression.
        2. Macrocephaly secondary to accumulation of storage material within the brain after about 15 months of age. There is no evidence of hepatosplenomegaly or other peripheral evidence of storage disease.
        3. Myoclonic seizures, most during the first year of life.
        4. Progressive macular degeneration leading to blindness, usually by 1 year of age.
        5. Deafness.
        6. Spasticity.
        7. Complete disability.

2. Subacute (juvenile) Tay-Sachs disease (2–18 years of age): characterized by progressive neurologic deterioration that mainly affects motor and spinocerebellar function leading to:
    1. Progressive spasticity with seizures and dementia
    2. A vegetative state by late childhood or mid-teens
3. Juvenile or subacute GM2-gangliosidosis (Maegawa et al. 2006)
    1. A group of inherited neurodegenerative diseases caused by deficiency of lysosomal beta-hexosaminidase resulting in GM2-ganglioside accumulation in brain.
    2. Clinically heterogeneous, not only in terms of age of onset and clinical features but also with regard to the course of the disease.
    3. In general, the earlier the onset of symptoms, the more rapidly the disease progresses.
    4. The Tay-Sachs and Sandhoff variants differed somewhat in the frequency of specific clinical characteristics.
    5. Speech deterioration progressed more rapidly than gait abnormalities in both the Tay-Sachs variant and Sandhoff variant groups.
    6. Among patients with the Tay-Sachs variant, the HEXA genotype showed a significant correlation with the clinical course.
4. Late-onset (adult) Tay-Sachs disease (Shapiro et al. 2008)
    1. A chronic, progressive, lysosomal storage disorder caused by a partial deficiency of beta-hexosaminidase A (HEXA) activity.
    2. Deficient levels of HEXA result in the intracellular accumulation of GM2-ganglioside, resulting in toxicity to nerve cells.
    3. Clinical picture varied between and within families and included spinocerebellar, various motor neuron, and cerebellar connection syndromes (Argov and Navon 1984).
    4. Clinical manifestations primarily involve the central nervous system (CNS) and lower motor neurons, including:
        1. Ataxia.
        2. Weakness.
        3. Spasticity.
        4. Dysarthria.
        5. Dysphagia.
        6. Dystonia.
        7. Seizures.

8. Psychosis: Psychosis is reported in 30–50% of adult-onset patients, and many are misdiagnosed with schizophrenia (MacQueen et al. 1998).
9. Mood disorders are present in more than 25% (MacQueen et al. 1998).
    1. Mania
    2. Depression
10. Cognitive decline (more than 20%).

5. The prevalence of peripheral nervous system: a predominantly axon loss polyneuropathy affecting distal nerve segments in the lower and upper extremities (27% of cases).

5. Late-onset GM2-gangliosidosis (Brett et al. 1973)
    1. Hexosaminidase A: Partial and profound deficiency
    2. Gait disturbance
    3. An exaggerated startle reaction to sound and an unusual type of cherry-red spot at the macula
    4. Optic atrophy in late stage
    5. Pathological changes: similar to Tay-Sachs disease

Diagnostic Investigations

1. Newborn screening: enzymatic diagnosis in dried blood spots on filter paper for Tay-Sachs and Sandhoff diseases (Chamoles et al. 2002).
2. Diagnosis and carrier testing (heterozygote screening) (Kaback et al. 1977).
    1. Indications for carrier testing.
        1. Fully or partially Jewish
        2. Pennsylvania Dutch
        3. Cajuns of Southern Louisiana
        4. French Canadians of Eastern Quebec
    2. Ashkenazi Jewish population screening for Tay-Sachs disease (Lew et al. 2015a).
        1. Should be offered to Ashkenazi Jewish (AJ) individuals of reproductive age in order to provide informed reproductive choice
        2. Partners of TSD carriers should be offered screening, regardless of heritage
3. Preconceptional counseling for at-risk couples.
4. Enzyme assay.
    1. Using fluorimetric study measuring activity of both Hex A and Hex B in either serum or leukocytes
    2. Decreased activity of Hex A with normal or increased activity of Hex B in carriers
    3. Limitations of serum assay
        1. Overlapping of the values between carriers and noncarriers
        2. Unreliable in pregnant women and in women taking oral contraceptives
        3. Inability to distinguish carriers of pseudodeficiency alleles from carriers of disease-causing mutations
    4. Clarification of abnormal or inconclusive results of enzyme assay by:
        1. Enzyme assay on leukocytes
        2. DNA mutation analysis for common mutations and pseudodeficiency alleles
5. In the future it would be expected that a laboratory using a single DNA-based technology could diagnose and screen for a myriad of human diseases including Tay-Sachs disease (Mahuran et al. 1990).
6. Next-generation DNA sequencing of HEXA: a step in the right direction for carrier screening (Hoffman et al. 2013).
7. Molecular genetic testing (Kaback and Desnick 2011).
    1. Targeted mutation analysis: using a panel of common *HEXA* mutations when assay of HEXA enzymatic activity is abnormal:
        1. In a symptomatic individual in order to identify the disease-causing mutations
        2. In an asymptomatic individual to evaluate for the presence of a pseudodeficiency allele
    2. Sequence analysis/mutation scanning: to identify *HEXA* mutations in an individual who:

    1. Is affected but had only one or neither mutation identified using a panel of standard mutations
    2. Has carrier-level enzymatic results but did not have a mutation identified using a panel of standard mutations
    3. Massively parallel DNA sequencing is expected to become the testing modality of choice over the coming years (Lew et al. 2015b).
3. CT scan of the brain: areas of low density in the basal ganglia and cerebral white matter
4. MRI of the brain.
    1. An increased signal in the basal ganglia and cerebral white matter on T_2-weighted images
    2. Thalamic T2 hypointensity: a diagnostic clue for Tay-Sachs disease (Güngör et al. 2016)
5. Brain imaging in late-onset GM2-gangliosidosis: Cerebellar atrophy, particularly of the vermis, was a prominent feature in all patients with normal-appearing cerebral hemispheres (Streifler et al. 1993).
6. In adults with cerebellar atrophy and signs of anterior horn disease, diagnostic considerations should include late-onset Tay-Sachs disease/GM2-gangliosidosis (Steiner et al. 2016).
7. MR spectroscopy (Aydin et al. 2005).
    1. Demonstrates an increase in myoinositol/creatine and choline/creatine ratios with a decrease in the N-acetyl aspartate/creatine ratio.
    2. The spectroscopy findings support demyelination, gliosis, and neuronal loss in the neuropathological process of Tay-Sachs disease.
8. Characteristic neuropathological findings (Kaback et al. 1993).
    1. Pathologic changes are restricted to the nervous system.
    2. Ballooning of neurons with massive intralysosomal accumulation of lipophilic membranous bodies.
    3. Nature and structure of the stored intraneuronal material : GM2-ganglioside.
    4. Ultrastructural demonstration of neuronal storage in fetal Tay-Sachs disease (Cutz et al. 1974).
    5. Abnormal cytoplasmic inclusion bodies identified in fetal spinal cord at 12 weeks and retina and spinal ganglia during 19th–22nd week of gestation (Adachi et al. 1974).
    6. Cisternae of the endoplasmic reticulum: the primary site of lipid accumulation in neurons during the fetal stage of Tay-Sachs disease (Adachi et al. 1974).
9. Chemical studies on three fetuses (Schneck et al. 1972).
    1. Absence of hexosaminidase A activities in all tissues in one fetus
    2. Increase in the percent of cerebral GM2-ganglioside
    3. Abnormal inclusion bodies seen in fetal neurons

Genetic Counseling

1. Recurrence risk.
    1. Patient's sib: 25%
    2. Patient's offspring
        1. Acute infantile form: not surviving to reproductive age.
        2. Late-onset form may reproduce: risk not increased unless the spouse is a carrier.
2. Prenatal diagnosis (Kaback and Desnick 2011) is available when HEXA enzyme assay has shown both parents to be heterozygous, and molecular genetic testing has ruled out the presence of a pseudodeficiency allele in either parent:
    1. Enzyme analysis (absence of hexosaminidase A) on cultured or uncultured amniocytes (O'Brien et al. 1971) or chorionic villus cells (Grebner and Jackson 1985).
    2. The use of MUGS (4-methylumbelliferyl-2-acetamido-2-deoxy-beta-D-glucopyranosyl-6-sulfate) as substrate for HEXA makes prenatal diagnosis by CVS

of families at risk for TSD simple, direct, and accurate (Callahan et al. 1990).

3. First-trimester prenatal diagnosis of Tay-Sachs disease (Grabowski et al. 1984): The diagnoses were based on the absence of beta-hexosaminidase A activity as determined by (1) specific enzyme assays, (2) anion-exchange chromatography, and (3) cellulose acetate gel electrophoresis.
4. DNA analysis when one of the common mutations had been identified in the family.
    1. Preferred method of prenatal diagnosis
    2. Less prone to error
5. Preimplantation genetic diagnosis (Hansis and Grifo 2001; Georgiou et al. 2014) may be available for families in which the disease-causing mutations have been identified in an affected family member.

3. Management (Desnick and Goldberg 1977).
    1. No effective treatment to alter the natural history.
    2. Primarily supportive.
        1. Provide adequate nutrition and hydration
        2. Manage infections
        3. Protect airway
        4. Control seizures
        5. Bowel management
    3. Psychologic care of carriers and affected families (Schweitzer-Miller 2001).
    4. Enzyme replacement therapy and bone marrow transplantation: not yet successful.
    5. Options to modify 25% risk of having an affected child with each pregnancy if both partners are found to be carriers (Sutton 2002).
        1. Prenatal diagnosis by amniocentesis or chorionic villus sampling
        2. Egg or sperm donation
        3. Preimplantation genetic diagnosis
        4. Adoption
    6. Coordinating adult education, carrier testing, and genetic counseling directed toward prospective prevention of a uniformly fatal childhood disease and demonstrate that such an effort can dramatically affect disease incidence (dramatic decreased in the incidence of TSD (Kaback et al. 1993).

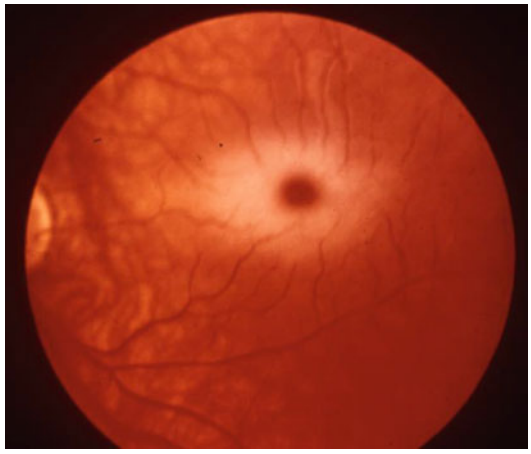

Fig. 1 A cherry-*red* spot on the fovea centralis of the macula from the fundus of an infant with Tay-Sachs disease

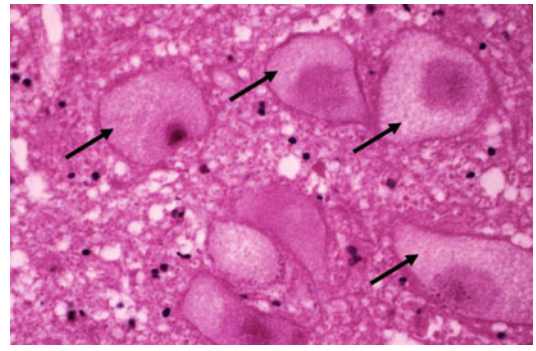

Fig. 3 A section of medulla showing a group of neurons with markedly distended foamy cytoplasm (*arrows*) due to accumulation of GM2-ganglioside (H & E, ×1,000)

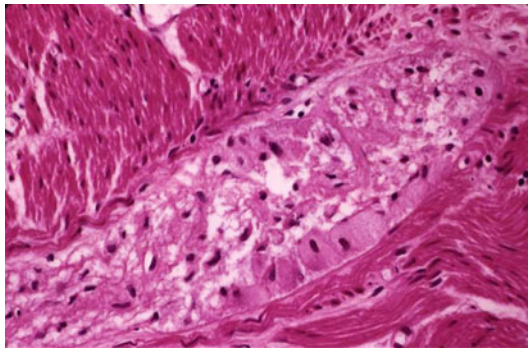

Fig. 2 Myenteric plexus of the rectum (H & E, ×400) showing many enlarged ganglion cells with abundant foamy cytoplasm due to ganglioside storage. Rectal biopsy can be a good source of neurons in confirming neuronal storage disease. In this patient, Tay-Sachs disease was confirmed by electron microscopic examination of ganglion cells

Tetrasomy 9p Syndrome

Contents

Tetrasomy 9p syndrome, a clinically diagnosable condition, is a rare cytogenetic disorder characterized by tetrasomy 9p associated with a distinctive patterns of multiple congenital anomalies. In *1973*, Ghymers et al. (1973) first described the syndrome.

Synonyms and Related Disorders

Supernumerary isochromosome 9p syndrome

Genetics/Basic Defects

1. Caused by de novo supernumerary isodicentric chromosome 9p (presence of four copies of the short arm of the chromosome 9) (9pter to 9q2101) (Abe et al. 1977)
    1. Pure tetrasomy 9p
    2. Tetrasomy involving the varying segment of the short arm of chromosome 9
2. Cytogenetic types of tetrasomy 9p
    1. Presence of an extra dicentric chromosome 9 consisting entirely of 9p
    2. Presence of an extra dicentric chromosome 9 consisting of 9p and the proximal part of 9q
    3. Mosaicism involving tetrasomy 9p: mosaic of i(9p) cells
    4. Nonmosaic partial tetrasomy involving all of the short arms and asymmetrical segments of the long arms (Shapiro et al. 1985)
3. Hypotheses proposed to explain tetrasomy 9p
    1. A meiosis I disturbance with nondisjunction and rearrangement in two of the four chromatids of a bivalent 9, resulting in the formation of an isochromosome 9p
    2. Meiosis II nondisjunction followed by rearrangements (isochromosome formation) with duplication of the short arm and loss of the acentric long arm at the subsequent mitosis
    3. Dicentric versus monocentric (de Azevedo Moreira et al. 2003)
        1. Using conventional cytogenetics and banding techniques revealed an additional dicentric 9p chromosome in most cases.
        2. Using molecular studies using a chromosome 9 classic satellite probe shows an error in the division of centromere 9 by a double-break event, resulting in the formation of a monocentric isochromosome 9p.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_226

Clinical Features

1. Tetrasomy 9p: a unique, clinically recognizable syndrome (Jalal et al. 1991; Fryns 1998)
2. Craniofacial abnormalities (El Khattabi et al. 2015)
    1. Delayed closure of the anterior fontanel
    2. Ocular hypertelorism
    3. Telecanthus
    4. Strabismus
    5. Enophthalmos/microphthalmia
    6. Epicanthal folds
    7. Prominent beaked or bulbous nose
    8. Down-turned corners of the mouth
    9. Microretrognathia
    10. Low-set, malformed ears
    11. Cleft lip/palate
    12. High-arched palate
3. Cardiac anomalies
    1. Ventricular septal defect
    2. Atrial septal defect
    3. Patent ductus arteriosus
    4. Persistent left superior vena cava
    5. Double outlet of the right ventricle
    6. Hypoplastic right ventricle
    7. Hypoplastic left heart ventricle
4. Lung anomalies
    1. Lung hypoplasia
    2. Abnormal lobulation of the lung
5. Renal anomalies
    1. Renal hypoplasia
    2. Multicystic dysplasia
    3. Hydroureter
    4. Hydronephrosis
6. Genital anomalies
    1. Cryptorchidism
    2. Genital hypoplasia
    3. Micropenis
    4. Hypoplastic shawl-like scrotum
    5. Ambiguous genitalia
    6. Duplications 9p may result in impairment of ovarian function (Cuoco et al. 1982)
7. Gastrointestinal anomalies
    1. Intestinal malrotation
    2. Hirschsprung disease (Melaragno et al. 1992)
8. CNS anomalies
    1. Psychomotor retardation
    2. Hypotonia
    3. Microcephaly
    4. Brachycephaly
    5. Hydrocephalus
    6. Cerebral hypoplasia
    7. Dandy-Walker cyst
    8. Absence of olfactory bulbs
    9. Hypoplastic cerebellum
9. Skeletal anomalies
    1. Growth retardation
    2. Short stature
    3. Short neck
    4. Dysplastic fingernails
    5. Limb anomalies
    6. Clinodactyly of the fifth fingers
    7. Club feet
    8. Articular dislocations
    9. Shortened hands and feet
10. Other features
    1. Single umbilical artery
    2. Failure to thrive
    3. Redundant skin
    4. Widely spaced nipples
    5. Single palmar crease
    6. Sacral dimple
    7. Mosaic tetrasomy 9p predisposes to pediatric-onset inflammatory myositis and lupus-like features (Frémond et al. 2015)
11. The severity of the phenotype correlates with size of the tetrasomic region and the degree of tissue mosaicism for the tetrasomy 9p.
12. A case of nonmosaic tetrasomy 9p with long-term survival reported (Tonk 1997)
13. Cases of isochromosome tetrasomy 9p mosaicism associated with a normal phenotype reported (Papoulidis et al. 2012)

Diagnostic Investigations

1. Cytogenetic studies to identify supernumerary marker chromosomes (Tan et al. 2007)
    1. Conventional and high-resolution analyses
    2. A whole-chromosome paint probe for chromosome 9 to identify the supernumerary chromosome, using the fluorescence in situ

hybridization (FISH) technique (Callen et al. 1992; Crolla et al. 1998; Eggermann et al. 1998)
3. Microdissection and reverse FISH (micro-FISH) (Mahjoubi et al. 2005; de Pater et al. 2006)
4. Multiplex-FISH (M-FISH) technique (Uhrig et al. 1999)
5. Centromere-specific multicolor-FISH assays (Nietzel et al. 2001)
6. AcroM-FISH technique (Langer et al. 2001): involves a newly generated probe mix, which consists of painting probes for all acrocentric chromosomes, centromere probes for chromosomes 13/21, 14/22, 15, and a probe specific for rDNA, each labeled with a specific combination of fluorochromes. This probe mix is sufficient to characterize approximately 80% of all SMCs (supernumerary marker chromosomes). For the other 20% of SMCs, chromosomes can be analyzed in a second hybridization by multicolor karyotyping, for example, multiplex FISH (M-FISH), to check for the presence of euchromatin of other chromosomes.
7. Tissue-limited mosaicism (Lloveras et al. 2004): Isochromosome 9p shows a strong propensity to tissue-limited mosaicism. It occurs predominantly in peripheral blood cultures, often at a lower frequency or even absent in skin, amniotic fluid, or chorionic villous cell cultures. Tissue-limited nature of mosaicism may render prenatal detection of this condition very difficult. This cytogenetic interpretation was substantiated by quantitative measurement of erythrocyte galactose-1-P-uridyltransferase (GALT) activity, which is consistent with the expression of four normal GALT genes (Papenhausen et al. 1990)
8. Array CGH is able to detect mosaicism, establish the euchromatic content of supernumerary marker chromosomes, and identify imbalances elsewhere in the genome allowing more accurate counselling and prognosis for patients (Shehab et al. 2011)

2. Echocardiography for cardiovascular malformations
3. Radiography
    1. Microcephaly
    2. Hypertelorism
    3. Hypoplastic first and 12th ribs
    4. Kyphoscoliosis
    5. Clinodactyly and brachymesophalangy of the fifth fingers
    6. Delayed ossification of pubic bones and ischiopubic synchondrosis
    7. Delayed ossification of femoral heads
    8. Spina bifida occulta
    9. Generalized osteoporosis
4. Ultrasonography of renal abnormalities

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: not increased
    2. Patient's offspring: patient not surviving to reproductive age
2. Prenatal diagnosis
    1. Ultrasonography (Dhandha et al. 2002; Tan et al. 2007; Nakamura-Pereira et al. 2009)
        1. Increased nuchal translucency in the first trimester
        2. Intrauterine growth retardation
        3. Genitourinary/renal anomalies
        4. Cleft lip/palate
        5. CNS anomalies
            1. Dandy-Walker malformation
            2. Ventriculomegaly
            3. Hypoplastic/absent vermis
            4. Agenesis of corpus callosum
        6. Limb malformations: bilateral club feet
        7. Vertebral anomalies
        8. Cardiac anomalies
        9. Genitourinary anomalies
        10. Polyhydramnios/oligohydramnios
        11. Absent nasal bone as a marker of tetrasomy 9p (Podolsky et al. 2011)
    2. 3D ultrasonography at 16 weeks' gestation (Lazebnik and Cohen 2015)
        1. Widely open metopic suture and anterior fontanel

2. Abnormal profile due to micrognathia and low-set posteriorly rotated ears
3. Abnormal connection between the posterior fossa and the fourth ventricle, suggesting Dandy-Walker malformation of the cerebellum
4. Echogenic focus in the fetal heart
5. Single umbilical artery
6. Cervical spine abnormality as well as 11 bilateral ribs
7. Bilateral rocker bottom clubfoot

3. Chromosome analysis to demonstrate tetrasomy of the short arm of chromosome 9 (+i(9)(p10)) of amniocytes (Tang et al. 2004), CVS, or fetal blood from cordocentesis (Schaefer et al. 1991): Microdissection and pre-G-banded FISH is important in determining the origin of supernumerary marker chromosome in prenatal diagnosis
4. Prenatal diagnosis of mosaic tetrasomy 9p (Wang et al. 2015)
   1. Karyotype: 47,XX,+idic(9)(q12)/47,XX,+idic(9)(q12)
   2. Partial G-banded and C-banded karyotype showed two normal chromosomes 9 and the i psu dic(9)(pter → q12::q12 → pter)
   3. FISH with subtelomere probe: A chromosome 9p specific subtelomeric probe (TelVysion 9p, green signal) (Vysis, Downers Grove, IL, USA) demonstrates green signals on both ends of the supernumerary idic(9)
5. Mosaic tetrasomy 9p at amniocentesis (Chen et al. 2014)
   1. Array comparative genomic hybridization analysis of uncultured amniocytes detected a genomic gain at 9p24.3-9q21.11.
   2. Interphase fluorescence in situ hybridization analysis of uncultured amniocytes using a 9p24.3-specific probe RP11-31 F19 (spectrum red) showed four red signals in 47.1% (49/104 cells) in uncultured amniocytes.
   3. Cytogenetic analysis of cultured amniocytes revealed a karyotype of 47, XX, +idic(9)(pter → q21.11::q21.11 → pter)[4]/46,XX[20] and 16.7% (4/24 colonies) mosaicism for tetrasomy 9p.
   4. Quantitative fluorescent polymerase chain reaction confirmed a maternal origin of tetrasomy 9p.
   6. Tissue specific mosaicism in tetrasomy 9p which rendered the anomaly undetectable by CVS. It also demonstrates the mild end of the clinical spectrum associated with tetrasomy 9p (Grass et al. 1993)
3. Management
   1. Early intervention programs for mild developmental delay with minor anomalies
   2. Supporting care for severe cases with early death

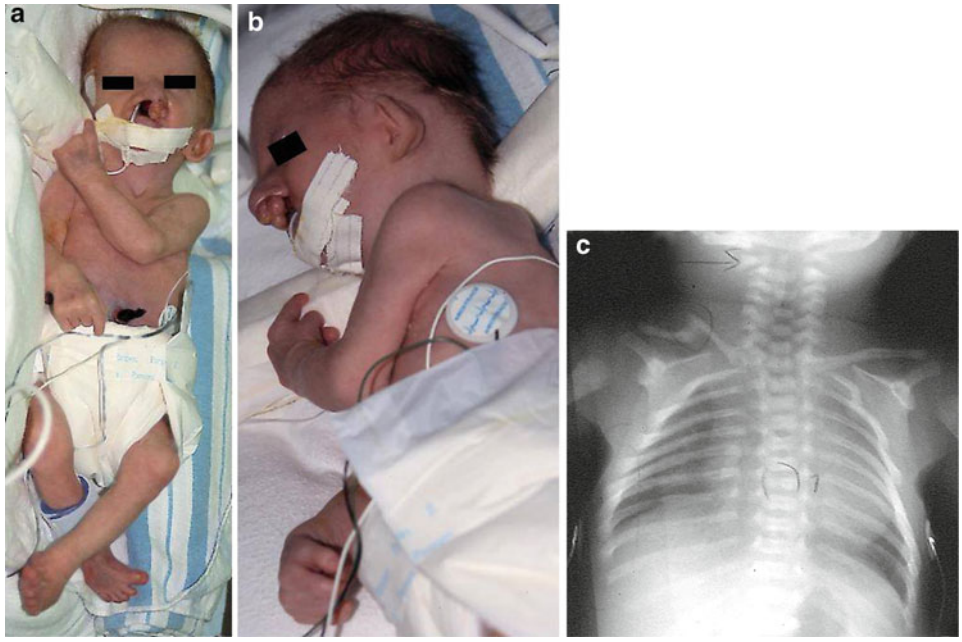

Fig. 1 (**a**–**c**) An infant (**a**, **b**) with tetrasomy 9p syndrome presenting with widened anterior fontanel, microbrachycephaly, a broad nasal root, telecanthus, bilateral cleft lip and palate, retromicrognathia, small eyes, low-set lop ears, and a skin tag on the antihelix of the right ears. In addition, the infant had short neck with excess nuchal fold, bilateral webbing of the anterior axillary folds, pectus excavatum, congenital heart defects, right hydronephrosis, diastasis recti with an umbilical hernia, a right inguinal hernia, sacral dimple with a tag, micropenis, bilateral metatarsus adductus, bilateral transverse palmar creases, clinodactyly of the fifth fingers, short thumbs, and hypoplastic nails. Chest X-ray (**c**) showed hemivertebrae in the thoracic spine and fractured right clavicle with callus formation. A rectal biopsy confirmed the diagnosis of Hirschsprung disease

Thalassemia

Contents

The term thalassemia was first applied to the anemias encountered frequently in people of the Italian and Greek coasts and nearby islands. The term now refers to a group of inherited disorders of globin chain synthesis. Thalassemia comprises of a group of hemoglobinopathies, which are classified according to the specific globin chain (α or β) whose synthesis is impaired. Thus, α-thalassemia and β-thalassemia are depression of synthesis of the respective chain.

Synonyms and Related Disorders

Alpha-thalassemia (Hb H disease or alpha-thalassemia intermedia, Hb Bart's hydrops fetalis, or alpha-thalassemia major); Beta-thalassemia (beta-thalassemia major or Cooley anemia or homozygous beta-thalassemia, beta-thalassemia intermedia or compound heterozygote, beta-thalassemia minor or beta-thalassemia trait

Genetics/Basic Defects

1. Inheritance
   1. Autosomal recessive.
   2. Most β-thalassemias are inherited in a Mendelian recessive fashion, but there is a subgroup of β-thalassemia alleles that behave as dominant negatives (Thein 2013).
2. α-Thalassemia syndromes (Kelly 2012)
   1. α-Thalassemia occurs when there is a defect or deletion in one or more of the four genes responsible for α-globin production, leading to insufficient or absent α-globin synthesis.
   2. A defect or deletion of one α-globin gene leads to a condition called silent trait that is completely asymptomatic.
   3. The presence of two defective α-globin genes causes α-thalassemia trait, manifesting as a mild microcytic, hypochromic anemia. Hemoglobin electrophoresis can aid in diagnosis, but only during the neonatal period, when hemoglobin Bart is detected at 3–10%. Because hemoglobin F predominates at birth, impaired production of α-globin chains results in excess unpaired γ-globin chains that form tetramers, making hemoglobin Bart. After birth, as the infant's dominant hemoglobin transitions from F to A, γ-globin chain production subsides, and hemoglobin Bart is

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_227

no longer detected. No treatment is necessary for α-thalassemia trait.

4. The presence of three defective α-globin genes causes hemoglobin H disease. Hemoglobin Bart is detected (15–30%) on electrophoresis during the neonatal period. Later in life, when hemoglobin A should predominate, excess unpaired β-globin chains accumulate and form tetramers, making hemoglobin H. Unstable hemoglobin H precipitates in circulating red blood cells, leading to hemolysis. Patients have microcytic, hypochromic anemia and hepatosplenomegaly and also may have bony abnormalities resulting from marrow expansion, as well as cholelithiasis and icterus. Transfusion usually is not required, but occasionally patients require splenectomy.
5. Hydrops fetalis occurs when all four α-globin genes are defective or absent. In the affected fetus, no α-globin chains are synthesized, and hemoglobin Bart is the predominant hemoglobin. Oxygen delivery to tissues is severely impaired, and the affected fetus has profound anemia, hepatosplenomegaly, and anasarca and usually is stillborn or dies shortly after birth. Lifelong transfusion therapy is required for those infants who survive.

3. α-Thalassemia (Vichinsky 2010)
    1. Normal fetal hemoglobin synthesis
        1. Early in gestation, embryonic hemoglobins (Gower1, Gower2, and Portland), which do not contain α-globin chains, are the predominant hemoglobins.
        2. They are rapidly replaced by fetal and then adult hemoglobin, which contain α-globin chains.
        3. Therefore, α-thalassemia mutations become phenotypically evident by 12 weeks of gestation.
    2. Synthesis of α-chains is directed by four α-genes, two on each chromosome 16.
    3. α-Thalassemia represents a group of conditions with reduced or absent synthesis of one to all four of α-globin genes.
        1. α-Thalassemia-2 (α-/αα): resulting from deletion of one of the two α-globin genes.
        2. α-Thalassemia-1 (−−/αα): resulting from deletion of both α-globin genes.
        3. Hb H disease (−−/-α): resulting from deletion of three α-globin genes.
        4. Hb Bart's hydrops fetalis (−−/−−): resulting from deletion of all four α-globin genes. Physiologically nonfunctional homotetramers γ_4 and β_4 make up most of the hemoglobin in the erythrocytes in infants with the Bart's hydrops fetalis syndrome.
    4. When both α-genes on a single chromosome are inactive, the designation α^o-thalassemia is used. When there is some production of α-globin chains, α^+-thalassemia is designated.
4. β-Thalassemia
    1. Synthesis of β-chains: directed by a single β-gene on each chromosome 11
    2. Caused by the reduced (β^+) or absent (β^o) synthesis of the β-globin chains of the hemoglobin tetramer which is made up of two α-globin and two β-globin chains ($\alpha_2\beta_2$)
    3. Mutations in β-thalassemia
        1. In contrast to the α-thalassemias, most of the common β-thalassemia mutants are caused by point mutations rather than by gene deletion.
        2. Single base-pair mutations in the DNA alter processing of messenger RNA: most common.
        3. Chain terminator defects.
        4. Frameshift mutations.
        5. Polyadenylation mutations.
        6. Promoter mutations.
    4. β^o-Thalassemia
        1. The mutations prevent β-globin chain synthesis entirely.
        2. Absent β-globin synthesis in β^o-thalassemia homozygotes.
        3. Accounts for about one-third of thalassemia patients.

5. β^{+}-Thalassemia
    1. The mutations prevent β-chain synthesis partially.
    2. β-Globin synthesis reduces to 5–30% of normal levels in β^{+}-thalassemia homozygotes.
6. β^{+}/β^{o}-Thalassemia compound heterozygotes

5. Pathogenesis (Yaish 2010)
    1. Basic defect in all types of thalassemia: imbalanced globin chain synthesis.
    2. A decrease in the rate of production of a certain globin chain (α, β, γ, δ) impedes hemoglobin (Hb) synthesis and creates an imbalance with the other globin chain that normally produce globin chains.
    3. Consequences of impaired production of globin chains.
        1. Result in less Hb deposit in each RBC, leading to hypochromasia.
        2. Deficiency in Hb causes RBCs to be smaller, leading to the classic hypochromic microcytic features of thalassemia.
6. Phenotype-genotype correlation (Origa 2015)
    1. Homozygosity or compound heterozygosity for β-thalassemia most commonly results in the clinical phenotype of transfusion-dependent thalassemia major.
    2. However, a consistent proportion of homozygotes develop milder forms, called thalassemia intermedia, which range in severity from thalassemia major to the β-thalassemia carrier state.
    3. Ascertained molecular mechanisms leading to thalassemia intermedia.
        1. β-Thalassemia mutations
            1. Mild mutation
            2. Silent mutation
            3. Mild/silent mutation
        2. Coinherited α-thalassemia
            1. Single α-globin gene deletion (-α/αα)
            2. Deletion of two α-globin gene (-α/-α or – /αα)
            3. Point mutations of the major α-2-globin gene
        3. Genetic determinant of high Hb F production
            1. Due to the β-thalassemia mutation per se (δβ-thalassemia, β-promoter deletion)
            2. Coinherited Agamma or Ggamma promoter mutation (−158 Ggamma (A → T); −196 Agamma (C → T))
            3. Heterocellular HPFH, BCL11A on chromosome 2, and HBS1L-MYB region on chromosome 6

Clinical Features

1. α-Thalassemia (Harteveld and Higgs 2010; Origa et al. 2013)
    1. The most common genetic disorder of hemoglobin synthesis, affects up to 5% of the world's population (Vichinsky 2010)
    2. Found in people of African descent, Indochina, Malaysia, and China
    3. Clinical classification of α-thalassemia (Galanello and Cao 2011)
        1. Silent carrier: clinically and hematologically normal
        2. Thalassemia trait
            1. Microcytosis
            2. Hypochromia
            3. Mild anemia
        3. Hb H disease
            1. Moderate to severe microcytic, hypochromic, hemolytic anemia
            2. Mild jaundice
            3. Moderate hepatosplenomegaly
        4. Hb Bart's hydrops fetalis syndrome
            1. Severe anemia
            2. Generalized edema
            3. Ascites
            4. Marked hepatosplenomegaly
            5. Skeletal and cardiovascular malformations, usually death in utero
    4. Severity of resulting anemia quite variable ranging from asymptomatic carriers to a fatal in utero disease: depends on the number of functioning α-genes
        1. α-Thalassemia-2 or silent carrier α-thalassemia (α-/αα) (deficiency of only one globin gene)

1. Twenty-five percent of African Americans
2. 3.4% of Greek Americans
3. Slight microcytic red blood cells
4. Borderline or minimal anemia

2. α-Thalassemia-1 or α-thalassemia trait (– /αα)(deficiency of two globin genes)
   1. Fifteen to twenty percent of Thai.
   2. Mildly anemic.
   3. Microcytic red blood cells.
   4. Slight variation in red blood cell size.
   5. Mild splenomegaly.
   6. Work capacity not impaired.
   7. Same phenotypic effect in the individual homozygous for α-thalassemia-2 (α-/α-): This form is much more common in black populations.
3. Hb H disease or α-thalassemia intermedia (−−/-α) (deficiency of three globin genes)
   1. One percent of Thai.
   2. Significant hypochromic anemia in the neonatal period.
   3. Microcytic anemia.
   4. Reticulocytosis.
   5. Jaundice.
   6. Splenomegaly (may be severe and occasionally complicated by hypersplenism).
   7. Growth retardation may be seen in children.
   8. Hemolysis precipitated by infections or oxidant drugs (e.g., iron, sulfonamides).
   9. Leg ulcers.
   10. Gallstones.
   11. Folic acid deficiency.
   12. Needs occasional transfusions, splenectomy, or avoidance of precipitating drugs.
   13. Severity of clinical features: related to the molecular basis of the disease. Patients with nondeletional types of Hb H disease are more severely affected than those with the common deletional types of Hb H disease.
4. Hb Bart's hydrops fetalis or α-thalassemia major (−−/−−) (deficiency of all four globin genes)
   1. Most severe form of α-thalassemia
   2. Incompatible with life unless intrauterine blood transfusion is given because not enough functional hemoglobin is produced to sustain tissue oxygenation
   3. Profound oxygen deprivation in utero with resulting heart failure (hydrops fetalis)
   4. Stillborn or die soon after birth
   5. Pale edematous infant with signs of cardiac failure (edema and ascites) and prolonged intrauterine anemia
   6. Massive hepatosplenomegaly
   7. Severe erythroblastic anemia
   8. Retardation in brain growth
   9. Skeletal and cardiovascular anomalies
   10. Enlargement of the placenta

2. β-Thalassemia (Cao and Galantello 2010; Kelly 2012; Origa 2015)
   1. Found largely in people of African and Mediterranean descent, Far East, Middle East, and the Asian subcontinent
      1. Highest incidence
         1. Cyprus (14%)
         2. Sardinia (12%)
         3. Southeast Asia
      2. The high gene frequency of beta-thalassemia in these regions
         1. Most likely related to the selective pressure from *Plasmodium falciparum* malaria, as it is indicated by its distribution quite similar to that of present or past malaria endemics. Carriers of beta-thalassemia are indeed relatively protected against the invasion of *Plasmodium falciparum*.
         2. However, because of population migration and, to a limited extent, slave trade, beta-thalassemia is, at present, also common in Northern Europe, North and South America, Caribbean, and Australia.

2. Classification of beta-thalassemia (Galanello and Origa 2010)
    1. Beta-thalassemia
        1. Thalassemia major
        2. Thalassemia intermedia
        3. Thalassemia minor
    2. Beta-thalassemia with associated Hb anomalies
        1. HbC/beta-thalassemia
        2. HbE/beta-thalassemia
        3. HbS/beta-thalassemia (clinical condition more similar to sickle cell disease than to thalassemia major or intermedia)
    3. Hereditary persistence of fetal Hb and beta-thalassemia
    4. Beta-thalassemia associated with other manifestations
    5. Beta-thalassemia-trichothiodystrophy
    6. X-linked thrombocytopenia with thalassemia
3. Clinical features dependent on reduced (β^+) or absent (β^o) synthesis of β-globin
    1. β-Thalassemia major (also known as Cooley's anemia or homozygous β-thalassemia)
        1. Due to inheritance of two β-thalassemia alleles, one on each copy of chromosome 11.
        2. Generally recognized to be a homozygous state for whichever thalassemia gene is involved.
        3. Clinically a severe disorder.
        4. Infants born free of significant anemia, protected by prenatal Hb F production.
        5. Onset: 6–12 months.
        6. Diagnosis: evident by 2 years of age.
        7. Manifestations in early childhood: anemia, pallor, growth retardation, tiredness, abdominal swelling due to hepatosplenomegaly, infection, and jaundice.
        8. Manifestations in childhood and adult: severe anemia, infection, tiredness, growth retardation, distinctive facies, hepatosplenomegaly, cardiomegaly, abdominal pain, leg ulcers, osteoporosis, and iron overload.
        9. At significant risk for developing overwhelming, often fatal infection after splenectomy (postsplenectomy syndrome).
        10. Severe anemia usually necessitating chronic blood transfusions.
        11. Craniofacial manifestation of β-thalassemia major (Javid and Said-Al-Naief 2015): The most characteristic oral and maxillofacial/head and neck skeletal changes are the upslanted eyes and the so-called chipmunk faces, with prominent frontal bossing, prominent cheekbones, and nasal bridge depression, accompanied by hypertrophied maxilla (often with exposure of the maxillary teeth) and mandible caused by excessive active bone marrow hyperplasia. In the maxilla, in particular, the large, widened medullary spaces and trabeculae radiographically mimic a "chicken wire" radiographic pattern.
        12. Prognosis: average survival of children with untreated thalassemia major (<4 years)
    2. β-Thalassemia intermedia (compound heterozygotes)
        1. Due to inheritance of two β-thalassemia mutations (one mild and one severe or two mild mutations) or occasionally due to inheritance of complex combinations such as α-β-thalassemia.
        2. Affected individuals: either compound heterozygotes for two different thalassemia genes or heterozygotes for a structural variant plus a thalassemia gene. Homozygotes for the milder β^+-thalassemia also have thalassemia intermedia.
        3. Less severe clinical phenotype: cardiomegaly, osteoporosis, fractures, arthritis, and splenomegaly in some patients.

4. Neurological complications of beta-thalassemia: Cognitive impairment, abnormal findings on evoked potentials, complications due to extramedullary hematopoiesis, cerebrovascular disease, and peripheral neuropathy comprise the broad spectrum of neurological involvement (Nemtsas et al. 2015).
5. Significant anemia but usually do not require chronic blood transfusions.

3. β-Thalassemia minor (also known as β-thalassemia trait or heterozygous β-thalassemia)
   1. Due to presence of a single β-thalassemia mutation and a normal β-globin gene on the other chromosome
   2. Clinically asymptomatic but may have mild or minimal anemia
4. Silent carrier β-thalassemia
   1. No symptoms except for possible low RBC indices.
   2. Mutation causing thalassemia is very mild and represents β + -thalassemia.

3. Practical guide to the diagnosis of thalassemia (Dumars et al. 1996)
   1. The first involves any patient with a low mean corpuscular volume (MCV) with or without anemia.
   2. The second is a neonatal screening result indicating possible presence of thalassemia.
   3. Finally, evaluation for thalassemia should be considered in the context of family planning or pregnancy in patients whose ethnicity indicates origin from high-risk geographic areas.

Diagnostic Investigations

1. Screening tests for thalassemias.
   1. Low MCV (mean corpuscular volume)
      1. Increased Hb A_2 and/or Hb F: indicate β-thalassemia syndrome
      2. Normal Hb A_2 and Hb F, and ferritin >20 ng/mL: suggest possible α-thalassemia syndrome
   2. Normal MCV, normal electrophoresis: thalassemia syndrome unlikely
2. α-Thalassemia (Chen 1992; Origa et al. 2013): More difficult to diagnose because characteristic elevations in Hb A_2 ($\alpha_2\delta_2$) or Hb F ($\alpha_2\gamma_2$), seen in β-thalassemia, do not occur.
   1. α-Thalassemia-2
      1. Laboratory notation: FA + Bart's
      2. Small amount of Hb Bart's (1–2%) in affected infants at birth
      3. Remainder of the hemoglobin: Hb F and Hb A ($\alpha_2\beta_2$)
      4. Hb F and Hb Bart's: disappear after a few months of age
      5. Minimal microcytosis: remains
   2. α-Thalassemia-1
      1. Laboratory notation: FA + Bart's (impossible to differentiate the two forms of α-thalassemia from the electrophoretic pattern).
      2. Slightly larger amount of Hb Bart's in cord blood (3–5%).
      3. Hb F and Hb Bart's: disappear after birth.
      4. Unequivocal microcytosis: Mean red cell volume of 65–70 fl/cell remains.
      5. Abnormally low Hb A_2 proportion.
   3. Hb H disease
      1. Reduction in α-chain does not affect the production of β-chain which is produced in excess and tends to form tetramers (β^4 or Hb H).
      2. Hb A + Hb H (β^4) + Hb Bart's (γ^4).
      3. Presence of Heinz bodies: inclusions representing β-chain tetramers (Hb H), which are unstable and precipitate in the RBC, giving the appearance of a golf ball
   4. Hb Bart's hydrops fetalis
      1. Hypochromic macrocytes with nucleated red blood cells
      2. γ^4 (Bart's hemoglobin): nonfunctional as an oxygen transporter
   5. Targeted mutation analysis
      1. Deletion of a single α-globin gene (α^+-thalassemia mutations)

2. Deletion of both α-globin genes on one chromosome (α°-thalassemia mutations)
3. Sequence variant $Hb^{Constant\ Spring}$
6. Sequence analysis: used to identify point mutations (including rare termination codon mutations and hyperunstable α-globin variants) in the coding regions of HBA1 and HBA2 when an α-globin deletion is not identified and suspicion for α-thalassemia is high
7. Deletion/duplication analysis can be used to detect common, rare, and/or novel deletions and duplications involving HBA1 and HBA2.

3. β-Thalassemia (Chen 1992)
   1. β-Thalassemia major
      1. Small, thin, and distorted red blood cells containing markedly reduced amounts of hemoglobin
      2. Peripheral blood smear
         1. Severe microcytic hypochromic anemia (no anemia at birth)
         2. Anisocytosis
         3. Poikilocytosis (speculated teardrop and elongated cells)
         4. Abundant nucleated red cells (i.e., erythroblasts)
         5. Occasional immature leukocytes
      3. Hemolytic anemia
      4. Hemoglobin profile: predominant Hb F
      5. In patient with homozygous β^{o}-thalassemia: absent Hb A with normal amounts of Hb A_2
      6. In newborn with β^{+}-thalassemia: Hb F (about 90%) decreases with advancing age but always considerably higher than normal (10–90%)
   2. β-Thalassemia intermedia (Haddad et al. 2014)
      1. Intermediate Hb concentration (7–10 g/dL)
      2. Microcytic hypochromic anemia
      3. HPLC electrophoresis
         1. Hb A2 (>4%)
         2. Hb F (5–99%)
      4. Molecular characteristics
         1. Mild/silent mutation.
         2. Coinheritance of α-thalassemia may be present.
         3. Hereditary persistence of Hb F, δ-β-thalassemia, Gγ XMN1 polymorphism.
   3. β-Thalassemia minor
      1. Mild hypochromic microcytosis (Rucknagel 1992)
      2. Target cells
      3. Mild to minimal anemia (hemoglobin concentration average 1–2 g/dL below normal)
      4. Elevation of Hb A_2 and Hb F (70–99%) during early years of life
      5. Anemia worsen during pregnancy
4. Imaging studies
   1. Chest X-ray to evaluate cardiac size and shape
   2. Skeletal survey
      1. Skeletal response to marrow proliferation
         1. Expanding marrow space
         2. Thinning of cortical bone
         3. Resorption of cancellous bone
         4. Resulting in generalized loss of bone density
         5. Frequent small lucencies resulting from focal proliferation of marrow
         6. "Periosteal response" caused by perforation of the cortex by hypertrophic and hyperplastic marrow subperiosteally
      2. Classic facies observed in thalassemia major
         1. Classic "hair-on-end" appearance of the skull
         2. Maxilla overgrowth resulting in maxillary overbite
         3. Prominent upper incisors
         4. Separation of the orbits
      3. Various bone deformities seen in ribs, long bones, and flat bones
      4. Premature fusion of the epiphyses
   3. MRI/CT scans to evaluate the amount of iron in the liver in patients on chelation therapy
5. Carrier screening
   1. α-Thalassemia (Vichinsky 2010)
      1. Commonly, microcytosis using an MCV <82 fL and/or hypochromia (MCH

<27 pg) is often used as a population screening technique.
1. Anemia is unreliable and is often not present in adults with two α-globin gene deletions.
2. Once iron deficiency is ruled out or corrected, microcytosis should be further evaluated in the individual and his or her partner in order to determine their risk for hydrops.

2. Molecular diagnosis for α-globin mutations: essential for at-risk couples.

2. β-Thalassemia
1. Ongoing in several at-risk populations in the Mediterranean (Cao et al. 2002).
2. Carrier testing relies on hematological analysis: When the hematological analysis indicates a beta-thalassemia carrier state, molecular genetic testing of *HBB* can be performed to identify a disease-causing mutation.

6. Molecular genetic testing for α- and β-thalassemias
1. α-Thalassemia (Origa et al. 2013)
1. *HBA1*, the gene encoding α_1-globin, and *HBA2*, the gene encoding α_2-globin, are the two genes most commonly associated with α-thalassemia.
2. Molecular genetic testing of *HBA1* and *HBA2* detects deletions in about 90% and point mutations in about 10% of affected individuals.

2. β-Thalassemia (Origa 2015)
1. Molecular genetic testing of the gene encoding the hemoglobin subunit beta (HBB): available clinically
1. Targeted mutation analysis
2. Sequence analysis

Genetic Counseling

1. Recurrence risk (Chen 1992)
1. α-Thalassemia
1. Patterns of inheritance of the α-thalassemia when both parents are α-thalassemia-1 (−−/αα).
1. 25% normal
2. Fifty percent α-thalassemia-1
3. Twenty-five percent Hb Bart's (hydrops fetalis)

2. Patterns of inheritance of the α-thalassemia syndrome when one parent is α-thalassemia-1 (−−/αα) and the other parent is α-thalassemia-2 (α-/αα).
1. Twenty-five percent normal
2. Twenty-five percent α-thalassemia-1
3. Twenty-five percent α-thalassemia-2
4. Twenty-five percent Hb H disease

3. If the carrier of α^+-thalassemia is a homozygote, clearly, the risk of Hb H disease is 1:2 (50%) (Harteveld and Higgs 2010).
4. Patient's offspring: not increased unless the spouse is a carrier.
5. Twenty-five percent of African Americans have heterozygous α-thalassemia-2 (α-/αα). Thus, 1.5% are homozygotes for α-thalassemia-2 (α-/α-). But since the more severe α-thalassemia-1 is not present, subsequent children are not at risk of having Hb H or Bart's hydrops fetalis.

2. β-Thalassemia (Galanello and Origa 2010)
1. Patient's sib: 25%
2. Patient's offspring: not increased unless the spouse is a carrier

2. Prenatal diagnosis: available to all families at risk of either severe α-thalassemia or β-thalassemia
1. α-Thalassemia
1. Ultrasonography (Tongsong et al. 1996).
1. Hepatosplenomegaly (>90%)
2. Cardiomegaly (>90%)
3. Edematous placenta (>90%)
4. Ascites (>90%)
5. Oligohydramnios (82%)
6. Subcutaneous edema (75%)
7. Decreased fetal movement (74%)
8. Cord edema (63%)
9. Enlarged umbilical vessel (62%)
10. Pericardial or pleural effusion (15%)

2. Sonographic markers of fetal α-thalassemia major (Li et al. 2015).
1. Classic sonographic characteristics of hydrops fetalis syndrome do not

appear until the late second trimester (Tongsong et al. 1996), but it has been reported that some cases of hydrops fetalis can be identified by sonography in the early second trimester (Lam et al. 1997).
2. Moreover, cardiovascular responses secondary to α-thalassemia major can take effect in the first trimester, bringing more blood flow to vital organs such as the heart and brain (Ghosh et al. 1994; Lam et al. 1999; Picklesimer et al. 2007).
3. Therefore, many sonographic markers may be observed before the onset of fetal hydrops (Ghosh et al. 1987) and could be used to detect fetuses with α-thalassemia major.
4. Among all markers, the cardiothoracic ratio, placental thickness, and middle cerebral artery PSV (peak systolic velocity) are the most studied ones.

3. Molecular hybridization technique to detect complete absence of α-genes in fetal amniocytes in a pregnancy at risk for homozygous α-thalassemia-1 and the hydrops fetalis syndrome (Dozy et al. 1979).
   1. The DNA obtained from cultured amniotic fluid cells was studied by hybridization with globin cDNA in solution and on filters (Southern technique).
   2. Both analyses demonstrated no alpha-globin structural genes.
   3. Following termination of the pregnancy, the diagnosis was established by the presence of only hemoglobins Bart's (gamma 4) and Portland (zeta 2 gamma 2) in the fetal blood.
4. Quantitative polymerase chain reaction for the rapid prenatal diagnosis of homozygous α-thalassemia (Hb Bart's hydrops fetalis).
5. Preimplantation genetic diagnosis (PGD) may be an option for some families in which the pathogenic variants have been identified (Origa et al. 2013).

2. β-Thalassemia
   1. Available to couples who are carriers of β-thalassemia and their hemoglobin gene mutations have been identified by DNA analysis.
   2. Direct DNA analysis by molecular hybridization methods for the presence of the thalassemia mutation from fetal cells obtained by amniocentesis and chorionic villus biopsy.
   3. Detection of point mutations in single gene disorders by enriching fetal cells from maternal blood by magnetic cell sorting followed by isolation of pure fetal cells by microdissection. In two pregnancies at risk for sickle cell anemia and beta-thalassaemia, we successfully identified the fetal genotypes (Cheung et al. 1996). Thus, prenatal diagnosis of single gene disorders by recovering fetal cells from maternal circulation appears to be a feasible approach.
   4. Approach to prenatal diagnosis complicated by presence of the heterogeneity of thalassemia mutations.
   5. Preimplantation genetic diagnosis available for at-risk pregnancies requires prior identification of the disease-causing mutations in the family (Galanello and Origa 2010).
3. Preimplantation genetic diagnosis (Cao and Kan 2013)
   1. Performed either by biopsy of one to two blastomeres in eight-cell embryos after in vitro fertilization (by intracytoplasmic sperm injection)
   2. By biopsy of trophectoderm cells from blastocyst (Kuliev et al. 1998; Kokkali et al. 2007).
4. Preconceptional diagnosis (Cao and Kan 2013)
   1. Based on the analysis of the first polar body of unfertilized eggs followed by analysis of the second polar bodies after fertilization, which is performed to avoid

misdiagnosis resulting from recombination during the first meiosis (Verlinsky et al. 1990).
2. Diagnosis was obtained by multiple nested PCR analysis to detect the mutations as well as polymorphic alleles at the β-globin cluster (Kuliev et al. 2011; Zachaki et al. 2011).
3. HLA typing of the embryo to select a nonaffected fetus HLA compatible with a previous affected sibling was recently proposed (Kuliev et al. 2011).

3. Management
   1. α-Thalassemia (Segel et al. 2002)
      1. No therapy necessary for patients with α-thalassemia trait
      2. Avoid exposure to oxidant medications (e.g., iron, sulfonamides) which accelerate precipitation of Hb H and exacerbate hemolysis
      3. Prompt treatment of infection especially in postsplenectomy
      4. Hb H disease
         1. Folate supplementation
         2. Chronic transfusion therapy (consider iron chelation therapy to avoid iron overloading)
         3. Splenectomy in rare instances of hypersplenism
         4. Allogeneic bone marrow transplantation limited to the most severely affected patients
      5. Bart's hemoglobinopathy
         1. Usually results in neonatal death.
         2. Patients rarely salvaged by intrauterine transfusions and subsequent stem cell transplantation.
         3. The diagnosis, management, and prognosis of homozygous α-thalassemia/hydrops fetalis is changing; advances in antenatal diagnosis, intrauterine intervention (Carr et al. 1995), and postnatal therapy have resulted in long-term survival of children previously felt to have an invariably fatal disease (Singer et al. 2000; Weisz et al. 2009; Vichinsky 2010).
      6. Homozygous α-thalassemia and hydrops fetalis (Vichinsky 2009)
         1. A complex, usually fatal disease that is devastating to the entire family.
         2. There is a diversity in the genotype and phenotype expression of this syndrome that presents challenges in at-risk couple counseling and population screening.
         3. Presently, counseling and testing of at-risk populations is inadequate.
         4. More cases are being diagnosed unexpectedly.
         5. Intrauterine transfusion therapy appears promising in minimizing the morbidity and mortality of homozygous α-thalassemia. However, most of these patients require lifetime transfusion therapy and chelation.
         6. Recent advances in stem cell transplantation have resulted in some patients being cured.
         7. Successful cases of related, unrelated, and mismatched stem cell transplantation for α-thalassemia major have been reported.
      7. α-Thalassemia syndromes are common and have a wide range of clinical phenotypes (Vichinsky 2013). Hemoglobin H disease morbidity is often underappreciated. These patients require early diagnosis and ongoing monitoring. Hemoglobin Bart's hydrops is a tragic, usually fatal complication that can be prevented by adequate screening and counseling. Improved outcome with intrauterine transfusions creates ethical issues for the family and health care providers.
   2. β-Thalassemia (Galanello and Origa 2010; Origa 2015)
      1. No specific therapy required for β-thalassemia trait.
      2. Regular blood transfusions in thalassemia major.
         1. Correct the anemia.
         2. Suppress erythropoiesis.

3. Inhibit increased gastrointestinal absorption of iron.

3. Treatment of individuals with thalassemia intermedia (Taher et al. 2012).
   1. Symptomatic treatment
   2. Blood transfusion
   3. Splenectomy
   4. Folic acid supplementation
   5. Iron chelation
   6. Treatment of extramedullary erythropoietic masses (radiotherapy, transfusions, or hydroxyurea in selected cases)
4. Iron chelation with desferrioxamine to eliminate the iron overload secondary to multiple blood cell transfusions and to increase iron absorption.
5. Role of natural agents (Kukreja et al. 2013).
   1. Various natural agents like angelicin, rapamycin, FT, bergamot, romidepsin, wheatgrass, *Curcuma comosa*, *Astragalus*, apicidin, curcuminoid, piceatannol, and resveratrol have been reported to induce HbF level in beta-thalassemic patients.
   2. Various natural compounds like wheatgrass, desferrioxamine, and *Tetracarpidium conophorum* have also been known for their iron chelation property for the treatment of beta-thalassemia.
   3. More data are needed on the bioavailability of these natural compounds and their effects on human.
6. Bone marrow transplantation (Lucarelli et al. 1995; Giardini and Lucarelli 1999) remains to be the only definitive cure currently available for patients with thalassemia.
   1. From an HLA-identical sib
   2. Outcome dependent on pretransplantation clinical conditions, specifically the presence of hepatomegaly, extent of liver fibrosis, and magnitude of iron accumulation
   3. Risk of chronic graft-versus-host disease (GVHD) of variable severity: 5–8%
7. Cord blood transplantation (Kelly et al. 1997; Locatelli et al. 2003).
   1. From a related donor offers a good probability of a successful cure and is associated with a low risk of GVHD.
   2. Possibility of using cord blood obtained from unrelated donors with a decrease in the incidence of graft-versus-host disease.
   3. Human umbilical cord blood contains hematopoietic stem cells capable of reconstituting bone marrow.
8. Recent trends in the gene therapy of β-thalassemia (Finotti et al. 2015).
   1. A strong emphasis on the most recent findings, for β-thalassemia model systems
   2. For β-, γ-, and anti-sickling β-globin gene addition and combinatorial approaches including the latest results of clinical trials
   3. For novel approaches, such as transgene-mediated activation of γ-globin and genome editing using designer nucleases

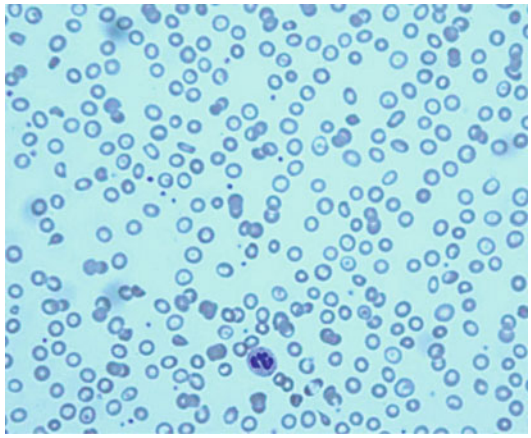

Fig. 1 Peripheral blood smear from a 58-year-old woman with microcytic anemia and frequent target cells (codocytes). Hemoglobin electrophoresis showed an AA pattern with an increased hemoglobin A_2 (5.8% by HPLC) consistent with beta$^+$- thalassemia trait

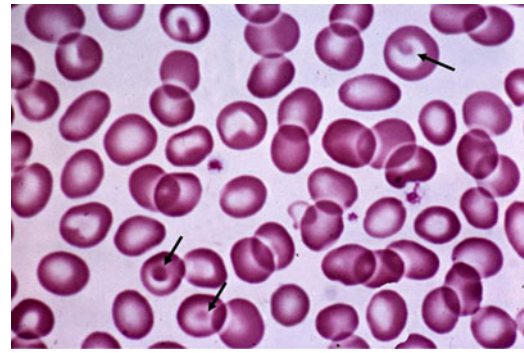

Fig. 2 Peripheral blood smear from a patient with alpha-thalassemia minor shows hypochromia, target cells (*arrows*), and anisopoikilocytosis (Wright-Giemsa stain, ×1,000)

Thanatophoric Dysplasia

Contents

Thanatophoric dysplasia was originally described by (Maroteaux et al. 1967). The term "thanatophoric" was coined to mean "death bearing" in Greek. Thanatophoric dysplasia is probably the most common lethal neonatal dwarfism with an estimated incidence of 0.2–0.5 per 10,000 births.

Synonyms and Related Disorders

Thanatophoric dysplasia type I (thanatophoric dwarfism; lethal short-limbed platyspondylic dwarfism, San Diego type; platyspondylic lethal skeletal dysplasia, San Diego type); Thanatophoric dysplasia type II (cloverleaf skull with thanatophoric dwarfism, thanatophoric dysplasia with kleeblattschadel, thanatophoric dysplasia with straight femur and cloverleaf skull)

Genetics/Basic Defects

1. Genetic heterogeneity:
   1. Sporadic in most cases
   2. A new autosomal dominant mutation (Martinez-Frias et al. 1988)
   3. Caused by mutations in the transmembrane domains of the fibroblast growth factor receptor 3 (*FGFR3*)
2. Having the most extreme micromelia and the most extensive craniofacial involvement compared to two other short-limb skeletal dysplasias (achondroplasia and hypochondroplasia) which are also caused by mutations of *FGFR3*.
3. Pathogenesis for the phenotypic features of thanatophoric dysplasia:
   1. Normal function of *FGFR3*: to regulate endochondral ossification by "putting the brakes on growth"
   2. "Gain-of-function" type of known mutations on *FGFR3*:
      1. Primarily affects the cranial base and nasal capsule (endochondral bones)
      2. With secondary effect on membrane bones which articulates with endochondral bones
4. Two major forms (TD1, TD2) of thanatophoric dysplasia, postulated based on subtle differences in skeletal radiographs and the underlying genetic mutation (Tavormina et al. 1995; Defendi 2014):

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_228

1. TD1:
   1. Curved femora
   2. Very flat vertebral bodies
   3. Very few TD1 patients with cloverleaf skull
   4. Molecular defect consisting of a stop codon mutation or missense mutation in the extracellular domain of the FGFR3 protein, resulting in a newly created cysteine residue (Arg248Cys, most common) (Rousseau et al. 1995, 1996)
2. TD2 (Partington et al. 1971; Norman et al. 1992):
   1. Straight femora
   2. Taller vertebral bodies
   3. Most TD2 patients with cloverleaf skull (severe craniosynostosis)
   4. Molecular defect consisting of a single-nucleotide substitution resulting in replacement of lysine with glutamine at position 650 (Lys650Glu) in the tyrosine kinase 2 domain of the receptor

5. Activating mutations in the *FGFR3* gene can cause the following conditions (Bonaventure et al. 1996a, b; Cohen 1998; Vajo et al. 2000; Karczeski and Cutting 2013):
   1. Achondroplasia
   2. Thanatophoric dysplasia type I and type II
   3. Hypochondroplasia
   4. Severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN)
   5. Crouzon syndrome with acanthosis nigricans
   6. Familial acanthosis nigricans
   7. Nonsyndromic coronal synostosis
   8. Platyspondylic lethal skeletal dysplasia, San Diego type (PLSD-SD)
   9. LADD syndrome (lacrimo-auriculo-dento-digital syndrome) (Levy-Hollister syndrome)

Clinical Features

1. Unique and homogeneous clinical features observed in patients with TD1
2. General features:
   1. Virtually lethal neonatally
   2. A few reports with survival up to 4–5 years of age with aggressive neonatal intervention:
      1. Markedly limited growth potential
      2. Markedly delayed cognitive development
      3. Respiratory insufficiency
      4. Neurologic abnormalities
      5. Long-term medical care and chronic ventilator dependence
3. Craniofacial features:
   1. Head:
      1. Disproportionally large (macrocephaly)
      2. Frontal bossing
      3. With or without cloverleaf (kleeblattschädel) anomaly of the skull resulting from premature closure of cranial sutures (Isaacson et al. 1983)
   2. Facial features:
      1. Bulging eyes
      2. Hypertelorism
      3. Severely depressed or indented nasal bridge
4. Short neck
5. Chest:
   1. Extremely narrow
   2. Constricted thoracic cage
   3. Reduced size of the thoracic cavity
   4. Short ribs
   5. Hypoplastic lungs
6. Protuberant abdomen
7. Limbs:
   1. Extremely short
   2. Thickened skin
   3. Excessive skinfolds
   4. Usually outstretched arms
   5. Externally rotated legs with abducted thighs
   6. Syndactyly
8. Early death in most children secondary to:
   1. Chest constriction and consequent respiratory insufficiency
   2. Foramen magnum stenosis resulting in failure of respiratory control
9. A few children with longer survival (up to 9–10 years) (Stensvold et al. 1986; Tonoki 1987; MacDonald et al. 1989):
   1. Respiratory insufficiency:
      1. Reduced chest circumference

2. Upper cervical cord compression resulting from a diminutive foramen magnum
2. Markedly limited growth potential
3. Markedly delayed cognitive development
4. Seizures
5. Hearing loss
6. Additional CNS anomalies (Wongmongkolrit et al. 1983; Coulter et al. 1991; Baker et al. 1997):
    1. Hydrocephalus
    2. Polymicrogyria
    3. Neuronal heterotopia
    4. Megalencephaly
    5. Cerebral gyral disorganization
    6. Hippocampal malformation
    7. Temporal lobe malformations
    8. Nuclear dysplasia
    9. Abnormal axonal bundles
    10. Cerebellar hypoplasia in the small posterior fossa
    11. Partial agenesis of the corpus callosum
    12. Spinal stenosis
    13. Hyperreflexia
    14. Clonus
7. Acanthosis nigricans, an associated rare skin disorder

10. Differential diagnosis (Schild et al. 1996):
    1. Achondroplasia:
        1. Autosomal dominant disorder
        2. Rhizomelic shortening of the bones, less prominent than thanatophoric dysplasia
        3. Macrocrania
        4. Heterozygous achondroplasia:
            1. Compatible with normal life span
            2. Normal intelligence
        5. Homozygous achondroplasia with two affected parents
    2. Campomelic dysplasia:
        1. Autosomal recessive disorder
        2. Typical anterior bowing of the lower limbs
        3. Hypoplastic fibula
        4. Hypoplastic scapulae
        5. A sex reversal phenomenon (phenotypical female with male karyotype)
    3. Osteogenesis imperfecta type II and type III:
        1. Varying degree of bone demineralization
        2. Shortened long bones with multiple fractures
        3. Blue sclerae
        4. Polyhydramnios frequently associated with type II
    4. Hypophosphatasia:
        1. Demineralization of bone tissue
        2. Lack of calcification of the fetal skull
        3. Mild-to-moderate shortening of limb bones
        4. Difficult to differentiate from osteogenesis imperfecta if fractures are present
    5. Achondrogenesis:
        1. Severe micromelia
        2. Poor ossification of the vertebral bodies, cranium, pelvis, and sacrum
        3. Narrow and shortened thorax
        4. Frequent complications with fetal hydrops and hydramnios
    6. Short rib-polydactyly and other rare skeletal dysplasia syndromes

Diagnostic Investigations

1. Radiographic features (Langer et al. 1987; Wilcox et al. 1998):
    1. Skull:
        1. Relatively large calvarium
        2. A small foramen magnum
        3. Trilobed skull with a towering calvarium and bitemporal bulging in the cloverleaf skull type (type II)
    2. Ribs:
        1. Very short ribs with cupped anterior ends
        2. Short ribs (type II)
    3. Vertebrae:
        1. Flat vertebral bodies (platyspondyly)
        2. Increasing intervertebral disk space
        3. "Inverted U-shaped or H-shaped" vertebral bodies (Weber et al. 1998)
        4. Narrow interpediculate distance at the lumbar level
        5. Taller vertebral bodies (type II)

4. Pelvis:
    1. Short
    2. Small sacrosciatic notches
5. Tubular bones:
    1. Extremely shortened long bones of the limbs
    2. Rhizomelic shortening of the limbs
    3. Flared metaphyses
    4. "Telephone receiver"-like curved femora in the noncloverleaf type
    5. Relatively straight femora (type II)

2. Histologic features:
    1. Generalized disruption of endochondral ossification (Yang et al. 1976; Horton et al. 1988; Lemyre et al. 1999):
        1. Hallmark of the histologic findings.
        2. Physeal growth zone shows minimal proliferation and hypertrophy of chondrocytes with the absence of column formation.
        3. Lateral overgrowth of metaphyseal bone around the physis.
        4. Mesenchymal cells extending inward from the perichondrium as a narrow band at the periphery of the physeal zone (the so-called fibrous bands, fibrovascular bands, and fibrovascular bundles). (Weber et al. (1998)
        5. Increased vascularity of the resting cartilage.
    2. Brain:
        1. Neuronal migration abnormalities of the temporal lobe
        2. Hydrocephalus
        3. Partial agenesis of the corpus callosum
        4. Upper cord compression
        5. Spinal stenosis

3. DNA mutation analysis of *FGFR3*:
    1. TD1:
        1. 742C → T (Arg248Cys): most common
        2. Tyr373Cys
        3. Ser249Cys
        4. Other missense mutations
        5. Stop codon mutations
    2. TD2: missense mutation of 1948A → G (Lys650Glu) in TD2
    3. Clinical testing:
        1. Targeted mutation analysis
        2. Sequence analysis of select regions of FGFR3 or of the entire *FGFR3* coding region

Genetic Counseling

1. Recurrence risk:
    1. Patient's sib: because TD generally occurs as the result of a de novo mutation, the risk to the sibs of a proband is small (Karczeski and Cutting 2008) (about 2%).
    2. Patient's offspring: not surviving to reproduction age.

2. Prenatal diagnosis:
    1. 2D, 3D, 4D ultrasonography (De Biasio et al. 2000; Machado and Bonilla-Musoles 2001; Chitty et al. 2013):
        1. Hydramnios in most cases.
        2. Increased nuchal translucency.
        3. Megacephaly with or without cloverleaf-shaped skull.
        4. The findings of dysmorphic choroid plexus, early-onset hydrocephalus, and cloverleaf skull at first-trimester scan may be early, useful ultrasound markers of TD type II (Tonni et al. 2014).
        5. Frontal bossing.
        6. Progressive hydrocephaly.
        7. Hypoplastic thorax disproportionately small in relation to the abdomen.
        8. Small chest and lung measurement to predict severe pulmonary hypoplasia.
        9. Short ribs.
        10. Short limbs with curved "telephone handle-shaped" or straight femurs.
        11. Excessive skin giving fetus a "boxer's face" appearance.
        12. Flattened vertebrae with increased intervertebral spaces, giving the vertebral bodies the form of an "H."
        13. The use of 4D real-time ultrasound gives the physician the possibility to discuss and counsel the patients with images

that are more understandable to the general public (Vasilj and Mišković 2012):
2. Prenatal radiography for documenting characteristic skeletal anomalies.
3. DNA mutation analysis of *FGFR3* in fetal cells from amniocentesis or CVS (Chen et al. 2001, 2002).
4. Noninvasive prenatal diagnosis: next-generation sequencing (NGS) for the analysis of cell-free fetal DNA in maternal blood (Chitty et al. 2013, 2015).
5. Prenatal and preimplantation genetic diagnosis may be available for families in which the disease-causing mutation has been identified.

3. Management (Karczeski and Cutting 2013):
   1. Limited intervention:
      1. Appropriate because of the inevitable lethal outcome
      2. Aggressive neonatal management, at times, not even resulting in short-term survival
   2. Debatable issues about the level of intensity of medical care for unanticipated long-term survival:
      1. Long-term medical care.
      2. Development of seizures, progression of craniocervical stenosis, ventilator dependence and limitations in motor and cognitive abilities (Nikkel et al. 2013).
      3. Requiring extensive health maintenance measures.
      4. Anticipate frequent medical exacerbations requiring recurrent hospitalizations.
      5. Possibility of lethal complication, an ever present concern.
      6. Special education programs for the longer survivals.

Fig. 1 (**a**–**c**) Front views of three infants showing frontal bossing, flat facies, short neck, micromelia, and small chest

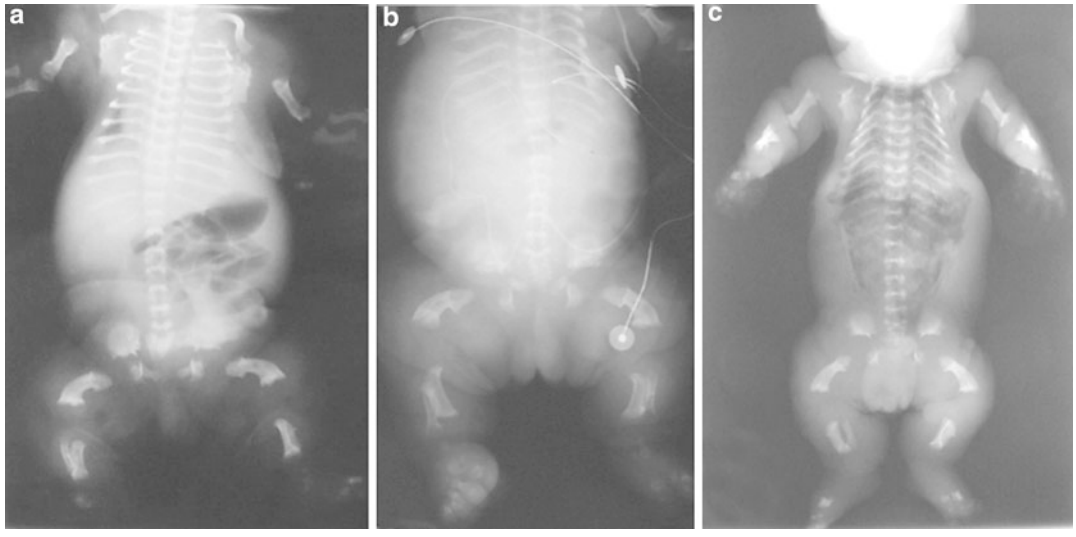

Fig. 2 (**a**–**c**) AP radiographic views of three infants with typical findings of TD1 showing profound platyspondyly, decreased thoracic volume, characteristic pelvic configuration, micromelia, and the so-called "telephone receiver" femoral bowing

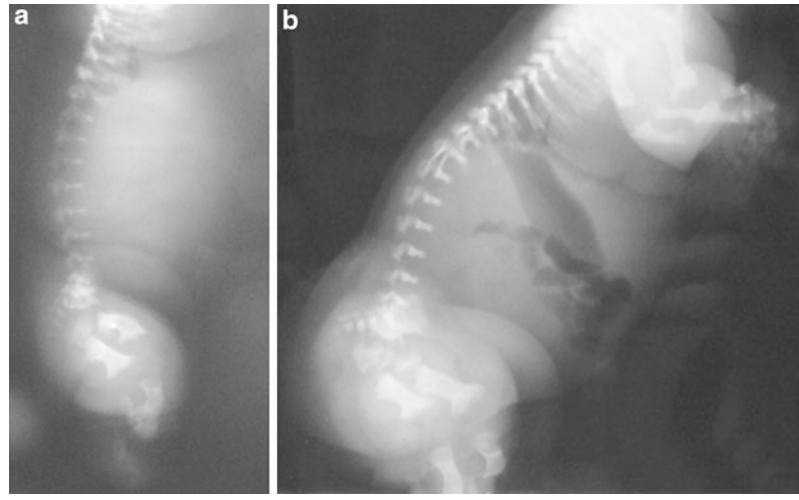

Fig. 3 (**a**, **b**) Lateral radiographic views of the spines of two infants with typical TD1 showing extreme platyspondyly and short ribs

Fig. 4 Gross appearance of a femur resembling a "telephone receiver"

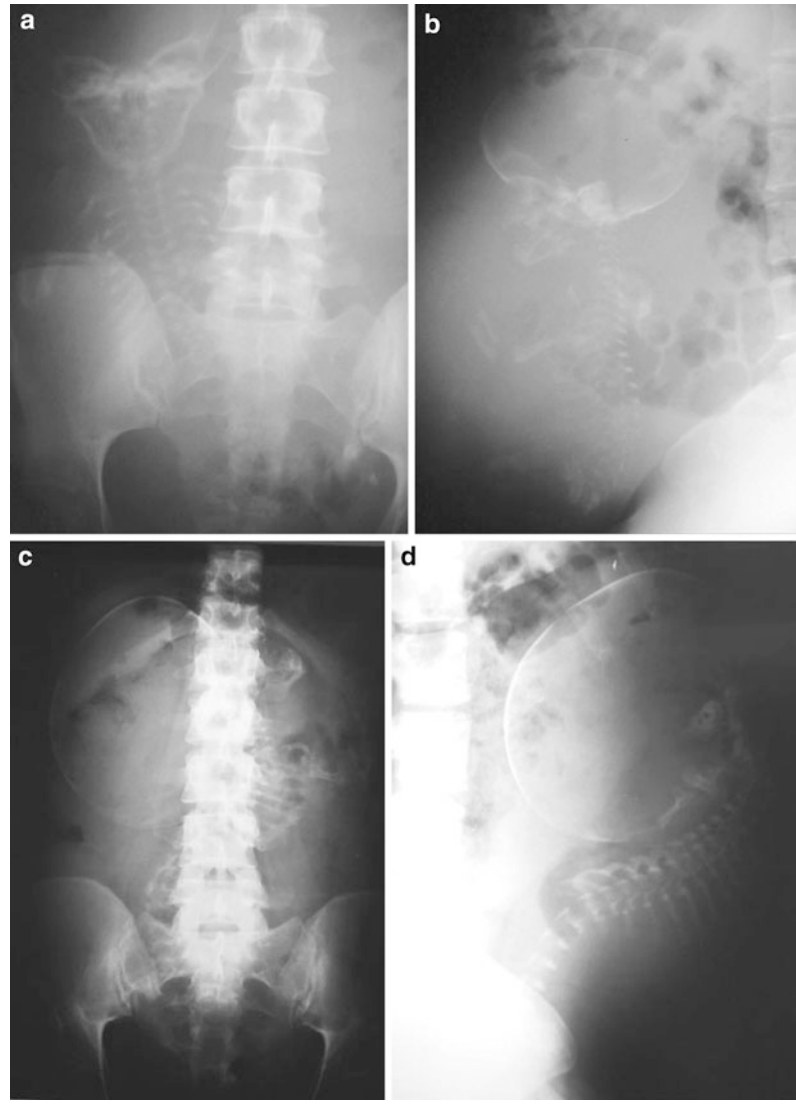

Fig. 5 (**a**–**d**) Prenatal radiographs of two fetuses affected with thanatophoric dysplasia showing platyspondyly, short ribs, and micromelia

Fig. 6 Thanatophoric dysplasia in identical twin fetuses. The pregnancy was terminated following ultrasonographic diagnosis at 22 weeks' gestation. The placenta was diamniotic monochorionic, consistent with monozygotic pregnancy

Fig. 7 Thanatophoric dysplasia with cloverleaf skull in a neonate. The head is large and trilobed. The narrow chest and rhizomelic shortening of limbs are similar to those of classic thanatophoric dysplasia. Radiograph revealed platyspondyly and small ilium that are similar to those of classic thanatophoric dysplasia (not shown). However, the femur is straight and not as curved as seen in the classic type (Courtesy of Dr. Samuel Yang)

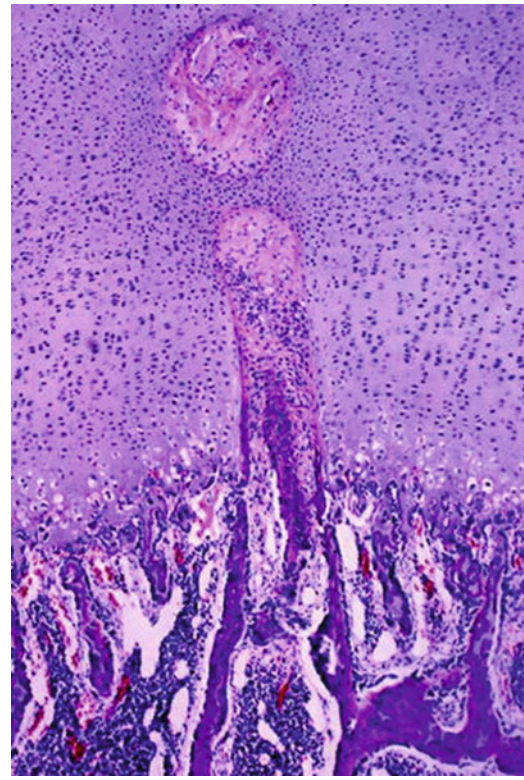

Fig. 8 Photomicrograph of the cartilage-bone junction, cloverleaf skull type of thanatophoric dysplasia. The physeal growth zone is markedly retarded and disorganized. Similar changes are seen in the classic-type thanatophoric dysplasia. A partially ossified cartilage canal is present at the center of physis. It is more prominent in size and number in the cloverleaf type than in the classic type

Fig. 9 A neonate with short-limb dwarfism, characterized by flat face, short neck, short chest, and micromelia. A single-sequence mutation (Nt742C > T) was identified in the *FGFR3* gene. This causes the substitution of arginine for cysteine at codon 248 (C248R). This mutation has been previously reported in thanatophoric dysplasia type I

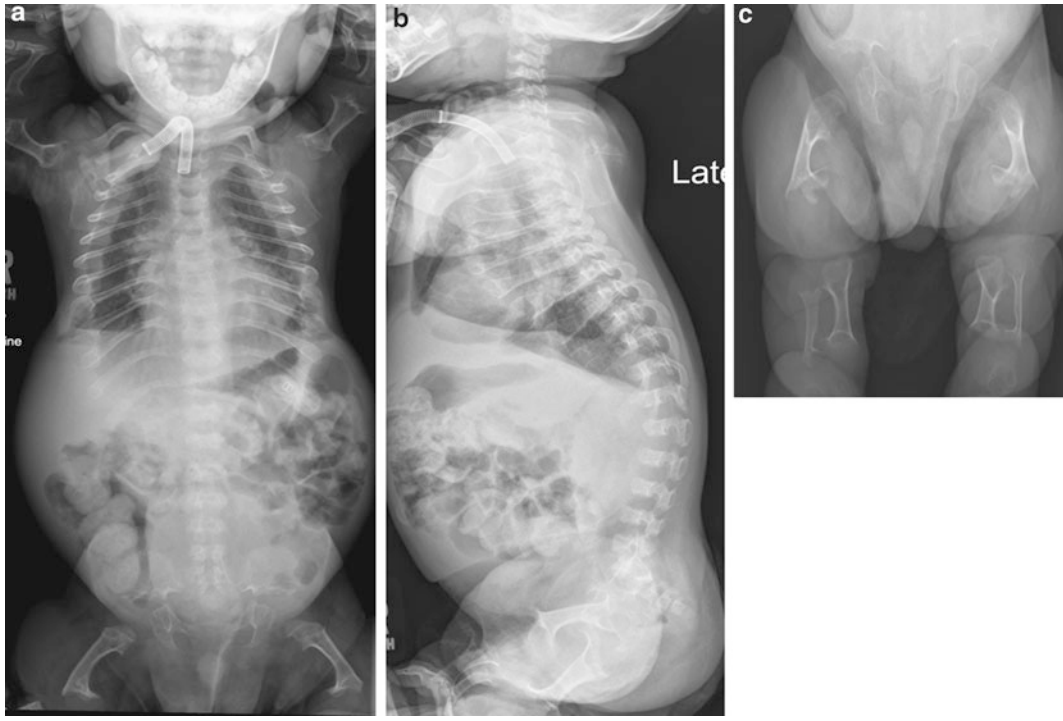

Fig. 10 (**a**–**c**) A 2-year-old boy was seen with diagnosis of type 1 thanatophoric dysplasia. Prenatal ultrasonographs noted features consistent with thanatophoric dysplasia. Amniocentesis at 21 weeks of gestation showed a 46,XY karyotype with DNA mutation study of amniocytes showing c.742C > T (Arg248Cys) in *FGFR3* gene, which confirmed the diagnosis of type 1 thanatophoric dysplasia. He has extremely short limbs with developmentally delay, especially in motor milestones. The radiographs showed bullet-shaped vertebral bodies with posterior scalloping. There was progressive narrowing of the interpediculate distances in the lumbar spine. The rib cage was small with short ribs and prominent anterior ends. The long bones of the lower extremities were markedly shortened with flaring and irregularity of the metaphyses. There was also bowing of bilateral femurs which appears as a typical "telephone receiver" femur. The iliac wings were short and squared with irregular acetabular roofs (Courtesy of Dr. Grace Guo)

Thrombocytopenia-Absent Radius Syndrome

Contents

Thrombocytopenia-absent radius (TAR) syndrome is a congenital malformation syndrome characterized by congenital hypomegakaryocytic thrombocytopenia and bilateral absence of the radii with presence of both thumbs.

