When a process is nonstationary, the covariance operator may have complicated time-varying properties and its estimation is arduous because we do not know *a priori* how to diagonalize them. In the following, we focus on the particular class of locally stationary processes, i.e., processes whose covariance operators are approximately convolutions.

Recently, researchers have turned their attention to locally stationary processes as a tool to model systems where the behavior varies as a function of time (e.g., Mallat *et al.* [22], Dahlhaus [23]). Though in the time–frequency plane the concept of local stationarity is easily grasped, it does not exist as a universally accepted definition, to date. In order to support an intuitive idea, suppose that for any t_0 the Wigner spectrum varies very little within an interval $[t_0 - \delta, t_0 + \delta]$. Such a parameter $\delta > 0$ is called the *stationarity length* and, in general, its value depends on t_0.

The question on how to adapt the analyzing window (or the kernel, in the case of a Cohen class transform) to the stationarity length of process is still open [11]. Several techniques have been formulated to select the best strategy and often they are based on optimization procedures. For instance, Kozek [24] proposed a minimum bias optimization criterion based on support properties of the AF. In principle, these methods are conceived to deal with stochastic processes or with a proper number of sample realizations and are not suitable to deal with a single signal.

Some new ideas may arise when working with random fluctuations produced by mechanical systems, which typically change slowly with time or space. These type of signals can be generally considered as locally stationary, since they appear in the time–frequency plane as a sum of modulated harmonics concentrated at the modal frequencies. In this case, the instantaneous spectrum of a single realization may reflect and be associated with some physical parameters, whose consistency is an indirect indicator of the transform suitability.

A simple case of locally stationary process is a uniformly modulated process that is constructed as $x(t) = c(t)x_0(t)$, where $c(t)$ is a slowly varying modulation function and $x_0(t)$ some stationary process. The time evolutions of such a process are depicted correctly by the following time-varying spectrum [25]:

$$P_F(t, f) = c^2(t)S_{F_0}(f) \tag{28}$$

When dealing with more general classes of oscillatory processes, a description of temporal evolutions of spectral components, frequency by frequency, produces

$$x(t) = \int_{-\infty}^{+\infty} A_x(t)X(f)\ \mathrm{e}^{\mathrm{j}2\pi ft}\,\mathrm{d}f \tag{29}$$

thus leading to Priestley's evolutionary spectrum [25, 26]

$$P_F(t, f) = |A_F(t, f)|^2 S_F(f) \tag{30}$$

The modulation function $A_F(t, f)$ is supposed to undergo a slow time evolution, which ensures an almost orthogonal decomposition. Priestley's spectrum retains satisfactory properties (e.g., nonnegativity) but misses uniqueness.

In locally stationary conditions, evolutionary representation supports an interesting time–frequency input–output relationship [27]

$$y(t) = \int_{-\infty}^{+\infty} H(t, f) A_x(t, f) X(f)\ \mathrm{e}^{j2\pi f t}\,\mathrm{d}f \quad (31)$$

where $H(t, f)$ is the transfer function of a time-varying filter. The important result is that the output is a modulated form of the filter (or system) transfer function. This is analogous to one-dimensional filtering in the frequency domain $Y(f) = H(f)X(f)$.

Finally, it is worthwhile noting that there is a theoretical link between evolutionary spectra and members of Cohen class of transforms [26] and, what is more, for slowly varying processes the Wigner spectrum approaches the evolutionary spectrum.

4 TIME–FREQUENCY ESTIMATION AND BEST WINDOWING

An attractive idea is to extend by analogy some properties of stationarity to local stationarity. For instance, an estimator for the time-varying spectrum of a locally stationary process, $T_F(t, f)$, may be obtained from a single realization $x(t)$ by selecting a proper analysis window/kernel and posing $B = \delta$ in equations (24) and (27):

$$V_F(t, f) = |T_x(t, f)| \quad (32)$$

where $T_x(t, f)$ is any quadratic TFR. It is likewise possible to track instantaneous relationships between signals. For instance, in multichannel measurements on structures, instantaneous estimators of amplitude ratio and phase difference between channels may be defined as follows [28, 29]:

$$AR_{ij}(t, f) = \sqrt{\frac{T_{x_i}(t, f)}{T_{x_j}(t, f)}};\ PH_{ij}(t, f) = phase\left\{T_{x_i, x_j}(t, f)\right\} \quad (33)$$

In linear time-invariant systems, equation (33) can support output-only modal identification procedures, as stability of such estimators discriminates modal components from exogenous frequency components over time. In fact, modal signals are characterized by amplitude and phase relationships that are not time-dependent and, therefore, their modal shape is constant over time. The identification of modal frequencies, therefore, reduces to a search for the particular values $f = f_k$ for which the estimators remain constant with respect to the time variable, in general, by resorting to multiple criteria techniques. In frequency intervals where a single modal component is predominant, the estimators tend to lead to a constant value in time. This property is progressively more closely satisfied up to an actual constant value at the modal frequencies.

By referring to the shear-type frame reported in Figure 4 [28], modal frequencies may be identified as minima in standard deviation plots (Figure 5) defined as

$$\int_0^T \left[PH_{ij}(t, f) - \overline{PH}\right]^2 \mathrm{d}t \quad (34)$$

where T is the length of the analyzed signal and $\overline{PH}$ indicates the mean value.

Once the modal frequencies have been identified, equations (33) supply the temporal evolution of the amplitude and phase ratios. Alternatively, modal shape estimators can be taken as

$$AR_{ij}(t, f)|_{f=f_k} = \left|\frac{T_{x_i z^{(k)}}(t, f)}{T_{x_j z^{(k)}}(t, f)}\right|_{f=f_k}$$

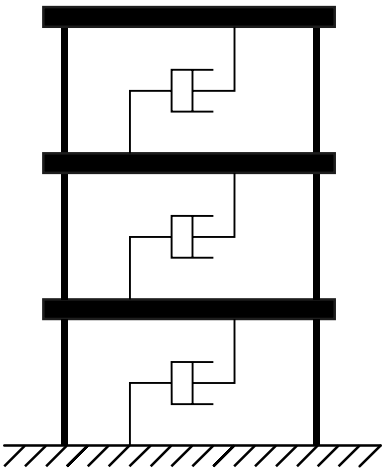

Figure 4. Model of a shear-type frame. [Reproduced with permission Ref. 28. © Elsevier, 2000.]

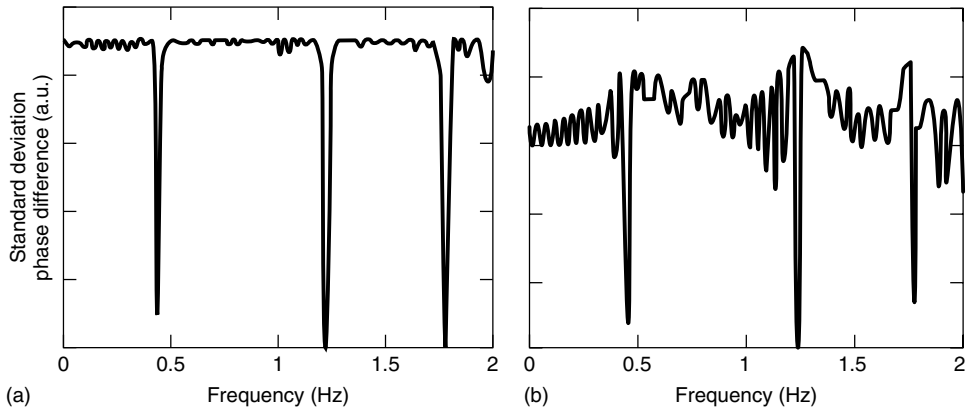

Figure 5. Standard deviation plots of the phase difference between the channel (equation 34) corresponding to the second story of the simulated structure and the reference channel (first story) as a function of frequency [28]. (a) Case with sine sweep excitation; (b) case of seismic excitation. [Reproduced with permission Ref. 28. © Elsevier, 2000.]

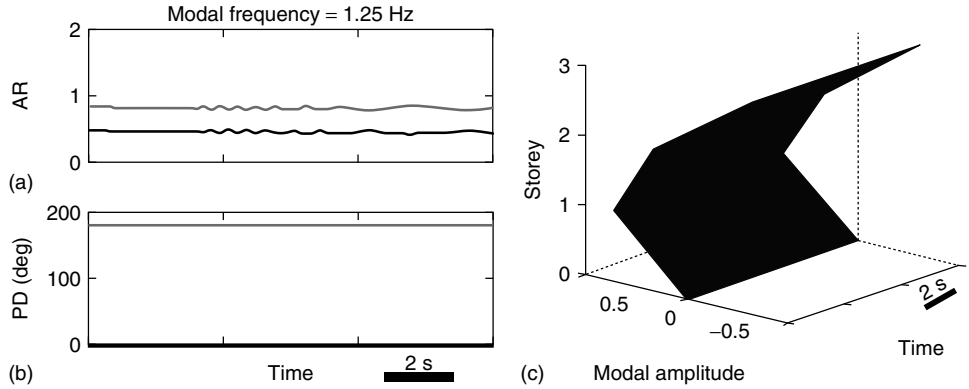

Figure 6. Evolution through time of modal amplitude ratios (a) and modal phase differences (b), as determined with respect to the reference channel (first story) for the second and third storys (sine weep excitation). Data refer to the second mode. The light and dark lines indicate the amplitude ratio and phase difference computed for the second and third story, respectively. Plot (c) shows the time evolution of the second modal shape estimate according to equation (35). [Reproduced with permission Ref. 28. © Elsevier, 2000.]

$$PH_{ij}(t, f)|_{f=f_k} = phase\left\{\frac{T_{x_i z^{(\omega)}}(t, f)}{T_{x_j z^{(\omega)}}(t, f)}\right\}\Bigg|_{f=f_k} \tag{35}$$

where $z^{(k)}(t)$ is a signal generated as a sinusoid with frequency equal to the kth modal frequency. The procedure is then repeated for all the signals at the ith and jth position. Figure 6 depicts the modal shape estimators (equation 35) for the second mode of the frame. These plots were all obtained using a CWD with $\sigma = 0.5$. This corresponds to applying the kernel $g(\nu, \tau) = \exp(-\nu^2\tau^2/\sigma)$ in equation (22) [30].

4.1 Best windowing

Typical questions about time–frequency estimation are how to select the optimal representation and window analysis and how many realizations of the process are needed to obtain an accurate estimate for $T_F(t, f)$.

While quadratic representations are very useful in analyzing strongly nonstationary signals, choosing the best kernel for a particular application appears to be a challenging task, as relationships with dynamic response characteristics are far from being trivial.

An alternative idea may consist of being satisfied with linear representations, which lend themselves to a clearer interpretation, and accepting the errors due to the fact that linear TFRs cause, in general, a distortion in the representation of the instantaneous power of stationary stochastic processes.

In principle, a suitable choice for the window of an STFT should be a function compactly supported in the interval $[t_0 - \delta, t_0 + \delta]$, and may vary according to a temporal law matched to the stationarity length of the process. Unfortunately, in most practical applications, the stationarity length δ is unknown.

Numerical studies have been performed in order to identify the influence of the analysis window on instantaneous spectral estimation via a STFT spectral function (equation 27). To this aim, an extensive set of dynamic response signals has been created numerically by exciting simple linear oscillators by means of white noise. The results reported here will focus on the following factors: type of window, window length (in samples), and decorrelation length of the process (related to damping) [8].

Equation (26) shows that the window may cause an error in the estimate and that the latter, when the number of realizations approaches infinity, decreases with increasing window temporal length. The effect of the window length (Figure 7) as well as the type of window has been examined.

Charts were then created to illustrate the accuracy of curve fitting as a function of the length of the windows in samples. The results, shown in Figure 8, indicate that, averaging over a finite number of realizations (in this case 30 demonstrated to be sufficient for a virtually exact fitting), windows of optimal length exist for the estimate of the "frequency response function" (FRF) and hence for the identification of modal parameters via linear TFRs. Such lengths are identified by minimum points in charts of the type shown in Figure 8.

In stationary conditions, the parameter that may affect the quality of time–frequency representation demonstrated to be the decorrelation length, and hence damping, while other factors such as the window shape were seen to be less relevant, at least for typical analysis windows [8]. Figure 9, which has been obtained from simulated examples, shows the evolution of the optimal length that the windows should have as a function of damping level (in this case for a Hanning-type window). This type of chart may be of practical use when representing the response of structures under ambient excitation. The choice of the optimal length for the STFT analyzing window, based on Figure 9, is conditioned by the availability of a raw estimate of damping.

5 MODEL-BASED TIME–FREQUENCY ESTIMATION

While linear representations, which permit a filter-bank interpretation, clearly allow reconstruction of the signal (e.g., equation 2), for energy decompositions the same property is less obvious. For Cohen class of transforms, the inversion is obtained from [31]

$$x(t')^* x(t) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \frac{T_x(u, f)}{g(\nu, t - t')} \times \mathrm{e}^{j2\pi f(t-t') + j2\pi\nu[u-(t-t')/2]} \, \mathrm{d}u \, \mathrm{d}f \, \mathrm{d}\nu \tag{36}$$

By taking a particular value of t', for instance, zero, we have

$$x(t) = \frac{1}{x(0)^*} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \frac{T_x(u, f)}{g(\nu, t - t')} \times \mathrm{e}^{j2\pi f t + j2\pi\nu(u - t/2)} \, \mathrm{d}u \, \mathrm{d}f \, \mathrm{d}\nu \tag{37}$$

One can easily notice that, according to equation (37), the signal can be recovered but only to within a constant phase factor.

5.1 Signal synthesis

In many practical applications, e.g., earthquake accelerogram generation, the main interest is in synthesizing signals with specific time–frequency features, rather than in signal reconstruction. Synthesis algorithms can also be used to perform time-varying filtering, multicomponent signal separation, and window and filter design. In this perspective, one might envisage filtering in the $t-f$ plane with [16, 18, 32]:

$$\tilde{T}(t, f) = \Gamma(t, f) T(t, f) \tag{38}$$

where $\Gamma(t, f)$ is referred to as *time–frequency mask*.

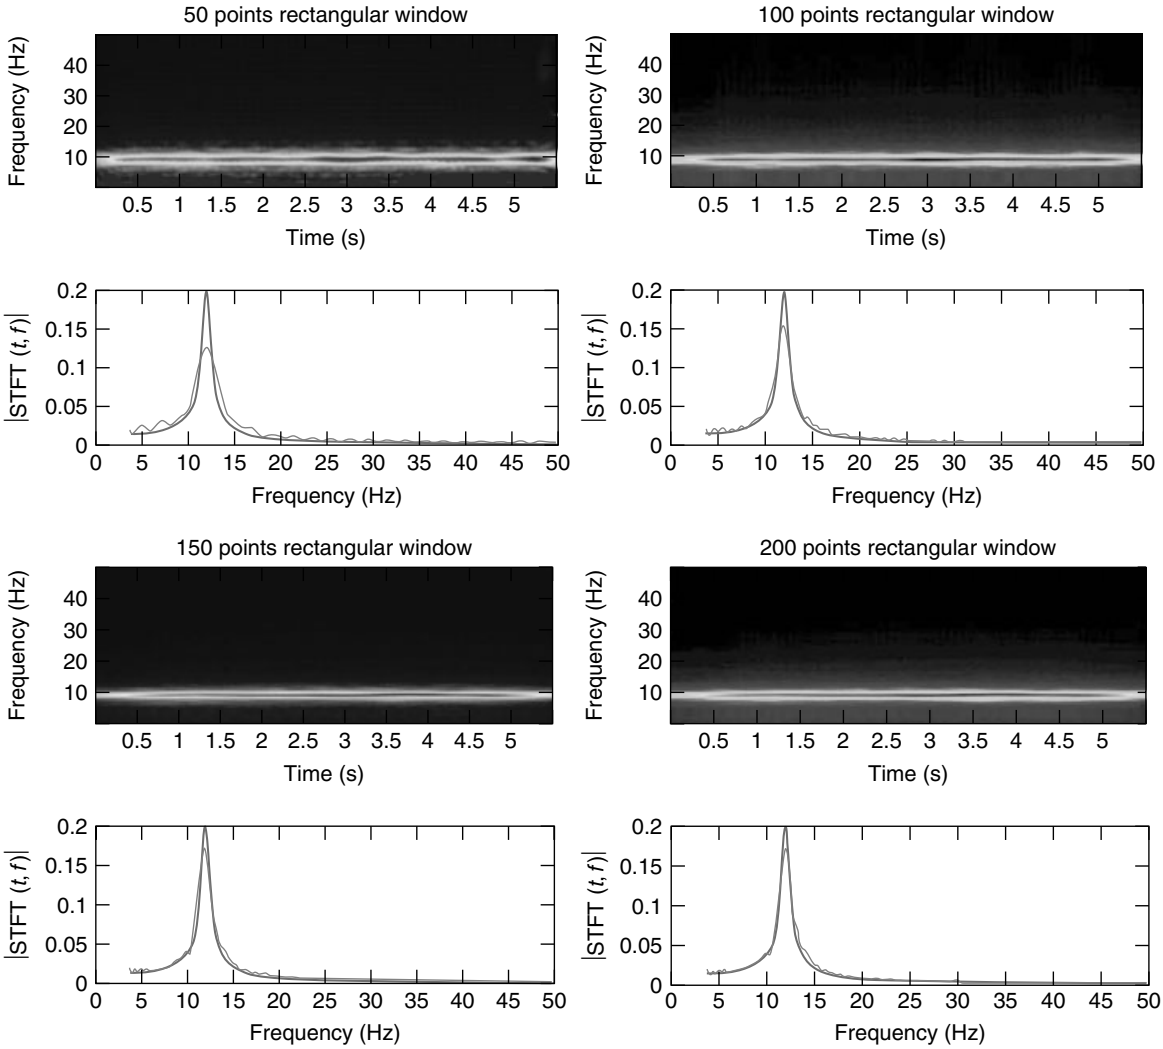

Figure 7. FRF estimation from STFT representations (average over 30 realizations) as a function of the window length (rectangular window). In sample instantaneous sections: original instantaneous spectrum (thin line) and estimated one (thick line). [Reproduced with permission from Ref. 8. © Elsevier, 2004.]

A major problem of the masking approach is that not all two-dimensional functions are valid TFRs. Instead, it is natural to resort to optimization techniques (e.g., least square methods), in order to find a time–frequency decomposition that best fits a time–frequency model.

Synthesis algorithms are usually formulated to find a signal $x(t)$ that minimizes the error ε_x between a given model, $\tilde{T}(t, f)$, and the transform of the signal $T_x(t, f)$ to be synthesized [1, 16, 32]

$$\varepsilon_x = \|T_x(t, f) - \tilde{T}(t, f)\| \longrightarrow \min_x \qquad (39)$$

Since for WD and other shift-invariant transforms the solution of the optimization process is not unique (e.g., $x(t)$ and $x(t)e^{j\alpha}$ have the same Wigner representation), the algorithm often contains a step to find the optimum phase factor.

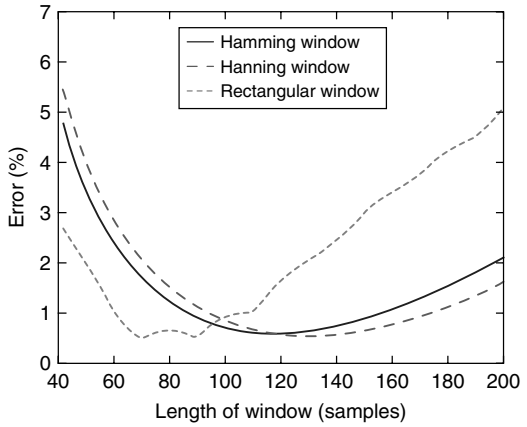

Figure 8. Error in the curve fitting performed on STFT as a function of window length (average over 30 realizations). [Reproduced with permission from Ref. 8. © Elsevier, 2004.]

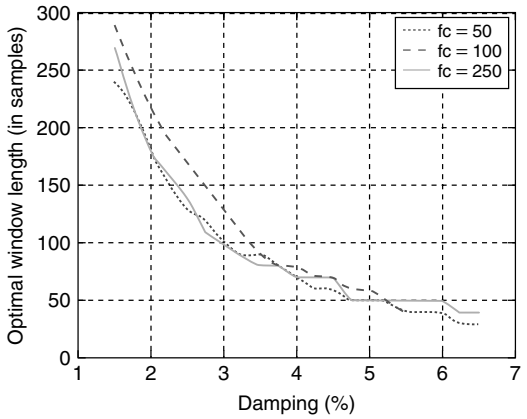

Figure 9. Optimal length in samples of the STFT (Hanning window) as a function of system's damping: curves obtained for three different values of sampling frequency. [Reproduced with permission from Ref. 8. © Elsevier, 2004.]

Under particular conditions, it proves advantageous to represent $x(t)$ in an orthonormal basis. Thus, by assuming a quadratic TFR, equation (39) becomes

$$x(t) = \sum_k \alpha_k q_k(t),$$

$$\varepsilon_x = \left\| \sum_k \sum_l \alpha_k \alpha_l^* T_{kl}(t, f) - \tilde{T}(t, f) \right\| \longrightarrow \min_{\alpha} \tag{40}$$

Such a formulation is certainly valid for linear dynamic systems, whose response is a sum of modal components.

5.2 Model identification

A formulation similar to that of equation (39) may be used also in solving the inverse problem, namely, finding a model that produces the same distribution as a measured signal.

When $x(t)$ is measured on a linear structure and we want to identify the dynamic model, a modal decomposition form is indicated for $\tilde{T}(t, f)$. As an example, a model identification can be obtained from the following unconstrained minimization:

$$\varepsilon_x = \left\| \sum_k \sum_l \alpha_k \alpha_l^* \tilde{T}_{kl}(t, f) - T_x(t, f) \right\| \longrightarrow \min_{\mathbf{p}} \tag{41}$$

where $\mathbf{p}$ is the global vector of parameters, which may contain α terms as well as other parameters of the model.

In some applications, as in structural control, the optimization can be performed on an online basis. For instance, a "block-by-block" synthesis/identification algorithm is performed on local, finite record intervals, whose length depends necessarily on the time–frequency analysis window or kernel. When parameters to be estimated retain a temporal significance (e.g., time-varying systems [33] or output-only identification), it may prove advantageous to perform an instantaneous minimization so as to obtain a punctual estimate of $\mathbf{p}$

$$\varepsilon_x(t) = \left| \int_{-\infty}^{+\infty} \left[\tilde{T}(t, f) - T_x(t, f) \right] \mathrm{d}f \right| \longrightarrow \min_{\mathbf{p}} \tag{42}$$

The most convenient minimization form and algorithm depends on the specific application. In the implementation of equations (39)–(42), the analytic signal is usually preferred to the real one, since it avoids cross-term interference between positive and negative frequencies.

5.2.1 Output-only identification of linear systems

Natural excitation of flexible structures (buildings, bridges, antennas, etc.) is characterized by slow

energy supply. Also based on the time-varying filter interpretation evoked in equation (31), in the time–frequency representation of locally stationary signals, we expect energy to concentrate around modal frequencies and be modulated according to the evolution of the TFR of the modulating waveform [2–8]. Consequently, the time–frequency model in equation (42) may be given the following (nonnegative) form [8]:

$$\tilde{T}(t, f) = \sum_k \sum_l \alpha_k(t)\alpha_l^*(t)\tilde{H}_k(f)\tilde{H}_l^*(f) \qquad (43)$$

where $\tilde{H}_k(f)$ is a scaled version the kth mode's FRF. In particular, for viscously damped dynamic systems the following expression holds:

$$\tilde{H}_k(f) = \left(f_k^2 + 2j\zeta_k f f_k - f^2\right)^{-1} \qquad (44)$$

If the assigned TFR has a stochastic nature (possibly obtained by ensemble averaging) and its modal components are uncorrelated, the cross terms vanish from equations (41) and (42). Correspondingly, also $T_F(t, f)$ tends to nonnegativity in accordance with the model in equation (43).

It is noteworthy that interference term suppression, as operated on deterministic signals by specific TFRs (property P9 in Table 2), appears to produce in equations (41) and (42) effects that are similar to those produced by a stochastic identification.

6 EXAMPLES

6.1 Identification of a system with polynomial nonlinearity in the stiffness

Let us consider a nonlinear system with a quadratic stiffness, as described by the following equation of motion:

$$m\ddot{y} + c\dot{y} + ky + k_2 y^2 = x(t) \qquad (45)$$

The input/output relationship is approximated by the following truncated Volterra series [34]:

$$\begin{aligned} Y(f) &= Y_1(f) + Y_2(f) \\ &= H_1(f)X(f) + \int_{-\infty}^{+\infty} H_2\left(f - f_1, f_1\right) \\ &\quad \times X\left(f - f_1\right) X\left(f_1\right) \mathrm{d}f_1 \end{aligned} \qquad (46)$$

In equation (46), $X(f)$ and $Y(f)$ are the Fourier transforms of the system's excitation and response, $Y_1(f)$ and $Y_2(f)$ are the Fourier transforms of the linear contribution and the quadratic contribution of the system response, and $H_1(f)$ and $H_2(f_1, f_2)$ are the system's linear and quadratic FRFs:

$$H_1(f) = \frac{1}{4\pi^2 m\left(-f^2 + i2\zeta f f_n + f_n^2\right)} \qquad (47)$$

$$\begin{aligned} H_2\left(f_1, f_2\right) &= -k_2 H_1\left(f_1\right) H_1\left(f_2\right) \\ &\quad \times H_1\left(f_1 + f_2\right) \end{aligned} \qquad (48)$$

where m is the mass, $\omega_n = 2\pi f_n = \sqrt{k/m}$ the natural frequency, $\zeta = c/(2\,\omega_n m)$ the damping coefficient, and k_2 the quadratic stiffness.

Assuming the signal $y(t)$ has been detected during N instants with a given sampling rate Δt, the response's STFT (model) has the following discrete expression [35]:

$$\begin{aligned} \sqrt{\tilde{T}[n, m]} &= \sum_{k=0}^{N-1} H_1[k]\cdot X[k]\cdot\Gamma^*[k - m]\cdot \mathrm{e}^{j\frac{2\pi kn}{N}} \\ &\quad + f_0\cdot\sum_{k=0}^{N-1}\sum_{r+s=k} H_2[r, s]\cdot X[r]\cdot X[s]\cdot\Gamma^*[k - m]\cdot\mathrm{e}^{j\frac{2\pi kn}{N}} \end{aligned} \qquad (49)$$

where $\Gamma(f)$ is a window function defined in the frequency domain, such that $\|\Gamma(f)\|^2 = 1$ and f_0 is an appropriate sampling frequency.

Let $\mathbf{p}$ be the vector of the unknown parameters of equation (45) and let us introduce the following objective function to be minimized at each time step n:

$$\begin{aligned} \varepsilon_y[n] &= \left|\sum_{m=0}^{N-1}\left[\tilde{T}[n, m] - SPEC_y^{(\gamma)}[n, m]\right]\right| \\ &\longrightarrow \min_{\mathbf{p}^T=\{f_n,\zeta,k_2\}} \end{aligned} \qquad (50)$$

The system parameters are as listed in Table 3. Assuming that the mass is known, $\mathbf{p}$ contains three parameters to be identified: f_n, ζ, and k_2. Minimization is performed on an online basis, by starting from

Table 3. Parameters of the nonlinear system to be identified [35]

m (kg)	10
ζ (%)	5
f_n (Hz)	3
k_2 (N m^{-2})	2 00 000

values obtained in the previous time step. A rough estimate of frequency and damping (e.g., obtained from a linear identification session) is needed for parameter initialization.

Let us consider the case of a measured Gaussian excitation with linearly modulated amplitude (Figure 10). Before proceeding with the identification, a parametric analysis on similar systems was performed in order to determine the best window length for the evaluation of the STFT and it was ascertained that a Hamming window with about 140 samples length was optimal. Figure 11 shows a STFT representation of system response over the first 40 s.

In order to assess the performance of the method in the presence of noisy measurements, numerical analyses are conducted by introducing white Gaussian noise into the signals. Even in the presence of noise in both input and output, instantaneous estimators give rise to a robust estimation of system parameters (Figures 12–14). The estimate of k_2 is seen to be the most adversely affected by the presence of noise.

6.2 Output-only linear identification of a real building

This paragraph examines an application of time–frequency instantaneous estimators to the identification of a real concrete building, namely, the Luciani Hospital of Caracas (Figure 15) [8].

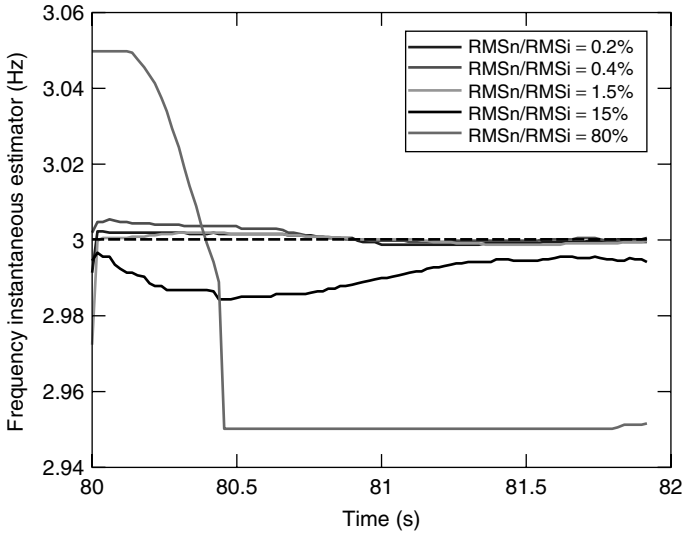

Figure 13. Nonlinear system identification: instantaneous estimator of frequency for different RMS noise levels in the response. [Reproduced with permission from aRef. 35. © Trans Tech Publications, 2005.]

On the basis of signals acquired in ambient excitation conditions, a preliminary structural identification was performed through a time-domain method, the ERA (eigensystem realization algorithm) [36] applied to random decrement functions [37] and a time–frequency instantaneous estimator (TFIE) method, based on equations (34) and (35) [28, 29]. For modal frequencies and shapes, the results yielded by the two methods were virtually the same.

Another type of dynamic test was performed by imposing an initial displacement of the structure with the aid of a hydraulic actuator positioned at roof level in an eccentric position. This type of excitation made it possible to work out, by means of current

Figure 15. View of Luciani Hospital in Caracas. [Reproduced with permission from Ref. 8. © Elsevier, 2004.]

techniques, a reliable assessment of damping that served as a useful term of comparison with the results yielded by the methods employed in ambient excitation conditions. It is known, in fact, that the latter situation is more critical, as it generally requires more complex identification tools leading to less accurate results.

With reference to Figure 9 and in view of the damping level expected, the analyzing window selected for a STFT analysis was a Hanning-type window with length = 100 samples. Figure 16 shows the SPEC of two signals measured along the two principal directions of the building.

The instantaneous identification was performed according to equations (42) and (43), with **p** vector containing all modal quantities α_k, f_k and ζ_k at a generic time $t = n\Delta t$

$$\varepsilon_x(n) = \left| \sum_{m=0}^{N-1} \left[\sum_k \sum_l \alpha_k \alpha_l^* H_k[m] H_l^*[m] - SPEC_x^{(\gamma)}[n,m] \right] \right| \longrightarrow \min_{\mathbf{p}} \qquad (51)$$

with $\mathbf{p} = \{\alpha_1 \quad \alpha_2 \quad .. \quad f_1 \quad f_2 \quad .. \quad \zeta_1 \quad \zeta_2 \quad ..\}$.

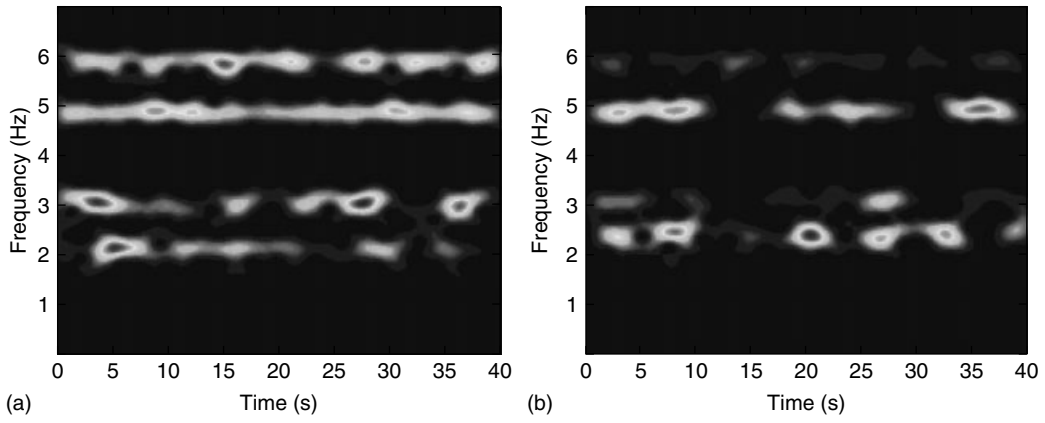

Figure 16. Structural identification of a large reinforced concrete building: spectrograms of two signals measured in (a) E–W and (b) N–S directions, respectively. [Reproduced with permission from Ref. 8. © Elsevier, 2004.]