Synonyms and Related Disorders

TAR syndrome

Genetics/Basic Defects

1. Genetic inheritance: autosomal recessive inheritance suspected based on the following observations
   1. Families with at least two affected children born to unaffected parents
   2. Rare instances of association with consanguinity
2. A microdeletion of chromosome 1q21.1: observed in all investigated patients with TAR syndrome (Klopocki et al. 2007; Tassano et al. 2015)
   1. Associated with an interstitial microdeletion of 200 kb on chromosome 1q21.1 in all 30 investigated patients with TAR syndrome, detected by microarray-based comparative genomic hybridization.
   2. Analysis of the parents revealed that this deletion occurred de novo in 25% of affected individuals.
   3. The recessive inheritance pattern of TAR syndrome requires an additional causative allele that until recently was unknown. A low-frequency single-nucleotide polymorphism (SNP) in the *RBM8A* gene is detected as the second causative allele in the origination of TAR syndrome (Albers et al. 2012).
3. Etiology of thrombocytopenia: unknown but is considered to be the result of a decreased production of platelets from the bone marrow

Clinical Features

1. Thrombocytopenia (100%)
   1. May be transient.
   2. Symptomatic in over 90% of cases within the first 4 months of life.
      1. Purpura
      2. Petechiae

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_229

3. Epistaxis
4. Gastrointestinal bleeding
    1. Hematemesis
    2. Melena
5. Hemoptysis
6. Hematuria
7. Intracerebral bleeding

3. More severe thrombocytopenia can be precipitated by stress, infection, gastrointestinal disturbances, or surgery (Fayen and Harris 1980).
4. Platelet count tends to rise as the child gets older and may approach normal levels in adulthood (spontaneous improvement of platelet counts after 1 year).

2. Upper extremity anomalies (100%) (Hall 1987)
    1. Bilateral absence of the radius (100%): the most striking skeletal manifestation
    2. Hand anomalies
        1. Presence of the thumbs (100%)
            1. An important clinical feature distinguishing TAR syndrome from other disorders featuring radial aplasia, which are usually associated with absent thumbs
            2. Relatively functional thumbs
            3. Thumbs often adducted
            4. Thumbs often hypoplastic
        2. Radially deviated
        3. Limited extension of the fingers
        4. Hypoplasia of the carpal and phalangeal bones
        5. Severe phenotype with phocomelia (Hall et al. 1969, 1987; Klopocki et al. 2007)
        6. Phocomelia and lower limb anomalies (28%) in TAR syndrome associated with 1q21.1 deletion (Houeijeh et al. 2011)
    3. Associated ulnar anomalies
        1. Usually short
        2. Usually malformed
        3. Absent ulna
            1. Absent bilaterally in about 20% of cases
            2. Absent unilaterally in about 10% of cases
    4. Associated humeral anomalies
        1. Often abnormal in about 50% of cases
        2. Absent humeri in about 5–10% of cases (rare phocomelia)
    5. Associated shoulder and arm anomalies
        1. One arm shorter than the other in about 15% of cases
        2. Hypoplasia of muscles and soft tissue in the arm and shoulder
        3. Abnormal shoulder joint secondary to abnormal humeral head
3. Lower limb anomalies (47%) (Ray et al. 1980; Christensen and Ferguson 2000; Greenhalgh et al. 2002)
    1. Correlation exists between the severity of skeletal changes in the lower limbs and the severity of abnormalities of the upper limbs.
    2. Variable involvement but usually milder than the upper limbs.
        1. Dislocation of the patella and/or of the hips
        2. Knee involvement
            1. Dysplasia: rare severe knee dysplasia due to agenesis of cruciate ligaments and menisci
            2. Ankylosis
            3. Subluxation
        3. Hip dislocation
        4. Coxa valga
        5. Absent tibiofibular joint
        6. Femoral or tibial torsion
        7. Lower limb phocomelia
        8. Valgus and varus foot deformities
        9. Abnormal toe placement
        10. Severe cases with lower limb phocomelia
4. Cow's milk intolerance (Whitfield and Barr 1976) (62%)
    1. Presentation symptoms
        1. Persistent diarrhea
        2. Failure to thrive
    2. Thrombocytopenia episodes
        1. Precipitated by introduction of cow's milk
        2. Relieved by its exclusion from the diet
5. Urogenital anomalies (23%)
    1. Horseshoe kidney
    2. Absent uterus
6. Cardiac anomalies (22–33%)
    1. Tetralogy of Fallot

2. Atrial septal defect
3. Ventricular septal defect

7. Other associated congenital anomalies
   1. Facial capillary hemangiomata in the glabella region
   2. Micrognathia
   3. Cleft palate
   4. Intracranial vascular malformation
   5. Sensorineural hearing loss
   6. Epilepsy
   7. Other skeletal anomalies
      1. Scoliosis
      2. Cervical rib
      3. Fused cervical spine
      4. Short stature
   8. Neural tube defect
8. Prognosis
   1. Variable clinical course among patients.
   2. Survival related to the severity and duration of thrombocytopenia.
   3. Good prognosis after surviving the first year of life.
   4. Early diagnosis and treatment with platelet therapy minimize mortality risks.
   5. Mental retardation secondary to intracranial bleed (7%).
   6. Good hand and upper extremity functions, especially if bilateral radial aplasia is the only skeletal abnormality.
9. Variable phenotypes of TAR syndrome associated with 1q21.1 deletion (Houeijeh et al. 2011)
   1. Ranging from syndactyly to severe TAR syndrome.
      1. A boy and a maternal uncle with TAR syndrome and a maternal aunt harboring isolated mild radial hypoplasia (Schnur et al. 1987)
      2. A stillbirth male fetus with TAR syndrome who had two paternal uncles presenting with isolated webbed toes (Donnenfeld 1994)
   2. Presence of one or more frequent event (s) (mTAR) that could modulate the expression of the deletion (Klopocki et al. 2007).
   3. Female predominance could suggest the presence of X-linked modifying factors (mTAR) (Schnur et al. 1987).
10. Differential diagnosis (Hall 1987; Hedberg and Lipton 1988; Greenhalgh et al. 2002; Toriello 2014)
    1. Holt-Oram syndrome (please see the chapter)
       1. An autosomal dominant condition caused by mutations in the *TBX5* gene
       2. Often with a family history of heart and limb defects
       3. Absence of the thumb associated with radial aplasia
       4. Absence of thrombocytopenia
       5. Conventional cytogenetic analysis: usually normal
    2. Roberts syndrome (please see the chapter)
       1. An autosomal recessive trait
       2. Pre- and postnatal growth retardation
       3. Facial clefting
       4. Genitourinary abnormalities
       5. Limb defects involving upper or lower limbs or both
       6. Conventional cytogenetic analysis: characteristic chromosome abnormality in the majority (79%) of cases
          1. Premature centromere separation (PCS)
          2. "Puffing" of the chromosomes caused by repulsion of the heterochromatic regions near the centromeres of chromosomes 1, 9, and 16 with splaying of the short arms of the acrocentric chromosomes and of distal Yp.33
          3. Evidence of abnormal mitosis
       7. Postulated that TAR syndrome and Roberts syndrome might be part of the same condition, with TAR syndrome being the milder and Roberts the severer variant
    3. Fanconi anemia (please see the chapter)
       1. An autosomal recessive disorder.
       2. Bone marrow failure.
       3. Skeletal defects.
       4. Cutaneous pigmentation.
       5. Microcephaly.
       6. Short stature.
       7. May present with thrombocytopenia.
       8. Upper limb abnormalities also involve the radial ray.

9. Hypoplastic thumbs may be accompanied by radial hypoplasia, but absence of the radius is associated with absence of the thumbs.
10. Spontaneous chromosome breakage, a consistent feature of Fanconi anemia and is a reliable diagnostic test.

4. Aase syndrome
   1. Radial hypoplasia
   2. Triphalangeal thumbs
   3. Hypoplastic anemia, similar to Blackfan-Diamond syndrome
   4. Thrombocytopenia, not a feature
5. Thalidomide embryopathy
   1. May present with radial anomalies of the upper limb
   2. Malformations of the lower limbs showing a less consistent pattern
   3. Diagnosed based on:
      1. Phenotype
      2. History of exposure to thalidomide during pregnancy
      3. Increasing use of thalidomide as a therapeutic agent for the treatment of conditions such as Beçhet disease, graft versus host disease, multiple myeloma, and Kaposi sarcoma
6. Rapadilino syndrome (acronym for *ra*dial defects, absent/hypoplastic *pa*tella (and high/cleft *pa*late), *di*arrhea (and joint *di*slocations), and little size, long/slender *no*se (and *no*rmal intelligence))
   1. Absent thumbs and radial aplasia/hypoplasia
   2. Patellar aplasia/hypoplasia
   3. Cleft palate
7. Other syndromes with limb reduction abnormalities predominantly involving the upper extremities (Donnenfeld et al. 1990)
   1. Duane anomaly-radial aplasia
      1. Duane anomaly (inability to abduct the eye)
      2. Radial anomalies of varying severity, ranging from thenar hypoplasia to radial aplasia
      3. Renal and skeletal anomalies
      4. Hearing loss or ear anomalies
   2. Adams-Oliver syndrome (please see the chapter)
      1. Transverse limb defects
      2. Aplasia cutis congenita
      3. Growth deficiency
   3. Aglossia-adactylia
      1. Absence/hypoplasia of digits
      2. Absence/hypoplasia of the tongue
   4. Amniotic band sequence (please see the chapter on "Amniotic Deformity, Adhesions, Mutilations (ADAM) Complex)"
      1. Limb constriction or amputation
      2. Asymmetric facial clefts
      3. Cranial defects
      4. Compression deformities
   5. CHILD syndrome
      1. Unilateral hypomelia
      2. Ichthyosiform erythroderma
      3. Cardiac septal defect
   6. Cornelia de Lange syndrome
      1. Micromelia
      2. Growth deficiency
      3. Facial dysmorphism
   7. Femur-fibula-ulnar syndrome
      1. Femoral/fibular defects associated with malformations of the arms
      2. Amelia
      3. Peromelia at the lower end of the humerus
      4. Humeroradial synostosis
      5. Defects of the ulna and ulnar rays
   8. Poland anomaly (please see the chapter on "► Möbius Syndrome")
      1. Unilateral defect of pectoralis major muscle
      2. Ipsilateral limb abnormalities
   9. VATER association (vertebral, anal, tracheoesophageal, renal, and radial anomalies) (please see the chapter "► VATER (VACTERL) Association)"
   10. Townes-Brocks syndrome

1. Imperforate anus (82%)
2. Dysplastic ears: overfolded superior helices and preauricular tags (88%) frequently associated with sensorineural or conductive hearing impairment (65%)
3. Thumb malformations (triphalangeal thumbs, duplication of the thumb (preaxial polydactyly), rarely hypoplasia of the thumbs)

11. Weyers ulnar ray/oligodactyly syndrome
    1. Deficient ulnar and fibular rays
    2. Oligodactyly
    3. Hydronephrosis

8. Megakaryocytic aplasia
    1. Amegakaryocytic thrombocytopenia
    2. Congenital hypoplastic thrombocytopenia with microcephaly
    3. Thrombocytopenia associated with trisomy 13 and trisomy 18

Diagnostic Investigations

1. Hematological studies
    1. Blood platelet counts: thrombocytopenia
    2. Anemia secondary to bleeding
    3. Eosinophilia
    4. Leukemoid reaction (Hall 1987)
        1. Reported in about 60–70% of patients during the first year of life
        2. White blood counts >35,000 per mm^3 with a shift to the left, particularly with the stress and infections
        3. Usually associated with worse thrombocytopenia and often with hepatosplenomegaly
    5. Bone marrow aspirates
        1. Normal or hypercellular bone marrow
        2. Hypomegakaryocytic thrombocytopenia (<100,000 platelets per mm^3) (Dell and Sheppard 1982; Hall 1987)
            1. Absence of megakaryocytes in two thirds of cases
            2. Decreased in number of megakaryocytes, which are small, immature, basophilic, and vacuolated, in the rest of cases
2. Chromosome analysis (normal): to differentiate from chromosome abnormality syndrome
3. Molecular genetic analysis
    1. Common microdeletion in patients with TAR syndrome that encompasses 200 kb and 11 genes on chromosome 1q21.1 (Klopocki et al. 2007)
        1. De novo deletion: 25%
        2. Deletion inherited from either the unaffected mother or the unaffected father: 75%
    2. Array comparative genomic hybridization (aCGH): individuals with TAR syndrome have a minimally deleted 200-kb region at chromosome band 1q21.1, which is distinct from the region involved in the 1q21.1 deletion/duplication syndrome. Deletion of this segment is necessary but not sufficient to cause the phenotype. Identification of the 200-kb minimally deleted region is sufficient to verify the diagnosis of TAR syndrome in individuals with bilateral absence of the radius and presence of thumbs (Toriello 2014).
    3. SNP array CGH analysis: thrombocytopenia-absent radius syndrome in a child showing a larger 1q21.1 deletion than the one in his healthy mother and a significant downregulation of the commonly deleted genes (Guastadisegni et al. 2012).
    4. Deletion/duplication analysis to identify a 200-kb minimally deleted region in chromosome band 1q21.1: sufficient to verify the diagnosis of TAR syndrome (Al Kaissi et al. 2015).
    5. Summary of molecular genetic testing used in TAR syndrome (Toriello 2014).
        1. Deletion/duplication analysis
        2. Sequence analysis
        3. Targeted mutation analysis
4. Radiography
    1. Upper extremities
        1. Bilateral radial aplasia
        2. Radial club hand

3. Hypoplastic carpals and phalanges
4. Thumb and fingers always present
5. Hypoplastic ulnae, humeri, and shoulder girdles
6. Syndactyly and clinodactyly of fingers and toes

2. Lower extremities
   1. Hip dislocation
   2. Femoral torsion
   3. Tibial torsion
   4. Knee dysplasia
   5. Absent patella
   6. Valgus and varus foot deformities
   7. Abnormal toe placement
   8. Overriding toes

Genetic Counseling

1. Recurrence risk (Toriello 2014)
   1. TAR syndrome: inherited in an autosomal recessive manner and results from compound heterozygosity of *RBM8A* pathogenic variants.
   2. Affected individuals: typically with one *R8BM8A* hypomorphic mutation along with a null mutation, usually a minimally deleted 200-kb region at chromosome band 1q21.1.
   3. Approximately 50–75% of probands have inherited the 200-kb minimally deleted region from an unaffected parents; the deletion occurs de novo in about 25–50% of probands.
   4. Sibs of a proband:
      1. If both parents carry one allele: at conception each sib of an affected individual has a 25% chance of being affected, a 50% chance of being an asymptomatic carrier, and a 25% chance of being unaffected and not a carrier.
      2. If only one parent is a carrier of a pathogenic variant (and the other mutation/deletion is de novo): each sib of an affected individual has a 50% chance of being an asymptomatic carrier and a 50% chance of being unaffected and not a carrier.
      3. When both parents are carriers: once an at-risk sib is known to be unaffected, the risk of his/her being a carrier is two thirds.
      4. Heterozygotes (carriers) are asymptomatic.
   5. Patient's offspring:
      1. The offspring of an individual with TAR syndrome: obligate heterozygotes (carriers) for a pathogenic variant in *RBM8A*.
      2. If an individual with TAR syndrome has children with a carrier of a pathogenic variant in *RBM8A*: their offspring have a 50% chance of being affected and a 50% chance of being carriers. This may account for the reports of parent-to-child transmission (Ward et al 1986).
2. Prenatal diagnosis: reported mostly in pregnancies with a prior affected sibling (Donnenfeld et al. 1990; Uhrig et al. 2007; Toriello 2014)
   1. Prenatal ultrasonography:
      1. Bilateral radial aplasia, club hands with normal thumbs, and metacarpals (Luthy et al. 1979).
      2. Phocomelia: most important differential diagnoses include TAR, Holt-Oral, and Roberts syndromes.
      3. First-trimester detection of TAR syndrome is feasible using 2D/3D US scanning combined with virtual reality (Baken et al. 2014).
   2. Cordocentesis:
      1. Often considered to evaluate fetal platelet count (thrombocytopenia) and establish the diagnosis of TAR syndrome and to differentiate from other syndromes with malformations of the upper limbs (Boute et al. 1996; Shelton et al. 1999; Tongsong et al. 2000; Bellver et al. 2005)
      2. Platelet counts: often <50 platelets/nl (normal range 150–400 platelets/nl) (Ballmaier et al. 1997)
      3. Carries 1–2% risk of fetal loss (22)
   3. X-ray (Omenn et al. 1973).
   4. Fetoscopy (Filkins et al. 1984).
   5. The sonographic finding of upper limb malformations in the fetus together with the

detection of the 1q21.1 microdeletion. Physical examination of the terminated fetus revealed malformed upper extremities and absence of both radii, with opposable thumbs in an adducted position (Uhrig et al. 2007).

6. Prenatal detection of TAR syndrome in a fetus with compound inheritance of an RBM8A SNP and a 334-kb deletion in the 1q21.1 region, detected by array-comparative genomic hybridization (Papoulidis et al. 2014).
7. Prenatal diagnosis and postmortem examination in a fetus with thrombocytopenia-absent radius (TAR) syndrome due to compound heterozygosity for a 1q21.1 microdeletion and a RBM8A hypomorphic allele.
8. Prenatal diagnosis for pregnancies at increased risk for TAR syndrome is possible using molecular genetic testing to detect the 200-kb minimally deleted region and ultrasound examination to evaluate the limbs (Bottillo et al. 2013).
9. Preimplantation genetic diagnosis: may be available for families in which the pathogenic variants have been identified.

3. Management (McLaurin et al. 1999; Wu et al. 2014; Toriello 2014)
   1. Platelet infusions
      1. Remains the only real option for treatment of thrombocytopenia
      2. To prevent the intracerebral hemorrhage, which was previously the main cause of mortality
      3. Potential risks of platelet transfusion
         1. Avoid platelet transfusion in older individuals whose platelet counts exceed a particular threshold (10/nL): alloimmunization and infection (hepatitis viruses, HIV).
         2. Anaphylaxis.
         3. Hemolytic reaction.
      4. Surveillance: platelet count whenever evidence of increased bleeding tendency (bruising, petechiae) occurs
   2. Avoidance of cow's milk to reduce the severity of gastroenteritis and to avoid exacerbations of thrombocytopenia
   3. Injury prevention strategies
      1. Avoid contact sports.
      2. Use appropriate protective gear (helmet, padding).
   4. Splenectomy usually effective for the treatment of thrombocytopenia in adults
   5. Bone marrow transplantation as an option for patients who continue to remain thrombocytopenic with bleeding despite platelet transfusions
   6. Physical and occupational therapies to improve function and quality of life
   7. Management of the upper extremity
      1. Postpone surgery till later as thrombocytopenic-related bleeding problems are less frequent in older individuals.
      2. Reconstructive surgery (Al Kaissi et al. 2015).
      3. Prosthetic fitting: generally rejected by patients as most patients are able to perform tasks by approximating themselves closely enough to an object to use their own hands.
      4. Adaptive devices for feeding, dressing, and toileting: generally well tolerated.
   8. Management of the lower extremity
      1. Rejection of any lower extremity intervention by most patients
      2. Use of power wheelchair or motorized cart for ambulation

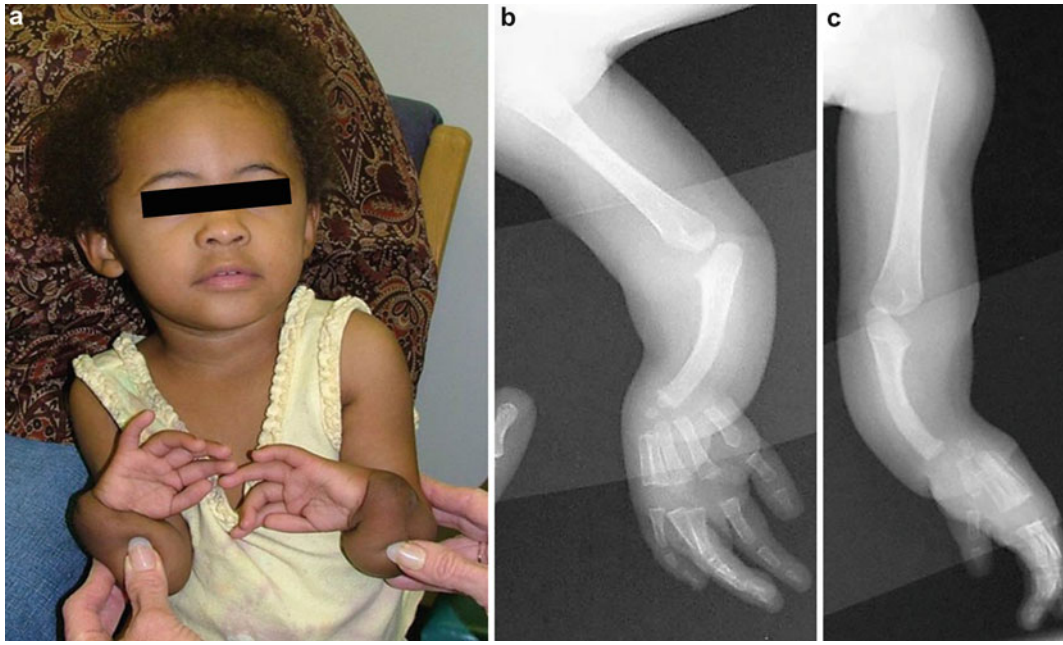

Fig. 1 (**a**–**c**) A 2 1/2-year-old girl with TAR syndrome (**a**) showing club hands with fingerlike thumbs and radial aplasia, illustrated by radiographs (**b**, **c**). The patient had thrombocytopenia early in life

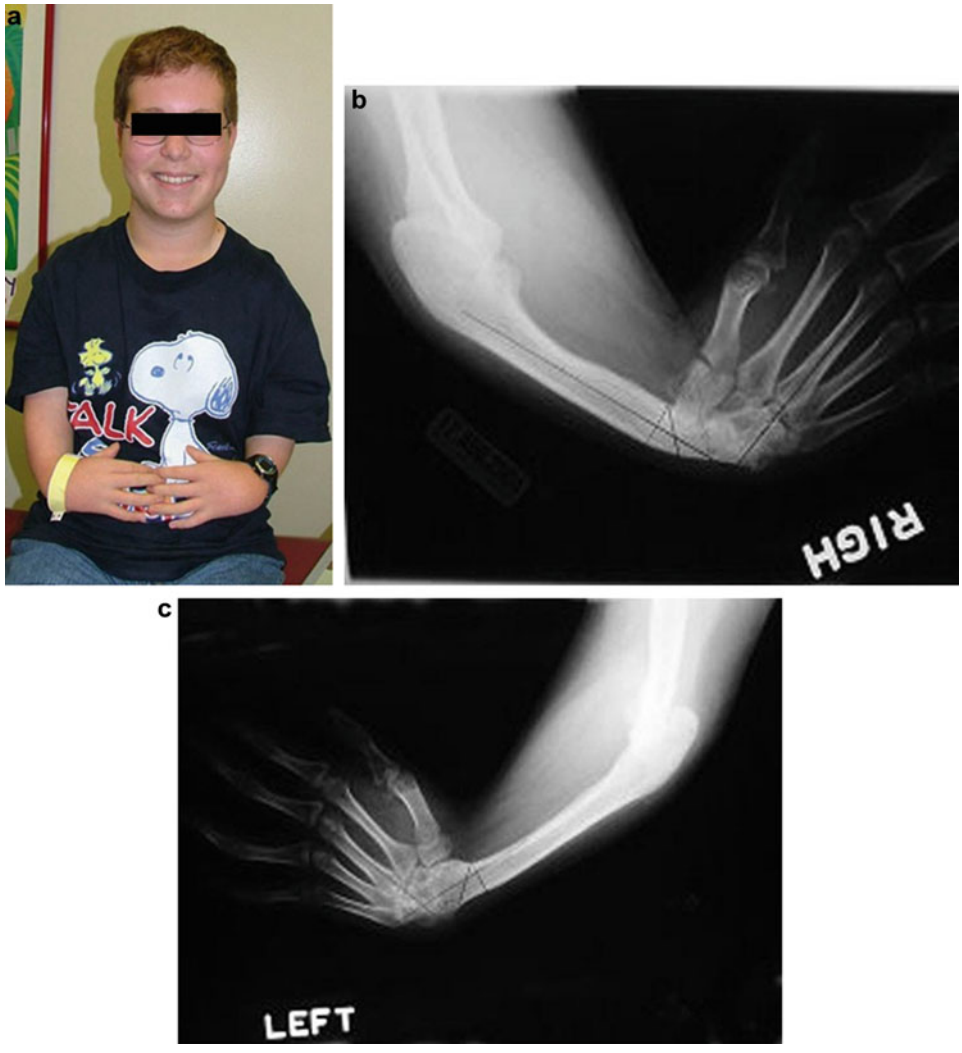

Fig. 2 (**a**–**c**) A 14-year-old boy with TAR syndrome showing similar clinical (**a**) and radiographic (**b**, **c**) features

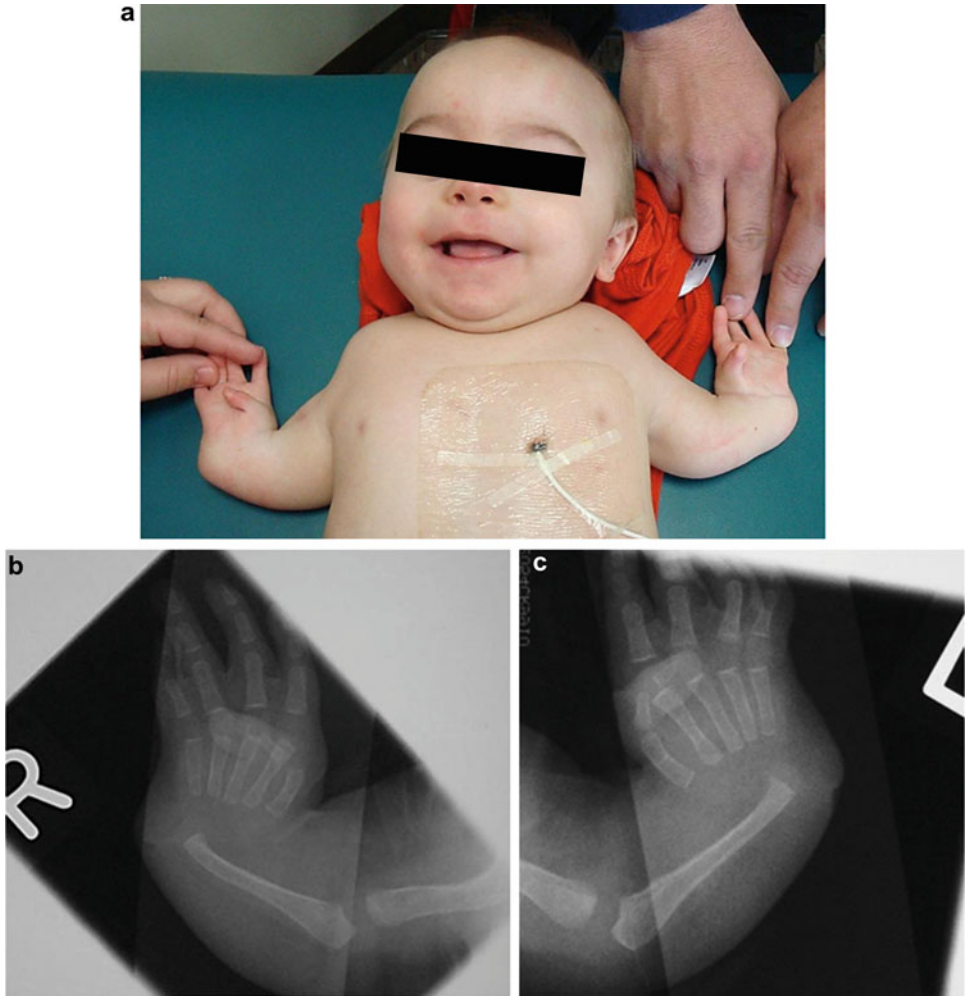

Fig. 3 (**a**–**c**) An 8-month-old boy (**a**) was noted to have club hands with radial aplasia (**b**, **c**). Platelet count was 28,000 at birth. He was diagnosed to have thrombocytopenia, necessitating repeat platelet infusions

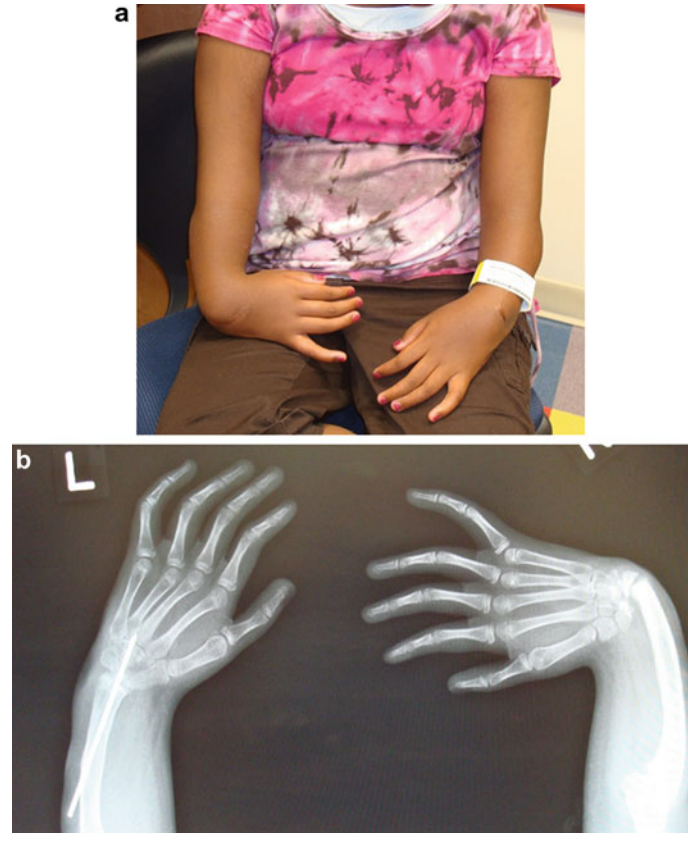

Fig. 4 (**a**, **b**) An 8-year-old girl with TAR syndrome showing similar clinical (**a**) and radiographic (**b**) features

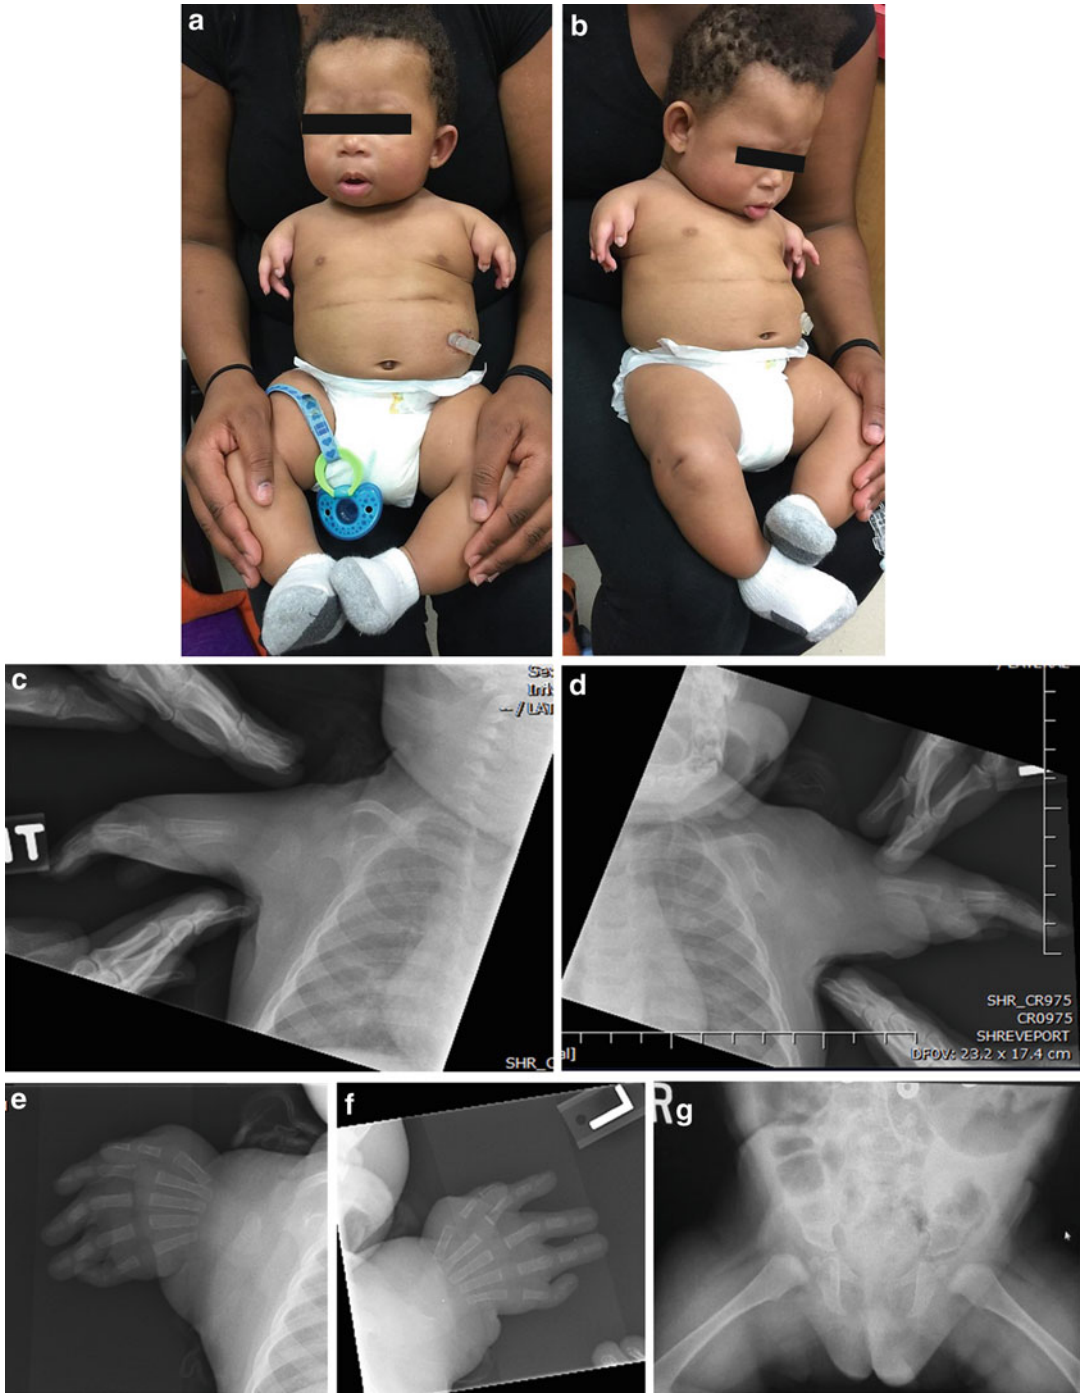

Fig. 5 (**a**–**g**) This 9-month-old boy was evaluated for thrombocytopenia-absent radius syndrome, showing phocomelia of both upper extremities (**a**, **b**). After delivery, she was noted to have phocomelia, abnormal legs and knees, and was in the hospital requiring repeat platelet transfusions due to thrombocytopenia (Platelet count of 20,000). Radiographs showed prominent hypoplasia and dysplasia of both humeri and shoulder girdles, radial and

Fig. 5 (continued) ulnar aplasia (**c**, **d**), presence of thumbs, hypoplasia of the middle and distal phalanges of the little fingers, and proximal soft tissue syndactyly between all digits (**e**–**f**). Hip radiograph showed bilateral hip dysplasia (**g**) with prominent genu varum deformity and bilateral flexion deformity at the knees (not shown). Microarray CGH identified a deletion of approximately 1,754 Mb at 1q21.1q21.2. This alteration span over the region 1q21.1 susceptibility locus for TAR syndrome, sufficient to verify the diagnosis of TAR syndrome (Al Kaissi et al. 2015)

Tibial Hemimelia

Contents

Tibial hemimelia, known as congenital longitudinal deficiency of the tibia, is a very rare anomaly with an incidence of approximately 1 in 1,000,000 births (Fernandez-Palazzi et al. 1998). It is characterized by deficiency of tibia with relatively intact fibula and marked shortening of the involved extremity with a severe equinovarus deformity (Weber 2007). Although the majority of cases of tibial hemimelia are sporadic, familial incidence of tibial aplasia has been observed (Fernandez-Palazzi et al. 1998; Javid et al. 2000; Leite et al. 2010).

Synonyms and Related Disorders

Tibial aplasia; Tibial hemimelia–polydactyly–triphalangeal thumb syndrome; Tibial hypoplasia

Genetics/Basic Defects

1. Etiology:
   1. Sporadic
   2. Autosomal dominant inheritance
   3. Possible autosomal recessive inheritance: report of isolated tibial hemimelia in two sibs born to phenotypically normal parents (McKay et al. 1984)
2. Molecular defect in tibial hemimelia–polydactyly–triphalangeal thumb syndrome (autosomal dominant trait):
   1. Identification of 404 G > C mutation in ZRS (zone of polarizing activity in developing embryonic limbs regulatory sequence) in a family with absent tibiae–polydactyly–triphalangeal thumbs with fibular dimelia, previously described by Vargas et al. (1995) and another family with tibial hemimelia–polydactyly–triphalangeal thumb syndrome (Wieczorek et al. 2010)
   2. Identification of 404 G > A mutation in ZRS in a sporadic case presenting with bilateral complete tibial hemimelia, preaxial polydactyly of the toes, and five-fingered hands (Cho et al. 2013)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_281

Clinical Features

1. The defect can range from moderate hypoplasia to the complete absence of the tibia (aplasia).
2. Can occur either as a solitary disorder or as a part of more complex malformation syndrome (Fernandez-Palazzi et al. 1998; Matsuyama et al. 2003).
3. Generally bilateral.
4. Shortened and medially bowed varus leg.
5. Fibular dimelia.
6. Frequently associated with preaxial mirror polydactyly of the feet or aplasia of the hallux (Verghese et al. 2007; Wilcox et al. 2015).
7. Associated foot anomalies include tibial ray(s) deficiencies or tarsal coalitions and hand malformations (Richieri-Costa et al. 1987; Schoenecker et al. 1989; Tokmakova et al. 2003; Lezirovitz et al. 2008).
8. Jones classification of congenital tibial aplasia and dysplasia (Jones et al. 1978):
    1. Type Ia, tibia not visible with hypoplastic distal femoral epiphysis
    2. Type Ib, absent tibia with normal distal femoral epiphysis
    3. Type II, absent distal tibia
    4. Type III, absent proximal tibia
    5. Type IV, hypoplastic distal tibia with ankle diastasis
9. Weber classification of tibial hemimelia (Weber 2008):
    1. I (tibial hypoplasia)
    2. II (tibial diastasis)
    3. III (distal tibial aplasia with (IIIa) or without (IIIb) cartilaginous anlage)
    4. IV (proximal tibial aplasia with (IVa) or without (IVb) cartilaginous anlage)
    5. V (bifocal tibial aplasia with (Va) or without (Vb) cartilaginous anlage)
    6. VI (tibial agenesis with double fibula with (Via) or without (VIb) cartilaginous anlage)
    7. VII (tibial agenesis with a single fibula with (VIIa) or without (VIIb) cartilaginous anlage)
10. Main syndromes associated with tibial hemimelia (Bergère et al. 2015):
    1. Tibial hemimelia–polysyndactyly–triphalangeal thumb syndrome (THPTTS):
        1. Tibial aplasia/hypoplasia
        2. Polysyndactyly
        3. Triphalangeal thumb
    2. Gollop–Wolfgang complex:
        1. Tibial aplasia/hypoplasia
        2. Femoral duplication
        3. Ectrodactyly
    3. Short rib polydactyly syndrome type 2 (Majewski type) (see the chapter):
        1. Micromelia
        2. Short ribs
        3. Polydactyly
    4. Trichorhinophalangeal syndrome type 2 (Langer–Giedion syndrome):
        1. Sparse scalp hair
        2. Bulbous nasal tip
        3. Short stature
        4. Multiple exostoses
    5. Split-hand/split-foot malformation:
        1. Tibial aplasia/hypoplasia
        2. Ectrodactyly of fingers and toes

Diagnostic Investigations

1. Radiographic features (Clément's classification) (Clement et al. 2000; Bergère et al. 2015):
    1. Type I (59%): total absence of the tibia
    2. Type IIa (10%):
        1. Presence of a proximal tibia (cartilaginous epiphysis).
        2. Although not detectable in young infants, the bone gradually develops via secondary ossification.
        3. Hypoplasia of the adjacent distal epiphysis of the femoris often observed.
    3. Type IIb (24%): presence of a proximal tibia comprising a portion of metaphysis and diaphysis, as well as a normal epiphysis and normal growth plate
    4. Type III (1.5%): presence of a distal tibia only

5. Type IV (5%):
    1. The entire tibia is present but shows either extensive hypoplasia or just hypoplasia of its distal end.
    2. The distal end is also tapered and sometimes deviates from the distal end of the fibula to articulate with the medial side of the ankle.
6. Other features:
    1. In most cases, the fibula is normal in both size and appearance, although shortened and/or deformed fibulas can be observed.
    2. The position of its proximal end depends on the presence and size of the tibia.
    3. Rarely, the fibula is also found to be absent.
    4. Unlike in fibular hemimelia, the femur is often normal.
    5. In other cases, tibial hemimelia can be associated with moderate femoral hypoplasia, femoral duplication, or hypoplasia of the distal femoral ossification center.
    6. The foot may be normal (but in varus equinus) or hypoplastic and deformed.
2. Molecular study of ZRS gene

Genetic Counseling

1. Recurrence risk depending on the etiology and the mode of inheritance:
    1. Patient's sib:
        1. Isolated: not increased
        2. Autosomal dominant inheritance: not increased unless a parent is affected
        3. Autosomal recessive inheritance: 25%
    2. Patient's offspring:
        1. Isolated: unknown
        2. Autosomal dominant inheritance: 50%
        3. Autosomal recessive inheritance: not increased unless the spouse is also a carrier
2. Prenatal diagnosis by ultrasonography: prenatal diagnosis of Gollop–Wolfgang complex was made by ultrasound at 17 weeks of gestation, showing tibial agenesis and femoral bifurcation (Mendilcioglu et al. 2009).
3. Management:
    1. Limb reconstruction (Al Kaissi et al. 2014):
        1. Transferring the upper end of the fibula to the intercondylar notch of the femur and correcting the equinovarus deformity of the ankle by centralizing the fibula into the talus.
        2. May be necessary to ablate the foot and hence the child becomes a below-knee amputee whose knee joint needs external support (Kalamchi and Dawe 1985; Loder and Herring 1987; Pattinson and Fixsen 1992).
    2. Limb-preservation (salvage) surgeries (Wada et al. 2006; Shahcheraghi and Javid 2015):
        1. Foot centralization
        2. Tibiofibular fusion for partial deficiency of the tibia
        3. Fibular transfer for complete deficiency of the tibia
        4. Leg lengthening of either femur or fibula

Fig. 1 A 15-year-old female, her 14-year-old brother, and their mother (**a**) were evaluated for multiple abnormalities of the limbs, including bilateral tibial aplasia. She was born with five fingers (**b**) on the right with fingerlike thumb, five digits on the left hand (**c),** and radial deviation of the right 2nd–3rd fingers (**d**) (radiograph of the left hand at 3 years and 8 months and the right hand at 15 years of age). She was also born with bilateral tibial aplasia (**e, f**) with dislocation at the knee joint, right foot with seven digits (**g**), left foot with six digits (**h**), clubfoot, and very short and curved fibulae. Both legs were amputated at the knees (**b)**

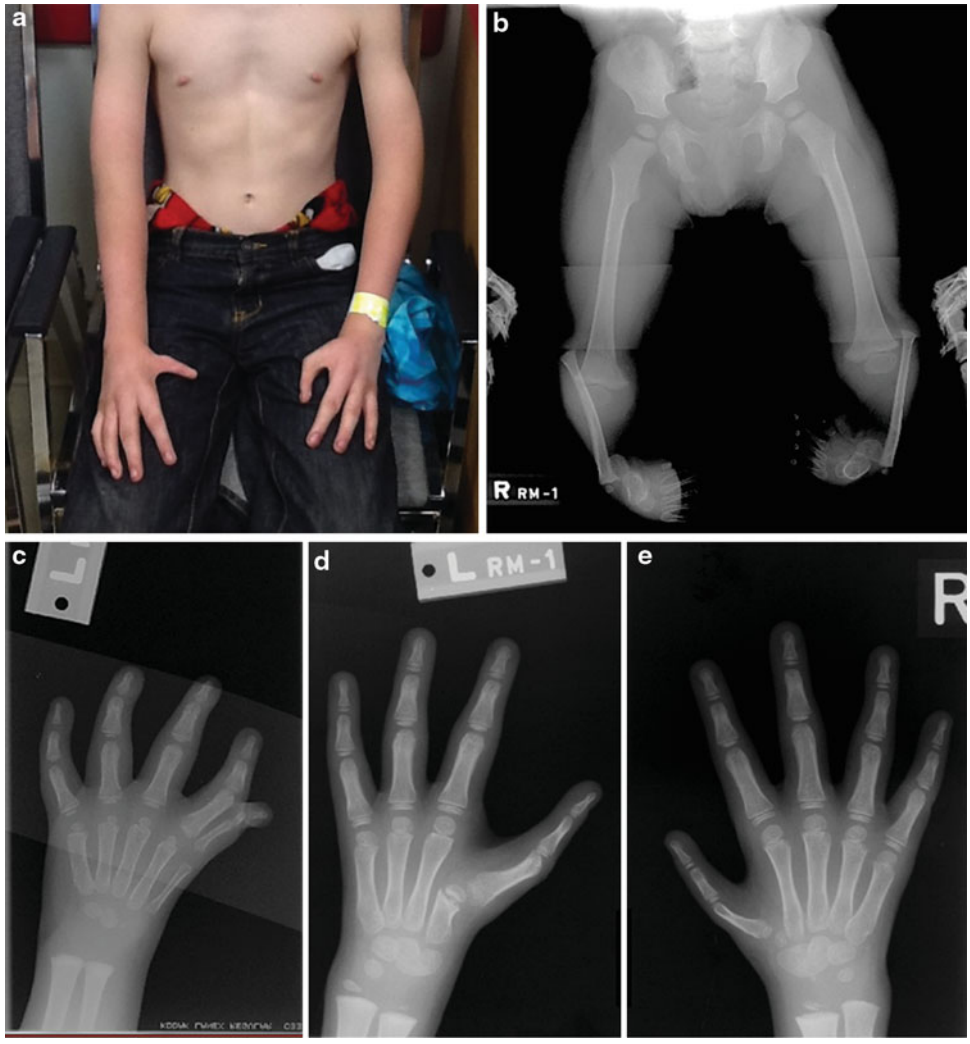

Fig. 2 Her brother (**a**) was born with absent tibias, dislocation and superior displacement of the fibula, and prominent clubfoot deformity with 14 toes (duplication of the 1st ray of both feet) (**b**). Left hand with hypoplastic thumb (**c**) which was removed (**d**), five digits on the right hand (**e**), and short forearms. Both legs were amputated at the knees

Fig. 3 The mother (**a**) had foreshortened forearms, clubhands with missing thumbs, and both hands with four fingers. The radiographs (**b–d**) showed the absence of bilateral tibias, bilateral clubfeet, left foot with five metatarsals and seven phalanges, and right foot with five metatarsals; short right radius, absent left radius, clubhands, four metacarpals, and absent bilateral thumbs. She was amputated at the knees (**a**)

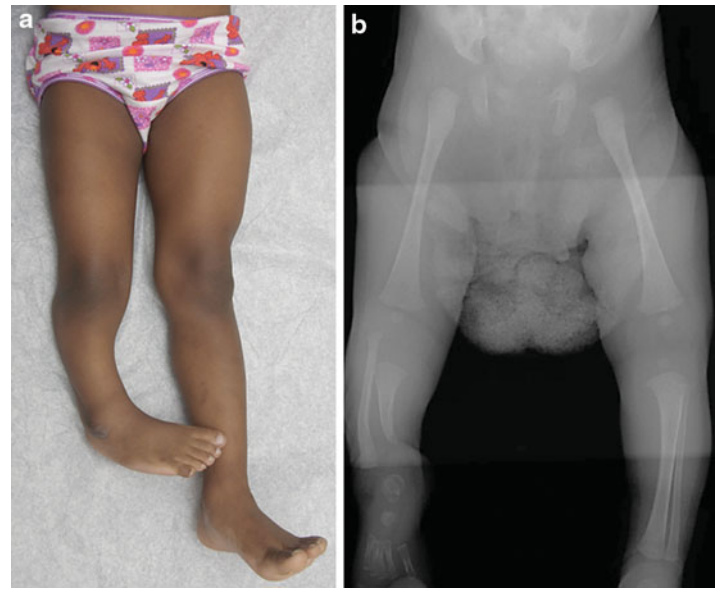

Fig. 4 A 3-year-old girl (**a**) was evaluated for right tibial hemimelia. The radiograph (**b**) at a month of age showed a shortened and deformed tibia with a deformed fibula of the right lower leg. The bilateral femurs, left tibia, and left fibula appear normal. Her family history shows an aunt and a cousin with clubfoot (Courtesy of Dr. Grace Guo)

Treacher-Collins Syndrome

Contents

Treacher-Collins syndrome (TCS), also called Treacher Collins-Franceschetti syndrome or mandibulofacial dysostosis, is an autosomal dominant disorder affecting the development of structures derived from the first and second branchial arches during early embryonic development (Poswillo 1975). The incidence is estimated to be 1 in 50,000 live births.

Synonyms and Related Disorders

Berry-Treacher Collins syndrome; Franceschetti-Zwahlen-Klein syndrome (Rogers 1964); Mandibulofacial dysostosis (Franceschetti and Klein 1949); Mandibulofacial dysostosis with microcephaly (mandibulofacial dysostosis, Guion-Almeida type); Treacher Collins-Franceschetti syndrome

Genetics/Basic Defects

1. Inheritance
    1. An autosomal dominant disorder (Murty et al. 1988)
        1. Rare incomplete penetrance
        2. Wide variability
    2. Forty percentage of cases have a previous family history.
    3. Sixty percentage of cases possibly arise from de novo mutations of *TCOF1*.
2. The *Treacher Collins-Franceschetti syndrome 1* (*TCOF1*) gene
    1. The only gene currently known to be associated with TCS
    2. Mapped to chromosome 5q32-q33.1
    3. Positional cloning of a gene (Treacle) involved in the pathogenesis of Treacher-Collins syndrome (The Treacher Collins Syndrome Collaborative Group 1996)
    4. Encoding a serine/alanine-rich protein, called "treacle" (Jones et al. 1999; Isaac et al. 2000)
    5. A complete coding sequence of the Treacher Collins-Franceschetti syndrome 1 gene (*TCOF1*) (Wise et al. 1997) has been identified (Dixon et al. 1997).
    6. Mutations in the *TCOF1* gene (Marszalek et al. 2002)
        1. Type of mutations

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_230

1. Deletions
2. Insertions
3. Missense mutations

2. Two mutations affecting splicing of the primary transcript are located in:
   1. Introns 3 (304 + 5 G → C)
   2. Introns 22 (3550 + 1G → A)
3. Most mutations result in a premature termination codon (Dixon 1996), producing a truncated protein devoid of the nuclear localization signals (NLSs).

3. TCS occurs as a result of a mutation in 1 of 3 genes: *TCOF1*, *POLR1C*, or *POLR1D* (Fisher 2011; Katsanis and Cutting 2012; Chung et al. 2014).
   1. Mutation of the *TCOF1* gene: most commonly found, accounting for 78%–93% of TCS cases.
   2. Mutations of *POLR1C* and *POLR1D* account for approximately 8%.
   3. TCS caused by heterozygous mutation in *TCOF1*, or less commonly *POLR1D*, is inherited in an autosomal dominant manner, whereas compound heterozygous mutations in *POLR1C* are inherited in an autosomal recessive manner.
   4. Autosomal dominant inheritance accounts for the majority of TCS cases.
   5. It is estimated that 60% of autosomal dominant cases of TCS arise as the result of de novo mutations, and 40% are familial.
4. Mandibulofacial dysostosis with microcephaly (Guion-Almeida type) (Huang et al. 2016)
   1. Mandibulofacial dysostosis with microcephaly (MFDM; MIM# 610536) is a multiple malformation syndrome comprising microcephaly, first and second branchial arch anomalies (Pierre-Robin sequence, malar hypoplasia, zygomatic clefting, microtia, middle ear malformations, choanal atresia, and/or auditory atresia), hearing loss, dysmorphic features, and variable systemic malformations (esophageal atresia, short stature, cardiac and/or genitourinary anomalies, and proximally placed thumbs) (Guion-Almeida et al. 2006; Wieczorek et al. 2007, 2009).
   2. Haploinsufficiency of *EFTUD2* (MIM# 603892), encoding U5–116 kDa, a spliceosomal GTPase, is responsible (Lines et al. 2012).
   3. The majority of described mutations are de novo, with a variety of documented mutation types (missense, nonsense, frameshift, splice site, and complete or partial gene deletions, including cytogenetically visible deletions); however, autosomal dominant inheritance and, less commonly, germline mosaicism have been reported (Lines et al. 2014).
   4. Mutations in several other genes involved in spliceosomal function or linked aspects of mRNA processing have also recently been identified in human disorders with specific craniofacial malformations (Lehalle et al. 2015).
      1. *SF3B4* in Nager syndrome, an acrofacial dysostosis (AFD)
      2. *SNRPB* in cerebrocostomandibular syndrome, characterized by Robin sequence and rib defects
      3. *EIF4A3* in the AFD Richieri-Costa–Pereira syndrome, characterized by Robin sequence, median mandibular cleft, and limb defects
      4. *TXNL4A* in Burn-McKeown syndrome, involving specific craniofacial dysmorphisms
5. Pathogenesis (Trainor et al. 2009)
   1. Prenatal mandibulofacial dysostosis: The pathogenesis of the events leading to the deformities of the first and second branchial arches is extrapolated to 7 weeks in utero (Behrents et al. 1977).
   2. Detection of an appropriate kinase activity in branchial arches I and II that coincides with peak expression of the Treacher-Collins syndrome gene product, treacle (Jones et al. 1999)
   3. General cranioskeletal hypoplasia occurs due to generation of insufficient neural crest cells.

4. Insufficient neural crest cell number is a consequence of neuroepithelial progenitor cell death.
5. Tcof1/Treacle is an important spatiotemporal regulator of ribosome biogenesis.
6. Haploinsufficiency of Tcof1/Treacle results in deficient ribosome biogenesis, which is incapable of meeting the proliferative needs of the neuroepithelium.
7. Deficient ribosome biogenesis leads to nucleolar stress activation and stabilization of p53, which causes the high degree of neuroepithelial apoptosis and consequent loss of neural crest cells.
8. In an experimental animal-based strategy, genetic and/or chemical inhibition of p53-dependent apoptosis can restore the normal complement of neural crest cells and prevent the development of TCS craniofacial anomalies.

Clinical Features

1. Interfamilial and intrafamilial variability (van Gijn et al. 2013)
2. Facial characteristics (Cobb et al. 2014)
    1. Usually present bilaterally and symmetrically
    2. Parotid gland hypoplasia/aplasia
    3. Pseudo macrorhinia: apparent large beak-like nose because of lack of malar development and hypoplastic supraorbital ridges
    4. Sideburn hair on cheek (25%)
3. Eyes/eyelids
    1. Short and downslanting palpebral fissures
    2. Colobomata and hypoplasia of the lower lids and lateral canthi
    3. Lower lid eyelashes aplasia
    4. Partial absence of eyelid cilia
    5. Hypertelorism
    6. Euryblepharon (a congenital anomaly characterized by sagging of the lateral aspect of the lower eyelid away from the eye)
4. Ears (Posnick and Ruiz 2000)
    1. External ear anomalies
        1. Small/absent, rotated, and low-set pinnas
        2. External auditory canals bilateral stenosis/atresia
        3. Extra ear tags and/or fistulas
    2. External auditory canal abnormalities
        1. Symmetric (88%)
        2. Atretic (54%)
        3. Stenotic (31%)
        4. Normal (15%)
    3. Middle ear cavity ossicular deformities
        1. Symmetric (96%)
        2. Hypoplastic (85%)
        3. Hypoplasia/agenesis of malleus and incus
        4. Monopodal stapes
        5. Ankylosis of stapes
    4. Conductive hearing loss results from variable degrees of hypoplasia of the external auditory canals and ossicles of the middle ears (Marres 2002).
5. Nose/mouth
    1. Respiratory compromise in severely affected patients as a result of the following two factors (Posnick and Ruiz 2000):
        1. Presence of maxillary hypoplasia, which tends to constrict the nasal passages and results in a degree of choanal stenosis or atresia
        2. Presence of mandibular micrognathia and a retropositioned tongue obstructing the oropharyngeal and hypopharyngeal spaces
    2. Nasal deformity
    3. Macrostomia (15%)
    4. Cleft palate with or without cleft lip (33%)
    5. Velopharyngeal incompetence
    6. Difficulties with swallowing and feeding secondary to musculoskeletal underdevelopment and cleft palate
    7. High-arched palate
    8. Dental anomalies (60%)
        1. Tooth agenesis (33%)
        2. Enamel deformities (20%)

3. Malposition of maxillary first molars (13%)
4. Malocclusion

9. Hypoplastic and retropositioned tongue
10. Open bite

6. Facial bone malformations: the most characteristic findings
   1. Hypoplasia of the malar bones
      1. Often with clefting through the arches
      2. Limited formation of the residual zygomatic complex
   2. Orbits
      1. Hypoplastic lateral aspects of the orbits
      2. Dysplastic inferior-lateral orbits
   3. Maxilla and mandible
      1. Characteristically hypoplastic (malar hypoplasia)
      2. Variable effects on the temporomandibular joints and the muscles of mastication
      3. Anterior open bite malocclusion
      4. A steep (clockwise-rotated) occlusal plane
7. Airways
   1. Airway problems secondary to mandibular hypoplasia
   2. Pharyngeal hypoplasia
   3. Choanal atresia
   4. Tracheo-esophageal fistula
   5. Small or obstructed nasal passages
8. Neurological
   1. Normal intelligence
   2. Conductive hearing loss
   3. Vision loss associated with strabismus, refractive errors, and Anisometropia
   4. Impaired vision (underdeveloped lateral orbit and extraocular muscles)
9. Sleep apnea and sudden infant death syndrome
10. Fetal phenotype: Affected fetuses identified prenatally or at autopsy tend to have a more severe phenotype than living patients, with an increased frequency of Pierre Robin sequence (Konstantinidou et al. 2013).
11. Differential diagnosis (Dixon 1995)
    1. Nager acrofacial dysostosis (please see the chapter on ▶ "Nager Acrofacial Dysostosis")
       1. Features similar to those of TCS
          1. Zygomatic hypoplasia
          2. Downward slanting of the palpebral fissures
          3. Micrognathia
          4. Anomalies of the external ears
          5. Cleft palate
       2. Limb defects (not observed in TCS)
          1. Often asymmetrical
          2. Preaxial limb defects
          3. Hypoplastic or absent thumbs
          4. Radial hypoplasia or aplasia
          5. Radioulnar synostosis
    2. Miller acrofacial dysostosis
       1. Facial features similar to TCS and Nager syndrome
       2. Limb defects
          1. Postaxial limb defects
          2. Most commonly with absence or incomplete development of the fifth digital ray of all four limbs
    3. Oculoauriculovertebral (OAV) spectrum
       1. OAV spectrum
          1. Sporadic occurrence in vast majority of cases
          2. One to two percentage of cases with a previous family history
          3. Includes hemifacial microsomia and Goldenhar syndrome
       2. Hemifacial microsomia
          1. Primarily affecting development of the ear, mouth, and mandible
          2. Wide variable expression
          3. Affecting primarily only one side of the face
       3. Goldenhar syndrome (please see the chapter on ▶ "Goldenhar Syndrome")
          1. Facial involvement
          2. Vertebral anomalies
          3. Epibulbar dermoids

Diagnostic Investigations

1. Radiography and CT for evaluation of craniofacial abnormalities (Megalhães et al. 2007)
   1. Mandibular hypoplasia

2. Bilateral condylar hypoplasia
3. Coronoid process absence/hypoplasia
4. Maxillary bone hypoplasia
5. Malar bone hypoplasia
6. Narrowed frontal bone
7. Maxillary sinus walls hypertrophy
8. Auricular canals atresia
9. C1-C2 fusion
10. Temporal muscle hypotrophy
11. Masseter muscle hypotrophy
12. Lateral pterygoid hypotrophy
13. Decreased oropharyngeal space
14. Conchae hypertrophy

2. Audiological evaluation for hearing impairment
3. DNA diagnosis: Direct sequencing of the coding and flanking intronic regions of *TCOF1* detects mutations in about 90–95% of patients (Katsanis and Cutting 2012).

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: low unless a parent is affected in which case the risk to the sibs is 50% or has germline mosaicism
   2. Patient's offspring: 50%
2. Prenatal diagnosis available for pregnancies at increased risk for TCS
   1. Two-dimensional and preferably three-dimensional sonography (Meizner et al. 1991; Ochi et al. 1998; Hsu et al. 2002; Pereira et al. 2013)
      1. Polyhydramnios
      2. Demonstration of characteristic facies of TCS (Crane and Beaver 1986; Cohen et al. 1995)
         1. Slanting forehead
         2. Downward slanting palpebral fissures
         3. Microphthalmos
         4. Micrognathia
         5. Abnormal appearance of the nose with narrow nostrils
         6. Cleft lip/palate
         7. Low-set dysplastic ears (microtia)
         8. Abnormal fetal swallowing
   2. Prenatal diagnosis of Treacher-Collins syndrome in the first trimester using combined linkage analysis and ultrasound imaging (Edwards et al. 1996).
   3. Amniocentesis or CVS
      1. To detect *TCOF1* mutation (Ellis et al. 2002)
      2. The disease-causing allele of an affected individual must be identified before prenatal testing can be performed.
      3. The presence of a *TCOF1* mutation detected by prenatal diagnosis does not predict the specific malformations or severity of the disease.
   4. Prenatal diagnosis by fetoscopy in the second trimester of pregnancy (Nicolaides et al. 1984)
      1. Mandibular hypoplasia
      2. Abnormalities of the palpebra and auricles
      3. An associated cleft palate
   5. Preimplantation genetic diagnosis may be available for families in which the disease-causing mutation has been identified in an affected family member.
3. Management
   1. Multidisciplinary team (Thompson et al. 2009)
      1. Geneticist
      2. Neonatologist
      3. Pulmonologist
      4. Ophthalmologist
      5. Otolaryngologist
      6. Audiologist
      7. Speech pathologist
      8. Dentist/orthodontist
      9. Radiologist
      10. Psychologist/social worker
      11. Craniofacial surgeons
   2. Severe case
      1. Secure airway by tracheostomy if necessary
      2. A gastrostomy for feeding
   3. To promote normal language development
      1. Cleft palate repair
      2. Evaluation by an otolaryngologist, audiologist, and speech pathologist
   4. Orthodontic alignment of the teeth

5. Craniofacial reconstruction (Posnick 1997)
    1. Zygomatic and orbital reconstruction
    2. Maxillomandibular reconstruction
    3. Nasal reconstruction
    4. Soft tissue reconstruction
    5. External ear reconstruction
    6. External auditory canal and middle ear reconstruction
    7. The improvement in the patients' facial appearance seems to have a direct, positive influence, creating psychosocial and social benefits for them (Arndt et al. 1987)
6. Bimaxillary orthognathic surgery in the Treacher-Collins patients may be performed safely with long-term dental and skeletal stability (Nguyen et al. 2016)

Fig. 2 An infant and his mother with Treacher-Collins syndrome showing similar features. The infant is mildly affected

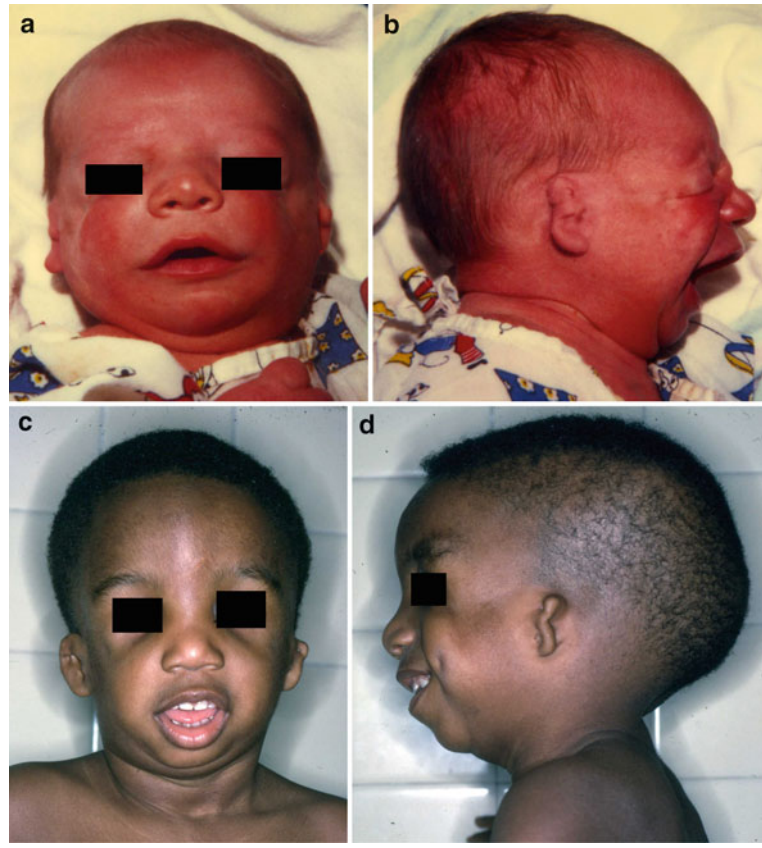

Fig. 3 (**a**–**d**) A newborn (**a**, **b**) and a child (**c**, **d**) with Treacher-Collins syndrome showing antimongoloid slant of the palpebral fissures, coloboma and hypoplasia of the lower lids, and microtia

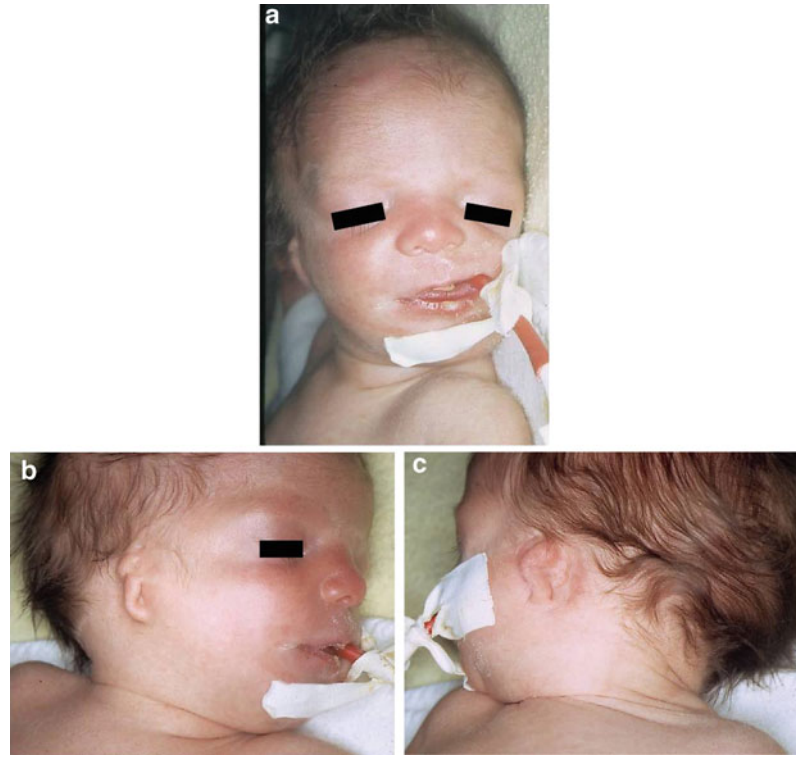

Fig. 4 (**a**–**c**) Another infant with typical Treacher-Collins syndrome

Trimethylaminuria

Contents

Trimethylaminuria, also called fish odor syndrome, is a metabolic disorder characterized by a distinctive decaying fish odor of sweat, urine, breath, and other body secretions due to the presence of abnormal amounts of the dietary-derived tertiary amine, trimethylamine (TMA).

Synonyms and Related Disorders

Fish-odor syndrome

Genetics/Basic Defects

1. Inheritance (Rehman 1999)
   1. Autosomal recessive (Ayesh et al. 1993)
   2. The incidence of heterozygous carriers of the allele for impaired *N*-oxidation is estimated to be of the order of 1%.
2. Basic defect
   1. Caused by deficiency of the flavin-containing mono-oxygenase isoform 3 (FMO3) (Akerman et al. 1999a, b). A defect in hepatic *N*-oxidation of dietary-derived TMA (trimethylamine) causes excess excretion of TMA, leading to affected individuals to have a body odor resembling rotten fish (Basarab 1999).
   2. Caused by loss-of-function mutations in the *FMO3* gene (mapped on 1q24.3) encoding an isoform of flavin-containing mono-oxygenase have been shown to underlie trimethylaminuria/fish odor syndrome (Lambert et al. 2001; Lunden et al. 2002).
   3. Defects in *FMO3* underlie fish-odor syndrome and that the Pro 153 → Leu 153 missense mutation described is a cause of this distressing condition (Dolphin et al. 1997).
   4. Common variants in the *FMO3* gene lead to greatly reduced enzyme activity in vivo, shown to cause mild to transient trimethylaminuria (Zschocke 1999).
   5. A report of a novel homozygous deletion of exons 1 and 2 in an Australian of Greek ancestry with trimethylaminuria, the first report of a deletion causative of trimethylaminuria (Forrest et al. 2001).
   6. Also can be caused by liver, kidney, and/or gastrointestinal dysfunction, including dietary carnitine overloading secondary to the gut-generated substrate overwhelming the hepatic enzymes' oxidizing capacity.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_231

7. Trimethylaminuria reflects how genetic constitution can adversely influence interactions with one's diet (Mitchell 2001).

3. TMA (Lunden et al. 2002)
   1. Trimethylaminuria (fish-odor syndrome) (Al-Waiz et al. 1987a, 1988)
      1. An inborn error of oxidative metabolism.
      2. Trimethylaminuria is an inborn error in the ability to *N*-oxidize TMA which is inherited as an autosomal recessive trait.
      3. Furthermore, an oral challenge dose with 600 mg of TMA may be used to identify carriers of the condition (Al-Waiz et al. 1989).
   2. Derived from the intestinal bacterial degradation of foods rich in choline and carnitine, such as egg yolk, liver, kidney, soybeans, peas, and saltwater fish
   3. Readily absorbed from the gut and is normally oxidized by the liver FMO3 to odorless trimethylamine *N*-oxide which is then excreted in the urine
   4. Impaired oxidation of TMA, thought to be the cause of the fish odor syndrome, is responsible for the smell of rotting fish.
4. FMO3
   1. One of the major enzyme systems protecting humans from the potentially toxic properties of drugs and chemicals.
   2. Converts nucleophilic heteroatom-containing chemicals and endogenous materials to polar metabolites, which facilitate their elimination.
   3. *N*-oxygenates trimethylamine to trimethylamine *N*-oxide which is excreted in a detoxication (Cashman 2000) and deoderation process.
   4. The *N*-oxidation of TMA in humans is polymorphic and under single gene diallelic control in which individuals who are homozygous for the variant allele exhibit marked *N*-oxidation deficiency and trimethylaminuria (Al-Waiz et al. 1987b).
   5. Prevalent polymorphisms of the human FMO3 may contribute to low penetrance and predispositions to diseases associated with adverse environmental exposures to heteroatom-containing chemicals, drugs (e.g., tricyclic antidepressants, ranitidine, amphetamine, methamphetamine, clozapine, chlorpromazine, methimazole), and endogenous amines.
5. Biological basis of primary trimethylaminuria (Christodoulou 2011)
   1. Dietary sources of choline, lecithin, and trimethylamine-*N*-oxide (TMAO) are converted to trimethylamine by anaerobic bacteria in the large intestine.
   2. Normally, any trimethylamine absorbed from the gut into the bloodstream is converted back to odorless TMAO by FMO3 in the liver.
   3. However, when this enzyme is defective, trimethylamine, which has the distinctive odor of "rotting fish," accumulates and is eliminated in sweat, urine, and breath.
6. Classification of the disorder (Mitchell 2001; Mitchell and Smith 2001; Cashman et al. 2003; Mackay et al. 2011)
   1. Primary genetic form (primary trimethylaminuria)
      1. The best understood of the various forms of the disorder
      2. Accounts for a large proportion of the known cases
      3. Human FMO3
         1. Highly polymorphic.
         2. Some mutations, either alone or in combination, are associated with dysfunctional enzyme activity and the metabolic disorder.
         3. Two relatively common polymorphisms (P153L and E305X) appear to account for the majority of severe cases of trimethylaminuria.
         4. Some other mutations are associated with inactivation of FMO3.
         5. Combinations of intragenic polymorphisms within FMO3 appear to determine a modified and less severe form of the condition.
         6. Some mutations appear to be benign.

2. Acquired form (secondary trimethylaminuria)
    1. Several cases of clinically and biochemically diagnosed trimethylaminuria have been reported to emerge in adult life.
    2. No previous history in childhood
    3. No familial background
    4. Possible mechanism: Viral hepatitis may have been responsible for precipitation of the condition possibly by insertion of viral DNA into the genome thereby affecting normal expression of the human *FMO3* gene.
    5. Transient childhood forms
        1. A transient or mild form of trimethylaminuria may occur during early childhood.
        2. Compound heterozygosity for several mutations has been detected by molecular analysis in some cases.
        3. As with her parents and one of her two brothers, the proband carried three polymorphisms: c.472 G > A p. E158K in exon 4, c.627 + 10 C > G (IVS5 + 10G > C) and c.485-21 G > A (IVS4-22G > A) in intronic regions. Despite the same genotypic condition only the girl had symptoms attributable to the trimethylaminuria (transient childhood form) (D'Angelo et al. 2014).
    6. Transient form associated with menstruation
        1. Fish odor intensifies with onset of menstruation.
        2. Trimethylaminuric condition deepens just prior to the onset of menstruation.
    7. Precursor overload
        1. Overload of precursors, such as choline, lecithin, and carnitine, saturates the existing levels of flavin monooxygenase.
        2. Exposure to unusually high levels of such precursors may hasten a fish odor syndrome, especially if the individual is a haplotype for certain mutations.
    8. Disease states that impair trimethylamine metabolism
        1. Advanced liver disease
        2. Advanced renal disease
        3. Association with temporal lobe epilepsy (Pellicciari et al. 2010) and behavioral disturbances
        4. Bacterial vaginosis with fish odor in vaginal secretions
    9. Exacerbating factors
        1. Pyrexic states
        2. Stress
        3. Puberty
        4. Sweating
        5. Exercise
        6. Emotional upsets
        7. Menstruation
        8. Oral contraceptives
        9. Foods rich in choline

Clinical Features

1. Present from birth but manifests itself with the introduction of a diet, including foods that contain high amounts of choline or trimethylamine *N*-oxide (Chalmers et al. 2006)
2. Unmistakable, strong fishy body odor from excess unmetabolized trimethylamine in the urine, sweat, and other body secretions (breath, saliva, vaginal secretions)
3. An early report of trimethylaminuria or fish odor syndrome in a child (Marks et al. 1976)
4. Seven percent of a group of subjects complaining of unpleasant body odor had the fish odor syndrome (Ayesh et al. 1993).
5. Skin sores induced by choline-rich foods
6. A case reported of trimethylaminuria that first developed in adulthood (Ruocco et al. 1989): a characteristic fish odor of his sweat, urine, and to his breath after the consumption of choline-rich foods. Elevated levels of trimethylamine were present in the urine after dietary tests and identified by means of gas chromatography.
7. Serious social/behavioral problems resulting from strong body odor (Mitchell 2001; Cashman et al. 2003)
    1. Subject to ridicule, loss of confidence, and school disruption

2. Destructive to personal, working, and career lives of the affected individuals
3. Clinical depression
4. Attempted suicide

8. Highly variable severity of the syndrome

Diagnostic Investigations

1. Use of choline loading as an aid to diagnosis of trimethylaminuria (Marks et al. 1977)
2. Demonstration of elevated TMA after a choline-rich diet by gas chromatography–mass spectrometry measurement. TMA challenge test (with a 600 mg TMA oral challenge dose and analysis of 0–8 h urine samples) is useful in confirming unequivocally the trimethylaminuric patients as well as indicating the status of the parents as carriers.
3. Quantitative determination of trimethylamine in urine by solid-phase microextraction and gas chromatography–mass spectrometry (Mills 1999)
4. Mass spectroscopy and proton nuclear magnetic resonance (NMR) spectroscopy (Murphy 2000)
    1. Have the advantage of being able to detect TMA and TMA *N*-oxide simultaneously with great sensitivity
    2. NMR has further advantage of requiring no prior extraction or separation of metabolites and thus measurement can be done directly on urine samples.
    3. Urinary TMA concentrations were reduced to virtually nil as measured by mass spectrometry after the elimination of the major choline sources (fish and eggs) from the diet (Hollinger and Sheikholislam 1991).
5. Increase in urinary excretion of trimethylamine with decreased trimethylamine oxide
6. Molecular genetic testing used in primary trimethylaminuria (Phillips and Shephard 2015)
    1. Sequence analysis of *FMO3* gene to detect mutations (~99%)
    2. Gene-targeted deletion/duplication analysis
7. Combination of the proton nuclear magnetic resonance (NMR) spectroscopy to assess activity of the mutant enzyme with gene sequence and expression technology provides a powerful means of determining genotype-phenotype relationships in trimethylaminuria (Murphy 2000).

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: 25%
    2. Patient's offspring: not increased unless the spouse is a carrier
2. Prenatal diagnosis: possible by demonstrating the previously characterized mutation in the fetal DNA obtained by amniocentesis or CVS
3. Preimplantation genetic diagnosis may be available for families in which the disease-causing mutations have been identified. (Phillips and Shephard 2015).
4. Management (Rehman 1999; Mitchell 2001; Chalmers et al. 2006)
    1. Restriction of dietary sources of trimethylamine: the main therapeutic approach (Chen and Aiello 1993; Phillips and Shephard 2015)
        1. Restriction of trimethylamine (milk obtained from wheat-fed cows)
        2. Restriction of its precursors including choline-rich food
            1. Egg yolk
            2. Liver
            3. Kidney
            4. Peas
            5. Beans
            6. Peanuts
            7. Soya products
            8. Brassicas (include cabbage, broccoli, and turnip)
            9. Legumes
            10. Fish
        3. Trimethylamine *N*-oxide (TMAO) source
            1. Some saltwater fish (cod, skate)
            2. Cephalopods (include cuttlefish, squid, and octopus)

3. Crustaceans (include crabs, lobsters, and shrimps)
4. Dietary restriction appears to be successful in the management of the majority of patients.
5. Appears to be most effective in mild to moderate forms of fish odor syndrome arising from particular mutations or haplotypes

2. Suitable diet include:
   1. Dark green leafy vegetables
   2. Fortified bread and cereals
   3. Orange juice
3. Freshwater fish may be eaten freely.
4. Avoid exacerbation factors such as pyrexia, stress, exercise, or any other cause of increased perspiration (Messenger et al. 2013)
5. Vitamin supplementation with riboflavin, a precursor of the FAD cofactor for flavin monooxygenase function, in an attempt to maximize any residual activity
6. Drug treatment: Occasionally a short course of metronidazole, neomycin, and lactulose may suppress production of TMA by reducing the activity of gut microflora in some patients (Fraser-Andrews et al. 2003).
7. Copper-chlorophyllin tablets to moderate gut flora activity and complex TMA
8. Use of "malodor suppressants" in hygiene products and soaps and body lotions with a low pH (3.5–6.5) to disguise the offensive smell of trimethylamine
9. If clinical improvement is not accomplished through diet alone, metronidazole may be used to decrease microbial gut flora and reduce TMA production (Treacy et al. 1995; Ferrari and Nield 2006; Mackay et al. 2011). Neomycin, activated charcoal, and lactulose have been used in the past but frequently cause diarrhea. To prevent treatment failure related to drug resistance, the administration of metronidazole for 1- to 2-week intervals interspersed with drug-free periods is advised (Treacy et al. 1995; Ulman et al. 2014).
10. Counseling of the social/behavioral problems
11. Gene therapy and enzyme induction with drugs provide hope for the future.

Fig. 1 (**a**–**d**) A 12-year-old girl (**a**, **b**) with trimethylaminuria showing multiple sores on the hands (**c**) and legs (**d**). At age 4, she developed unpleasant fish odor and constant scratching of her skin. Trimethylaminuria was diagnosed based on markedly increased urinary TMA by gas chromatography after loading with choline. The patient started with a baseline level of 0.28 mg TMA/mg creatine that is four times of control. After 8, 16, and 24 h of loading with choline, the values went up to 2.8 mg (41×), 3.99 mg (57×), and 9.93 mg (95×), respectively. In addition, the diagnosis of Prader-Willi syndrome was made at age 9 because of relative obesity, hypotonia, delayed psychomotor development, almond-shaped eyes, small hands and feet, and presence of chromosome abnormality of del(15)(q11q13)

Triploidy

Contents

Triploidy is defined as the presence of three sets of haploid (69) chromosomes. Triploid fetuses occur in about 1% of recognized pregnancies, 1 in 100,000 liveborns, and constitute about 15% of all fetuses with chromosome abnormalities. There is a slight excess of males (M1.5: F1). Most triploid fetuses often result in spontaneous abortions between 7 and 17 weeks of gestation. However, rare instances of a live triploid infant have been reported (Allen and Pritchard 2000).

Synonyms and Related Disorders

Diandric triploidy; Digynic triploidy; Diploidy/triploidy mosaicism; Partial hydatidiform mole of the placenta; Triploid fetus (69,XXY, 69, XXX, diploid/triploid mosaicism)

Genetics/Basic Defects

1. Origin of triploidy (Allen and Pritchard 2000; Baumer et al. 2000; Benn et al. 2001; Daniel et al. 2001)
    1. Diandric origin of the triploid fetuses (type I)
        1. Mechanisms of paternal origin of the supernumerary haploid set (Egozcue et al. 2002)
            1. Dispermy: fertilization of a haploid egg by two haploid sperms (dispermy) accounting for 66% (most common mechanism leading to triploidy)
            2. Faulty meiotic division in the male: fertilization of a normal ovum by a diploid sperm (diandry) (about 24%)
        2. Characteristics of diandric fetuses
            1. Relatively normal fetal growth
            2. Slight macrocephaly
            3. Marked syncytiotrophoblastic hyperplasia
            4. Hydatidiform changes of the placental villi (partial mole) (large cystic placenta)
    2. Digynic origin of triploid fetuses (type II)
        1. Mechanisms of maternal origin of the supernumerary haploid set

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_232

1. Mitotic errors in female germ cell precursors: fertilization of a diploid ovum by a normal sperm (digyny) (about 10%)
2. Errors in maternal meiosis: an error at meiosis I or II or incorporation of the second polar body postulated

2. Characteristics of digynic fetuses
   1. Generally marked fetal (asymmetric) growth retardation
   2. Relative macrocephaly
   3. Small, noncystic placenta
   4. Maternally derived triploidy was often found in those fetuses that survived until late pregnancy.
   5. The extra set was maternal in origin in all cases, supporting previous research indicating longer in utero survival of maternally derived triploid fetuses. These findings provide evidence for an instance of genomic imprinting in humans (Dietzsch et al. 1995).

2. Diploidy/triploidy mosaicism
   1. Mechanisms (Phelan et al. 2001)
      1. Postzygotic maldivision of a triploid or diploid zygote
      2. Incorporation of the second polar body into a daughter nucleus of the developing embryo: Second polar body incorporation into a blastomere results in 46, XX/69, XXX mixoploidy (Muller et al. 1993).
      3. Fertilization of a diploid ovum with incorporation of the second diploid polar body
      4. Fertilization of the first polar body and ovum by individual spermatozoa with suppression of one second polar body
      5. Dispermy or diploid sperm fertilization with incorporation of an independently fertilized second polar body
      6. Chimera formation by union of diploid and triploid embryos
      7. Vanishing twin and chimerism
   2. Characteristics of diploid/triploid fetuses: rarer and less severe phenotype than true triploidy
3. Triploidy and in vitro fertilization (IVF)/intracytoplasmic sperm injection (ICSI) (Dayal et al. 2009)
   1. Diandric triploidy is observed with spontaneous as well as conventional IVF and is assumed to be the most common form of triploidy (Jun et al. 2006).
   2. Intracytoplasmic sperm injection, by its virtue of injecting a single sperm into a single oocyte, negates the potential for dispermic triploidy.
   3. Digynic triploidy occurs secondary to failed meiosis II expulsion of the second polar body and subsequent fertilization of a diploid oocyte. Cytogenetic evidence of three pronuclei post-ICSI zygotes that result from failed extrusion of the second polar body (Tsuchiya et al. 2002).
   4. Mechanistically, this may occur with a damaged metaphase plate or oocyte cytoskeleton (Kimura and Yanagimachi 1995), after abnormal spindle formation or increased female age (Spandorfer et al. 1998; Tsuchiya et al. 2002). The latter etiologies may represent an occult oocyte factor.
4. Two different forms of hydatidiform mole (Lawler et al. 1982a, b; Devriendt 2005)
   1. Complete hydatidiform mole
      1. A complete hydatidiform mole is diploid, i.e., the presence of 46 chromosomes, but all chromosomes are of paternal origin.
      2. The complete moles (Szulman and Surti 1978)
         1. Undergo early and total hydatidiform change from edema to central cistern formation, the embryos proper having perished before the establishment of a functioning circulation.
         2. Trophoblastic hyperplasia is conspicuous and the connection of this group to chorioncarcinoma is well established.
      3. As always in the case of the uniparental origin of one or more

chromosomes, this requires at least two sequential errors.
    1. The most frequent mechanism of origin is the fertilization of an oocyte without nucleus (or with inactivated nucleus) by a single sperm, followed by duplication of the haploid genome (Lawler et al. 1982b).
    2. In the remainder (20–25%), an enucleated oocyte is fertilized by two sperm cells (Kovacs et al. 1991).
    3. A third possible cause, the fertilization of an empty oocyte by a diploid sperm cell, is extremely rare (Zaragoza et al. 2000).
  4. As expected also in the hydatidiform mole, all mitochondria have an exclusively maternal origin (Azuma et al. 1991).
  5. Biparental complete hydatidiform mole: In exceptional cases (~10 families have been reported) of histologically typical complete hydatidiform mole, a biparental origin of the chromosomes has been found (reviewed by Fisher et al. 2004).
2. Partial hydatidiform mole
    1. In the partial moles there is a slow hydatidiform change that affects only some of the villi, but which seems to follow along the same lines as in complete moles (Szulman and Surti 1978).
        1. There is focal moderate trophoblastic hyperplasia, villous "trophoblastic inclusions" (that appear in triploids only), and maze-like central cisterns in the later cases.
        2. The partial mole, 46 XX, partakes of morphologic characteristics of both main syndromes and may represent an unusual syndrome of its own.
    2. The partial mole is caused by a triploidy, the presence of three copies of each chromosome.
    3. Triploidy is one of the most common chromosomal anomalies, with an incidence of 10% in spontaneous abortions (Hassold et al. 1980).
    4. The extra haploid set of chromosomes can have either a maternal origin (and then called digynic triploidy) or paternal (diandric triploidy).
    5. The majority of triploidies are sporadic, but a few cases have been reported with recurrent triploidy in three pregnancies (Pergament et al. 2000; Brancati et al. 2003; Huang et al. 2004). In all three cases, the origin of the triploidy could be investigated at least in one pregnancy and all were of maternal origin (digynic). This observation could be explained by a genetic defect in the maternal meiosis.
    6. In digynic triploidy, no partial mole is observed. All paternally derived triploids (diandric) in which a pathologic diagnosis could be made were partial moles, whereas only three of 15 maternally derived triploids (digynic) on which a diagnosis could be made were molar (Jacobs et al. 1982).
    7. Using polymorphic pericentromeric markers, it was shown that the majority of digynic triploidy is the result of errors in the second meiotic division. Digyny accounted for the majority of triploids, even in the embryonic and fetal periods (McFadden and Langlois 2000).
    8. A predominance of maternal origin of the extra haploid set in triploidies diagnosed prenatally, mainly due to longer survival time for digynic triploidies (Miny et al. 1995).
    9. More than 90% of partial moles are secondary to diandric triploidy, and this condition accounts for most cases of persistent trophoblastic disease after partial mole (Jauniaux 1999).
    10. So far, no proven cases of familial recurrent triploidy have been reported.
    11. The majority of triploid fetuses ascertained through a spontaneous abortion are diandric.

Clinical Features

1. The clinical syndrome associated with triploidy (Wertelecki et al. 1976)
    1. Quite typical but is rarely reported in near-term stillborns and newborns
    2. The occurrence of a large placenta with areas of hydatidiform changes in combination with an edematous fetus with macroglossia, facial clefts, eye defects, dysplastic cranial bones, omphalocele, meningomyelocele, syndactyly, and, in males, genital maldevelopment is suggestive of a triploid chromosomal constitution.
2. Prenatal history
    1. IUGR
        1. Asymmetrical (digynic)
        2. Symmetrical (diandric)
    2. Prematurity
    3. Hydrops
    4. Polyhydramnios
    5. Oligohydramnios
    6. Partial hydatidiform mole (placenta)
3. Craniofacial features
    1. Dysplastic calvarium
    2. Microcephaly
    3. Large posterior fontanelle
    4. Ocular hypertelorism or hypotelorism
    5. Epicanthal folds
    6. Exomphalos
    7. Microphthalmia
    8. Iris and choroid colobomas
    9. Midfacial hypoplasia
    10. Arhinia
    11. Small upturned nose
    12. Choanal atresia
    13. Single nostril (in holoprosencephaly)
    14. Micrognathia
    15. Cleft lip/palate
    16. Low-set ears
    17. Short neck
    18. Thick nuchal fold
    19. Cystic hygroma
4. CNS
    1. Hypotonia
    2. Arnold-Chiari malformation
    3. Posterior fossa cyst (Dandy-Walker malformation)
    4. Holoprosencephaly
    5. Hydranencephaly
    6. Hydrocephalus (20%)
    7. Absent corpus callosum (15%)
    8. Absent gyri of the brain
    9. Hypoplastic cerebellum
    10. Absent first cranial nerve
    11. Encephalocele
    12. Lumbosacral meningomyelocele (20%)
5. Gastrointestinal malformations
    1. Omphalocele
    2. Ventral wall defects
    3. Incomplete rotation of colon
    4. Agenesis of gallbladder
    5. Meckel diverticulum
    6. Duodenal atresia
    7. Malfixation of cecum
    8. Inguinal hernia
6. Endocrine abnormalities
    1. Adrenal hypoplasia (Kalousek 1984)
    2. Thyroid hypoplasia
    3. Lingual thyroid
    4. Thymic hypoplasia
    5. Leydig cell hyperplasia
    6. Gonadal dysgenesis
7. Genitourinary abnormalities
    1. 69,XXY triploid fetus
        1. Varying degree of ambiguous genitalia (40%)
        2. Hypospadias (40%)
        3. Cryptorchidism (85%)
        4. Micropenis (75%)
        5. Scrotal abnormalities (60%) including bifidity, scrotal hypoplasia, or agenesis
        6. Leydig cell hyperplasia (20%)
        7. Sex reversal (an example of true hermaphroditism associated with multiple malformations): bilateral ovotestes but no evidence of Müllerian derivatives (Petit et al. 1992)
    2. 69,XXX triploid fetus
        1. Gonadal dysgenesis
        2. Renal abnormalities
            1. Multicystic kidneys

2. Hydronephrosis
3. Glomerulosclerosis

8. Gastrointestinal abnormalities
   1. Omphalocele
   2. Diaphragmatic hernia
   3. Gastroschisis
   4. Malrotation
   5. Gallbladder hypoplasia
   6. Pancreas hypoplasia
9. Cardiovascular anomalies
   1. VSD
   2. ASD
   3. PDA
   4. PA
   5. Tetralogy of Fallot
   6. Truncus arteriosus
   7. Aberrant right subclavian artery
   8. Cardiomegaly
10. Respiratory tract abnormalities
    1. Small chest
    2. Pulmonary hypoplasia
    3. Absent lung lobation
    4. Congenital cystic adenomatoid malformation of the lung
11. Axial skeleton of triploidy fetuses: The most remarkable findings in the axial skeleton of triploid fetuses are vertebral fusions in six of 15 cases (Kjaer et al. 1997).
12. Triploidy syndrome encompasses features found in trisomies 13, 18, and 21 (Saadi et al. 1976).
13. Phenotype of triploidy embryos (Harris et al. 1981)
    1. Retarded limb development
    2. Facial dysplasia
    3. Subectodermal hemorrhage
    4. Cystic chorionic villi
14. Prognosis (intrauterine and postnatal survival) (Baumer et al. 2000)
    1. Majority die early in gestation.
    2. Very few surviving into the third trimester
    3. The fetuses rarely survive to delivery.
       1. Profoundly malformed
       2. Growth-restricted
       3. Survival measured in hours to days
       4. Unusually long survival (2 months) in a case of full triploidy of maternal origin (Fryns et al. 1977)
       5. A report of digynic triploid infant surviving for 46 days (Hasegawa et al. 1999)
    4. Fetuses with extra maternal haploid set of chromosomes appear to survive longer in utero than those with extra paternal haploid set of chromosomes (Allen and Pritchard 2000).
    5. Some cases of diploid/triploid mixoploidy survive after the neonatal period, which is exceptional: a report of triploid-diploid mosaicism in a deeply mentally retarded adult (Fryns et al. 1980)
15. Diploid/triploid mosaicism (Carakushansky et al. 1994; Van De Laar et al. 2002)
    1. A well-known, clinically recognizable syndrome (Tharapel et al. 1983)
    2. Common features
       1. Mental retardation
       2. Growth retardation
       3. Body and/or facial asymmetry
       4. Hypotonia
       5. Truncal obesity
       6. Prominent forehead
       7. Depressed nasal bridge
       8. Micrognathia
       9. Malformed low-set ears
       10. Syndactyly
       11. Clinodactyly
       12. Transverse palmar creases
       13. A small phallus
       14. Cryptorchidism
       15. Precocious puberty
    3. Additional features
       1. Sandal gap
       2. Short halluces
       3. Seizures
       4. Respiratory distress
       5. Microstomia
       6. Irregular skin
       7. Feeding difficulties
       8. Muscular atrophy of the limbs
    4. Rarer and less severe than true triploidy in which infants can survive beyond neonatal period till over 20 years
    5. Presence of a normal diploid cell line and a second triploid cell line in varying degrees and with varying tissue distribution

Diagnostic Investigations

1. Karyotype of fetus and newborn (Niebuhr 1974; Blackburn et al. 1982)
    1. 69,XXX (one third of cases)
    2. 69,XXY (two thirds of cases)
    3. 68,XX (extremely rare) (Kaffe et al. 1989; Merlob et al. 1991)
    4. 45,X/68,XX mixoploidy: A chromosomal microarray demonstrated monosomy X, but her atypical phenotype prompted further evaluation with a chromosome analysis (Posey et al. 2016).
    5. Evidence of a second gamete fusion after the first cleavage of the zygote in a 47,XX, +18/70,XXX,+18 mosaic. A remarkable diploid-triploid discrepancy after CVS (Tuerlings et al. 1993)
        1. A 70,XXX,+18 karyotype was found by chorionic villus sampling, while the fetal fibroblast culture of the affected fetus revealed a 47,XX,+18 karyotype.
        2. From several possible mechanisms, it was assumed that a second gamete fusion occurred after the first cell division of the zygote. According to this interpretation, the mosaicism arose in very early pregnancy (at the two-cell stage). This discrepancy can therefore be explained by selection pressure, due to the differentiation processes in the embryonic tissues.
    6. Diploid/triploid mosaicism
        1. Less severe phenotype
        2. More compatible with life
        3. Harder to diagnose clinically
        4. Peripheral lymphocyte cultures showing a normal karyotype only
        5. Need fibroblast culture to show the cell line with triploid complement
    7. The finding that certain chromosome regions demonstrate a variable fluorescence pattern which can be used as markers offers a possibility to study the origin of several chromosome abnormalities and especially triploidy (Jonasson et al. 1972)
    8. Specific terminal DNA replication sequence of X chromosomes in different tissues of a live-born triploid infant (Yu et al. 1983)
    9. Molecular determination of the origin of the extra haploid set of chromosomes
        1. Fluorescent polymerase chain reaction (F-PCR) analysis of short tandem repeats (STRs) located on chromosomes such as 21, 18, and 13 (Bán et al. 2002)
        2. Assessment of numerous polymorphic DNA markers
2. Radiographic findings in live-born triploidy (Silverthorn et al. 1989)
    1. Poor ossification of calvarium
    2. Small anterior fontanelle
    3. Craniolacunae
    4. Chondrodysplasia punctata-like calcification
    5. Vertebral fusions
    6. Harlequin orbits
    7. Gracile ribs
    8. Upswept clavicles
    9. Diaphyseal overtubulation of long bones
    10. Vertical ilia
    11. Proximal radioulnar synostosis
    12. Asymmetry of occipitoparietal calvaria (50%)
    13. Less specific findings showing many similarities to those found in trisomy 18
3. CT and MRI of the brain
    1. Cortical hypoplasia
    2. Agenesis of corpus callosum (15%)
    3. Hypoplasia of basal ganglia/occipital lobe
    4. Dandy-Walker anomaly
    5. Arnold-Chiari malformation
4. Histopathology of the placenta
    1. Partial hydatidiform mole change of villi on gross and microscopic examination.
    2. The partial mole is caused by a triploidy (Devriendt 2005).
    3. The villi with molar change show hydropic swelling of the stroma, and trophoblastic proliferation (hyperplasia) is also present in scattered areas.
    4. Irregular cystic cavitation may be seen in larger hydropic villi.

5. Partial hydatidiform mole occurs in a minority of triploid conceptuses (MacFadden and Pantzar 1996).

5. Histology of bone and cartilage in the axial skeleton of human triploidy fetuses (Nolting et al. 2002)
    1. The radiographic characteristics of the vertebral corpora observed in frontal and lateral projection varied from small cleft vertebral corpora to fusions between the individual corpora.
    2. Histological examination of the vertebral corpora confirmed the abnormal pattern of ossification seen radiographically.
    3. As a new finding, abnormal metachromasia of the ground substance was observed in the cartilage.
6. A retrospective pathologic review of nearly 100 spontaneous abortions of cytogenetically verified triploid constitution (Szulman et al. 1981)
    1. A majority (86%) falling within the category of partial hydatidiform mole, the chief criteria being:
        1. Focal syncytiotrophoblastic hyperplasia
        2. Focal villous edema leading to cistern formation
        3. Scalloped outline of villi
        4. Frequent "trophoblastic inclusion" formation
    2. The minority (14%) of the conceptuses were nonmolar with a normal or hypoplastic trophoblast.
    3. The triploid fetuses in both groups tended to die at about 8 weeks' menstrual age. Intrauterine retention was generally prolonged in the partial moles, whereas nonmolar conceptuses tended to abort within the first trimester, often with live or recently dead fetuses.

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: The true recurrence risk for cytogenetic abnormalities in subsequent offspring is uncertain but may be slightly increased and higher than expected (Graham et al. 1989).
    2. Patient's offspring: a lethal condition not surviving to reproduce
2. Prenatal diagnosis
    1. First-trimester markers screening (De Graaf et al. 1999)
        1. Low serum marker pregnancy-associated plasma protein A (PAPP-A)
        2. Low serum marker free β-chain of chorionic gonadotrophin (free β-hCG)
    2. Second trimester maternal serum screening (Benn et al. 2001)
        1. High maternal serum hCG associated with triploidy
            1. Nearly always indicating placenta with partial mole (93%)
            2. A high frequency of open neural tube defects or ventral wall defects (29%)
            3. With either XXX or XXY karyotype
        2. Low hCG associated with triploidy
            1. Infrequently associated with a molar placenta (9%)
            2. Not appear to be associated with open neural tube defects or ventral wall defects
            3. An excess of XXX over XXY karyotypes
        3. Highly abnormal maternal inhibin and beta-human chorionic gonadotropin levels along with severe HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome at 17 weeks' gestation with triploidy (Craig et al. 2000)
        4. Large placentas with molar changes (diandry) generally associated with increased maternal serum AFP (MSAFP) and high hCG levels
        5. Elevated MSAFP appeared to be related to the presence of a partial mole (Pircon et al. 1989)
        6. Those with digyny and small monocystic placentas generally associated with normal MSAFP and low hCG

3. Screening for triploidy by fetal nuchal translucency and maternal serum free beta-hCG and PAPP-A at 10–14 weeks of gestation (Spencer et al. 2000)
    1. The median multiple of the median (MoM) fetal nuchal translucency (NT) thickness was significantly increased (1.89 MoM).
    2. The maternal serum total and free beta-human chorionic gonadotrophin (hCG) were increased (3.13 MoM and 4.59 MoM, respectively).
    3. The alpha fetoprotein (AFP) was increased (2.14 MoM).
    4. The pregnancy-associated plasma protein A (PAPP-A) was decreased (0.12 MoM).
4. Placental insufficiency as a possible cause of low maternal serum human chorionic gonadotropin and low maternal serum unconjugated estriol levels in triploidy (Fejgin et al. 1992)
5. Pregnancies complicated by triploidy (Rijhsinghani et al. 1997)
    1. The risk of developing preeclampsia or hypertension in the second trimester was 35%.
    2. It appears that elevated serum hCG levels and placentomegaly are associated with a higher risk of preeclampsia but low hCG levels are not.
6. Isolation of nucleated red blood cells from the maternal peripheral circulation at the first trimester (12 weeks gestation): FISH analysis using X and Y and other chromosome-specific probes (De Graaf et al. 1999)
7. Amniocentesis/CVS
    1. Triploidy
    2. Diploidy/triploidy mosaicism
    3. Mixoploidy for trisomy 13 and triploidy detected by amniocentesis at 18 weeks of gestation (Phelan et al. 2001)
        1. Mixoploidy for trisomy 13 and triploidy was confirmed postnatally in blood, skin, and placenta.
        2. Examination of chromosome heteromorphisms and DNA markers suggested the presence of two maternal contributions in the triploid cell line. In addition, the extra chromosome 13 in the trisomic cell line was derived from the mother.
8. Ultrasonography of structural anomalies compatible with triploidy (Mittal et al. 1998; Fernández-Moya et al. 2000; Chen et al. 2013; Zalel et al. 2016)
    1. Severe, early onset asymmetrical growth restriction in the late first and early second trimester (the head size remains almost normal whereas the remainder of the fetal body and skeleton is severely growth-restricted)
    2. Oligohydramnios, asymmetric growth restriction, and a small placenta when the third set of chromosomes is maternal
    3. Large, hydropic-appearing placenta consistent with partial moles (60–80%) when the third set of chromosomes is paternal
    4. Most common sonographic abnormalities (Jauniaux et al. 1996)
        1. Large thickened placenta containing multiple sonolucent areas
        2. Characteristic sharply defined, large and small cystic spaces within the placenta
        3. Hydrops
        4. Ventriculomegaly
        5. Dandy-Walker malformation
        6. Holoprosencephaly
        7. Agenesis of the corpus callosum
        8. Micrognathia
        9. Heart anomalies
        10. Echogenic bowel
        11. Omphalocele
        12. Absent gallbladder
        13. Renal malformations
        14. Thickened nuchal folds
        15. Neural tube defects
        16. Club feet
        17. Syndactyly of the third and fourth fingers
        18. Clenched hands

9. The phenotype described from 54 fetuses by prenatal imaging and autopsy findings (Toufaily et al. 2016)
    1. The presence of major malformations and growth restriction during pregnancy makes triploidy a potential diagnosis.
    2. There are no obligate clinical features in triploidy.
    3. Syndactyly, especially 3–4 syndactyly of the hands, is a distinctive feature.
    4. Cystic changes in the placenta can be seen by ultrasound during pregnancy.
    5. There was no difference in the phenotype between triploid infants associated with partial moles and those with nonmolar placentas.
10. The combination of ultrasonographic examination of the fetoplacental features and measurement of the maternal serum level of human chorionic gonadotropin enables the diagnosis of most cases of triploidy at 10–14 weeks' gestation (Jauniaux et al. 1997).
11. Preimplantation genetic diagnosis in conjunction with in vitro fertilization by a single sperm injection: a viable approach when there are clinical or genetic indications of repeated dispermy, unreduced (diploid) spermatozoa, or unreduced (diploid) oocytes (Pergament et al. 2000)

3. Management
    1. No treatment available for true triploidy, a lethal condition.
    2. Supportive therapy for diploid/triploid mosaicism who may survive beyond neonatal period.

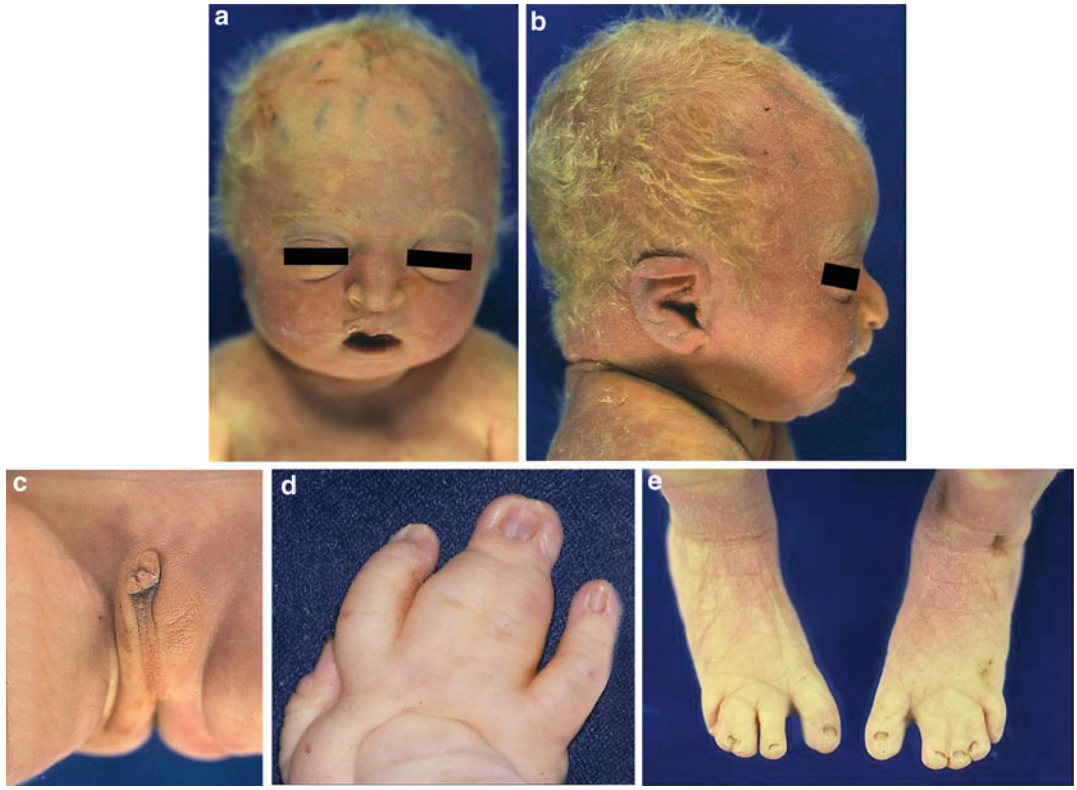

Fig. 1 (**a**–**e**) A newborn (**a**, **b**) with triploidy (69,XXY) showing woolly hair, distinctive facial appearance (epicanthal folds, microphthalmia, beaked nose, small mouth, receding jaw, low-set and malformed ears), partial syndactyly between third-fourth fingers (**d**) and toes (**e**), and ambiguous genitalia (**c**). The infant also had bilateral coloboma and cataracts, short neck, loud continuous heart murmur along the *left* sternal border, and bilateral transverse palmar creases. The infant died at 25 h

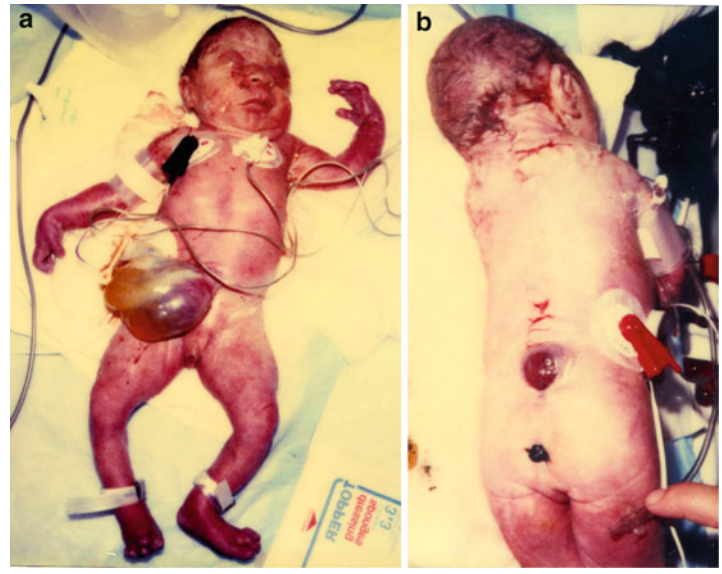

Fig. 2 (**a**, **b**) An infant with triploidy showing abnormal craniofacial features, omphalocele, thick nuchal fold, and lumbosacral meningomyelocele

Fig. 3 (**a**–**c**) An infant (**a**, **b**) with triploidy (69,XXX) showing low-set/ malformed ears, syndactyly of two-three-four fingers (**c**), spina bifida, and pulmonary hypoplasia at autopsy. The infant also had a large ventricular septal defect

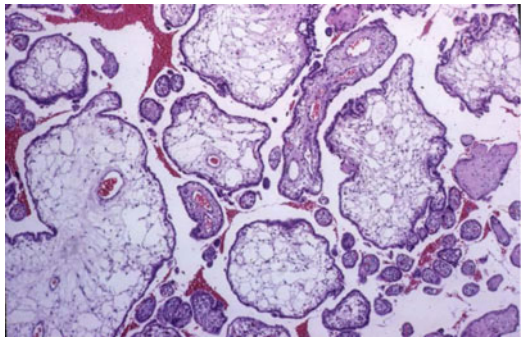

Fig. 4 Partial mole of triploidy placenta. Many villi are enlarged, hydropic, and hypovascular. Prominent infolding and nests of trophoblastic cells in the villous stroma are seen in other areas

Fig. 5 A G-banded karyotype showing 69,XXX

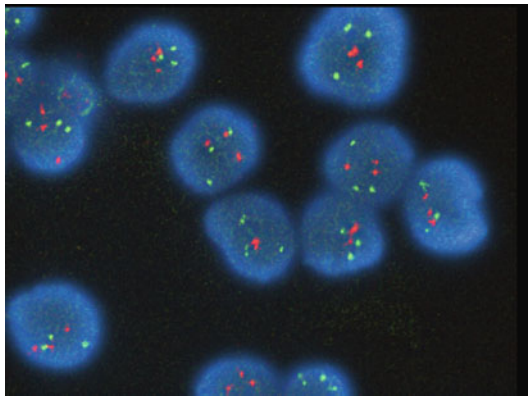

Fig. 6 Triploidy for all chromosomes shown by multicolor FISH on interphase cells. Three copies of chromosome 13 (*green*) and chromosome 21 (*orange*) are shown here

Trismus-Pseudocamptodactyly Syndrome

Contents

The trismus-pseudocamptodactyly syndrome, a relatively rare hereditary disorder, is characterized by inability to open the mouth fully, pseudocamptodactyly, mild foot deformities, and mild short stature. This malformation syndrome was first reported by Hecht and Beals and Wilson et al. in 1969 (Hecht and Beals 1969; Wilson et al. 1969). The term Dutch-Kentucky syndrome was coined for trismus pseudocamptodactyly by Mabry et al. (1974), because the earliest affected member was a young Dutch girl who emigrated to the Southern United States soon after the American Revolution.

Synonyms and Related Disorders

Autosomal dominant distal arthrogryposis type 7 (trismus-pseudocamptodactyly syndrome); Dutch-Kentucky syndrome; Hecht syndrome; Hecht-Beals syndrome

Genetics/Basic Defects

1. Inheritance
    1. Autosomal dominant: multiple affected individuals from a family (O'Brien et al. 1984)
    2. High penetrance
    3. Variable expression (Ter Haar and Van Hoof 1974; Robertson et al. 1982; Tsukahara et al. 1985)
2. Caused by a single mutation, p.R674Q, in *MYH8* (myosin heavy chain 8) gene (Toydemir et al. 2006a; Minzer-Conzetti et al. 2008)
3. Genetic basis of disease in a family with autosomal dominant core-rod myopathy and in three families with autosomal dominant distal arthrogryposis type 7 (trismus-pseudocamptodactyly syndrome) (Mabry et al. 1974; Davidson et al. 2013)
    1. Surprisingly, affected individuals in all four families share a unique three base pair deletion (c.20_22del) in TPM2 (β-tropomyosin).
    2. This dominant mutation results in deletion of a highly conserved amino acid (p.K7del).
    3. The molecular consequences of this mutation were explored using simulated modeling and by expression studies in the zebrafish, in which the mutation appears to disrupt intermolecular interactions and alter mutant TPM2 distribution.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_233

4. The findings expand the clinical, pathological, and pathomechanistic spectrum of TPM2-related disorders.

4. Pathogenesis
    1. Possible mechanisms of trismus
        1. The shortened lengths of certain mastication muscles presumed to be responsible for the clinical manifestations
            1. Temporalis muscle
            2. Internal pterygoid muscle
            3. Masseter muscle
        2. Enlarged coronoid processes
            1. Resulted from tension exerted by short temporal muscle tendon units
            2. Impinging on the body of the zygomatic bone and inner margin of the arch, thereby limiting mandibular excursion
        3. Secondary to an abnormal ligament between the maxilla and that of the mandible anterior to the masseter muscles
        4. Fibrotic abnormality of the masseter muscle mass in the vicinity of the ascending ramus
    2. Pseudocamptodactyly of fingers
        1. More appropriate term than camptodactyly since it is
            1. Not associated with progressive deformities
            2. Not associated with fixed joint contractures
        2. Caused by a shortening of the flexor digitorum profundus muscle tendon units, involving all fingers
    3. Foot deformities explainable by a shortening of the various muscle tendon groups in the leg and foot
    4. Several individuals with this mutation also had a so-called variant of Carney complex (a high incidence of myxomas, skin pigmentation disorders, endocrine tumors, or overactivity in schwannomas that manifest with cardiac myxomas and spotty skin pigmentation) (Veugelers et al. 2004), suggesting that the pathogenesis of trismus-pseudocamptodactyly syndrome and Carney complex might be shared. However, none of the individuals with trismus-pseudocamptodactyly syndrome studied had features of Carney complex, and p.R674Q was not found in 49 independent cases of Carney complex that were screened. The findings show that distal arthrogryposis syndromes share a similar pathogenesis and are, in general, caused by disruption of the contractile complex of muscle (Toydemir et al. 2006a).
    5. The trismus found in trismus-pseudocamptodactyly syndrome can also be present in Freeman-Sheldon syndrome (also known as distal arthrogryposis type 2A) and Sheldon-Hall syndrome (also known as distal arthrogryposis type 2B) (Hall et al. 1982). Both of these conditions are caused by mutations in the *MYH3* gene (Toydemir et al. 2006b), confirming the hypothesis that the distal arthrogryposis syndromes are caused by aberrant function of the contractile complex of fast-twitch myofibers.

Clinical Features

1. Highly variable expression
2. Two main clinical features (Chen et al. 1986, 1992)
    1. Limited excursion of the mandible
        1. Trismus (restricted opening of the mouth)
            1. Limited mouth opening and shortened flexor muscle-tendon units (Markus 1986)
            2. A leading symptom of trismus pseudocamptodactyly syndrome (Hertrich and Schuch 1991)
            3. Present at birth and persisting throughout life
            4. Greatly variable degree of restricted opening of the mouth
            5. The mouth opening is measured between the incisal edges of the central upper and lower incisors (in millimeter).

6. Children: less than the value for normal children (36.6 ± 5.7 for age 7 years to 47.2 ± 6.4 for age 18 years)
7. Adults: less than the value for normal adults (53.8 ± 6.5 for males, 50.4 ± 5.9 for females)

2. Mastication problems
3. Feeding problems with inadequate caloric intake
4. Swallowing difficulty (dysphagia)
5. Difficulty with dental care
6. Delayed in speech development
7. Difficulty in endotracheal intubation for general anesthesia

2. A flexion deformity of the fingers
   1. Clenched fists may be present at birth.
   2. Typically crawling on the knuckles later in infancy
   3. Occurring with wrist extension (pseudocamptodactyly) which is reversed by wrist flexion
   4. Flexion of the fingers when the hand is dorsiflexed in minimally affected patients
   5. Pronounced flexion with ulnar deviation of the fingers in severely affected patients

3. Other clinical features
   1. Lower extremity and foot deformities (5% of cases)
      1. Mild calcaneovalgus
      2. Equinovarus
      3. Metatarsus varus
      4. Camptodactyly
      5. Vertical talus
      6. Hammertoe deformities
      7. Shortening of both the gastrocnemiae and hamstring muscles
   2. Soft-tissue syndactyly occasionally present
   3. Mild short stature
   4. Facial asymmetry, ptosis, downslanting palpebral fissures and multiple joint involvement, with bilateral hip dysplasia, reduced elbow supination, vertical tali and talipes in addition to the classical findings of trismus and pseudocamptodactyly (Minzer-Conzetti et al. 2008)

4. Differential diagnosis of restricted mouth opening and/or (pseudo)camptodactyly
   1. Restricted mandibular opening caused by
      1. Intra-articular processes
         1. Trauma
         2. Infection
         3. Ankylosis
      2. Extra-articular processes
         1. Soft tissue and bony obstructions
         2. Neurologic disorders such as tetanus
   2. Trismus in temporomandibular joint dysfunction
   3. Trismus caused by hypoplasia and fibrosis of the muscles around the mouth in Freeman-Sheldon syndrome
   4. Trismus and camptodactyly in patients with distal arthrogryposis who may have hyperextension of the metacarpophalangeal joints but also have contractures of the hips and feet, and short stature
   5. Trismus with a fixed facies secondary to hypoplasia or atrophy of small muscle fibers in Schwartz-Jampel syndrome
   6. A new arthrogryposis syndrome with facial and limb anomalies
      1. An autosomal dominant disorder
      2. Small mouth and jaw with limited jaw movement in infancy
      3. Associated with short stature and severe flexion contractures of the hands and feet
   7. Digitotalar syndrome
      1. An autosomal dominant disorder
      2. Flexion deformities
      3. Ulnar deviation and narrowing of the fingers
      4. Soft-tissue webbing causing abnormal positions of the thumbs
      5. A vertical talus

Diagnostic Investigations

1. Radiography
   1. Enlargement of the coronoid processes
   2. Normal hands and forearms
2. Manometry for demonstrating abnormal swallowing

3. Histology of the affected muscles showing presence of fibrous tissue along with some muscle atrophy
4. Molecular genetic testing of *MYH8* mutations

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: not increased unless a parent is affected (a mildly affected parent may be missed) or has germinal mosaicism (Bonapace et al. 2010)
   2. Patient's offspring: 50%
2. Prenatal diagnosis: not been reported but possible in family at risk by *MYH8* mutation analysis of fetal DNA obtained from amniocentesis of CVS, provided the mutation has been previously identified in the affected family member
3. Management
   1. Use a flattened nipple to assist feeding in infancy.
   2. Anesthetic implications (Browder et al. 1986)
      1. Limited excursion of the mandible
      2. Potentially difficult or impossible to apply artificial ventilation and endotracheal intubation
      3. Inhalational anesthesia with spontaneous breathing (Vaghadia and Blackstock 1988) recommended for minor surgery
      4. Bullard laryngoscope, an excellent device for intubating patients with limited mouth opening (Lano and Werkhaven 1997)
      5. Fiber-optic nasotracheal intubation (Seavello and Hammer 1999)
      6. Needs for emergency tracheostomy and cricothyrotomy
   3. Surgical release in the severe cases of trismus
      1. Bilateral coronoid amputation to resolve the trismus. The procedure was successful and the patient achieved normal function (Carlos et al. 2005).
      2. Bilateral coronoidotomies (Lefaivre and Aitchison 2003; Gasparini et al. 2008; Balkin et al. 2015) with excision of accessory fibrous tissue
      3. Bilateral excision of hypertrophic coronoid processes
      4. Surgical release of the shortened muscle-tendon units
      5. Ongoing physical therapy with postsurgical stretching of the jaw opening on a daily basis to avoid relapse
   4. Surgical flexor slide-through procedure on the flexion tendons of the forearms

Trisomy 13 Syndrome

Contents

In 1960, Patau et al. first recognized the relation of trisomy 13 to a clinical syndrome. Incidence is estimated to be 1/4,000–1/10,000 live births. The prevalence at birth was 1 per 29,374 based on liveborn and stillborn probands (Goldstein and Nielsen 1988).

Synonyms and Related Disorders

Mosaic trisomy 13; Partial trisomy 13; Patau syndrome; Translocation trisomy 12

Genetics/Basic Defects

1. Trisomy 13
    1. Mechanism: due to meiotic nondisjunction
        1. Maternal origin of the extra chromosome (90%)
        2. Stage of nondisjunction: mostly maternal meiosis I (vs. meiosis II in trisomy 18)
        3. Paternal origin of the extra chromosome (10%): The majority is primarily postzygotic mitotic errors.
    2. Frequency: 75% of cases
2. Translocation trisomy 13
    1. Mechanism: de novo (75%) or familial transmission (25%)
    2. Frequency: 20% of cases
    3. Trisomy 13 due to t(13;13): The structural abnormalities are usually isochromosomes originating in mitosis.
    4. Despite a maternal origin of the trisomy 13, we cannot therefore infer anything about the parental origin of the chromosomes 13 and 14 involved in the translocation in the de novo t(13q14q) case nor for the two t(13;13) chromosomes showing a meiotic origin of the trisomy (Robinson et al. 1996).
3. Mosaic trisomy 13
    1. Mechanism: due to postzygotic (postfertilization) mitotic nondisjunction
    2. Frequency: 5% of cases
    3. Variable phenotype from full trisomy to near normal (Delatycki and Gardner 1997)
    4. Variable mental retardation with longer survival
    5. Trisomy 13/triploidy mosaicism: a rare event

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_235

4. Partial trisomy 13
    1. Partial trisomy of proximal segment with nonspecific clinical features and little similarity to full trisomy 13
    2. Partial trisomy of distal segment with specific clinical features

Clinical Features

1. General
    1. Low birth weight
    2. Thrombocytopenia
2. CNS
    1. Severe mental retardation
    2. Holoprosencephaly
    3. Seizures
    4. Central apnea
    5. Natural history of psychomotor development: clearly functioning in the severe to profound developmentally handicapped range, children did achieve some psychomotor maturation and always continued to learn (Baty et al. 1994b)
    6. A range of developmental skills are attainable for children with trisomy 13 (Bruns 2015)
3. Craniofacial abnormalities (Taylor 1968)
    1. Microcephaly
    2. Wide sagittal sutures
    3. Wide fontanels
    4. Scalp defect (aplasia cutis congenita, 50%)
    5. Capillary hemangioma of the forehead
    6. Ocular abnormalities
        1. Microphthalmia/anophthalmia
        2. Colobomas
        3. Retinal dysplasia
    7. Cleft lip/palate
    8. Abnormal auricles
    9. Low-set ears
    10. Sensorineural and conductive deafness
    11. Recurrent otitis media
    12. Abundant nuchal skin folds: increased nuchal translucency in trisomy 13 fetuses at 10–14 weeks of gestation (Snijders et al. 1999)
4. Cardiovascular abnormalities
    1. Ventricular septal defect
    2. Atrial septal defect
    3. Patent ductus
    4. Coarctation of the aorta
    5. Dextrocardia
5. Gastrointestinal abnormalities
    1. Omphalocele
    2. Malrotation
    3. Umbilical hernia
    4. Inguinal hernia
    5. Accessory spleen
    6. Heterotopic pancreatic tissue
    7. Meckel's diverticulum
    8. Diaphragmatic defects
    9. Large gallbladder
6. Genitourinary abnormalities
    1. Polycystic kidneys
    2. Cryptorchidism
    3. Hypospadias
    4. Bicornuate uteri
    5. Abnormal fallopian tubes
    6. Hypoplastic ovaries
7. Skeletal abnormalities
    1. Polydactyly
    2. Posterior prominence of heel
    3. Flexed fingers
    4. Hypoplasia of pelvis
    5. Shallow acetabulum
    6. Thin posterior ribs
    7. Flexion deformity of large joints
    8. Limb deficiency (5.3%) (Martínez-Frías et al. 2000)
    9. Radial aplasia
    10. Hyperconvex narrow fingernails
8. Dermatoglyphics
    1. Transverse palmar crease
    2. t′
    3. Hallucal arch fibular or loop tibial
9. Others
    1. Thymic cyst
    2. Persistence of fetal hemoglobin
    3. Rarely reported with teratoma (Dorum et al. 2016)
10. Prognosis
    1. Majority of trisomy 13 conceptuses
        1. Abort during pregnancy
        2. Stillborn

2. Twenty-five percent die by 24 h of life
3. Forty-five percent die by 1 month of life
4. Sixty percent die by 6 months of life
5. Seventy-two die by 1 year of age
6. The median survival time was 8.5 days (1-412 days) (Brewer et al. 2002)
7. Usual mode of death: primary apnea (Wyllie et al. 1994)
8. Early mortality was the most common outcome, but 10–13% survived for 10 years. Among children who underwent surgical interventions, 1-year survival was high (Nelson et al. 2016).
9. Survivals up to 11 and 19 years old reported (Redheendran et al. 1981; Zoll et al. 1993)

11. Mosaic trisomy 13
    1. The phenotype ranges
        1. Typical features of trisomy 13
        2. More mild mental retardation or even normal intellectual function (rare), milder physical features, and longer survival
    2. The range in clinical severity is likely due to the varying proportion of trisomy 13 cells and their distribution within the body.
    3. A report of a patient with trisomy 13 mosaicism with hemangiomas and port wine stains, without structural defects (Wieser et al. 2015)
12. Partial trisomy 13 of the proximal segment
    1. Severe mental retardation
    2. Large nose
    3. Short upper lip
    4. Receding mandible
    5. Clinodactyly of the fifth fingers
    6. The findings of persistent fetal Hb and increased number of nuclear projections on neutrophils are consistent findings associated with partial trisomy of a proximal segment of chromosome 13 and are diagnostic for trisomy of a partial segment of chromosome 13 that contains bands 13q12 and 13q14 (Rogers 1984).
13. Partial trisomy 13 of the distal segment
    1. Severe mental retardation
    2. Bushy eyebrows (synophrys) with long incurved lashes
    3. Frontal capillary hemangioma
    4. Long philtrum
    5. Prominent antihelix
    6. Further delineation of the clinical picture of trisomy for the distal segment of chromosome 13: report of three cases (Schinzel et al. 1976)
        1. Common clinical features included normal birth weight, postnatal asphyxia, convulsions, severe psychomotor retardation, normal growth, and a distinct pattern of dysmorphias consisting of trigonocephalic head with prominent metopic suture, long and markedly curved eyelashes, a stubby nose, increased distance between nose and upper lip, high-arched palate, misshapen ears with virtually absent lobules and prominent anthelices which are curved in a sharp angle, and hemangiomata.
        2. Features present in two cases were microcephaly, long and narrow fingers with convex nails, and hexadactyly.
    7. The physical features of polydactyly and hemangioma have been mapped to bands 13q31 and 13q32→13qter and provide a differential diagnosis for a distal trisomic segment of chromosome 13 that may include bands 13q22→13qter (Rogers 1984).
14. Phenotype-karyotype correlation in patients trisomic for various segments of chromosome 13 (Tharapel et al. 1986)
    1. Persistence of fetal hemoglobin (Hb F), increased projections of polymorphonuclear leucocytes (PMN), depressed nasal bridge, cleft lip/palate, and clinodactyly were more frequent in patients with proximal trisomy 13.
    2. In the distal trisomy group, the common features included haemangioma, bushy eyebrows, long curled eyelashes, prominent nasal bridge, long philtrum, thin upper lip, highly arched palate, and hexadactyly.
    3. In addition, several other features were common to both the groups, often showing

inconsistency even when the same segment was in trisomy.

Diagnostic Investigations

1. Cytogenetic studies
   1. Conventional technique
   2. FISH of interphase cells for rapid diagnosis
   3. Parental karyotyping in case of translocation trisomy 13
   4. Trisomy 13 mosaicism
2. Echocardiography for cardiovascular anomalies
3. EEG: hypsarrhythmia
4. Neurosonographic diagnosis of thalamic/basal ganglia vasculopathy in trisomy 13: an important diagnostic aid (Chabra et al. 1997)
   1. A linear, branching, echogenic pattern in the thalamus/basal ganglia
   2. Doppler evaluation of the thalamus/basal ganglia confirmed these linear echogenicities to be of vascular origin.
5. CT/MRI for central nervous system anomalies
6. Radiography
   1. Wide anterior fontanel
   2. Presence of a cervical rib
   3. Absence of the 12th rib
   4. Anomalies of rib morphology
   5. Low acetabular angle
   6. Long distal phalanges
   7. Cranial bone abnormalities in case of holoprosencephaly
   8. Vertebral fusions (Kjaer et al. 1997)
   9. Clefting of the vertebral bodies
   10. Abnormal postsphenoid component of the sphenoid bone
   11. Agenesis of the nasal bones
7. Placenta: Partial molar change of the placenta may rarely occur in trisomy 13 (Has et al. 2002).
8. Pathology of trisomy 13 syndrome (Moerman et al. 1988)
   1. Eight patients showed abnormal development of the forebrain and midline facial structures (holoprosencephaly).
   2. Cardiovascular malformations were invariably present, the leading malformation being an infundibular ventricular septal defect often in combination with dextroposition of the aorta and abnormalities of the semilunar valves.
   3. Histological abnormalities giving evidence of organ dysplasia were observed in the central nervous system, eyes, pancreas, kidneys, and ovaries.
9. Gross anatomical dissections (Colacino and Pettersen 1978; Pettersen et al. 1979)
   1. A muscle phenotype which includes the absence of palmaris longus, palmaris brevis, plantaris, and peroneus tertius; the presence of pectorodorsalis muscles and muscles from the central tendon of the diaphragm to the pericardium near the pulmonary veins; and variations in the extensor indicis, extensor carpi radialis longus and brevis, biceps, and suprahyoid muscles is discussed.
   2. The brain defects which include absent olfactory bulbs and tracts and hypoplastic commissures are compared to those defects seen in cases of alobar holoprosencephaly wherein severe defects of the ethmoid bone are concomitants.

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. Trisomy 13: about 1 in 4,000
      2. De novo translocation: about 1 in 4,000
      3. Familial translocation: 5–15%
      4. Mosaicism: 1 in 4,000
   2. Patient's offspring: not surviving to reproductive age
2. Prenatal diagnosis
   1. Prenatal ultrasonography (Benacerraf et al. 1988; Nyberg and Souter 2001; Tongsong et al. 2002): prevalence of ultrasound abnormalities (91%) (Lehman et al. 1995)
      1. General
         1. IUGR (48%)
         2. Single umbilical artery
         3. Polyhydramnios (15%)

4. Oligohydramnios (12%)
2. Cranium and CNS abnormalities (58%)
   1. Holoprosencephaly (39%)
   2. Neural tube defects
   3. Lateral ventricular dilatation without holoprosencephaly (9%)
   4. Enlarged cisterna magna or Dandy-Walker variant (15%)
   5. Microcephaly (12%)
   6. Linear branching echogenicity of the thalamus or basal ganglia (representing vasculopathy)
   7. Choroid plexus cyst
3. Facial anomalies
   1. Cyclopia
   2. Proboscis
   3. Hypotelorism
   4. Hypoplastic midface
   5. Cleft lip/palate (36%)
   6. Micrognathia
4. Neck anomalies
   1. Nuchal thickening
   2. Cystic hygroma
   3. Hydrops
   4. Lymphangiectasia
5. Chest/cardiac abnormalities
   1. Diaphragmatic hernia
   2. Ventricular septal defect
   3. Hypoplastic left heart
   4. Echogenic chorda tendineae (30%)
6. Renal abnormalities (33%)
   1. Echogenic kidneys
   2. Pyelectasis
   3. Enlarged kidneys
   4. Hydronephrosis
7. Abdominal abnormalities
   1. Omphalocele
   2. Echogenic bowel (6%)
   3. Bladder exstrophy
8. Limb abnormalities (33%)
   1. Clenched and overlapping digits
   2. Polydactyly
   3. Radial aplasia
   4. Short femur length
   5. Talipes equinovarus
   6. Rocker bottom feet
9. Trisomy 13 can resemble a triploid partial mole in utero without the potential long-term risk to the mother of persisting trophoblastic disease, as villous molar changes can obviously develop without trophoblastic dysplasia (Jauniaux et al. 1998).
10. Trisomy 13 should be included in the differential diagnosis when preeclampsia associated with hydropic changes of the placenta (partial hydatidiform mole) occurs early in gestation (Curtin et al. 2001).

2. A prospective validation study of screening for trisomies 21, 18, and 13 by a combination of maternal age, fetal nuchal translucency, fetal heart rate, and serum free ß-hCG and PAPP-A at 11+0 to 13+6 weeks' gestation in 108,982 singleton pregnancies: detected 90, 97, and 92% of trisomies 21, 18, and 13, respectively, as well as >90% of cases of monosomy X, >85% of triploidies, and >30% of other chromosomal abnormalities, at false positive rates of 4% (Santorum et al. 2016).
3. Chromosome analyses
   1. Amniocentesis
   2. Prenatal diagnosis of mosaicism for triploidy and trisomy 13 (Phelan et al. 2001)
      1. The infant had features common to both trisomy 13 and triploidy: intrauterine growth retardation (IUGR), small abnormal ears, cleft palate, and a small jaw. In addition, he had complete cutaneous syndactyly of fingers 3 and 4 and partial syndactyly of the toes, as seen in triploidy.
      2. Mixoploidy for trisomy 13 and triploidy was confirmed postnatally in blood, skin, and placenta.
      3. Examination of chromosome heteromorphisms and DNA markers suggested the presence of two maternal contributions in the triploid cell line.
      4. In addition, the extra chromosome 13 in the trisomic cell line was derived from the mother.
   3. CVS, followed by amniocentesis or fetal blood sampling, to differentiate between

confined placental mosaicism and true fetal karyotypic abnormality (Smith et al. 1999)
4. Nonmosaic trisomy 13 in the villus mesenchyme indicated the presence of a trisomic cell line in the fetus proper (Hahnemann and Vejerslev 1997)
5. Fetal cells isolated from maternal blood (Oosterwijk et al. 1998) using either flow sorting or magnetic sorting
6. Fetal blood sampling may have a role in mosaic trisomy 13 as the risk for abnormal outcome increases with positive confirmation (Wallerstein et al. 2000).
7. Noninvasive prenatal screening for fetal trisomies 21, 18, 13, and the common sex chromosome aneuploidies from maternal blood using massively parallel genomic sequencing of DNA (Porreco et al. 2014)
8. A positive cell-free fetal DNA testing result may not be representative of the fetal karyotype because of placental mosaicism. Cytogenetic analysis should be performed when abnormal cell-free fetal DNA test results are obtained (Liu et al. 2014).
9. Noninvasive prenatal detection of trisomy 13 using a single nucleotide polymorphism- and informatics-based approach: accurately detects trisomy 13-affected fetuses noninvasively and with high calculated accuracy (Hall et al. 2014).

4. Dilemma for genetic counseling with trisomy 13 mosaicism (Delatycki et al. 1998)
    1. Infrequent occurrence
    2. Single-cell pseudomosaicism (3.3%)
    3. Multiple-cell pseudomosaicism (4%)
    4. Often represents pseudomosaicism or confined placental mosaicism
    5. Prenatal diagnosis of mosaic trisomy 13 by amniocentesis in which no prenatal ultrasound abnormalities were noted (Eubanks et al. 1998)
    6. True fetal mosaicism (in the context of low-level single-digit percentage mosaicism): not necessarily associated with congenital defects and/or mental abnormalities
    7. An optimistic approach in case of normal ultrasonography and absence of trisomy 13 cells in the fetal blood
    8. Possibility of adverse phenotype and intellectual function in case of true low-level fetal mosaicism
3. Management
    1. Feedings
        1. Nasal tube feeding
        2. Oral gastric tube feeding
        3. Gastrostomy feeding
    2. Home oxygen therapy and home mechanical ventilation (Ishitsuka et al. 2015)
    3. Nissan fundoplication for gastresophageal reflux
    4. Risk for anesthesia
    5. Early intervention programs
    6. Seizure control
    7. Monitor apneic spells
    8. Treat infections
    9. Symptomatic treatment for heart failure
    10. Cardiac operation rarely performed
    11. No adverse reactions attributable to immunization (Baty et al. 1994a)
    12. Treatment decisions in a stable gray zone: If survival rates are low but not too low, neurocognitive impairment is severe but not total, and treatment is not so burdensome as to be inhumane, then parental values should drive decisions (Lantos 2016).
    13. Children with a postnatal diagnosis were treated “as any other children” until the diagnosis, which may give them a survival advantage, independent of palliative care. Rigorous transparency regarding specific interventions and outcomes may help personalize care for these children (Janvier et al. 2016).
    14. Shared decision making integrated with pathways approach is a model that demonstrates professional commitment beyond the most immediate crisis or decision point. This model, which incorporates ethically grounded decision making, guides clinicians and families from the time of

initial diagnosis, through the remainder of the care of the child and family (Andrews et al. 2016).

Trisomy 18 Syndrome

Contents

Edwards et al. and Smith et al. independently described trisomy 18 syndrome in 1960 (Edwards et al. 1960; Smith et al. 1960). It is the second most common autosomal trisomy after trisomy 21. Prevalence is approximately 1 in 6,000–8,000 live births.

Synonyms and Related Disorders

Edwards syndrome

Genetics/Basic Defects

1. Caused by an extra chromosome 18 resulting from nondisjunction in meiosis (Bugge et al. 1998)
   1. Maternal origin of an extra chromosome 18 in 90% of cases
   2. An error in maternal meiosis II is the most frequent cause of nondisjunction for chromosome 18, unlike all other human trisomies that have been studied, which show a higher frequency in maternal meiosis I.
   3. Increased incidence with advanced maternal age
2. Types of trisomy 18
   1. Full trisomy 18 in 95% of cases
   2. Rare mosaicism and translocation cases: translocation trisomy giving rise to partial trisomy 18 syndrome
   3. Trisomy 18 mosaicism with a mild phenotype (Collins et al. 1995)
3. Preponderance of females with trisomy 18 in liveborns (sex ratio 0.63) (sex ratio defined as the number of males divided by the number of females) compared to fetuses diagnosed prenatally (sex ratio 0.90) indicating a prenatal selection against trisomy 18 males after the time of amniocentesis (Nicolaidis and Petersen 1998)
4. The smallest extra region necessary for expression of serious anomalies of trisomy 18: Two critical regions, one proximal (18q12-q21.2) and one distal (18q22.3-qter), which work jointly to produce the typical trisomy 18 phenotype.

Clinical Features

1. Prenatal history (Chen 2011)
   1. Maternal polyhydramnios possibly related to defective fetal sucking and swallowing reflexes in utero

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_236

2. Oligohydramnios secondary to renal defects
3. Disproportionately small placenta
4. Single umbilical artery
5. Intrauterine growth retardation
6. Weak fetal activity
7. Fetal distress

2. Clinical history
   1. Apneic episodes
   2. Poor feeding
   3. Marked failure to thrive
3. Detailed clinical features (Taylor 1968)
4. Physical growth: profound growth retardation
5. Central nervous system (CNS)
   1. Inevitable profound delay in psychomotor development and mental retardation (100%)
   2. Natural history of psychomotor development: clearly functioning in the severe to profound developmentally handicapped range, children did achieve some psychomotor maturation and always continued to learn (Baty et al. 1994b)
   3. Neonatal hypotonia followed by hypertonia
   4. Jitteriness
   5. Apnea
   6. Seizures
   7. Malformations
      1. Microcephaly
      2. Cerebellar hypoplasia
      3. Meningoencephalocele
      4. Meningomyelocele
      5. Anencephaly
      6. Hydrocephaly
      7. Holoprosencephaly
      8. Arnold-Chiari malformation
      9. Hypoplasia or aplasia of the corpus callosum
      10. Defective falx cerebri
      11. Frontal lobe defect
      12. Abnormal gyri
      13. Migration defect
      14. Arachnoid cyst
6. Cranial
   1. Microcephaly
   2. Elongated skull
   3. Narrow bifrontal diameter
   4. Wide fontanels and cranial sutures
   5. Prominent occiput
7. Facial
   1. Microphthalmia
   2. Ocular hypertelorism
   3. Epicanthal folds
   4. Short palpebral fissures
   5. Iris coloboma
   6. Cataracts
   7. Corneal clouding
   8. Abnormal retinal pigmentation
   9. Short nose with upturned nares
   10. Choanal atresia
   11. Micrognathia/retrognathia
   12. Microstomia
   13. Narrow palatal arch
   14. Infrequent cleft lip and cleft palate
   15. Low-set, malformed ears (faun-like with flat pinnae and a pointed upper helix)
   16. Other uncommon but relevant abnormalities (Rosa et al. 2013)
      1. Microtia (18%)
      2. Orofacial clefts (12%)
      3. Preauricular tags (10%)
      4. Facial palsy (4%)
      5. Encephalocele (4%)
      6. Absence of external auditory canal (2%)
      7. Asymmetric face (2%)
8. Skeletal
   1. Severe growth retardation
   2. Characteristic hand posture, with clenched hands with the index finger overriding the middle finger, and the fifth finger overriding the fourth finger
   3. Camptodactyly
   4. Radial hypoplasia or aplasia
   5. Thumb aplasia
   6. Syndactyly of the second and third digits
   7. Arthrogryposis
   8. Rocker-bottom feet with prominent calcanei
   9. Talipes equinovarus
   10. Hypoplastic nails
   11. Dorsiflexed great toes
   12. Short neck with excessive skin folds

13. Short sternum
14. Narrow pelvis
15. Limited hip abduction
16. Scoliosis (Ries et al. 1990)
17. Severe kyphoscoliosis and tendency to spontaneous fracture of long bones emerging later

9. Cardiac malformations in more than 90% of infants with trisomy 18
    1. Ventricular septal defects
        1. Present in about two-thirds of cases
        2. Large defect unlikely to undergo spontaneous closure
    2. Polyvalvular heart disease pulmonary and aortic valve defects)
    3. Double outlet right ventricle
    4. Atrial septal defects
    5. Patent ductus arteriosus
    6. Overriding aorta
    7. Coarctation of aorta
    8. Hypoplastic left heart syndrome
    9. Tetralogy of Fallot
    10. Transposition of great arteries
    11. Endocardial fibroelastosis
    12. Persistent left superior vena cava
    13. Absent right superior vena cava
    14. Dextrocardia
10. Pulmonary
    1. Pulmonary hypoplasia
    2. Abnormal lobation of the lung
11. Gastrointestinal
    1. Omphalocele
    2. Malrotation of the intestine
    3. Ileal atresia
    4. Common mesentery
    5. Meckel diverticulum
    6. Esophageal atresia with or without tracheoesophageal fistula
    7. Diaphragmatic eventration
    8. Prune belly anomaly
    9. Diastasis recti
    10. Abnormal lobulation of the liver
    11. Absent or hypoplasia of gallbladder
    12. Absent appendix
    13. Accessory spleens
    14. Exstrophy of cloaca
    15. Pyloric stenosis
    16. Common mesentery
    17. Megacolon
    18. Imperforate or malpositioned anus
    19. Pilonidal sinus
    20. Umbilical, inguinal, or diaphragmatic hernias
12. Genitourinary
    1. Micromulticystic kidneys
    2. Double ureters
    3. Megaloureters
    4. Hydroureters
    5. Hydronephrosis
    6. Horseshoe kidneys
    7. Ectopic kidney
    8. Unilateral renal agenesis
    9. Cryptorchidism, hypospadias, and micropenis in males
    10. Hypoplasia of labia and ovaries, bifid uterus, hypoplastic ovaries, and clitoral hypertrophy in females
13. Endocrine
    1. Thymic hypoplasia
    2. Thyroid hypoplasia
    3. Adrenal hypoplasia
14. Dermatoglyphics
    1. Increased number of simple arches (6 or more) on the finger tips
    2. Transverse palmar crease
    3. Increased atd angle
    4. Clinodactyly of the fifth fingers with a single flexion crease
15. Prognosis
    1. Approximately 95–97.5% of conceptuses with trisomy 18 die in embryonic or fetal life.
    2. Only 30% of live fetuses at midtrimester amniocentesis surviving to term.
    3. Five to ten percent of affected children survive beyond the first year.
    4. The chance of survival to 1 month, 1 year, and 10 years is 70%, 10%, and 1%, respectively (Weber et al. 1964).
    5. Rare reports of long survival into teens (Surana et al. 1972; Smith et al. 1978; Mehta et al. 1986) and 20s (Smith et al. 1989).
    6. High mortality rate secondary to cardiac and renal malformations, feeding

difficulties, sepsis, and central apnea caused by CNS defects.
7. Severe psychomotor and growth retardation invariably present for those who survive beyond infancy.
8. Milder nonspecific phenotype in mosaic trisomy 18 correlates with the proportion of normal cells in the body.
9. Older individuals with trisomy 18 are at risk to develop a Wilms tumor (Carey and Barnes 2016).

Diagnostic Investigations

1. Conventional cytogenetic study to detect full trisomy, mosaic trisomy, or rare translocation type trisomy 18
2. Trisomy 18 mosaicism: clues to the diagnosis (Bass et al. 1982)
    1. Because of his prolonged survival and an atypical phenotype, skin fibroblast cultures from a new biopsy were established at age 18, and only normal 46,XY cells were observed, while peripheral blood lymphocytes still demonstrated 47,XY, + 18.
    2. This patient and six others with trisomy 18 mosaicism illustrate the advisability of looking for such a pattern in individuals whose phenotype in early life is not fully consistent with the trisomy 18 syndrome.
3. Echocardiographic features (Alizad and Seward 2000)
    1. Ventricular septal defect
    2. Atrial septal defect
    3. Patent ductus arteriosus
    4. Pulmonary stenosis
    5. Tetralogy of Fallot
    6. Bicuspid aortic valve
    7. Transposition of the great vessels
    8. Coarctation of the aorta
4. Barium swallow for gastrointestinal anomalies
5. Ultrasound for genitourinary anomalies
6. Skeletal radiography
    1. Phocomelia
    2. Absent radius
    3. Tight flexion of the fingers with second over the third and the fifth over the fourth
    4. Talipes equinovarus
    5. Short sternum
    6. Hemivertebrae
    7. Fused vertebrae
    8. Short neck
    9. Scoliosis
    10. Rib anomaly
    11. Dislocated hips
    12. Pattern of malformations in the axial skeleton in human trisomy 18 fetuses (Kjaer et al. 1996)
        1. Malformations occurred in the occipital field in all fetuses. This was a characteristic notching, either unilateral or bilateral, of the basilar part of the occipital bone.
        2. Nasal bones were abnormal in 8 cases, either absent or hypoplastic.
        3. Malformations were found in the thoracic and/or lumbosacral field in 7 fetuses.
        4. A single abnormality was found in the cervical spine in one fetus.
7. Histopathological study of temporal bone (auditory organ) (Tadaki et al. 2003)
    1. External ear: arctation or atresia of external acoustic meatus (38%)
    2. Middle ear
        1. Anomalies of auditory ossicles (61%)
            1. Incus or malleus
            2. Stapes
        2. Absence or aberration of tensor tympani muscle or its tendon (31%)
        3. Complete absence or hypoplasia of stapedial muscle or its tendon (28%)
    3. Inner ear
        1. Hypoplasia of the ductus semicirculares (37%)
        2. Shortened cochlea (22%)
        3. Anomalies of stria vascularis (22%)
        4. Absence or hypoplasia of lymphatic valve in utricle (21%)
        5. Enlargement of canaliculus cochleae (11%)
    4. Facial nerve: geniculate ganglion cells displaced into the internal auditory meatus (53%)

8. Anatomical analysis of the developmental effects 18-trisomy syndrome (Bersu and Ramirez-Castro 1977)
    1. Of the usual muscles of facial expression, occipitofrontalis and the auricular and nasal muscles were hypoplastic in all eight bodies and each subject showed extensive fusion of the muscles around the corner of the mouth.
    2. There was a supernumerary muscle band that extended from the region near the corner of the mouth to the occipital attachment of trapezius.
    3. The otomandibular region showed a variable spectrum of muscular, skeletal, arterial, and salivary gland variations bilaterally. Three of the bodies had infrahyoid muscle variations.
    4. Abnormalities of the upper and lower limbs (Ramirez-Castro and Bersu 1978)
        1. Muscle variations concentrated along the radial margin of the forearm and hand, the absence of the definitive musculocutaneous nerve in all of the limbs, and reductions of the radial artery
        2. The characteristic flexion deformities of the fingers seem to be due to a displacement of the tendons of extensors digitorum and digiti minimi.
9. Thirty-one autopsy cases of trisomy 18 (Kinoshita et al. 1989)
    1. Cardiovascular anomalies were consistently present; ventricular septal defect and patent ductus arteriosus being the most common malformations.
    2. Various other internal malformations including the Arnold-Chiari malformation were observed.