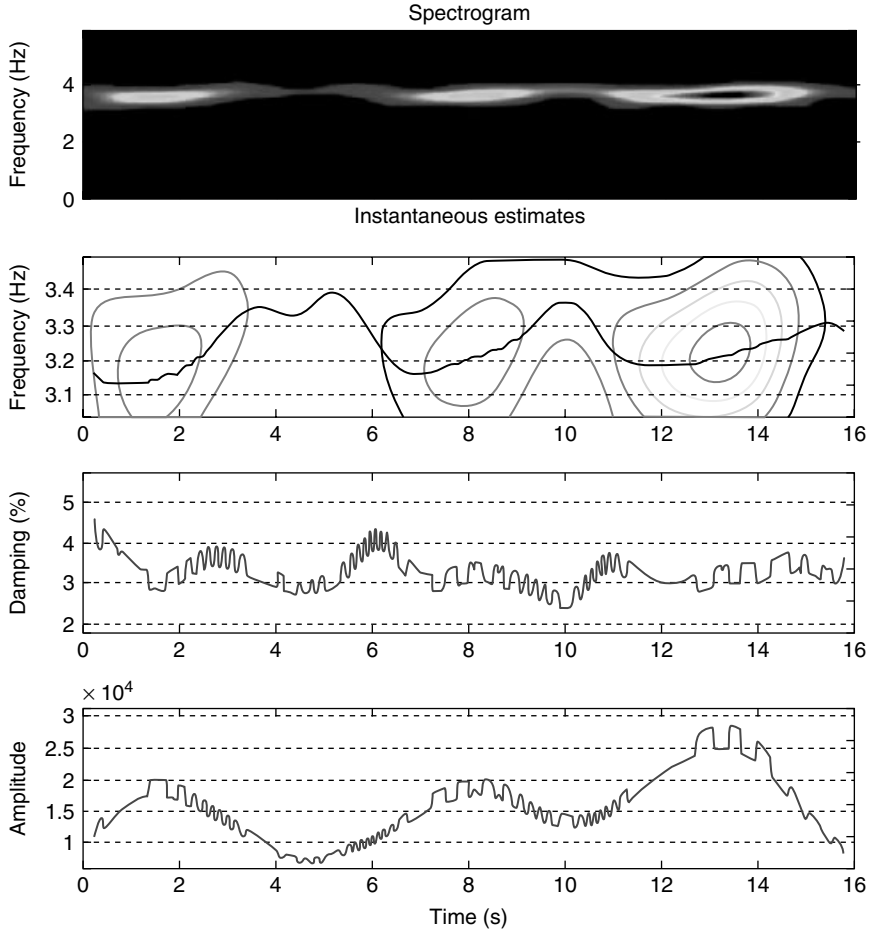

Figure 17. Instantaneous estimators calculated for the third vibration mode on a signal measured under ambient excitation. [Reproduced with permission from Ref. 8. © Elsevier, 2004.]

Figure 17, centered on the third identified mode, which involved a strong torsional component, shows the instantaneous estimators obtained from one of the signals relating to ambient excitation. In this figure, the typical SPEC representation is complemented by a contour plot showing the position of the "ridge". The identification of the ridge of a surface depends on its definition [12], in our case it is identified by the path of frequency, $f_3(n)$, as determined from equation (51). Other diagrams plot the punctual values of amplitude α_3 and equivalent viscous damping ζ_3, associated with the third vibration mode. We can see that the estimates turn out to be very good, especially in the time segments where the amplitude of the modal component to be identified is greater.

As a matter of fact, the estimation accuracy of equation (51) was seen to depend on the relative energetic importance of the modes. A possible solution can be the introduction of functions allowing for the relative energetic importance of the kth mode as a function of time. In this example, a final estimate for the kth modal damping resulted from a weighted average over different signals, based on the following weighting function:

$$w_k(t) = \frac{\alpha_k(t)|\tilde{H}_k(f_k)|}{\left[\sum_k \sum_l \alpha_k(t)\alpha_l^*(t)\tilde{H}_k(f_k)\tilde{H}_l^*(f_k)\right]} \quad (52)$$

Both in the instantaneous optimization (equation 51) and in weighted average (equation 52), parameters to be optimized were initialized with values of the preliminary identification. Results of damping identification, in ambient excitation and free decay conditions respectively, are summarized in Tables 4 and 5.

Table 4. Structural identification of Domingo Luciani Hospital building from ambient excitation signals: modal frequencies and damping identified with ERA and TFIE methods [8]

Mode	ERA		TFIE	
	Frequencies (Hz)	Damping (%)	Frequencies (Hz)	Damping (%)
1	2.37	2.51	2.35	2.76
2	2.70	2.18	2.68	2.97
3	3.25	3.79	3.30	3.21

Reproduced with permission from Ref. 8. © Elsevier, 2004.

Table 5. Results of identification procedure in free decay conditions [8]

Mode	Frequencies (Hz)	Damping (%)
1	2.35	2.71
2	2.68	2.78
3	3.21	3.15

Reproduced with permission from Ref. 8. © Elsevier, 2004.

We can conclude that in this application the accuracy afforded by the damping estimation method based on time–frequency instantaneous estimators was seen to be appreciably higher than the accuracy offered by current "output-only" identification methods. Conversely, the main drawback of time–frequency techniques is increased complexity and computational cost.

7 ACHIEVEMENTS AND PERSPECTIVES IN SHM APPLICATIONS

Difficulties encountered in SHM applications mostly arise due to the lack of accurate models to interpret the dynamic response of a system. More recently, however, diagnostic methods have been supported by data processing tools, which possess considerable potential in treating and correlating large amounts of data. Time–frequency analysis has, therefore, been used as an effective tool for practitioners, especially in dynamics, where it naturally provides information on the temporal behavior of vibrations.

Many successful applications of time–frequency tools to SHM have been reported. Most of them, including damage feature extraction, singularity detection, denoising, etc., circumvent modeling difficulties, since they do not require the system to be identified. The SHM strategy often reduces to the evaluation of symptoms reflecting the presence and the nature of the defect.

When a model or certain features of the system dynamics are known *a priori*, time–frequency algorithms admit their embedding into structural identification procedures. Accurate identification results, as those supplied by time–frequency methods, may constitute the basis for periodic and continuous SHM systems.

1 INTRODUCTION

Time–frequency analysis provides information on how the spectral content of a signal evolves in time, which is important when analyzing and interpreting nonstationary signals (*see also* **Time–frequency Analysis**; **Damage Detection Using the Hilbert–Huang Transform**). The wavelet transform (WT) has been gaining in popularity as the time–frequency transform of choice since its first influx into mainstream mathematics and engineering in the early 1990s. A WT is an integral transform. Hence, like Fourier transforms, it decomposes a signal into its constituent parts using a set of basis functions. However, unlike Fourier transforms, the choice of the bases is not limited to sinusoids. Sinusoids are not localized in time and thus, a Fourier transform is unable to extract time–frequency information from signals. To achieve this, a short-time Fourier transform (STFT) is used as a variation of the conventional Fourier transform. It uses a fixed window time function to obtain information on how the frequencies in the signal are changing in time. Wavelet basis functions, on the other hand, are localized both in time and frequency and can be dilated (compressed or stretched) and translated along a signal to extract both time and frequency information.

The advantage of the WT over the STFT is the ability to achieve flexible windowing time corresponding to the desired frequency information. Higher frequencies have better time resolution and lower frequencies have better frequency resolution (Figure 1). Variable resolution is often beneficial as it allows the low-frequency components, which usually give a signal its main characteristics or identity (such as modes), to be distinguished from one another in terms of frequency content, while providing an excellent temporal resolution of the high-frequency components, which add the nuances to the signal's behavior.

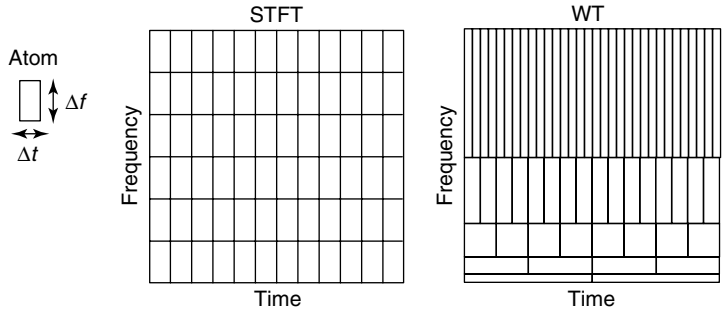

Figure 1. Time–frequency atoms of the STFT and WT.

The WT is readily applicable to the field of structural health monitoring (SHM) because of its time–frequency localization property. SHM involves the observation of a system over time/space using periodically sampled dynamic response measurements from an array of sensors. There are two different ways of assessing the health of the system: the knowledge-based approach and the signal-based approach.

The knowledge-based approach involves creating a model of the system under analysis. Damage is then identified by a change in this model. The basic premise is that damage will alter the stiffness, mass, or energy dissipation properties of the system, which, in turn, will alter the dynamic response of the system. Most of the research under this approach leads to system identification. The signal-based approach relies on the extraction of damage-sensitive features from the measured response signals. Analysis and processing of these features are then used to determine the current state of health of the system. This category includes research related to advanced signal processing, statistical analysis, and pattern recognition. The next section summarizes some of the papers that describe the use of wavelet analysis in SHM using both the knowledge-based and the signal-based approaches.

2 REVIEW OF LITERATURE

Recently, time–frequency and timescale analysis tools, particularly the wavelet analysis technique, have been proven to be powerful methods for assessment of structural health and fault monitoring. Early investigations by Staszewski and Tomlinson [1] and Wang and McFadden [2] in this area used wavelet analysis to detect local faults in machineries. A continuous wavelet transform (CWT) with a Morlet basis function was used for the studies. Several other researchers have carried out the investigations on the detection of damage based on changes in wavelet coefficients of time-domain responses. Melhem and Kim [3] carried out research to detect damage on full-scale concrete structures using a CWT and wavelet ridges. Kim and Melhem [4] have focused on reviewing the research carried out on damage detection in beams, mechanical gears, and rollers by the discrete wavelet transform (DWT) and CWT, using a Gabor, a low-oscillation Gaussian, and a Mexican hat basis function. Hou *et al.* [5] studied accumulated damage occurrences due to the San Fernando earthquake excitations, and identified the change in structural stiffness from spikes in the wavelet coefficients using multiresolution analysis (MRA). A DWT was used by Moyo and Brownjohn [6] to detect the anomalous behavior of a bridge structure from the abrupt changes in the wavelet coefficients. Damage assessment of bridges based on energy calculation was carried out by Sun and Chang [7] using a wavelet packet transform and neural networks. A CWT with a Littlewood–Paley (L–P) basis was used by Basu [8] to detect stiffness degradation in structures, and by Goggins *et al.* [9] to study the seismic response of concentrically braced frames, by correlating the wavelet coefficients at different scales. Gurley *et al.* [10] detected first and higher order correlation by using a CWT to construct filtered wavelet coherence and bicoherence maps to monitor offshore structures.

There has also been significant development, in the recent years, on wavelet-based damage detection associated with identifying singularities in the

response signal either in time or in space, or any of their derivatives. Singularity detection through wavelets has been discussed in detail by Mallat [11]. Some of the key research in this area has been carried out by Robertson *et al.* [12], who identified a rattle in a structure using wavelet-based Holder exponents. Damage detection in beams using spatial wavelet analysis is also a problem of singularity detection. Gentile and Messina [13] have investigated the selection criteria for a wavelet basis function in the presence of measurement noise and demonstrated the performance of Gaussian and Symlet wavelets. Okafor and Dutta [14], Chang and Chen [15], Loutridis *et al.* [16], Liew and Wang [17], and Wang and Deng [18] have used the spatial response data for beam structures to detect damage by applying different wavelets (both the CWT and DWT). Spanos *et al.* [19] have used a CWT modulus map for spatial wavelet analysis in damaged beams by suppressing boundary effects. Zhu and Law [20] have diagnosed damage in bridges without interrupting operations by using the CWT and relating the damage to the variation in the wavelet coefficient. Other researches related to spatial damage identification include those by Patsias and Staszewski [21] on the use of video camera–based dynamic shape identification, Lam *et al.* [22] on a Bayesian approach for detection of crack in the presence of an obstruction, Kim *et al.* [23] on the use of 2-D MRA-based Haar wavelets on plates, and Pakrashi *et al.* [24] on the wavelet–kurtosis-based damage detection and calibration, showing the effectiveness of the Coiflet 4 wavelet. Most of the research work discussed so far broadly covers the category of the signal-based approach to SHM, since it involves signal processing with pattern recognition/feature identification.

Wavelet analysis has also been used for identification of systems (knowledge-based approach) including nonstationary and nonlinear systems. Staszewski [25, 26], Kyprianou and Staszewski [27] have used the CWT to identify nonlinear systems and damping in dynamical systems. Other applications of the CWT include identification of modal parameters by Ruzzene *et al.* [28], extraction of impulse response functions by Robertson *et al.* [29], and identification of dynamic modal parameters of a bridge by Piombo *et al.* [30]. Identification of parameters of time-varying systems has been carried out by Ghanem and Romeo [31] using an orthogonal DWT. Basu *et al.* [32] have used WT packets to identify stiffness variation in structural systems.

A different approach was used by Tian *et al.* [33], who analyzed the flexural waves in beams using a CWT (Morlet wavelet), and detected damage by considering the lag of the waves. Other papers include the work by Staszewski *et al.* [34] on damage detection based on Lamb waves using both the CWT and orthogonal DWT, and a recent review on time–frequency and timescale analysis for SHM by Staszewski and Robertson [35].

3 TYPES OF WAVELET TRANSFORMS

The WT is a timescale transform, which provides information about how the spectral content of a signal is changing in time. WTs can be categorized into three main types: the continuous, discrete, and orthogonal transform.

3.1 Continuous wavelet transform

The CWT, $WT(u, s)$, is obtained by convolving the signal $f(t)$ with a set of basis functions created from the translations (u) and dilations (s) of a mother wavelet Ψ:

$$WT(u, s) = \frac{1}{\sqrt{s}} \int_{-\infty}^{\infty} f(t)\psi^* \left(\frac{t-u}{s} \right) \mathrm{d}t \quad (1)$$

These basis functions are defined as

$$\psi_{u,s}(t) = \frac{1}{\sqrt{s}} \psi \left(\frac{t-u}{s} \right) \quad (2)$$

where u defines the time shift and s defines the scale.

The analyzing functions or "basis functions" of a WT are called *wavelets*. The wavelets are scaled to obtain a range of frequencies. They are also translated to provide the time information in the transform. A typical wavelet basis with translated and dilated versions is shown in Figure 2. This wavelet is called a *Mexican hat*, and is obtained by the second derivative of the Gaussian function. The WT works as a filter, allowing only a certain time and frequency content through. Any given atom in the time–frequency map of the WT (Figure 1) represents the correlation

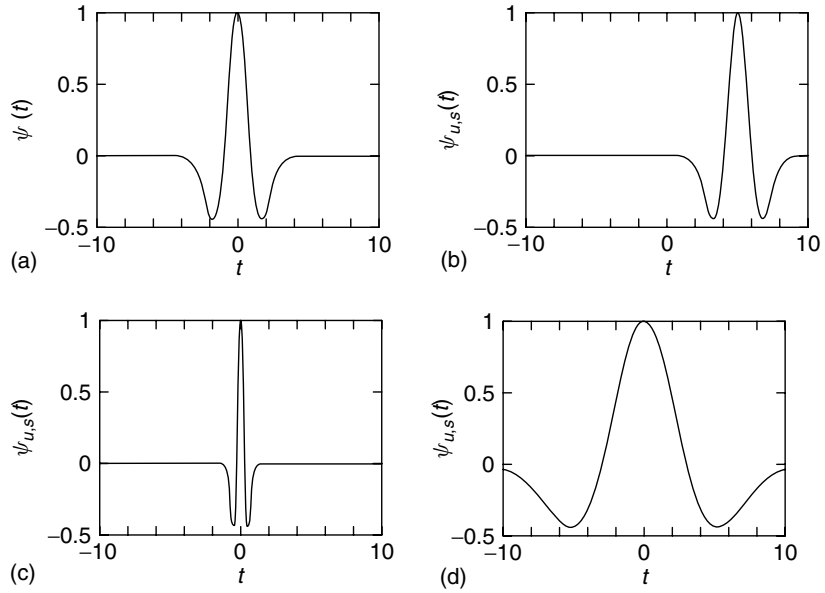

Figure 2. Dilations and translation of a mother wavelet. (a) A typical mother wavelet, (b) translated wavelet, (c) dilated wavelet (compressed) and (d) dilated wavelet (stretched).

between the wavelet basis function at that frequency dilation and the signal in that time segment. The frequency content of the WT is represented in terms of scales, which are inversely related to frequencies. The squared amplitude of the CWT is therefore called the *scalogram*. The relationship between scales and frequencies is easily found and a time–frequency map can be formed from the scalogram.