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. De novo full trisomy 18: 1% or less.
        2. Low-grade parental mosaicism has been reported in two occasions in sporadic cases of trisomy 18.
        3. A parent being a balanced carrier of a structural rearrangement: increased recurrence risk pending on the type of structural rearrangement and the pattern of segregation.
    2. Patient's offspring: unlikely to survive to reproduction
2. Prenatal diagnosis
    1. Prenatal screening in families without history of trisomy 18 using maternal serum markers
        1. Low human chorionic gonadotropin hCG) and low unconjugated estriol (uE3) in maternal serum during midtrimester: useful predictors for an increased risk for trisomy 18 (Leporrier et al. 1996)
        2. Possible future first-trimester biochemical screening for trisomy 18: reduced levels of pregnancy-associated plasma protein A (PAPP-A) and free beta-human chorionic gonadotropin (beta-hCG) at 8–13 weeks gestation. The mean MOM in affected pregnancies was 0.25 for PAPP-A and 0.34 for free beta-hCG.
        3. First-trimester screening for trisomy 18 using a combination of maternal age, PAPP-A, and beta-hCG: reported to achieve a detection rate of 76.6% with a false-positive rate of 0.5% (Biagiotti et al. 1998)
        4. Noninvasive prenatal screening for fetal trisomies 21, 18, 13, and the common sex chromosome aneuploidies from maternal blood using massively parallel genomic sequencing of DNA (Porreco et al. 2014)
        5. A prospective validation study of screening for trisomies 21, 18, and 13 by a combination of maternal age, fetal nuchal translucency, fetal heart rate, and serum-free ß-hCG and PAPP-A at 11+0 -13+6 weeks' gestation in 108,982 singleton pregnancies: detected 90, 97, and 92% of trisomies 21, 18, and 13, respectively, as well as >90% of cases of monosomy X, >85% of triploidies, and

>30% of other chromosomal abnormalities, at false positive rates of 4% (Santorum et al. 2016).

2. Prenatal ultrasonography (Benacerraf et al. 1988; Nyberg et al. 1993; Shields et al. 1998; Kroes et al. 2014; Niknejadi et al. 2014): The majority of fetuses with trisomy 18 have detectable structural abnormalities.
    1. First-trimester sonographic findings (Sepulveda et al. 2010)
        1. Nuchal translucency (77–91%) (Nicolaides et al. 1992)
        2. Absent/hypoplastic nasal bone (53%)
        3. Generalized subcutaneous edema (49%)
        4. Omphalocele (21%)
        5. Abnormal posturing of hands (6%)
        6. Megacystis (4%)
        7. Cardiac defect (4%)
        8. Pleural effusions (4%)
        9. Echogenic yolk sac (4%)
    2. Oligohydramnios/polyhydramnios (12%)
    3. Intrauterine growth retardation (29%)
    4. Two-vessel umbilical cord (40%)
    5. CNS
        1. Abnormally shaped fetal head (strawberry or lemon) (43%)
        2. Microcephaly
        3. Dandy-Walker malformation (posterior fossa enlargement associated with cerebellar hypoplasia)
        4. Enlarged cisterna magna
        5. Choroid plexus cysts (43%)
        6. Neural tube defects (9%)
    6. Micrognathia
    7. Thickened nuchal skin fold
    8. Cystic hygroma or lymphangiectasia (14%)
    9. Omphalocele (20%)
    10. Esophageal atresia
    11. Cardiac defects (37%): septal defects with polyvalvular disease
    12. Diaphragmatic hernia
    13. Renal anomalies (9%)
        1. Polycystic kidneys
        2. Horseshoe and ectopic kidneys
    14. Limb abnormalities
        1. Clenched hands with overlapping index finger (89%): a tell-tale signs of trisomy 18 (Lam and Tang 1999)
        2. Forehand and hand abnormalities such as a short radial ray
        3. Rocker-bottom feet
        4. Club feet
    3. 3D/4DUS offers diagnostic advantages for most anomalies associated with trisomy 18, especially anomalies of the extremities and face (Zheng et al. 2008).
    4. Amniocentesis or CVS by conventional cytogenetic or FISH techniques
        1. Straight trisomy 18
        2. Trisomy 18 mosaicism: 54% risk for an abnormal outcome, including phenotypically abnormal offspring, IUGR, or fetal demise. The risk is increased with increasing percentage of amniotic fluid trisomic cell line.
    5. Culturing fetal hematopoietic stem-progenitor cells from maternal blood during pregnancy: a new strategy holding great promise for noninvasive prenatal genetic diagnosis
    6. Trisomy diagnosis from single cells using multiple STR markers for either preimplantation genetic diagnosis or, potentially, diagnosis from fetal cells isolated from maternal blood (Findlay et al. 1998)
3. Management (Carey 2000)
    1. Genetic counseling in prenatally diagnosed trisomy 18 (Adler and Kushnick 1982)
        1. Traumatic experience in the lives of all couples having a fetus with trisomy 18
        2. Emotional upheaval persisting for variable time periods after the diagnoses and the decisions concerning the pregnancy outcomes
    2. When prenatal or neonatal diagnosis of trisomy 18 is made, the counseling of the family should be realistic, but not desolate. The parents can find it difficult to accept the lack of certainty of the newborn situation, but they have to be prepared for both the probability of death and the possibility of living (Carey 1992). Because the parents

have to make practical decisions concerning resuscitation, surgery, and life support (Cereda and Carey 2012)

3. Medical care of trisomy 18 infants
    1. Supportive
    2. Treat infections
        1. Otitis media
        2. Upper respiratory infections (bronchitis, pneumonia)
        3. Urinary tract infections
    3. No adverse reactions attributable to immunization (Baty et al. 1994a)
    4. Nasogastric and gastrostomy supplementation for feeding problems
    5. Orthopedic management of scoliosis secondary to hemivertebrae
    6. Primarily medical management of congenital heart disease
    7. Diuretic and digoxin for congestive heart failure
    8. Referral for early intervention including physical and occupational therapy
    9. Psychosocial management: Discuss implications, possible outcomes, and available supportive services in the community.
    10. Severe developmental delay exhibited by long-term survivors presenting the greatest challenge to parental coping during the childhood years
    11. Informed and empathetic care to families undergoing a complex grieving process that combines both the reactive grief predominant in chronic illness and the preparatory grief associated with impending death (Van Dyke and Allen 1990)
    12. According to Janvier et al. (2012), parents expressed concerns that interventions were not being offered due to their child's diagnosis.
    13. A range of developmental skills is noted with strengths in the language and communication, gross and fine motor, and social-emotional domains including indicating preferences, exploration of objects, and a range of voluntary mobility. These results serve to expand the knowledge base on developmental status for these groups and advance the need to further explore developmental abilities rather than focus on deficits (Bruns 2015).
    14. A substantial number of patients with trisomy received surgery and were then discharged home, but, of these, a considerable number required home medical care. This included home oxygen therapy, home mechanical ventilation, and tube feeding (Ishitsuka et al. 2015).
    15. Children with a postnatal diagnosis were treated "as any other children" until the diagnosis, which may give them a survival advantage, independent of palliative care. Rigorous transparency regarding specific interventions and outcomes may help personalize care for these children (Janvier et al. 2016).
    16. Evidence for greater provision of necessary and aggressive medical interventions for children with trisomy 18. It is hoped that perceptions regarding children with trisomy 18 will become more positive and interventions more widely offered and provided to this group (Donovan et al. 2016).
4. Surgical care of trisomy 18 infants: Because of the extremely poor prognosis, surgical repair of severe congenital anomalies such as esophageal atresia or congenital heart defects (Embleton et al. 1996) is not likely to improve the survival rate of infants and should be discussed with families.

Fig. 5 (**a**–**d**) Two infants with trisomy 18 showing small eyes, micro/retrognathia, and low-set/malformed ears

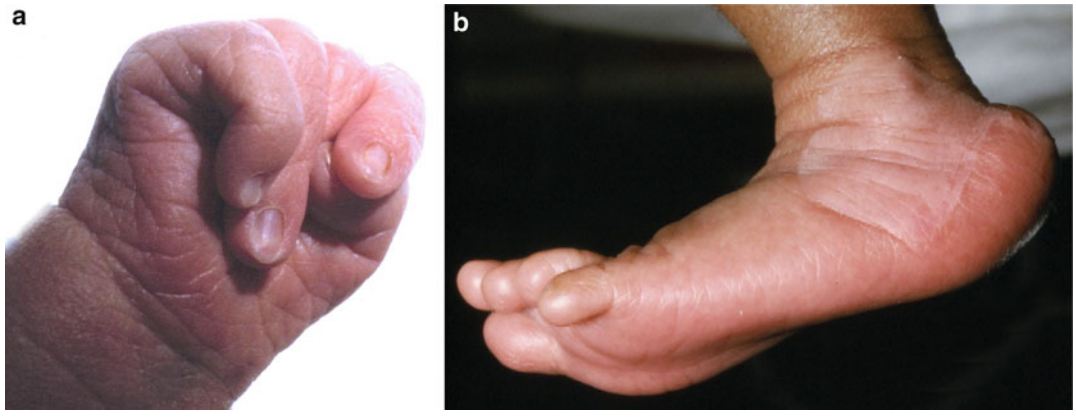

Fig. 6 (**a**, **b**) Typical hand grasping pattern (*left*) and rocker-bottom feet with prominent calcaneus (*right*) observed in trisomy 18

Fig. 7 Trisomy 18 karyotype (47,XY,+18)

Fig. 8 Translocation trisomy 18 karyotype [46,XX,+18,der(13)t(13;18)(q10;q10)]

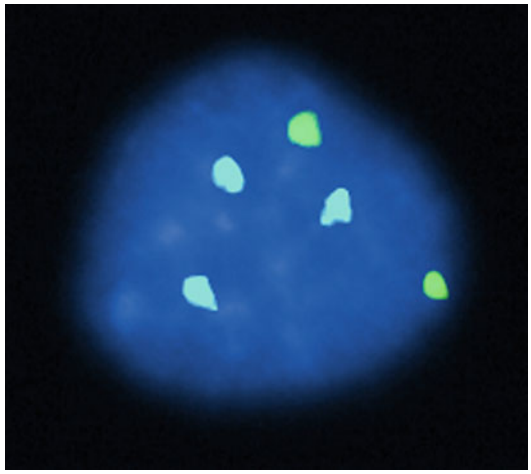

Fig. 9 Trisomy 18 shown by FISH (CEP X/SpectrumGreen, CEP 18/SpectrumAqua, Vysis/Abbott) on an uncultured amniocyte. Three copies of the aqua signal are present in the cells (CEP 18). Two copies of the green signal (CEP X) confirm a female fetus

Trisomy 8 Mosaicism Syndrome

Contents

In 1971, de Grouchy et al. (1971) first described trisomy 8 mosaicism which was further delineated by Fryns et al., Sanchez and Yunis, Schinzel, and Riccardi in 1977. This syndrome, also known as Warkany syndrome, is a well-recognized syndrome despite its phenotypic variability.

Synonyms and Related Disorders

Warkany syndrome

Genetics/Basic Defects

1. Trisomy 8 mosaicism: chromosome complement mosaic for chromosome 8 (presence of a chromosomally normal cell line in addition to the trisomic 8 cell line) (Fineman et al. 1975)
    1. A case of trisomy 8 mosaicism detected prenatally in a single clone of amniotic fluid culture, and confirmed on fetal blood and on peripheral lymphocytes after birth.
    2. A follow-up was performed over 3 years, showing a clinically normal female with cognitive, neuropsychological, and linguistic development in a normal range (Camurri and Chiesi 1991).
2. Origin of trisomy 8 mosaicism
    1. Different from the common autosomal trisomies that usually result from maternal meiotic errors.
    2. Trisomy 8 in spontaneous abortions: meiotic origin in the majority of cases.
    3. Postzygotic (mitotic) nondisjunction error in a diploid conceptus: the most likely origin of trisomy 8 in the live-born population.
    4. Postzygotic (mitotic) nondisjunction error in a diploid conceptus, followed by nonrandom distribution of aneuploid cells between the different compartments.
    5. Affected fetuses usually show a pattern of absence, or low levels of trisomy in cytotrophoblast cells (STC villi), high levels in extraembryonic mesoderm (LTC villi), and again low levels of trisomic cells in AF cells and/or fetal blood lymphocytes.
    6. LTC villi are more likely to reflect the true fetal chromosomal constitution than STC villi.
    7. The chromosomal mechanisms accounting for the WS include either literal trisomy 8 (aneuploidy), usually if not always with

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_234

mosaicism, or translocation leading to partial trisomy 8 (8q2). In addition, some patients with mosaic trisomy 8 may not have the Warkany syndrome (Riccardi 1977).

8. A report on a mildly dysmorphic male patient with partial low-level trisomy 8 mosaicism due to a pseudoisodicentric chromosome 8 with normal 6.0 SNP microarray and high resolution chromosome analyses in lymphocytes. The aneuploidy was detected in fibroblasts and confirmed by FISH in lymphocytes. This report elaborates further the clinical variability seen in trisomy 8 mosaicism (Leon et al. 2011).

Clinical Features

1. Wide range of phenotypic variation ranging from normal individual to severe malformation syndrome (Fineman et al. 1975; Kurtyka et al. 1988; Agrawal and Agrawal 2011) and cytogenetic expression (Jordan et al. 1998; Udayakumar and Al-Kindy 2013)
2. Central nervous system (Habecker-Green et al. 1998)
    1. Intelligence: range from normal to mental retardation
    2. Agenesis of the corpus callosum
    3. Arrhinencephaly
3. Craniofacial features
    1. Skull
        1. Asymmetrical skull
        2. Microcephaly
        3. Hydrocephaly
        4. Prominent forehead
        5. Flattened occiput
        6. Low posterior hairline
    2. Eyes
        1. Ocular hypertelorism
        2. Deep-set eyes
        3. Strabismus
        4. Corneal clouding
        5. Cataracts
        6. Amblyopia
    3. Nose
        1. Plump nose with broad base
        2. Prominent nares
    4. Mouth
        1. Micrognathia
        2. Everted lower lip
        3. High palate
        4. Cleft soft palate
    5. Low-set and malformed ears
4. Chest
    1. Pectus excavatum
    2. Widely spaced nipples
5. Heart: congenital heart disease
6. Gastrointestinal tract
    1. Meckel diverticulum
    2. Hirschsprung disease
    3. Anal anomalies
7. Genitourinary tract
    1. Cryptorchidism
    2. Unilateral renal agenesis
    3. Wilms tumor
    4. Ureteral anomalies
    5. Perineal anomalies
    6. Inguinal hernia
    7. Genital hypoplasia in males
8. Skeletal system
    1. Short stature
    2. Abnormal clavicle
    3. Absent or dysplastic patellae
    4. Joint contracture or limitation
    5. Vertebral anomalies
    6. Narrow pelvis
    7. Rib anomalies
    8. Scoliosis
    9. Camptodactyly of second through fifth fingers and toes
9. Skin
    1. Deep palmar skin furrows
    2. Deep plantar skin furrows: a hallmark of the syndrome
10. Neoplasia in individuals with trisomy 8 mosaicism (Habecker-Green et al. 1998)
    1. Leukemia
    2. Wilms tumor
    3. Cystic renal tumors
    4. Gastric Leiomyosarcoma
    5. Gestational trophoblastic disease

11. Fertility: an increased risk of infertility for males and females with trisomy 8 mosaicism (Habecker-Green et al. 1998)
12. Life expectancy: usually normal

Diagnostic Investigations

1. Necessary to perform both karyotyping and FISH to detect low mosaic trisomy 8
2. Traditional cytogenetic diagnosis
    1. Detection of mosaic trisomy 8 from various tissue.
    2. Abnormal cell line tends to decrease from lymphocytes with time (Jordan et al. 1998).
    3. In older patients, aneuploidy can sometimes be demonstrated in fibroblast cultures only.
3. Interphase fluorescent in situ hybridization (FISH) using a chromosome 8 centromere-specific probe
4. Array comparative genomic hybridization (array-CGH)

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: recurrence risk not increased
    2. Patient's offspring
        1. An increased risk of spontaneous abortion for trisomic conceptuses
        2. Fetuses with complete trisomy 8: nonviable
        3. Chromosomally normal pregnancies possible
2. Prenatal diagnosis
    1. Ultrasonography (Gün et al. 2012)
        1. Bilateral renal pyelectasis
        2. Single umbilical artery
        3. Polyhydramnios
        4. Axial view of the head demonstrating the "teardrop sign" in the lateral ventricle (ventriculomegaly)
        5. Agenesis of corpus callosum
        6. 3D surface rendering of the fetal dysmorphic face
            1. Prominent forehead and ears
            2. Hypertelorism
            3. Broad-based nose
            4. Large mouth
            5. Large head
    2. Prenatal cytogenetic diagnosis of mosaicism
        1. Metaphase analysis of cultured cells from either amniotic fluid or chorionic villi (Guichet et al. 1995): currently the standard technique (analysis of 30 colonies needed to exclude 10% mosaicism with a 95% confidence level)
        2. Interphase fluorescent in situ hybridization (FISH) with a centromere-specific probe: to further define the level of mosaicism
        3. The application of interphase FISH to uncultured amniocytes is better than cordocentesis in prenatal confirmation of trisomy 8 mosaicism (Chen et al. 2012).
        4. Array comparative genomic hybridization (array-CGH): enables faster results than standard cell culture and metaphase analysis (capable of detecting mosaicism at levels as low as 7%)
        5. A report of a case of a fetus mosaic for trisomy of the entire long arm (q) of chromosome 8 without additional chromosomal aberrations (Wood et al. 2008).
            1. The diagnosis was made by amniocentesis performed following an 18 week sonogram that showed multiple fetal anomalies.
            2. Mosaicism for trisomy 8q was confirmed by routine karyotyping and fluorescent in situ hybridization (FISH) analysis.
            3. The case proved useful for testing the sensitivity of array comparative genomic hybridization (array-CGH) with respect to segmental trisomy in the presence of chromosomal mosaicism.
3. Problems in genetic counseling (Rodriguez et al. 2013)
    1. Prediction of phenotype difficult since clinical severity is not related to the level of mosaicism

2. Problems in detecting trisomy 8 mosaicism in chorionic villi (Klein et al. 1994)
    1. Do not necessarily reflect a constitutional mosaicism of the fetus
    2. Most likely represent confined placental mosaicism (a chromosomally abnormal cell line limited to the trophoblast tissue and/or extraembryonic mesoderm, with a normal karyotype in the fetus proper)
    3. In large published series of amniotic fluid chromosome analysis, 0.2% of cases are mosaic, and in addition, up to 8% of cases have single or multiple cell pseudomosaicism (Hsu et al. 1992)
    4. Possible false-negative cases of trisomy 8 mosaicism in short-term culture villi, as well as cultured amniotic fluid cells (Schneider et al. 1994; Hanna et al. 1995)
    5. Follow-up investigations in fetal blood cells recommended when trisomy 8 mosaicism is encountered in chorionic villi
    6. Very low-level trisomy 8 mosaicism may be compatible with a normal phenotype
3. Difficulties in the prenatal diagnosis of trisomy 8 mosaicism (van Haelst et al. 2001)
    1. When found in chorionic villi, it mostly represented confined placental mosaicism, while in a case of true fetal trisomy 8 mosaicism, the cytotrophoblast cells showed a normal karyotype. So, the cytotrophoblast compartment of chorionic villi is a poor indicator of the presence or absence of fetal trisomy 8 mosaicism.
    2. Follow-up investigations including amniocentesis and especially fetal blood sampling are required to come to a definite prenatal diagnosis of trisomy 8 mosaicism.
4. Problems in detecting trisomy 8 mosaicism in amniotic fluid
    1. Amniocentesis: not the best way to reveal trisomy 8 mosaicism
    2. Cases of missed trisomy 8 mosaicism reported (Tsai et al. 2014)
3. Management
    1. Mostly supportive.
    2. A report of a patient with constitutional mosaic trisomy 8 syndrome and infantile spasms, who became seizure free after treatment with adrencorticotropic hormone and clonazepam (Datta et al. 2010).
    3. Constitutional trisomy 8 mosaicism (CT8M) in a healthy bone marrow donor: Confirmation of first reported donor origin trisomy 8 (Uddin et al. 2010). The diagnosis of CT8M in the donor was completely serendipitous as it was only identified after the recipient developed donor-derived T8, post-transplant (Frey et al. 2008).
    4. Surgical management may be needed for those individuals with major malformations.
    5. While taking into consideration the natural prognosis, underlying malformations, and surgical benefits and risks, the indications for cardiac surgery in patients with mosaic trisomy 8 should be carefully individualized (Hasegawa et al. 2016).

Tuberous Sclerosis

Contents

Tuberous sclerosis is the second most common neurocutaneous syndrome after neurofibromatosis. The term "tuberous sclerosis" derived from the "tubers" (swellings or protuberances) and areas of "sclerosis" (hardening) of the cerebral gyri that calcifies with age. The classic description of the syndrome includes Bogt's triad: mental retardation, seizures, and adenoma sebaceum (a misnomer) or facial angiofibromas. Tuberous sclerosis affects about 1 in 6,000 newborns (Osborne et al. 1991).

Synonyms and Related Disorders

Tuberous sclerosis complex

Genetics/Basic Defects

1. Inheritance
   1. Autosomal dominant
      1. Almost complete penetrance
      2. Extremely variable in its manifestations and severity (Northrup et al. 1993)
   2. Sporadic (new mutations) in two thirds of cases
2. Caused by mutations in either of the following two tuberous sclerosis complex (*TSC*) genes (Jones et al. 1997, 1999; O'Callaghan and Osborne 2000; Curatolo et al. 2008)
   1. *TSC1* (Fryer et al. 1987)
      1. Located on chromosome 9q34 (Haines et al. 1991; van Slegtenhorst et al. 1998).
      2. Encodes protein, hamartin (TSC1), a protein implicated in regulating cell adhesion via interactions with cortical actin filaments and a plasma membrane binding protein ezrin-radixin-moesin, part of a Rho-mediated signaling pathway.
      3. Approximately 50% of tuberous sclerosis families show linkage to *TSC1*.
      4. Mutations occurrence: 10–15% of sporadic cases.
      5. Most described mutations in the *TSC1* gene result in a truncated protein (Young et al. 1998).
      6. Phenotype: less severe
   2. *TSC2* (Kandt et al. 1992; Henske et al. 1995)
      1. Located on chromosome 16p13.3 (European Chromosome 16 Tuberous Sclerosis Consortium 1993)
      2. Encodes protein, tuberin (TSC2), a protein implicated in regulating cytoplasmic vesicle transport to the cell membrane

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_237

3. Approximately 50% of families show linkage to *TSC2*.
4. Mutation occurrence: 75–80% of sporadic cases
5. Many mutations in the *TSC2* gene are large (contiguous) deletions, which may involve the *PKD1* gene, resulting in a severe phenotype called very early onset polycystic kidney disease.
6. Phenotype: more severe

3. Both *TSC1* and *TSC2*
   1. Have properties consistent with tumor suppressor genes functioning according to Knudson's "two-hit" hypothesis (Green et al. 1994; Yeung 2003).
   2. The clinical variability occurs secondary to the random nature of the second "hit" in individuals carrying a germ line mutation.
   3. Loss of heterozygosity for *TSC1* or *TSC2* gene
      1. Suggests that one mutation is acquired embryonically and another is acquired later on somatically (two-hit hypothesis).
      2. Observed in 41% of all hamartomas including renal angiomyolipomas, cardiac rhabdomyomas, and subependymal giant cell astrocytomas.
4. Hamartin and tuberin (van Slegtenhorst et al. 1998)
   1. Widely expressed in the brain
   2. May interact as part of a cascade pathway that modulates cellular differentiation, tumor suppression, and intracellular signaling
5. Mosaicism in tuberous sclerosis reported
   1. Somatic mosaicism: The mutation is not found in all cell lines.
   2. Gonadal mosaicism (Rose et al. 1999): The mutation found only in gonadal cells and is therefore transmitted to offspring while parents are spared from any disease manifestation.
6. Genotype-phenotype correlations (Dabora et al. 2001)
   1. Overlap of many clinical features exists among the patients with *TSC1* and *TSC2* mutations.
   2. Sporadic patients with TSC1 mutations
      1. On average, milder phenotypic manifestations compared with patients with TSC2 mutations
      2. Lower frequencies of seizures
      3. Lower frequencies of moderate to severe mental retardation
      4. Fewer subependymal nodules and cortical tubers
      5. Less severe kidney involvement
      6. No retinal hamartomas
      7. Less severe facial angiofibroma
   3. Some features are rare or not seen at all in *TSC1* patients.
      1. Grade 2–4 kidney cysts or angiomyolipomas
      2. Forehead plaques
      3. Retinal hamartomas
      4. Liver angiomyolipomas
   4. Both germ line and somatic mutations are less common in TSC1 than TSC2.
   5. Patients without mutation
      1. Milder than patients with TSC2 mutations
      2. Somewhat distinct from patients with TSC1 mutations

Clinical Features

1. Characteristic cutaneous features (virtually 100% of cases) (Nevin and Pearce 1968; Schwartz et al. 2007)
   1. Hypomelanotic macules ("ash-leaf spots") (87–100% of cases) (Fitzpatrick 1991)
      1. One of the earliest skin lesions (often present at birth)
      2. Commonly on trunk and buttocks, rarely on the face, and best appreciated by the Wood's fluorescence lamp
      3. Not specific to tuberous sclerosis because they are seen in unaffected children
      4. Smaller depigmented spots over the anterior shins: characteristically distributed in a "confetti" fashion (clustered skin lesions with a reticulated appearance)
   2. Shagreen patches (a form of collagenomas) (20–80%)

1. Elevated discolored skin lesions commonly over lumbosacral region, observed in about 21% of patients
2. Age at presentation: birth to adulthood

3. Facial angiofibromas (adenoma sabaceum) (47–90%)
   1. One of the most common and specific cutaneous manifestations - Multiple facial angiofibromas are a pathognomic features of TSC (Trauner et al. 2003)
   2. Causing the most disfigurement among the skin lesions
   3. Red to brown nodules, observed over the nose and cheeks in bilaterally symmetrical butterfly distribution. Rarely segmental tuberous sclerosis may present as unilateral facial angiofibromas.
   4. Age of presentation
      1. Usually appear after 2 years of age
      2. Increase in size and number of facial angiofibromas with time
      3. Observed in about 80% of adults with tuberous sclerosis
   5. Chance of small and discrete papules of facial angiofibromas to become confluent and fungating lesions
4. Forehead fibrous plaque (15%)
   1. Large fibromas without angiomatous appearance on the scalp or the forehead areas
   2. Yellowish-brown or skin-colored plaques of variable size and shape usually located on the forehead or scalp
   3. Present at any age and can be seen at birth or early infancy
5. Periungual fibromas (17–87%)
   1. Skin-colored or reddish nodules seen on the lateral nail groove, nail plate, or along the proximal mail folds
   2. More commonly found on the toes than on the fingers
   3. Characteristically appear during puberty and persist through life
6. Café au lait spots: seen in 15–30% of patients with tuberous sclerosis
7. "Confetti-like" macules (2.8%)
   1. Multiple, 1–2 mm white spots symmetrically distributed over extremities
   2. Present at the second decade or adulthood
8. Molluscum fibrosum pendulum (skin tags) (23%)
   1. Multiple soft pedunculated skin growths on neck, rarely in axilla or groin
   2. More common during first decade of life, rarely during infancy

2. CNS abnormalities (the most common manifestations of the disorder)
   1. Epilepsy
      1. The major neurologic manifestation, affecting 85% of patients
      2. Onset usually at few months of age
      3. Typically with initial classic hypsarrhythmia and infantile spasms (Yeung 2002), which transform into adult-type partial complex or tonic-clonic seizures
      4. Carries a poor prognosis with cognitive impairment
      5. Intractable seizures
   2. Presence of cortical "tubers" (O'Callaghan 2008)
      1. A pathognomonic sign.
      2. Tubers are developmental abnormalities of the cerebral cortex.
      3. The lesions have lost the normal six-layered laminar architecture of the cerebral cortex and contain dysplastic neurones, astrocytes, and characteristic giant cells.
      4. Tubers can be identified in fetal life and persist throughout life.
      5. Tubers do not increase in number after birth, although they may become more visible on magnetic resonance imaging as the brain myelinates in the first 2–3 years of life.
   3. Subependymal nodules (abnormal neuronal and glial elements): the most common cerebral lesion
   4. Cortical or subcortical white matter tubers (70% of cases)
      1. Composed of abnormal giant astrocytes.
      2. Found in 90% of patients with tuberous sclerosis.

3. Large cortical tubers may occasionally block the foramen of Monro resulting in hydrocephalus.
5. Subependymal giant cell astrocytomas
    1. The most common CNS tumors (6–14%).
    2. Subependymal nodules, small hamartoma lining the ventricles, may calcify.
    3. A radiologically confirmed cortical tuber or calcified subependymal nodule are highly suggestive of tuberous sclerosis.
    4. Rare malignant transformation of these astrocytomas, accounting for 25% of deaths in tuberous sclerosis.
6. Other abnormalities
    1. Cerebral atrophy
    2. Cerebral infarct
    3. Cerebral aneurysm
    4. Arachnoid cyst
    5. Chorea (rare manifestation) (Sha et al. 2009)

3. Developmental disorders (>50%) (Curatolo et al. 1991; Gutierrez et al. 1998)
    1. Childhood
        1. Learning disabilities
        2. Behavioral problems
        3. Pervasive developmental disorder
        4. Autism more common in childhood (Gillberg et al. 1994; Baker et al. 1998)
        5. Hyperactivity or attention deficit hyperactivity disorder (ADHD)
        6. Aggression
    2. Adulthood: mental retardation present in less than 50% of the affected individuals
4. TSC-associated neuropsychiatric disorders (Hunt and Dennis 1987; Ng et al. 2015)
    1. Behavioral
        1. Sleep disturbances
        2. Aggressive behaviors
        3. Temper tantrums
        4. Depressed mood
    2. Psychiatric
        1. Attention-deficit hyperactivity disorder
        2. Autism or autism spectrum disorder
        3. Depressive disorders
        4. Anxiety disorders
    3. Intellectual
        1. May function within normal range
        2. Severe to profound impairment of global intellectual ability
    4. Academic
        1. Reading skills
        2. Writing and spelling
        3. Mathematical skills
    5. Neuropsychological
        1. Attention deficits (selective attention, sustained attention, and attention switching)
        2. Executive deficits (planning, poor sequencing, perseveration)
        3. Receptive and expressive language deficits
        4. Memory deficits (working memory, episodic memory)
        5. Visuospatial deficits
    6. Psychosocial
        1. Psychological impact of disorder
        2. Self-esteem
        3. Family stressors
        4. Resillience factors
5. Ocular involvement (at least 50% of the patients)
    1. Retinal and optic nerve astrocytic hamartomas (the most frequent manifestations)
    2. Retinal phakoma
        1. Astrocytomas of the retina
        2. Often called “mulberry lesions”
        3. Absence of the normal “red reflex” in the newborn suggests the presence of retinal phakoma.
    3. Visual loss resulting from
        1. Macular hamartoma
        2. Vitreous hemorrhage
        3. Papilledema or optic atrophy secondary to intracranial tumors
    4. Rare sector hypopigmentation of the iris, vitiligo, or poliosis of the eyelid and eyelashes
6. Dental involvement: important findings
    1. Pitting of the dental enamel
        1. Invariably present in the permanent teeth
        2. Seen in the primary (deciduous) teeth (30%)

3. Rarely produce symptoms
2. Gingival angiofibromas (50% of children; 70% of adults)

7. Neoplasms affecting heart, kidneys, lungs, and other organ systems
   1. Cardiac rhabdomyomas (Caldemeyer and Mirowski 2001)
      1. The commonest cardiac tumors of childhood and are often associated with TSC
      2. The earliest diagnostic finding in some patients detected on prenatal sonography
      3. Detected by echocardiography, rarely causing problems
      4. Observed in two thirds of affected children. However, more than 80% of children with cardiac rhabdomyomas have tuberous sclerosis.
      5. Usually resolve spontaneously or regress with age
      6. A rare cause of prenatal and neonatal cardiac failure, mostly from dysrhythmias
      7. Rare tumor obstruction to cardiac valves or chambers
   2. Renal cysts or angiomyolipomas (70–80% of patients) (Stillwell et al. 1987; Ewalt et al. 1998; Martignoni et al. 2003)
      1. Bilateral multiple renal angiomyolipomas (70%)
         1. Diagnostic of tuberous sclerosis
         2. Renal angiomyolipomas are benign tumors but contain vascular tissue, which may cause bleeding, hypovolemic shock, and renal failure.
      2. Epithelial cysts (20%)
      3. Polycystic kidney disease (2–3%)
      4. Rare occurrence of renal cell carcinoma (<1%) (Al-Saleem et al. 1998)
      5. Malignant angiomyolipoma (<1%) (Al-Saleem et al. 1998)
      6. Benign adenomatous hamartoma (oncocytoma) (<1%)
      7. Lymphangioleiomyomatosis of the renal sinus: rare
   3. Pulmonary manifestations (Caldemeyer and Mirowski 2001)
      1. Lymphangio(leio)myomatosis (1–6% of patients) (Strizheva et al. 2001)
         1. Observed almost exclusively in young female patients, suggesting that a hormonal component is involved in the development of pulmonary sequelae (Lendvay and Marshall 2003)
         2. Affects between 26% and 39% of women with TSC
         3. Progressive, diffuse interstitial disease, detected by chest radiographs which show diffuse reticular pattern and multiple cyst lesions in the lungs
         4. Often complicated by pneumothorax from rupture of subpleural pulmonary cysts
         5. The end-stage disease shows "honeycomb" lungs.
         6. No effective treatment that reverse the progression of the lung disease (one of the causes of early mortality in TSC patients (Hancock and Osborne 2002))
      2. Multifocal micronodular pneumocyte hyperplasia (Vicente et al. 2004)
         1. Affects men and women
         2. May accompany lymphangioleiomyomatosis
   4. Hamartomas and polyposis of the stomach, intestine, and colon
      1. Almost never cause significant symptoms
      2. Occasional GI bleeding leading to positive tests for fecal occult blood
   5. Hepatic cysts and angiomyolipomas (up to 24%)
      1. Asymptomatic and nonprogressive
      2. Marked female predominance
   6. Vascular lesions (Salerno et al. 2010)
      1. Aneurysms
         1. Aorta
         2. Pulmonary artery
         3. Intracranial arteries (internal carotid, middle cerebral)
         4. Axillary artery
         5. Subclavian artery
         6. Iliofemoral artery

2. Stenotic-occlusive disease
    1. Aorta
    2. Common iliac artery
    3. Coronary artery
    4. Moyamoya disease
    5. Renal artery
    6. Mesenteric arteries
7. Arterial aneurysms reported in the brain, aorta, and axillary arteries
8. Musculoskeletal manifestations (Bernauer et al. 2001)
    1. Sclerotic and hypertrophic lesions of bone
        1. Mostly an incidental finding
        2. Occasionally palpable and associated with pains
        3. Common locations including calvarium, pelvis, vertebrae, and long bones
    2. Bone lucencies
        1. Nonspecific hamartomas
        2. Found in the phalanges of the hands and feet
        3. Usually asymptomatic
        4. Involvement in two thirds of patients
8. Pregnancy does not increase the risk of developing renal and pulmonary complications in women with tuberous sclerosis (Mitchell et al. 2003).
9. Diagnostic criteria of tuberous sclerosis complex (first proposed in 1992) (Avellino et al. 1997). The presence of one of the primary diagnostic criteria is considered sufficient to diagnose tuberous sclerosis complex.
    1. Primary features
        1. Facial angiofibromas
        2. Multiple ungula fibromas (or periungual fibromas in the absence of trauma)
        3. Cortical tuber (histologically confirmed)
        4. Subependymal nodule or giant cell astrocytomas (histologically confirmed)
        5. Multiple calcified subependymal nodules protruding into the ventricle (radiographic evidence)
        6. Multiple retinal astrocytomas (retinal hamartomas)
    2. Secondary features
        1. Affected first-degree relative
        2. Cardiac rhabdomyoma (histologic or radiographic confirmation)
        3. Other retinal hamartomas or achromic patch
        4. Cerebral tubers (radiographic confirmation)
        5. Noncalcified subependymal nodules (radiographic confirmation)
        6. Shagreen patch
        7. Forehead plaque
        8. Pulmonary lymphangiomyomatosis (histologic confirmation) (lymphangioleiomyomatosis)
        9. Renal angiomyolipoma (radiographic or histologic confirmation)
        10. Renal cysts (histologic confirmation)
    3. Tertiary features
        1. Hypomelanotic macules (three or more ash-leaf spots)
        2. "Confetti" skin lesions
        3. Renal cysts (radiographic evidence)
        4. Randomly distributed enamel pits in deciduous or permanent teeth
        5. Hamartomatous rectal polyps (histologic confirmation)
        6. Bone cysts (radiographic evidence)
        7. Pulmonary lymphangiomyomatosis (radiographic evidence)
        8. Cerebral white-matter "migration tracts" or heterotropias (radiographic evidence)
        9. Gingival fibromas
        10. Hamartoma of other organs (histologic confirmation)
        11. Infantile spasms
    4. Diagnostic criteria
        1. Definitive: either 1 primary, 2 secondary, or 1 primary plus 2 tertiary features
        2. Probable: either 1 secondary plus 1 tertiary or 3 tertiary features
        3. Suspect: either 1 secondary or 2 tertiary features
10. The Tuberous Sclerosis Consensus Conference: devised the above clinical diagnostic criteria in 1998 (Roach et al. 1992, 1998, 1999; Weiner et al. 1998; Lendvay and Marshall 2003)

1. Major features
    1. Facial angiofibromas or forehead plaque
    2. Nontraumatic ungual or periungual fibroma
    3. Hypomelanotic macules (three or more)
    4. Shagreen patch (connective tissue nevus)
    5. Multiple retinal nodular hamartomas
    6. Cortical tuber
    7. Subependymal nodule
    8. Subependymal giant cell astrocytoma
    9. Cardiac rhabdomyoma, single or multiple
    10. Lymphangiomyomatosis
    11. Renal angiomyolipoma
2. Minor features
    1. Multiple, randomly distributed pits in dental enamel
    2. Hamartomatous rectal polyps
    3. Bone cysts
    4. Cerebral white matter radial migration lines
    5. Gingival fibromas
    6. Nonrenal hamartoma
    7. Retinal achromic patch
    8. "Confetti" skin lesions
    9. Multiple renal cysts
3. Diagnostic criteria
    1. Definitive diagnosis: presence of two major features or one major feature plus two minor features
    2. Probable diagnosis: presence of one major feature plus one minor feature
    3. Possible diagnosis: presence of one major feature or two or more minor features

11. Tuberous Sclerosis Complex Diagnostic Criteria Update: Recommendations of the 2012 International Tuberous Sclerosis Complex Consensus Conference (Northrup & Krueger 2013)
    1. Genetic diagnostic criteria
        1. The identification of either a TSC1 or TSC2 pathogenic mutation in DNA from normal tissue is sufficient to make a definite diagnosis of tuberous sclerosis complex (TSC).
        2. A pathogenic mutation is defined as a mutation that clearly inactivates the function of the TSC1 or TSC2 proteins (e.g., out-of-frame indel or nonsense mutation), prevents protein synthesis (e.g., large genomic deletion), or is a missense mutation whose effect on protein function has been established by functional assessment (www.lovd.nl/TSC1, www.lovd/TSC2, and Hoogeveen-Westerveld et al. 2012, 2013).
        3. Other TSC1 or TSC2 variants whose effect on function is less certain do not meet these criteria, and are not sufficient to make a definite diagnosis of TSC.
        4. Ten percent to 25% of TSC patients have no mutation identified by conventional genetic testing, and a normal result does not exclude TSC, or have any effect on the use of clinical diagnostic criteria to diagnose TSC.
    2. Clinical diagnostic criteria: definite diagnosis (two major features or one major feature with two minor features); possible diagnosis (either one major feature or two minor features)
        1. Major features
            1. Hypomelanotic macules ($\geq$3, at least 5-mm diameter)
            2. Angiofibromas ($\geq$3) or fibrous cephalic plaque
            3. Ungual fibromas ($\geq$2)
            4. Shagreen patch
            5. Multiple retinal hamartomas
            6. Cortical dysplasias (includes tubers and cerebral white matter radial migration lines)
            7. Subependymal nodules
            8. Subependymal giant cell astrocytoma
            9. Cardiac rhabdomyoma
            10. Lymphangioleiomyomatosis (LAM)
            11. Angiomyolipomas ($\geq$2) (A combination of LAM and angiomyolipomas without other features does not meet criteria for a definite diagnosis)

2. Minor features
    1. "Confetti" skin lesions
    2. Dental enamel pits (>3)
    3. Intraoral fibromas (≥2)
    4. Retinal achromic patch
    5. Multiple renal cysts
    6. Nonrenal hamartomas

12. Prognosis
    1. The mild form of tuberous sclerosis: live full life without loss of function
    2. The severe form: significant morbidity and mortality from seizures, mental retardation, and associated cardiac, retinal, renal, and pulmonary pathology
    3. Renal disease: the most common cause of death (Shepherd et al. 1991)
    4. Association with sudden death (Byard et al. 2003; Noone et al. 2009)
        1. Cardiac arrhythmia
        2. Epilepsy
        3. Intratumoral hemorrhage
        4. Additional complications
            1. Cardiac outflow obstruction
            2. Obstructive hydrocephalus
            3. Aneurysm rupture
            4. Spontaneous pneumothorax

Diagnostic Investigations

1. Cutaneous evaluation including Wood's lamp
2. Ophthalmologic evaluation for hamartomas
3. Echocardiography to identify rhabdomyomas (Gibbs 1985; Smith et al. 1989; Jozwiak et al. 1994; Tworetzky et al. 2003)
4. ECG for cardiac arrhythmias (Curatolo et al. 1991)
5. EEG for seizures
6. Radiography of the skull (Caldemeyer and Mirowski 2001)
    1. Calcification frequently seen in subependymal nodules and giant cell astrocytomas.
    2. Less commonly seen in cortical and white matter tubers.
    3. Calcification increases with the age of the patient.
7. Plain chest radiographic films: diffuse reticular pattern in lymphangiomyomatosis of the lung
8. Pulmonary CT scan
    1. Diffuse interstitial changes with infiltrates.
    2. Cystic changes.
9. Body CT (Avila et al. 2010)
    1. The number of sclerotic bone lesions seen at body CT is of value in the diagnosis of TSC and in the differentiation of patients with sporadic lymphangioleiomyomatosis from those with TSC/lymphangioleiomyomatosis.
    2. The CT finding of multiple sclerotic bone lesions might be added to the diagnostic criteria of TSC.
10. Renal ultrasound/CT/MRI
    1. Assess angiomyolipomas
    2. Assess renal cysts
11. Neuroimagings by MRI or CT of the brain (Houser et al. 1991; Altman et al. 1988; Baron and Barkovich 1999)
    1. Calcification best detected on computed tomography
    2. Magnetic resonance imaging more sensitive for detecting small subependymal nodules and cortical and white matter tubers, especially when not calcified
        1. Extent and number of cortical tubers
        2. Subependymal gliomas
        3. Dilated lateral ventricles
        4. Hamartomatous foci
        5. Vascular dysplastic lesions such as aneurysms
        6. Identify subependymal giant cell astrocytomas before occurrence of obstructive hydrocephalus
12. Histologic findings
    1. Angiofibromas
        1. Atrophic sebaceous glands with dermal fibrosis and dilation of some capillaries
        2. "Glial" appearance of fibrosis due to the large size and stellate shape of the fibroblasts
        3. Absence of elastic tissue in the angiofibromas
    2. Ungual fibromas
        1. Fibrosis
        2. Rare capillary dilation

3. Shagreen patches
    1. Increased dense sclerotic mass of broad collagenous bundles
    2. Normal collagen bundles sometimes arranged in an interwoven pattern
    3. Reduced elastic tissue
4. Hypopigmented ash leaf macule
    1. Normal melanocytes numbers with decreased pigmentation
    2. Smaller melanosomes with defective melanization by electron microscopy

13. Molecular testing of the TSC1 and TSC2 genes: clinically available (Northrup et al. 2011)
    1. Complicated by the large size of the two genes, the large number of disease-causing mutations, and the high rate of somatic mosaicism (10–25%) (Sampson et al. 1997; Au et al. 1998a, b; Verhoef et al. 1999)
    2. Sequence analysis
    3. Deletion/duplication analysis: A deletion of the two contiguous genes (*TSC2* and *APKD1*) likely responsible if a child with tuberous sclerosis is found to have polycystic kidney disease (Brook-Carter et al. 1994)

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. One to 4% recurrence risk (in case of unaffected parents) due to germ line mosaicism and nonpenetrance of the disorder recommend a conservative recurrence risk of 2–3% for families with apparently sporadic tuberous sclerosis due to germline mosaicism (Rose et al. 1999)
        2. Fifty percentage if one of the parent is affected
    2. Patient's offspring: 50%
2. Prenatal diagnosis (Milunsky et al. 2009)
    1. Prenatal ultrasonographic detection of cardiac lesions consistent with rhabdomyoma
        1. Fifty percentage risk for tuberous sclerosis in the fetus
        2. Cardiac rhabdomyomas (Bader et al. 2003)
            1. The most common cardiac tumor diagnosed in utero and in children
            2. Favorable natural history of tumors detected prenatally: Most tumors regress after the third trimester.
            3. In rare cases, there is progression in utero with a fetal demise risk of 4–6%.
    2. Prenatal MRI imaging: 2nd trimester diagnosis of subependymal tubers (Levine et al. 2000)
    3. Prenatal diagnosis/preimplantation genetic diagnosis for at-risk pregnancies requires prior identification of the disease-causing mutation in the family.
3. Management (Muller 2001; Franz 2014)
    1. Multidisciplinary team approach
    2. Early intervention programs
    3. Assess intellectual function and educational needs
    4. Psychiatric and behavioral problems (Muzykewicz et al. 2007)
        1. The most common formal diagnoses were anxiety disorders (28%), mood disorders (26%), adjustment disorders (21%), ADHD (21%), and mental disorders not otherwise specified due to general medical condition (42%).
        2. Citalopram demonstrated efficacy in treating anxiety and depression.
        3. Risperidone, in treating problematic behaviors.
    5. Pharmacologic management of behavioral problems
    6. Treat cardiac failure or cardiac arrhythmias
    7. Anticonvulsants for seizure control
        1. Treatment for infantile spasm is difficult because it is often intractable to conventional antiepileptic drugs.
            1. ACTH among other anticonvulsant therapies with variable benefits.
            2. Vigabatrin (Hancock and Osborne 1999).
        2. Early control of seizures has a crucial role in preventing subsequent epileptic

encephalopathy, and in reducing the cognitive/behavioral consequences of seizures, but does not guarantee for a normal mental outcome in children with TSC (Bombardieri et al. 2010).

8. Rapamycin and clinical trials (Orlova and Crino 2010)
    1. Rapamycin
        1. A macrolide antibiotic that has important regulatory effects on cell growth, proliferation, and inflammation via its inhibitory action on mammalian target of rapamycin
        2. Has been used as an immunomodulatory agent following organ transplantation and has a moderate-risk side effect profile
    2. Both preclinical and clinical trial data suggest that rapamycin may provide a possible therapy for TSC: The benefits may only be realized during active therapy.
        1. Reduction of angiomyolipomas volume
        2. Modest improvement of pulmonary function testing
9. Surgical care
    1. Laser treatment of facial angiofibromas
    2. Removal of ungual fibromas by laser, diathermy, liquid nitrogen, or dermabrasion
    3. CSF shunting to relief raised intracranial pressure
    4. Epilepsy surgery (Baumgartner et al. 1997): Unifocal onset seizures and mild to no developmental delay at the time of surgery are predictive of excellent long-term outcome (Jarrar et al. 2004)
        1. Focal cortical resection (tuberectomy)
        2. Lobar or multilobar resection
        3. Corpus callosotomy
    5. Vagus nerve stimulation
    6. A partial nephrectomy or selective embolization preferable to total nephrectomy for treating angiomyolipomata
    7. Cystic renal lesions rarely required surgery
    8. Renal transplantation for end-stage renal insufficiency resulting from replacement of renal parenchyma by angiomyolipomas and growing cysts or from the removal of the kidneys for intractable hemorrhage (Papaioannou et al. 2003)
        1. Offers prolonged survival
        2. Appears to be the treatment of choice in such patients
4. Updated treatment recommendations (de Waele et al. 2014)
    1. Renal manifestations
        1. In the case of angiomyolipomas larger than 3.5–4 cm, renal arterial embolization followed by corticosteroids, or kidneysparing surgery, is used to avoid total nephrectomy.
        2. Pharmacological intervention using mTORi (mammalian target of rapamycin inhibitor) can obviate the need for surgery by reducing angiomyolipoma volume.
    2. Extrarenal manifestations
        1. Traditionally, the management of SEGA (subependymal giant cell astrocytomas) that are growing and/or causing clinical signs of intracranial hypertension or unexplained changes in neurological status or TAND (TSC-associated neuropsychiatric disorders) symptoms was surgical resection.
        2. SEGA surgery is associated with significant morbidity such as hemiparesis, hydrocephalus, intracranial bleeding, infection, precocious puberty, neuropathic headache and cognitive decline, and mortality (6.2%).
        3. Surgical resection should be performed for acutely symptomatic SEGA.
        4. For growing but otherwise asymptomatic SEGA, either surgical resection or treatment with mTORi can be effective. mTORi also have beneficial effects on all the other clinical features of TSC. In selected LAM patients with moderate-to-severe lung disease or rapid progression, treatment with an mTORi may be used to stabilize or improve lung function, quality of life, and functional performance.

5. Everolimus is approved by the European Medicines Agency (EMA) and the Food and Drug Administration (FDA) for use in TSC patients with SEGA requiring therapeutic intervention who are not amenable to surgery.
6. Topical treatment of facial angiofibromas with sirolimus has extensively been reported to yield positive results.
7. Recently, it has been demonstrated that everolimus has a partial effect on epilepsy, decreasing the frequency and severity of seizures.

Fig. 1 (**a**, **b**) An ash leaf spot is observed in a child affected with tuberous sclerosis, inherited from his mother who has characteristic facial angiofibromas with symmetrical "butterfly" distribution on the nasolabial folds and cheeks

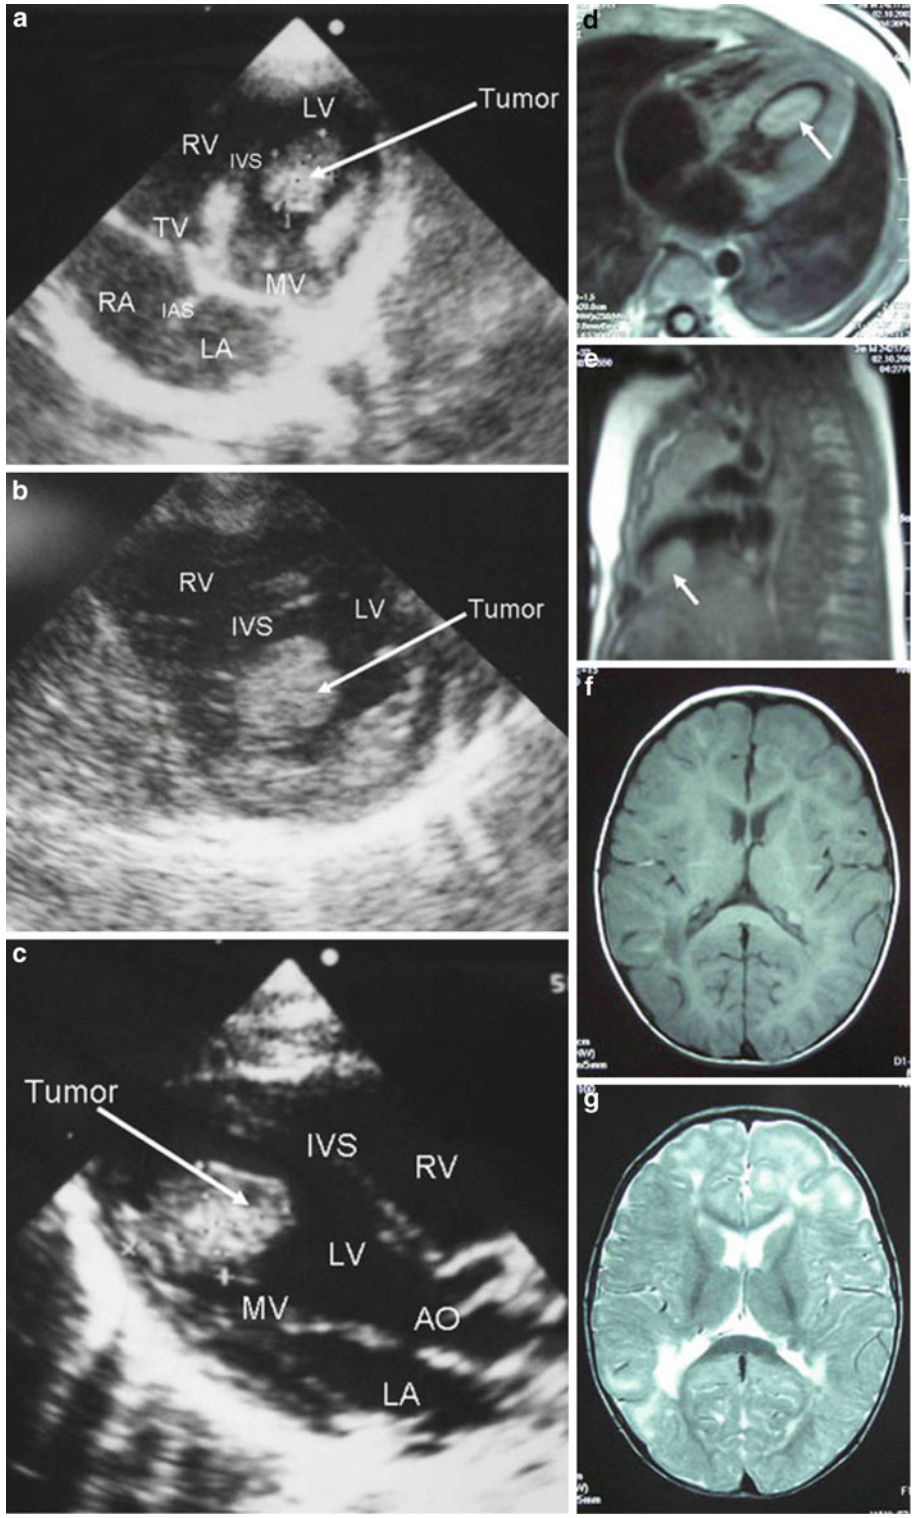

Fig. 2 A 3-month-old infant was found to have small angiofibromatous skin lesions on the cheek, two depigmented spots on the back, and a white round lesion in the left fundus. Echocardiography showed a tumor

Fig. 3 (**a**, **b**) Severe facial angiofibromas in symmetrical butterfly distribution over nose and cheek with a large forehead plaque. Some angiofibromas have become confluent and fungating lesions

Fig. 2 (continued) (measured 2 × 1 cm) in the left ventricular cavity (**a**, four chamber view; **b**, short axis view; **c**, long axis view). MRI with T1-enhanced images (**d**, **e**) showed the same rhabdomyoma (*arrow*) in the left ventricular cavity. T1-enhanced (**f**) and T2-enhanced (**g**) images of the brain showed many lesions at subcortical white matter indicated by high or low signals. Some lesions can be seen in the periventricular region. Abbreviations: AO *aorta*, IAS *interatrial septum*, IVS *interventricular septum*, LA *left atrium*, LV *left ventricle*, MV *mitral valve*, RA *right atrium*, RV *right ventricle*, TV *tricuspid valve*

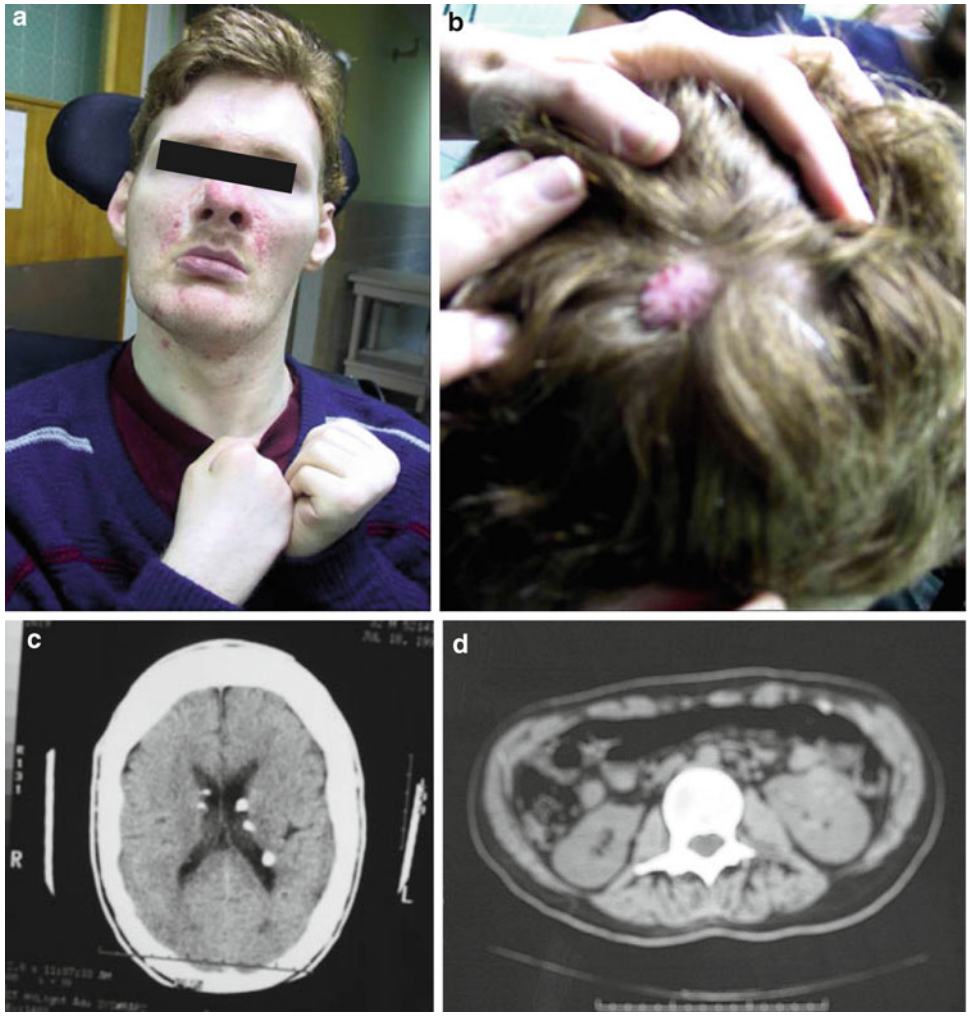

Fig. 4 (**a**–**d**) An adult with tuberous sclerosis showing typical facial angiofibromas and a scalp plaque. CT of the brain showed presence of calcified subependymal nodules. CT scan of the abdomen demonstrates an enlarged left kidney. Histologic examination of the tumor showed renal cell carcinoma

Fig. 5 (**a**, **b**) Two adults with tuberous sclerosis showing typical facial angiofibromas and mental retardation

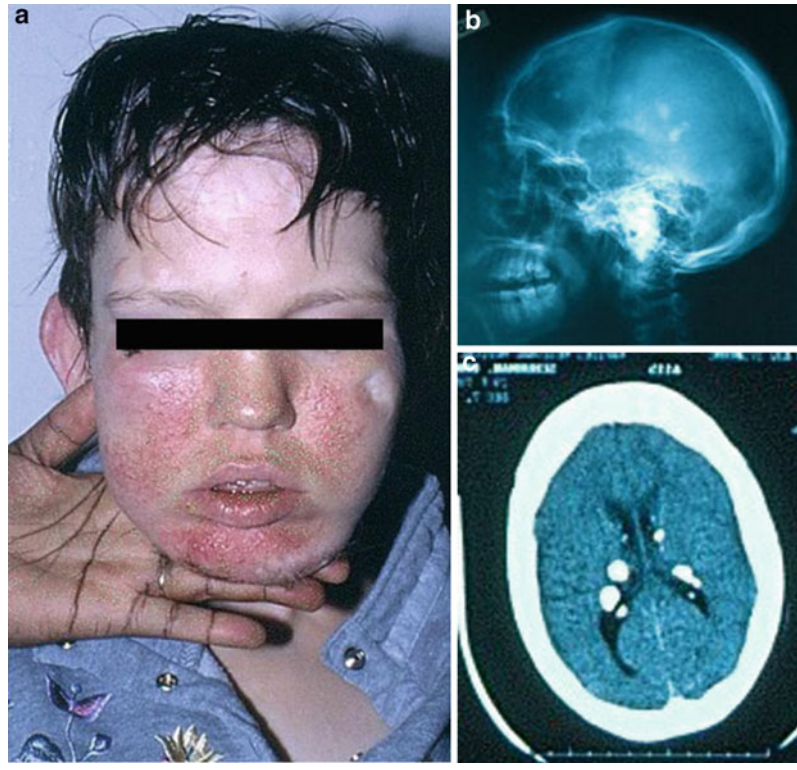

Fig. 6 (**a**–**c**) An adult with tuberous sclerosis with typical facial angiofibromas and mental retardation. A plain skull X-ray film and a CT of the brain demonstrated intracranial calcifications

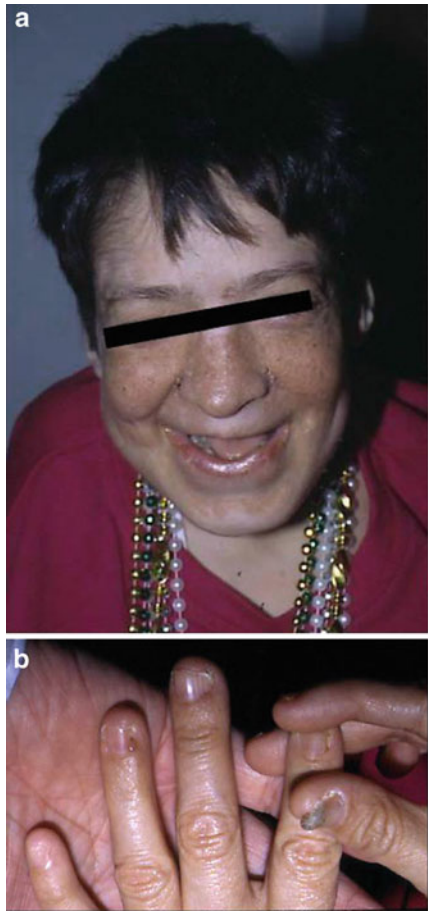

Fig. 7 (**a**, **b**) An adult with tuberous sclerosis showing typical facial features. Periungual (*fourth finger*) and ungual (*thumb*) fibromas were present

Fig. 8 (**a**–**c**) An adult with tuberous sclerosis showing typical facial angiofibromas, a scalp plaque, and a large depigmented lesion on the back

Fig. 9 (**a**, **b**) Shagreen patches are seen in upper back and lower back in two different patients with tuberous sclerosis

Fig. 10 (**a**–**f**) A 10-year-old female was hospitalized for papilledema and was subsequently diagnosed with the brain tumor (subependymal giant cell astrocytoma). She has tuberous sclerosis with facial angiofibromas (**a**), hypopigmented macules on antecubital, scapular, and leg regions (**b**–**d**), and Shagreen patches in the lumbar and sacral areas (**e**–**f**) (Courtesy of Dr. Susonne Ursin)

Turner Syndrome

Contents

In *1938*, Turner (1938) reported a syndrome of sexual infantilism, short stature, webbed neck, cubitus valgus, and primary amenorrhea in seven female patients. Later in 1954, it was observed that the ovaries were usually replaced by streaks of stroma without follicles; hence, the name gonadal agenesis. Negative sex chromatin was discovered in 1954; only one X chromosome was demonstrated cytogenetically in these patients in 1959.

About 99% of 45,X fetuses abort spontaneously, usually before 28 weeks, and only 1% of these fetuses survive to term. Despite this, Turner syndrome is a relatively common chromosome disorder affecting 1 in 2,500 female live births. About 10% of all spontaneous abortuses have a 45,X karyotype.

Synonyms and Related Disorders

45,X Turner syndrome; 45,X/46,XX mosaic Turner syndrome; 45,X/46,X,r(X) ring chromosome X mosaic Turner syndrome; 46,X,i(X)(q10) isochromosome Xq syndrome.

Genetics/Basic Defects

1. Caused by complete or partial X chromosome monosomy in all or some of the body cells.
2. Short stature and skeletal manifestations (short fourth metacarpals, cubitus valgus, Madelung deformity, high-arched palate, and short neck) are attributed to haploinsufficiency of the *SHOX*, the short-stature homeobox-containing gene on the pseudoautosomal region of the sex chromosomes (Xp22 and Yp11.3). *SHOX* gene is also known as *PHOG* gene (Ellison et al. 1997) for pseudoautosomal homeobox-containing osteogenic gene, lying on the very tip of the short arm of both sex chromosomes (Binder et al. 2000).
3. Involvement of SHOX in idiopathic growth retardation and in the short stature phenotype of Turner syndrome patients (Rao et al. 1997).
4. Estrogens exert a maturational effect on skeletal tissues that are susceptible to premature fusion of growth plates because of haploinsufficiency of *SHOX*, facilitating the

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_238

development of skeletal lesions (Kosho et al. 1999).

5. Chromosome locus (Wolff et al. 2010).
    1. A majority of genes associated with the physical features observed in Turner syndrome are located on Xp (Xp11.2-p22) (Zinn et al. 1998).
    2. Loci contributing to ovarian function reside in Xq (Xq24) (Schlessinger et al. 2002).
6. Karyotype findings associated with Turner syndrome (Wolff et al. 2010)
    1. Prenatal
        1. Approximately 1–2% of conceptuses have a 45,X karyotype.
        2. The fetuses typically have ultrasound findings such as cystic hygroma or nuchal thickening.
        3. A majority of cases with mosaicism for a 45,X cell line and a cell line with a second structurally normal sex chromosome result in the birth of a child with a normal phenotype (Chang et al. 1990; Koeberl et al. 1995).
    2. Postnatal
        1. Apparently nonmosaic monosomy X is found in 45% of patients with Turner syndrome postnatally.
        2. A structural chromosome abnormality or mosaicism for 45,X and another cell line is found in the lymphocytes of the remaining patients with Turner syndrome.
7. Chromosome mosaicism in Turner syndrome (Fernández et al. 1996)
    1. A molecular investigation of 25 patients who had Turner syndrome and who had previously been subject to analysis using cytogenetic techniques.
    2. When in situ hybridization and polymerase chain reaction (PCR) techniques were applied, a larger number of mosaic individuals were observed than were detected by cytogenetic methods.
    3. This was mainly because of the presence of the cell line 46,XX.
    4. The most frequent mosaics.
        1. 45,X/46,XX (36%).
        2. The presence of isochromosomes comprised 24% and fragments 12%.
        5. The patients who had been previously diagnosed with mosaicism displayed a higher complexity in their karyotypes because of the presence of new cellular lines.
        6. The isodicentric X chromosome for the long arm, idic(Xq), gave rise to complex mosaics of up to nine cell lines.
        7. The application of fluorescence in situ hybridization and PCR led to a clearer definition of alterations at the centromeric level and the identification of the nature of chromosome fragments.
8. Review of new data supports the hypothesis that all viable 45,X cases are cryptic mosaics with a rescue cell line, implying an origin by mitotic loss (Hook and Warburton 2014).
9. Presence of Y chromosome material (Wolff et al. 2010).
    1. Mosaicism for a cell line with a normal or abnormal Y chromosome is identified in 6–11% of patients with Turner syndrome with standard cytogenetic techniques.
    2. 45,X/46,XY mosaicism can present with a wide variety of phenotypes (Rosa et al. 2014).
    3. The great majority of structurally abnormal Y chromosomes found in Turner syndrome mosaics contain two copies of virtually all of the functional Y chromosome euchromatin (Robinson et al. 1999).
    4. Risk of developing gonadoblastoma (Page 1994; Cools et al. 2006).
        1. A gonadoblastoma is a neoplasm composed of germ cells and sex cord elements with an excellent prognosis if detected early.
        2. Gonadoblastoma can progress to dysgerminoma with metastatic potential.
        3. A gonadoblastoma susceptibility locus has been proposed for the pericentromeric region of the Y chromosome (Tsuchiya et al. 1995; Lau 1999).
        4. The neoplasm does not appear to correlate with the presence of *SRY*.

5. Presence of occult Y chromosome mosaicism.
    1. Eight percentage of cases detected by molecular or standard cytogenetic techniques: Of these 12% of cases had gonadoblastoma
    2. Zero to four percentage of cases detected by FISH using a probe for the Y centromere (DYZ3) (Hanson et al. 2002; Wiktor and Van Dyke 2005)

10. Pathogenesis (Ogata and Matsuo 1995)
    1. Gonadal dysgenesis: Oocytes undergoing accelerated degeneration during the first meiosis, resulting in loss of nearly all oocytes by late childhood
    2. Somatic stigmata
        1. Lymph fluid stasis caused by lymphatic hypoplasia results in distension of the main and tributary lymphatic ducts and generalized lymphedema.
        2. Distended lymphatics and lymphedema cause mechanical extension of surrounding tissues, giving rise to deformations recognized as lymphatic obstruction stigmata:
            1. Webbed neck
            2. Low posterior hairline
            3. Rotated auricles
            4. Puffy hands and feet
            5. Redundant skin
            6. Nail hypoplasia
            7. Whorl dominant fingertip pattern

11. Phenotype-karyotype correlation
    1. Phenotype results from haploid dosage of genes that are common to the X chromosome that escape X inactivation (Zinn et al. 1993).
    2. Absence or deletion of the short arm of the X chromosome correlates with Turner stigmata (Ogata et al. 2001):
        1. Short stature
        2. Broad chest
        3. Widespread nipples
        4. Webbing of the neck
        5. Peripheral lymphedema at birth
        6. Short fourth metacarpals
        7. Hypoplastic nails
        8. Multiple pigmented nevi
        9. Coarctation of the aorta
    3. Absence or deletion of the long arm of the X chromosome correlates with infertility and gonadal dysgenesis.
    4. The degree of mosaicism correlates with the presence of clinical features of Turner syndrome.
    5. Severe phenotype associates with a small or tiny ring X chromosome which lacks the *XIST* (X-inactive-specific transcript) at Xq13 (Cervantes et al. 2001):
        1. Loss of *XIST* results in functional X disomy for the sequences contained in the ring.
        2. Some r(X), ascertained because of severe phenotypes, undergo X inactivation.
    6. The severe phenotype of females with tiny ring X chromosomes is associated with inability of these chromosomes to undergo X inactivation (Migeon et al. 1994, 2000).
    7. Mental retardation in patients with a small ring X chromosome (Van Dyke et al. 1992).
        1. High risk of mental retardation results from lack of lyonization of the ring X due to loss of the X inactivation center.
        2. Excluding those with a small ring X, mental retardation is not significantly increased in patients with Turner syndrome.
    8. Unexpected mild phenotype in some cases with ring(X) chromosome (Turner et al. 2000).
    9. A comparison of the clinical and cytogenetic findings in nine patients with a ring (X) cell line and 16 45,X patients (Collins et al. 1994).
        1. The ring (X) patients lacked many of the “classic” Turner’s syndrome features and the majority were not karyotyped until after the age of 11, usually because of pubertal failure.
        2. They also showed a reduction in IQ of 11 points compared with the 45,X group.

3. Some ring (X) patients show characteristic facial features
    1. A broad nose with anteverted nostrils
    2. Prominent philtrum
    3. Long palpebral fissures
    4. A wide mouth with a thin upper lip
4. Neither the physical features nor the IQ are related to the parental origin of the chromosome error.
5. In the majority of cases, the ring (X) chromosome was late replicating.

12. Cytogenetic findings in a consecutive series of 478 patients with Turner syndrome (Kleczkowska et al. 1990)
    1. Classic, 45,X karyotype (52.1%)
    2. Mosaic 45,X/46,XX (10.9%)
    3. Mosaic 45,X/47,XXX and other "superfemale" cell lines (4.6%)
    4. Isochromosomes i(Xq) and i(Xp) (16.1%)
    5. Ring chromosomes r(X) (4.4%)
    6. Other structural aberrations of the X chromosome (7.7%)
    7. Mosaic 45,X/46,XY patients (4%)
13. A cytogenetic and molecular study of 211 patients with clinical diagnosis of Turner syndrome (Jacobs et al. 1997)
    1. Cytogenetic study.
        1. 97 patients to have a 45,X constitution
        2. 15 to be 45,X/46,XX or 45,X/47,XXX mosaics
        3. 86 to have a structurally abnormal X
        4. 13 to have a structurally abnormal Y chromosome
    2. Molecular methods were used to look for cryptic X and Y chromosome mosaicism in patients with a 45,X constitution.
        1. Two cryptic X but no cryptic Y mosaics were detected.
        2. In 74% of the 45,X patients, the X was maternal in origin.
        3. The i(Xq)s were approximately equally likely to involve the paternal or maternal chromosome, while the majority of deletions and rings and virtually all the abnormal Y chromosomes were paternal in origin.
        4. The preponderance of paternal errors in Turner syndrome may result from the absence of pairing along the greater part of the XY bivalent during paternal meiosis I, which may make the sex chromosomes particularly susceptible to both structural and nondisjunctional errors during male gametogenesis.
14. Mother and daughter with 45,X/46,X,r(X) (p22.3q28) and mental retardation (Matsuo et al. 2000)
    1. One or more of these MRX (X-linked mental retardation) genes, subject to X-inactivation, are lost from the ring X chromosome.
    2. The reduced expression of the MRX gene (s) caused by random X-inactivation has resulted in mental retardation in the mother and daughter.

Clinical Features

1. Skeletal manifestations (Hall and Gilchrist 1990; Ogata and Matsuo 1995; American Academy of Pediatrics. Committee on Genetics. 1995)
    1. Short stature (100%): an invariant feature in the 45,X Turner syndrome
    2. Characteristic growth pattern
        1. Intrauterine growth retardation
        2. Progressive decline in growth velocity in childhood
        3. Lack of pubertal growth spurt
        4. Delayed growth cessation
    3. Cubitus valgus
    4. Madelung deformity of the wrist (a bayonet-like deformity of the wrist) with decreased extension and supination as a presenting sign of Turner syndrome (Schwartz and Summer 2000)
    5. Hypoplastic nails
    6. Short fourth metacarpals
2. Characteristic craniofacial features
    1. Down slanting of the palpebral fissures
    2. Epicanthal folds
    3. Occasional ptosis and strabismus

4. Midfacial hypoplasia
5. Broad nasal bridge
6. High-arched palate
7. Micrognathia
8. Rotated auricles

3. Teeth
   1. Crowding
   2. Malocclusion
4. Neck
   1. Short and broad neck
   2. Webbed neck (pterygium colli) with low posterior hairline from the resolution of the cystic hygroma that was present in fetal life
5. Chest
   1. Shield chest
   2. Increased internipple distance (Chen et al. 1974)
6. Congenital heart defects (26%) (Subramaniam 1989; Gøtzsche et al. 1994; Mortensen et al. 2012; Granger et al. 2016)
   1. Aortic valve abnormalities (18%)
      1. Bicuspid aortic valve
      2. Partially fused and unicuspid aortic valves
   2. Aortic stenosis
   3. Coarctation of the aorta (10%)
   4. Aneurysm (aortic root dilatation)
   5. Cystic medial necrosis of the aorta
7. Vascular anomalies
   1. Multiple intestinal telangiectasia
   2. Hemangiomas
   3. Lymphangiectasia
   4. Venous ectasias
   5. Intermittent and recurrent gastrointestinal bleeding
   6. Protein-losing enteropathy secondary to gastrointestinal lymphangiomas
   7. Chylous fluid accumulation in the abdomen and chest
8. Lymphatic phenotype in Turner syndrome (Atton et al. 2015)
   1. Peripheral lymphedema in the newborn infant involves dorsum of the hands and feet
   2. The majority of patients presented at birth with four-limb lymphedema, which often resolved in early childhood, but frequently recurred in later life.
   3. The swelling was confined to the legs and hands with no facial or genital swelling.
   4. There was only one case of suspected systemic involvement (intestinal lymphangiectasia).
   5. The lymphoscintigraphy results suggest that the lymphatic phenotype of Turner syndrome may be due to a failure of initial lymphatic (capillary) function.
9. Nail dysplasia
   1. Concave fingernails
   2. Upturned toenails
10. Skin
    1. Redundant skin
    2. Multiple pigmented nevi
    3. Tendency of hypertrophic scarring or keloid formation
11. Gonadal dysgenesis
    1. Sexual infantilism: one of the most common clinical findings
    2. Primary amenorrhea (the rule)
    3. Spontaneous menstruation occurring in about 5% of patients. Some of these women even give birth (3–5%).
    4. Delayed pubertal development in most patients
    5. Up to 30% of patients with at least some pubertal development indicating the presence of follicles in their ovaries in adolescence (Hreinsson et al. 2002)
    6. A high frequency of miscarriage reported among the spontaneous pregnancies of women with Turner syndrome
    7. Progressive ovarian failure
    8. Infertility/sterility
12. Genitourinary lesions
    1. Horseshoe and ectopic kidneys
    2. Ovarian abnormalities (Granger et al. 2016)
       1. Streak ovaries
       2. Ovarian failure
    3. Ureteropelvic obstruction
    4. A double collecting system
    5. A bifid renal pelvis
    6. Hydronephrosis
    7. Vaginal agenesis: rare
13. Hypertension (common even without cardiac or renal malformations)

14. Conductive and sensorineural hearing losses
15. Autoimmune disease
    1. A markedly increased incidence of thyroid antibodies
    2. Lymphocytic thyroiditis (Chen et al. 1978)
    3. Autoimmune hypothyroidism
    4. Impaired serum glucose tolerance in 25–60% of patients
    5. Diabetes mellitus in 5% of patients
    6. An increased incidence of inflammatory bowel disease
        1. Regional enteritis
        2. Ulcerative colitis
    7. Rheumatoid arthritis
    8. Acute hyperthyroidism: rare
16. Patients with Turner syndrome are extraordinarily prone to abnormalities constituting the metabolic syndrome (Gravholt et al. 1998)
    1. Ischemic heart disease, hypertension, and stroke
    2. Dyslipidemia
    3. Insulin-dependent and noninsulin-dependent diabetes mellitus
    4. Obesity
    5. Hyperinsulinemia
    6. Hyperuricemia
17. Abnormal dermatoglyphics
    1. Predominant digital whorls
    2. Distal triradii
18. Psychosocial aspects (Chen et al. 1981)
    1. Significantly higher verbal level than performance level attributed to a specific space-form perception deficit
    2. Arithmetic subtests: most difficult among verbal subtests
    3. Difficulty in performance
        1. Reading
        2. Figure drawing
        3. Geometry
        4. Arithmetic
19. Presence of Y chromosome material in some cases of Turner syndrome
    1. A high risk of developing gonadoblastoma and dysgerminoma
    2. Requiring preventive removal of the dysgenetic gonads
20. Mosaic patients with a structurally abnormal X chromosome
    1. Classic Turner phenotype
        1. X-derived marker in majority of cases
        2. Usually a large ring X chromosome that includes *XIST* not associated with a severe phenotype, although a low IQ or even mental retardation has been observed in some cases
    2. Severe phenotype
        1. Mental retardation
        2. Dysmorphic features uncharacteristic of Turner syndrome
        3. Observed in patients associated with a small or tiny ring X chromosome lacking the *XIST* gene at Xq13
21. Mosaicism in 45,X Turner syndrome (Held et al. 1992)
    1. In vivo selection of structurally altered sex chromosomes exists.
    2. Thus, the observation of apparent nonmosaic 45,X chromosomal complements in liveborn individuals with Turner syndrome does not contradict the hypothesis that some degree of mosaicism is necessary for survival in early pregnancy.
22. Postnatal outcomes of prenatally diagnosed 45,X/46,XX (Tokita and Sybert 2016)
    1. Relative to those diagnosed postnatally, prenatal patients were more likely to have normal growth and normal secondary sexual development, less likely to manifest distinctive Turner syndrome features such as nuchal webbing and edema, and had significantly fewer renal defects.
    2. These differences underscore the need for a nuanced approach to prenatal counseling in cases of 45,X/46,XX mosaicism.

Diagnostic Investigations

1. Endocrine study
    1. Very low estrogen levels.
    2. Elevated pituitary gonadotrophins after puberty.
    3. The majority of Turner syndrome patients suffer from accelerated loss of primordial follicles. Low circulating levels of anti-

Müllerian Hormone (AMH) may predict lack of spontaneous puberty in prepubertal girls and imminent premature ovarian insufficiency in Turner syndrome women with preserved ovarian function (Lunding et al. 2015).

2. Karyotype analyses
    1. 45,X
        1. Observed in 50% of cases
        2. Maternal origin of the X chromosome in two thirds of cases
    2. Structurally abnormal sex chromosome, such as i(Xq)
    3. Mosaicism with a second cell line containing a normal or abnormal X or Y
        1. Most common forms of mosaicism (Saenger et al. 2001)
            1. 45,X/46,XX
            2. 45,X/46,X,i(Xq)
        2. Containing a sex marker chromosome in about 20% of cases
            1. Sex marker chromosome: usually an X chromosome
            2. Second cell line containing a structurally abnormal Y chromosome in 6% of cases
    4. Determination of the chromosomal origin of sex marker chromosomes
        1. Fluorescence in situ hybridization (FISH)
        2. Primed in situ labeling (PRINS) diagnostic for repetitive sequences in specific human chromosomes
    5. Painting probes and libraries and PCR to detect "hidden" mosaicism (Fernández-García et al. 2000; De Oliveira et al. 2009)
        1. Classical alpha-satellite probes for the X (CEP-X) chromosome and Y chromosomes (CEP-Y) (Vysis)
        2. Whole chromosome painting probes (WCP-X, WCP-Y) (Vysis)
        3. XIST-digoxigenin (Oncor) hybridizing specifically to Xq13.2 indicating the X-inactivation center
        4. DXZ4-biotin (Oncor) hybridizing specifically to a cluster of 50–100 copies of a 3-kb repeat in the Xq24 region
        5. Subchromosomal painting libraries (SCPL116 specific for the short arm of the X chromosome, SCPL102 specific for the long arm of the X chromosome)
        6. Using PCR to detect Y chromosome-specific sequences
3. Molecular diagnosis of Turner syndrome (Gicquel et al. 1992)
    1. DNA analysis appears to be a useful and rapid tool in screening for Turner's syndrome.
    2. It could be an alternative to cytogenetic analysis in diagnosing the disorder when severe growth retardation or delayed puberty are not accompanied by a Turner phenotype.
4. Cytogenetic and molecular analysis of sex-chromosome monosomy (Hassold et al. 1988)
    1. The level of mosaicism is much higher among live-born than among spontaneously aborted 45,X conceptions, as has been noted by other investigators (Hook and Warburton 1983).
    2. This suggests that the extraordinarily high in utero lethality of the 45,X condition is largely restricted to those cases lacking a second cell line and implies that most, if not all, live-born 45,X's are mosaics (Hook and Warburton 1983).
    3. This suggestion is supported by recent molecular analyses that have detected Y-chromosome mosaicism among Turner syndrome individuals previously classified as being "pure" 45,Xs on cytogenetic examination (Muller et al. 1987).
    4. Continued use of X chromosome- and Y chromosome-specific probes to study mosaicism will determine the extent to which the presence of a second cell line affects survival of 45,X conceptions.
5. Identification of specific X and Y sequences
    1. Important for establishing phenotype-karyotype correlations
    2. Important for adequate genetic counseling
    3. PCR to identify the presence or absence of specific Y sequences

6. Echocardiography for cardiovascular malformations
7. Renal ultrasound for renal anomalies
8. Radiography (Finby and Archibald 1965; Lesczynki and Kosowica 1965)
    1. Madelung deformity
        1. Prominent and dorsally dislocated but reducible distal ulna
        2. Short and bowed radius
        3. Carpal articular surface of the radius tilted in a volar and ulnar direction producing a triangular configuration and premature fusion of the ulnar side of the radial growth plate
    2. Short fourth metacarpals and metatarsals
    3. Short distal phalanges with tufting
    4. Carpal bone fusion
    5. A coarse, reticular pattern of the carpal bones: more reliable and specific on hand and wrist films (Bercu et al. 1976)
    6. Pes cavus
    7. Irregular tibial metaphyses with mushroom projections on the medial surface of the proximal tibial metaphyses
    8. Spine
        1. Schmorl's nodes (abnormalities of cartilaginous end plates)
        2. Scheuermann's disease of the vertebrae (osteochondrosis of vertebral epiphyses in juveniles)
        3. Scoliosis
        4. Lack of lumbar lordosis
        5. Congenital hip dislocation
    9. Skull
        1. Midfacial hypoplasia
        2. An obtuse cranial base angle
        3. Short cranial base
    10. Osteoporosis
9. Other investigations
    1. Blood pressure measurement for hypertension
    2. Thyroid function
    3. Routine otological and audiologic follow-up of patients with Turner syndrome for conductive and sensorineural hearing loss is warranted from the time of diagnosis (Güngör et al. 2000)
    4. Orthodontic evaluation
    5. Orthopedic evaluation
    6. Glucose intolerance

Genetic Counseling

1. Recurrence risk: The mode of inheritance is sporadic.
    1. Patient's sib: low
    2. Patient's offspring: rarely pass to offspring due to infertility
2. Prenatal diagnosis
    1. Maternal serum screening
        1. Slightly decreased levels of α-fetoprotein and unconjugated estriol
        2. Elevated hCG and inhibin A
    2. Ultrasonographic screening (Hunter et al. 1982)
        1. Fetal hydrops
        2. Increased nuchal translucency
        3. Fetal cystic hygroma
        4. Fetal ascites
        5. Coarctation of the aorta
        6. Left-sided cardiac defects
        7. Brachycephaly
        8. Lymphedema
        9. Renal anomalies
        10. Intrauterine growth retardation
        11. Polyhydramnios
        12. Oligohydramnios
    3. Elevated second-trimester maternal serum β-human chorionic gonadotropin and amniotic fluid alpha-fetoprotein as indicators of adverse obstetric outcomes (high risk of fetal death) in fetal Turner syndrome (Alvarez-Nava et al. 2015)
    4. Karyotype of fetal cells from amniocentesis or CVS using standard cytogenetic, FISH, or microarray analysis
        1. A karyotype consistent with diagnosis of Turner syndrome
        2. Phenotype of the individual cannot be predicted based on the karyotype
        3. Follow laboratory guideline recommendations for prenatal diagnosis of Turner syndrome (Wolff et al. 2010)

3. Management (Sybert 2001; Davenport 2010)
    1. Health supervision: This set of guidelines is designed to assist the pediatrician in caring for the child in whom the diagnosis of Turner syndrome has been confirmed by karyotype (American Academy of Pediatrics. Committee on Genetics 1995).
    2. The prevalence of aortic dilatation and cardiac disease in Turner syndrome is high and the risk of aortic dissection increases with age. This must be carefully followed (Levitsky et al. 2015).
    3. Psychosocial counseling
        1. Degree of parental understanding and appropriate attitudes toward the patient with Turner syndrome depends, in general, on good family relationships, socioeconomic level of the family, and appropriate physician's counseling
        2. Short stature: a major concern when entering school
        3. Pubertal failure and sterility: major concerns to the parents and patients at pubertal age
        4. Webbed neck less frequent concern cosmetically unless that defect is marked and visible
        5. Occasional parental rejection and over protectiveness
        6. Child's adjustment to the disease influenced by parental personalities and their ability to cope with the implications of the syndrome
        7. Development of a high degree of social competency permitting patients to be integrated into a society where they will be self-sufficient and self-sustaining
    4. Psychosocial and sexual functioning in women with Turner syndrome (Pavlidis et al. 1995)
        1. Health status was associated with self-concept.
        2. Sexual satisfaction was related to both a higher frequency of intercourse and a higher self-reported health status.
    5. Bone fragility is recognized as one of the major lifelong comorbidities in TS (Turner syndrome) subjects (Faienza et al. 2016).
        1. The pathogenetic mechanisms responsible of bone impairment remain to be well clarified, although estrogen deficiency and X chromosomal abnormalities represent important factors.
        2. An enhanced spontaneous osteoclastogenesis has been demonstrated to occur in girls and young women with TS before and after pubertal induction with ERT (estrogen replacement therapy).
        3. This process seems to be more active in girls before puberty induction and supported by the high FSH (follicle-stimulating hormone) serum levels observed at prepubertal stage, while in young women on continuous ERT, the effects on osteoclasts seem to be mediated mostly by high RANKL (receptor activator of nuclear factor kappa-B ligand) levels.
        4. We recommended to consider the average age of 9 years as a crucial time point for the introduction of ERT.
        5. In the future, a neutralizing FSH antibody could be useful.
        6. In the meantime, a regimen combining the earlier introduction of ERT with rGH (recombinant growth hormone) treatment in girls with TS could have the effect to reduce FSH levels and to preserve bone health in these subjects.
    6. Estrogen replacement therapy: Current evidence suggests a benefit of ERT and HDL (high density lipoprotein) cholesterol (Clintron et al. 2016)
        1. To induce near normal pubertal development
        2. To prevent osteoporosis
        3. To reduce the risk of developing cardiovascular disease
    7. Growth hormone (GH) therapy (with or without anabolic steroids) for short stature
        1. Standard of care for girls with Turner syndrome (Bondy 2007)
        2. Girls treated with GH at 5.7 years (mean) averaged 7.2 cm taller than those in the control group (Stephure 2005)

3. Recombinant human growth hormone (rGH) has been approved by the Food and Drug Administration for treatment of short stature in Turner and Noonan syndromes (Chacko et al. 2012)

8. TS patients presenting with severe liver atrophy and disturbance of the major portal inflow should be indicated for liver transplantation (Kawabata et al. 2016)
9. Pregnancies among women with Turner syndrome: rare (Hovatta 1999; Cabanes et al. 2010; Mortensen et al. 2010)
    1. The most serious maternal complications
        1. Worsening of preexisting hypertension
        2. Aortic dissection
    2. A high risk of miscarriages and stillbirths among spontaneous pregnancies
    3. Seventy five percentage of spontaneous pregnancies: normal karyotype

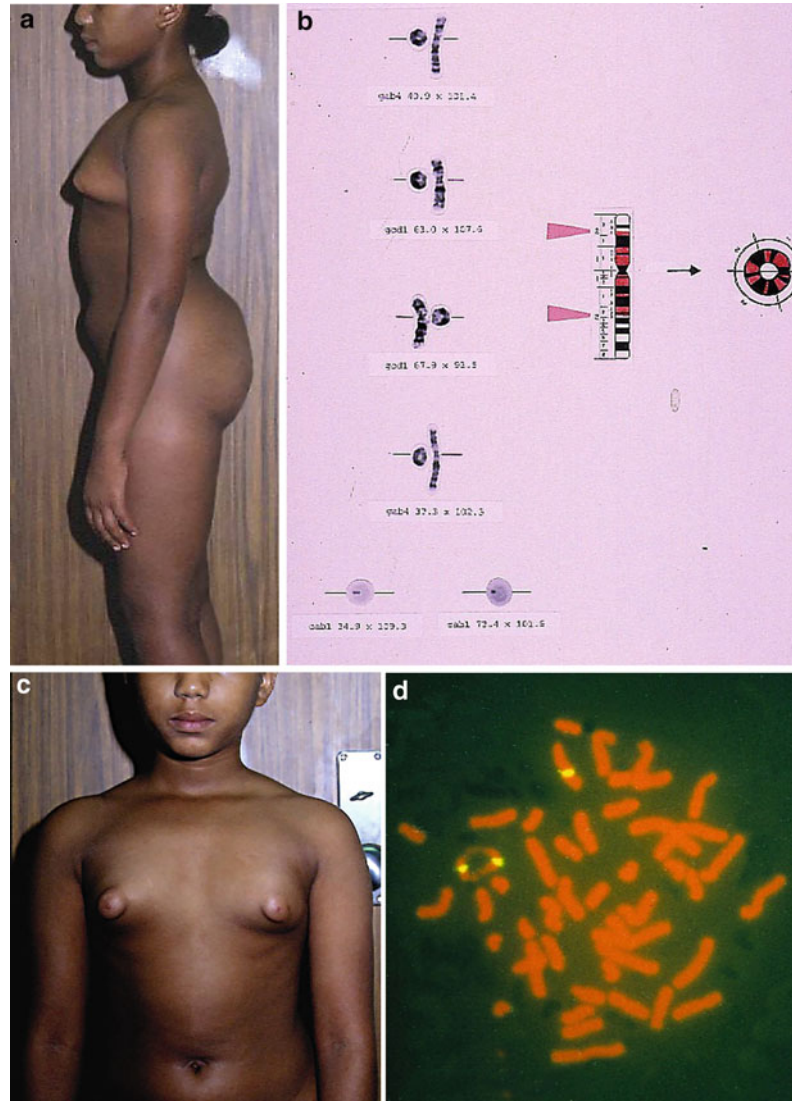

Fig. 11 (a–d) A girl (a, *b*) with 45,X/46,X,r(X) ring chromosome X Turner mosaicism. The ring chromosome is illustrated by partial karyotype with ideogram and FISH (c) with an X chromosome centromeric probe (d)

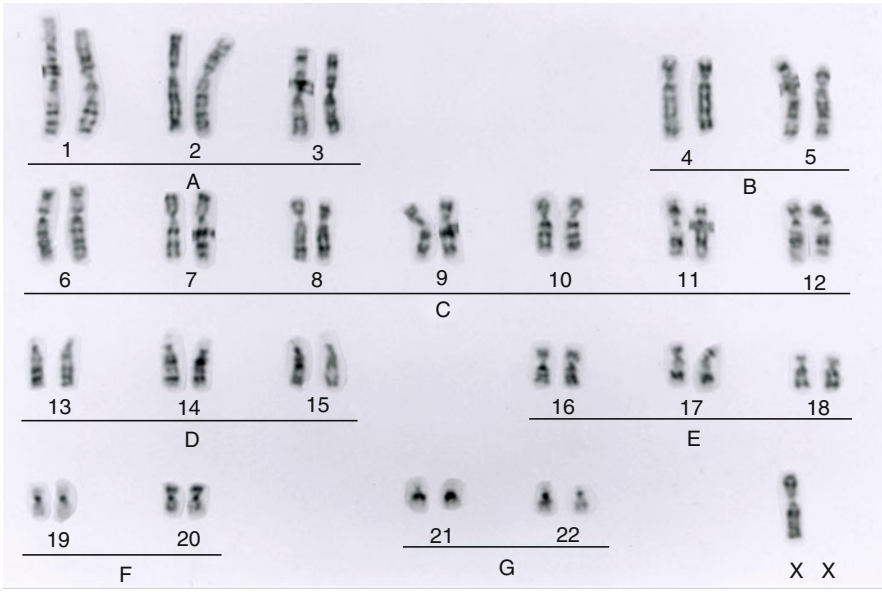

Fig. 12 45,X karyotype

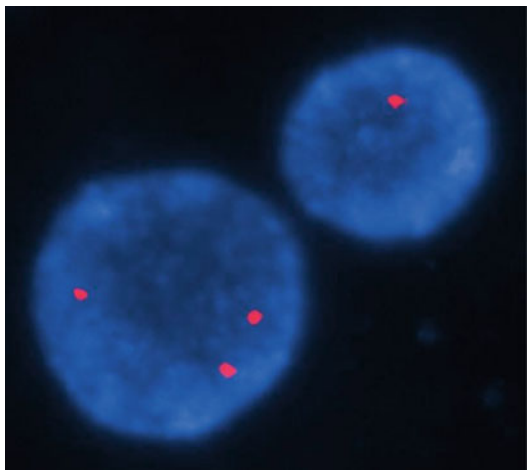

Fig. 13 FISH showing a mosaic fetus with XXX/X (CEP X/SpectrumOrange). Three copies of the orange signal are in the XXX cells and one copy in the monosomy X cells

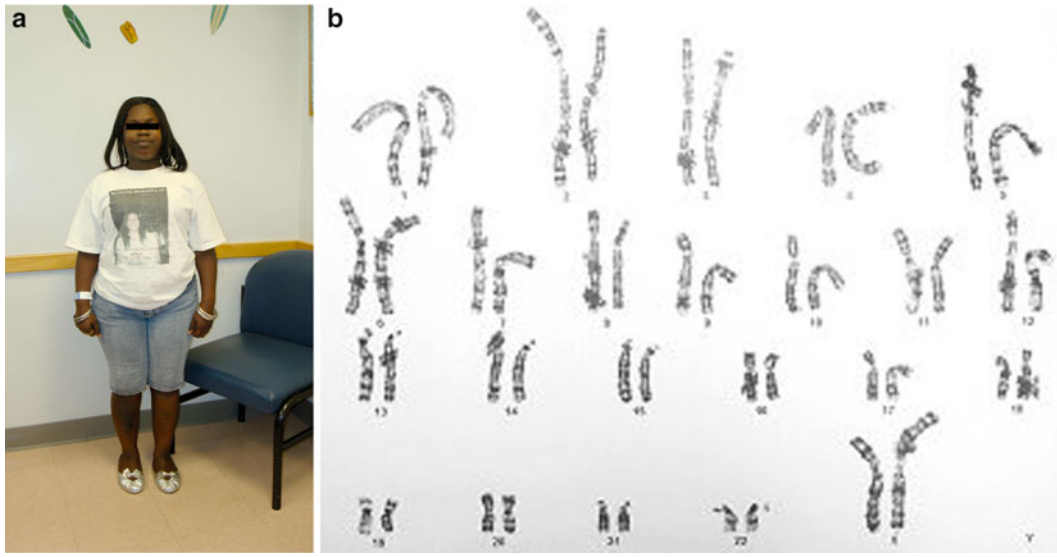

Fig. 14 (a, b) This 18-year-old adolescent girl (a) was evaluated for absence of menarche. She was noted to have Turner stage II breasts, absence of axillary hair, and scanty pubic hair. However, she has average stature for her age. The karyotype (b) shows 46,X,i(X)(q10) confirming the diagnosis of isochromosome Xq syndrome

Twin-Twin Transfusion Syndrome

Contents

Twin-twin transfusion syndrome results from imbalance in the net flow of blood leading to intrauterine blood transfusion from one twin to another twin as a serious complication in 10–30% of monochorionic diamniotic twin pregnancies (Banek et al. 2003; Weber and Sebire 2010).

Genetics/Basic Defects

1. Cause: a serious complication of monozygotic, monochorionic twin pregnancy through placental vascular anastomoses (unilateral arteriovenous anastomoses), resulting in transfusion of blood from one fetal twin to another twin (Banek et al. 2003).
2. Pathogenesis.
    1. Imbalance in net blood flow through transplacental fetofetal transfusion, resulting in a discrepancy in blood volume distribution in two twins
    2. The donor twin
        1. Becoming hypovolemic, hypotensive, and oliguric
        2. Leading to oligo-/anhydramnios and growth restriction
    3. The recipient twin
        1. Becoming hypervolemic, hypertensive, and polyuric
        2. Leading to polyhydramnios and congestive heart failure
3. Fetal cardiovascular hemodynamics in twin-twin transfusion syndrome (Wohlmuth et al. 2016).
    1. Twin-twin transfusion syndrome (TTTS) complicates 10–15% of monochorionic-diamniotic pregnancies.
    2. It originates from unbalanced transfer of fluid and vasoactive mediators from one twin to its co-twin via placental anastomoses.
    3. This results in hypovolemia in the donor and hypervolemia and vasoconstriction in the recipient twin.
    4. Consequently, the recipient demonstrates the following cardiovascular alterations:
        1. Atrioventricular valve regurgitation
        2. Diastolic dysfunction
        3. Pulmonary stenosis/atresia that do not necessarily correlate with Quintero stages
    5. Selective fetoscopic laser photocoagulation of placental vascular anastomoses disrupts the underlying pathophysiology and usually

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_239

improves cardiovascular function in the recipient with normalization of systolic and diastolic function within weeks after treatment.
6. Postnatal studies have demonstrated early decreased arterial distensibility in ex-donor twins, but 10-year follow-up is encouraging with survivors showing normal cardiovascular function after TTTS.

4. Early prediction of twin-to-twin transfusion syndrome: A correlation exists between the subsequent development of TTTS and intertwines nuchal translucency (NT) discrepancy, (NT > 95th centile), crown-rump length discrepancy, or ductus venosus reverse flow at the first trimester scan (Stagnati et al. 2016).

Clinical Features

1. Donor twin
   1. Birth weight: small for gestational age
   2. Pallor and anemic
   3. Poor peripheral perfusion
   4. Oligohydramnios in the amniotic sac secondary to hypovolemia and decreased urine output
   5. Stuck twin phenomenon (the twin appears in a fixed position against the uterine wall) resulting from severe oligohydramnios
   6. Hydrops fetalis secondary to anemia and high-output heart failure
2. Recipient twin
   1. Birth weight: larger at birth
   2. Plethoric and ruddy
   3. Jaundice
   4. Polyhydramnios in the amniotic sac secondary to hypervolemia and increased fetal urine output
   5. Hydrops fetalis secondary to hypervolemia
   6. Hypertension
   7. Hypertrophic cardiomegaly
   8. Right-sided heart failure with tricuspid regurgitation and right ventricular outflow tract obstruction
   9. Increased risk of cardiac malformations
   10. Intravascular coagulation
   11. Rate and outcomes of pulmonary stenosis (PS) and functional pulmonary atresia (PA) in recipient twins with twin-twin transfusion syndrome (Ortiz et al. 2016):
      1. PS and PA were observed in 10.8% of recipients.
      2. Among these, about one third showed persistence of pulmonary valve pathology after delivery, which stresses the need for strict follow-up.
3. Staging of twin-twin transfusion syndrome: Quintero staging system (Quintero et al. 1999; Taylor et al. 2002; Bebbington 2010; Kontopoulos et al. 2016)
   1. Stage 1
      1. Bladder in the donor twin still visible
      2. Polyhydramnios in recipient sac (MVP >8 cm) and oligohydramnios in the donor sac (MVP <2 cm)
   2. Stage 2
      1. No longer visible bladder in the donor twin.
      2. No critically abnormal Doppler studies (CADs). CADs was defined as absent/reverse end-diastolic velocity in the umbilical artery, reverse flow in the ductus venosus, or pulsatile flow in the umbilical vein.
   3. Stage 3: Doppler abnormality consisting of absent or reverse flow in the umbilical artery, reverse flow in the ductus venosus, or pulsatile flow in the umbilical vein
   4. Stage 4: Ascites or hydrops in either fetus
   5. Stage 5: Demise of one or both fetus
4. Prognosis
   1. Premature delivery in case of mild to moderate twin-twin transfusion syndrome
   2. Guarded with possible serious maternal and fetal complications
   3. Antenatal death as well as neonatal death secondary to preterm delivery
   4. Survival rate for those diagnosed before 28 weeks: 20–45%
5. Antenatal factors that predict poor outcome:
   1. Early gestational age at diagnosis with delivery before 28 weeks of gestation

2. Fetal polyhydramnios requiring multiple therapeutic amniocenteses
3. Fetal hydrops
4. Absent or reversed diastolic flow in umbilical artery Doppler studies

6. Neonatal complications (Blickstein 1990)
   1. Neurologic sequelae in 25% of surviving twin in case of fetal demise in other twin
   2. Divergent intrauterine growth in association with subsequent physical and mental deficiencies in the smaller twins
   3. Thrombocytopenia suggested as the cause of cataracts, impaired hearing, and growth retardation of the donor twin
   4. Intrauterine growth deficiency of the brain and profound neonatal hypoglycemia implicated as reasons for cerebral impairment of the donor twin, resulting in subsequent lower intelligence compared with its co-twin
   5. Circulatory overload with heart failure if severe hypervolemia occurs
   6. Occlusive thrombosis due to hyperviscosity
   7. Polycythemia that may lead to severe hyperbilirubinemia and kernicterus
   8. Brain damage with cerebral palsy, microcephaly, or encephalomalacia
   9. Clinical consequences of twin-to-twin transfusion (Chiang et al. 2003)
      1. Newborn infants with twin-to-twin transfusion were at risk for development of renal insufficiency, periventricular leukomalacia, and necrotizing enterocolitis.
      2. Intrauterine fetal demise of one twin and severe anemia (hemoglobin <10 g/dl) at birth were poor prognostic factors.
7. Maternal complications
   1. Secondary to multiple gestations
      1. Preeclampsia
      2. Preterm labor
      3. Hemorrhage
      4. Diabetes
   2. Maternal mirror syndrome
      1. A rare complication associated with fetal hydrops
      2. Also known as "Ballantyne syndrome" or "triple edema syndrome"
      3. A syndrome of severe water retention that "mirrors" fetal hydropic changes
      4. Frequent occurrence in the mid-trimester

Diagnostic Investigations

1. Difference in birth weight: intertwin difference $>20\%$ (heavier twin $= 100\%$) (Quintero 2003)
2. CBC to demonstrate intertwin differences of hemoglobin level (difference ≥ 5 g/dL) (Quintero 2003)
   1. Anemia: frequently in donor twin at birth
   2. Polycythemia: frequently in recipient twin at birth
3. Blood chemistry
   1. Hypoglycemia in either twins
   2. Hypocalcemia, hypoproteinemia in donor twin
   3. High creatinine in either twins with renal dysfunction
4. Thrombocytopenia in either twins
5. Hyperbilirubinemia in polycythemic recipient twin
6. Imagings
   1. Cranial ultrasound: intraventricular hemorrhage and periventricular leukomalacia in premature twins
   2. Chest radiography: pleural effusions and cardiomegaly in hydrops fetalis
   3. Echocardiography
      1. Myocardial dysfunction/hypertrophy
      2. Valvular insufficiency
      3. Pericardial effusion
   4. Renal ultrasound: abnormal renal echogenicity indicating hypoxic-ischemic cortical necrosis
   5. Abdominal ultrasound: ascites in hydrops fetalis
7. Demonstration of transplacental vascular connections: an important criterion for the diagnosis of the twin-twin transfusion syndrome (Blickstein 1990)
   1. Donor twin
      1. Placenta
         1. Pale

2. Swollen
3. Atrophied

2. Amniotic membrane showing amnion nodosum in the presence of oligohydramnios

2. Placenta of the recipient twin
1. Red
2. Congested
3. Hypertrophied

8. Surgical pathologic assessment of vascular anastomoses in monochorionic placentas with strong clinical correlation of placental types and occurrence of twin-twin transfusion (Bermúdez et al. 2002; Taylor et al. 2003)
1. Type A (placenta without vascular anastomoses): 0%
2. Type B (placenta with only deep arteriovenous anastomoses): 81%
3. Type C (placenta with only superficial anastomoses): 1%
4. Type D (placenta with combined deep arteriovenous and superficial anastomoses): 18%

9. Sonographic criteria for determining chorionicity (Barss et al. 1985)
1. Dichorionic
1. Separate placentas
2. Well-visualized septum

2. Monochorionic diamniotic
1. One placenta
2. A paper-thin, reflective hair-like septum (only small parts visible)

3. Dichorionic diamniotic: septum readily seen with a thickness similar to one wall of the umbilical cord

Genetic Counseling

1. Recurrence risk
1. Patient's sib: not increased unless in another pregnancy with monochorionic twinning (twin-twin transfusion syndrome affects 10–15% of monochorionic twins)
2. Patient's offspring: not increased unless in pregnancy with monochorionic twinning

2. Prenatal diagnosis (Blickstein 1990)
1. Changes in carbohydrate and fatty acid metabolic profiles in the amniotic fluid are noted in recipient sacs of TTTS pregnancies with cardiac dysfunction, and further changes are noted after treatment (Dunn et al. 2016).
2. Ultrasonography.
1. The required ultrasound (US) criteria (Cincotta and Fisk 1997)
1. Monochorionicity: most accurately diagnosed in the first trimester by the lack of chorion between the two amniotic sacs of the two twins and/or the presence of only a single extra-embryonic coelom
2. A marked discordance in amniotic fluid volume between the twins (known as the oligo/polyhydramnios sequence)
3. A discordance in size with the larger twin in the polyhydramniotic sac

2. First-trimester ultrasound determination of chorionicity in twin gestations (Maruotti et al. 2016)
1. The lambda sign predicts chorionicity with a high degree of accuracy before 14 weeks of gestation.
2. Presence of the lambda sign indicates dichorionicity.
3. Absence of the lambda sign indicates monochorionicity.

3. Divergent fetal size: striking differences in the sizes of the twins
1. Disparity in size of intertwin abdominal circumference (difference >18 mm).
2. Disparity in size or in the number of vessels in the umbilical cords: The donor twin may have a single umbilical artery. The size of the umbilical cord of the recipient twin may be much larger than that of its co-twin.

4. Divergent size of amniotic sacs (Quintero 2003)
1. Presence of polyhydramnios (largest pocket >8 cm) in one sac (the

recipient twin persistently has a distended bladder and produces a large amount of urine)
2. Presence of oligohydramnios (largest pocket <2 cm or stuck twin) in other sac (the donor twin produces little urine)

5. "Stuck twin" sign: a growth-retarded fetus tightly enwrapped within its membrane and trapped or stuck against the uterine wall due to oligohydramnios
6. Determination of monozygosity
   1. Like-sex twins
   2. Monochorionic diamniotic placentation (absence of twin peak sign, thin separating membrane, and single placenta showing divergent echogenicity of the cotyledons supplying the two cords)
7. A hydropic placenta: a marker of anemia, even before the fetus itself becomes hydropic (de Laat et al. 2009)
8. Evidence of hydrops in either twin
9. Evidence of congestive cardiac failure in the recipient twin
10. A sonographic staging classification for twin-twin transfusion syndrome allowing for the grading of the severity of the disease by standardized criteria (Quintero 2003)
    1. Stage I: visible bladder of the donor twin, normal Doppler studies
    2. Stage II: not visible bladder of the donor twin (during the length of examination, usually 1 h), not critically abnormal Doppler studies
    3. Stage III: critically abnormal Doppler studies in either twin, characterized as absent or reverse end-diastolic velocity in the umbilical artery, reverse flow in the ductus venosus, or pulsatile umbilical venous flow
    4. Stage IV: ascites, pericardial or pleural effusion, scalp edema, or overt hydrops of one or both twins
    5. Stage V: presence of one or both demised twins

3. Fetal echocardiography (Moon-Grady 2014).
   1. Possible advantages.
      1. Assessment of cardiovascular adaptation to intertwin transfusion
      2. Early recognition of deterioration
      3. Evaluation of antenatal management
   2. Fetal heart rate monitoring: A silent, sinusoidal pattern in tracings of the fetal heart rate may indicate signs of fetal anemia.
   3. Doppler studies.
      1. Detection of arterio-arterial anastomoses in monochorionic twins
      2. Doppler velocimetry of the umbilical arteries: intertwin differences in systolic/diastolic ratio >0.4 predicting growth discordancy of at least 350 g
   4. 2D ventricular assessment.
      1. Cardiomegaly
      2. Systolic dysfunction
      3. Hypertrophy
   5. Color Doppler AV valve assessment.
      1. Tricuspid regurgitation
      2. Mitral regurgitation
   6. Spectral (PW) Doppler.
      1. Tricuspid inflow
      2. Mitral inflow
      3. Ductus venosus "a" wave
      4. Umbilical venous pulsations
   7. Great vessel assessment.
      1. 2D outflow tracts
      2. Color dropper
4. Ultrasound-guided fetal blood sampling.
   1. Establishing the diagnosis of monozygosity when blood group studies are performed on both twins.
   2. Allowing an accurate antenatal assessment of the intertwin hemoglobin difference and consequently establishing the diagnosis of twin-twin transfusion.
   3. Revealing the degree of fetal anemia in the donor twin.
   4. Intrauterine death of one monochorionic twin in twin-twin transfusion syndrome puts the survivor at high risk of intrauterine death or of developing ischemic/hypoxic lesions. The fetal blood sampling is

a useful diagnostic tool to identify those fetuses that are not anemic and hence unlikely to be at risk of developing a cerebral lesion (Senat et al. 2002).

5. Fetoscopy: demonstration of perimortem fetofetal hemorrhage in twin-twin transfusion syndrome (Quintero et al. 2002).
    1. Plethora donor twin
    2. Pale recipient twin: consistent with perimortem fetofetal hemorrhage from recipient to donor twin

3. Management (Cincotta and Fisk 1997; Crombleholme 2003)
    1. General approach
        1. Monochorionic twining at high risk for twin-twin transfusion syndrome
        2. Requiring close obstetrical monitoring
        3. Requiring specialized care in neonatal intensive care unit
    2. Postpartum therapies
        1. Directed towards the problems of each twin, such as prematurity, anemia, polycythemia, and hydrops fetalis
        2. Severely anemic donor twin: requires packed red blood cell transfusions or partial exchange transfusions
        3. Polycythemic recipient twin: requires partial exchange transfusion to lower serum hematocrit
    3. Prenatal therapies (van Gemert et al. 2001; Ropacka et al. 2002; Gardiner et al. 2003; Walker et al. 2007)
        1. Treating the mother with digoxin with favorable results when the recipient twin is showing signs of cardiac failure (edema, ascites, and hydramnios) (De Lia et al. 1985).
        2. Treatment options.
            1. Prevent preterm labor and preterm premature rupture of the membranes from polyhydramnios (amniodrainage and septostomy)
            2. Isolate the twin circulations (cord ligation and selective laser photocoagulation)
        3. Serial amniodrainage (amnioreduction): currently the most widely used therapy because it is simple and requires commonly available skills and equipment.
            1. Removing large volumes of amniotic fluid from the recipient twin's sac.
            2. Reducing the amniotic fluid volume, thereby reducing the risk of preterm labor or ruptured membranes.
            3. Early, rapid, and radical amniodrainage is an effective and low-cost therapy for severe twin-twin transfusion syndrome (Jauniaux et al. 2001).
            4. The use of therapeutic amnioreduction was associated with a satisfactory perinatal survival rate for early stage disease (Duncombe et al. 2003).
            5. Overall perinatal survival with serial aggressive amnioreduction: about 60% in uncontrolled published series.
            6. Double survival rate (50%) and single survival rate (20%) in severe twin-twin transfusion syndrome presenting before 28 weeks of gestation.
            7. Fail to address the underlying cause of twin-twin transfusion syndrome.
            8. Complications: uterine contractions, premature rupture of membranes, chorioamnionitis, abruptio placenta, and inadvertent septostomy resulting in iatrogenic monoamniotic twins.
        4. Amniotic septostomy: intentionally puncturing the intertwine septum.
            1. To create a hole in the intertwine membrane between the anhydramniotic donor's sac and the hydramniotic recipient's sac
            2. Restoring normal amniotic fluid pressure gradient, allowing fluid to move along a hydrostatic gradient from the hydramnios sac into the oligohydramnios sac
            3. Also an inadvertent occurrence during amnioreduction procedure

4. Limited experience
5. Endoscopic laser coagulation of all placental vascular anastomosis (Wee and Fisk 2002).
    1. Fetoscopic laser coagulation of placental vascular anastomoses: the treatment of choice for severe twin-twin transfusion syndrome, interrupting blood flow between the twins and relieving uterine overdistension related to severe polyhydramnios (Diehl et al. 2014).
    2. Reduces and abolishes intertwine transfusion by ablating chorionic plate anastomoses, producing functionally dichorionic pregnancies.
    3. Proponents arguing that the procedure reduces the risk of neurological injury in survivors.
    4. Overall survival rate (58%) with single survival of 32% and double survival of 42% for cases presenting prior to 18 weeks.
    5. Fetoscopic laser photocoagulation for fetofetal transfusion syndrome in monochorionic triamniotic as well as dichorionic triamniotic triplets seems a valuable treatment (Ishii et al. 2014).
    6. Rare fetal complications (relationship to the procedure not established): aplasia cutis, limb necrosis, amniotic bands, and microphthalmia/anophthalmia.
    7. The incidence of prenatal brain damage is low following fetoscopic laser selective coagulation and is strongly associated with incomplete surgery (Stirnemann et al. 2016).
    8. Fetoscopic laser surgery for twin-twin transfusion syndrome is associated with an increased risk of funisitis (Zhao et al. 2016).
6. Selective feticide by cord occlusion (umbilical cord ligation) (Deprest et al. 2000): used as a last resort in cases in which both twins are at risk because of the serious condition of one twin.
    1. Considered in case of monochorionic twin pregnancy in which one twin is a nonviable fetus, especially the condition is compromising the nonaffected fetus.
    2. A typical example in twin reversed arterial perfusion sequence. The relatively normal twin risks high-output cardiac failure, complications of polyhydramnios, and death in utero.
    3. Another example of twin-twin transfusion syndrome, in which one fetus has major congenital anomalies or in utero-acquired abnormality, such as demonstrable cerebral lesions, terminal cardiac failure, or other conditions with a poor prognosis.
    4. Benefits of selective termination of the affected twin: Arrest the fetofetal transfusion process and protect the survivor.
7. In general, twin-twin transfusion syndrome diagnosed before 26 weeks of gestation has significantly better survival rates and fewer neurological sequelae after laser ablation therapy than amnioreduction. Twin-twin transfusion syndrome diagnosed after 26 weeks can best be treated by amnioreduction or delivery.
8. The perinatal survival of twin-twin transfusion syndrome pregnancies managed without in utero procedures is approximately 30% overall and 63% in the four most recent series when diagnosed at $<$ or $=$ 28 weeks (Berghella and Kaufmann 2001).
9. Outcomes of patients with twin-twin transfusion syndrome who were treated with either serial amniocentesis or selective laser photocoagulation of communicating vessels according to disease severity (stage): a relationship between perinatal morbidity and

mortality rates and stage in serial amniocentesis but not in selective laser photocoagulation of communicating vessel-treated twin-twin transfusion syndrome patients (Quintero 2003; Quintero et al. 2003).

10. Prompt recognition and management of the hemodynamic and hematological problems of infants with the acute types of twin-twin transfusion syndrome will result in optimal neurodevelopmental outcome (Seng and Rajadurai 2000).
11. In 42 twin gestations with stuck twin associated with acute hydramnios, targeted ultrasound cordocentesis in each fetus and therapeutic amniocentesis were performed (Weiner and Ludomirski 1994).
    1. The diagnosis of chronic twin-to-twin transfusion syndrome required: sonographic evidence of monochorionicity; rapid reaccumulation of fluid after amniocentesis; discordant fetal size, and divergent fetal hematocrit measurements with at least one above or below the 95% confidence interval for gestational age.
    2. These criteria were met in 20 of 42 (48%) pregnancies. The mean gestation was 23.8 +/− 2 weeks (range 21–27 weeks).
    3. In four pregnancies, the transfer of adult RBCs from the donor to the recipient was documented.
    4. Monochorionicity was confirmed in all postnatally.
    5. All recipients had polycythemia and hyperproteinemia. Hydrops developed only in the recipient twin (6 of 20) and was associated with an elevated umbilical venous pressure.
    6. All pregnancies were treated with aggressive serial therapeutic amniocenteses.
12. Antenatal management of twin-twin transfusion syndrome (TTTS) and twin anemia-polycythemia sequence (TAPS) (Slaghekke et al. 2016).
    1. Fetoscopic laser photocoagulation: a feasible treatment for twin-to-twin transfusion syndrome (Nakata et al. 2016; Thia et al. 2016) and clearly the only therapy that halts the disease process and allows both fetuses an opportunity to survive and protects a surviving co-twin in the event of the demise of one twin (Behrendt and Galan 2016).
    2. The optimal management for TTTS is fetoscopic laser coagulation of the vascular anastomoses, preferably using the Solomon technique in which the whole vascular equator is coagulated. The Solomon technique is associated with a reduction of residual anastomosis and a reduction in postoperative complications (Behrendt and Galan 2016).
    3. The optimal management for TAPS is not clear and includes expectant management, intrauterine transfusion with or without partial exchange transfusion, and fetoscopic laser surgery.

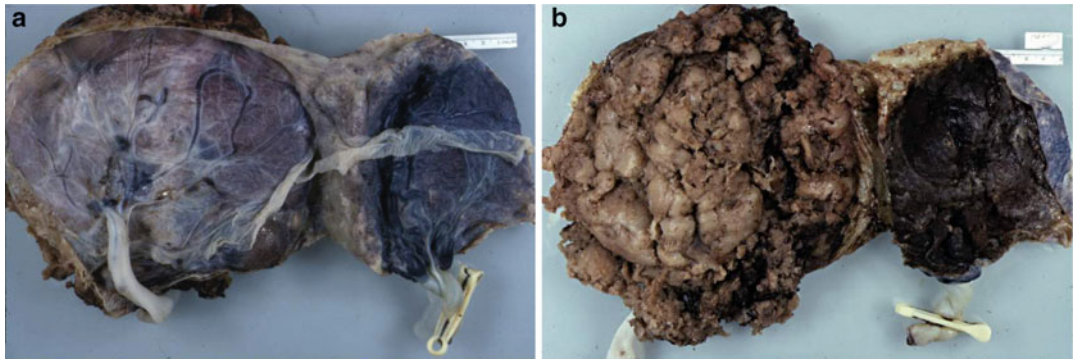

Fig. 1 (**a**, **b**) Diamniotic monochorionic twin placenta with features of twin-twin transfusion (the placental disks are not fused in this case): The placenta corresponding to the recipient twin (*right*) is small but plethoric and dark in color (**b**). The placenta of the donor twin (*left*) is large but anemic, pale, and edematous (**a**). The amniotic sacs were removed at the margins of the placental disks. The root of the thin monochorionic septum between the two sacs is shown on the fetal surface (first picture). The color difference between the two placentas is better shown on the maternal surface (second picture)

Fig. 2 The donor twin (*right*) showing smaller and pallor and the recipient twin (*left*) showing larger and plethoric at birth

Tyrosinemias

Contents

The genetic tyrosinemias, autosomal recessive disorders, are characterized by the accumulation of tyrosine in body fluids and tissues. There are three types of tyrosinemias: Types I, II, and III. Type I has a prevalence of about 1 in 100,000 newborns in the general population. Type III is extremely rare (Fig. 1).

Synonyms and Related Disorders

Congenital tyrosinosis; Fumarylacetoacetate hydrolase deficiency; Hawkinsinuria; Hepatorenal tyrosinemia; Hereditary tyrosinemia; Tyrosinemia, Type I; Tyrosinemia, Type II (oculocutaneous tyrosinemia, keratosis palmoplantaris with corneal dystrophy, Richner-Hanhart syndrome); Tyrosinemia, Type III

Genetics/Basic Defects

1. Tyrosinemia, Type I (Scott 2006)
    1. Caused by a deficiency of fumarylacetoacetate hydrolase (FAH) (Lindblad et al. 1977)
    2. Coded by the gene localized at 15q23-q25
2. Tyrosinemia, Type II
    1. Caused by a deficiency of tyrosine aminotransferase (TAT) (Goldsmith et al. 1973)
    2. Coded by the gene localized at 16q22
    3. More common in Italy where a common mutation (R57X) has been identified (Huhn et al. 1998)
3. Tyrosinemia, Type III
    1. Caused by a deficiency of 4-hydroxyphenylpyruvic dioxygenase (4-HPPD).
    2. Coded by the gene localized at 12q24-qter.
    3. A single mutation, A33T, is common in each of the families in which Hawkinsinuria has been identified (Tomoeda et al. 2000). Hawkinsinuria is somewhat unique in that it is inherited as an autosomal dominant, while other mutations of 4-HPPD cause the autosomal recessive tyrosinemia, Type III.

Clinical Features

1. Tyrosinemia, Type I (Scott 2006; de Laet et al. 2013)
    1. Onset of disease
        1. Onset before 6 months of age: acute severe liver involvement
        2. Onset after 6 months of age (van Spronsen et al. 1994):
            1. Mild liver dysfunction
            2. Renal involvement
            3. Growth failure
            4. Rickets
    2. Hepatic disease
        1. Acute severe liver involvement: common with clotting abnormalities, ascites, and edema secondary to hypoalbuminemia
        2. Frequent hemorrhage
        3. Usually mild jaundice
        4. Firm and hard liver on physical examination
        5. Go on to develop cirrhosis, liver nodules, and hepatocellular carcinoma
    3. Renal disease
        1. Characteristic finding: tubular disorder with a Fanconi syndrome, the severity of which is variable.
        2. Typical features: aminoaciduria, glycosuria, phosphaturia, and renal tubular acidosis.
        3. Hypophosphataemic rickets.
        4. May progress to nephrocalcinosis, glomerulosclerosis, and chronic renal failure.
        5. Although renal disease may be the predominant feature, there is always some coexisting liver disease of varying severity.
    4. Neurologic disease
        1. Porphyria-like syndrome: most characteristic, usually precipitated by intercurrent infection
        2. Crises
            1. Pain can be severe including abdominal pain mimicking an acute surgical emergency.
            2. Weakness.
            3. Autonomic changes such as hypertension.
            4. Acute progressive ascending motor neuropathy, often with respiratory distress requiring assisted ventilation.
2. Tyrosinemia, Type II
    1. Ocular symptoms
        1. Onset: during first year of life.
        2. Recalcitrant pseudodendritic keratitis with photophobia, scleral inflammation, and pain (Macsai et al. 2001).
        3. Some degree of corneal ulceration and occasional birefringent crystals of tyrosine may be observed by slit lamp examinations.
    2. Skin lesions
        1. Hyperkeratotic plaques on the soles of the feet and palms of the hands.
        2. Dramatic yellowish thickening associated with the hyperkeratosis may be seen in the plantar surface of the digits (Rehak et al. 1981).
        3. Hyperkeratosis of the elbows, knees, and ankles has been reported in older individuals.
    3. Developmental delay: common
    4. No liver involvement
3. Tyrosinemia, Type III
    1. The rarest of the disorders of tyrosine metabolism
    2. Ambiguous clinical phenotype (Mitchell et al. 2001)
        1. Intellectual disability
        2. Ataxia
        3. Detected on routine screening (Mitchell et al. 2001)
        4. No liver involvement but has skin and ocular changes similar to tyrosinemia, Type II
    3. Hawkinsinuria (a variant of 4-HPPD deficiency)
        1. Affected children may demonstrate chronic acidosis and failure to thrive if fed standard infant formulas or if fed cow's milk as primary nutritional source (Danks et al. 1975).

2. Infants nourished with breast milk: escape symptoms during infancy.

Diagnostic Investigations

1. Clinical laboratory tests (Scott 2006; King et al. 2014)
    1. Tyrosinemia, Type I
        1. Acute early phase: may progress to acute liver necrosis, ascites, jaundice, and gastrointestinal bleeding
            1. Prothrombin and partial thromboplastin times: markedly prolonged.
            2. Other clotting factors: preservation of Factor V and Factor VIII, but decrease in Factors II, VII, XI, XI, and XII.
            3. Liver function tests: modestly elevated transaminase and normal or only slightly elevated serum bilirubin (Mitchell et al. 2001).
            4. Striking biochemical feature: a markedly elevated α-fetoprotein averaging approximately 160,000 ng/ml at the time of diagnosis.
            5. Presence of a characteristic odor of "boiled cabbage" or "rotten mushrooms" and elevation of α-fetoprotein often lead to the clinical recognition of tyrosinemia, Type I, from other causes of acute liver failure; documentation of elevations of plasma tyrosine, methionine, and phenylalanine and succinylacetone in the urine or plasma confirms the diagnosis.
            6. Marked elevation of succinylacetone in the urine or plasma can be considered pathognomonic for tyrosinemia, Type I.
        2. More chronic form of the disorder: renal involvement (major manifestations)
            1. Renal tubular dysfunction involves a generalized aminoaciduria, phosphate loss, and, for many, renal tubular acidosis (Roth et al. 1991).
            2. Renal loss of phosphate is believed to be the mechanism for the development of rickets.
            3. Growth failure is ascribed to the chronic illness from poor nutrition, liver involvement, and/or chronic renal disease.
    2. Tyrosinemia, Type II
        1. Plasma tyrosine levels: typically >500 μM/L, may exceed 1,000 μM/L
        2. Other amino acids: normal including methionine and phenylalanine
        3. Urine organic acids: an increased excretion of *p*-hydroxyphenylpyruvate, *p*-hydroxyphenyllactate, *p*-hydroxyphenylacetate, and small quantities of *N*-acetyltyrosine and 4-tyramine.
    3. Tyrosinemia, Type III
        1. Plasma concentration of tyrosine: from 350 to 650 μM/L.
        2. Increased excretion of 4-hydroxyphenylpyruvic acid, 4-hydroxyphenyllactate, and 4-hydroxyphenylacetate.
        3. The precise quantities vary with protein intake.
2. Imaging (de Laet et al. 2013)
    1. Bone X-ray of the wrist and chest: to define tubulopathy
    2. Ultrasound: to identify echogenicity of the parenchyma and nodular lesions of the liver and monitor kidney growth and changes in renal parenchyma
    3. CT scan with contrast: to identify malignant change of the liver (need a risk-benefit analysis to avoid extra radiation in children)
    4. MRI: best technique to differentiate nodules and carcinomas
3. Molecular genetic analysis for tyrosinemia, Type I
    a. Targeted mutation analysis for the four common FAH pathogenic variants.
    b. Sequence analysis of the entire coding region can detect pathogenic variants in >95% of affected individuals.

Genetic Counseling

1. Recurrence risk
   1. Autosomal recessive inheritance
      1. Patient's sib: each sibling of an affected patient has a 25% chance of being affected, a 50% risk of being an asymptomatic carrier, and a 25% chance of being unaffected and not carrier.
      2. Patient's offspring: not increased unless the spouse is a carrier.
   2. Autosomal dominant inheritance
      1. Patient's sib: each child of an affected individual has a 50% chance of inheriting the mutation.
      2. Patient's offspring: 50%.
2. Prenatal diagnosis (King et al. 2014)
   1. Molecular genetic analysis for tyrosinemia, Type I: If the *FAH* pathogenic variants have been identified in an affected family member, prenatal testing for pregnancies at increased risk may be available from a clinical laboratory that offers either testing of this gene or custom prenatal testing. Prenatal diagnosis of tyrosinemia type 1 using next generation sequencing (Rafati et al. 2016)
   2. Preimplantation genetic diagnosis: an option for some families in which the FAH pathogenic variants have been identified.
3. Management (Scott 2006)
   1. Tyrosinemia, Type I
      1. Artificial formula low in phenylalanine and tyrosine (utilization of a nutritionist skilled in metabolic disorders)
         1. Moderately useful in reducing succinylacetone
         2. Some benefit in the more chronic forms of the disease
         3. Not very effective in acute stage of the disorder in young children
      2. Nitisinone, [2-(2-nitro-4-trifluoromethylbenzoyl)-1,3 cyclohexanedione (NTBC)], which blocks p-hydroxyphenylpyruvic acid dioxygenase (*p*-HPPD) and prevents the accumulation of fumarylacetoacetate and its conversion to succinylacetone
         1. Should begin as soon as the diagnosis is confirmed.
         2. At least 90% of patients with acute form will respond to nitisinone therapy.
         3. Major complications: tyrosine crystal deposition in the cornea, causing photophobia and an ocular inflammatory response. To prevent this, tyrosine concentrations should be monitored and the children utilize a phenylalanine- and tyrosine-restricted diet.
         4. Require long-term monitoring for possible development of hepatocarcinoma (MRI or CT scans of the liver annually).
      3. Prevention/treatment of secondary complications: carnitine deficiency, osteoporosis, and rickets that are secondary to renal tubular Fanconi syndrome
      4. Liver transplantation
         1. Reserved for children who have severe liver failure at presentation and fail to respond to nitisinone therapy
         2. For children who have documented evidence of malignant changes in hepatic tissue
   2. Tyrosinemia, Type II
      1. A low-protein diet and use of a special formula free of phenylalanine and tyrosine: effective in lowering the plasma level of tyrosine to <600 μM
      2. Resolution of both eye and skin symptoms within days to several weeks after institution of the diet and special formula
   3. Tyrosinemia, Type III: a diet low in phenylalanine and tyrosine can lower plasma tyrosine.

Fig. 1 This 2.5-year-old Palestine girl was seen because of an abnormal newborn screen which showed an abnormal amino acid profile with a succinylacetone level of 3.6 umol/L with a normal being less than 0.40 umol/L. Her alpha-fetoprotein level was greater than 20,000. Her plasma tyrosine was 524 uM with a normal of 28–134. Her urinary organic acid, succinylacetone, was 15 millimoles per mole creatinine which is significantly elevated as normal is zero (0). These results confirmed the diagnosis of tyrosinemia, Type I. Family history showed that the mother's sister has a son and a daughter with tyrosinemia, Type I

Fig. 2 Previous patient at 5 years of age. She had a G-tube placement and gallbladder removed when she was 4. Her Gallbladder was only working 27%, the G-tube was placed to help give her the nutrition she was missing from her diet restriction when her body started to become very weak and ill all the time due to her not drinking her formula. At the age of 3, she was diagnosed with kidney stones and had a stent placed to help remove the stones.

Ulnar-Mammary Syndrome

Contents

Ulnar-mammary syndrome (UMS) was originally described by Gilly (1882) in 1882 in a woman with mammary hypoplasia, inability to lactate, and absence of the third to fifth digits and ulna. Later in 1978, Pallister et al. (1976) reported a complex malformation syndrome in a young woman with abnormal development of ulnar rays, forearms, mammary gland tissue, axillary apocrine glands, teeth, palate, vertebral column, and urogenital system. Ulnar-mammary syndrome is a pleiotropic disorder affecting limb, apocrine gland, teeth, hair, and genital development.

The incidence of UMS is unknown. Ulnar longitudinal deficiencies in general are rare, occurring 1 in 25000 births (Koskimies et al. 2011). The largest series of UMS contains three patients from a single family (Bamshad et al. 1995). Further case reports primarily in the genetics literature, bring the total to 117 reported cases (Ramirez and Kozin 2014).

Synonyms and Related Disorders

Pallister ulnar-mammary syndrome (Gonzalez et al. 1976; Pallister et al. 1976); Schinzel syndrome (Hecht and Scott 1984; Schinzel 1987)

Genetics/Basic Defects

1. Inheritance: autosomal dominant with variable expression (Schinzel et al. 1987; Sherman et al. 1986; Linden et al. 2009; Wollnik et al. 2002)
2. A gene for UMS mapped to chromosome 12q23-q24.1 (Bamshad et al. 1995)
3. Caused by mutations that disrupt the DNA-binding domain of the T-box gene, *TBX3* (Coll et al. 2002)
4. Mutations in human *TBX3* alter limb, apocrine, and genital development (Sasaki et al. 2002) in UMS (Bamshad et al. 1997).
5. No obvious phenotypic differences between those who have missense mutations and those who have deletions or (Bamshad et al. 1999)
6. The UMS gene, *Tbx3*, is required for development of posterior forelimb bones, muscles, and their attachment sites (Colasanto et al. 2016): Although descriptions of UMS limb phenotypes have entirely focused on bone phenotypes, the abnormal surface anatomy of UMS individuals (indicative of underlying soft tissue defects; Bamshad et al. 1999) and aberrant locomotion of Tbx3 mutant mice (Emechebe

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_240

et al. 2016) suggests that *TBX3* may play a broader role in musculoskeletal development than previously thought.

Clinical Features

1. The clinical expression of UMS is highly variable (Bamshad et al. 1996; Ramirez and Kozin 2014): Limb deficiencies in most patients
2. Posterior limb defects
    1. Widely variable
    2. Ulnar ray defects in most patients
        1. Hypoplasia of the terminal phalanx of the fifth digit
        2. Complete absence of the ulna and third, fourth, and fifth digits
    3. Postaxial digital duplications with or without contralateral limb deficiencies
    4. Camptodactyly
    5. Digital fusion
3. Apocrine gland abnormalities
    1. Mammary gland abnormalities: variable
        1. Hypoplasia to aplasia of the mammary glands and hypoplasia of the nipples
        2. Accessory nipples
        3. Inability to nipple feed
        4. Normal breast development and lactation
    2. Decreased ability to sweat
    3. Reduced body odor
    4. Absent axillary perspiration
    5. Sparse axillary hair
4. Genital abnormalities: hypogenitalism
    1. Affected males
        1. Delayed puberty
        2. Diminished to absent axillary hair
        3. Micropenis
        4. Cryptorchidism
        5. Small testes
        6. Shawl scrotum
        7. Reduced fertility
    2. Affected females
        1. Diminished to absent axillary hair
        2. Imperforate hymen in some affected females
5. Facial features (Joss et al. 2011)
    1. Upslanting PFs
    2. Wide nasal base
    3. Full cheek/wide midface
    4. Broad nasal tip
    5. Small nostrils
    6. Downturned mouth
    7. Pointed/prominent chin
6. Oral abnormalities (Joss et al. 2011)
    1. Misplaced/crowded teeth
    2. Absent teeth (canines)
    3. Hypodontia
    4. Bifid/broad uvula
    5. Tongue ties
7. Other abnormalities
    1. Delay puberty
    2. Short stature
    3. Obesity
    4. Scanty lateral eyebrows
    5. Subglottic stenosis
    6. Pyloric stenosis
    7. Renal agenesis/malformation
    8. Pulmonary hypoplasia
    9. Inguinal hernia
    10. Anal atresia/stenosis
    11. Musculoskeletal abnormalities
        1. Short forearms
        2. Hypoplastic humeri, scapulae, and clavicles
        3. Hypoplastic pectoralis major muscles
        4. Short, stiff, and crooked terminal phalanges of fourth to fifth toes
8. Differential diagnosis
    1. Hand-foot-uterus syndrome (Rogers and Anderson 1995)
        1. Autosomal dominant disorder
        2. Allelic to UMS speculated
        3. Manifestations similar to UMS include the following:
            1. Digital hypoplasia
            2. Carpal fusion
            3. Supernumerary nipples
            4. Genital anomalies
    2. Split hand/split foot syndrome: a causal relationship to UMS suggested (Franceschini et al. 1992)
        1. A three-generation family in which mother, maternal grandfather, and two

(male and female) children have variable manifestations of the UMS, including ulnar ray defects, obesity, hypogenitalism, delayed puberty, hypoplasia of nipples and apocrine glands, and a previously undescribed ectopia of upper canines.
2. The index patient also had split-hand appearance on the right due to complete absence of the 4th ray.

3. Scalp-ear-nipple syndrome (Edwards et al. 1994)
   1. Overlapping manifestations with UMS
      1. Mammary hypoplasia
      2. Diminished axillary perspiration
      3. Dental abnormalities: widely spaced or missing secondary teeth
      4. Digital syndactyly: characteristic limb anomaly found in this syndrome (vs limb deficiency or duplications in UMS)
   2. Aplasia cutis congenita of the scalp
   3. Alteration of the shape of the external ear: cupped or folded and stood out from the head
   4. Reduced axillary apocrine secretion and axillary hair growth
   5. Brittle finger nails
4. Limb-mammary syndrome: a new genetic disorder with mammary hypoplasia, ectrodactyly, and other Hand/Foot anomalies maps to human chromosome 3q27 (van Bokhoven et al. 1999)
   1. A report on a large Dutch family with a syndrome characterized by severe hand and/or foot anomalies, and hypoplasia/aplasia of the mammary gland and nipple.
   2. Less frequent findings include lacrimal-duct atresia, nail dysplasia, hypohydrosis, hypodontia, and cleft palate with or without bifid uvula.
   3. This combination of symptoms has not been reported previously, although there is overlap with the UMS and with ectrodactyly, ectodermal dysplasia, and clefting syndrome.
   4. Allelism with UMS and other related syndromes was excluded by linkage studies with markers from the relevant chromosomal regions.
   5. A genome-wide screening with polymorphic markers allowed the localization of the genetic defect to the subtelomeric region of chromosome 3q.
   6. Haplotype analysis reduced the critical region to a 3-cM interval of chromosome 3q27.
5. Patients with contiguous gene deletion of *TBX5* and *TBX3* with features of both Holt-Oram syndrome and UMS (Alby et al. 2013; Bogarapu et al. 2014)
   1. Bilateral symmetric limb malformations
   2. Congenital cardiac defects
   3. Rapidly progressive cardiac conduction disease
   4. This contiguous gene syndrome is reminiscent of Okihiro syndrome (congenital cardiac defects, anal atresia, and radial ray defects) and emphasizes the importance of array-CGH as a diagnostic tool in atypical syndromic presentations (a wide range of clinical consequences) with high intrafamilial variability.

Diagnostic Investigations

1. Radiography
   1. Short and stiff fifth finger
   2. Absent fifth finger ray
   3. Absent fourth finger ray
   4. Absent fourth to fifth finger rays
   5. Absent third to fifth finger rays
   6. Camptodactyly
   7. Hypoplastic/absent/deformed ulna
   8. Hypoplastic/absent/deformed radius
   9. Hypoplastic humerus, scapula, clavicle, and pectoralis major muscle
   10. Absent xiphisternum
   11. Postaxial polydactyly
   12. Short, stiff fourth and fifth toes
2. Endocrine investigations for hypogenitalism
3. Mutation analysis

1. Missense mutations (L143P and Y149S)
2. Nonsense mutation (Q360TER, S343TER)
3. Splice-site mutations (IVS2 + 1G → C, IVS6 + 2T → A) producing a truncated protein product
4. Frameshift mutations of small duplications

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: not increased unless a parent is affected
   2. Patient's offspring: 50%
2. Prenatal diagnosis
   1. Ultrasonography and fetoscopy: possible to pregnancy at risk with presence of obvious fetal skeletal anomalies
   2. Mutation analysis of amniocytes and CVS: possible to families with identified mutation causing UMS
3. Management
   1. Orthopedic management of limb defects
   2. Orchiopexy for cryptorchidism
   3. Testosterone management for hyogonadism in male patients
   4. Bottle feeding of infants born to mothers who has hypoplastic or absent nipples

Fig. 1 A newborn (**a**, **b**) with UMS showing ulnar hypoplasia (missing fourth and fifth fingers) (**c**), ectrodactyly, syndactyly, and hypoplasia of the breast and nipples (**d**). The infant also had cryptorchidism, anal atresia, pulmonary hypoplasia, pyloric stenosis, and bilateral renal hypoplasia

Urofacial Syndrome

Contents

Urofacial syndrome (UFS), also known as Ochoa syndrome, is characterized by severe voiding dysfunction and peculiar facies, i.e., inversion of facial expression with grimacing while smiling (Ochoa and Gorlin 1987; Ochoa 1992, 2004). UFS may be more common than was previously thought, and it is likely that cases are missed because of failure to recognize the characteristic grimacing (Garcia-Minaur et al. 2001).

Synonyms and Related Disorders

Ochoa syndrome (Elejalde 1979)

Genetics/Basic Defects

1. Autosomal recessive inheritance (Al-Qahtani 2003) based on:
   1. Affected siblings (Bertolotti et al. 2007)
   2. Normal parents
   3. Presence of consanguinity
2. Mutations with a loss of function in the *Heparanase 2* (*HPSE2*) gene were identified in all urofacial syndrome patients originating from Colombia, the United States, and France (Pang et al. 2010).
   1. HPSE2 encodes a 592 aa protein that contains a domain showing sequence homology to the glycosyl hydrolase motif in the heparanase (*HPSE*) gene, but its exact biological function has not yet been characterized.
   2. Complete loss of HPSE2 function in urofacial syndrome patients suggests that HPSE2 may be important for the synergic action of muscles implicated in facial expression and urine voiding.
3. Whole-genome SNP mapping in one affected individual defined an autozygous region of 16 Mb on chromosome 10q23-q24, within which a 10 kb deletion encompassing exons 8 and 9 of *HPSE2* was identified (Daly et al. 2010). Homozygous exonic deletions, nonsense mutations, and frameshift mutations in five further unrelated families confirmed *HPSE2* as the causative gene for UFS.
4. Genetic homogeneity of the urofacial (Ochoa) syndrome confirmed in a new French family (Chauve et al. 2000).
5. Homozygosity and linkage-disequilibrium mapping of the urofacial (Ochoa) syndrome gene to a 1-cM interval on the chromosome 10q23-q24 (Wang et al. 1997).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_241

6. Most individuals with urofacial syndrome genetically studied to date carry biallelic, postulated functionally null mutations of *HPSE2* or, less commonly, of *LRIG2* (Woolf et al. 2014).
7. Biallelic mutations in *HPSE2* gene on chromosome 10q23-q24, predicted to abolish activity of heparanase 2, cause urofacial syndrome in families from different ethnic groups (Daly et al. 2010).
8. *LRIG2* mutations cause urofacial syndrome (Sturart et al. 2013).
    1. A subset of UFS-affected individuals have biallelic mutations in *LRIG2*, encoding leucine-rich repeats and immunoglobulin-like domains 2, a protein implicated in neural cell signaling and tumorigenesis.
    2. Importantly, rare variants in *LRIG2* might be relevant to nonsyndromic bladder disease.
    3. Previously, UFS was also shown to be caused by mutations in *HPSE2*, encoding heparanase-2.
    4. LRIG2 and heparanase-2 were immunodetected in nerve fascicles growing between muscle bundles within the human fetal bladder, directly implicating both molecules in neural development in the lower urinary tract.
9. Report of a family of three siblings, with an emphasis on the abnormalities in facial expression (Ganesan and Thomas 2011).
    1. Careful examination shows an unusual co-contraction of the orbicularis oculi and orbicularis oris muscles only when full facial expressions are exhibited, across a range of emotional or voluntary situations.
    2. This suggests a peripheral disorder in facial muscle control.
    3. Two thirds of patients have anal sphincter abnormalities.
    4. Aberrant organization of the facial motor and urinary-anal sphincter nuclei may explain these symptoms.

Clinical Features

1. Characteristic facial expression.
    1. Inversion of the facial expression when attempting to smile or laugh
    2. Facial grimace while smiling
    3. Smile looking like weeping
    4. Peculiar facial expression on smiling
2. Urinary manifestations: The urofacial syndrome (Ochoa syndrome) is considered to represent a subgroup of the nonneurogenic bladder dysfunction, characterized by nonneuropathic bladder-sphincter dysfunction, along with a characteristic inversion of the facial expression with laughing (Stamatiou et al. 2011).
    1. Bladder dysfunction
        1. Intermittent urinary flow
        2. Residual urine after voiding
        3. Enuresis
        4. Polyuria
    2. Urinary tract infection
    3. Hydronephrosis
3. Twelve out of 15 patients had nocturnal lagophthalmos (a novel sign). Lagophthalmos (inability to close the eyelids completely) may lead to keratitis, corneal abrasion, infection, vascularization, and in extreme cases, ocular perforation, endophthalmitis, and loss of the eye (Mermerkaya et al. 2014).
4. Constipation.
5. The urinary abnormalities may lead to renal deterioration and ultimate failure if untreated.

Diagnostic Investigations

1. Renal ultrasonography.
2. Radionuclide renogram and renal scan for a boy with incontinence, frequent infections of the urinary tract, and gene mutations consistent with Ochoa syndrome (Infante et al. 2013).
    1. Nuclear medicine images showed extensive bilateral renal scarring.
    2. Diuretic renogram showed obstructive pattern.

3. Voiding cystourethrogram (VCUG).
4. Urodynamic studies.
5. Abdominal sonograms (Al-Qahtani 2003): gall bladder stones, septated gall bladder.
6. Exome capture and massively parallel sequencing identifies a novel *HPSE2* mutation (Al Badr et al. 2011).
9. Early diagnosis of the urofacial syndrome is essential to prevent irreversible renal failure (Nicanor et al. 2005)
10. Kidney transplantation for a case of deteriorating renal function (Muños Fernández et al. 2001)

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: 25%
   2. Patient's offspring: not increased unless the spouse is a carrier or affected
2. Prenatal diagnosis (Newman et al. 2013)
   1. Molecular genetic testing. If the disease-causing mutations have been identified in an affected family member, prenatal testing for pregnancies at increased risk is possible either through a clinical laboratory or a laboratory offering custom prenatal testing.
   2. Fetal ultrasonography. In families at risk of having an affected child, prenatal ultrasound of the urinary tract may show megacystis, hydroureteronephrosis, or renal pelvis dilatation in an affected pregnancy. These features are not specific for UFS.
   3. Preimplantation genetic diagnosis may be an option for some families in which the disease-causing mutations have been identified.
3. Management (Aydogdu et al. 2010)
   1. Intermittent urinary catheterization
   2. Appendicovesicostomy may be required for continent urinary diversion
   3. Nocturnal bladder emptying with an indwelling nighttime catheter for polyuria
   4. Antibiotic prophylaxis
   5. Anticholinergic therapy
   6. Intravesical botulinum toxin injection
   7. Bowel management
   8. Augumentation cystoplasty

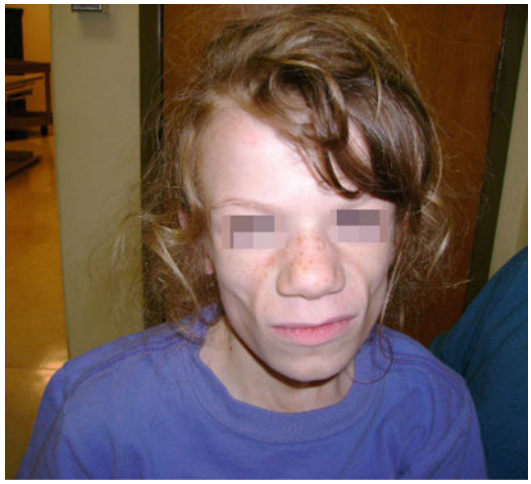

Fig. 1 This 7-year-old girl presented with vague abdominal discomfort associated with nausea, nonbilious vomiting, and weight loss for past 8–10 weeks duration. Abdominal CT revealed bilateral hydronephrosis. Note the "grimace" facial appearance after smiling

Fig. 3 Patient's VCUG showed smooth bladder wall

Fig. 2 Patient's CT scan of the abdomen showed bilateral hydronephrosis

VATER (VACTERL) Association

Contents

VATER association is an acronym for the following nonrandom association of defects: *V*ertebral defects, *A*nal atresia, *T*racheoesophageal fistula with *E*sophageal atresia, and *R*enal or *R*adial defects (Quan and Smith 1973; Smith 1974; Temtamy and Miller 1974). VACTERL association is an expanded acronym to include *C*ardiac defects and *L*imb defects. Diagnosis of VACTERL association is made if three out of the seven above defects are present in an infant. The incidence is estimated to be 1.6 cases in 10,000 live births.

Genetics/Basic Defects

1. Etiologic heterogeneity
    1. Isolated cases in most cases
    2. Reports of rare familial cases (single gene disorders)
    3. Reports of chromosome abnormality cases
    4. Recognized syndromes or phenotypes
    5. Observed more frequently in infants of diabetic mothers
2. Pathogenesis: suggestion of a defective mesodermal development during embryogenesis due to a variety of causes, leading to overlapping manifestations (Khoury et al. 1983)
3. Molecular basis of VACTERL association
    1. Report of a family in which a female infant was born and died at age 1 month due to renal failure. The mother and sister later developed classic mitochondrial cytopathy, associated with the A-to-G point mutation at nucleotide position 3243 of mitochondrial DNA (Damian et al. 1996; Stone and Biesecker 1997).
    2. Mitochondrial NP 3243 point mutation considered not a common cause of VACTERL association (Damian et al. 1996).
    3. Sonic hedgehog in the human: a possible explanation for the VATER association (Arsic et al. 2002).
    4. In addition to core Hedgehog pathway components, several Sonic hedgehog target genes, *Forkhead* and *5′Hoxd* genes (*Hoxd12* and *Hoxd13*), have also been implicated in VACTERL (Ngan et al. 2013).
    5. VACTERL: (polytopic) developmental field defect, instead of VACTERL association or VACTERL syndrome (Martinez-Frias and Frias 1999; Martinez-Frias et al. 2001).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_242

6. Recently, microdeletions of the FOX gene cluster at 16q24.1, comprising four genes, *FOXF1*, *MTHFSD*, *FOXC2*, and *FOXL1*, were reported to cause a phenotype resembling VACTERL association, with vertebral anomalies, gastrointestinal atresias (esophageal, duodenal, and anal), congenital heart malformations, and urinary tract malformations, as well as a rare lethal developmental anomaly of the lung, alveolar capillary dysplasia (Shaw-Smith 2010).
7. Targeted resequencing of 29 candidate genes and mouse expression studies implicate *ZIC3* and *FOXF1* in human VATER/VACTERL association (Hilger et al. 2015).
8. According to epidemiological studies, the majority of patients with VATER/VACTERL association present with a "renal" phenotype comprising a large spectrum of congenital renal anomalies. This finding is supported by evidence linking all of the human disease genes for the VATER/VACTERL association identified to date, namely, *FGF8*, *FOXF1*, *HOXD13*, *LPP*, *TRAP1*, and *ZIC3*, with renal malformations (Reutter et al. 2016).
9. So far, the *ZIC3* gene has been demonstrated to cause X-linked VACTERL association (Chen et al. 2016a). Different types of *ZIC3* mutations, including point mutations, deletions, and polyalanine expansion, have been reported to be responsible for both VACTERL or VACTERL-like association (Wessels et al. 2010; Chung et al. 2011; Hilger et al. 2015).