Since the WT works in a manner similar to the STFT, by convolving the signal with a function that varies both in time and frequency, it suffers from similar limitations in the resolution of the time–frequency map. Both transforms are confined by the uncertainty principle, which limits the area of a time–frequency atom in the overall time–frequency map (Figure 1). The biggest difference between the two transforms is that the atoms in the WT map are not a constant shape. In the lower frequencies, the atoms are fatter, providing a better resolution in frequency and worse resolution in time, whereas in the upper frequencies the atoms are taller, providing better time resolution and worse frequency resolution. This variable resolution can be advantageous in the analysis of structural time response data.

The CWT gets its name from the fact that the mother wavelet is continuously shifted across the length of the data being analyzed. This smooth shifting means that the time/frequency atoms shown in Figure 1 overlap one another, providing redundant information. A representation of this overlapping in the scales/frequencies is shown in Figure 3.

The variable windowing feature of wavelet analysis leads to an important property exhibiting constant-Q factor (defined as the ratio of the center frequency to bandwidth) analysis. For STFT, at an analyzing frequency ω_0, changing the window width increases or decreases the number of cycles of ω_0 inside the window. In the case of WTs, with the change in window width, mean dilation or compression of the wavelet function changes. Hence, the carrier frequency becomes ω_0/a, for a window width changing from T to aT. However, the number of cycles inside the window remains constant.

The frequency resolution is proportional to the window width both in the case of STFT and WT. However, for WT, a center frequency shift necessarily accompanies a window width change (timescaling). Thus, Q factor is invariant with respect to wavelet dilation and these dilated wavelets may be considered

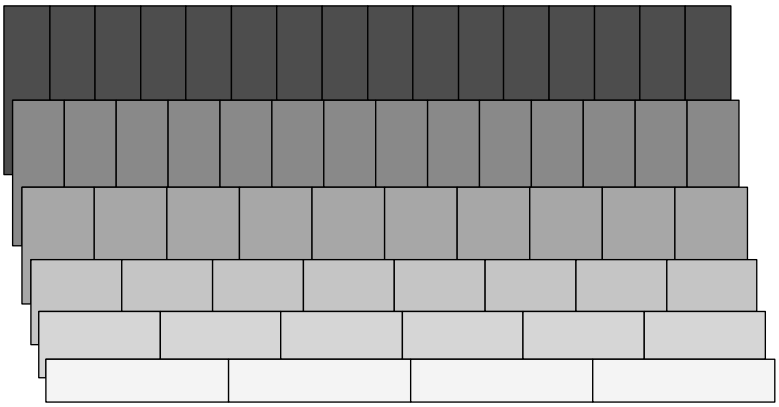

Figure 3. Continuous WT.

as constant-Q band-pass filters giving rise to the frequency selectivity of the CWT.

Since the WT is an alternative representation of a signal, it should retain the characteristics of the signal including the energy content in the signal. Thus, there should exist a similar relation to Parseval's theorem, which provides the energy relationship in the Fourier domain. The total energy of a signal in wavelet domain representation is [36]

$$E_f = \frac{1}{C_\psi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} |WT(u,s)|^2 \frac{\mathrm{d}s\, \mathrm{d}u}{s^2} \qquad (3)$$

where, C_ψ is a scalar constant related to the Fourier transform of the wavelet basis (called *admissibility constant*). The wavelet basis functions can be normalized in a way such that it can attain a value of unity. The differential energy of the signal in the differential tile of scale-translation plane in wavelet domain is $|WT(u,s)|^2(\mathrm{d}s\, \mathrm{d}u/s^2)$, which leads to the construction of the scalogram.

3.2 Discrete wavelet transform

The major difference between the CWT and DWT comes in the way that the transforms are performed. With the CWT, the signal is projected on to a continuous set of frequency bands; and, the original can be reconstructed from all the frequency components. The DWT discretizes the time and scale parameters to eliminate redundancy while retaining the ability to recover the original signal without loss. This means that the discrete transform obtains only a subset of the time/scale wavelet atoms that are found using the CWT, thus providing a more compact representation of the signal.

The discrete grid on the timescale plane corresponds to a discrete set of continuous functions. The higher the subsampling of the grid, the smaller the redundancy of the WT. Dyadic discretization is one way of obtaining a countable subset, and is the most commonly used. This is the discretization shown in Figure 1.

The DWT is defined at discrete points j, k using the formula

$$DWT(j,k) = \int_{-\infty}^{\infty} f(t)\psi_{j,k}^*(t)\, \mathrm{d}t \qquad (4)$$

where

$$\psi_{j,k}(t) = \frac{1}{\sqrt{s_0^j}} \psi\left(\frac{t - kus_0^j}{s_0^j}\right) \qquad (5)$$

If s_0 is chosen to be two, then the frequency sampling is called *dyadic*.

3.2.1 Multiresolution analysis

A more common way of representing the DWT is through an MRA approach. This approach was first suggested by Mallat [11], as a fast algorithm for performing the WT. The MRA approach can also be used to examine a signal at different resolutions or scales.

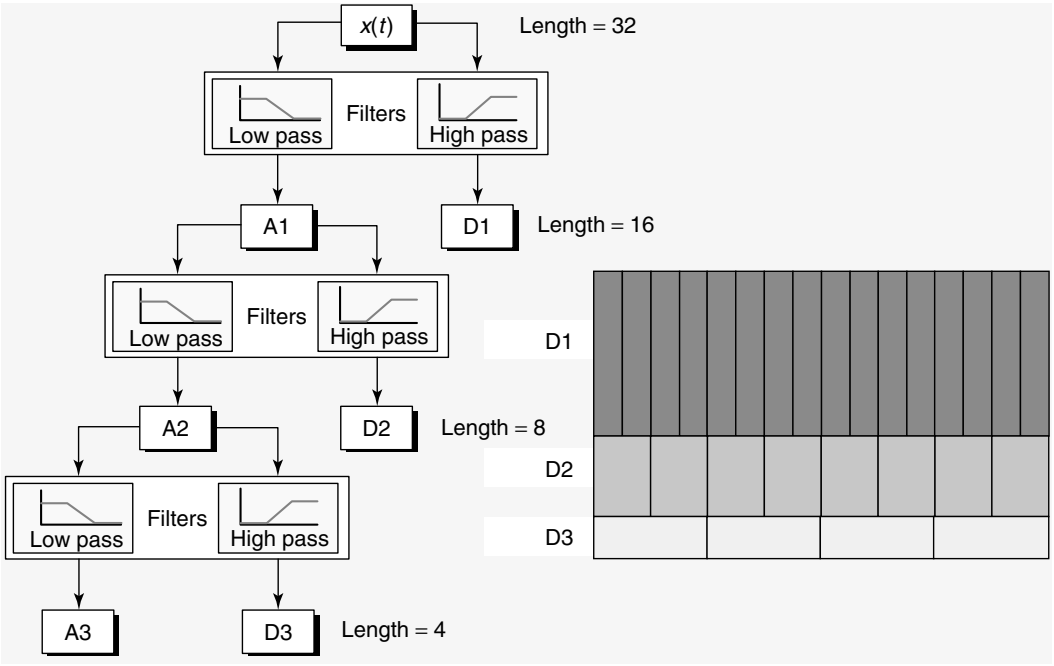

Figure 4. Filtering approach used for performing DWT.

The process works as shown in Figure 4. The original signal, $x(t)$, passes through two complementary filters, a low-pass and a high-pass filter, resulting in two signals. The signal, a, that emerges from the low-pass filter contains the low-frequency content, or approximations of the signal. The signal, d, that emerges from the high-pass filter contains the high-frequency content, or details of the signal. This procedure is then repeated on the signal a, thus removing more of the high-frequency content with each application. The result of the successive applications of the filters is a series of approximations of the signal with progressively more of the detail removed. Also obtained are a series of details of the signal, which constitutes the DWT, as demonstrated in Figure 4. Each application of the filters results in a different "level" of resolution, and these levels can be examined independently or in comparison for the extraction of damage-sensitive features.

The filters are based on both a mother and a father wavelet. The father wavelet is used as a low-pass filter or scaling function, defined as

$$\phi_{j,k} = 2^{-j/2}\phi\left(\frac{t-2^j k}{2^j}\right) \tag{6}$$

while the mother wavelet is used as the high-pass filter, and is defined as

$$\psi_{j,k} = 2^{-j/2}\psi\left(\frac{t-2^j k}{2^j}\right) \tag{7}$$

The j indexes the scale and the k indexes the translation. These functions are used to compute the approximations and details as

$$a_{j,k} = \int x(t)\phi_{j,k}(t)\,\mathrm{d}t \tag{8}$$

$$d_{j,k} = \int x(t)\psi_{j,k}(t)\,\mathrm{d}t \tag{9}$$

A signal, $x(t)$, can then be represented as a weighted sum of the scaling and wavelet functions up to a scale J:

$$x(t) = \sum_k a_{J,k}\phi_{J,k}(t) + \sum_{j=1}^{J}\sum_k \mathrm{d}_{j,k}\psi_{j,k}(t) \tag{10}$$

3.3 Orthogonal wavelet transform

An orthogonal WT is created from a wavelet whose dilations and translations form a set of orthogonal basis functions. When an orthonormal set of basis functions are used, there is no redundancy in the transform. A lack of redundancy means that the transformed signal can be recovered with the least information possible.

Orthogonality means that the inner product $\langle \psi_{j,k}, \psi_{j',k'} \rangle$ satisfies the condition [37]

$$\langle \psi_{j,k}, \psi_{j',k'} \rangle >= \begin{cases} 1 \text{ for } j = j' \text{ and } k = k' \\ 0 \text{ otherwise} \end{cases} \quad (11)$$

By choosing $a_0 = 2$ and $b_0 = 1$, a discretization based on a dyadic grid is obtained. The wavelets therefore assume the form

$$\psi_{j,k}(t) = 2^{-j/2} \psi \left(2^{-j} t - k\right) \quad (12)$$

The discretization on the dyadic grid leads to the dyadic WT. If there is a wavelet function that yields an orthonormal wavelet decomposition, then it can be shown that the wavelet coefficients for an orthonormal DWT are simply the samples of the CWT on the dyadic grid.

Nonorthogonal wavelet functions tend to artificially add in energy (due to the overlap) and require renormalization to conserve the information. The major drawback of using orthogonal wavelets is that localization of signal features is not possible.

3.4 Wavelet packets

While the constant-Q factor and coarser frequency resolution at high frequencies make the wavelet analysis computationally efficient, this may be a disadvantage for analysis of some signals for SHM. Better resolution at high frequencies can be obtained by wavelet packet construction.

The DWT based on MRA splits the signal into two bands, a higher band (by using a high-pass filter) and a lower band (by using a low-pass filter). The lower band is subsequently again split in two bands. This concept can be generalized by splitting the signal into several bands each time. In addition, there could be further splitting of higher bands too, not just the lower band. This generalization of MRA produces outputs called *wavelet packets*. This is a deviation from constant-Q analysis and achieves desired frequency resolution at high-frequency bands. Wavelet packets through arbitrary band splitting can choose the most suitable resolution to represent a signal.

The resolution of signals with wavelet packets is not only possible using MRA-based frequency filters in the time domain (starting with Haar wavelets) but also in the frequency domain. For the arbitrary resolution using frequency-domain-based filters, the construction for wavelet packets should be based on a modified L–P wavelet basis. The application of wavelet packets is particularly useful in system identification and damage detection for SHM where finer resolution at higher frequency is desired.

4 CHOICE OF WAVELET METHOD

4.1 Type of transform

The redundancy and time efficiency of the continuous wavelet transform and DWTs largely dictate what applications they are best used for. The CWT offers improved resolution, which creates an increase in computational time and memory required to calculate the coefficients. Therefore, the CWT is better used for analysis where one is trying to draw out features in a signal. The DWT is very time efficient, even faster than the fast Fourier transform (FFT). With improved time efficiency, however, comes a very sparse representation of the signal, which is not good for finding features in a signal. It is best used for compression (storage), denoising, and fast calculations such as matrix multiplications. Fast calculations can be very advantageous when trying to perform on-line health monitoring.

4.2 Mother wavelet

Each type of WT requires the choice of a mother wavelet from which the basis functions are created. There are an infinite number of mother wavelets that can be used. To be classified as a mother wavelet, the function must first satisfy the following conditions:

1. The function must have zero mean: $\int_{-\infty}^{\infty} |\psi(t)| \, dt = 0$.
2. Admissibility condition: $\int_0^{\infty} (|\hat{\psi}(\omega)|^2/\omega) \, d\omega < \infty$, where $\hat{\psi}(\omega)$ is the Fourier transform of ψ.

Basically, these properties mean that a wavelet is a function that must oscillate (hence the term *wave*), and that the oscillations must eventually damp out to zero.

Any given atom in the time–frequency map of the WT (Figure 1) represents the correlation between the wavelet basis function at that frequency dilation and the signal in that time segment. Therefore, if a basis function is used that is very similar to a feature of interest, the correlation between the wavelet and the signal at the point where the feature exists is very high. This is how wavelets can be used to draw out features in a signal. One can actually tailor a wavelet to resemble a feature of interest.

The most basic wavelet is the Gabor wavelet. It is simply a Fourier transform, which uses a Gaussian window to obtain time information [11]:

$$\psi(t) = g(t) \, e^{i\eta t} \tag{13}$$

where $g(t) = (1/(\sigma^2\pi)^{1/4}) e^{(-t^2/2\sigma^2)}$ is the Gaussian window.

The choice of which mother wavelet to use for analysis can greatly affect the results. For compression or denoising, it is important to choose a wavelet that closely resembles the function that is being analyzed. If this is achieved, only very few of the wavelet coefficients will be nonzero. If the function is smooth, a higher order wavelet is more appropriate. A lower order wavelet (such as the Haar wavelet) is good for identifying discontinuities in a signal. For feature extraction, one sometimes uses a wavelet that resembles the feature of interest.

When trying to obtain a good time–frequency representation of a signal, a continuous wavelet is usually the best. The most commonly used continuous wavelet is the Grossman–Morlet wavelet. This wavelet is complex valued. A complex-valued wavelet can be helpful when performing a convolution since it has the same convolution properties as the Fourier transform, meaning that a convolution becomes just a simple multiplication. A complex-valued wavelet can also provide phase information about the signal. The Grossman–Morlet wavelet is similar to a sine function with a Gaussian window:

$$\psi(t) = e^{(-\sigma^2 t^2 - i2\pi f_0 t)} \tag{14}$$

The term f_0 is the center frequency of the sinusoid and σ determines the width of the frequency band. Also, t is the time variable and i the imaginary value $\sqrt{-1}$.

Orthogonal wavelets offer a representation of the signal with as little information as is possible, and without redundancy. These features are very useful in denoising and in matrix multiplications. The best-known orthogonal wavelets are the Daubechies wavelets. Daubechies found a countable set of dyadic wavelets for the orthogonal decomposition that also has compact support. Other orthogonal wavelets include Coiflet, Symlet, and B-Spline. Battle–Lemarie and Meyer wavelets have orthonormal bases. Biorthogonal wavelets are special cases of discrete wavelets. They consist of two wavelet sets: one for decomposition and another for reconstruction.

Other features of the wavelet that are important in choosing the correct one are regularity, vanishing moments, and time–frequency localization. These features, however, are beyond the scope of this article. As stated by Staszewski [37], the proper use and interpretation are far more important in wavelet analysis than the choice of wavelet.

4.3 Wavelet features

After the type of WT has been decided upon, the task of interpreting the wavelet data arises. Many different approaches exist, and are based on the type of structure being examined and the type of damage that is being monitored. This section goes over some of the approaches and features that can be extracted from the wavelet data.