Clinical Features

1. VACTERL association: clinical variability (Weaver et al. 1986; Corsello et al. 1992; Oral et al. 2012)
   1. *V*ertebral anomalies
      1. Transitional vertebrae
      2. Hemivertebrae
      3. Fused vertebrae
      4. Block vertebrae
      5. Hypersegmentation of the vertebrae
      6. Hypersegmentation of the ribs
      7. Scoliosis
      8. Spina bifida
      9. Sacral anomalies
      10. Incomplete pedicle
      11. Sternal anomalies
   2. *A*nal and urachal anomalies
      1. Anal atresia with or without fistula
      2. Persistent urachus (cloacas)
      3. Rectrourethral prostatic fistula
      4. Rectrourethral bulbar fistula
      5. Cutaneous (perineal) fistula
      6. Vestibular fistula
      7. Ectopic anus
   3. *C*ardiac anomalies (Cunningham et al. 2013)
      1. Ventricular septal defect
      2. Atrial septal defect
      3. Patent ductus arteriosus
      4. Tetralogy of Fallot
      5. Transposition of the great arteries
      6. Other cardiovascular anomalies: right aortic arch, double aortic arch, coarctation of the aorta, dextrocardia, total anomalous pulmonary venous drainage, persistent left superior vena cava, congenital mitral stenosis, right anomalous coronary artery, single umbilical artery
   4. *T*racheoesophageal fistula
   5. *E*sophageal atresia
   6. *R*enal anomalies
      1. Renal agenesis/dysgenesis
      2. Ectopic kidney
      3. Horseshoe kidney
      4. Dysplastic kidney
      5. Duplex kidney
      6. Cystic dysplastic kidney
      7. Ureteral/urethral anomalies
      8. Hydronephrosis
      9. Renal ectopia
      10. Vesicoureteral reflux
      11. Posterior urethral valves
      12. Ureteropelvic junction obstruction
      13. The most common renal manifestation (RM) was vesicoureteral reflux in addition to a structural defect (present in 27%), followed by unilateral renal

agenesis (24%), and then dysplastic/multicystic kidneys or duplicated collected system (18% for each) (Cunningham et al. 2014). Twenty-two (88%) of the 25 patients with a structural RM had an associated anorectal malformation.

7. *L*imb defects
    1. Radial aplasia/dysplasia
    2. Hypoplastic thumbs
    3. Triphalangeal thumb
    4. Preaxial polydactyly
    5. Syndactyly
    6. Radioulnar synostosis
    7. Tibial developmental field defect (the dyad of tibial hypoplasia and homolateral hallucal deficiency/polydactyly) is the most common lower limb malformation pattern in VACTERL association (Castori et al. 2008)

2. Other associated abnormalities
    1. Failure to thrive
    2. Short stature
    3. Wide cranial suture
    4. Large fontanel
    5. Potter facies
    6. Ophthalmological abnormalities (Say et al. 1977)
    7. Ear anomalies
    8. Cleft palate
    9. Laryngeal stenosis
    10. Gastrointestinal anomalies
        1. Malrotation
        2. Meckel diverticulum
        3. Duodenal atresia
        4. Pyloric atresia
        5. Ileal atresia
        6. Pancreatic heterotopia
        7. Vermiform appendix agenesis
        8. Omphalocele
        9. Inguinal hernia
    11. Genital anomalies
        1. Hypospadias
        2. Cryptorchidism
        3. Bifid scrotum
        4. Micropenis
    12. Neurological anomalies
        1. Tethered cord
        2. Spinal dysraphia
        3. Occipital encephalocele
    13. Anomalies more commonly associated with CHARGE association

3. The spectrum of congenital anomalies of the VATER association (Botto et al. 1997)
    1. Of infants with VATER association, 74.8% had additional defects: Genital defects, cardiovascular anomalies, and small intestinal atresias were positively associated with VATER association.
    2. Infants with VATER association that included both renal anomalies and anorectal atresia were significantly more likely to have genital defects.
    3. A subset of infants with VATER association also had defects described in other associations, including diaphragmatic defects (Chen et al. 2016b), oral clefts, bladder exstrophy, omphalocele, and neural tube defects.

4. Morbidity and mortality in patients with VACTERL associations (Iuchtman et al. 1992)
    1. Morbidity
        1. During the first year of life, there was considerable morbidity resulting from the tracheoesophageal abnormalities.
        2. Anorectal, renal, or skeletal anomalies rarely caused death, but, when severe, were associated with a poor quality of life.
    2. Mortality rate (24%)
        1. Most deaths: caused by cardiovascular abnormalities.
        2. Infants weighing less than 2,050 g had a mortality rate of 26%, double that of heavier infants.

5. Differential diagnosis: conditions with multiple features in common with VACTERL association (Solomon 2011)
    1. Alagille syndrome (please see the chapter on "► Alagille Syndrome")
        1. Common features: vertebral anomalies, cardiac anomalies; may have renal anomalies
        2. Distinct features: bile duct paucity and cholestasis, ophthalmologic anomalies (especially posterior embryotoxon),

neurological anomalies, characteristic facial appearance; heterozygous mutations in *JAG1*, *NOTCH2*

2. Baller-Gerold syndrome
    1. Common features: radial anomalies, may also include anal anomalies
    2. Distinct features: craniosynostosis, skin anomalies, heterozygous mutations in *RECQL4*
3. CHARGE syndrome (please see the chapter on "▶ CHARGE Syndrome")
    1. Common features: cardiac malformations, genitourinary anomalies; may also include tracheoesophageal fistula
    2. Distinct features: colobomata, choanal atresia, neurocognitive and growth impairment, ear anomalies, cranial nerve dysfunction, characteristic facial features, heterozygous mutations in *CHD7*
4. Currarino syndrome
    1. Common features: sacral malformations, anorectal malformations
    2. Distinct features: presacral mass, heterozygous mutations/deletions of *HLXB9*
5. 22q11.2 deletion syndrome (also known by other names, such as DiGeorge syndrome or velocardiofacial syndrome) (please see the chapter on "▶ Del (22q11.2) Syndrome")
    1. Common features: cardiac malformations, renal anomalies, other VACTERL-type anomalies also reported
    2. Distinct features: hypocalcemia, palatal anomalies, learning difficulties, immune dysfunction, neuropsychiatric disturbances, characteristic facial features, deletion of one copy of chromosome 22q11.2
6. Fanconi anemia
    1. Common features: virtually all features of VACTERL association may occur; radial anomalies are considered an especially key feature
    2. Distinct features: hematologic anomalies, pigmentation anomalies, recessive or X-linked mutations in multiple genes (typically detected by chromosomal breakage studies)
7. Feingold syndrome (please see the chapter on "▶ Feingold Syndrome")
    1. Common features: GI atresia, cardiac defects, renal anomalies
    2. Distinct features: brachymesophalangy, toe syndactyly, microcephaly, cognitive impairment, characteristic facial appearance, heterozygous mutations in *MYCN*
8. Fryns syndrome
    1. Common features: GI malformations, cardiac defects, GU anomalies
    2. Distinct features: diaphragmatic defects, neurocognitive impairment, characteristic facial appearance, no well-characterized unifying causes
9. Holt-Oram syndrome (please see the chapter on "▶ Holt-Oram Syndrome")
    1. Common features: cardiac malformations, limb malformations
    2. Distinct features: cardiac conduction disease (also reported in VACTERL association), heterozygous mutations in *TBX5*
10. Müllerian duct aplasia, renal aplasia, and cervicothoracic somite dysplasia (MURCS association); also known as Mayer-Rokitansky-Küster-Hauser syndrome type II
    1. Common features: vertebral anomalies, renal anomalies, GU anomalies, and anorectal malformations; may also have cardiac and limb anomalies
    2. Distinct features: syndactyly and hearing loss have been described, causes unknown; likely heterogeneous
11. Oculo-auriculo-vertebral syndrome (please see the chapter on "▶ Goldenhar Syndrome")
    1. Common features: vertebral anomalies, cardiac abnormalities, limb abnormalities, urogenital anomalies

2. Distinct features: ear anomalies (microtia), hemifacial microsomia, neurocognitive impairment, facial clefts (also described in patients with VACTERL association), causes unknown (likely heterogeneous)

12. Opitz G/BBB syndrome
    1. Common features: anal anomalies, heart defects, TEF, hypospadias
    2. Distinct features: hypertelorism, syndactyly; X-linked form (heterozygous/hemizygous mutations in *MID1*); autosomal dominant form (some cases due to deletion 22q11.2
13. Pallister-Hall syndrome
    1. Common features: imperforate anus, renal anomalies, limb anomalies (postaxial polydactyly should serve as a clue for the Pallister-Hall syndrome)
    2. Distinct features: hypothalamic hamartoma, bifid epiglottis (ranging to more severe types of clefts), nail hypoplasia, heterozygous mutations in *GLI3*
14. Townes-Brocks syndrome
    1. Common features: imperforate anus, thumb anomalies, renal anomalies, cardiac anomalies
    2. Distinct features: dysplastic ears, hearing loss, heterozygous mutations in *SALL1*
15. VACTERL with hydrocephalus (Lomas et al. 1998)
    1. Common features: all core component features of VACTERL
    2. Distinct features: hydrocephalus, heterozygous mutations in *PTEN*, heterozygous/hemizygous mutations in *ZIC3*; X-linked and recessive forms have been described

Diagnostic Investigations

1. Radiography (Barnes and Smith 1978; Fernbach and Glass 1988) for vertebral and limb defects and other malformations
2. Echocardiography for congenital heart defects
3. GI investigation for TE fistula or esophageal atresia
4. Renal ultrasonography for renal dysplasia
5. Urological evaluation of urogenital defects
6. Chromosome analysis

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: low recurrence risk unless in a single gene disorder (Auchterlonie and White 1982; Bartels et al. 2012)
    2. Patient's offspring: low recurrence risk unless in a single gene disorder
2. Prenatal diagnosis by ultrasonography (McGahan et al. 1988; Miller and Kolon 2001; Santos et al. 2013) revealing multiple congenital anomalies compatible to VATER/VACTERL association
    1. Vertebral anomalies
    2. Anorectal anomalies
    3. Congenital heart defects
    4. TE fistula or esophageal atresia
    5. Renal anomalies
    6. Limb defects
    7. Important clues (Tongsong et al. 1999)
        1. Radial atresia
        2. Absent or collapsed stomach
        3. Polyhydramnios
    8. Prenatal diagnosis of radial ray defects in fetuses conceived by assisted reproductive technology should include a differential diagnosis of VACTERL association with anorectal malformation. VACTERL association with hydrocephalus may occur in pregnancy after in vitro fertilization and embryo transfer (Chen et al. 2013).
3. Management
    1. Medical care
    2. Surgical care (Weber et al. 1980)
        1. TE fistula and/or esophageal atresia
        2. Major cardiac defects
        3. Urogenital anomalies
        4. Skeletal and limb defects
        5. Infants with the VATER association can lead reasonably normal lives following aggressive operative treatment and supportive care (Figs. 1–5).

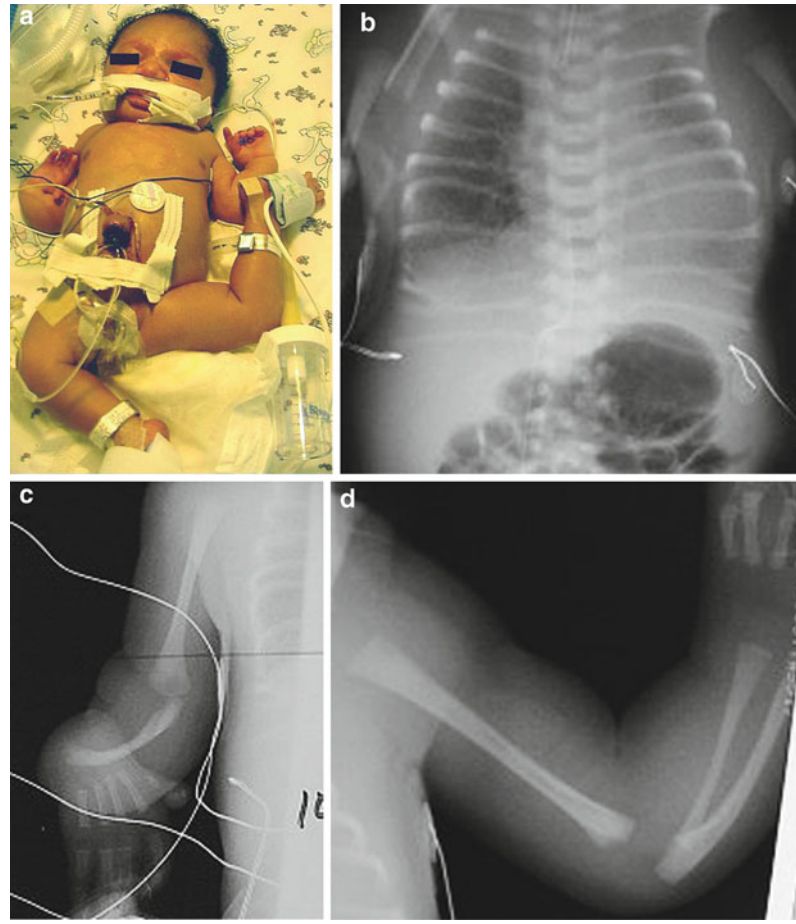

Fig. 1 (**a**–**d**) An infant (**a**) with VATER association showing club hands, abnormally rotated left lower limb, fused/split ribs, hemivertebrae (**b**), radial aplasia on the right (**c**), and radioulnar fusion on the left elbow (**d**)

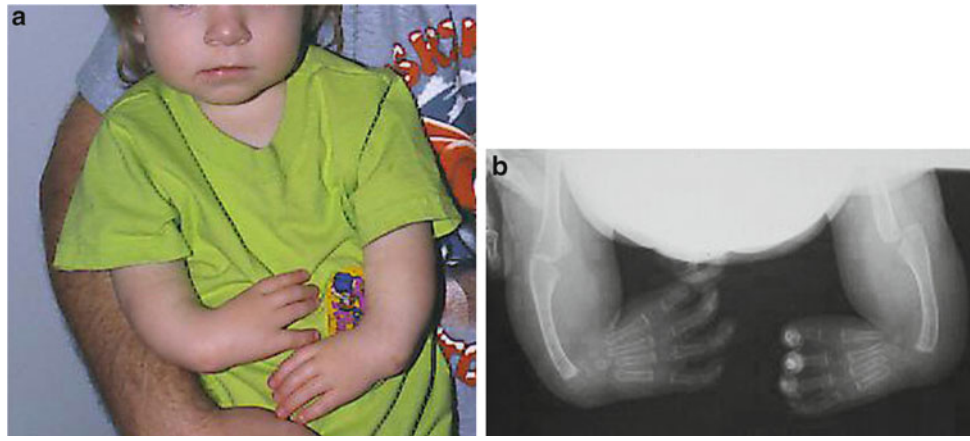

Fig. 2 (**a**, **b**) A child (**a**) with VATER association showing club hands and missing thumbs. Radiograph showed absence of the first phalanges and metacarpals and radial aplasia (**b**)

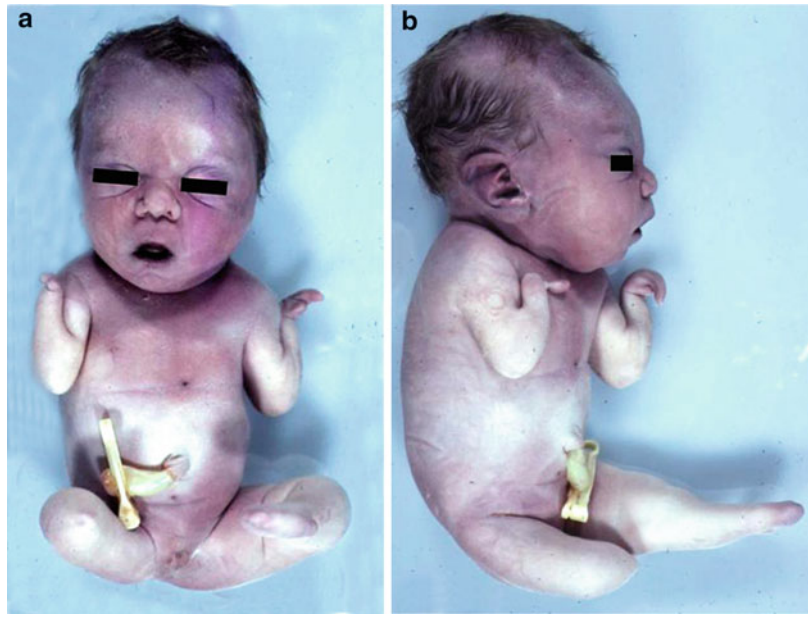

Fig. 3 (**a**, **b**) A male neonate with VATER association showing phocomelia, rudimentary external genitalia, and anal atresia, congenital heart anomalies (type 2 truncus arteriosus, tricuspid valve atresia, ventricular septal defect, large atrial septal defect), type 1 tracheoesophageal fistula, nonlobated lungs, agenesis of kidneys and ureters, malrotation of bowel, and vesicocolonic fistula were demonstrated in the necropsy

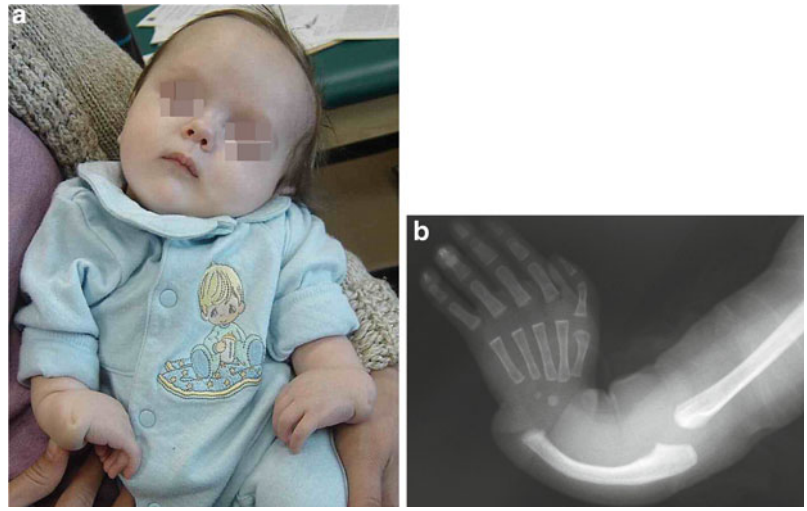

Fig. 4 (**a**, **b**) An infant with club hands (**a**) and radial aplasia, illustrated by a radiograph (**b**)

Fig. 5 (**a**–**c**) A girl with VATER association showing a remnant left thumb (**a**), anal atresia (**b**), and colostomy (**c**)

Von Hippel-Lindau Disease

Contents

Von Hippel-Lindau disease (VHL) is a rare hereditary cancer syndrome. The prevalence is estimated at 1 in 85,000 with an incidence of 1 in 45,500 live births (Friedrich 2001).

Synonyms and Related Disorders

Angiomatosis retinae; Von Hippel-Lindau syndrome

Genetics/Basic Defects

1. Inheritance (Schimke et al. 2009)
    1. Autosomal dominant
    2. Reduced penetrance (95% penetrance at age 60)
    3. Positive family history in up to 80% of cases
    4. Sporadic new mutation in about 20% of cases
    5. Parental mosaicism described
2. Molecular pathogenesis of VHL disease
    1. VHL disease.
        1. Caused by deletions or mutations in a tumor suppressor gene (Latif et al. 1993), the *VHL* gene, located on chromosome 3p25–26, which encodes an ubiquitin ligase that is involved in the cellular response to hypoxia
        2. Two-hit theory of Knudson in a familial cancer syndrome such as VHL disease (Lubensky et al. 1998)
            1. Although sporadic cases require a "2-hit" model of gene inactivation, familial cases require only a single "hit" because one allele is already affected at the time of conception (Wizigmann-Voos and Plat 1996).
            2. Prediction of the genotype of each neoplasm which consists of an allele with an inherited germ line mutation and loss of the second wild-type allele through allelic deletion.
            3. Loss of heterozygosity at chromosome 3p at the *VHL* gene region has been demonstrated in different VHL disease-associated tumors.
        3. A germ line mutation in the *VHL* gene (Hes et al. 2003)
            1. Predisposes carriers to tumors in multiple organs
            2. Consistently detected in 100% of classic families with more than one

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_243

affected family member or classic sporadic patients with multiple VHL-related tumors
3. Missense mutations leading to an amino acid substitution in *VHL* gene product pVHL, observed in 40% of the families with an identified *VHL* gene germ line mutation
4. Microdeletions, insertions, splice site, and nonsense mutations, all predicted to lead to a truncated protein: observed in 30% of the families
5. Large deletions including deletions encompassing the entire gene: account for the remaining 30% of the *VHL* gene germ line mutations

4. Somatic mutations
   1. Report of a case of somatic mosaicism in the asymptomatic mother of a VHL patient who was subsequently diagnosed with pheochromocytoma (Murgia et al. 2000). This is the first report providing molecular evidence of somatic mosaicism in von Hippel-Lindau disease. Mosaicism could provide some genetic explanation for the clinical heterogeneity and variable severity of the VHL phenotype, and should be considered, as a possible event when evaluating sporadic cases of VHL or patients with isolated VHL-related tumors.
   2. Independent somatic alteration of both alleles of the VHL tumor suppressor gene leading to tumorigenesis in nonfamilial (VHL-related) tumors. Somatic VHL gene mutations and allele loss: frequent events in sporadic clear cell renal cell carcinomas and sporadic central nervous system hemangioblastoma, uncommon in sporadic (i.e., nontumor syndrome associated) pheochromocytoma (Hes et al. 2003).

2. *VHL* gene.
   1. Mapped on chromosome 3p25
   2. Involved in blood vessel formation by regulation of the activity of hypoxia-inducible factor (HIF)-1α

3. Patients with VHL disease.
   1. With a positive family history: have inherited an inactive *VHL* allele from an affected parent
   2. Without a positive family history: have a parent who is mosaic for a *VHL* mutation, presumably as the result of a de novo mutation during early development
4. Angiogenesis of VHL tumors: critical role of inactivation of *VHL* gene.
   1. Overexpression of vascular endothelial growth factor (VEGF) resulting in hypervascularization
   2. Negative regulation of hypoxia-inducible mRNAs including VEGF mRNA by VHL protein
5. Tumor development in VHL disease.
   1. Inactivation of the VHL tumor suppressor gene is an early, causal event in the development of clear cell renal cell carcinomas and hemangioblastomas. Its protein product, pVHL, is part of an E3 ubiquitin ligase complex that targets HIFα subunits for destruction in the presence of oxygen (Kaelin 2003). Accordingly, pVHL-defective tumor cells overproduce a variety of HIF target genes, which have been implicated in metabolism, mitogenesis, and angiogenesis.
   2. Linked to inactivation or loss of the remaining wild-type *VHL* allele in a susceptible cell, leading to loss of the *VHL* gene product pVHL.
   3. Inactivation of *VHL* gene contributing to tumorigenesis of the VHL tumor since VHL protein is required for the downregulation of transcription activity of certain genes.
6. *VHL* gene alterations in sporadic benign and malignant pheochromocytomas (Dannenberg et al. 2003).
   1. No distinction in the nature of *VHL* alterations between benign and malignant pheochromocytomas and no correlation with histopathologic or clinical features.

2. Novel VHL mutations in sporadic pheochromocytomas: slightly correlated with malignancy.
3. *VHL* mutations may have some impact on the malignant transformation of pheochromocytomas.

7. Clinical and laboratory studies of VHL disease have provided a paradigm for demonstrating the importance of familial cancer syndromes in elucidating mechanisms of tumorigenesis in familial and sporadic cancer (Clifford and Maher 2001).

3. Cytogenetic abnormalities in tumors of patients with von Hippel-Lindau disease (Jordan et al. 1989)
   1. A deletion of 3p may be a primary cytogenetic change in renal cell carcinomas (RCCs) associated with VHL disease in addition to playing a role in sporadic RCC.
   2. Duplications of 5q and deletions of 14q may be important secondary changes in the progression of the malignant phenotype.
4. Genotype-phenotype correlations (Neumann and Bender 1998; Couch et al. 2000)
   1. Families with pheochromocytoma have in >90% missense mutations, whereas families with renal cell carcinoma show the entire spectrum of the mutations in the *VHL* gene (Neumann et al. 1995).
   2. The mutations associated with VHL type 1 (without pheochromocytoma) are deletions and protein-truncating mutations such as nonsense mutations and microdeletions-insertions in most families.
   3. In VHL type 2 (with pheochromocytoma), 96% of families have missense mutations. However, not all missense mutations are associated with a high risk of pheochromocytoma.
   4. A substantial proportion of patients with familial pheochromocytoma have VHL gene mutations. but in contrast, most familial clusters of clear cell renal cell carcinoma (RCC) without evidence of VHL do not have germline VHL mutations (Richards et al. 1998).
   5. Visual morbidity secondary to retinal hemangioblastoma was not related to the type of extraocular manifestation but appeared to be related to the type of germline mutation (Dollfus et al. 2002).
   6. HIF-α binding site missense mutations elevate age-specific risk for CNS hemangioblastoma (Lee et al. 2016).

Clinical Features

1. Great variation in the clinical presentation with variable age of onset (Schimke et al. 2009)
2. Several characteristic features of VHL but no single unique pathognomonic findings (Couch et al. 2000)
3. Classification of VHL disease: The classic VHL phenotypes (Schimke et al. 2009; Sano and Horiguchi 2003; Bausch et al. 2013)
   1. VHL type 1
      1. Typical VHL manifestations such as hemangioblastomas of the CNS and/or retina and clear cell renal cell carcinomas, pancreatic cysts, and neuroendocrine tumors
      2. Without pheochromocytoma
      3. Truncating or null mutations in the VHL gene (deletions or frameshift, nonsense, or splice site mutations) observed in approximately 96–97% of patients with type 1 VHL
   2. Subtypes of type 1 VHL
      1. VHL type 1 A
         1. Frequency of pheochromocytoma: low
         2. Frequency of renal cell carcinoma: low
      2. VJL type 1B
         1. Frequency of pheochromocytoma: low
         2. Frequency of renal cell carcinoma: high
   3. VHL type 2
      1. With pheochromocytomas
      2. Missense mutations observed in 92–98% of patients with type 2 VHL

4. Subtypes of type 2 VHL
    1. VHL type 2 A
        1. Frequency of pheochromocytoma: high
        2. Frequency of renal cell carcinoma: low
        3. VHL without predisposition to renal cell carcinoma and pancreatic neuroendocrine tumor
        4. Specific mutations (Y98H, Y112H, V116F, L188 V) in the *VHL* gene conferring an increased risk for VHL disease
    2. VHL type 2B
        1. Frequency of pheochromocytoma: high
        2. Frequency of renal cell carcinoma: low
        3. VHL with predisposition to renal cell carcinoma and pancreatic neuroendocrine tumor
        4. Specific mutations (R167Q, R167W) in the *VHL* gene conferring an increased risk for VHL disease
    3. VHL type 2C
        1. No associated tumors
        2. VHL with only pheochromocytoma manifestation (no other manifestations)
        3. Specific mutations (V155 L, R238W) in the *VHL* gene conferring an increased risk for VHL disease
4. Tumors/cysts linked to VHL disease, typically develop in the second, third, and fourth decades of life (Findeis-Hosey et al. 2016)
    1. Retinal angioma/hemangioblastoma
        1. Responsible for the first manifestation of VHL in 50% of the patients
        2. Retinal lesions
            1. Formerly called retinal angiomas
            2. Histologically identical to hemangioblastomas
            3. Identified in about 70% of the patients
            4. Bilateral in about 50% of the patients
            5. Multiple in about 66% of the patients
        3. Complications when the condition is unrecognized and untreated at early stage
            1. Majority of retinal angiomas eventually hemorrhage
            2. Resulting in massive exudation and retinal detachment
            3. Ultimate development of neovascular glaucoma and blindness
    2. Cerebellar hemangioblastomas (80% of CNS hemangioblastoma) (Friedrich 2001)
        1. The most common initial manifestation (34.9%)
        2. Cumulative occurrence: 60.2%
        3. The most common cause of death (47.7%)
        4. Symptoms and signs
            1. Headache
            2. Slurred speech
            3. Nystagmus
            4. Positional vertigo
            5. Labile hypertension (without pheochromocytoma)
            6. Vomiting
            7. Wide-based gait
            8. Dysmetria
    3. Spinal hemangioblastoma (20% of CNS hemangioblastoma) (Friedrich 2001)
        1. More specific for VHL disease
        2. About 80% of cases are caused by VHL.
        3. Cumulative occurrence (14.5%)
        4. Symptoms and signs
            1. Pain
            2. Sensory and motor loss secondary to cord compression
    4. Renal lesions
        1. Clear cell renal cell carcinoma (ccRCC) accounts for ~80% of all RCC, and biallelic *VHL* gene defects occur in ~75% of sporadic ccRCC (Shenoy and Pagliaro 2016).
        2. Renal cysts: precursor lesions to clear cell renal cell carcinomas (75% of patients with VHL) which is a frequent cause of death.
    3. Hemangioblastoma.

4. Renal cell adenoma.
5. Renal cell carcinoma (20–40%).

5. Endocrine manifestations of von Hippel–Lindau disease (Cassol and Mete 2015)
   1. Pancreatic neuroendocrine proliferations
      1. Ductuloinsular complexes
      2. Islet dysplasia
      3. Endocrine microadenoma
      4. Neuroendocrine tumors
   2. Pheochromocytomas
   3. Extra-adrenal paragangliomas
6. Pheochromocytomas (tumor of adrenal medulla)
   1. Type 1 families
      1. Absence of pheochromocytomas.
      2. Most type 1 families are affected by deletions or premature termination mutations.
   2. Type 2 families (7–20% of families)
      1. Presence of pheochromocytomas.
      2. Most type 2 families are affected by missense mutations.
   3. Arg238trp and arg238gln mutations: associated with a 62% risk for pheochromocytoma
   4. Location of tumors
      1. Usually located in one or both adrenal glands
      2. May present anywhere along the sympathetic axis in the abdomen or thorax (paragangliomas) or head and neck (chemodectomas)
   5. Symptoms and signs
      1. Sustained or episodic hypertension
      2. Asymptomatic
7. Pancreatic lesions
   1. Type of lesions
      1. Simple pancreatic cysts
      2. Serous cystadenomas
      3. Pancreatic neuroendocrine tumors
   2. Rarely causing endocrine or exocrine insufficiency unless the lesion is extensive
   3. Occasionally causing biliary obstruction secondary to cysts in the head of the pancreas
8. Liver lesions
   1. Hemangiomas
   2. Cyst
   3. Adenoma
   4. Carcinoid of the common bile duct
9. Splenic lesions
   1. Hemangiomas
   2. Cyst
10. Pulmonary lesions
    1. Hemangiomas
    2. Cyst
11. Bladder hemangioblastoma
12. Endolymphatic sac tumors of the inner ears (labyrinth)
    1. Tinnitus or vertigo
    2. Deafness
13. Papillary cystadenomas of the epididymis in males
    1. Relatively common in males
    2. Unilateral: rarely causing problem
    3. Bilateral: infertility
14. Papillary cystadenomas of the broad ligament in females: much less common
15. Skin lesions
    1. Nevus
    2. Café au lait spot
16. Bone lesions
    1. Hemangioma
    2. Cyst

5. Diagnosis of VHL disease usually made on clinical grounds (Sanfilippo et al. 2003)
   1. A positive family history of VHL disease plus one of the following lesions (hemangioblastoma or visceral lesion):
      1. Retinal hemangioblastoma
      2. Cerebellar hemangioblastoma
      3. Pheochromocytoma
      4. Renal cell carcinoma
      5. Multiple pancreatic cysts
   2. A negative family history of VHL disease needs one of the following (Friedrich 2001):
      1. Two or more retinal or cerebellar hemangioblastomas, or
      2. One hemangioblastoma plus one visceral tumor
6. Prognosis (Maher et al. 1990)
   1. Life expectancy: $<$50 years

2. Major causes of death (Shanbhogue et al. 2016)
    1. Renal cell carcinoma: the leading cause of death
    2. Cerebellar hemangioblastoma
3. Improved prognosis in patients with:
    1. Earlier diagnosis
    2. Regular monitoring for predictable complications
    3. Followed by early interventions
    4. Even though the risk of VHL related death has decreased significantly, the main cause of death is still CNS hemangioblastomas (Binderup et al. 2016)

Diagnostic Investigations

1. Biochemical test: elevated urinary catecholamines (VMA, metanephrine, and total catecholamine) suggesting pheochromocytoma even in the absence of hypertension
2. Eye examinations (Sanfilippo et al. 2003)
    1. Ophthalmoscopy.
    2. Fluorescein angiography, a valuable tool useful in detecting subclinical fundus lesions.
    3. Annual audiometry as a first-line endolymphatic sac tumor screening tool, and in countries where periodic surveillance magnetic resonance imaging of the central nervous system is performed, specific images of the inner ear should be included (Paulsen et al. 2011).
        1. Audiometric abnormalities in patients with von Hippel-Lindau disease without magnetic resonance imaging-visible endolymphatic sac tumors could be due to microscopic endolymphatic sac tumors.
        2. Determination of audiometric endolymphatic sac tumor characteristics could further target screening and improve endolymphatic sac tumor diagnosis.
3. Imaging features (Choyke et al. 1995; Khan 2015)
    1. Radiography for rare associated bone cysts and osseous hemangiomas (Leung et al. 2008)
    2. Ultrasound examinations
        1. Evaluation of the epididymis and broad ligament
        2. Screening of the kidneys
    3. CAT scan (Torreggiani et al. 2002; Taouli et al. 2003)
        1. CNS hemangioblastomas
            1. Cystic lesions (75%)
            2. An enhancing lesion with multiple cystic areas (15%)
            3. An enhancing solid mass (10%)
        2. Retinal hemangiomas too small to be depicted on CT scans, the diagnosis mainly dependent on the results of an ophthalmoscopic examination
        3. CNS hemangioblastomas and retinal angiomas: the commonest and usually the earliest features of the disease
        4. Papillary endolymphatic sac tumors presenting as a thin peripheral rim of calcification, representing the expanded cortex of petrous bone
        5. Low sensitivity in the detection of renal cell carcinoma associated with VHL
            1. Not reliable in differentiating cystic renal cell carcinomas, cancers within a cyst, and atypical cysts
            2. Impossible to differentiate a renal cell adenoma from a renal cell carcinoma
        6. Pheochromocytoma
            1. Most tumors are localized in the adrenal glands, but 15–18% of the lesions are found in an extraadrenal location (paragangliomas).
            2. The diagnosis is based on biochemical tests (serum and urinary catecholamines) and imaging.
            3. On CT (Neumann et al. 1998), pheochromocytoma typically appears as a solid or complex cystic mass with some areas of necrosis and hemorrhage, possible calcifications, and marked enhancement.

7. Pancreatic masses (Charlesworth et al. 2012)
    1. Simple pancreatic cysts: benign
    2. Serous cystadenomas: benign
    3. Pancreatic neuroendocrine tumors: typically nonsecretory islet cell tumors and may occasionally be malignant (Hammel et al. 2000)
8. Other abdominal lesions
    1. Liver cysts
    2. Cystadenomas of the epididymis and of the broad ligament

4. ^{68}Ga DOTATATE PET/CT
    1. Endolymphatic sac tumor showing increased activity (Papadakis et al. 2016a)
    2. Epididymal cystadenomas in VHL showing increased activity (Papadakis et al. 2016b)
5. MRI to document the presence of CNS and visceral tumors
    1. MRI appearances of a CNS hemangioblastoma: a well-demarcated cystic lesion with a highly vascular mural nodule that always abuts on the pia mater
    2. Spinal hemangioblastomas: intramedullary tumors in most patients (75%) but may be radicular (20%) or intradural extramedullary (5%)
    3. Pheochromocytoma: high signal intensity on T2-weighted MRI, differentiating it from adrenal cortical nodules
    4. Endolymphatic sac tumors: high signal intensity with T1 imaging on MRI as a mass on the posterior wall of the petrous part of the temporal bone
6. Radionuclide studies
    1. To provide an indication of metabolic activity of CNS tumors by positron emission tomography (PET) with 2-[fluorine 18]-fluoro-2-deoxy-D-glucose (FDG)
    2. To detect bone metastases resulting from primary malignant tumor of bone of VHL
    3. To assess renal function prior to resection of renal tumors
    4. To detect pheochromocytoma using iodine-131 metaiodobenzylguanidine (^{131}I MIBG)
7. Angiography
    1. Hemangioblastoma: a hypervascular lesion with intense and prolonged early enhancement of the mural nodule associated with dilated feeding vessels
    2. Endolymphatic sac tumors
        1. Hypervascular on angiography and the blood supply is derived from the external carotid artery
        2. Large tumors with an additional blood supply from the internal carotid artery and posterior circulation

4. Cytogenetic and fluorescence in situ hybridization studies on sporadic and hereditary tumors associated with VHL (Decker et al. 1994)
    1. FISH with single copy probes for interphase cytogenetics detected four subclones with deletions in the VHL region in 8/22 tumors, including four tumors which appeared cytogenetically normal.
    2. FISH proved to be a powerful tool in tumor genetic studies, especially helpful in detecting tumor subclones in benign and slowly growing tumors.
    3. FISH: a simple and reliable method to detect VHL germline deletions and practically useful in cases where other methods of screening have failed to detect a VHL gene abnormality (Pack et al. 1999).
5. Histologic features of VHL tumors (Sano and Horiguchi 2003)
    1. High degree of vascularization
    2. Presence of a clear cell component
6. NIH group recommendation for monitoring VHL patients and family members (Friedrich 2001)
    1. Birth to 2 years
        1. Annual physical examination
        2. Annual ophthalmologic examination
    2. 2–10 years: urinary catecholamines every 1–2 years
    3. 11–19 years
        1. Biannual MRI of the brain and spine

2. Annual ultrasound examination of abdomen
3. CT scans of abdomen every 6 months if renal cysts or tumor present

4. 20–59 years: annual CT scan of abdomen
5. 60 years and above without VHL
   1. MRI of the brain and spine every 3–5 years
   2. CT scan of the abdomen every other year
6. Not necessary to monitor the family members identified previously with an empiric risk of 50% of being affected but are found not to have inherited the mutation

7. Molecular genetic analysis
   1. Considered standard for the evaluation of patients and families with suspected VHL disease: detects mutations in nearly 100% of affected individuals.
   2. Clinical testing.
      1. Sequence analysis
      2. Deletion/duplication analysis
   3. Identification of *VHL* gene germ line mutations.
      1. Identification of constitutional *VHL* gene deletions by FISH using probes from the *VHL* gene critical region in 3p25.3
         1. Offers a comprehensive way to screen for the presence of germ line deletions because it enables visualization of individual cells
         2. May identify mosaicism or cryptic translocation events that cannot be readily detected by other molecular strategies in patients with submicroscopic germ line deletions and a normal karyotype
         3. Enable to identify a de novo mosaic for the *VHL* gene deletion
      2. Molecular diagnosis accomplished in virtually all families with classic VHL disease (families with multiple tumors) and in the majority of isolated patients with multiple VHL-associated tumors
         1. Qualitative and quantitative Southern blotting to detect partial or complete gene deletions responsible for 28% of all cases
         2. FISH to confirm deletions
         3. DNA-sequence analysis of the protein-encoding region (all three exons) to detect point mutations in the remainder (72%) of the cases
         4. It is now possible to identify germline mutations in virtually all families with VHL (Stolle et al. 1998)
   4. Mosaicism.
      1. A potential cause for failure of molecular diagnosis in VHL.
      2. Individuals with mosaicism:
         1. Asymptomatic
         2. Manifesting as a single-system disease
         3. Manifesting as a multisystem disease
      3. Kindreds with germline mutations identified in offspring with mosaic parents: Mosaicism in VHL is important to search for and recognize when an individual without a family history of VHL has VHL (Sgambati et al. 2000).
   5. Identification of a mutation in a proband allows the identification of mutation carriers among family members who do not yet exhibit any clinical manifestation of VHL.
   6. DNA polymorphism analysis as a method for identifying VHL disease gene carriers among asymptomatic members of disease families (Glenn et al. 1992).

Genetic Counseling

1. Recurrence risk
   1. Patient's sib
      1. A small risk of having a sib with VHL since parental mosaicism accounts for some apparently sporadic or new cases of VHL.
      2. A 50% risk of having a sib with VHL disease if one of the parent is clinically affected or has a disease-causing *VHL* gene mutation.
   2. Patient's offspring
      1. A 50% risk of inheriting the VHL disease-causing mutation.

    2. An individual mosaic for a disease mutation is at increased risk of having affected offspring, despite negative testing for the mutation by routine DNA diagnostic tests.
2. Prenatal Testing and Preimplantation Genetic Diagnosis (PGD) (Frantzen et al. 2015)
    1. Once the VHL pathogenic variant has been identified in an affected family member, prenatal testing and preimplantation genetic diagnosis (PGD) for a pregnancy at increased risk for VHL syndrome are possible options.
    2. PGD has been successfully used in pregnancies at risk for VHL syndrome (Rechitsky et al. 2002, Simpson et al. 2005).
3. Management
    1. All patients with pheochromocytomas should be screened for MEN-2 and von Hippel-Lindau disease to avert further morbidity and mortality in the patients and their families (Neumann et al. 1993). All patients in families with MEN-2 or von Hippel-Lindau disease should be screened for pheochromocytoma, even if they are asymptomatic.
    2. Ocular management (Sanfilippo et al. 2003).
        1. Laser photocoagulation therapy or cryotherapy of retinal lesions
        2. Several treatment strategies on the horizon that show promise for the ocular management of VHL disease
            1. Vascular endothelial growth factor (VEGF) inhibitors
            2. Use of radiotherapy, such as brachytherapy or linear accelerator-based radiosurgery
    3. In general, pancreatic NET with or without VHL disease shows a slow-growth phenotype and patients have a good prognosis. VHL patients at lower metastatic risk from pancreatic neuroendocrine tumor should be spared the risks of surgical resection (Tamura et al. 2010).
    4. Surgery: the mainstay of treatment for the tumors arising in patients with VHL disease (Sanfilippo et al. 2003).
        1. Renal cell carcinomas
            1. Partial nephrectomy or radiofrequency ablation to spare renal function if tumor involvement is not extensive.
            2. Total nephrectomy often necessary for extensive tumor involvement.
        2. Resection of symptomatic brain stem hemangioblastomas, in general, is a safe and effective management strategy in patients with VHL disease. Most patients maintain their preoperative functional status, although long-term decline in functional status may occur due to VHL disease-associated progression (Wind et al. 2011).
        3. Pregnant patients with spinal hemangiomas and VHL must be closely monitored for neurological compromise, as pregnancy can exacerbate both symptomatic and previously asymptomatic lesions. Patients must be evaluated on a case-by-case basis for surgical intervention, which should be carefully considered if clinical function begins to decline (Hayden et al. 2009).
        4. Stereotactic radiosurgery has been proposed as an alternative treatment strategy for CNS hemangioblastomas (Richard et al. 2000; Wind et al. 2011).
        5. Possibility of proliferative changes and tractional retinal detachment can arise following photocoagulation for retinal capillary hemangiomas in patients with VHL (Suzuki et al. 2016).
        6. In the future, antiangiogenic drugs could represent a potential medical treatment of CNS hemangioblastomas in view of their highly vascular structure (Richard et al. 2000).
    5. Somatic inactivation of the *VHL* gene is the main molecular event in most sporadic RCC, and the treatment of advanced RCC has been revolutionized by targeted therapy with drugs that block angiogenesis. These drugs are now in first line in metastatic sporadic RCC and have shown promising results for RCC, pancreatic neuroendocrine

tumors, and malignant pheochromocytomas in VHL patients (Richard et al. 2013).

6. Therapeutic management of central nervous system hemangioblastomas: ranging from neurosurgical resection, radiation therapy, and systemic therapies (Hodgson et al. 2016).
7. VHL appears to be a pivotal gene in the oxygen-sensing pathway, mainly involved in targeting the hypoxia-inducible factors for ubiquitination. This discovery is opening the way for the development of new specific drugs inhibiting hypoxia-inducible factors and/or their downstream targets, possibly representing an attractive treatment not only for von Hippel-Lindau disease but also for sporadic renal cell carcinomas and others cancers (Richard 2003).
8. Missense mutations can result in the translation of functional VHL protein (pVHL) that is rapidly degraded resulting in functional loss of the pVHL, and inhibitors of pVHL degradation may slow protein degradation and restore pVHL function (Schunemann et al. 2016).

Waardenburg Syndrome

Contents

Waardenburg syndrome (WS) is a rare autosomal dominant disorder characterized by patchy depigmentation, sensorineural hearing loss, and other developmental defects. There are four types of this syndrome. Types I and II are more common than types III and IV. The overall syndrome affects about 1 in 42,000 people (Waardenburg 1951).

Synonyms and Related Disorders

Klein-Waardenburg syndrome (Waardenburg syndrome with upper limb anomalies); Tietz/Waardenburg type 2A syndrome; Waardenburg syndrome with dystopia canthorum; Waardenburg syndrome with or without neurologic involvement; Waardenburg syndrome without dystopia canthorum; Waardenburg-Shah syndrome (Waardenburg syndrome with Hirschsprung disease)

Genetics/Basic Defects

1. Inheritance: genetic heterogeneity (Hageman and Delleman 1977)
    1. Autosomal dominant
        1. Type I (Waardenburg syndrome): presence of dystopia canthorum (lateral displacement of the inner canthi of the eyes in the presence of normal interpupillary distance)
        2. Type II (Waardenburg syndrome with ocular albinism; absence of dystopia canthorum)
        3. Type III (Klein-Waardenburg syndrome; presence of musculoskeletal abnormalities) (Klein 1983)
    2. Autosomal recessive: Type IV (Shah-Waardenburg syndrome or Waardenburg-Hirschsprung disease) (Bonnet et al. 1996)
2. Cause (Read and Newton 1997; Pingault et al. 2010)
    1. Type I and Type III (Hoth et al. 1993):
        1. Mutations in *PAX3* (paired box) gene on chromosome 2q35.
        2. Two similar mutations in close proximity can result in significantly different phenotypes, WS type I in one family and WS type III in another.
    2. Type II:
        1. Some patients are associated with mutations in *MITF* (microphthalmia associated transcription factor) gene

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_244

(Tassabehji et al. 1994; Yang et al. 2013) on chromosome 3p12-p14.1 (Hughes et al. 1994)
2. Mutations in *SOX10* gene (encoding the Sry BOX10 transcription factor) on chromosome 22q13 (Bondurand et al. 2007; Iso et al. 2008)
3. Homozygous deletions of snail homolog 2 (*SNAI2*) in two patients (Sanchez-Martin et al. 2002)

3. Tietz syndrome and Waardenburg syndrome type 2A are allelic conditions caused by MITF mutations (Cortés-González et al. 2016):
   1. Tietz syndrome is inherited in an autosomal dominant pattern and is characterized by congenital deafness and generalized skin, hair, and eye hypopigmentation.
   2. Waardenburg syndrome type 2A typically includes variable degrees of sensorineural hearing loss and patches of de-pigmented skin, hair, and irides.
   3. Posterior microphthalmos might be part of the clinical characteristics of Tietz/Waardenburg syndrome type 2A and expand both the clinical and molecular spectrum of the disease.
4. Type IV (Fernández et al. 2014) :
   1. Mutations in the genes for endothelin-3 (*EDN3*) (Hofstra et al. 1996) on chromosome 20q13.2-q13.3 or endothelin B receptor (*EDNRB*) on chromosome 13q22.
   2. Mutations in *SOX10* gene (Touraine et al. 2000).
   3. Shah-Waardenburg syndrome or Waardenburg syndrome type 4 (WS4) is a neurocristopathy characterized by the association of deafness, depigmentation, and Hirschsprung disease. Three disease-causing genes have been identified so far for WS4: *EDNRB*, *EDN3*, and *SOX10*.
   4. *SOX10* mutations, found in 45–55% of WS4 patients, are inherited in autosomal dominant way.
   5. In addition, mutations in *SOX10* are also responsible for an extended syndrome involving peripheral and central neurological phenotypes, referred to as PCWH (peripheral demyelinating neuropathy, central dysmyelinating leucodystrophy, Waardenburg syndrome, Hirschsprung disease).
   6. Such mutations are mostly private, and a high intra- and interfamilial variability exists.
3. Pathogenesis: None of the following theories explains all the features of Waardenburg syndrome (Dourmishev et al. 1999).
   1. Deficient neural crest theory (Mallory et al. 1986)
      1. Developmental abnormality of the neural crest as a cause of the disease
      2. Supported by the association of Waardenburg syndrome with aganglionic megacolon
   2. As a part of the first arch syndrome theory
   3. A relationship of Waardenburg syndrome with status dysraphicus theory
   4. Intrauterine necrosis theory
4. Interaction among SOX10, PAX3, and MITF, three genes altered in Waardenburg syndrome: An interaction between three of the genes that are altered in WS, could explain the auditory-pigmentary symptoms of this disease (Bondurand et al. 2000)
5. Genotype-phenotype correlations (DeStefano et al. 1998)
   1. Specific mutations in the *PAX3* gene correlate with the expression of different features of Waardenburg syndrome.
   2. Odds for the presence of eye pigment abnormality, white forelock, and skin hypopigmentation were 2, 8, and 5 times greater, respectively, for individuals with deletions of the homeodomain and the Pro-Ser-Thr-rich region compared to individuals with an AA substitution in the homeodomain. Odds ratios that differ significantly from 1.0 for these traits may

indicate that the gene products resulting from different classes of mutations act differently in the expression of WS.

Clinical Features

1. Wide clinical spectrum.
2. Facial appearance:
    1. Dystopia canthorum (lateral displacement of the medial canthi)
    2. Bushy eyebrows with synophrys
    3. A narrow nose with prominent nasal root
    4. Marked hypoplasia of the nasal bone
    5. Short philtrum
    6. Short/retro positioned maxilla
3. Congenital sensorineural deafness (deafmutism) (Song et al. 2016):
    1. Waardenburg syndrome is the most common syndromal cause of deafness and is responsible for 2–3% of congenital deafness.
    2. Mutations in *SOX10* (96.5%), *MITF* (89.6%), and *SNAI2* (100%) are more frequently associated with hearing impairment than other mutations.
    3. The distinct disease-causing genes are able to better predict the auditory phenotype compared with different clinical types of WS.
    4. Consequently, it is important to confirm the clinical diagnosis of WS with molecular analysis in order to optimally inform patients about the risk of hearing loss.
4. Pigmentary abnormalities:
    1. Cutaneous pigmentary abnormalities
        1. Achromatic spots, with sharply defined irregular borders and containing scattered islands of hyperpigmentation, resemble those of piebaldism.
        2. Hyperpigmented macules on normally pigmented skin that have been described as a “patchy skin” and give the cases a “dappled appearance”
    2. Hair pigmentary abnormalities
        1. White forelock (may be evident at birth, soon afterwards, or develop later)
        2. Premature graying of the scalp hair and of the eyebrows, cilia, or body hair
    3. Fundus pigmentary abnormalities
        1. Albinotic fundi (generalized decrease in retinal pigment) (Delleman and Hageman 1978)
        2. Pigmentary mottling in the periphery
    4. Partial albinism
    5. Heterochromia (different color) of the iris
    6. Bilateral isohypochromia iridis (pale blue eyes)
    7. Ocular albinism (type II)
5. Musculoskeletal abnormalities (type III, Klein-Waardenburg syndrome) (Goodman et al. 1982):
    1. Ortho-osteomyo-dysplasia of the upper limbs
    2. Bilateral upper limb defects
    3. Flexion contractures
    4. Fusion of the carpal bones
    5. Syndactyly
6. Congenital aganglionic megacolon association (type IV, Shah-Waardenburg syndrome).
7. Occasional associated anomalies (da-Silva 1991).
    1. Cleft lip/palate
    2. Neural tube defects
    3. Facial asymmetry
    4. Facial palsy
    5. Hypokalemic periodic paralysis
    6. Preauricular pit
    7. Hypoplasia of the middle ear ossicles
    8. Blepharoptosis
    9. Microphthalmia
    10. Hypertelorism
    11. Iris coloboma
    12. Fixed dilated pupil, anterior lenticonus
    13. High-arched palate
    14. “Cupid bow” configuration of the upper lip
    15. Prognathism
    16. Microcephaly

17. Mental retardation
18. Esophageal atresia with tracheoesophageal fistula
19. Imperforate anus
20. Bifid spine
21. Vertebral agenesis
22. Absence of vagina and right adnexal uteri
23. Syndactyly
24. Cardiovascular anomalies
25. Polythelia
26. Urinary anomalies
27. Hyperkeratosis of palms and soles
28. Black forelock
29. Hyperpigmented skin lesions

8. Diagnostic criteria for Waardenburg type I and type II as proposed by the Waardenburg Consortium. To be affected with Waardenburg type I, an individual must have two major or one major plus two minor criteria. To be affected with Waardenburg type II, an individual should show two major features (with one major feature of an affected first-degree relative who should show two major features) (more stringent criteria by Liu et al. 1995) (Read and Newton 1997; Konno and Silm 2001).
    1. Major criteria
        1. Congenital sensorineural hearing loss
        2. Pigmentary disturbances of iris
            1. Complete heterochromia iridium (two eye of different color)
            2. Partial or segmental heterochromia (segments of blue or brown pigmentation in one or both eyes)
            3. Hypoplastic blue eyes (characteristically brilliant blue in both eyes)
        3. Hair hypopigmentation (white forelock)
        4. Dystopia canthorum, or
        5. Affected first-degree relatives
    2. Minor criteria
        1. Congenital leukoderma (several areas of hypopigmented skin)
        2. Synophrys or medial eyebrow flare
        3. Broad and high nasal root
        4. Hypoplasia of alae nasi
        5. Premature graying of hair (scalp hair predominantly white before age 30)

Diagnostic Investigations

1. Audiologic evaluation for hearing loss
2. Histochemical studies of achromic skin
    1. Absent melanocytes
    2. Presence of only a few dihydroxyphenylalanine (dopa)-positive cells
3. Ultrastructural findings of depigmented skin
    1. Absence or dramatically reduced melanocytes
    2. Dendritic cells containing poorly melanized melanosomes
    3. Absence of melanosomes in the keratinocytes
4. Chromosome abnormalities observed in type I Waardenburg syndrome (Konno and Silm 2001)
    1. Inversion 2q35-q36.1
    2. Deletion 2q35-q36.2
    3. Del(2)(q34;q36.2)
5. Molecular studies of mutations for different types of Waardenburg syndrome (Konno and Silm 2001; Milunsky 2014)
    1. Testing methods
        1. Sequence analysis for gene mutations
        2. Deletion/duplication analysis for gene deletions
        3. Diagnostic exome sequencing can be a useful tool for the identification of pathogenic gene variants in WS patients and for differentiation between WS and similar disorders (Jang et al. 2015)
    2. Different types of Waardenburg syndrome
        1. Waardenburg syndrome type I: *PAX3* gene mutation
        2. Waardenburg syndrome type II: 15–20% of cases have heterozygous mutation in the *MITF* gene.
        3. Waardenburg syndrome type III: interstitial deletion of chromosome 2 (2q35-q36.2) including the *PAX3* gene
        4. Waardenburg syndrome type IV:
            1. Mutations in the gene encoding endothelin-3 (Edn 3) or one of its receptors, the endothelin-B receptor (Ednrb)
            2. Mutations in *SOX10*

Genetic Counseling

1. Recurrence risk
   1. Autosomal dominant inheritance
      1. Patient's sibs: not increased unless one of the parent is also affected or has germinal mosaicism (Kapur and Karam 1991)
      2. Patient's offspring: 50%
   2. Autosomal recessive inheritance
      1. Patient's sibs: 25%
      2. Patient's offspring: not increased unless the spouse is a carrier or affected
2. Prenatal diagnosis (Milunsky 2014)
   1. Possible when a mutation has been defined in the family
   2. Impossible to predict how severe the fetus will be affected
3. Preimplantation genetic diagnosis: available for families in which disease-causing mutation has been identified (Milunsky 2014)
4. Management (Konno and Silm 2001)
   1. No effective treatment available.
   2. Photoprotection to protect the amelanotic areas from burning with sun exposure:
      1. Sunscreens
      2. Camouflage
         1. Hair dye
         2. Dermablend
   3. Autologous grafts or transplants of autologous cultured melanocytes used to repigment the areas of hypomelanosis (piebaldism).
   4. Important to diagnose and improve hearing loss: auditory habilitation with a cochlear implant with excellent prognosis (Cullen et al. 2006).
   5. Folate supplementation during pregnancy advisable for a fetus at risk for Waardenburg type I, although the risk for neural tube defect is low.
   6. WS has features that can be important for anaesthetic management, including laryngomalacia, multiple muscle contractures, limited neck movements, cyanotic cardiomyopathy and electrolyte imbalance (Peker et al. 2015).
   7. Cochlear implantation could be a good treatment option for hearing loss in Waardenburg syndrome (Koyama et al. 2016).

Weill-Marchesani Syndrome

Contents

Weill-Marchesani syndrome (WMS), a rare connective tissue disorder, was first described by Weill in 1932 (Weill 1932) and further delineated by Marchesani in 1939 (Marchesani 1939). It is also known as spherophakia-brachymorphia syndrome or congenital mesodermal dysmorphodystrophy.

Synonyms and Related Disorders

Congenital mesodermal dysmorphodystrophy; Marchesani syndrome; Glaucoma-lens ectopia-microspherophakia-stiffness-shortness (GEMSS) syndrome; Spherophakia-brachymorphia syndrome

Genetics/Basic Defects

1. Autosomal dominant (AD) inheritance (Faivre et al. 2003b)
    1. Caused by heterozygous mutations within the fibrillin-1 gene which is mapped to chromosome 15q21.1 (Wirtz et al. 1996).
    2. Autosomal dominant WMS and Marfan syndrome appear to be allelic conditions at the fibrillin-1 locus.
    3. Coin the acronym GEMSS syndrome (Glaucoma, Ectopia, Microspherophakia, Stiff joints, Short stature) to distinguish this dominant Weill-Marchesani-like syndrome from the classic, recessively inherited syndrome (Verloes et al. 1992).
2. Autosomal recessive (AR) inheritance with occasional brachymorphism in heterozygotes
    1. Homozygosity mapping of an autosomal recessive WMS gene to chromosome 19p13.3-p13.2 (Faivre et al. 2002).
    2. *ADAMTS10* (a disintegrin-like and metalloprotease with thrombospondin motifs 10) mutation cause autosomal recessive Weill-Marchesani syndrome (Dagoneau et al. 2004; Shah et al. 2014; Steinkellner et al. 2014).
    3. ADAMTS10 is a member of the extracellular matrix protease family and is expressed in skin, fetal chondrocytes, and fetal and adult hearts.
3. Clinical homogeneity (fail to distinguish AR and AD inheritance in individual cases) and genetic heterogeneity (two modes of inheritance (AR and AD) have been reported) (Faivre et al. 2003a)

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_245

4. Possible genetic carriers in the spherophakia-brachymorphia syndrome (Kloepfer and Rosenthal 1955)
    1. Criteria are presented which were found useful to distinguish 38 heterozygous carriers of the spherophakia-brachymorphia gene from 36 homozygous normals and 5 homozygous affected individuals.
    2. With the exception of 17 individuals (8 under 3 years old) information was sufficient to classify all persons observed.
    3. Four of these 17 could be placed in heterozygous or normal groups from pedigree relationship and subjective impressions.
    4. Anthropometric stigmata which were found most useful to distinguish the various genotypic groups were short stature, short fingers, and wide atd angles.

Clinical Features

1. Unable to distinguish autosomal recessive and autosomal dominant WMS by clinical features alone.
2. Proportionate short stature.
    1. Heights of adult males: 142–169 cm
    2. Heights of adult females: 130–157 cm
3. Ophthalmological features (Chu 2006).
    1. Microspherophakia (small spherical lens)
        1. The most important clinical feature of the syndrome
        2. Golden ring in the eyes due to reflection of light from 360° periphery of small crystalline globular lens (microspherophakia) with stretched zonules (Nayak et al. 2015)
    2. Ectopia lentis: usually results in downward displacement of the lens
    3. Lenticular myopia: usually the first ophthalmologic finding and is progressive
    4. Secondary glaucoma
        1. Resulting from pupillary block (Willi et al. 1973) in most cases due to forward movement of the lens or by dislocation of the lens into the anterior chamber
        2. The most serious complication because it can lead to blindness
4. Presenile vitreous liquefaction has been described in a large family with autosomal dominant WMS (Evereklioglu et al. 1999).
5. Skeletal features.
    1. Brachydactyly
    2. Enlarged interphalangeal joints
    3. Joints stiffness
    4. Pectus excavatum
    5. Scoliosis
6. Occasional cardiac features (Kojuri et al. 2007).
    1. Mitral valve prolapse
    2. Mitral valve insufficiency
    3. Mitral valve stenosis (van de Woestijne et al. 2004)
    4. Pulmonary hypertension
    5. Subvalvular fibromuscular aortic stenosis
    6. Congenital pulmonic valve stenosis
    7. Patent ductus arteriosus
    8. Ventricular septal defect
    9. Prolonged QT interval
7. Normal intelligence.
8. Similarity of geleophysic dysplasia and Weill-Marchesani syndrome (Kochhar et al. 2013).
    1. Although similar in phenotype, they can be distinguished clinically.
        1. Weill-Marchesani syndrome, on the basis of microspherophakia and ectopia lentis
        2. Geleophysic dysplasia by progressive cardiac valvular thickening, tracheal stenosis, and/or bronchopulmonary insufficiency, often leading to early death
    2. Mutations in *FBN1*, *ADAMTS10*, or *ADAMTS17* cause Weill-Marchesani syndrome by disrupting the microfibrillar environment, while geleophysic dysplasia is associated with enhanced TGF-β signaling mediated through mutations in *FBN1* or *ADAMTSL2*.
    3. A 35-year-old woman with geleophysic dysplasia, with short stature, small hands and feet, limitation of joint mobility, mild skin thickening, cardiac valvular disease, restrictive pulmonary disease, and microspherophakia was studied.

    1. Sequencing of *ADAMTSL2* demonstrated two changes: IVS8-2A>G consistent with a disease-causing mutation and IVS14-7G>A with potential to generate a new splice acceptor site and result in aberrant mRNA processing.
    2. The unaffected mother carries only the IVS8-2A>G transition providing evidence that the two changes are in trans-configuration in the patient.
9. The evolving phenotype of Weill-Marchesani syndrome – diagnostic confusion with geleophysic dysplasia (Pimienta et al. 2013).
    1. Clinical findings and evolving phenotype for a period of 18 years in a patient whose diagnosis, and distinguishing characteristics, transformed from geleophysic dysplasia to WMS.
    2. Molecular testing demonstrated novel mutations in the *ADAMTS10* gene confirming a diagnosis of autosomal recessive WMS in the proposita.

Diagnostic Investigations

1. Confirmation by molecular genetic testing in addition to clinical features.
    1. *ADAMTS10* sequence analysis available clinically to identified homozygous mutations in autosomal recessive WMS.
    2. Significance of mutations in *FBN1* in autosomal dominant WMS is unclear.
2. Carrier testing for relatives at risk requires prior identification of the disease-causing mutations in the family.
3. ECG and echocardiography (Kojuri et al. 2007).
    1. The most noteworthy ECG abnormality was prolonged QTc (QTc>0.46 sec) which was detected in three patients (50%).
    2. The most common echocardiographic abnormality was mitral valve prolapse (MVP) which was detected in three patients (50%), two of whom also had prolonged QTc.
    3. The criterion for the diagnosis of MVP was systolic displacement of the mitral valve leaflets by more than 2 mm above the plane of the annulus in the parasternal view.
    4. One patient had severe congenital valvular aortic stenosis (maximum gradient = 107 mmHg) and was scheduled for aortic valve replacement.
4. Ultrasound biomicroscopy: a useful technique to confirm the diagnosis of spherophakia (Macken et al. 1995).
5. The use of extended-depth spectral-domain optical coherence tomography supported the diagnosis of subclinical Weill-Marchesani syndrome in a patient without other commonly associated findings and provided a better understanding of the mechanism of angle closure in this patient (Cobot et al. 2014).
6. Electron microscopy and immunological studies of skin fibroblasts from WMS patients suggest that the syndrome is associated with impairment of the extracellular matrix.
7. Histology of the lens in the WMS (Fujiwara et al. 1990).
    1. Degeneration and necrosis of the epithelial cells of the lens are caused by various factors including aging, inflammation, trauma, and surgery.
    2. Destruction of the cortical fibers is a common histological change seen in lenses with senile cortical cataracts; in the present case of Weill-Marchesani syndrome it was considerable.
8. Histopathology of the lenses (Lim et al. 2016).
    1. The epithelial cell changes, hyaloid degeneration, and subcapsular cortical fiber changes.
    2. The authors attributed these changes to physical and mechanical factors, because the lens is highly mobile and often comes in contact with the iris.

Genetic Counseling

1. Recurrence risk
    1. Patient's sib

1. Autosomal dominant inheritance
    1. Fifty percent risk if one parent is affected
    2. Recurrence risk: small if neither parent is affected
2. Autosomal recessive inheritance: 25% affected, 50% carriers

2. Patient's offspring
    1. Autosomal dominant inheritance: 50% risk
    2. Autosomal recessive inheritance: 100% obligatory carriers for a disease-causing mutation in the *ADAMTS10* gene

2. Prenatal diagnosis/preimplantation genetic diagnosis (Tsilou and MacDonald 2013)
    1. Prenatal diagnosis: If the disease-causing mutation(s) have been identified in the family, prenatal diagnosis for pregnancies at increased risk is possible by analysis of DNA extracted from fetal cells obtained by amniocentesis (usually performed at ~15–18 weeks' gestation) or chorionic villus sampling (usually performed at ~10–12 weeks' gestation).
    2. Preimplantation genetic diagnosis: may be an option for some families in which the disease-causing mutation(s) have been identified.
3. Management
    1. Early detection and removal of an ectopic lens to decrease the possibility of pupillary block and glaucoma.
    2. A dislocated spherophakic lens may cause severe corneal endothelial dysfunction due to corneolenticular contact, and prompt lensectomy is important to prevent such complications (Chung et al. 2007).
    3. Medical treatment of glaucoma: difficult because of paradoxical response to miotics and mydriatics.
    4. Surgical management of glaucoma.
        1. Peripheral iridectomy to prevent or relieve pupillary block
        2. Trabeculectomy in advanced chronic angle closure glaucoma
    5. Airway management: difficult during anesthesia because of stiff joints, poorly aligned teeth, and maxillary hypoplasia.
    6. Periodic ophthalmic examinations for early detection and removal of an ectopic lens.
    7. Avoid ophthalmic miotics and mydriatics to prevent inducing pupillary block.
    8. Advanced chronic angle closure glaucoma in Weill-Marchesani syndrome may be treated with a combination of lensectomy, anterior vitrectomy, and sutured intraocular lens and Molteno tube shunt surgery (Harasymowycz and Wilson, 2004).
    9. Removal of the microspherophakia is recommended to control intraocular pressure and improve vision. Advanced glaucoma in Weill-Marchesani syndrome should be treated with combined glaucoma surgery and lens extraction (Guo et al. 2015).
    10. Anesthetic management (Dal et al. 2003; Karabiyik 2003).
        1. Airway control and intubation may be difficult in patients with WMS because of stiff joints, poorly aligned teeth, and maxillary hypoplasia with a narrow palate.
        2. Special consideration should be given to difficult intubation, cardiac abnormalities, and patient positioning (Riad et al. 2006).
        3. Secure the airway with a laryngeal mask airway (LMA) rather than an endotracheal tube.
        4. The LMA was inserted cautiously without hyperflexion or extension to the neck, with careful placement through the abnormal teeth structure.

Fig. 1 (**a**–**c**) A 14-year-old female (**a**) with Weill-Marchesani syndrome. She had short stature, spherophakia, and brachydactyly. She was again followed at 30 years of age with findings of short stature, shallow orbits, small eyes, myopia, brachydactyly, and enlarged and stiff interphalangeal joints (**b**, **c**). Her daughter has small lens/cornea, short stature, and brachydactyly

Williams Syndrome

Contents

In 1961, Williams et al. (1961) described children with a constellation of abnormalities including "unusual" facial features, growth retardation, supravalvular aortic stenosis, and cognitive impairment. In 1962, Beuren et al. (1962) described a series of children with similar features, dental anomalies, peripheral pulmonary artery stenosis, and friendly personalities. Consequently, Williams syndrome (WS) is also known as Williams-Beuren syndrome (WBS). These characteristics are observed in virtually every patient with Williams syndrome, now known to be caused by a microdeletion of chromosome 7q11.23. The incidence of the syndrome is estimated to be between 1 in 20,000 and 1 in 50,000 live births.

Synonyms and Related Disorders

Chromosome 7q11.23 deletion syndrome; Williams-Beuren syndrome

Genetics/Basic Defects

1. Inheritance
   1. Sporadic new deletion in most cases
   2. Autosomal dominant inheritance with variable clinical expression within and between families (Morris et al. 1993; Õunap et al. 1998; Pankau et al. 2001)
   3. Rare autosomal dominant transmission of microdeletion involving the Williams syndrome critical region in a few cases
2. A disorder of microdeletion or contiguous gene deletion (Pober 2010)
3. Association of the elastin (*ELN*) gene disruption by chromosome translocation or partial deletion involving chromosome 7q11.23 and the supravalvular aortic stenosis (Curran et al. 1993): the first clue to the location of the Williams syndrome microdeletion
4. Caused by the haploinsufficiency of genes within a microdeletion of the long arm of chromosome 7 (7q11.23) involving the elastin locus (Lowery et al. 1995; Nickerson et al. 1995; Hirota et al. 1996)
5. Deletions in the *ELN* gene (Osborne 1999; Donnai and Karmiloff-Smith 2000)
   1. Pathogenesis (Ewart et al. 1993):
      1. Identification of hemizygosity at the elastin locus using genetic analyses in four familial and five sporadic cases of WS.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_246

   2. Fluorescent in situ hybridization and quantitative Southern analyses confirmed these findings, demonstrating inherited and de novo deletions of the elastin gene.
   3. These data indicate that deletions involving one elastin allele cause WS and implicate elastin hemizygosity in the pathogenesis of the disease.
2. Mechanism: deletions typically caused by unequal recombination during meiosis (Urban et al. 1996): The deletions are rather uniform in size as they arise spontaneously by inter- or intrachromosomal crossover events within misaligned duplicated regions of high sequence identity that flank the typical deletion (Francke 1999).
3. Deletion with equal frequency on the maternally or paternally inherited chromosome 7.
4. A total of at least 16 genes mapped within the commonly deleted interval.
5. *ELN* gene mutations:
   1. Responsible for supravalvular aortic stenosis and other vascular stenoses (Li et al. 1997)
   2. Possibly responsible for some of the connective tissue problems: lax joints, premature aging of the skin, joint contractures, a hoarse voice, bladder and bowel diverticula, hernias
   3. Majority of patients with Williams syndrome with large deletion spans (approximately 1.5 Mb of DNA), which contain many genes that contribute to the additional clinical symptoms not seen in patients with isolated supravalvular aortic stenosis
6. Genetic studies demonstrate that isolated nonsyndromic supravalvular aortic stenosis is associated with intragenic deletions within the *ELN* gene, while Williams syndrome involves deletions spanning the entire *ELN* gene (Lashkari et al. 1999).
7. Other genes identified in the commonly deleted region: e.g., *LIMK1*, *CLIP-115*, *CYLN2*, *GTF21RD1*, and *STX1A* (Jurado 2003; Hoogenraad et al. 2004). With the exception of elastin, no definite role in the Williams phenotype has been shown for these other genes to date, and indeed for many genes haploinsufficiency is unlikely to have an effect (Metcalfe 1999).
8. Neither LIMK1 hemizygosity (contrary to a previous report) nor STX1A hemizygosity is likely to contribute to any part of the WS phenotype, and they emphasize the importance of such patients for dissecting subtle but highly penetrant phenotypes (Tassabehji et al. 1999).

Clinical Features

1. Characteristic dysmorphic facies (Burn 1986), frequently referred to as elfin facies (100%). Effort must be made to curtail the use of "elfin facies" to denote a resemblance to a mythological creature since the term is not well received by family members (Lashkari et al. 1999; American Academy of Pediatrics Committee on Genetics 2001).
   1. Broad forehead
   2. Medial eyebrow flare
   3. Strabismus
   4. Periorbital fullness
   5. Stellate lacy iris pattern
   6. Short nose with bulbous nasal tip
   7. Flat nasal bridge
   8. Malar flattering
   9. Prominent full cheeks and lips
   10. Long smooth philtrum
   11. Wide mouth
   12. Pointed chin
   13. Mild micrognathia
   14. Long narrow face and long neck in older children and adults
2. Spectrum and significance of ocular features (Greenberg and Lewis 1988)
   1. A stellate pattern of the anterior iris stroma which was observed only in individuals with blue or hazel iris color (62%)
   2. Strabismus (29%), most commonly esotropia
   3. Hypermetropic discs (55%)

4. A simplex vertical branching of the central retinal vessels at the disc (70%)
5. Situs inversus vasorum (15%)

3. Cardiovascular diseases (Hallidie-Smith and Karas 1988; Eronen et al. 2002)
   1. Supravalvular aortic stenosis (80%), often a progressive condition that may require surgical repair
   2. Generalized arteriopathy (narrowing of arteries secondary to abnormal elastin protein, an important component of elastic fibers in the arterial wall)
      1. Arterial stenoses make up the large majority of cardiovascular issues in patients with WS (Collins 2013). Sudden death in patients with WS is significantly greater than in the general population. Prolongation of the QTc is common in patients with WS.
      2. Peripheral pulmonary artery stenosis often present in infancy and usually improves over time.
      3. Possible worsening over time of the coarctation of the aorta, renal artery stenosis, and systemic hypertension.
      4. Possible narrowing of any arterial wall since elastin protein is an important component of elastic fibers in the arterial wall.
   3. Other congenital cardiac defects
      1. Mitral valve prolapse (11.6%)
      2. Bicuspid aortic valve (15%)
      3. Aortic hypoplasia
      4. Septal defects
      5. Left ventricular hypertrophy
4. Variable mental retardation (75%)
5. Characteristic cognitive/behavioral profile (90%) (Pober and Dykens 1996)
   1. Characteristic behavioral pattern
      1. Relative preservation of linguistic abilities
      2. Gross deficiencies in visual-spatial processing and motor skills
   2. Motor disabilities affecting balance, strength, coordination, and motor planning
   3. Delayed speech acquisition, followed by excessive talking ("cocktail party" verbal abilities)
   4. Overfriendliness and an empathetic nature
   5. Uncontrollable loquacity
   6. Behavioral problems (Kaplan et al. 2001)
      1. Hypersensitivity to sound (hyperacusis)
      2. Sleep problems
      3. Attention deficit/hyperactivity disorder (ADHD)
      4. Anxiety
      5. Distractability
      6. Inflexibility
      7. Ritualism
   7. A cognitive and behavioral phenotype (Udwin and Yule 1991)
      1. Concentration difficulties.
      2. Excessive anxiety.
      3. Poor relationships with peers.
      4. Significantly poorer visuospatial and motor skills.
      5. However, the Williams syndrome children were not uniformly poor in all areas of nonverbal abilities.
6. Other features
   1. Growth
      1. Postterm birth (>41 weeks)
      2. Failure to thrive
      3. Short stature (50%)
      4. Hypothyroidism
      5. A premature and abbreviated pubertal growth spurt
   2. CNS/neurologic findings (Chapman et al. 1996)
      1. Tone abnormalities varied as a function of age, with younger children frequently exhibiting decreased tone and older subjects almost exclusively having increased tone (muscle hypotonia early, muscle tone increases with age, hypertonia in some cases)
      2. The gait (awkward gait) and coordination abnormalities (poor coordination) persisted among older subjects, indicating that they were not simply maturational problems.
      3. Chiari I malformation.
      4. Hyperreflexia of the lower extremities.
   3. EENT
      1. Ocular findings
         1. Strabismus

2. Hyperopia
3. Stellate iris
4. Retinal vessel tortuosity

2. Chronic otitis media
3. Sensorineural and/or conductive hearing loss: present in 22.6% of children and adults with WS (Barozzi et al. 2012)
4. Dental abnormalities
    1. Hypodontia/Microdontia
    2. Malocclusion
    3. Overbite
    4. Excessive interdental spacing
    5. Small roots
    6. High incidence of caries
5. A hoarse or brassy voice

4. GI
    1. Difficulty feeding
    2. Gastroesophageal reflux/vomiting
    3. Prolong colic
    4. Bowel diverticula
    5. Hernias
    6. Rectal prolapse
    7. Constipation
    8. Peptic ulcers
5. Renal findings (Pober et al. 1993)
    1. Bladder diverticula: the most common defects
    2. Renal artery stenosis
    3. Renal agenesis
    4. Marked asymmetry in kidney size
    5. Small kidneys
    6. Solitary kidney
    7. Pelvic kidney
    8. Duplicated kidneys
    9. Horseshoe kidney
    10. Renal cysts
    11. Nephrocalcinosis
    12. Vesicouriteral reflux
6. Orthopedic problems
    1. Low/hoarse voice
    2. Hernias
    3. Joint laxity mostly during infancy
    4. Joint contractures may develop by childhood and adolescence (50%).
    5. Radioulnar synostosis
    6. Kyphosis
    7. Lordosis
    8. Scoliosis
    9. Hallux valgus
    10. Hypoplastic nails
    11. Clinodactyly of fifth fingers
7. Social phenotype of Williams syndrome (Järvinen et al. 2013)
    1. A strong drive to approach strangers
    2. A gregarious personality
    3. Heightened social engagement yet difficult peer interactions
    4. High nonsocial anxiety
    5. Unusual bias toward positive affect
    6. Diminished sensitivity to fear
8. Idiopathic infantile hypercalcemia (15%)
    1. Symptoms and signs of hypercalcemia (usually resolves during childhood)
        1. Extreme irritability
        2. Vomiting
        3. Constipation
        4. Muscle cramps
    2. Possible lifelong persistence of abnormal calcium and vitamin D metabolism
    3. Hypercalcinuria predisposing to nephrocalcinosis
9. Neuropsychological, neurological, and neuroanatomical profile of Williams syndrome (Bellugi et al. 1990)
    1. A dissociation between language and cognitive functions in Williams syndrome adolescents
    2. Exhibit an unusual fractionation of higher cortical functioning, with marked cognitive deficits, but selective sparing of syntax
    3. Peaks and valleys of abilities specific to Williams syndrome individuals
10. Three physical manifestations were noted which have not been emphasized in the previous reports of this condition (Morris and Carey 1990)
    1. Unusual sacral creases were found in 25/48 patients
    2. A linear array of hemangiomas (nevus flammeus) on the back in 3/48
    3. Limitation of supination in 5/48
11. Natural history of Williams syndrome: a progressive disorder with multisystem involvement (Morris et al. 1988)

12. Williams syndrome in adults (Morris et al. 1990)
    1. Variable in clinical presentation, ranging from severely affected patients with complicated medical histories to mildly affected patients who are generally in good health (Lopez-Rangel et al. 1992).
    2. Cardiovascular complications were common including hypertension, supravalvular aortic stenosis, aortic hypoplasia, pulmonic artery stenosis, peripheral stenoses, and mitral valve prolapse.
    3. Joint limitation was progressive, often accompanied by kyphoscoliosis and lordosis.
    4. Recurrent urinary tract infections led to radiologic studies showing urethral stenosis and bladder diverticula and vesicoureteral reflux.
    5. Gastrointestinal problems included obesity, chronic constipation, diverticulosis, and cholelithiasis.
    6. Hypercalcemia was documented, although others had hypercalcemic symptoms (abdominal pain, polyuria, and constipation).
    7. One 45-year-old man had parathyroid hyperplasia.