When using a CWT, damage-sensitive features are usually extracted from the scalogram. The scalogram is the squared modulus of the WT, represented in a two-dimensional plot. For a structural system, most of the energy in the scalogram is concentrated at the modes of vibration. One can also examine the power spectrum of the WT, which is the scalogram integrated over time. The power spectrum is similar

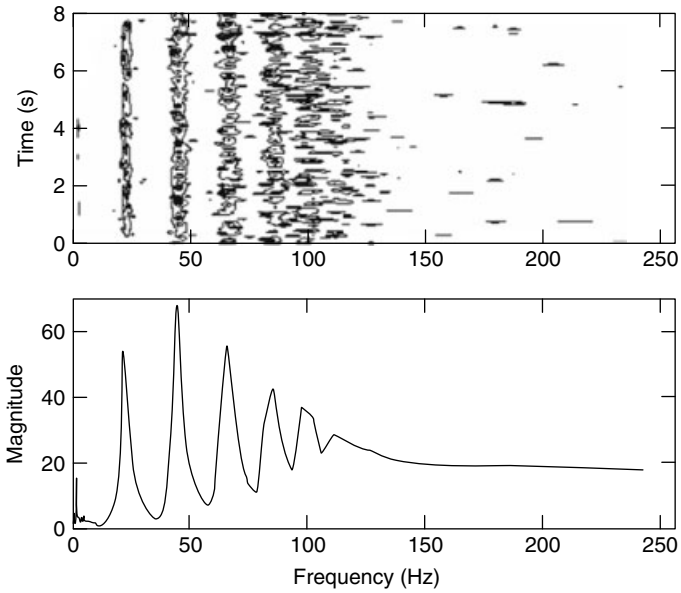

Figure 5. Wavelet transform and scalogram of an 8-DOF system.

to an FFT-based power spectrum and provides a one-dimensional view of the energy distribution in the signal across the frequencies. The variable window size of the WT means that the resolution of the power spectrum is greater at the low frequencies, which can be useful in identifying the modes of a structure. Figure 5 shows the scalogram and wavelet-based power spectrum of the time response of an 8-DOF (degree of freedom) spring-mass system subjected to random excitation. Notice that the structural modes in the lower frequencies are easily identifiable as vertical lines in the scalogram, whereas the higher frequency modes are indistinguishable owing to both the resolution of the WT in the high frequencies and the sampling rate of the data.

Sometimes the modes of a system change during time. This variation is easily seen in a time–frequency representation of the structural response. Methods have been developed to extract the needed data from the wavelet scalogram to exactly determine how the modes are changing. The concept of ridges and skeletons of the WT was developed by Tchamitchian and Torresani [38], and involves the extraction of the instantaneous amplitude and frequency content from a signal. A ridge is a string of high-magnitude wavelet coefficients, such as the ones seen in Figure 5, which represent a mode of the structure. If a mode is changing in time, the ridge is no longer a straight line, but it is curved. The skeleton is then the values of the WT restricted to its ridge. By examining the ridges and skeletons, one can identify information about the amplitude and frequency modulation of a signal, which is useful for the identification of nonstationary and nonlinear systems, and for damping estimates [25, 26].

The presence of spikes in the high-frequency region of a scalogram can indicate the presence of a discontinuity in the signal. Mallat [11] first introduced a method for detecting singularities in a signal by examining the evolution of the modulus maxima (large magnitude coefficients) of the WT across the scales. The decay of this maxima line can be used to determine the regularity (Holder exponent) of the signal at the given time point. A signal with low regularity can indicate a discontinuity in the signal, which can be caused by the opening and closing of cracks or by a rattle resulting from the loss of preload in a bolted connection (see [29] for further discussion).

When using a DWT or an orthogonal WT, damage is found by examining either the scalogram or the individual levels of the WT, as shown in the multiresolution approach. The process of denoising, for example, involves retaining only those values in the DWT scalogram that are above a certain value. Noise

does correlate well with the wavelet basis functions and therefore shows up as low-level values in the scalogram. Inverse wavelet transforming the retained values results in a time signal with the noise removed. See the examples below for a demonstration of how the DWT levels can be used for damage identification.

5 EXAMPLES OF WAVELET ANALYSIS

5.1 Continuous wavelet transform

Identifying and quantifying the level of damage in composite materials is becoming a large area of research in SHM. The most common forms of damage for composites include matrix breakage, debonding between matrix and fibers, and fiber delamination. Quite often, damage is not readily visible and must be identified using nondestructive evaluation techniques (NDTs). A number of different NDT approaches exist, including acoustic emission, electrical impedance, and Lamb wave propagation.

In this example, Lamb wave propagation is used to detect the presence of a delamination in a carbon fiber composite plate. The Lamb wave is a high-frequency (megahertz)-guided longitudinal wave that can travel long distances through a material. By propagating such waves through composite materials, faults or damage in the material can be located. The Lamb wave propagation method works as follows. An array of Piezoelectric Transducers (PZT) sensors are placed on the plate as shown in Figure 6. One PZT is activated as an actuator to launch elastic waves (the input) through the plate, and responses are measured by other PZT patches acting as sensors or possibly some other device. The structure can be systematically surveyed by sequentially using each of the PZT patches as an actuator and the remaining PZT patches as sensors. The technique looks for the possibility of damage by tracking changes in the PZT responses from a baseline "undamaged" signal. Features that might indicate damage include signal attenuation, delay, or reflection. These features are difficult to locate by examining the time response signals, and so tools such as the WT are used to draw out these features.

Staszewski [37] provides a wonderful example of wavelet analysis of Lamb wave data. Lamb waves were launched into a 600-mm^2 plate using conventional PZTs, and monitored using an embedded optical fiber connected to a Mach–Zehnder interferometer [37]. Figure 7(a) shows normalized S_0 Lamb wave responses along with power spectra and

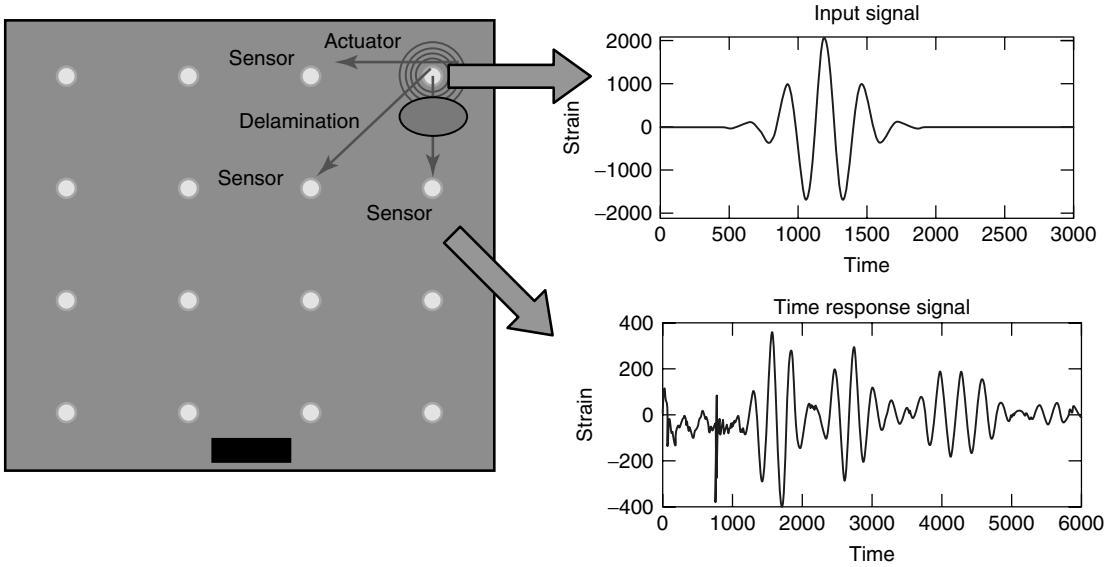

Figure 6. Example of Lamb wave propagation for damage diagnosis: composite plate under examination and input/output signals.

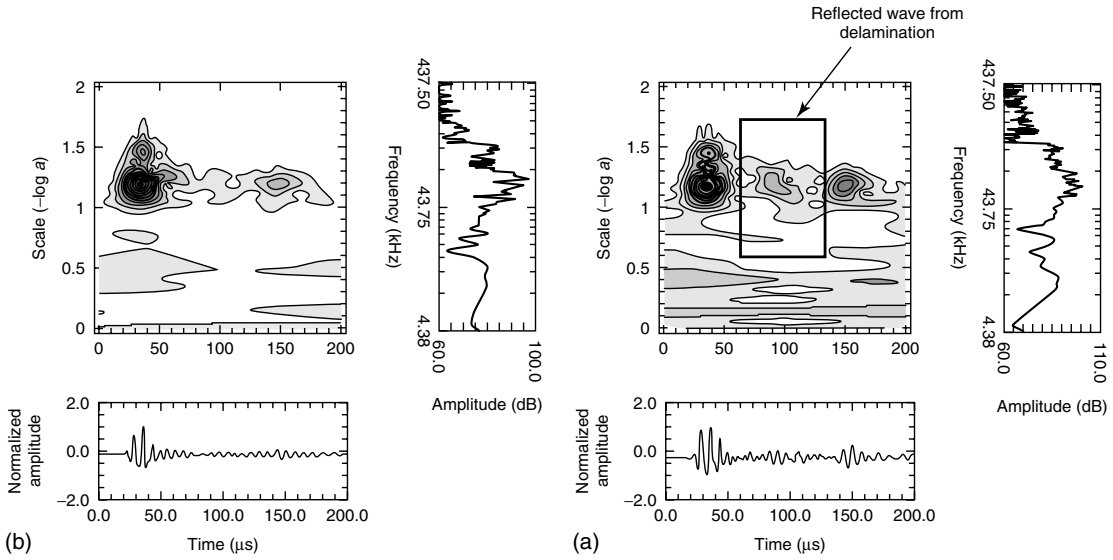

Figure 7. Continuous wavelet transform analysis of Lamb wave reflection data from a composite plate: (a) no damage present and (b) delamination present. (Staszewski [37], Reproduced by permission of Academic Press.)

contour plots of the WT modulus for a baseline "undamaged" signal. Figure 7(b) then shows the same plots for data obtained from the same composite plate with a delamination present. In Figure 7(b), a wave reflection is seen at about 90 μs as identified by an increase in the WT modulus. The reflection is due to a 400-mm^2 delamination in the plate, which is about 0.1% of the total area. The visibility of the delamination is significantly improved by the WT. A variety of methods can then be used to try to automatically identify the changes in the wavelet modulus data.

5.2 Orthogonal discrete wavelet transform

As shown previously, a signal $x(t)$ can be decomposed using a DWT into a series of resolution levels. By examining an individual level, one can identify the contribution of a given frequency band to the overall signal energy. The lower levels correspond to the lower frequencies and have the smallest bandwidth. At each increasing level, the central frequency doubles, as well as the bandwidth. The central frequency at level j is

$$f_{c_j} = 2^j \frac{f_s}{N} \tag{15}$$

where f_s is the sampling frequency and N is the number of time points in the signal.

Staszewski [37] used this decomposition to analyze the Lamb wave signal discussed in the previous section. A Daubechies fourth-order wavelet was used for analysis. Figure 8(a) shows the orthogonal wavelet decomposition of the Lamb wave response for an undamaged plate, and Figure 8(b) shows the decomposition of the Lamb wave response from the plate with a delamination present. The top row in each of the figures represents the original time response data. The following rows show the eight highest wavelet levels. Examination of these levels reveals a feature in the "damaged" data that is not present in the baseline data. On level 4, a spike in the data at 0.11 ms represents a reflection due to the delamination in the plate.

Though the applications of continuous and discrete (or orthogonal) wavelets are quite often different, this Lamb wave example has shown how both transforms can be used on the same data. The results are different, but both transforms are able to identify the presence of damage in the composite plate.

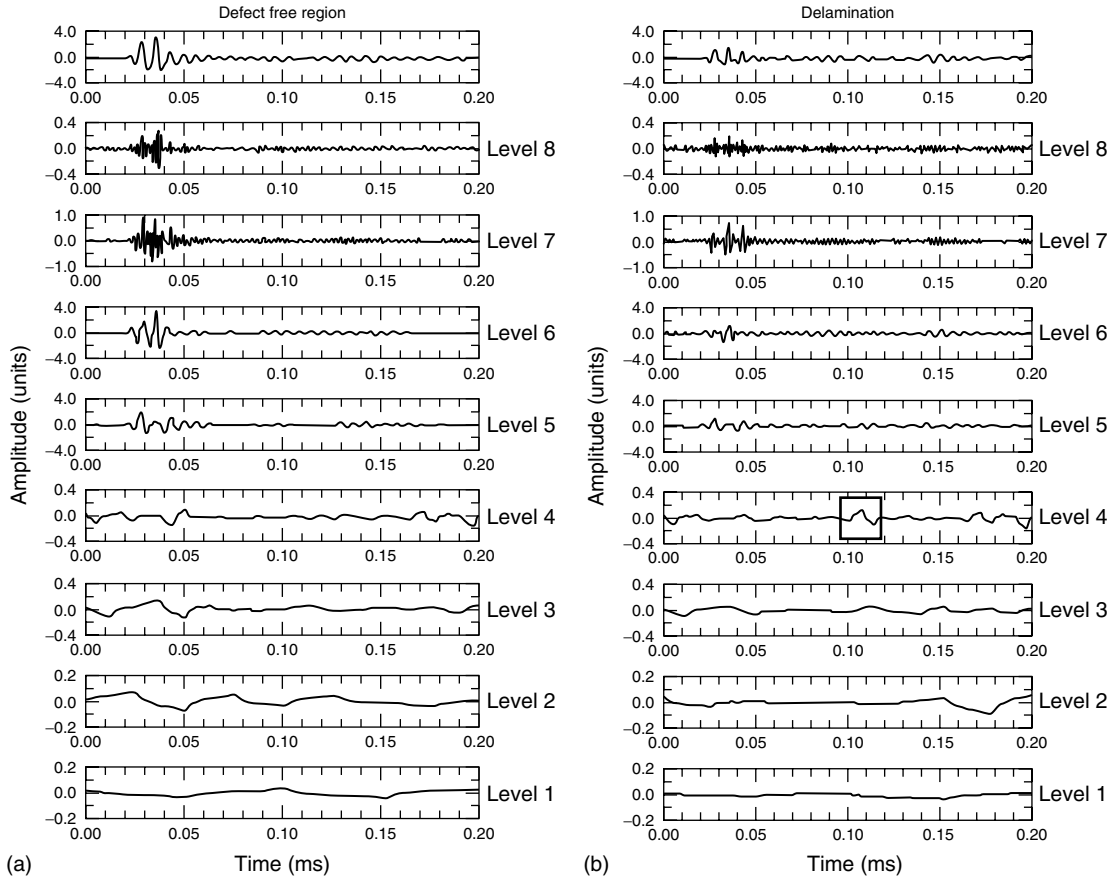

Figure 8. Orthogonal wavelet decomposition of Lamb wave data from a composite plate: (a) no damage present and (b) delamination present. (Staszewski [37], Reproduced by permission of Academic Press.)

5.3 Wavelet packets

Structural systems accumulate damage under both service load and environmental excitations. Examples include fatigue in rotating wind turbine blades or degradation in bridges with opening and closing of cracks manifested in the variation of stiffness. Under certain loading conditions, structures may also suffer significant damage that changes the dynamical and mechanical parameters. In all such cases, a time-varying representation of the stiffness is more appropriate. Identification of the modal parameters is vital in assessing the condition of the structure as well as for diagnosing its failure. Further, the information of stiffness and the variation of stiffness with time are of importance in designing control strategies e.g., for active and semiactive tuned mass dampers.

The temporal variation in the frequency content of the response signal of a structure modeled as a stiffness varying multi-degree-of-freedom (MDOF) system can be used to obtain the variation of the characteristic stiffness of the system. While wavelet analysis techniques have been successfully used mostly in off-line identification of the time-varying structural dynamic parameters of a system, it has the potential for on-line identification, using time–frequency localization properties. The on-line identification of system parameters can be achieved in a simple and computationally straightforward way by using wavelet analysis for an adaptive control application. A wavelet-based on-line identification of stiffness via the identification of modal parameters (assuming the masses to be known) of a structural system, modeled as an MDOF system (shown in Figure 9), has been

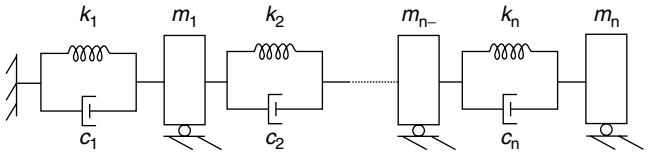

Figure 9. MDOF system.

illustrated through the following example (Basu *et al.* [39]). A modified L–P wavelet basis with wavelet packets has been used in the proposed algorithm.

It can be shown that for each of the modal equations in an MDOF system, the local energy content of the modal response z_k around the time $t = b$ can be expressed by a proportional term as follows:

$$E_j z_k(b) \propto \frac{1}{s_j} \int_{b-\varepsilon}^{b+\varepsilon} |WT(u, s_j)|^2 \, \mathrm{d}u \qquad (16)$$

where, the dilation parameter j is discretized. Since the WT localizes information, wavelet coefficients outside the range $[b - \varepsilon, b + \varepsilon]$ do not contribute to the local energy content around $t = b$. The modified L–P function (Basu *et al.* [39]) has been used as the wavelet basis for analysis, and is characterized by the Fourier transform:

$$\hat{\psi}(\omega) = \frac{1}{\sqrt{F_1(\sigma - 1)}}, \; F_1 \leq |\omega| \leq \sigma F_1 \qquad (17)$$

where, F_1 is the initial cutoff frequency of the mother wavelet and σ is a scalar to be chosen by the user to generate nondyadic nonoverlapping (orthogonal) frequency bands for wavelet bases generated by dilations.

For an m-DOF system, the m bands with the m time-varying natural frequency parameters $\omega_k(b); k = 1, \ldots, m$ correspond to m local maxima in the variation of energy of the rth DOF, $E_j x_r(b)$ (or its proportional quantity $(1/s_j) \int_{b-\varepsilon}^{b+\varepsilon} |WT(u, s_j)|^2 \, \mathrm{d}u$) with different values of the band parameter 'j'. Wavelet packets are applied for better resolution of the modal frequency parameters desired to be obtained with better precision as shown by Chakraborty *et al.* [40]. Once the bands corresponding to the m modes with the parameters $\omega_k(b)$ are obtained, the time-varying mode shapes $\{\phi(b)\}^k$ can be found by

$$\pi_r^j(b) = \frac{WT \; x_r(b, s_j)}{WT \; x_1(b, s_j)} = \frac{\phi_r^k(b)}{\phi_1^k(b)} \qquad (18)$$

To illustrate the application of the tracking methodology, an example of a 2-DOF system has been considered (see [39]). The masses of the first and second floors are $m_1 = 10$ unit and $m_2 = 15$ unit, respectively. The stiffness of the first and second floors are $k_1 = 2500$ unit and $k_2 = 4500$ unit, respectively. These parameters lead to the first natural frequency and mode shape as $\omega_1 = 9.04 \, \mathrm{rad\,s^{-1}}$ and $\{\phi_{11} \, \phi_{21}\} = \{11.37\}$, respectively. A band-limited white-noise excitation has been simulated and applied at the base. The range of frequencies is kept wide enough to cover the frequencies of the system to be identified. The response of the system is simulated with 5% of modal damping (proportional). For the frequency-tracking algorithm, a moving window of 400 time steps equal to 4.16 s has been chosen. For the identification of the 2-DOF system, the parameters F_1 and σ are taken as $8.25 \, \mathrm{rad\,s^{-1}}$ and 1.2, respectively.

Figure 10 shows the tracking of the first natural frequency and the ratio ϕ_{21}/ϕ_{11} corresponding to the first mode shape (assuming $\phi_{11} = 1$, without loss of generality). To further observe if the proposed method can track a sudden change in the stiffness(es) of an MDOF system and follow the restoration to the original stiffness value(s), the stiffnesses k_1 and k_2 of the 2-DOF are changed to 5000 and 5200 units, respectively at an instant of 5.72 s in time. Subsequently, the stiffnesses are restored to their original value at 12.48 s. During the changed phase, the fundamental natural frequency and the mode shape are changed to $\omega_1 = 11.57 \, \mathrm{rad\,s^{-1}}$ and $\{\phi_{11} \, \phi_{21}\} = \{11.57\}$, respectively. Figure 11 shows the tracked first natural frequency and the ratio of ϕ_{21}/ϕ_{11}. As expected, there is a time lag in tracking the frequency and mode shape. The change in the

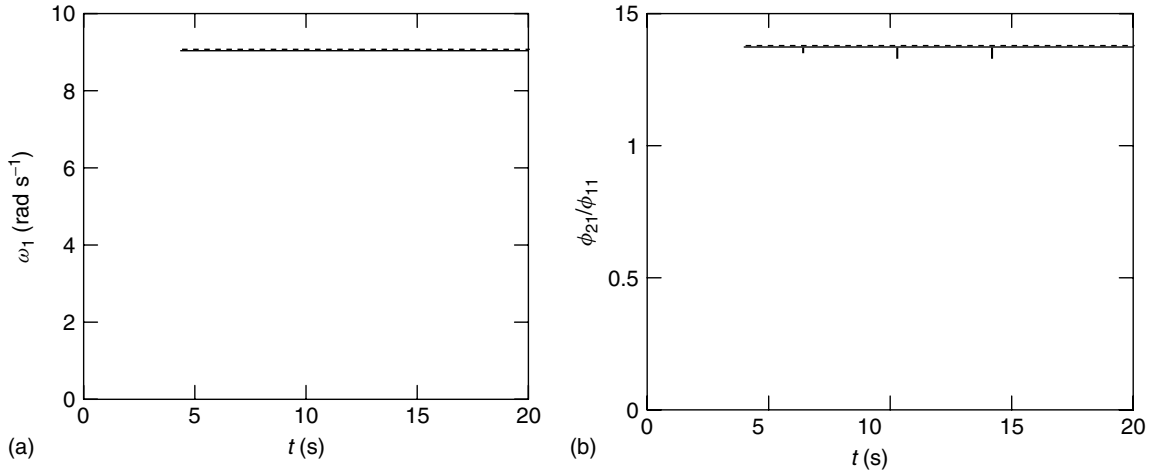

Figure 10. On-line tracking of parameters of a 2-DOF (a) fundamental frequency and (b) fundamental mode shape ("———" actual, "- - - - " estimated).

frequency is tracked in (three) steps corresponding to the subbands of frequencies considered for the wavelet packets.

6 CONCLUSIONS

The application of wavelet analysis as a time–frequency tool for SHM has been discussed in this article. A brief literature review on the use of wavelet analysis as a powerful tool for assessment of structural health and fault detection has been presented.

The different types of WTs with their mathematical basis have been reviewed. The similarities and differences of wavelet analysis with STFT have been highlighted. Further, the constant-Q property of wavelet analysis and the construction of a scalogram from the CWT have been discussed. The relation between CWT and DWT has been presented. Also, the construction of an MRA-based fast algorithm for calculating the DWT has been discussed. It has been shown that the DWT can be considered as a filtering approach as evidenced by the MRA. The discussion on orthogonal WT has also revealed that the

wavelet coefficients from an orthonormal DWT are the samples of the CWT on the dyadic grid. The orthogonal wavelets offer a minimal set for the representation of a signal with no redundancy, whereas the CWT has a large number of redundant coefficients. The redundancy of CWT makes it unsuitable for exact reconstruction of signals, but it may be desirable for extracting features from a signal. While the constant-Q property of wavelets is an advantage for computational efficiency, the concept of wavelet packets has been discussed for better resolution at high frequencies. The properties of the different types of WTs decide the choice of a particular one for an application.

Two illustrative examples have been provided in this article. The first one involves the use of Lamb waves to detect a delamination in a carbon fiber composite plate. CWT and orthogonal DWT (Daubechies order 4) have been successfully used for this purpose. The second example involves the application of orthogonal wavelet packets based on a modified L–P wavelet basis. The wavelet packets are used for on-line detection of the stiffness of a structural system via the identification of modal parameters.

Chapter 34
Nonlinear Features for SHM Applications

Jonathan M. Nichols[1] and Michael D. Todd[2]

[1] *US Naval Research Laboratory, Washington, DC, USA*
[2] *Department of Structural Engineering, University of California, San Diego, CA, USA*

1 INTRODUCTION

A *feature* is a quantity extracted from measured system response data that indicates the presence, location, and/or level of damage present in the system [1]. The dominant approaches in the literature, covered in previous articles in this collection (*see* **Signal Processing for Damage Detection**), involve features derived from linear models, assumptions, or signal processing techniques [2, 3]. However, there are several situations where nonlinearity plays a role in the damage-detection problem and where the use of nonlinear features is appropriate. Perhaps the most important of such situations is where the healthy structure is appropriately modeled as linear and where damage causes a nonlinearity. In this case, the problem of damage detection can be equated with nonlinearity detection. Nonlinear system-identification techniques can further be used to indicate both the magnitude and type of nonlinearity. In other cases, the structure is appropriately modeled as nonlinear throughout the damage progression. Nonlinear features can improve the ability to track damage in this case. Still other researchers have used nonlinearity to enhance the sensitivity of a particular damage-detection scheme by tuning the excitation to elicit a specific structural response, amenable to nonlinear feature-based analysis. Each of these approaches is described in what follows, along with the appropriate citations.

It is first useful to define exactly what is meant by a "nonlinear feature". Nonlinearity is, of course, a property of the underlying system and not of the data. Rather than saying we have a "nonlinear time

 ISBN: 978-0-470-05822-0.

series", it is more appropriate to say we have "a time series produced by a nonlinear system". As a result, a "nonlinear feature" is one that is designed to take advantage of certain relationships among time series produced by a nonlinear system.

First, consider a linear, time-invariant single-degree-of-freedom (DOF) system. The input–output relationship for such a system may be modeled via the convolution

$$y(t) = \int_{-\infty}^{\infty} h(\theta)x(t-\theta)\,\mathrm{d}\theta \tag{1}$$

that is to say the response $y(t)$ is a superposition of input "impulses", $x(t)$, and the impulse response function $h(t)$. The statistical properties of the output are

$$\begin{aligned}
E[y(t)] &= \int_{-\infty}^{\infty} h(t-\theta_1)E[x(\theta_1)]\,\mathrm{d}\theta_1 \\
E[y(t)y(t+\tau_1)] &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(t-\theta_1)h(t+\tau_1-\theta_2)E[x(\theta_1)x(\theta_2)]\,\mathrm{d}\theta_1\,\mathrm{d}\theta_2 \\
&\vdots \\
E\left[\prod_{m=0}^{M-1} y(t+\tau_m)\right] &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\cdots\int_{-\infty}^{\infty}\prod_{m=0}^{M-1} h(t+\tau_m-\theta_{m+1})E\left[\prod_{m=0}^{M-1} x(\theta_{m+1})\right]\prod_{m=0}^{M-1}\mathrm{d}\theta_{m+1} \quad (\tau_0=0)
\end{aligned} \tag{2}$$

If the driving signal $x(t)$ is iid, zero-mean Gaussian noise, all odd-ordered moments vanish, e.g., $E[y(t)y(t+\tau_1)y(t+\tau_2)] = 0$, while the even-ordered expectations become functions of the autocovariance $E[y(t)y(t+\tau_1)]$ [4]. Thus, for a linear, Gaussian-excited system, the output relationship $E[y(t)y(t+\tau_1)]$ is sufficient to characterize the response. However, if nonlinearities are present equation (1) does not hold and it is likely that there exist nonzero components in the higher-order correlations, e.g., $E[y(t)y(t+\tau_1)y(t+\tau_2)] \neq 0$. A feature that captures this relationship is, therefore, taking advantage of the fact that the underlying system is nonlinear. One feature that targets this third moment, the bispectrum, is explored later (the use of other higher-order correlations in detecting damage-induced nonlinearities in a structure is also discussed). Even if the driving term $x(t)$ is non-Gaussian, second-order statistics are still sufficient to describe the linear response provided that the distribution of $y(t)$ is also known. It can be shown, for example, that normalized versions of the higher-order correlations can be used effectively to detect nonlinearity in non-Gaussian processes [5].

Additionally, for the systems described by equation (1), certain quantities like natural frequency are invariant to the amplitude of excitation. For nonlinear systems, this is not true; in fact, tracking the amplitude varying properties is one way to diagnose the type of nonlinearity. It should be pointed out that the focus here is on linear *time-invariant* systems. In much of what follows, the features presented implicitly assume that the practitioner is dealing with stationary structural response data. For nonstationary response data, the estimation of many of these features becomes difficult, and fewer methods are available.

In short, there is a large body of literature concerning the use of nonlinear features in structural health monitoring (SHM). In the sections that follow, an effort is made to describe these works and place them in context. The list is not exhaustive, but may hopefully help the reader appreciate the various techniques available and the situations in which they have been used successfully.

The main reason for wanting to use nonlinear features in SHM is, of course, that often there exists a significant amount of nonlinearity in the dynamics of the structure being monitored. A prime example is the aforementioned scenario whereby damage causes a healthy structure that is well described by a linear model to exhibit nonlinearity. This fact has been exploited by a number of researchers in the field.

A few examples of nonlinear behavior in damaged structures are cited here (*see* **Civil Infrastructure Load Models for Structural Health Monitoring**; **Failure Modes of Aerospace Materials**).

1. Cracking
A cracked structure, for example, is often modeled as a nonlinearity. For example, Brandon [6] considers both crack and clearance nonlinearities as the damage mechanism. Friswell and Penny consider the modeling of cracks using a bilinear stiffness term [7]. Zhang and Testa [8] also explored the nonlinearity due to the opening/closing of a crack in an experimental beam structure.

2. Impacts and/or rattling
Impacts, or clearance nonlinearities also present an obvious situation where damage equates with nonlinearity. Brown and Adams [9], Rutherford *et al.* [10], and Nichols *et al.* [11] have all explored loosening connections as a nonlinear damage mechanism. This type of nonlinearity is also referred to in may works as *backlash* (for example, [12, 13]).

3. Delamination
Delamination has also been modeled as a damage-induced nonlinearity in composite structures. The work of Schwarts-Givli *et al.*, for example, considers both contact and geometric nonlinearity in modeling damaged sandwich panels. Earlier work by Hunt *et al.* [14] considered a low-dimensional model of a delaminated strut. The delamination was modeled as a local buckling resulting in a nonlinear response. A similar model was proposed by Murphy *et al.* and was shown to agree well with experiment [15]. A separate nonlinear model for delaminated beams was also given in [16].

4. Stick/slip, rub
In the analysis of rotating machinery, rotor–stator "rub" is viewed as a damage mechanism. An experimental study illustrating rub as a source of nonlinearity can be found in [17]. Detection of this type of damage was studied in [18, 19]. Additionally, jointed structures often exhibit stick–slip behavior. Both modeling and simulation of this type of behavior in bolted joints were studied by Song *et al.* [20], among others. "Fretting" wear is another damage mechanism arising from stick–slip behavior and has been studied by a number of authors (for example, [21]).

Additionally, there are a number of structures that exhibit significant nonlinearity regardless of damage. Monitoring such structures can therefore be aided by the use of nonlinear features. A comprehensive look at nonlinearity in structural dynamics has been presented by Worden and Tomlinson [22] and also in a recent review article by Kerschen *et al.* [23].

The following sections in this article describe some broad classes of where the role of nonlinearity in system response is either exploited or imposed to extract damage-sensitive features. These classes may be grouped as (i) direct tests of the definition of nonlinearity, (ii) phase space methods, (iii) higher-order spectra, (iv) the method of surrogate data, and (v) imposed nonlinearity.