Diagnostic Investigations

1. Echocardiography for cardiac lesions.
2. Ultrasonography:
    1. Bladder and kidneys
    2. Intravascular ultrasound imaging: to detect vascular wall thickening with secondary lumen narrowing
3. Serum creatinine level.
4. Blood calcium levels to detect hypercalcemia during early infancy.
5. Thyroid function test.
6. Ophthalmologic evaluation for strabismus and retinal vessel tortuosity.
7. Urinalysis to detect hypercalcinuria.
8. Renal ultrasound for possible nephrocalcinosis if hypercalcinuria is noted.
9. Intravascular ultrasound imaging: to detect generalized arteriopathy (Rein et al. 1993).
10. Radiography: osteosclerosis of the metaphyses of long bones, the skull vault, or lamina dura of the alveolar bone in adolescence and adulthood, if overt hypercalcemia is present.
11. Multidetector row computed tomography (MDCT) (Das et al. 2014):
    1. Arterial stenosis is a matter of concern for the majority of patients with WBS. Most affected patients experience a mild course, but a small number, especially those with associated coronary artery disease and SVAS, require careful observation either with echocardiography or other noninvasive imaging.
    2. MDCT evaluation of complex cardiovascular abnormalities of WBS including coronary artery disease is feasible with modern MDCT scanners.
12. Several unreported biochemical alterations, related to haploinsufficiency for specific genes at 7q11.23, are relatively common in WBS (Palacios-Verdú et al. 2014):
    1. Triglyceride plasma levels were significantly decreased in individuals with WBS while cholesterol levels were slightly decreased compared with controls.
    2. Hyperbilirubinemia, mostly unconjugated, was found in 18.3% of WBS cases and correlated with subclinical hypothyroidism and hypotriglyceridemia, suggesting common pathogenic mechanisms.
13. Full cytogenetic studies:
    1. Larger deletions detectable by standard cytogenetic techniques, especially by high-resolution chromosome analysis
    2. To rule out possible chromosomal rearrangements involving the 7q11.23 locus as well as any other cytogenetic abnormalities
14. Fluorescence in situ hybridization (FISH) with a cosmid probe corresponding to *ELN* for diagnostic testing: remains the most

widely used laboratory test (Lowery et al. 1995)
1. Ninety-nine percent of the patients with a hemizygous submicroscopic deletion of 7q11.23 detectable by FISH
2. Cases undetectable by FISH
    1. Rare cases with a smaller deletion which does not fully encompass the FISH probe
    2. Cases with phenocopies of Williams syndrome with same clinical phenotype produced by mutation or deletion of other gene(s)
    3. Cases with a Williams syndrome-like phenotype associated with various cytogenetic rearrangements

15. Other diagnostic laboratory tests (Pober 2010):
    1. Microsatellite marker analysis.
    2. Intragenic restriction fragment length polymorphism (RFLP) and the gene dosage of ELN using FP4 probe (Mari et al. 1995).
    3. Multiplex ligation-dependent probe amplification.
    4. Quantitative polymerase-chain-reaction (qPCR) assay.
    5. Array comparative genomic hybridization (array-CGH).
    6. Array-CGH and qPCR are useful for detection of deletion sizes and prediction of the interrupted genes and their impact on the disease phenotype (Hussein et al. 2016).
16. Molecular genetic testing (to detect deletion of the WBSCR critical region) (Morris 2013):
    1. FISH
    2. Deletion/duplication testing

Genetic Counseling

1. Recurrence risk
    1. Patient's sib (Lashkari et al. 1999):
        1. Recurrence risk low (<1%) (most cases are sporadic and neither parent is affected).
        2. Presence of a small theoretical risk of germ line mosaicism in an unaffected parent (Kara-Mostefa et al. 1999).
        3. If a parent is affected, the risk is 50%.
    2. Patient's offspring: 50% recurrence risk of having an affected offspring in individuals who have the deletion of the Williams syndrome critical region (parent-to-child transmission observed occasionally)
2. Prenatal diagnosis
    1. Prenatal ultrasonography: a well-defined WBS prenatal phenotype cannot be delineated (Marcato et al. 2014)
    2. Amniocentesis or CVS
        1. Rarely utilized because most cases are sporadic and no prenatal indicators exist for low-risk pregnancies
        2. Utilized for pregnancies at 50% risk of having Williams syndrome
        3. FISH probe covering approximately 180 kb of the critical region deleted in the Williams syndrome including *ELN* gene, lim-kinase1 (*LIMK1*), and the D7S613 locus
3. Prenatal diagnosis and preimplantation genetic diagnosis (PGD) for at-risk pregnancies require molecular genetic testing that detects deletion of the WBSCR (Morris 2013)
4. Management
    1. Management of hypercalcemia (Lashkari et al. 1999)
        1. Limit high calcium food
        2. Avoid preparations containing vitamin D
    2. Supravalvular aortic stenosis (a life-threatening component of the phenotype): surgically correctable
    3. Early dental care
    4. Education and vocational concerns
        1. Early daily learning activities and strategies
            1. Auditory cues
            2. Music activities, singing/rhyming songs, and toys with soft sounds
            3. Teaching communication skills through daily routines
            4. Use of language expansions and parallel talk
        2. Special education for older children

3. Restrictive levels of care required for most adult patients
5. Social and emotional concerns
   1. At increased risk for exploitation and abuse
   2. Teaching of appropriate social skills
6. Psychotherapy
   1. Verbally oriented psychotherapy
   2. Group therapy

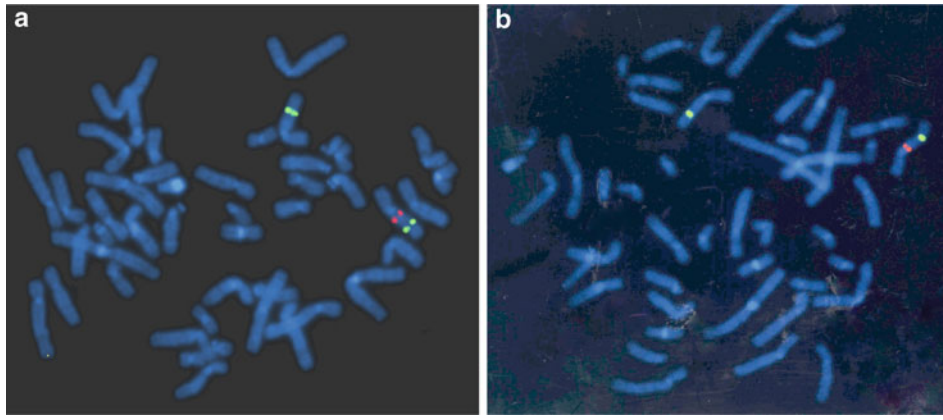

Fig. 7 (**a**, **b**) FISH showing the classic microdeletion seen in Williams syndrome (7p11.23) [LSI® Williams Syndrome (Elastin Gene) Region Probe, Vysis/Abbott]. The metaphase cells show only one chromosome 7 homologue with the orange signal (normal chromosome 7). The hemizygous deletion is shown on the chromosome with only the green loci [internal control probes for D7S486 and D7S522 (7q31)]

Winchester Syndrome

Contents

Winchester syndrome was one of the first recognized autosomal-recessive, multicentric forms of the disorder. It was originally described nearly 50 years ago in two sisters with severe skeletal and joint deformities. Their unaffected, healthy parents were first cousins (Winchester et al. 1969). The children suffered from progressive bilateral and symmetric osteolysis of the carpals and tarsals, interphalangeal joint erosions mimicking juvenile idiopathic arthritis, generalized osteoporosis, and eventual loss of function of the larger joints, including the shoulder, elbow, hip, and knee joints.

Synonyms and Related Disorders

Arthritis; Inherited osteolysis syndromes; Multicentric osteolysis; Multicentric osteolysis, nodulosis, and arthropathy (MONA); Nodulosis, arthropathy, and osteolysis (NAO); Torg syndrome; "Vanishing bone" syndromes

Genetics/Basic Defects

1. Winchester syndrome is caused by mutations of matrix metalloproteinase 2 gene (*MMP2*) located on chromosome 16q13-q21 (Martignetti et al. 2001; Rouzier et al. 2006).
2. Homozygous mutations in membrane type-1 metalloproteinase (MT1-MMP or MMP14): identified in the cultured fibroblasts from a patient with Winchester syndrome. The resulting hydrophobic-region signal-peptide substitution (p.Thr17Arg) decreases MT1-MMP membrane localization with consequent impairment of pro-MMP2 activation (Evans et al. 2012).
3. MONA (multicentric osteolysis, nodulosis, and arthropathy [MIM 259600]) and Winchester syndromes have been grouped together as allelic disorders on the basis of their phenotypic overlap and the discovery of *MMP2* mutations in two recently diagnosed Winchester families (Al Aqeel et al. 2000; Al-Aqeel 2005; Zankle et al. 2005, 2007; Mosig et al. 2008).

Clinical Features

1. Onset of the condition: toward the end of the first year of life with symmetrical painful swelling of the hands, fingers, wrists, and ankles (Al Kaissi et al. 2011).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_271

2. Intermittent polyarthralgia: resulting in progressive joint contractures.
3. Oval or linear raised areas of thickened skin may appear over the back, flanks, and lateral aspects of the arm. These lesions spread to cause leathery, thickened, hypertrichotic, and pigmented skin.
4. Other features:
    1. Corneal opacities appearing in mid-childhood
    2. Retarded growth
    3. Carpal and tarsal osteolysis
    4. Rheumatoid-like destruction of the small joints
    5. Gingival hypertrophy
5. Classification of osteolysis described by Hardegger et al. (1985):
    1. Type 1, hereditary multicentric osteolysis with dominant transmission
    2. Type 2, hereditary multicentric osteolysis with recessive transmission
    3. Type 3, nonhereditary multicentric osteolysis with nephropathy
    4. Type 4, Gorham–Stout syndrome
    5. Type 5, Winchester syndrome defined as a multicentric disease of autosomal-recessive inheritance
6. Classification of osteolysis as proposed by the 2001 Nosology of the International Skeletal Dysplasia Society (Spranger et al. 2002):
    1. Multicentric hands and feet
        1. Multicentric carpal–tarsal osteolysis with and without nephropathy: AD
        2. Winchester syndrome: AR
        3. Torg syndrome (includes NAO syndrome) (Torg et al. 1969): AR (*MMP2* mutations)
    2. Distal phalanges
        1. Hajdu–Cheney syndrome: AD
        2. Mandibuloacral syndrome: AR
    3. Diaphyses and metaphyses
        1. Familial expansile osteolysis: AD (*RANK* mutation)
        2. Juvenile hyaline fibromatosis including systemic juvenile hyalinosis: AR (*CMG2* mutations)
7. Zankl et al. (2005, 2007) defined a continuous clinical spectrum involving Torg syndrome, Winchester syndrome (OMIM 277950), and NAO syndrome.
    1. Torg syndrome
        1. Presence of multiple, painless, subcutaneous nodules and mild to moderate osteoporosis and osteolysis that is usually limited to the hands and feet.
        2. Radiographically, the osteolysis is accompanied by a characteristic widening of the metacarpal and metatarsal bones.
    2. NAO syndrome
        1. Only been described in patients from Saudi Arabia
        2. Generally more severe, with multiple prominent and painful subcutaneous nodules, massive osteolysis in the hands and feet, and generalized osteoporosis
        3. Additional features including coarse face and body hirsutism
    3. Winchester syndrome
        1. There are severe osteolysis in the hands and feet and generalized osteoporosis and bone thinning, similar to NAO, but subcutaneous nodules are characteristically absent.
        2. Various additional features including coarse face, corneal opacities, gum hypertrophy, and EKG changes.
8. Differential diagnosis (Vanatka et al. 2011):
    1. Juvenile idiopathic arthritis
        1. Positive rheumatoid factor test
        2. Presence of rheumatoid nodules
        3. Characteristic pattern of bone destruction
        4. Painful periarticular inflammation
        5. Increased erythrocyte sedimentation rate
    2. Other osteolytic and arthritis-like diseases and syndromes
        1. Idiopathic multicentric osteolysis: a uncommon disease presenting during childhood with resorption of the carpus and tarsus with nephropathy
        2. Inherited multicentric osteolysis (Lee et al. 2010)

1. A rare familial skeletal condition characterized by osteolysis leading to bone dysplasia.
2. Affected patients frequently experience pain, dysfunction, and disability.
3. The condition has been reported in literature with synonymous names such as "vanishing bone" syndrome; inherited osteolysis/arthritis syndromes; multicentric carpal–tarsal osteolysis; nodulosis, arthropathy, and osteolysis (NAO); and Torg–Winchester syndrome (Al Aqeel et al. 2000; Martignetti et al. 2001; Mosig et al. 2007).
4. Clinical symptoms or signs usually occur early in childhood (usually 2nd or 3rd year of life). Findings include multiple bone and joint pain and bony "dysplasia" with associated decreased range of movement and function.
5. Diagnosis is usually made with characteristic osteolytic changes on radiological investigations.
6. Serologic and histologic investigations are always negative for classical inflammatory or autoimmune causes.

Diagnostic Investigations

1. Radiology (Grover et al. 2009)
   1. Multifocal osteoporosis
   2. Progressive osteolysis
   3. Degenerative changes in the vertebral bodies and carpal and tarsal bones, including the metaphyses and epiphyses
2. Diagnostic criteria (Winter 1989): above skeletal radiologic characteristics combined with at least two of the following features:
   1. Short stature
   2. Progressive articular contractures
   3. Corneal opacities
   4. Thickened hyperpigmentation or hirsutism of the skin
   5. Hypertrophy of the gums
   6. Coarsened facial features
3. Molecular genetic analysis of *MMP2* gene (clinical research laboratories listed in www.GeneTests.org)
   1. Multicentric osteolysis, nodulosis, and arthropathy: sequence analysis of the entire coding region
   2. Winchester syndrome: sequence analysis of the entire coding region

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: 25%
   2. Patient's offspring: not increased unless the spouse is also a carrier
2. Prenatal diagnosis: has not been accomplished
3. Management
   1. Anti-inflammatory therapy
   2. Surgical treatments, including soft tissue release with pinning or joint arthrodesis, may offer pain relief and improve alignment, but outcomes are inconsistent.
   3. Pamidronate treatment in multicentric osteolysis
      1. It was reported to show no improvement in peripheral osteolysis in multicentric osteolysis and nodular arthropathy caused by mutation in matrix (Phadke et al. 2007).
      2. Patients with inherited multicentric osteolysis may benefit from bisphosphonate therapy. These benefits may include pain relief, decreased analgesic requirements, improved BMD, and potentially reducing new fracture or osteolytic collapse risk (Lee et al. 2010).

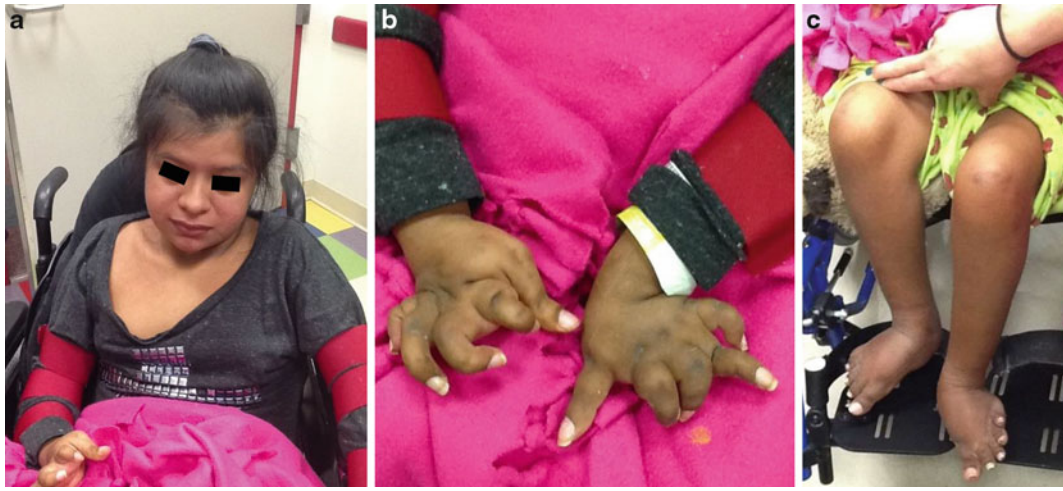

Fig. 1 (**a**–**c**) A 17-year-old Hispanic female was admitted for evaluation of severe joint contractures. Symptoms started at 2 years of age with fever, joint pain, and swelling. She was diagnosed with juvenile idiopathic arthritis (*JIA*) and treated with corticosteroids, methotrexate, and anti-inflammatory medications. Therapy was subsequently discontinued due to lack of response. Her symptoms progressed to joint contractures and inability to walk. Her brother had similar disease and died of respiratory complications at the age of 14 years. On examination, the patient was a small-built, wheelchair-bound teenager with severe flexion contractures in the wrists, fingers, knees, ankles, and toes without synovitis or joint effusions. Laboratory studies showed no signs of inflammation, and rheumatoid factor (RF) and anti-cyclic citrullinated peptide were negative (Velayuthan et al. 2014). Based on the clinical and following radiographic findings, the patient was diagnosed with Winchester syndrome

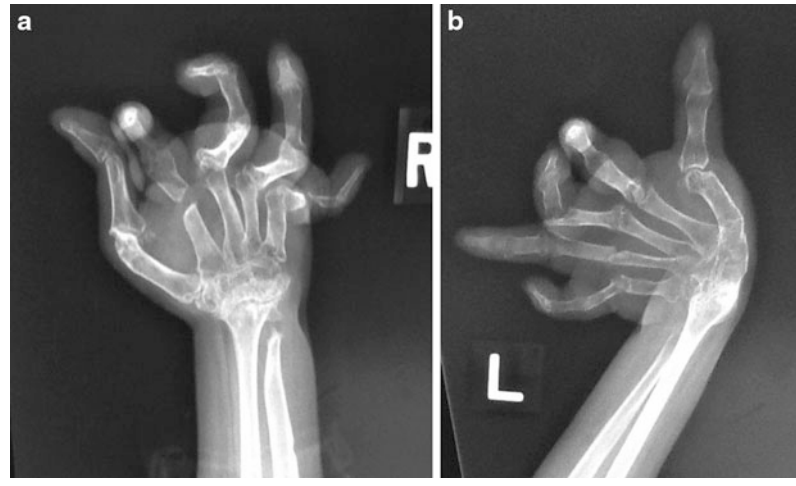

Fig. 2 (**a**, **b**) Fingers, hands, and wrists are markedly deformed with destructive arthritis in metacarpal, phalangeal, and interphalangeal joints. Distal ends of both ulnas and distal end of the second metacarpal/proximal end of the second proximal phalange of the right hand are markedly eroded. Generalized osteopenia of phalanges and metacarpals with thin cortices seen as thin (pencil) lines are noted

Fig. 3 (**a**, **b**) Destruction of tarsals and fusion of interphalangeal joints are seen on both foot

Fig. 4 Erosion of left femoral head is seen

Fig. 5 The knees are ankylosed (only right knee is shown)

Wolf–Hirschhorn Syndrome

Contents

Wolf–Hirschhorn syndrome (WHS) is a chromosome 4p deletion syndrome, first described by Cooper and Hirschhorn in 1961, followed by the report of Wolf et al. in 1965. The incidence is estimated to be approximately 1 in 50,000 births.

Synonyms and Related Disorders

Chromosome 4p16.3 deletion syndrome; Pitt-Rogers-Danks syndrome

Genetics/Basic Defects

1. Caused by the deletion of the distal short arm of chromosome 4 (Altherr et al. 1997; Dufke et al. 2000; Battaglia et al. 2001)
    1. Variable size of the deletion
    2. Deletion of the terminal band (4p16.3): essential for full expression of the phenotype
    3. Identification of a 165 kb minimal critical region (WHSCR) within 4p16.3 (Wilson et al. 1981; Wright et al. 1997; Rauch et al. 2001)
    4. Mechanism of deletions
        1. De novo deletions (75%): interstitial deletion of preferential paternal origin (Dallapiccola et al. 1993) in 85–90%
        2. Deletions resulting from unusual cytogenetic abnormality (12%) such as ring chromosome 4
        3. Deletions resulting from unbalanced product of a parental chromosomal rearrangement (Ogle et al. 1996), usually of a reciprocal translocation (Lurie et al. 1980) (10–15%)
2. Types of chromosome abnormalities
    1. Detectable by conventional cytogenetic technique: large deletions
    2. Detectable only by molecular methods
        1. Terminal microdeletions
        2. Interstitial microdeletions
        3. Cryptic translocations
3. Genotype–phenotype correlation (Wieczorek et al. 2000; Zollino et al. 2000, 2003, 2008)
    1. Patients with a large 4p16.3 deletion, averaging between 5 and 18 Mb: causing the widely recognizable WHS phenotype.
        1. Severe mental and growth retardation
        2. Major malformations
        3. Seizures
        4. Characteristic facial appearance with wide forehead, large and protruding

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_247

eyes, hypertelorism, prominent glabella, down-turned mouth, and micrognathia
2. Patients with a 4p16.3 microdeletion not exceeding 3.5 Mb.
   1. Milder phenotype
   2. Lack major congenital malformations
3. Patients with a very large deletion exceeding 22–25 Mb, causing a severe phenotype that can hardly be defined as typical WHS.
4. Using genotype–phenotype correlation analysis in eight informative patients, Zollino et al. (2003) characterized the following distinctive WHS clinical signs that represent the minimal diagnostic criteria for this condition and mapped this basic phenotype outside the currently defined WHSCR and designated as a new critical region, WHSCR-2.
   1. Presence of typical facial appearance
   2. Mental retardation
   3. Growth delay
   4. Congenital hypotonia
   5. Seizures
5. Genotype–phenotype correlation study using microarray and FISH-based molecular cytogenetic investigations (Shimizu et al. 2014).
   1. Chromosomal rearrangements in all patients including previously unreported complex chromosomal mosaicism.
   2. Demonstrated the correlation of deletion size from 4pter with seizure severity and with occurrence of renal hypoplasia/dysplasia and structural ocular anomalies.
   3. Described additional clinical features including hypercholesterolemia.
   4. Moreover, a new susceptible region distal to the previously supposed candidate gene *LETM1* was suggested for the occurrence of seizures.

4. *LETM1* (Schlickum et al. 2004)
   1. A gene deleted in WHS encodes mitochondrial protein.
   2. Current evidence suggests that at least some (neuromuscular) features of WHS may be caused by mitochondrial dysfunction.

Clinical Features

1. Maternal gestational history (Battaglia et al. 2015)
   1. Intrauterine growth retardation
   2. Decreased fetal movements
   3. Small placenta
2. Developmental history
   1. Delayed psychomotor development
   2. Difficulty in ambulation, often with ataxic gait
   3. Seizures (>75% of cases)
3. Behavior history
   1. Stereotypes
      1. Holding the hands in front of the face
      2. Hand washing or flapping
      3. Patting self on chest
      4. Rocking
      5. Head shaking
      6. Stretching of legs
   2. Absence of speech
   3. Babbling or guttural sounds, occasionally modulated in a communicative way
   4. Comprehension limited to simple orders or to a specific context
   5. Affect disorder that improves over time
   6. Walking with or without support
   7. Self-feeding
   8. Helps in dressing and undressing self
   9. Improved abilities and adaptation to new situations
   10. Communicative abilities and verbal comprehension with extension of the gesture repertoire and decreased occurrence of withdrawal and anxiety behaviors
4. Growth: Severe growth retardation (short stature)

5. CNS
    1. Profound mental retardation
    2. Microcephaly
    3. Seizures (50–100%)
    4. Congenital hypotonia with muscle hypotrophy particularly of the lower limbs
    5. Malformation (33%)
        1. Hypoplasia of cerebellum
        2. Cavum or absent septum pellucidum
        3. Agenesis of corpus callosum
        4. Hypoplasia or absence of olfactory bulbs and tracts
        5. Microgyria
        6. Migration defects
        7. Hydrocephalus
6. Skull
    1. Frontal bossing
    2. High frontal hairline
    3. Hemangioma over forehead or glabella
    4. Scalp defect with or without underlying bony defect
7. Face: characteristic dysmorphic features collectively described as "Greek warrior helmet" facies (prominent glabella, hypertelorism, broad beaked nose, and frontal bossing)
8. Eyes
    1. Hypertelorism
    2. Down-slanting palpebral fissures
    3. Epicanthal folds
    4. Strabismus
    5. Coloboma
    6. Proptosis due to hypoplasia of orbital ridges
    7. Ectopic pupils
    8. Esotropia
    9. Ptosis
    10. Microphthalmia
    11. Megalocornea
    12. Sclerocornea
    13. Cataracts
    14. Hypoplastic anterior chamber and ciliary body of iris
    15. Persistence of lenticular membrane
    16. Hypoplastic retina with formation of rosettes
    17. Cup-shaped optic disks
    18. Congenital nystagmus
    19. Early-onset glaucoma
    20. Rieger anomaly
9. Nose
    1. Broad or beaked nose
    2. Nasolacrimal duct stenosis or atresia
10. Mouth
    1. Short upper lip
    2. Short philtrum
    3. Cleft lip or palate
    4. Bifid uvula
    5. Carplike mouth
    6. Micrognathia
    7. Retrognathia
11. Ears
    1. Low-set ears
    2. Large, floppy, or misshapen ears
    3. Microtia
    4. Preauricular dimples
    5. Chronic otitis media with effusion
    6. Sensorineural hearing loss
12. Cardiovascular
    1. Atrial septal defect
    2. Ventricular septal defect
    3. Persistent left superior vena cava
    4. Valve abnormalities
    5. Complex cardiac defects
13. Pulmonary
    1. Bilateral bilobed or trilobed lungs
    2. Lung hypoplasia secondary to diaphragmatic hernia
14. GI anomalies
    1. Diastasis recti
    2. Umbilical or inguinal hernias
    3. Accessory spleens
    4. Absent gallbladder
    5. Diaphragmatic hernia
    6. Intestinal malrotation
15. Genitourinary anomalies (25%)
    1. Hypoplastic kidneys
    2. Cystic dysplastic kidneys
    3. Unilateral renal agenesis
    4. Hydronephrosis
    5. Exstrophy of the bladder
    6. Hypoplastic external genitalia
    7. Cryptorchidism and hypospadias in males

8. Hypoplastic Mullerian derivatives (i.e., agenesis of vagina, cervix, or uterus; hypoplastic uterus; ovarian streaks) in females

16. Skeletal anomalies (60–70%)
    1. Long slender fingers with additional flexion creases
    2. Long narrow chest
    3. Hypoplastic widely spaced nipples
    4. Hypoplasia or duplication of thumbs and great toes
    5. Talipes equinovarus
    6. Hypoplasia of pubic bones
    7. Vertebral and rib anomalies
    8. Defective calvarium ossification
    9. Scoliosis
    10. Kyphosis
    11. Osteoporosis
    12. Delayed bone maturation
    13. Sacral dimple
17. Infection prone, immunodeficiency
18. Malignant hematological disorders (Sharathkumar et al. 2003)
    1. Myelodysplastic syndrome
    2. Leukemia
19. Dermatoglyphics
    1. Hypoplastic dermal ridges
    2. Transverse palmar creases (25%)
    3. Excess of digital arches
    4. t or t′
20. Pitt-Rogers-Danks syndrome (PRDS) (Pitt et al. 1984; Clemens et al. 1996; Wright et al. 1998)
    1. Phenotypic overlap with WHS.
        1. Prenatal and postnatal growth retardation
        2. Microcephaly
        3. Seizures
        4. Developmental delay
        5. Facial features
            1. A wide mouth
            2. Short upper lip
            3. Flat philtrum
            4. Beaked nose
            5. Prominent eyes
            6. Maxillary hypoplasia
    2. Microdeletion of 4p16.3 detected in most cases.
    3. Current evidence suggests that PRDS is not a separate clinical entity but may represent the milder end of the WHS spectrum (Battaglia and Carey 1998).
21. Fetal phenotype
    1. Major anomalies
        1. Intrauterine growth retardation
        2. Microcephaly
        3. Cleft palate
        4. Corpus callosum agenesis
        5. Ventricular septal defect
        6. Diaphragmatic hernia
        7. Renal hypoplasia
    2. Minor anomalies
        1. Scalp defect
        2. Hypertelorism usually with a prominent glabella
        3. Pulmonary isomerism
        4. Common mesentery
        5. Hypospadias
        6. Sacral dimple
22. Prognosis (Shannon et al. 2001)
    1. Crude infant mortality rate: 17%.
    2. Mortality rate in the first 2 years: 21%.
    3. Cases with large de novo deletions are more likely to die than those with smaller deletions.
    4. Follow-up of patients, spanning 23 years, showed a slow but constant evolution over time, in all areas (Battaglia et al. 2008).
        1. There was an improvement of the motor, and the communicative skills, and of the verbal comprehension with extension of the gesture repertoire and a reduction of isolation and anxiety.
        2. Forty-five percent of patients were able to walk, either independently or with support (range: 2–12 years); 18% could help dressing and undressing themselves and doing simple household tasks.
    5. Causes of death.
        1. Birth anoxia
        2. Withdrawal of treatment after premature delivery
        3. Lower respiratory tract infections

4. Sudden unexplained death
5. Congenital anomalies, such as congenital heart disease, dysplastic kidneys, renal hypoplasia, diaphragmatic hernia, and pulmonary hypoplasia

Diagnostic Investigations

1. Conventional cytogenetic studies: most common method to detect chromosome arm 4p deletions (60–70% of deletions) (Johnson et al. 1976; Chen 2015).
2. High-resolution cytogenetic studies: to detect smaller deletions of chromosome band 4p16.3 (Fang et al. 1997).
3. Fluorescence in situ hybridization (FISH) using Wolf–Hirschhorn critical region probe (Fryns et al. 1998; Roulston et al. 1991): detecting >95% of deletions. Molecular cytogenetic studies using FISH allow the diagnosis to be made in patients with very small deletions or cryptic translocations. FISH uses genetic markers that have been precisely localized to the area of interest. The absence of signal from either the maternal or the paternal allele for the marker is indicative of monosomy for that chromosomal region.
4. Array comparative genomic hybridization (aCGH).
    1. A new technology that can analyze the entire genome at a significantly higher resolution over conventional cytogenetics to characterize unbalanced rearrangements.
    2. Chromosome microarray can detect all currently known deletions of WHS critical region and can determine if the deletion is "pure" or part of a more complex imbalance (Ikonomou et al. 2013).
    3. Thirty-three patients with WHS were analyzed using aCGH (South et al. 2008).
        1. Observation of a much higher than expected frequency of unbalanced translocations (15/33, 45%).
        2. Seven of these 15 cases were cryptic translocations not detected by a previous karyotype combined with WHS-specific FISH.
5. Immune workup (Hanley-Lopez et al. 1998).
    1. Common variable immunodeficiency
    2. Immunoglobulin A (IgA) and immunoglobulin G2 (IgG2) subclass deficiency
    3. IgA deficiency
    4. Impaired polysaccharide responsiveness
    5. Normal T-cell immunity
6. Radiography.
    1. Delayed bone maturation
    2. Microcephaly
    3. Hypertelorism
    4. Micrognathia
    5. Anterior fusion of vertebrae
    6. Fused ribs
    7. Dislocated hips
    8. Proximal radioulnar synostosis
    9. Clubfeet
7. Echocardiography to detect heart defects.
8. Renal ultrasound to detect renal anomalies.
9. MRI and CT scans to demonstrate underlying brain pathology including agenesis of corpus callosum and ventriculomegaly.
10. EEG for seizure monitoring.
11. Swallowing study for feeding difficulty.
12. Comprehensive audiologic and otologic evaluation to rule out possible hearing impairment (Lesperance et al. 1998).
13. Ophthalmologic examination.
14. Developmental testing.
    1. Speech and motor evaluation
    2. Appropriate psychometric evaluation
15. Growth charts are available from 0 to 4 years of age, based on the study of 101 individuals (Anntonius et al. 2008). The use of these specific growth charts is recommended because standard growth charts are inapplicable for patients with WHS.

Genetic Counseling

1. Recurrence risk
    1. Patient's sib
        1. De novo deletion cases: no significant increased risk

2. Deletion resulting from a parental chromosomal rearrangement: increased risk for unbalanced product in offspring
2. Patient's offspring: reproduction unlikely due to mental retardation

2. Prenatal diagnosis available to families in which one parent is known to be a carrier of a chromosome rearrangement by amniocentesis, CVS, or PUBS
   1. Ultrasonography to detect in utero manifestation of distinct phenotype (Tachdjian et al. 1992)
      1. Severe intrauterine growth retardation
      2. Increased nuchal fold thickness
      3. Microcephaly
      4. Typical facial appearance described as "Greek warrior helmet" facies (Ikonomou et al. 2013)
      5. Hypertelorism, usually with prominent glabella
      6. Micrognathia
      7. Cleft lip and palate
      8. Diaphragmatic hernia
      9. Anomalous urinary stream from the ventral surface of the penis (possible hypospadias by color flow map (Ikonomou et al. 2013))
   2. Chromosome analysis (Dietze et al. 2004; Ikonomou et al. 2013)
      1. Conventional karyotyping: 46,XY,del(4)(p16.3).
      2. FISH using specific probe locus-specific identification (LSI) Wolf–Hirschhorn/CEP4 (4p16.3): observation of only one copy of the region 4p16.3.
      3. Multiplex ligation-dependent probe amplification-specific molecular probe detected a 19-Mb deletion of the gene *LETM1* 1.81 Mb from the telomere.
      4. Whole chromosome painting.
3. Management (Battaglia and Carey 1999; Battaglia et al. 1999; Chen 2015)
   1. Multidisciplinary team approach
      1. Early intervention program to improve motor development, cognition, communication, and social skills
      2. Speech, physical, and occupational therapies
      3. Appropriate school placement
   2. Manage feeding difficulties and failure to thrive
      1. Gavage feeding
      2. Gastrostomy
      3. Occasional gastroesophageal fundoplication
   3. Anticonvulsants including bromide therapy (Shimizu et al. 2014) for seizure control
   4. Orthopedic care for skeletal abnormalities
      1. Clubfoot
      2. Scoliosis
      3. Kyphosis
   5. Care for possible immunodeficiency

Fig. 1 (**a**–**e**) A patient with Wolf–Hirschhorn syndrome at different ages showing characteristic facial features consisting of prominent glabella, hypertelorism, beaked nose, and frontal bossing, collectively described as "Greek warrior helmet" facies

Fig. 2 (**a**–**c**) A girl with WHS showing characteristic face and deletion of WHS locus (FISH)

Fig. 3 (**a**–**f**) Four children with WHS showing characteristic facial features of the syndrome

Fig. 4 (**a**–**d**) Two siblings with WHS showing characteristic features of the syndrome

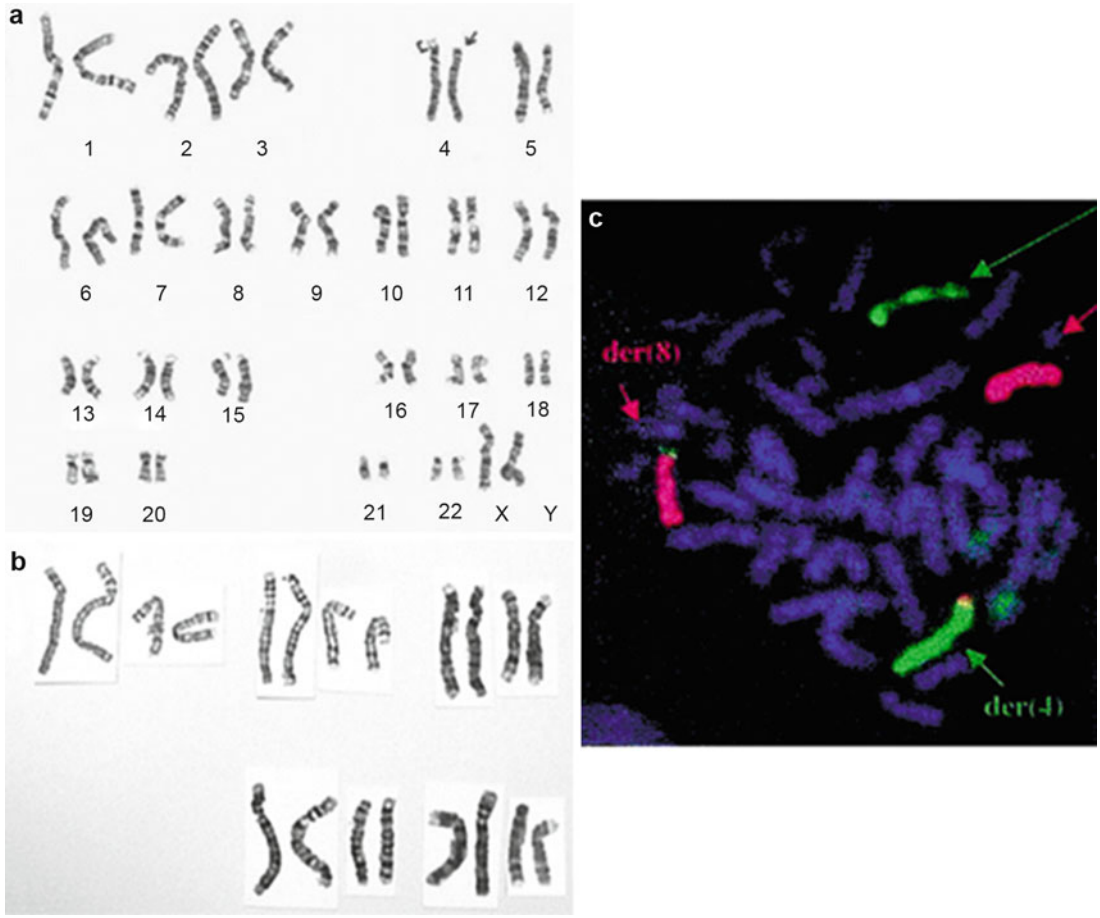

Fig. 5 (**a**–**c**) Karyotype of the sister showing deletion of 4p, derived from the mother with balanced translocation (4p;8p) (partial karyotypes). FISH analysis with whole chromosome paint specific for chromosome 4 (wcp4/SpectrumGreen) and chromosome 8 (wcp8/SpectrumOrange) demonstrated a t(4;8) in all metaphases analyzed. These results confirmed a reciprocal translocation between chromosome 4 and chromosome 8 in the mother

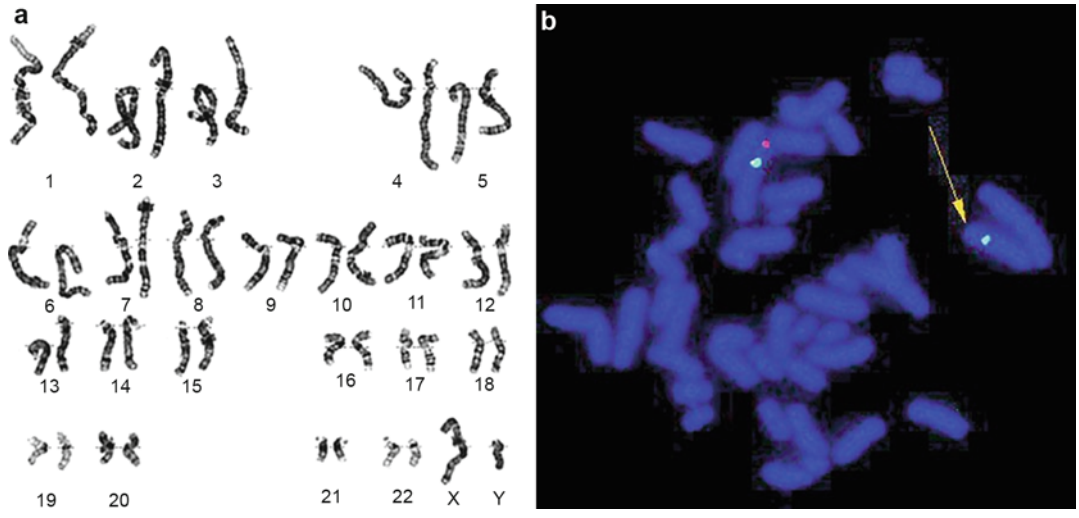

Fig. 6 (**a**, **b**) Karyotype and FISH of another patient with Wolf–Hirschhorn syndrome (4p)

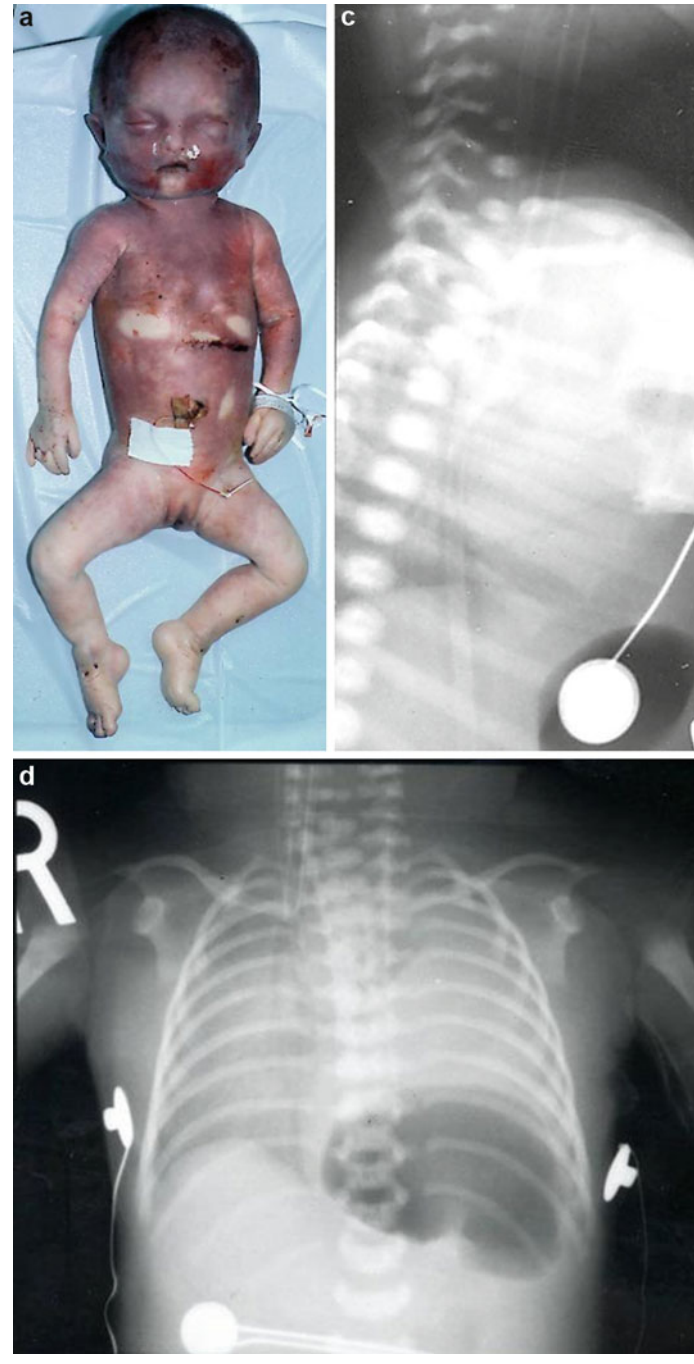

Fig. 7 (**a**–**c**) A fetus with WHS showing broad triangular-shaped nasal root and the flat facial profile resembling "Greek warrior helmet." The radiographs show hypoplasia of the cervical vertebral bodies

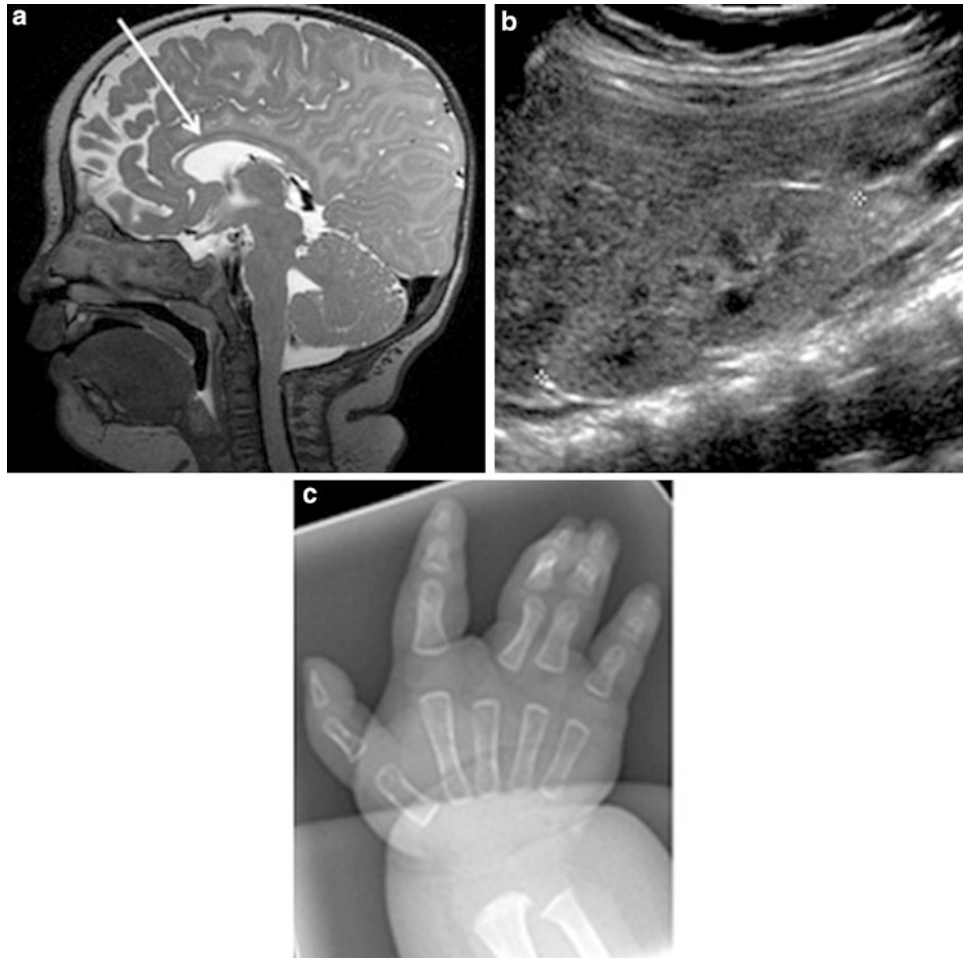

Fig. 8 (**a**–**c**) The 2-year-old female was diagnosed to have Wolf–Hirschhorn syndrome based on chromosome 4p deletion noted on amniocentesis. Clinical features are characterized by secundum atrial septal defect with pulmonary stenosis, global developmental delay, seizure disorder, tethered cord status post repair at 1 year of age, neurogenic bladder, vesicoureteral reflux, chronic kidney disease secondary to renal dysplasia, gastroesophageal reflux status post repair Nissen fundoplication, cortical visual impairment, right hand syndactyly, chronic lung disease, and precocious puberty. Immunoglobulin study revealed very low IgG (185), normal IgA (38), and low IgM (13). MRI of the brain at 6 month of age (**a**) demonstrated global reduction in cerebral white matter volume and severe diffuse thinning of the corpus callosum (*arrow*) and prominence of the lateral and third ventricles. These features have been reported in patients with Wolf–Hirschhorn syndrome. Renal ultrasound at 1 year 3 months of age (**b**) demonstrated increased echogenicity of the renal parenchyma with decrease in corticomedullary differentiation. Findings are suggestive of renal disease with dysplastic change. Right hand radiography at 1 year 7 months of age (**c**) showed soft tissue fusion of the third and fourth digits with mildly dysmorphic phalanges along the third digit and retarded bone age. The left hand was normal (not shown) (Courtesy of Dr. Guo)

X-Linked Agammaglobulinemia

Contents

X-linked agammaglobulinemia (XLA) was first described by Bruton in 1952 (Bruton 1952). It is a prototypical humoral immunodeficiency characterized by early onset of bacterial infections, profound hypogammaglobulinemia, and marked decrease of the peripheral B-lymphocyte population. Associated infections, particularly bacterial meningitis and pneumonia, are often life threatening.

Synonyms and Related Disorders

Agammaglobulinemia tyrosine kinase; B-cell progenitor kinase; Bruton-type agammaglobulinemia; Immunodeficiency 1

Genetics/Basic Defects

1. An X-linked recessive disorder (Sideras and Smith 1995).
2. The responsible gene for XLA (named as Bruton's tyrosine kinase, *BTK*) (Vihinen et al. 1999), mapped on Xq21.3-Xq22, is mainly involved in early B-cell maturation through its function in pre-B-cell receptor signaling pathway, and its absence causes an arrest in B-cell development.
3. Xq22.1 contiguous gene deletion syndrome of X-linked agammaglobulinemia associated with Mohr-Tranebjærg syndrome (MTS) (Shaker et al. 2016):
   1. Microarray identified a 111-kb deletion of genetic material from chromosome region Xq22.1, resulting in the absence of the *BTK*, *TIMM8A*, and *TAF7L* genes.
   2. These genes are respectively responsible for agammaglobulinemia, MTS (deafness-dystonia-optic atrophy syndrome), and spermatogenesis.
4. Mutations in the *BTK* gene cause XLA: 90–95% of males with presumed XLA have mutations in Btk (Conley et al. 1998). The other patients are likely to have defects in other genes.
5. Point mutations were the most common mutations detected, accounting for 68% of all mutations. Deletions and insertions were also seen in a few cases (Singh et al. 2016).
6. The defect in differentiation of pre-B cells into B cells is not absolute in patients with XLA (Conley 1985). The immature phenotype of the B cells additionally suggests that there may be a block in the maturation of B

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_248

cells at more than one stage of differentiation in this disorder.

7. Genetic analysis of patients with defects in early B-cell development: Polymorphic variants in the components of the pre-B cell and B-cell receptor complex, particularly micro heavy chain and lambda5, may contribute to the severity of XLA (Conley et al. 2005).
8. The whole-exome sequencing revealed a somatic mutation in *MLL2* (a histone methyltransferase) in the sample from the onset of B-cell precursor acute lymphoblastic leukemia (BCP-ALL). This study suggests that the alterations of *BTK* and *MLL2* synergistically function as leukemogenesis (Hoshino et al. 2015).
9. Genotype phenotype correlation:
    1. Polymorphic variants in Tec (a cytoplasmic tyrosine kinase that might substitute for BTK) were not correlated with phenotypic markers; however, the specific mutation in Btk did influence disease severity. Mutations that conceivably allow the production of some Btk, amino acid substitutions or splice defects that occur at conserved but not invariant sites in the splice consensus sequence were associated with older age at diagnosis, a higher percentage of B cells in the peripheral circulation and higher concentrations of plasma IgM (Broides et al. 2006).
    2. Globally, a genotype-phenotype correlation is observed, but individual discrepancies between the severity of the mutation and the clinical and analytic phenotype suggest that other loci or ambient factors significantly influence the disease presentation and evolution (López-Granados et al. 2005).
    3. Severe genotypes do not necessarily lead to severe phenotypes. Moreover, a considerable number of patients with mild phenotype showed a severe mutation with a tendency toward C substitution in the polymorphic site on TEC intron 1 (Teimourian et al. 2008).
10. Female XLA can result from heterozygous *BTK* gene abnormality and extreme nonrandom inactivation of X chromosome on which normal *BTK* gene is located (Takada et al. 2004).

Clinical Features

1. Presenting manifestations
    1. Infections in affected boys after the decline of passively transferred maternal antibodies: the major presenting feature
        1. Most frequently respiratory tract and gastrointestinal tract infections (91%), often protracted and recurrent, presenting as otitis media, pneumonitis, and diarrhea.
        2. Other common infections:
            1. Conjunctivitis
            2. Sinusitis
            3. Skin infection
        3. *S. pneumoniae* and *H. influenzae*: the most common organisms found prior to diagnosis and may continue to cause sinusitis and otitis after diagnosis and the initiation of gamma globulin therapy.
        4. Monoarticular or oligoarticular arthritis (20%) affecting large joints: the most common being knees, shoulders, ankles, wrists, and elbows.
        5. Central nervous system infections (16%): meningitis/encephalitis.
        6. Septicemia (10%) excluding bacterial meningitis and associated bacteremia.
        7. Virtually, all patients had infections at more than one anatomic site and on more than one occasion.
    2. Autoimmune or inflammatory disease: a significant proportion of patients with XLA have symptoms that are consistent with a diagnosis of arthritis, inflammatory bowel disease or other inflammatory condition (Hernandez-Trujillo et al. 2014).
    3. Neutropenia (10%): always occur in association with infection, and in all cases resolved after treatment with antibiotics and γ-globulin.
    4. Failure to thrive: a relatively infrequent occurrence.

5. Fever of unknown origin.
6. Complications of immunizations such as paralytic poliomyelitis following live virus vaccine and vaccinia gangrenosum following smallpox vaccination.

2. Age at onset of symptoms
   1. By age 4 months (25%)
   2. By age 8 months (50%)
   3. By age 12 months (75%)
   4. By age 18 months (90%)
3. Chronic complications
   1. Chronic pulmonary disease (46%): the most frequent long-term complication of XLA
      1. Obstructive pulmonary disease (half of cases)
      2. Combined obstructive and restrictive disease (half of cases)
   2. Sensory neurologic disorders
      1. Hearing loss (32%) as a consequence of chronic otitis media and meningoencephalitis
      2. Delayed acquisition of speech (14%)
      3. Learning disorders (15%)
      4. Significant motor dysfunction as a consequence of encephalitis
         1. Hemiparesis
         2. Ataxia
         3. Diplegia
         4. Quadriplegia
4. Miscellaneous illnesses
   1. Dermatomyositis-like syndrome occurred in association with arthritis and with meningitis/encephalitis
   2. Viral infections
      1. Disseminated enterovirus infection
      2. Disseminated adenovirus infection
   3. Hematologic abnormalities: uncommon in treated patients
      1. Chronic Coombs' positive hemolytic anemia
      2. Transient neutropenia and transient thrombocytopenia in conjunction with infection: resolved when the infection resolved
      3. Insulin-dependent diabetes mellitus
5. Clinical findings leading to the diagnosis of X-linked agammaglobulinemia (Conley and Howard 2002)
   1. The majority of patients with XLA were recognized to have immunodeficiency during or shortly after their first hospitalization for infection.
   2. Most of the patients had a history of recurrent otitis at the time of diagnosis, which when combined with the physical finding of markedly decreased or absent tonsils and cervical lymph nodes, could have alerted physicians to the diagnosis of XLA.
6. Complications of γ-globulin therapy
   1. Rash
   2. Fever
   3. Apparent anaphylactic-like symptoms
   4. Acrodynia secondary to γ-globulin preparations containing mercury as a preservative
7. Causes of death
   1. The two major causes of death (Lederman and Winkelstein 1985)
      1. Chronic pulmonary disease with resultant cardiac failure
      2. Disseminated viral infections which characteristically caused a dermatomyositis-like syndrome, hepatitis, pneumonitis, and meningoencephalitis
   2. Cardiorespiratory failure (38%): consequence of chronic pulmonary disease and cor pulmonale
   3. Severe viral infections (50%)
   4. Fulminant necrotizing hepatitis
   5. Aspiration as a consequence of poliomyelitis-related neurologic impairment
   6. Systemic staphylococcal infections

Diagnostic Investigations

1. Clinical clues to the diagnosis of XLA:
   1. Chronic or recurrent nature of infections.
   2. Infections at more than one anatomic location.
   3. Family history of immunodeficiency.
   4. An important clinical clue: absent or barely detectable tonsils and cervical lymph nodes.

5. About 60% of individuals with XLA are recognized as having immunodeficiency when they develop a severe, life-threatening infection such as pneumonia, empyema, meningitis, sepsis, cellulitis, or septic arthritis (Zhu et al. 2015).

2. Clinical laboratory findings in affected individuals
    1. Concentration of serum immunoglobulins:
        1. The serum IgG concentration: typically less than 200 mg/dL
        2. The serum concentrations of IgM and IgA: typically less than 20 mg/dL (Although decreased serum concentration of IgG and IgA can be seen in children with a constitutional delay in immunoglobulin production, low serum IgM concentration is almost always associated with immunodeficiency.)
    2. Antibody titers to vaccine antigens: Affected individuals fail to make antibodies to vaccine antigens like tetanus, *H. influenzae*, or *S. pneumoniae*.
    3. Lymphocyte cell surface markers: markedly reduced numbers of B lymphocytes (CD 19 + cells) in the peripheral circulation (<2% in almost all patients): the most distinctive laboratory finding.
    4. Bruton's tyrosine kinase protein (measured by flow cytometry) is absent in most of the patients.
    5. Severe neutropenia: seen in about 10–25% of individuals at the time of diagnosis, usually in association with pseudomonas or staphylococcal sepsis. Neutropenia is generally not seen after the initiation of gamma globulin therapy (Farrar et al. 1996).
3. The diagnosis of XLA (Ochs and Smith 1996) is based on:
    1. The presence of lymphoid hypoplasia
    2. Markedly reduced serum levels of all 3 major classes of immunoglobulins
    3. Failure to make antibody to antigenic stimulation
    4. Almost complete absence of B lymphocytes in the peripheral blood
4. Molecular genetic testing
    1. Mutations in *BTK*: detectable by sequence analysis in approximately 90% of males with early-onset infections, hypogammaglobulinemia, and absent B cells.
    2. Duplications or deletions in *BTK* gene: detectable by duplication/deletion analysis in 10% of affected males.
    3. Molecular genetic testing of the *BTK* gene is the most reliable way to identify female carriers of XLA.
    4. Single-stranded conformation polymorphism (SSCP) analysis for mutation screening in the BTK (Bruton's tyrosine kinase) gene: molecular genetic testing by SSCP analysis provides an accurate tool for the definitive diagnosis of XLA and the discrimination of borderline cases, such as certain hypogammaglobulinemia or common variable immunodeficiency patients with overlapping clinical features (Holinski-Feder et al. 1998).
5. Diagnosis considered established only in those individuals who have a mutation in the *BTK* gene or who have a maternal uncle or cousin with absent B cells
6. Carrier detection in typical and atypical X-linked agammaglobulinemia (Conley and Puck 1988)
    1. Combining the production of somatic cell hybrids that selectively retain the active X chromosome with the use of X-linked restriction fragment length polymorphisms permits the distinction of the two X chromosomes.
    2. Three obligate carriers of typical XLA and four women whose sons might be considered to have atypical or sporadic XLA were studied.
    3. B cell hybrids from all seven women demonstrated exclusive use a single X as the active X.
    4. In addition, B cell hybrids from four of eight women at 25% or 50% risk of being carriers exhibited nonrandom X chromosome inactivation, indicating that these women were also carriers of X-linked forms of hypogammaglobulinemia.

5. These results illustrate a technique that can be used both to help define XLA and to provide carrier detection for all women at risk of being carriers of this disorder.

7. Application of carrier testing to genetic counseling for X-linked agammaglobulinemia (Allen et al. 1994):
   1. Female carriers of XLA, although asymptomatic, have a characteristic B cell lineage-specific skewing of the pattern of X inactivation. Skewing apparently results from defective growth and maturation of B cell precursors bearing a mutant active X chromosome.
   2. Primary carrier analysis to examine patterns of X inactivation in CD19+ peripheral blood cells (B lymphocytes) was conducted using quantitative PCR at the androgen-receptor locus. Obligate carriers of XLA demonstrated >95% skewing of X inactivation in peripheral blood CD19+ cells but not in CD19 cells.
8. Clinical and mutational characteristics of X-linked agammaglobulinemia and carrier identification by flow cytometric assessment combined with genetic analysis (Kanegane et al. 2001):
   1. Flow cytometric assessment revealed the deficient BTK expression status in 78 families (93 patients), and mutations in BTK were identified in 76 of 78 families with presumed XLA.
   2. Of the patients with normal BTK expression, two showed missense mutations in which the normal amount of altered BTK transcript would cause the XLA phenotype.
   3. As many as 30% of these patients with XLA were clinically or genetically recognized beyond 5 years of age.
   4. Higher concentrations (>300 mg/dL) of serum IgG were evident in the cases diagnosed among adults, seemingly preventing severe infections.
   5. Fifty-seven of 70 mothers of patients with BTK deficiency were diagnosed as obligate carriers on the basis of a bimodal BTK expression pattern.
   6. Nine of the remaining 13 mothers showing nonmosaic BTK expression had no mutations in 2 alleles; surprisingly, the other 4 mothers had the mutated alleles.

Genetic Counseling

1. Recurrence risk
   1. Obligatory carriers: Mothers who have an affected son and one other affected relative in the maternal line (e.g., brother, uncle, nephew)
   2. Negative family history in 50% of affected males: two possibilities exist regarding his mother's carrier status and carrier risks of extended family members
      1. The mother is a carrier of a disease-causing mutation (80–85% of cases).
      2. The mother is not a carrier and the affected male has a de novo disease-causing mutation (15–20% of cases).
   3. Patient's sib
      1. When the mother is a carrier
         1. A 50% chance of transmitting the *BTK* mutation by the mother in each pregnancy.
         2. Male sibs who inherit the mutation will be affected.
         3. Female sibs who inherit the mutation will be carriers.
      2. When the mother's carrier status is unknown and if the proband is the only affected individual in the family, the mother has an approximately 80% chance of being a carrier.
         1. Male sibs have a 40% chance of being affected.
         2. Female sibs have a 40% chance of being carriers.
      3. When the mother is not a carrier (no evidence of her son's BTK disease-causing mutation present in DNA extracted from her leukocytes) and if the affected son represents a single case in the family, the male sibs are still at

increased risk (<5%) of being affected because of the possibility of the presence of germ line mosaicism.

4. Patient's offspring
    1. No sons will inherit the mutant allele and therefore will not be affected.
    2. All daughters will inherit the mutant allele and will be carriers.

2. Molecular analysis of the *BTK* gene is a favorable tool for the diagnosis of XLA and for accurate carrier determination, which is essential for subsequent genetic consulting (Qin et al. 2013; Zheng et al. 2014)
3. Prenatal diagnosis: available to pregnancies of women who are carriers
    1. The usual procedure: to determine fetal sex by performing chromosome analysis on fetal cells obtained by chorionic villus sampling (CVS) at about 10–12 weeks of gestation or by amniocentesis usually performed at about 15–18 weeks of gestation.
    2. If the fetal karyotype is 46,XY and if the disease-causing mutation has been identified in a family member, DNA from fetal cells can be analyzed for the known disease-causing mutation.
    3. Preimplantation genetic diagnosis (PGD) (Smith and Berglöf 2016): available for families in which the disease-causing mutation has been identified in an affected family member. However, the reliability of PGD for XLA has not yet been proven.
4. Management
    1. Gamma globulin replacement (weekly subcutaneous injection or intravenous infusion every 2–4 weeks) and aggressive use of antibiotics:
        1. Improve the outlook for affected patients: a remarkable improvement in the health and well-being after therapy is started.
        2. Early intravenous immunoglobulin replacement therapy achieving residual IgG levels >500 mg/dL is effective in preventing severe acute bacterial infections and pulmonary insufficiency. More intensive therapy may be required to fully prevent the onset of bronchiectasis, chronic sinusitis, and nonbacterial infections, particularly enteroviral infections, in all cases (Quartier et al. 1999).
        3. Decrease in systemic infections such as sepsis and meningitis/ meningoencephalitis (Plebani et al. 2002).
        4. Acute, life-threatening infections: rare in patients with XLA who are receiving intravenous gamma globulin.
        5. Chronic lung disease and enteroviral infections still develop in some patients.
        6. Shulman disease (eosinophilic fasciitis) in X-linked agammaglobulinemia (Pituch-Noworolska et al. 2016)
            1. The patient was diagnosed with XLA in the first year of life, followed by regular substitution of immunoglobulins.
            2. The symptoms of pain, edema of muscles of the right shank with skin edema and discoloration after mild injury were noted in a 13-year-old boy.
            3. Shulman disease was diagnosed after 6 months of symptoms, based on histopathology of muscle and skin biopsy.
            4. Before the diagnosis, nonsteroid anti-inflammatory drugs (NSAID) were used with a transient effect.
            5. After the diagnosis, therapy included steroids, immunoglobulins in a high dose and immunosuppression, with improvement of clinical symptoms.
    2. Use of infliximab, a chimeric antitumor necrosis factor alpha monoclonal antibody, in X-linked agammaglobulinemia associated enteropathy (Davey et al. 2014). The use of infliximab in X-linked agammaglobulinemia associated enteropathy.
    3. Use of ibrutinib (Imbruvica) (Ponader and Burger 2014):
        1. The highly encouraging clinical results led to breakthrough therapy designation for ibrutinib by the US Food and Drug

Administration for patients with CLL (chronic lymphocytic leukemia), MCL (mantle-cell lymphoma), and Waldenströom macroglobulinemia, and the recent US Food and Drug Administration approval of ibrutinib (Imbruvica) for previously treated patients with MCL (in November 2013) and CLL (in February 2014).

2. With these exciting new developments, BTK has become a role model for translational research, in which basic research defined the genetic and molecular basis of XLA.
3. These developments allowed for innovative development of BTK inhibitors that already have an impact on the lives of many patients suffering from B-cell malignancies.

4. Inactivated polio vaccine rather than live oral polio vaccine is given to children with XLA and their sibs.
5. Report a series of 6 XLA patients with bronchiectasis who underwent lung transplantation: Short-term outcomes were excellent; however, long-term outcomes were disappointing with a high incidence of pulmonary sepsis and chronic lung allograft dysfunction (Barnes et al. 2015).
6. Molecular genetic testing of at-risk male relatives as soon after birth as possible to ensure that gamma globulin replacement therapy is initiated in affected individuals.
7. Adults with XLA: become productive members of society and excel in many areas despite the disease impacts on the daily lives (Winkelstein et al. 2008).
8. Splice-correction strategies for treatment of X-linked agammaglobulinemia (Bestas et al. 2015):
    1. As for many other genetic diseases, gene therapy represents a future option for XLA.
    2. The transient need of BTK in B cells, which differentiate into long-lived protective plasma cells, makes splice correction therapy particularly feasible for XLA.

Fig. 1 A 5-year-old boy was evaluated for immune deficiency because of recurrent respiratory tract infections (two pneumonias since late infancy) and one episode of meningitis. Recent immunoglobulin levels revealed IGA of <5 mg/dL (22–159), IGG of 115 mg/dL (141–1,135), and IGM of 11 mg/dL (47–200). Flow cytometry (immune deficiency panel) showed CD3, 92.9% (3,498); CD4, 43% (1,645); CD8, 46% (1,747); CD4/CD8, 1:1.1; CD19, 0.1% (4); and CD16 + CD56+, 6.2% (233). These findings are consistent of B-cell defect with normal T cell subsets and normal NK cells. Bruton's tyrosine kinase mutation analysis revealed a novel mutation in the splice site of exon 6 (g.58919 G > C). Previously, a mutation at this splice site (g.58919) G > A has been reported in the BTKBASE. The impact on protein structure and function for this mutation, assessed using a splice site prediction software, would be the same as that reported for g.58919 G > A. The patient currently receives intravenous immunoglobulin (610 mg/kg) and is responding well

Fig. 2 A 3-year-old male, a brother of the above patient, was also evaluated for immune deficiency because of recurrent upper respiratory infections in the first 2–3 months of life, three pneumonias in later infancy, and a pneumococcus meningitis recently. Recent immunoglobulin levels were IGA of <5 mg/dL, IGG of 184 mg/dL, and IGM of 10 mg/dL. Flow cytometry (immune deficiency panel) revealed CD3, 8 % (1,979); CD4, 55 % (1,365); CD8, 27 % (679); CD4/CD8 ratio, 2:1; CD19+, 1.4 % (34); and CD16+ CD56+, 11 % (270). The patient currently receives intravenous infusion of immunoglobulin (680 mg/kg) and responds well

X-Linked Ichthyosis

Contents

X-linked ichthyosis is a relatively common genetic disorder of keratinization. It is the second most common type of ichthyosis after vulgaris. The incidence is estimated to be between 1 in 2,000 and 1 in 6,000 male live births.

Synonyms and Related Disorders

Placental steroid sulfatase deficiency; Steroid sulfatase deficiency

Genetics/Basic Defects

1. Inheritance
    1. X-linked recessive.
    2. Usually affects males only.
    3. Transmitted by carrier females (about 1 in 2,000 women are carriers of steroid sulfatase (STS) enzyme deficiency).
    4. Most apparently, sporadic cases appear to be inherited based on biochemical analysis (as their mothers showed low values of STS enzyme activity) (Cuevas-Covarrubias et al. 1999).
    5. Reports of a few affected female patients (Mevorah et al. 1981; Murtaza et al. 2014).
2. Etiology (Janniger and Schwartz 2011)
    1. Caused by a deficiency of STS enzyme (Crawfurd 1982)
    2. The *STS* gene
        1. Mapped on the distal part of the short arm of the X chromosome (Xp22.3).
        2. Close to the pseudoautosomal region.
        3. Unlike most X chromosome genes, the *STS* gene escapes the X-inactivation process.
3. Molecular defects
    1. Deletion of the entire steroid sulfatase (*STS*) gene: the most common molecular defect in X-linked ichthyosis (XLI) patients (observed in 90% of patients) (Shapiro et al. 1989).
    2. Partial deletion or point mutation (observed in 10% of patients).
    3. The deletion of *STS* gene may occasionally extend to involve neighboring genes (interstitial and terminal deletions of Xp22.3), resulting in a contiguous gene defect and may be associated with the following conditions. Depending on the length of the

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_249

deletion, these disorders occur independently from each other or in combination as a contiguous gene syndrome (Paige et al. 1994; Aviram-Goldring et al. 2000).
    1. Kallmann syndrome (hypogonadotropic hypogonadism and anosmia)
    2. X-linked chondrodysplasia punctata
    3. Short stature
    4. Mental retardation (Gohlke et al. 2000)
    5. Ocular albinism
    6. Ichthyosis
4. Segregation analysis of paternal transmission of the affected X chromosome (Toral-Lopez et al. 2008): *STS* gene deletion may occur in male meiosis as a result of:
    1. An intrachromosomal event
    2. Recombination between S232 sequences on the same DNA molecule
    3. During the process of DNA replication

Clinical Features

1. Cutaneous manifestation (Hernandez-Martin et al. 1999; Jasmi and Al-Khenaizan 2002)
    1. Generalized scaling of the skin (ichthyosiform hyperkeratosis)
        1. Early onset: usually at birth or within 4 months of life
        2. Large, dark-brown polygonal scales
            1. Usually symmetrically distributed
            2. More prominent on the trunk and the extensor aspects of the limbs
            3. Usually the flexures less affected
        3. Face usually free from scales, except in the preauricular areas, giving the classic "unwashed appearance," which is considered by many to be pathognomonic
        4. Sparing palms and soles in most cases
    2. Normal nails and hair
    3. Seasonal influence
        1. Improve during the summer
        2. Worsen during dry, cold weather
2. Extracutaneous manifestations
    1. Corneal opacities
        1. The most common extracutaneous features
        2. Secondary to deposits of cholesterol sulfate crystals
        3. Asymptomatic (not affecting the visual acuity)
        4. Occurring in the posterior capsule of Descemet's membrane or the corneal stroma (Aviram-Goldring et al. 2000)
        5. More frequent during the 2nd and 3rd decades of life
        6. Observed in 10–50% of affected males and carrier females
    2. Cryptorchidism (Traupe and Happle 1986)
        1. Occurring in 10–20% of patients (versus the incidence of cryptorchidism in the normal population of 1%)
        2. Possible mechanisms
            1. A deficit in the STS enzyme
            2. A genetic disturbance located on the short arm of chromosome X close to the *STS* gene
    3. Patients at an increased risk of testicular cancer development
    4. CNS manifestations
        1. Epileptic seizures
        2. Reactive psychological disorders
    5. Clinical manifestations as a part of the contiguous gene syndrome expression
        1. Kallmann syndrome
        2. Short stature
        3. Mental retardation
        4. X-linked chondrodysplasia punctata
    6. Other rare manifestations
        1. Pyloric hypertrophy
        2. Congenital abdominal wall defect
        3. Acute lymphoblastic leukemia
3. Steroid sulfatase deficiency during pregnancy in carrier females
    1. Leads to an overall decrease in the levels of estrogen
    2. Causes poor cervical dilatation and prolonged labor
    3. Frequently necessitates a caesarean section

Diagnostic Investigations

1. Direct biochemical demonstration of STS deficiency (undetectable levels of STS activity) from the following tissue (Bradshaw and Carr 1986; Hernandez-Martin et al. 1999; Jasmi and Al-Khenaizan 2002):
    1. Placenta
    2. Skin fibroblasts
    3. Leukocytes
    4. Keratinocytes
2. Demonstration of an increase in substrates of STS
    1. Dihydroepiandrosterone sulfate (DHEAS)
    2. Cholesterol sulfate
3. Electrophoresis: rapid migration of serum cholesterol sulfate (negatively charged and carried by low-density lipoprotein (LDL) particles) toward the positive pole during electrophoresis
4. Molecular genetic diagnosis yielding reliable results in most affected patients
    1. Detection of complete deletion of the STS gene in most patients
        1. Fluorescence in situ hybridization (FISH)
        2. Southern blotting (Bonifas and Epstein 1990)
        3. Multiplex polymerase chain reaction (PCR) (Nomura et al. 1995)
    2. Partial deletion by FISH: may provide a false-negative FISH result
    3. A very small number of cases carrying point mutations instead of deletions at the *STS* gene: undetectable by Southern blot or PCR
    4. Phenotype spectrum of X-linked ichthyosis identified by chromosome microarray diagnosis: STS deletions may cause a milder skin phenotype than the typical presentation of X-linked ichthyosis (Hand et al. 2015)
    5. Carrier detection
        1. STS enzyme assay (Cuevas-Covarrubias et al. 1995)
        2. FISH technique especially useful in carrier detection since the enzymatic assay often provides inconclusive results
        3. Somatic and germinal mosaicism for the steroid sulfatase gene deletion in a steroid sulfatase carrier (Cuevas-Covarrubias et al. 2002)

Genetic Counseling

1. Recurrence risk (Ivich 2015)
    1. Patient's sib (given that the mother is a carrier)
        1. Fifty percent of male sibs affected
        2. Fifty percent of female sibs carriers
    2. Patient's offspring
        1. Affected male patients
            1. Male offspring normal
            2. All female offspring carriers
        2. Affected female patients (heterozygous)
            1. Fifty percent of male offspring affected
            2. Fifty percent of female offspring carriers
        3. Affected female patients (homozygous)
            1. All male offspring affected
            2. All female offspring carriers
2. Prenatal diagnosis
    1. Maternal plasma demonstrating low or undetectable unconjugated estriol levels in routine maternal serum screening, which is associated with the following conditions (Braunstein et al. 1976; Ahmed et al. 1998; Zalel et al. 1996; Kashork et al. 2002):
        1. Placental steroid sulfatase deficiency (Lykkesfeldt et al. 1984)
        2. Fetal death
        3. Miscarriages
        4. Anencephaly
        5. Fetal adrenal hypoplasia
        6. High-dose corticosteroid therapy
        7. Aneuploidies
            1. Down syndrome
            2. Triploidy
        8. Smith-Lemli-Opitz syndrome in rare cases

2. Maternal urine (Glass et al. 1998) and plasma (Keren et al. 1995) profile of affected fetuses indicating a primary placental sulfatase deficiency (low estriol levels) (Basler et al. 1992)
3. Amniocentesis (Aviram-Goldring et al. 2000)
    1. Elevated sulfated steroids in the amniotic fluid
    2. FISH to detect deletion in one copy of X chromosome at region Xp22.3 using steroid sulfatase probe (Lebo et al. 1993; Watanabe et al. 2003)
4. Skin biopsy through fetoscopy to measure sulfated steroid

3. Management (Hernandez-Martin et al. 1999)
    1. Most patients have disease limited to the skin.
    2. Spontaneous improvement in most cases with age and during summer months and hardly require any treatment.
    3. Attempt to diminish the abnormal cohesion of corneocytes by facilitating their separation in the milder forms.
        1. Topical keratolytics
        2. Emollients
        3. Hydrating agents
    4. Retinoids for potential treatment in severely affected patients.
    5. Liarozole, a imidazole derivative which inhibits cytochrome P450 to increase the level of endogenous retinoid acid by blocking its P450-dependent catabolism.
    6. Examination of male patients to detect cryptorchidism which has an increased risk of testicular cancer.