2 TESTING THE DEFINITION OF NONLINEARITY

Probably the most well-known methods of capturing nonlinearity are adaptations to linear approaches. For example, traditional linear signal processing (e.g., the power spectral density) provides information about second-order statistics in a time series. However, if higher-order correlations (nonlinearity) are present, they still show up by violating expected properties of the linear system. Any nonlinear system H is fundamentally defined by a violation of the following rule of homogeneity (scalability) and superposition:

$$H\left(\sum_n a_n x_n\right) = \sum_n a_n H\left(x_n\right) \tag{3}$$

where the x_n are inputs to the system, weighted by a_n. Linear systems must fundamentally obey this equation. Considering a single input x_1 that results in a system response y_1 and a scaled input $x_2 = ax_1$ that results in an output y_2, equation (1) becomes

$$y_1(t) = \int_{-\infty}^{\infty} h(\theta) x_1(t-\theta)\,\mathrm{d}\theta$$

$$y_2(t) = \int_{-\infty}^{\infty} h(\theta) x_2(t-\theta)\,\mathrm{d}\theta$$

$$y_1(t) = \int_{-\infty}^{\infty} h(\theta) x_1(t-\theta)\,\mathrm{d}\theta$$

$$
\begin{aligned}
y_2(t) &= \int_{-\infty}^{\infty} h(\theta) a x_1(t-\theta)\,\mathrm{d}\theta \\
y_1(t) &= \int_{-\infty}^{\infty} h(\theta) x_1(t-\theta)\,\mathrm{d}\theta \\
y_2(t) &= a\int_{-\infty}^{\infty} h(\theta) x_1(t-\theta)\,\mathrm{d}\theta \\
Y_1(\omega) &= H(\omega) X_1(\omega) \\
Y_2(\omega) &= a H(\omega) X_1(\omega)
\end{aligned} \tag{4}
$$

where the Fourier transform has been taken in the last line to translate into the frequency domain (i.e., $Y_1(\omega)$, $H(\omega)$, and $X_1(\omega)$ are the Fourier transforms of $y_1(t), h(\theta)$, and $x_1(t)$, respectively). The frequency response function (FRF) is defined as the frequency domain ratio of output to input, so that for linear systems, $Y_2(\omega)/X_2(\omega) = aY_1(\omega)/\big(aX_1(\omega)\big) = Y_1(\omega)/X_1(\omega)$. This identity is readily tested in system response by merely applying two inputs of different magnitude to the system and observing whether the resulting measured FRFs are identical or not.

Superposition may also be readily tested by applying different inputs individually and then collectively to the system, since

$$
\begin{aligned}
y(t) &= \int_{-\infty}^{\infty} h(\theta)\left(x_1(t-\theta) + x_2(t-\theta)\right)\mathrm{d}\theta \\
&= \int_{-\infty}^{\infty} h(\theta) x_1(t-\theta)\,\mathrm{d}\theta \\
&\quad + \int_{-\infty}^{\infty} h(\theta) x_2(t-\theta)\,\mathrm{d}\theta \\
Y(\omega) &= H(\omega)X_1(\omega) + H(\omega)X_2(\omega) \\
&= Y_1(\omega) + Y_2(\omega)
\end{aligned} \tag{5}
$$

The SHM community has long exploited, particularly in applications involving rotating machinery, a consequence of superposition violations known as *harmonic generation*. The response of a linear, single-DOF system to broadband Gaussian inputs shows a single resonant peak when viewed in the frequency domain; similarly, a linear system excited by a pure tone results in a pure tone at that same frequency in the output (at steady state). However, if that same system possesses a nonlinearity, those single tonal peaks distort, and additional peaks at harmonic frequencies appear. These can be used to diagnose the presence and sometimes the type of nonlinearity. In damage detection, for example, Adams and Farrar used frequency domain Auto-Regressive eXogenous input (ARX) models to capture the influence of harmonics and use them as a damage indicator [24]. Work by Bovsunovsky and Surace [25] similarly used superharmonics to diagnose cracks in a beam structure. Their work showed that changes in the harmonics were found to be more sensitive to damage than were the changes to the main resonant peak. Recent work by Parsons and Staszewski [26] also focused on harmonic generation in the detection of fatigue cracks in an aluminum plate using ultrasonic techniques. As an example, consider the composite-to-metal jointed structure shown in Figure 1. A full description of the system and experiment is given in [27]. To detect the bolt loosening, random excitation was applied near the beam center and the strain response near the joint was recorded. The bolt was fully tightened in the undamaged scenario and damage was taken as a loosened connection. The power spectral density of both the undamaged and damaged response data is also shown in Figure 1. The appearance of additional spectral peaks is a signature of nonlinearity, which, in this case, corresponds to bolt loosening. Other work by Adams has focused on modifying the traditionally "linear" concept of a transmissibility function to accommodate nonlinearity in a health monitoring context [28]. Wong and Chen accounted for nonlinearity in a similar fashion, using the concept of an "equivalent linearization stiffness matrix" to detect and locate damage in a simulated 5-DOF structure [29]. D'Souza and Epureanu also viewed nonlinearity as a perturbation to a linear problem. By identifying the size of the perturbation, they could identify both the location and magnitude of nonlinear damage. This method was referred to as *rank perturbation*, a full description of which is given in [30]. Still others have captured nonlinearity by focusing on amplitude dependence in system properties (e.g., natural frequency) that would be invariant to amplitude under the hypothesis of a linear structure obeying equation (1). Neild *et al.*, for example, looked at the frequency variations with amplitude in the response of two reinforced concrete beams [31] and were able to successfully deduce the presence of crack damage. Other work by Feldman [32] (to be described later), also showed amplitude dependencies in natural frequency in a

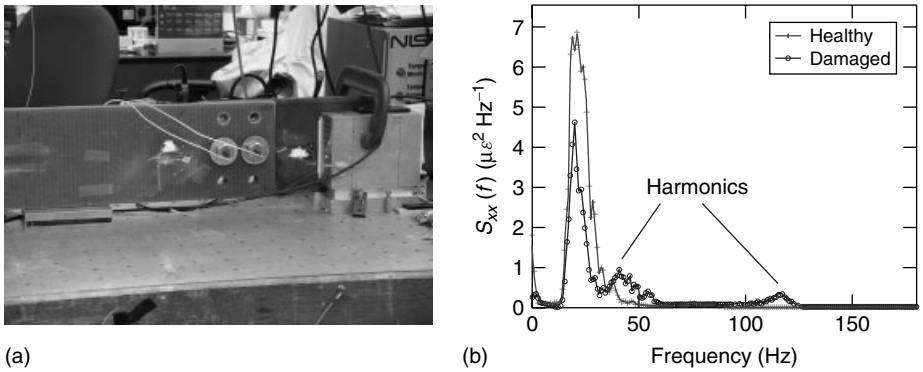

Figure 1. (a) Experimental bolted joint structure and (b) power spectral density estimated from strain response. Both the fully clamped (undamaged) and loosened (damaged) connections are shown.

cracked structure. Autoregressive, moving average models with exogenous inputs (ARMAX models) are another favorite system-identification procedure for linear systems. However, for systems possessing nonlinearity, the dynamics are more appropriately captured using a nonlinear, autoregressive, moving average model with exogenous inputs (NARMAX model). Wei *et al.* used NARMAX models, relating input/output data, to detect delamination in an experimental composite structure. Changes in the model structure were found to correlate well with damage [33]. Other tests of linearity definition violation include reciprocity checks (testing the symmetry of the FRF), nulls in the coherence function, and loss of identity in Hilbert transformations of the FRF. These methods are extensively reviewed in [22].

Finally, we mention an approach for detecting nonlinearities that cause discontinuities in structural response data. The approach is to use estimates of the Holder exponent as damage-sensitive feature. This feature measures the degree of differentiability or "smoothness" of a function; thus, a small Holder exponent indicates strong discontinuity and vice versa. In [34], a procedure for capturing the time varying nature of the Holder exponent has been developed based on wavelet transforms. This procedure has been successfully applied to detect loose components in a harmonically excited mechanical system.

3 PHASE SPACE METHODS

A number of approaches to SHM rely on a *phase space* analysis of the response data. Assume that there exists an M-DOF structure, governed by the state equations:

$$\dot{\mathbf{x}}(t) = F(\mathbf{x}(t), \boldsymbol{\mu}) \tag{6}$$

where $F(\cdot)$ is a deterministic function of both the system state and a vector of system parameters $\boldsymbol{\mu}$. In a structural dynamics context, the parameter vector might consist of stiffness, mass, and damping parameters. The state vector $\mathbf{x}(t) \equiv (x_1(t), x_2(t), \ldots, x_M(t))$ consists of all the system variables, e.g., positions and velocities of lumped mass elements. As the dynamics of the system evolve in time, they trace out a unique trajectory in this state space. Under the dissipation present in any real system (due to various sources), all trajectories eventually settle onto a dynamical *attractor*, given a deterministic input. The attractor may be viewed as a geometric object in state space. Changes in the system parameters (e.g., stiffness and damping) alter the resulting attractor, and thus various researchers have used attractor properties as a source of damage-sensitive features.

Central to these approaches is the problem of phase space reconstruction. Typically, we cannot measure all of the state variables in experiment; thus, we only have access to part of the state space. Fortunately, there exists a technique whereby the variables that are not observed can be qualitatively reconstructed such that the geometry of the underlying attractor is preserved. A full discussion of attractor reconstruction and the theorems that underlie it would be prohibitive. A comprehensive look at the reconstruction problem is found in [35] for both uni- and multivariate data. Assuming a univariate measurement (let us say only measurements of acceleration

at one point on the structure are available), the reconstructed state space is given by

$$\mathbf{x}(n) = (x(n), x(n+T), \ldots, x(n+(d-1)T)) \quad (7)$$

where T is a measure of time delay and d is the embedding dimension. Prescriptions for choosing these quantities are found in [35]. If d and T are chosen properly, the vector $\mathbf{x}(n)$ is topologically equivalent to the "true" state vector from equation (6). Figure 2 shows a two-dimensional view of attractor reconstructions, formed by embedding an undamaged and damaged response. The system of interest in this case was an 8-DOF spring–mass system driven with the output of a chaotic oscillator. Details of this approach are given in Section 6 and a full description of the simulations are documented in [36].

Once the attractor has been reconstructed, a number of metrics can be used to identify damage-induced changes to the dynamics. Most of these metrics are based on the geometry of the attractor and are not restricted to looking at a specific temporal relationship (e.g., covariance). Thus, these methods are capable of capturing correlations of any order in the data (see again equation (2)) and are appropriate for capturing the effect of structural nonlinearity on the response.

The correlation dimension is one such metric frequently used in the nonlinear time series analysis community as a descriptor of nonlinear processes. This feature effectively quantifies, on average, how local probability estimates scale with "bin size". Although a number of other measures of dimension exist (e.g., information dimension), the correlation dimension is probably the most widely used method for quantifying the geometry of a collection of points. More specifically, given a reconstructed attractor $\mathbf{x}(n)$, the correlation integral (as used in practice) reads as

$$C(r) = \frac{2}{N(N-2W-1)} \times \sum_{i=1}^{N} \sum_{j:|i-j|>W}^{N} \Theta(r - \|\mathbf{x}(i) - \mathbf{x}(j)\|) \quad (8)$$

where $\Theta(\cdot)$ is the Heaviside step function, r is a threshold parameter, and W is a Theiler window (designed to eliminate temporally correlated points from the sum [38]). It should be noted that an estimate of the probability density for point i, assuming a stationary, ergodic process, is given by

$$\hat{p}(r, \mathbf{x})(i) = \frac{1}{N} \sum_{j}^{N} \Theta(r - \|\mathbf{x}(i) - \mathbf{x}(j)\|) \quad (9)$$

Thus, the correlation integral is related to the average probability density of points on an attractor, estimated using length scale r. Probability is, in fact, one example of a measure of a collection of points. The correlation dimension quantifies how $C(r)$ scales with r. Thus, assuming the scaling law $C(r) \sim r^{d_c}$, the slope of the $\log(C(r))$ versus $\log(r)$ plot gives the correlation dimension, d_c. Often, damage causes an increase in the dimensionality of the structure's response. By monitoring these changes, one can detect damage.

This metric has been used by Logan and Mathew [39, 40] for bearing fault diagnosis. Similarly, it has been used by Craig *et al.* [41] in detecting clearance nonlinearities, as well as by Wang *et al.* for detecting damage in rotating machinery [42]. Trendafilova [43] has also made use of this feature in several works. A comparison of the above-described estimator of dimension to a different estimator (based on the

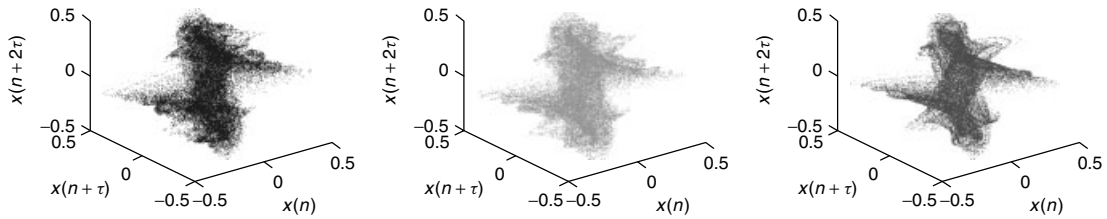

Figure 2. Reconstructed attractors for a "fixed-free" 3-DOF system described in [37]. Damage was taken as a stiffness reduction between masses 2 and 3. A number of features may be extracted from these geometric objects for comparison and thus damage tracking.

principle of maximum likelihood) in the context of health monitoring was given in [44] in diagnosing a loosening joint.

Still other researchers have focused on attractor-based measures derived straight from the local probability structure of the data. Epureanu and Yin [45] computed estimates of the local probability density as given by equation (9) and then used the resulting distribution on the attractor as the damage indicating feature. In that study, the structure of interest was a nonlinear aeroelastic plate subject to stiffness degradation.

Trendafilova also looked at the local probability structure of data in a health monitoring context [43]. Todd *et al.* used the statistics of local neighborhoods of points on an attractor to detect stiffness degradations in a simulated structure [36]. More specifically, they looked at the average ratio of local attractor variances (ALAVRs) between an undamaged and damaged attractor. This metric was designed to capture damage-induced distortions to the attractor geometry and showed greater sensitivity to the damage than some other metrics. Other metrics derived from attractors include autoprediction error and cross-prediction error [46–48]. Hively and Protopopescu [49] also used a phase space measure of probability to distinguish between healthy and damaged motor-driven systems.

Additionally, some attention has been given to using Lyapunov exponents (LEs) as a damage indicating feature. A system's LEs capture the rate at which trajectories in phase space diverge or converge in each of the phase space directions. The maximal LE was used in [43] in the analysis of a reinforced concrete plate subject to increasing static loads. This metric was also used in [13] in detecting backlash in robot joints. Golnaraghi [50] also used LEs (as well as dimension estimates) in detecting gear damage. Overbey and Todd [37] considered local LEs (and thus, local attractor stability) as a metric for comparison.

4 HIGHER-ORDER SPECTRA

When identifying changes to linear system parameters, the focus is often on the power spectral density of the response data. By the Wiener–Khintchine relations, the power spectral density is simply the Fourier transform of the second moment about the mean (first line of equation (2)). Analogously, Fourier transforms of higher-order cumulants result in higher-order spectra (*see* **Higher Order Statistical Signal Processing** for a more complete discussion). A good example of this is the bispectrum or, its normalized form, the bicoherence. The bispectrum associated with the measured signal $x(t)$ is defined as the double Fourier transform of the third moment about the mean, i.e.,

$$\begin{aligned} B(\omega_1, \omega_2) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} & E[(x(t) - \bar{x}) \\ & \times (x(t+\tau_1) - \bar{x})(x(t+\tau_2) - \bar{x})] \\ & \times \mathrm{e}^{-\mathrm{i}(\omega_1\tau_1 + \omega_2\tau_2)}\, \mathrm{d}\tau_1\, \mathrm{d}\tau_2 \end{aligned} \tag{10}$$

By equation (2), this quantity is nonzero if the process is non-Gaussian. Conversely, a linear structure driven with Gaussian noise has a bispectrum which is zero everywhere. Nonlinearity results in peaks in the bispectrum, which can be used for purposes of detection (see example below). A normalized version of the bispectrum, the bicoherence can similarly be used to detect nonlinearity in non-Gaussian processes (e.g., a linear structure driven with non-Gaussian noise). Rivola and White [51] used the bicoherence to detect cracks in an experimental beam structure while Zhang *et al.* [52] focused on detecting gear faults, both using the bispectrum. The bispectrum was also used to assess the magnitude of a bilinear stiffness nonlinearity, simulating a crack, in a simple spring–mass system [53]. Other higher-order spectra (e.g., the trispectrum) have been considered for damage detection as well [54]; however, the estimation of such spectra remains a difficult challenge. An example of bispectral detection of nonlinearity is presented graphically in Figure 3. The system of interest is a 2-DOF spring–mass–damper structure with $m_1 = m_2 = 1.0$ (kg), $k_1 = k_2 = 1000$ (N m^{-1}) and $c_1 = c_2 = 3.0$ [N·s m^{-1}] and the forcing is taken as a realization of an iid Gaussian process. The governing equations are

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \begin{Bmatrix} \ddot{x}_1 \\ \ddot{x}_2 \end{Bmatrix} + \begin{bmatrix} c_1 & -c_2 \\ -c_2 & c_2 \end{bmatrix} \begin{Bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{Bmatrix} + \begin{bmatrix} k_1 & -k_2 \\ -k_2 & k_2 \end{bmatrix} \begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} = \begin{Bmatrix} 0 \\ \mathcal{N}(0,1) \end{Bmatrix} \tag{11}$$