Fig. 1 A sporadic case of X-linked ichthyosis showing thick, large, polygonal, *dark-brown* scales involving the extensor

Fig. 2 X-linked ichthyosis affecting three boys in a family

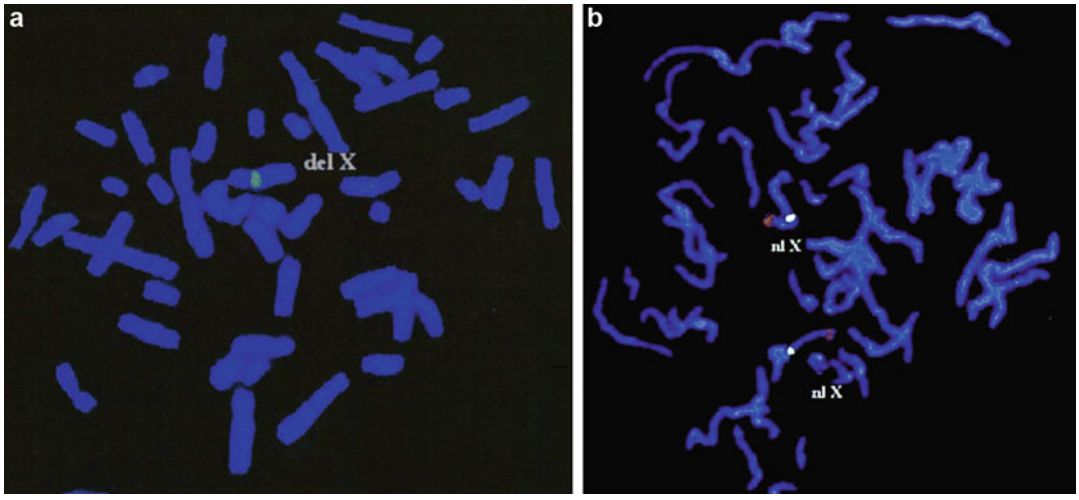

Fig. 3 (**a**, **b**) Abnormal FISH analysis showed a deletion in the steroid sulfatase critical region on the X chromosome [del(X)(p22.3p22.3)(STS-)] in a male fetus (*left photo*). The case was ascertained because of undetectable UE3 from maternal serum screen. The *right photo* (FISH) showed a normal XX control

Fig. 4 (**a**–**d**) This 2-month-old premature male infant was evaluated for X-linked ichthyosis. During pregnancy, the mother was noted to have an extremely low maternal serum unconjugated estriol levels (0.1 MOM; 0.9 MOM) which indicated an increased risk for X-linked ichthyosis due to positive family history (maternal grandfather is affected of ichthyosiform hyperkeratosis). The mother was found to be a carrier (46,XX,ish del(X)(p22.3p22.3) (STS-)), a female karyotype with a deletion including the steroid sulfatase gene in the terminal short arm of an X chromosome. Amniocentesis was performed with FISH analysis showing deletion of steroid sulfatase locus, indicative of X-linked ichthyosis of the fetus (**a**). Physical examination of the infant (**b**–**d**) showed generalized dark-brown scaling (polygonal) of the skin (ichthyosiform hyperkeratosis). In addition, the infant has moderate umbilical hernia and bilateral inguinal hernias (**b**).

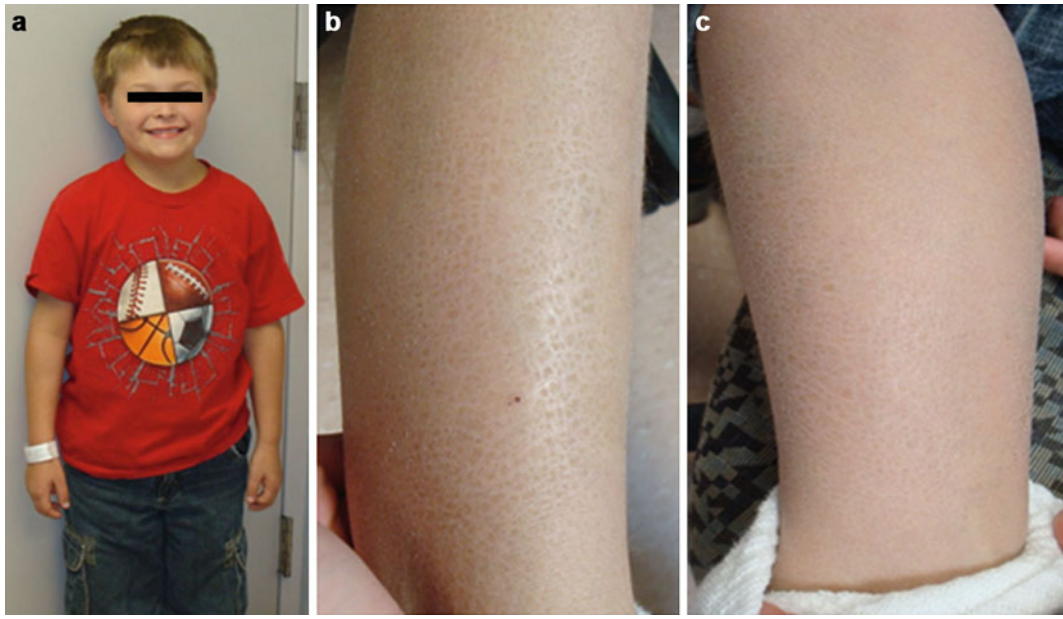

Fig. 5 (**a–c**) This 7-year-old boy was evaluated for X-linked ichthyosis with generalized thick, polygonal, and light-brown scales (ichthyosiform hyperkeratosis). He is tall with height of 130 cm. The chromosome study showed 47,XYY (not shown)

XX Male

Contents

46,XX maleness (XX male syndrome) is a rare disorder occurring in about 1 in 20,000–25,000 newborn males (De la Chapelle 1972; Rajender et al. 2006). Three clinical categories of sex-reversed 46,XX individuals have been identified: (1) XX males with normal external or internal genitalia; (2) XX males with ambiguity, usually detected at birth by external genital ambiguities such as hypospadias, micropenis, or clitoromegaly; and (3) XX true hermaphrodites, who carry internal or external genital ambiguities detected at birth (Valetto et al. 2005). Recently, the term "46,XX testicular DSD (disorder of sex development)" has been proposed for XX male or XX sex reversal (Lee et al. 2006; Hughes et al. 2006; Hughes 2008).

Synonyms and Related Disorders.

46,XX disorder of sex development; 46,XX sex reversal syndrome.

Genetics/Basic Defects

1. Sex differentiation: Please see the chapter on ▶ "XY Female" (Vilain 2009).
2. The *SRY* gene (Valetto et al. 2005).
   1. Located in the short arm of Y chromosome (Yp11.32) near the pseudoautosomal boundary of the Y chromosome.
   2. Encodes the sex-determining region Y protein.
   3. Has many predicted properties of the testis-determining factor (TDF) (Sinclair et al. 1990).
   4. XX transgenic mice carrying the murine *SRY* gene developed as phenotypic male mice (Koopman et al. 1991).
   5. Loss-of-function mutations in the *SRY* gene: can cause a complete sex reversal (genetically male individuals developing as XY females, presenting a streak gonad lacking germ cells) (Jager et al. 1990; Hawkins et al. 1992).
   6. The gene most commonly known to be associated with 46,XX testicular DSD.
      1. Presence of Y chromosome material including *SRY* in some XX individuals: leads to testis determination and the development of a male phenotype.
      2. The majority of XX males carry the *SRY* gene, with the *SRY* gene translocated into the terminus of the X chromosome short arm, as a result of an

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_250

XY chromosomal interchange during paternal meiosis, leading to the differentiation of primary gonads into testes (Fechner et al. 1993; Gao et al. 2013).
3. *SRY*-negative individuals resulting from *SRY* gene mutation.

7. Description of three novel 46,XX-SRY-negative patients, two brothers, and an unrelated man with testicular DSD and azoospermia, who carry a microduplication upstream of SOX9. The detailed analyses of these patients and the incorporation of the published datasets have enabled the minimal critical region located ~600 kb upstream of SOX9 to be resolved to an approximately 40 kb element that contains putative enhancers elements and DNA-binding sites for known factors to be involved in early testis formation (Hyon et al. 2015).
8. 46,XX testicular disorder of sex development caused by *SOX9* duplication (Xia et al. 2013).
9. Several genetic mishaps conceive the 46, XX male genotype (Rizvi 2008).
    1. An original 47,XXY configuration with the loss of the Y chromosome early in embryogenesis
    2. A loss-of-function gene mutation on an autosomal chromosome or on the X chromosome that leads to an aberrancy in the testis differentiation pathway
    3. Possibility that 46,XX males actually have a "hidden" cell line with a Y chromosome present ("cryptic mosaicism")
    4. Translocation of the Y chromosome fragment containing the *SRY* gene to the short arm of an X chromosome or an autosome by unequal interchange between homologous regions during paternal meiotic division (Rego et al. 1996)
        1. The affected individual has male sexual characteristics because of the Y fragment, with the testis-determining factor, being located on the autosome or X chromosome, despite the XX sex chromosome pattern.
        2. If the translocation is in a "pseudoautosomal region" proximal to the *SRY* gene, there may be no significant outcome.
        3. Only if the translocation involves the SRY region of the Y chromosome, then the X chromosome will "act" like a Y chromosome in determining the phenotypic gender of the person.

3. Pathogenesis of 46,XX sex reversal syndrome: currently not clear with the following hypotheses (Wang et al. 2009):
    1. Hypothesis of target gene mutation (Liu et al. 2005)
        1. The structural gene that determines human gender may be located in the autosome, which is regulated by the inhibition of X chromosome and the activation of Y chromosome.
        2. 46,XX individuals, due to defects of the inhibition of X chromosome, result in spontaneous activation of the downstream gene in the absence of *SRY* gene, transform into 46,XX males.
    2. Hypothesis of overexpression of *SOX9* gene (SRY box-related gene 9 located in 17q24.3-q25.1): Upregulation of *SOX9* expression caused by chromosomal abnormalities or mediated by other bypass activation (e.g., PGD2) may result in the occurrence of the *SRY*-gene-negative 46, XX male patient.
    3. Hypothesis of Xp-Yp translocation: Abnormal exchange of the ends of X-Y chromosomes (Xp-Yp translocation) occurred during paternal sperm meiosis resulting in X-type sperm containing *SRY* gene, which could lead to 46,XX offspring when combining with eggs.
4. Approximately 85% of individuals with 46, XX testicular DSD (Queipo et al. 2002; Zenteno-Ruiz et al. 2001).
    1. *SRY* positive

2. Phenotypically males with unambiguous male genitalia at birth
3. Not diagnosed until puberty when they fail to proceed normally

5. Remaining 15% of individuals with 46,XX testicular DSD (Zenteno-Ruiz et al. 2001; Kusz et al. 1999).
   1. Genital ambiguity
   2. *SRY* positive in only a minority of cases
6. XX male sex reversal with genital abnormalities associated with a de novo *SOX3* gene duplication (Moalem et al. 2012).
7. Demonstration of altered *SOX3* expression in an individual with XX male sex reversal and suggests that *SOX3* can substitute for *SRY* to initiate male development in humans (Haines et al. 2015).
8. *NR5A1*, previously associated with 46,XY DSD and 46,XX primary ovarian insufficiency, as a novel gene for 46,XX (ovo)testicular DSD (Baetens et al. 2016).
   1. Testicular and ovotesticular DSD may represent different phenotypes resulting from a common cause.
   2. *NR5A1*, a well-established gene for male gonadal development, is also involved in correct female gonadal development, the exact molecular mechanisms of which are still elusive.
   3. Identical NR5A1 missense mutations in two unrelated 46,XX individuals with testicular tissues (Igarashi et al. 2016).
9. 46 XX ovotesticular DSD may present with virilization at puberty and may be accompanied by dysmorphic features (Selver Eklioglu et al. 2015).
10. A proposed classification of causes of 46,XX disorders of sex development (DSD) (Hughes 2008; Öcal et al. 2015).
    1. Disorders of gonadal (ovarian) development
       1. Gonadal dysgenesis
       2. Ovotesticular DSD
       3. Testicular DSD (e.g., *SRY*+, *dup SOX*9, RSP01)
    2. Androgen excess
       1. Fetal
          1. 3β-Hydroxysteroid dehydrogenase 2 (HSD3B2)
          2. 21-Hydroxylase (CYP21A2)
          3. P450 oxidoreductase (POR)
          4. 11β-Hydoxylase (CYP11B1)
          5. Glucocorticoid receptor mutations
       2. Fetoplacental
          1. Aromatase (*CYP19*) deficiency
          2. Oxidoreductase (*POR*) deficiency
       3. Maternal
          1. Maternal virilizing tumors (e.g., luteomas)
          2. Androgenic drugs
    3. Other
       1. Syndromic associations (e.g., cloacal anomalies)
       2. Müllerian agenesis/hypoplasia (e.g., MURCS)
       3. Uterine abnormalities (e.g., MODY5)
       4. Vaginal atresia (e.g., McKusick-Kaufman)
       5. Labial adhesions

Clinical Features

1. Natural history (Vilain 2009)
   1. Approximately 80% of patients
      1. Present after puberty with normal pubic hair and normal penile size, but small testes, gynecomastia, and sterility resulting from azoospermia.
      2. The small testes are usually soft but may become firmer with age.
      3. A minority have cryptorchidism and/or anterior hypospadias (Boucekkine et al. 1994).
      4. Gender role and gender identity are reported as male for the common, unambiguous presentation, but systematic psychosexual assessment has not been performed on a significant number of individuals with 46,XX testicular DSD.
   2. Approximately 20% of patients: ambiguous genitalia noted at birth, typically

penoscrotal hypospadias with or without chordee
3. Untreated patients: similar to typical consequences of testosterone deficiency
    1. Low libido and possible erectile dysfunction
    2. Decrease in secondary sexual characteristics, such as sparse body hair, infrequent need to shave, and reduced muscle mass
    3. Increase in fat mass with lower muscle strength
    4. Increased risk of osteopenia
    5. Increased risk of depression
2. SRY-positive 46,XX males
    1. Present after puberty
        1. Shorter-than-average stature (De la Chapelle 1972)
        2. Gynecomastia
        3. Small testes
        4. Azoospermia
    2. Rarely present with atypical genitalia and are less likely than individuals with *SRY*-negative 46,XX males to have gynecomastia (Ferguson-Smith et al. 1990; Boucekkine et al. 1994; Ergun-Longmire et al. 2005)
3. SRY-negative 46,XX males
    1. Tend to present with ambiguous genitalia at birth, such as penoscrotal hypospadias and cryptorchidism
    2. If untreated, almost always develop gynecomastia around the time of puberty
4. Genotype-phenotype correlations
    1. Presence of *SRY*: often associated with the presence of normal male external genitalia
    2. Absence of *SRY*: more often associated with ambiguous genitalia (Grigorescu-Sido et al. 2005)
    3. Genotype-phenotype correlation: not entirely reliable because a small number of individuals with *SRY*-negative 46,XX males have normal external genitalia (Vilain et al. 1994; Zenteno et al. 1997; Kolon et al. 1998; Vernole et al. 2000; Abusheikha et al. 2001)
5. Long-term outcome: most had male sexual potential and male sex identity as long as testicular tissues were preserved (Kojima et al. 2009)
6. Familial sex reversal (Sarafoglou and Ostrer 2000)
    1. Familial true hermaphroditism and XX maleness
        1. True hermaphroditism is a distinct clinical entity based on the histological findings of the gonads.
        2. True hermaphrodites contain both ovarian and testicular gonadal tissue separately or, more commonly, together as ovotestis.
        3. In contrast, XX males have only testes, and their phenotype varies from normal male to a male with genital ambiguity.
        4. Greater than 80% of the XX males have an *SRY* gene, almost always transmitted as the result of an aberrant Y-to-X chromosomal interchange (Fechner et al. 1993).
        5. Like individuals with Klinefelter syndrome, these males have small testes, but invariably, their stature is significantly shorter.
        6. The majority of the XX males with genital ambiguity, such as micropenis, hypospadias, and cryptorchidism, do not have *SRY* genes (6).
        7. The induction of testicular tissue in this subgroup of XX males underlines the role of genes other than SRY that are involved in sex determination.
    2. Familial 46,XY complete gonadal dysgenesis
        1. Individuals affected with 46,XY complete gonadal dysgenesis lack testicular development and present with streak gonads, well-developed Mullerian structures, absent Wolffian structures, and female phenotype.
        2. Because no other somatic abnormalities are present, they are usually not diagnosed until puberty, when they present

with absence of secondary sexual characteristics and amenorrhea.
3. Genetically, complete 46,XY gonadal dysgenesis is a very heterogeneous disorder with both Y-linked and non-Y-linked forms. Eighty percent of patients with sporadic or familial 46,XY gonadal dysgenesis do not have a mutation or deletion of the *SRY* gene, indicating that other autosomal or X-linked genes have a role in sex determination.
4. Whereas the majority of the cases occur sporadically, there are several reports of pedigrees with familial transmission of the disorder.

3. Familial partial gonadal dysgenesis and embryonic testicular regression syndrome
   1. The term "partial gonadal dysgenesis" has been used to describe individuals who have partial testis determination, dysgenetic gonads, a mix of Mullerian and Wolffian structures, and ambiguous genitalia.
   2. Other terms used to describe this syndrome are "mixed gonadal dysgenesis" or "dysgenetic male pseudohermaphroditism."
   3. It is regarded as part of the clinical spectrum of 46,XY gonadal dysgenesis.
   4. The gonadal histology of patients with 46,XY partial gonadal dysgenesis consists of poorly formed seminiferous tubules in combination with ovarian-like stroma.
   5. Gonads can be dysgenetic in one side and normal testis on the other side or dysgenetic bilaterally.
   6. "Embryonic testicular regression syndrome" is a term used to describe the spectrum of genital anomalies resulting from regression of testis development from 8 to 14 weeks of gestation.
   7. For example, if the regression of the fetal testes occurs between the 8 and 10 weeks of gestation, the individual may have complete absence of gonads, rudimentary Mullerian and/or Wolffian ductal structure, hypoplastic uterus, and female genitalia with or without ambiguity. This condition has been referred as true agonadism or gonadal agenesis.
   8. Regression of the testes after the critical period of male differentiation (around 12–14 weeks) results in anorchia, where the individual has male internal and external genitalia.
   9. Partial testicular regression after the critical period would result to a male phenotype as in anorchia but with small rudimentary testes (Acquafredda et al. 1987).

7. Differential diagnosis
   1. Syndromic XX testicular DSD.
   2. Isolated XX testicular DSD.
   3. Sex chromosome abnormalities.
      1. Klinefelter syndrome
      2. 46,XX/46,XY
      3. 45,X/46,XY
   4. Mosaic duplication of 17q23.1-q24.3 including *SOX9* gene.
   5. 46,XX ovotesticular DSD.
   6. 21-hydroxylase deficiency causing congenital adrenal hyperplasia.
   7. Prenatal exposure of a pregnancy to androgens with an XX karyotype can cause virilization resulting in an infant with ambiguous genitalia that may look similar to those of a male with 46,XX testicular DSD and genital ambiguity.
      1. Externally administered androgens such as danazol
      2. Endogenously produced androgens by the mother

Diagnostic Investigations

1. Routine cytogenetic studies: 46,XX karyotype (Vilain 2009)
2. Endocrine studies
   1. Hypergonadotropic hypogonadism secondary to testicular failure (Pérez-Palacios et al. 1981).

1. Moderately elevated basal serum concentrations of LH and FSH
2. Usually decreased serum testosterone concentration
3. HCG stimulation test
    1. Low to subnormal testosterone response
    2. Little or no elevation of serum testosterone concentration

2. Preservation of hypothalamic-pituitary axis: GnRH stimulation test shows a normal LH and FSH response (not warranted for diagnosis).

3. Testicular biopsies (De la Chapelle 1981)
    1. Decrease in size and number of seminiferous tubules
    2. Peritubular fibrosis
    3. Absence of germ cells
    4. Hyperplasia of Leydig cells
4. Molecular genetic testing
    1. Fluorescence in situ hybridization (FISH) using commercially available FISH probe to locate *SRY* gene on the short arm of one X chromosome
    2. PCR amplification
        1. Used when FISH fails to detect the *SRY* region
        2. More likely to detect a small amount of Y chromosome translocated onto the X chromosome
        3. To detect the Y chromosome material in an individual who is an XX-*SRY*-positive/XX-*SRY*-negative mosaic
    3. Comparative genomic hybridization (CGH) method to identify the small unbalanced chromosome rearrangement implicated in an XX male (Rigola et al. 2002)

Genetic Counseling

1. Recurrence risk (Vilain 2009)
    1. Patient's sib
        1. Sibs of a proband with *SRY* translocation to an X chromosome
            1. Proband with a de novo translocation (in most cases): has a low risk to XX sibs (<1%). No instances of germline mosaicism have been reported, but it remains a possibility.
            2. Proband with familial translocation (father carrying two copies of SRY, one translocated to his X chromosome and one on his Y chromosome): XX sibs will have 46,XX testicular DSD or XX true hermaphroditism; XY sibs will not be affected.
        2. Sibs of a proband with *SRY* translocation to an autosome
            1. Proband with a de novo translocation: risk to sibs not increased.
            2. Proband with familial translocation (father carrying an *SRY* gene translocated onto an autosome): XX sibs of a proband each have a 50% chance of inheriting the translocated *SRY* gene and will have 46,XX testicular DSD or XX true hermaphroditism.
        3. Sibs of a proband with SRY-negative 46, XX testicular DSD: 25% risk
    2. Patient's offspring
        1. Men with SRY-positive 46,XX testicular DSD: infertile
        2. Men with SRY-negative 46,XX testicular DSD: infertile
2. Prenatal diagnosis
    1. Available for pregnancies at risk for SRY-positive 46,XX DSD from fetal cells obtained by amniocentesis or CVS using FISH.
    2. Fetal karyotype discordant with the phenotypic sex observed by ultrasound examination in most cases.
    3. An *SRY*-positive result decreases but does not exclude the likelihood of ambiguous genitalia.
    4. Prenatal diagnosis has been described in several cases (Margarit et al. 1998; Trujillo-Tiebas et al. 2006).
    5. Cell-free fetal DNA (cfDNA) testing: detection of Y chromosome in a 46,XX male with SRY translocation (Benedict et al. 2015).
        1. cffDNA screening in the first trimester indicated presence of Y

chromosome material, consistent with a male fetus.
2. On the ultrasound, a phenotypic male fetus was observed.
3. Results of the amniocentesis, however, revealed 46,XX.
4. A follow-up ultrasound was performed to reassess fetal anatomy following the results of the amniocentesis, which again confirmed nonambiguous male genitalia in the fetus.
5. A fluorescence in situ hybridization probe for the *SRY* gene and X chromosome centromeric control probe DXZ1 were used to analyze metaphase cells. Results indicated that the *SRY* region was present on the distal short arm of one of the X chromosomes [46,XX.ish der(X)t(X;Y)(p22.3;p11.3)(SRY+,DXZ1+)].
6. In summary, a fetus with a 46,XX karyotype with an SRY translocation and normal male genitalia on ultrasound was accurately detected as being male on cffDNA testing. The finding presents an exciting and novel capability of cfDNA technology, but at the same time highlights the limitations of using this new technology as a complementary tool in prenatal care.

3. Management
   1. Testosterone replacement therapy: low-dose testosterone therapy: initiate after age 14 years
      1. Testosterone enanthate injection: preferred
      2. Transdermal patches and gels
   2. Reduction mammoplasty for gynecomastia for:
      1. Failure of regression of gynecomastia after testosterone replacement therapy
      2. Presence of gynecomastia causing psychological distress
   3. Male-to-female transsexual operation for an XX male patient who is eager to live as a female (Kurita et al. 2006)
      1. Resection of the penis
      2. Repositioning of the urethra
      3. Vaginal construction
   4. Orchiopexy
   5. Calcium, exercise, vitamin D, biphosphonates, or calcitonin for osteopenia
   6. Psychological support

Fig. 1 (**a**–**c**) A 19-year-old phenotypically male patient has been evaluated for slightly high-pitched voice, gynecomastia (**a**), and cryptorchidism on the right, a small atrophic testis on the left (**b**, **c**), and penile hypospadias (**c**). Chromosome study revealed 46,XX

XXX Syndrome

Contents

Females with a 47,XXX karyotype were first described by Jacobs (1979). The incidence of 47,XXX among female newborns is approximately 1 in 1,000 live births (Pennington et al. 1980). It is the most common female chromosomal abnormality. As some individuals are only mildly affected or asymptomatic, it is estimated that only 10% of individuals with trisomy X are actually diagnosed (Tartaglia et al. 2010).

Synonyms and Related Disorders

47,XXX; Trisomy X syndrome

Genetics/Basic Defects

1. Etiology: An extra chromosome X is responsible for 47,XXX.
2. Mechanism of the origin for the 47,XXX condition (Hassold et al. 1990; May et al. 1990).
    1. Almost all 47,XXX result from maternal nondisjunction.
    2. Typically at meiosis I.
    3. The risk of trisomy X increases with advanced maternal age and errors at maternal meiosis I, but not maternal meiosis II.
    4. Postzygotic nondisjunction occurs in approximately 20% of cases.
3. The phenotype in trisomy X is hypothesized to result from overexpression of genes that escape X-inactivation, but genotype-phenotype relationships remain to be defined (Tartaglia et al. 2010).
4. 47,XXX male.
    1. Complex mosaicism in a 53-year-old Japanese male with 46,XX/47,XXX/48,XXXX may be due to the age-related increase in mitotic nondisjunction which is prone to occur in rapidly dividing lymphocytes and to the presence of two randomly inactivated X chromosomes which may behave asynchronously during mitosis.
    2. Clinical features (bilateral hypoplastic scrotal testes, normally formed small penis, relatively poor pubic hair development (tanner stage 3), gynecomastia, age-appropriated male height, and mental retardation) of this male would primarily be explained by the genetic information on the SRY (+) der (X) chromosome and his advanced age (Ogata et al. 2001).

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_251

Clinical Features

1. No specific phenotype exists in 47,XXX females (Chudley et al. 1990).
2. A higher incidence of minor anomalies.
    1. Epicanthal folds
    2. Upslanting palpebral fissures
    3. Ear abnormalities
    4. Clinodactyly
3. Growth and development (Linden et al. 1988; Otter et al. 2010).
    1. Birth weights tend to be slightly lower than the general population.
    2. The physical phenotype shows earlier growth and longer legs.
    3. Taller in older children.
    4. Relative microcephaly.
    5. Hypotonia.
    6. At risk for mild speech/language and motor delays and learning disabilities.
    7. The behavioral phenotype often shows auditory processing disorders, disorders in language development, and problems in forming stable interpersonal relationships.
    8. Psychiatric disorders seem to be more common in triple X syndrome.
    9. Quality of life seems to increase after leaving school.
    10. Intelligence.
        1. Normal range
        2. Lower intelligence quotients (10–15 points) in comparison to unaffected sibs
4. Brain structure and behavioral characteristics in 47,XXX syndrome (Lenroot et al. 2014).
    1. The most common psychiatric disorders present in trisomy X girls included:
        1. Anxiety disorders (40%)
        2. Attention-deficit disorder (17%)
        3. Depressive disorders (11%)
    2. The most strongly affected brain regions are consistent with phenotypic characteristics such as:
        1. Language delay
        2. Poor executive function
        3. Heightened anxiety
5. Expanding the phenotypes of triple X syndrome (Wigby et al. 2016)
    1. Common physical features include hypertelorism, epicanthal folds, clinodactyly, and hypotonia.
    2. Medical problems included dental disorders (44.4%), seizure disorders (16.2%), and genitourinary malformations (12.2%).
6. Gonadal structures and function.
    1. Heterosexual
    2. Normal secondary sexual characteristics
    3. Normal menstruation
    4. Fertility usually normal
    5. Late menarche
    6. Occasional amenorrhea
    7. Premature ovarian failure
    8. Sterility with streak gonads
7. Congenital anomalies reported in a very small number of patients (Barr et al. 1969; Bağci et al. 2010).
    1. Urogenital tract abnormalities
    2. Brain abnormalities including encephalocele and seizures
    3. Skeletal abnormalities
    4. Congenital heart defects
    5. Intestinal atresia
    6. Craniofacial abnormalities
8. Adaptation status: variable (Harmon et al. 1998).
    1. At risk for intellectual and psychological problems
    2. 47,XXX women during adolescence and young adulthood
        1. Less well adapted
        2. With more stress
        3. With work, leisure, and relationship problems
        4. With a lower IQ
        5. With more psychopathology when contrasted with the comparison group
    3. Most 47,XXX women
        1. Self-sufficient
        2. Functioning reasonably well
9. 45,X/47,XXX mosaicism and short stature (Everest et al. 2015).
    1. Phenotypes tend to be milder.

2. The height may be quite short in a way that is out of proportion to the relative mildness of the remainder of the phenotype.

10. De novo Xp terminal deletion in a triple X female with recurrent spontaneous abortions (Malla et al. 2014).
    1. Xp terminal deletion of the extra copy of X chromosome was the only possible cause of recurrent spontaneous abortions.
    2. As the female had two normal copies of X chromosome, no syndromic facies or dysmorphism was observed.
11. Differential diagnosis prior to definitive karyotype results includes (Tartaglia et al. 2010):
    1. Fragile X (please see the chapter on "Fragile X Syndrome")
    2. Tetrasomy X
    3. Pentasomy X (please see the chapter on "XXXXX Syndrome")
    4. Turner syndrome mosaicism (please see the chapter on "Turner Syndrome")

Diagnostic Investigations

1. Chromosome analysis.
2. Triple X syndrome and puberty: focus on the hypothalamus-hypophysis-gonad axis (Stagi et al. 2016).
    1. Triple X syndrome patients showed premature activation of the GnRH pulse generator, even without puberty signs.
    2. Both basal and peak LH and FSH are more elevated than in control subjects, whereas E2 and inhibin levels and ovarian volume are reduced, which may contribute to a reduced gonadal function.
3. Triple X syndrome should also be suspected in patients with short stature, elevated estradiol and low level of IGF-1, even with normal result of arginine provocation test (Li et al. 2012).
4. Psychological and psychiatric evaluation when needed.

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: not increased
    2. Patient's offspring (Dewhurst 1978)
        1. An increased risk of a cytogenetically abnormal child but the extent of the risk cannot yet be determined.
        2. Majority of offspring normal.
2. Prenatal diagnosis
    1. By fetal karyotyping from amniocytes or CVS, followed by detailed ultrasonographic examinations of multiple organ systems to screen for possible associated congenital malformations (Bağci et al. 2010).
    2. The frequency of the diagnosis of the 47, XXX karyotype by genetic amniocentesis is estimated to be 1/1000, the same incidence as in the newborn population (Linden et al. 1988).
    3. A rare case of massive congenital bilateral chylothorax in a hydropic fetus with true mosaicism 46,XX/47,XXX (Cremonini et al. 2014).
3. Management
    1. Infancy/toddler: assess milestones
    2. Childhood
        1. Assess school performance
        2. Provide intervention if needed
            1. Speech/language therapy
            2. Physical/occupational therapy
            3. Educational remediation
    3. Adolescence: usually no intervention needed
    4. Adulthood: annual physical examination

XXXXX Syndrome

Contents

49,XXXXX (pentasomy X), a rare sex chromosome aneuploidy, was first described by Kesaree and Woolley (1963). The birth prevalence of pentasomy X is estimated to be one in 85,000 females (Martini et al. 1993).

Synonyms and Related Disorders

49,XXXXX syndrome; Penta X; Pentasomy X syndrome

Genetics/Basic Defects

1. Etiology: Three extra X chromosomes are responsible for the pentasomy X syndrome (Brody et al. 1967; Archidiacono et al. 1979).
2. Parental origin of the extra chromosomes: All four X chromosomes in 49, X polysomies were maternal in origin (Leal et al. 1994; Cho et al. 2004).
3. Occurrence of a 49,XXXXX complement: secondary to sequential nondisjunctions in meiosis I and meiosis II in the mother (Kassai et al. 1991; Martini et al. 1993).
    1. Involves the survival of both X chromosomes in a single oocyte through both meiotic divisions (Deng et al. 1991)
        1. Once between homologous X chromosomes at the first meiosis
        2. Twice between sister chromatids in both X chromosomes in the secondary oocytes at the second meiosis
    2. Followed by the fertilization by a sperm contributing the fifth chromosome X
4. Formation of four Barr bodies.
    1. Lyon hypothesis
        1. Inactivation of all X chromosomes but one
        2. Accounts for the viability of the X chromosome aneuploidies
    2. Inactivation of four X chromosomes resulting in four Barr bodies
5. Four presumably inactive X chromosomes were late replicating but not in a strictly synchronous fashion (Monheit et al. 1980).
6. X chromosome inactivation in a 49,XXXXX pentasomy (Moraes et al. 2009): 12% of X chromosomes with the M1 haplotype, 43.5% of X chromosomes with the M2 haplotype, and 100% of the paternal X chromosome (with the P haplotype) were likely to be functionally active in the proband's cells, a finding

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_252

indicating that disruption of X inactivation was associated with her severe phenotype.

7. Effect of supernumerary X chromosomes: a direct relationship between the number of supernumerary X chromosomes and phenotypic abnormalities and mental retardation, with each additional chromosome increasing the severity (Linden et al. 1995).
    1. Affects somatic development most significantly
        1. Skeletal abnormalities
        2. Cardiovascular abnormalities
    2. Delays sexual development
    3. Affects cognitive development
        1. Severe mental retardation
        2. Language delay (both expressive and receptive language)
        3. Behavioral problems

Clinical Features

1. Growth and development
    1. Prenatal growth retardation
    2. Small birth weight
    3. Low postnatal weight
    4. Failure to thrive
    5. Hypotonia
    6. Short stature
    7. Delayed psychomotor retardation
    8. Mental retardation
2. Craniofacial features
    1. Microcephaly
    2. Flattened occiput
    3. Epicanthus
    4. Upslanting palpebral fissures
    5. Ocular hypertelorism
    6. Uncoordinated eye movements
    7. Flat broad nose
    8. Cleft palate
    9. Low-set ears
    10. Malformed teeth
3. Skeletal abnormalities
    1. Short neck
    2. Lax joints
    3. Multiple dislocations (Dryer et al. 1979)
        1. Shoulders
        2. Elbows
        3. Hips
    4. Radioulnar synostosis
    5. Spinal abnormalities
    6. Thenar atrophy (Demirhan et al. 2015)
    7. Clinodactyly of the fifth fingers
    8. Lower leg abnormalities
        1. Genu valgum
        2. Talipes
        3. Metatarsus varus
    9. Delayed bone age
4. Congenital heart defects
    1. Ventricular septal defect
    2. Patent ductus arteriosus
5. Abnormal lobulation of the lungs
6. Renal hypodysplasia (Toussi et al. 1980)
7. Sexual development
    1. Delayed puberty
    2. Incomplete secondary sexual development
    3. Small uterus
    4. Hypoplastic/absent ovaries
        1. Composed mainly of stroma and atrophic follicles
        2. Absence of ova
        3. Unilateral absence of an ovary (Toussi et al. 1980)
    5. Reduced fertility
8. Normal external genitalia
9. Dermatoglyphics
    1. Finger-dermal-ridge hypoplasia and a low total ridge count, consistent with the inverse proportion between the number of X chromosomes and the total ridge count (exceptions exist)
    2. Transverse palmar creases
10. 48,XXXX/49,XXXXX mosaicism (Cirillo Silengo et al. 1979)
    1. The physical findings are similar to those of the cases with a penta-X chromosome and are also similar to the signs of the more common 49,XXXXY syndrome of males (Sergovich et al. 1971).
    2. In both instances, the dysmorphic features are less impressive than the mental retardation and the skeletal malformations.
    3. A newborn girl with a life-threatening laryngomalacia and extreme hypotonia (Schoubben et al. 2011).

11. 47,XXX/48,XXXX/49,XXXXX mosaicism (Wood et al. 2011)
    1. Primary amenorrhea
    2. Physical features
        1. Epicanthal folds
        2. Long philtrum
        3. High-arched palate
        4. Facial asymmetry
        5. Short webbed neck
        6. Low posterior hairline
        7. Mild scoliosis
        8. Cubitus valgus
        9. Clinodactyly
        10. Osteoporosis
        11. Premature ovarian failure
        12. Mental retardation

Diagnostic Investigations

1. Chromosome analysis
    1. 49,XXXXX karyotype in peripheral blood lymphocytes and skin fibroblasts (Funderburk et al. 1981).
    2. Fluorescence in situ hybridization (FISH), using DNA probe for α-satellite sequence in chromosome X (DXZ1), reveals five signals representing the presence of XXXXX.
2. Radiography
    1. Dislocations of the shoulder (with hypoplasia of the glenoid process) (Dryer et al. 1979), elbows, and/or hips
    2. Radioulnar synostosis
    3. Clinodactyly

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: not increased
    2. Patient's offspring: not reported due to severe mental retardation
2. Prenatal diagnosis
    1. Ultrasonography.
        1. Cystic hygroma (Sepulveda et al. 1999)
        2. Transient hydrops fetalis (Aytac et al. 2012)
        3. Bilateral radioulnar synostosis
        4. Dandy-Walker malformation (Myles et al. 1995)
        5. X pentasomy in an intracytoplasmic sperm injection pregnancy detected by nuchal translucency testing (Cheng et al. 2008)
    2. Amniocentesis and CVS.
        1. Chromosome analysis
        2. FISH (Myles et al. 1995) using DNA probe (DXZ1) applied to uncultured amniocytes
    3. The need to include a noninvasive prenatal test (NIPT), which expands clinical coverage to include the X and Y chromosomes in routine prenatal diagnosis as molecular noninvasive tool, and three-dimensional ultrasound to detect any helpful indicative echographic prognostic signs should be evaluated (Samango-Sprouse et al. 2013; Pirollo et al. 2015).
3. Management
    1. Physical/occupational therapy
    2. Speech therapy

XXXXY Syndrome

Contents

49,XXXXY syndrome was first described by Fraccaro and Lindsten in 1960. The incidence is estimated to be approximately 1 in 85,000 newborn males (Pallister 1982).

Synonyms and Related Disorders

48,XXXY/49,XXXXY mosaicism; 49,XXXXY syndrome

Genetics/Basic Defects

1. Etiology: three extra X chromosomes are responsible for the 49,XXXXY syndrome.
2. Mechanism.
    1. All four X chromosomes are of maternal in origin.
    2. Resulting from successive nondisjunctions in maternal meiosis I and II, fertilized by a normal Y sperm (Deng et al. 1991; Villamar et al. 1989; Chen et al. 2000; Etemadi et al. 2015).
    3. Inactivation of three out of four X chromosomes results in three Barr bodies (Lyon hypothesis).
3. Effect of supernumerary X chromosomes: a direct relationship between the number of supernumerary X chromosomes and phenotypic abnormalities and mental retardation, with each additional chromosome increasing the severity.
    1. Somatic development most significantly affected
        1. Skeletal abnormalities
        2. Cardiovascular abnormalities
    2. Gonadal development in males: particularly susceptible to extra genetic material
        1. Addition of a single X chromosome to a 46,XY karyotype resulting in seminiferous tubal dysgenesis rendering infertile such males with Klinefelter syndrome.
        2. Additional extra X chromosomes in polysomy X males such as 48,XXXY and 49,XXXXY can result in not only infertility but also hypoplastic and malformed genitalia.
    3. Affects cognitive development
        1. Severe mental retardation
        2. Language delay (both expressive and receptive language)
        3. Behavioral problems

H. Chen (ed.), *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_253

Clinical Features

1. A distinct phenotype (Peet et al. 1998).
2. "Classic triad" (Peet et al. 1998).
    1. Mental retardation
    2. Radioulnar synostosis
    3. Hypogonadism
3. Growth and development.
    1. Growth retardation
    2. Severe speech impairment
    3. Varying degree of mental retardation
4. Craniofacial features.
    1. Microcephaly
    2. A full, round face
    3. Ocular hypertelorism
    4. Upslanted palpebral fissures
    5. Epicanthus
    6. Broad nasal bridge
    7. Micrognathia
    8. Prognathism
    9. High-arched or cleft palate
    10. Irregular teeth implantation
    11. Malformed ears
5. Ocular abnormalities: The dural ectasia may have facilitated access of cerebrospinal fluid through anomalous optic nerves, resulting in neurosensory (macular) detachment (Hajrasouliha et al. 2016).
6. Webbed and short neck.
7. Congenital heart defects (Karsh 1975).
    1. Patent ductus arteriosus
    2. Atrial septal defect
    3. Pulmonic stenosis
    4. Tetralogy of Fallot
8. Musculoskeletal abnormalities (Sprouse et al. 2013).
    1. An increased incidence of;
        1. Hypotonia
        2. Clubfoot
        3. Avascular necrosis of the femoral head
        4. Radioulnar synostosis (Kidszun et al. 2012)
        5. Pes planus
    2. Short stature
    3. Proximal tibiofibular synostosis (Nishimura et al. 2008)
    4. Vertebral anomalies
    5. Clinodactyly of the fifth fingers
    6. Coxa valga
    7. Genu valgum
9. Genital abnormalities.
    1. Hypoplastic male genitalia.
    2. Micropenis.
    3. Hypospadias.
    4. Small testes.
    5. Hypogonadism.
    6. Infertility.
    7. Cryptorchidism: very common and absence of Leydig's cells may differentiate the XXXXY chromosome anomaly from polysomic variants of Klinefelter's syndrome (Zaleski et al. 1966).
    8. Leydig cell tumor (Maqdasy et al. 2015).
10. Renal abnormalities: hydronephrosis caused by intravesical ureterocele (Kojima et al. 1999).
11. A high incidence of both atopy and antibody deficiency in boys with 49,XXXXY (Keller et al. 2013).
12. Dermatoglyphics.
    1. Decrease in total finger ridge count
    2. Transverse palmar creases
13. Psychological/behavioral features (Curfs et al. 1990; Lomelino and Reiss 1991).
    1. Language development: severely retarded with a remarkable discrepancy between language expression and comprehension
    2. Emotional disturbances with low frustration level
    3. Adaptive function higher than cognitive function
    4. Timid and shy
    5. Strong reaction to minor changes
14. The phenotypic presentation of the boys with 49,XXXXY (Gropman et al. 2010).
    1. Shares some characteristics with 47, XXY
    2. Other unique and distinctive features
        1. Previously unappreciated intact nonverbal skills are evident in conjunction with moderate to severe developmental dyspraxia.
        2. Variability in clinical and cognitive functioning may reflect skewed X inactivation, mosaicism, or other factors that warrant further investigation.

15. 48,XXXY/49,XXXXY mosaicism (Milani et al. 2015).
    1. Report of the first case of a craniocervical junction (CVJ) malformation associated with 48,XXXY/49,XXXXY syndrome.
    2. The mosaicism can lead to a milder neuroradiological phenotype.
    3. Mosaicism could also have an effect on two different embryogenetic components of CVJ (the central pillar and the surrounding rings) leading to different and coexisting dysmorphic aspects (platybasia and hyperhypoplastic occipital condyles).
    4. Skeletal abnormalities are not exclusively related to the limbs, but also to the axial structures (such as the cervical spine) and could give neurological signs.
    5. Considering all the reported abnormalities and the possible relevant clinical impact of some findings, the neuroradiological assessment (MRI and CT) seems potentially useful in the diagnostic approach to patients with 48,XXXY and 49,XXXXY syndrome.

Diagnostic Investigations

1. Chromosome analysis showing 49,XXXXY.
2. Radiography (Houston 1967).
    1. Elbows
        1. Proximal radioulnar dysostosis
        2. Radioulnar dislocation without synostosis
        3. Elongated upper radius
        4. Wide, club-shaped proximal ulna
    2. Wrists and hands
        1. Elongated distal ulna
        2. “Pseudoepiphyses”
        3. Clinodactyly of the fifth fingers
        4. Brachymesophalangia V
        5. Retarded bone age
        6. Corner defect in capitate
        7. Poor modeling of the fifth metacarpals
    3. Pelvis and hips
        1. Coxa valga
        2. Narrow iliac wings
    4. Knees
        1. Shallow intercondylar fossa
        2. Genu valgum
    5. Ankles and feet
        1. Gap between the first and second toes
        2. Short wide distal phalanx of the great toes
    6. Skull
        1. Sclerotic cranial sutures
        2. Thick cranial vault
        3. Ocular hypertelorism
        4. J-shaped sella
        5. Prognathism
    7. Spine
        1. Scoliosis
        2. Thoracic kyphosis
        3. Square vertebral bodies
    8. Sternum
        1. Thick
        2. Abnormal segmentation
3. Echocardiography for congenital heart defects.
4. EEG for seizure activity (Galasso et al. 2003).
5. MRI of the brain (Hoffman et al. 2008).
    1. Varying degree of brain volume loss.
    2. Abnormalities in white matter.
    3. Enlargement in the occipital horn of the left hemisphere (Galasso et al. 2003).
    4. Cerebral white matter changes in children are generally considered suggestive of an underlying metabolic defect. Our findings and the review of the literature also strongly suggest that chromosomal abnormalities, and in particular 49,XXXXY syndrome, should also be considered (Tabarki et al. 2012).
6. A pediatric magnetic resonance imaging study: Brain morphological abnormalities in 49, XXXXY syndrome (Blumenthal et al. 2013).
    1. Total brain size was significantly smaller and rates of brain abnormalities such as colpocephaly, plagiocephaly, periventricular cysts, and minor craniofacial abnormalities were significantly increased.
    2. White matter lesions were identified in 50% of subjects, supporting the inclusion of 49, XXXXY in the differential diagnosis of small multifocal white matter lesions.

3. Further evidence of abnormal development of white matter was provided by the smaller cross sectional area of the corpus callosum.
4. These results suggest that increased dosage of genes on the X chromosome has adverse effects on white matter development.

7. Frontal aslant tract abnormality on diffusion tensor imaging in an aphasic patient with 49, XXXXY syndrome: A poorly developed frontal aslant tract may underlie the expressive language deficits and provide some insight into the role of X chromosome in modulating the development of language tracts (Dhakar et al. 2016).
8. Histology of testicular biopsies: dysgenesis of testicular germ cells and tubules leading to fibrosis.
9. Fetal pathology (Rehder et al. 1986).
    1. Facial aspect featuring fetal Down's syndrome
    2. Hypogenitalism and hypogonadism with excessive reduction of germ cells
    3. Skeletal abnormalities that may be interpreted as early changes, preceding phalangeal shortening V and radioulnar synostosis.

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: not increased
    2. Patient's offspring: no offspring due to infertility of the condition
2. Prenatal diagnosis
    1. Ultrasonography (Chen et al. 2000; Schluth et al. 2002)
        1. Intrauterine growth retardation
        2. Hydrops fetalis
        3. Cystic hygroma (Sepulveda et al. 1999): the commonest finding (Peitsidis et al. 2009)
        4. Polyhydramnios
        5. Clubfoot
        6. Micropenis
    2. Amniocentesis and CVS
        1. Chromosome analysis
        2. FISH using DNA probe (DXZ1) applied to uncultured amniocytes
3. Management
    1. Early intervention and stimulation programs
        1. Speech/language therapy
        2. Physical/occupational therapy
    2. Testosterone replacement therapy
        1. Continuous treatment with testosterone can have a beneficial effect on neurobehavioral phenotype and psychosocial adaptation in patients with sex chromosome aneuploidy (Galasso et al. 2003).
        2. After 12 months of treatment, normalization of testosterone levels was observed. There was also an increase in pubic hair growth, testicular volume and penis size, weight loss, homeostatic model assessment index reduction, and the normalization of vitamin D values. Moreover, the patient showed greater interaction with the social environment and context (Mazzilli et al. 2016).

XY Female

Contents

XY females are completely sex-reversed individuals who are phenotypically females with 46,XY karyotype, failure to develop secondary sex characteristics, amenorrhea, and "streak gonads."

Synonyms and Related Disorders

46,XY female with complete gonadal dysgenesis; 46,XY female with partial gonadal dysgenesis; 46,XY disorder of sex development; 46,XY sex reversal syndrome; Androgen Insensitivity Syndrome; Embryonic testicular regression syndrome

Genetics/Basic Defects

1. Inheritance: genetic heterogeneity (Simpson et al. 1981; Sarafoglou and Ostrer 2000).
    1. Familial 46,XY complete gonadal dysgenesis.
        1. Genetically, complete 46,XY gonadal dysgenesis is a very heterogeneous disorder with both Y-linked and non-Y-linked forms.
        2. Eighty percent of patients with sporadic or familial 46,XY gonadal dysgenesis do not have a mutation or deletion of the SRY gene, indicating that other autosomal or X-linked genes have a role in sex determination.
        3. Whereas the majority of the cases occur sporadically, there are several reports of pedigrees with familial transmission of the disorder.
        4. One would not expect a Y-linked form of familial 46,XY dysgenesis, because affected 46,XY individuals are usually sterile females and, thus, unable to pass on the mutant gene. Yet, one third of the described SRY mutations are inherited. In all three pedigrees, the fathers carried the transmitted mutation without being mosaic for wild-type SRY and mutant SRY alleles.
        5. Less puzzling are the familial cases of 46,XY gonadal dysgenesis for which the father has mosaicism for an SRY mutation.
        6. Familial 46,XY sex reversal can be paternally inherited (Bhagavath et al. 2014).
            1. This is the first report of a familial 46, XY sex reversal in three siblings

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_254

caused by paternally inherited deletion in the region upstream of SOX9.
2. Our report further confirms that a 67 kb region upstream of SOX9 gene is critical for the development of testis from the indeterminate gonad.
3. Small deletions confined around this region can result in sex reversal without campomelic or acampomelic dysplasia and could predispose to gonadoblastoma.

7. Evidence for an X-specific gene involved in sex determination was first postulated after the identification of a family with three phenotypic 46,XY females in three different sibships related via the maternal line. Later, another pedigree demonstrated five phenotypic 46, XY females in three different sibships and with a similar mode of transmission of the disorder.
8. An autosomal recessive mode of inheritance has been postulated as another mechanism for 46,XY sex reversal because of the rate of affected individuals are ~28.6% in one pedigree or by virtue of the association of 46,XY gonadal dysgenesis with other syndromic features.

2. Familial partial gonadal dysgenesis and embryonic testicular regression syndrome.
   1. The term "partial gonadal dysgenesis" has been used to describe individuals who have partial testis determination, dysgenetic gonads, a mix of Mullerian and Wolffian structures, and ambiguous genitalia. Other terms used to describe this syndrome are "mixed gonadal dysgenesis" or "dysgenetic male pseudohermaphroditism." It is regarded as part of the clinical spectrum of 46,XY gonadal dysgenesis. The gonadal histology of patients with 46,XY partial gonadal dysgenesis consists of poorly formed seminiferous tubules in combination with ovarian-like stroma. Gonads can be dysgenetic in one side and normal testis on the other side or dysgenetic bilaterally.
   2. "Embryonic testicular regression syndrome" is a term used to describe the spectrum of genital anomalies resulting from regression of testis development from 8 to 14 weeks of gestation.
      1. If the regression of the fetal testes occurs between the 8 and 10 weeks of gestation, the individual may have complete absence of gonads, rudimentary Mullerian and/or Wolffian ductal structure, hypoplastic uterus, and female genitalia with/or without ambiguity. This condition has been referred as true agonadism or gonadal agenesis.
      2. Regression of the testes after the critical period of male differentiation (around 12–14 weeks) results in anorchia, where the individual has male internal and external genitalia.
      3. Partial testicular regression after the critical period would result to a male phenotype as in anorchia but with small rudimentary testes.
   3. The etiology of either of the above syndromes is very heterogeneous.
      1. Some of the subjects with 46,XY partial gonadal dysgenesis seem to have autosomal abnormalities.
      2. Sporadic cases of partial gonadal dysgenesis have been described with mutations of the WT1 genes and deletions of 9p and 10q chromosomes.
      3. Only two SRY mutations, a de novo deletion 3′ to the SRY-ORF and a missense mutation 5′ to SRY-ORF, have been found in two subjects with sporadic partial gonadal dysgenesis.
      4. The causes of the vast majority of cases of partial gonadal dysgenesis or embryonic testicular regression are unknown.
      5. Analysis of families with several affected individuals with either 46,

XY partial gonadal dysgenesis or embryonic testicular regression syndrome implicate X-linked, autosomal recessive, or autosomal dominant inheritance.

3. The mechanism of familial sex reversal seems to be due to SRY mutations, mutations in autosomal or X-linked genes, and gonadal mosaicism or chimerism for a Y chromosome-bearing cell line.
    1. As has been shown for SRY and for other sex-determining genes, such as *SOX9*, *WT1 SF-1* (Siklar et al. 2014), and *XH2*, there is phenotypic variability associated with different mutations.
    2. Novel mutation of the sex-determining region on the Y chromosome in a 46,XY female patient with monolateral dysgerminoma (Battaglia et al. 2013).
    3. A 46,XY female DSD patient with bilateral gonadoblastoma, a novel *SRY* missense mutation combined with a *WT1* KTS splice-site mutation (Hersmus et al. 2012).
    4. As a guide for identifying new genes, presence of syndromic features may be suggestive of mutation in a known gene.
    5. Preliminary linkage studies demonstrate that other genes, the identities of which have not yet been established, are likely to play a role.

2. Sexual differentiation (Michala and Creighton 2010): Genetic sex is determined at conception, when the ovum is fertilized by an X or Y chromosome containing spermatozoon (Ahmed and Hughes 2002).
    1. Testicular development
        1. The presence of the Y chromosome directs testicular development, through a switch gene present on its short arm, called the *SRY* gene (Sinclair et al. 1990).
        2. This, along with other testes-determining factors (TDFs), will guide the differentiation of the undifferentiated gonad into testicular tissue (Cameron and Sinclair 1997).
        3. Further genital differentiation is promoted by hormones that are produced by testicular tissue and that will lead to virilization.
        4. Sertoli cells produce anti-Müllerian hormone (AMH), which triggers the regression of Müllerian structures while Leydig cells secrete testosterone, which promotes the development of Wolffian structures into the vas deferens, seminal vesicles, and epididymis (Rey and Picard 1998).
        5. Testosterone is further converted into dihydrotestosterone (DHT), a potent androgen, in the periphery, leading to the virilization of the external genitalia (Zhu et al. 1998).
    2. Ovarian development
        1. Ovarian tissue develops in the absence of TDFs and in the face of the antitesticular action of the genes *DAX1* (Swain et al. 1996), *Rspo1*, and *WNT4.*
        2. Ovaries do not produce hormones during fetal life and the development of female genitalia is independent of hormone production.
        3. The fetus is recognizable as male or female at 12 weeks, and this can be identified ultrasonographically from the second trimester of pregnancy onwards (Odeh et al. 2009).

3. *SRY* gene and its mouse homologue, *Sry* (Goodfellow and Lovell-Badge 1993; Schäffler et al. 2000).
    1. The sex-determining region on the Y chromosome
        1. Mapped to the short arm of the Y chromosome.
        2. Encodes for a testis-determining factor (TDF).
        3. Candidate gene narrowed down to a 35-kb interval on the Y chromosome adjacent to the pseudoautosomal boundary which contains a Y chromosomal-specific sequence, named SRY (sex-determining region Y gene).
        4. Demonstration that female mice transgenic for Sry developed into

sex-reversed males (Koopman et al. 1991) despite an XX karyotype provided the confirmation of SRY being the TDF that directs the undifferentiated gonad into a testis (Berta et al. 1990).

2. Deletions or mutations occurring in the *SRY*
    1. Result in failure of testis development
    2. Sex differentiation along the female pathway

4. Mechanism of male to female sex reversal (abnormalities of XY sex determination).
    1. SRVX, a sex reversing locus in Xp21.2-> p22.11 (Arn et al. 1994).
        1. SRVX is inferred a part of a pathway of sex-determining genes that includes SRY and SRA1, the latter recently assigned to chromosome 17q.
        2. If mutation of SRA1 or SRVX can reverse the sex of the XY fetus, this would explain why mutation within SRY is found only sporadically in women with XY gonadal dysgenesis.
    2. The region Xp21.3-p22.11 is critical for sex determination (Harley and Goodfellow 1994).
        1. If the presence of two active copies of the Xp distal region correlates with impaired testis formation, a gene normally subject to X inactivation is involved in sex determination.
        2. The association of sex determination, X-inactivation, and gene dosage is seductive.
    3. Mutations in the SRY gene resulting in XY females with gonadal dysgenesis (vs. translocation of this gene sequence to X chromosome giving rise to XX males) (Hawkins 1995).
        1. Several genes are involved in the process of sex differentiation, including *SRY*, *RSPO1*, *SOX9*, *NR5A1*, *WT1*, *NR0B1*, and *WNT4* (Helszer et al. 2013b).
        2. Increasing variety of unique mutations within SRY gene reported in patients with gonadal dysgenesis/XY reversal (Jäger et al. 1990). These patients are, in general, normal 46,XY females with complete gonadal dysgenesis (Hawkins et al. 1992b).
    3. *SRY* gene mutations noted in 15–20% of cases with complete gonadal dysgenesis (Graves et al. 1999).
        1. Most mutations are located in the High Mobility Group (HMG) box.
        2. XY sex reversal associated with a deletion 5′ to the SRY "HMG box" in the testis-determining region (McElreavey et al. 1992).
        3. Loss of sequences 3′ to the testis-determining gene, SRY, including the Y pseudoautosomal boundary associated with partial testicular determination (McElreavey et al. 1996).
        4. De novo mutations affect only one individual in a family in the majority of cases.
        5. Phenotypic variability is associated with different mutations.
    4. About one third of the *SRY* mutations reported are inherited.
        1. No apparent explanation available to explain why an inherited SRY mutation which results in sex reversal in the offspring is associated with a normal male phenotype in the father and sometime in brothers and uncles.
        2. Paternal mosaicism for the mutant *SRY* provides an explanation for the other familial cases of XY gonadal dysgenesis.
    5. Eighty percent of patients with sporadic or familial 46,XY gonadal dysgenesis lack a mutation or deletion of the SRY gene, indicating that other autosomal or X-linked genes have a role in sex determination.
    6. Familial mutation in the testis-determining gene SRY shared by an XY female and her normal father: The allelic variant of SRY transmitted in this family and shared by both a phenotypic female (proband) and a phenotypic male (proband's father) emphasizes the

importance of modifier genes in the sex determination pathway (Jordan et al. 2002).

4. *Sox9*.
    1. Another gene (*SOX9*) involved in sex determination identified by positional cloning of a chromosomal breakpoint has been identified in the XY female with campomelic dysplasia (Kwok et al. 1995), a condition in which three quarters of XY patients show genital and gonadal malformations.
    2. Belongs to a family of SRY-box-related (SOX) genes which encode proteins with at least 60% amino acid homology to the HMG box of the SRY protein.
5. *Atrx*.
    1. The gene responsible for the ATR-X syndrome causes α-thalassemia, severe mental retardation, and multiple congenital anomalies which may include 46,XY gonadal dysgenesis and undermasculinization.
    2. The C-terminal region of the protein has been lost in most cases where there has been gonadal dysgenesis associated with ATR-X syndrome.
6. Deletions of variable portions of the short arm of chromosome 9 (*DMRT-1* identified as a candidate gene) result in partial or complete gonadal dysgenesis in XY females (Calvari et al. 2000).
7. XY sex reversal and gonadal dysgenesis due to 9p24 monosomy (McDonald et al. 1997).
    1. The observation that all seven patients with sex reversal share a deletion of the distal short arm of chromosome 9 is consistent with the hypothesis that the region 9p24 contains a gene or genes necessary for male sex determination.
    2. This present case narrows the chromosome interval containing a critical sex determination gene to the relatively small region 9p24.
8. Sex-reversing Xp duplication (Xp21) (Bardoni et al. 1994).
5. Classification of 46,XY disorders of sex development (DSD) (Hughes 2008; Mendonca et al. 2009).
    1. 46,XY DSD due to gonadal (testicular) development
        1. Gonadal agenesis
        2. Complete or partial gonadal dysgenesis (e.g., *SRY*, *SOX9*, *SF1*, WT1, DHH)
        3. Ovotesticular DSD
        4. Embryonic testis regression syndrome
        5. Gonadal dysgenesis associated with syndromic phenotype
    2. Disorders of androgen syndromes
        1. Disorders of androgen synthesis
            1. LH receptor mutations
            2. Smith-Lemli-Opitz syndrome
            3. Steroidogenic acute regulatory protein mutations
            4. Cholesterol side-chain cleavage (*CYP11A1*)
            5. 3β-hydoxysteroid dehydrogenase 2 (*HSD3B2*)
            6. 17α-hydroxylase/17,20-lyase (*CYP17*)
            7. P450 oxidoreductase (*POR*)
            8. 17β-hydoxysteroid dehydrogenase (*HSD17B3*)
            9. 5α-reductase 2 (*SRD5A2*)
        2. Disorders of androgen action
            1. Androgen insensitivity syndrome
            2. Drugs and environmental modulators
    3. Others
        1. Syndromic associations of male genital development (e.g., cloacal anomalies, Robinow, Aarskog, hand-foot-genital, popliteal pterygium)
        2. Persistent Müllerian duct syndrome
        3. Vanishing testis syndrome
        4. Congenital hypogonadotropic hypogonadism
        5. Cryptorchidism (*INSL3*, *GREAT*)
        6. Environmental influences
        7. Nonclassical forms
            1. Isolated hypospadias (*CXorf6*)
            2. 46,XY gender identity disorders (male to female transsexualism)

Clinical Features

1. Clinical presentation of an XY female (Berkovitz 1992; Michala and Creighton 2010)
    1. Primary amenorrhea with delayed puberty (Swyer syndrome)
        1. 46,XY females (individuals with 46, XY complete gonadal dysgenesis) (Mannaerts et al. 2015).
        2. Diagnosis usually not made until puberty when the patient presents with delayed pubertal development.
        3. Unambiguous female phenotype with completely female external genitalia.
        4. Gonadal dysgenesis (streak gonads).
        5. Well-developed Müllerian structures: Lack of secretion of anti-Müllerian hormone (AMH) results in the normal development of the uterus, fallopian tubes, and vagina.
        6. Absence of testicular development (Vilain et al. 1993).
        7. Absence of Wolffian structures.
        8. Absence of other somatic abnormalities.
        9. Absence of secondary sexual characteristics.
        10. Amenorrhea.
        11. High risk of developing gonadal tumors (Du et al. 2014).
            1. Gonadoblastoma
            2. Dysgerminoma (Morerio et al. 2002)
    2. Androgen insensitivity syndrome (AIS) (Ramprasad et al. 2012) (please see the chapter on "► Androgen Insensitivity Syndrome")
        1. AIS was first described in details by Morris (1953), who provided the descriptive terms – testicular feminization syndrome – for this disorder, which is inherited as X-linked recessive disorder.
        2. The underlying pathology is the inability of the end organs to respond to androgens, either due to lack of androgen cytosol receptor or defect in the receptor.
        3. Genotypically, they are male (XY) but phenotypically and psychologically female (Ahlquist 1994), usually present with primary amenorrhea or infertility with well-developed breast, but absent axillary and pubic hair, normal external genitalia, and short and blind vagina. The upper two thirds of vagina, uterus, and tubes are absent. Gonads (testes) are normally developed but abnormally positioned, either placed in the labia, or inguinal canal or intra-abdominal.
        4. The hormone profile in these individual is typical – high LH, normal to slightly elevated testosterone levels, high estradiol (for men), and normal to elevated FSH.
        5. There is correlation between specific androgen receptor mutation and phenotype corresponding to androgen insensitivity syndrome (Helszer et al. 2013a).
    3. Ambiguous genitalia at birth or virilization at puberty: Possible causes:
        1. Mixed gonadal dysgenesis
        2. 5α-reductase deficiency
        3. 17β-hydroxysteroid dehydrogenase deficiency
        4. Partial androgen insensitivity syndrome
        5. Leydig cell hypoplasia
    4. Inguinal hernia: Possible causes:
        1. Complete androgen insensitivity syndrome (Nair Rema and Bhavana 2012)
        2. 5α-reductase deficiency
        3. 17β-hydroxysteroid dehydrogenase deficiency
        4. Partial androgen insensitivity syndrome
    5. Discordant phenotype to karyotype following prenatal diagnostic testing: can be due to all conditions
    6. Testing following the diagnosis of an affected sibling: can be due to all conditions
2. Differential diagnosis
    1. Individuals with 46,XY partial gonadal dysgenesis (also called 46,XY mixed gonadal dysgenesis or dysgenetic male pseudohermaphroditism) (Barr et al. 1967)

1. Majority of patients present in the newborn period for evaluation of ambiguous genitalia.
2. Partial testicular determination. The extent of masculinization of the external genitalia depends on the extent of testicular differentiation.
3. Dysgenetic gonads.
4. Presence of Müllerian and Wolffian structures.
5. Regarded as the clinical spectrum of 46, XY gonadal dysgenesis.

2. Individuals with 46,XY embryonic testicular regression syndrome (also called true agonadism or gonadal agenesis)
   1. A term used to describe the spectrum of genital anomalies resulting from regression of testis development from 8 to 14 weeks of gestation
   2. Regression of the fetal testes between 8 and 10 weeks of gestation
      1. Complete absence of gonads
      2. Rudimentary Müllerian and/or Wolffian ductal structures
      3. Hypoplastic uterus
      4. Female genitalia with/or without ambiguity
   3. Regression of the testes after the critical period of male differentiation (around 12–14 weeks)
      1. Anorchia
      2. Partial testicular regression resulting in a male phenotype as in anorchia but with small rudimentary testes

Diagnostic Investigations

1. Karyotype analysis
   1. 46,XY in phenotypic females
   2. To exclude 45,X/46,XY and other forms of mosaicism, served to exclude the more common forms of gonadal dysgenesis
2. Molecular analysis for *SRY* gene
   1. Nucleotide substitutions (missense/nonsense) (Hawkins et al. 1992a; Veitia et al. 1997)
   2. Deletions
   3. Insertions
3. Ultrasonography/laparotomy
   1. Complete gonadal dysgenesis
      1. Streak gonads
      2. Presence of Müllerian ducts
      3. Absence of Wolffian ducts
   2. Partial gonadal dysgenesis
      1. Dysgenetic gonads
      2. Presence of Müllerian and Wolffian structures
4. Gonadal histology
   1. Streak gonads
      1. Absence of primordial follicles
      2. Wavy ovarian stroma intermixed with fibrous tissue
   2. Gonadal tumors observed in about 30% of cases
      1. H-Y antigen in 46,XY pure testicular dysgenesis (Nazareth et al. 1979)
      2. Gonadoblastomas: usually benign
      3. Dysgerminoma
      4. Embryonal carcinoma: more life-threatening
5. Biochemical findings
   1. Elevated levels of FSH and LH
   2. Low levels of estradiol
   3. No elevation of androgen levels

Genetic Counseling

1. Recurrence risk
   1. Patient's sib: recurrence risk depending on whether the inheritance is X-linked recessive, male-limited autosomal dominant, or autosomal recessive.
   2. Patient's offspring: The patients are nonreproductive.
   3. To rule out the disease in siblings because of the presence of familial aggregation.
   4. Recurrent 46,XY sex reversal secondary to paternal somatic and germ-line mosaicism for a sex-determining region on Y (SRY) missense mutation (Hines et al. 1997).

2. Prenatal diagnosis: demonstration of the sexual discrepancy between fetal karyotype (XY) and ultrasonographic fetal phenotype (Bretelle et al. 2002)
    1. To exclude sample error and placental mosaicism
    2. Detailed fetal ultrasound examination to check for syndromic gender discrepancy such as:
        1. Campomelic dysplasia (skeletal malformation) (please see the chapter on "Campomelic Dysplasia")
        2. Denys-Drash syndrome
        3. Smith-Lemli-Opitz syndrome (please see the chapter on "Smith–Lemli–Opitz Syndrome")
            1. Microcephaly
            2. Abnormal cholesterol metabolism
        4. Alfi syndrome
            1. Craniostenosis
            2. Trigonocephaly
            3. Multiple congenital anomalies
    3. Prenatal diagnosis possible by SRY analysis for XY gonadal dysgenesis (SRY-negative XY female and SRY-positive XY female)
        1. FISH using SRY probe on metaphase chromosomes
        2. Sequencing of entire coding region
3. Management (Portuondo et al. 1986)
    1. Laparoscopy and gonadal biopsy might be useful in some patients to avoid confusion between XY gonadal dysgenesis and testicular feminization syndrome.
    2. Early diagnosis of XY gonadal dysgenesis is always desirable, and bilateral gonadectomy is indicated to avoid malignancy as soon as the diagnosis is made in patients with a Y chromosome and elevated FSH levels.
    3. Surgical removal of the gonads from patients with testicular feminization should be delayed until the completion of puberty because of the low risk of malignancy.
    4. Initiate cyclic hormonal therapy with estrogen and progesterone at puberty.
    5. Vaginoplasty should be performed in adolescence to prevent the risk of vaginal stenosis.
    6. Successful twin pregnancy after embryo donation to a patient with XY gonadal dysgenesis (Sauer et al. 1989).
    7. Psychological counseling.
        1. Raise as a female.
        2. Information regarding the condition and the karyotype should be provided to the patient and her family.
        3. Increase patient's knowledge about medical and surgical history and karyotype.
        4. Counseling for sexual function.
        5. Achievement of pregnancy in some patients following in vitro fertilization with a donor egg.

Fig. 1 (**a**–**c**) A patient (**a**, **b**) with 46,XY female with gonadal dysgenesis at 42 years of age. Patient has short stature (4′6″), primary amenorrhea, lack of secondary sex characteristics (absent axillary hair (**c**), poor breast development), but normal female external genitalia. Laparotomy revealed absent Wolffian structures and presence of uterus and streak gonads which were excised

XYY Syndrome

Contents

In 1961, Sandberg et al. (1961) described an XYY man. The incidence is estimated to be approximately 1 in 1,000 live male newborns and more frequent in infertile population (Martin 2008).

Genetics/Basic Defects

1. Caused by an additional Y chromosome in males (Rives et al. 2003).
2. Mechanisms of the extra Y chromosome in 47, XYY males (Robinson and Jacobs 1999).
    1. Paternal nondisjunction at meiosis II after a normal chiasmate meiosis I (84%)
    2. Postzygotic mitotic error or nondisjunction at meiosis II after a nullichiasmate meiosis I (16%)
3. Spermatogenesis.
    1. Normal spermatogenesis in majority of XYY males.
        1. The supernumerary Y chromosome probably lost at the early stage of spermatogenesis
        2. A large proportion of primary spermatocytes containing only one Y chromosome
    2. Altered spermatogenesis in a proportion of XYY males: Persistence of the supernumerary Y chromosome through meiotic prophase increases spermatocyte degeneration.
    3. The abnormal mode of pairing caused by the presence of the extra Y chromosome disturbs achievement of spermatogenesis resulting in severe oligoasthenoteratozoospermia. In contrast, the loss of the supernumerary Y before meiosis allows achievement and normal sperm production (Gabriel-Robez et al. 1996).
    4. Preferential Y-Y pairing and synapsis and abnormal meiotic recombination in a 47, XYY man with nonobstructive azoospermia (Wu et al. 2016).
4. A higher incidence of the XYY complement in the institutions for the retarded, the mentally ill, the criminally insane, and the aggressive offender: controversial and biased.
5. Expression of *NLGN4Y*, a gene that may be involved in synaptic function, is increased in boys with XYY, and the level of expression correlates with overall social responsiveness and autism symptoms (Ross et al. 2015). Thus, further investigation of NLGN4Y as a plausible ASD risk gene in XYY is warranted.

H. Chen, *Atlas of Genetic Diagnosis and Counseling*,
DOI 10.1007/978-1-4939-2401-1_255

Clinical Features

1. Earlier observation of the association between the additional Y chromosome and aggressive behavior: considered to be due to selection bias and has since been challenged (Court Brown 1968; Money et al. 1975; Hoffman 1977; Linden et al. 2002).
2. No consistent physical stigmata or medical disorders.
3. Growth and development.
    1. Increased growth velocity during earliest childhood
    2. Tall stature
    3. Oral features: larger tooth size (macrodontia), dental agenesis, taurodontism (Scheidt et al. 2015)
    4. At risk for mild speech/language and motor delays and learning disabilities
4. Intelligence.
    1. Normal range
    2. IQ: 10–15 points lower than siblings
5. Behavioral profile.
    1. Childhood temper tantrums
    2. No increased incidence of aggression
    3. Heterosexual
    4. Autism spectrum disorders (Margari et al. 2014)
6. Normal reproduction.
7. Normal adult adaptation.
8. Physical phenotypic features were similar in boys diagnosed prenatally vs. postnatally. Prenatal diagnosis was associated with higher cognitive function and less likelihood of an ASD diagnosis (Bardsley et al. 2013).
9. Many men with 47,XYY karyotype are fertile in spite of their sex chromosome abnormalities.
10. Nonmosaic 47,XYY syndrome presenting with male infertility (El-Dahtory and Elsheikha 2009; Abdel-Razic et al. 2012).
11. Combination of XYY and XXYY syndromes associated with cognitive, affective dysfunction and renal malrotation (Resim et al. 2015).
12. Diagnosis and mortality in 47,XYY persons: a registry study (Stochholm et al. 2010).
    1. A significant delay to diagnosis
    2. Reduced life expectancy
    3. An increased total and cause-specific mortality

Diagnostic Investigations

1. Chromosome analysis to detect 47,XYY.
2. Psychological and psychiatric evaluations when needed.
3. Studies of sperm karyotypes or FISH analysis of sperm: The majority of sperm are chromosomally normal in 47,XYY men (Martin et al. 2001).
4. EEG (Tomiero et al. 2011).
    1. Normal background activity and sleep organization
    2. Particular local spikes and sharp waves localized mostly over the vertex and/or central-temporal regions which increased during sleep
5. Genetic variations associated with XYY syndrome result in increased brain matter volumes, a finding putatively related to the increased frequency of ASDs in individuals with this condition. In addition, frontotemporal grey and white matter reductions in XYY syndrome provide a likely neuroanatomical correlate for observed language impairments (Bryant et al. 2012).
6. 47,XXY (Klinefelter syndrome) and 47,XYY (Abramsky and Chapple 1997).
    1. Most males born with these chromosome patterns will go through life without being karyotyped.
    2. The commonest indication for a 47,XYY male to be karyotyped will be developmental delay and/or behavior problems.
    3. The commonest indication for a Klinefelter male to be karyotyped will be hypogonadism and/or infertility.

Genetic Counseling

1. Recurrence risk
    1. Patient's sib: not increased.

2. Patient's offspring: Patient generally has chromosomally normal children, despite the high theoretical risk of aneuploidy.

2. Prenatal diagnosis
   1. Ultrasonography: a hypoplastic nasal bone and a large facial angle might be important sonographic phenotypes of male fetuses with 45,X/47,XYY mosaicism (Lin et al. 2015).
   2. Fetal karyotyping from amniocytes or CVS.
3. Management (Bender et al. 1984; Linden et al. 2002)
   1. The extra Y chromosome represents a risk factor for motor and language development, but the environment remains a primary force in shaping the child's development.
   2. The increased frequency of prenatal detection of 47,XYY by amniocentesis necessitates the importance of making accurate information about the developmental prognosis of these individuals.
   3. Infancy and toddler: assess developmental milestones.
   4. Childhood: assess school performance and provide intervention if needed.
   5. Adolescence: no intervention needed.
   6. Adulthood: annual physical examination.
   7. Positive effects of early androgen therapy on the behavioral phenotype of boys with 47,XXY (Samango-Sprouse et al. 2015).