The stiffness matrix is bilinear in nature, described by

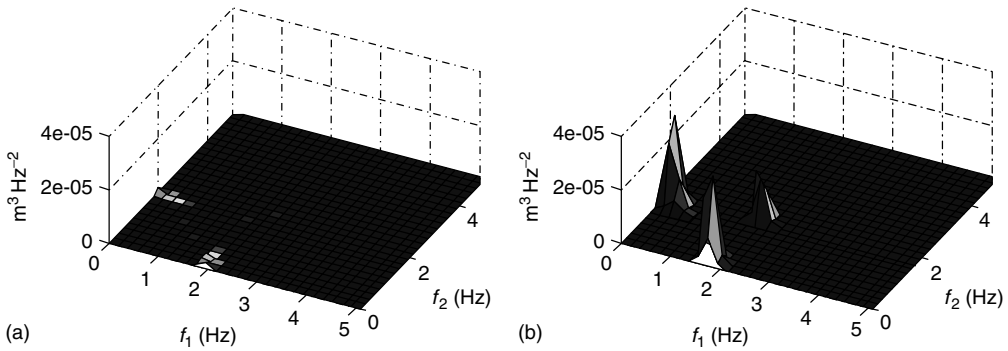

Figure 3. Magnitude bispectrum for a Gaussian driven, 2-DOF structure. (a) Result for the linear system and (b) magnitude bispectrum of the response of the first mass where a bilinear stiffness of 50% was placed in between the masses.

$$k_2(x_2 - x_1) = \begin{cases} k_2(x_2 - x_1) & (x_2 - x_1) \geq 0 \\ \delta k_2(x_2 - x_1) & (x_2 - x_1) < 0 \end{cases} \quad (12)$$

where the parameter $0 < \delta \leq 1$ controls the degree of bilinearity in the stiffness element. For a linear structure, $\delta = 0$ and the bispectrum of the mass 1 response is shown in Figure 3. Using a simple crack model, we allow the damage structure a bilinear stiffness with $\delta = 0.5$. The bispectrum for the bilinear response is also shown in Figure 3. Clearly, the nonlinearity results in nonzero values for the bispectral density, showing peaks at the systems' first resonant frequency. The locations and magnitude of these poles can, in fact, be determined analytically and used to establish the Type-I and Type-II errors of such a detector [55]. The peak height for the magnitude bispectrum is, therefore, a useful nonlinear feature, capable of capturing certain kinds of damage-induced nonlinearity.

5 REFERENCE-FREE APPROACHES TO NONLINEARITY DETECTION

As was stated earlier, damage often results in the presence of a nonlinearity in a structure whose dynamics are otherwise better described by a linear model. There is a potentially large advantage to casting damage detection as a problem of nonlinearity detection, namely, the practitioner can pose the question in the absence of a baseline or reference data set. The null hypothesis of a linear (healthy) structure can be tested at any point in the structure's life and can be accomplished without comparing newly acquired features to those extracted from a pristine structure's response. This is important because effects other than damage often cause changes to the feature being monitored (e.g., temperature and sensor drift). Methods that rely on baseline data sets tend to see these changes as damage and, as a result, suffer from false positives. In the following approaches, any changes that do not influence the underlying model (linear/nonlinear) do not influence the diagnosis.

One promising approach to nonlinearity detection in SHM is the work of Park *et al.* [56, 57]. This work uses high-frequency Lamb waves to interrogate the structure. If the structure is linear, the reflected wave has a certain shape. Damage-induced nonlinearities cause a change in the received signal. The practitioner is testing whether or not the reflected wave comes from a linear or nonlinear model. This diagnosis can, in principle, be made without referencing back to previously acquired data. This approach, therefore, has the benefits mentioned above, namely, the method is not severely influenced by many sources of environmental variability.

There are also several works that make use of a nonlinearity detection scheme referred to as the *method of surrogate data*. This approach was developed by the physics community over the last 15 years and recently applied to the problem of damage detection. The idea is to perform a randomization of the acquired data such that the statistical properties of the data associated with a linear, time-invariant model (the null hypothesis) are preserved while those associated with nonlinearity are destroyed. One can then compare an appropriately chosen feature

computed from the data to those computed from some number of surrogates. If the measured data came from a damaged structure, there will be statistically significant differences in these feature values. If the measured data came from a healthy structure, the surrogate feature values and data feature values will be statistically indistinguishable. This approach has been used by both Trendafilova and Brussel [13] and Nichols *et al.* [27, 58] as a damage-detection strategy.

Algorithms for generating surrogate data are numerous and are tailored to different null hypotheses. The most often used algorithm is the iterative amplitude-adjusted Fourier transform (IAAFT) approach of Schreiber [59]; however, this approach can sometimes lead to a larger than expected number of false rejections of the null. A separate approach that preserves the correct variance among the surrogate population is given by Dolan [60] and is referred to as the digitally filtered, shuffled (DFS) algorithm.

Figure 4 shows some sample results from the bolted-joint experiment of Figure 1. The goal was to detect the bolt loosening using ambient vibrations (excitation was a realization of a process described by the Pierson–Moskowitz distribution for wave height) and in the presence of varying temperature. All data were recorded at a sampling rate of 2 kHz using a fiber-optic strain sensor located on the beam, near the joint. Ten separate time series were collected, each consisting of 2^{15} points, for the clamped beam while six time series (also consisting of 2^{15} points) were collected from the beam in a loosened condition (either finger-tight or loose). Forty surrogates, each made using the aforementioned DFS algorithm, were then generated. The bicoherence function was estimated for both data and surrogates, and the final feature was taken as the average of the estimated bicoherence function over all frequencies. Figure 4 shows the average bicoherence feature, b_{avg}, for the data (cross) and surrogates (dot) for each of the collected time series. The ambient temperature for this experiment, as measured at the beam surface, was 40 °C. Clearly, the response is consistent with a linear model until the joint loosens at which point nonlinearity becomes evident. Figure 4 shows a repeat of the experiment, but with data collected at a surface temperature of 30 °C. This temperature shift altered the beam's natural frequencies for the clamped (undamaged) condition, potentially resulting in false-positive diagnosis for modal-based features. However, the temperature variation does not influence the ability to correctly classify the response as linear (undamaged) or nonlinear (damaged).

6 EXPLOITING NONLINEARITY IN SHM

A number of researchers have attempted to use nonlinearity to their advantage in the damage-detection problem. Yin and Epureanu [61], for example, used nonlinear feedback to enhance the

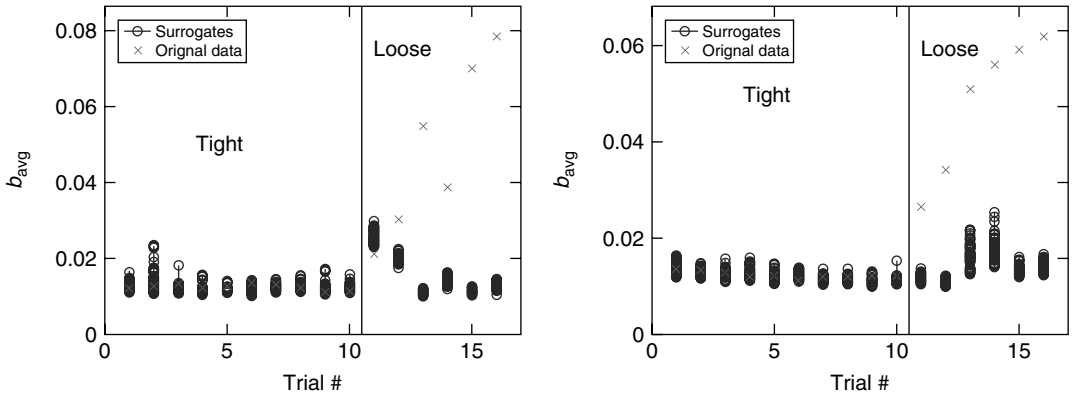

Figure 4. Average bicoherence feature computed for data and surrogates over 16 separate trials. The first 10 trials were with the beam in the fully clamped (linear) condition. The last six trials were for data collected in finger-tight or loose conditions. The data for the two figures were recorded at 40 and 30 °C, respectively. Separation of surrogates from data indicates significant amounts of nonlinearity accompanying the bolt loosening.

sensitivity of their damage-detection approach. The idea is to create a bifurcation point in the system, via feedback control, such that a small change to the parameter of interest (damage) causes a large change in system behavior. This change can then be easily detected.

Another recently developed approach works by tailoring a highly nonlinear forcing function to excite the structure's dynamics. The properties of the forcing are such that damage causes an increase in the dimension (specifically the information dimension that is closely related to the aforementioned correlation dimension) of the response. The relationship between an "undamaged" and "damaged" structure's response, in this case, is conjectured to be nonlinear and, thus, is best captured using a nonlinear feature. Assume the structure's dynamics are governed by a function $F(\cdot)$ and there exists a separate system used to force the structure governed by $G(\cdot)$ and described by the state vector $\mathbf{z}$. The coupled forcing/structure dynamics are given by

$$\begin{aligned} \dot{\mathbf{x}} &= F(\mathbf{x}, \mu) + B\mathbf{z} \\ \dot{\mathbf{z}} &= G(\mathbf{z}) \end{aligned} \tag{13}$$

where B is a constant coefficient matrix that simply couples the structure to the forcing. It can be shown that if the excitation is deterministic and has a positive LE (the dynamics are chaotic), and the Lyapunov exponents of the forcing are in the correct range, the dimension of the response $\mathbf{x}$ changes as the structure's parameter μ changes. More specifically, a change in μ is conjectured to cause a loss of continuity in the function $\phi(\cdot)$ relating an undamaged response $\mathbf{x_u}(n)$ to a "damaged" response $\mathbf{x_d}(n)$, i.e., $\mathbf{x_d}(n) = \phi(\mathbf{x_u})$. Figure 5 illustrates this approach in schematic form. A common drive signal results in two different structural responses (one undamaged, one damaged) that are related by the function ϕ. With an appropriately chosen drive signal, the properties of ϕ are altered by damage. The theorems that underlie this approach are presented in [62–64]. Any metric that can capture the degradation in the continuity of ϕ is a potential damage indicator. To date, several metrics have been tried, including Holder exponents [65], continuity statistics [66], and prediction error [47]. In some cases, this approach can produce improved results over those obtained by more standard combinations

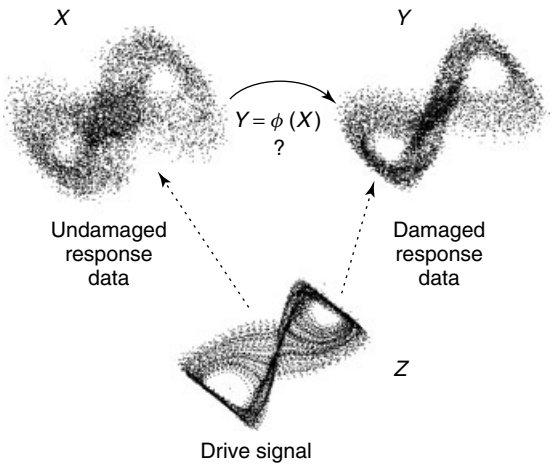

Figure 5. Illustration of the functional relationship between a "damaged" and an "undamaged" response attractor. Capturing the damage-induced changes to this function has produced several viable SHM techniques.

of excitation and feature. The approach is appropriate for linear or nonlinear damage. Other works that focus on the mapping between an undamaged and damaged attractor include those of Chelidze *et al.* [67] and Cusumano *et al.* [68]. In these works, the authors were able to track the battery discharge in a vibrating beam system by tracking changes to the mapping between attractors. More recent work by these authors has led to improvements in the approach, referred to as *phase space warping*. These works are documented in [69, 70].

7 IDENTIFYING THE TYPE OF NONLINEARITY

The problem of nonlinearity detection still poses a number of open questions and will no doubt continue to receive attention. However, some researchers have made progress in identifying the specific type and magnitude of nonlinearity. This is especially valuable if the type and degree of damage is required. Feldman [71, 72] and later Staszewski [73] described an approach for identifying nonlinearity based on the so-called "backbone" curves for a nonlinear system. These curves are obtained via time–frequency analysis and can be used to discern the *form* of the underlying nonlinearity. Feldman then used this approach to detect damage

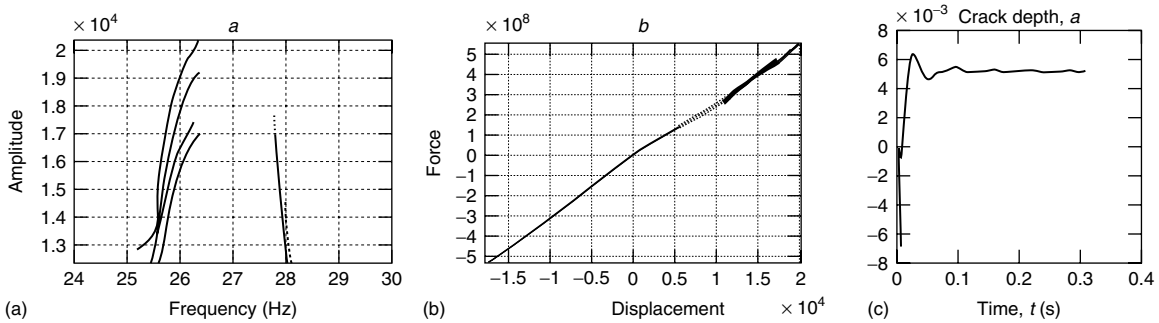

Figure 6. Estimated force characteristic of a crack and notch structure: (a) backbone curve, (b) spring force characteristic, and (c) identification of crack depth. [Reprinted with permission.]

in a rotor system, correctly identifying both the type and location of the defect [32]. This same procedure was also used recently by Tjahjowidodo *et al.* [12] in identifying backlash in a mechanical system.

Figure 6 illustrates Feldman's approach to diagnosing a crack in a rotor system. The first subplot shows the amplitude dependence on frequency, indicating that there exists a nonlinearity. The second plot shows the backbone curve for the rotor system and indicates a slight bilinearity in the stiffness. The final plot demonstrates how the approach detects the size of the crack as a function of time. Relatively few of the existing nonlinear system-identification techniques have been applied to SHM. However, a comprehensive review of system identification for nonlinear structural systems can be found in Worden and Tomlinson [22].

8 SUMMARY

The use of nonlinear features in the SHM problem can be appropriate in a number of instances. These features take advantage of relationships among the response data that are not found in linear systems. The result is that in some cases these features provide a more powerful approach to detecting, quantifying, and locating damage in structures. This article reviews a number of these features, presents the motivation for using them, and describs the context in which they were used. The list is not exhaustive, but should give the reader a good feel for the types of features that have been used to date.

Chapter 33

Dimensionality Reduction Using Linear and Nonlinear Transformation

Gaëtan Kerschen and Jean-Claude Golinval

Aerospace and Mechanical Engineering Department (LTAS), University of Liège, Liège, Belgium

1 INTRODUCTION

In many domains of applied sciences, dealing with large data sets is a central issue. In structural dynamics and particularly in large civil infrastructure applications, densely distributed sensors are required for reliable health monitoring procedures. With the recent advances in communication technology, wireless monitoring systems have emerged as a promising and practical solution in this context [1–3]. There is, therefore, a clear trend toward very large experimental data sets, and dimensionality reduction has become an important step of structural health monitoring [4].

Many dimensionality reduction techniques have been proposed in the statistical literature. The present article is biased toward one popular technique, called *proper orthogonal decomposition* (*POD*). This method may serve two purposes, namely, order reduction by projecting high-dimensional data onto a lower dimensional space and feature extraction by revealing relevant but unexpected structure hidden in the data. The key idea of the POD is to reduce a large number of interdependent variables to a much smaller number of uncorrelated variables while retaining as much as possible of the variation in the original variables. An orthogonal transformation to the basis of the eigenvectors of the sample covariance matrix is performed, and the data are projected onto the subspace spanned by the eigenvectors corresponding to the largest eigenvalues. This transformation decorrelates the signal components and maximizes variance.

The most striking property of the POD is its optimality in the sense that it minimizes the average squared distance between the original signal and its reduced linear representation. Although it is frequently applied to nonlinear problems, it should be borne in mind that the POD only gives the optimal approximating linear manifold in the space represented by the data. As stated in [5], the

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

POD is "a safe haven in the intimidating world of nonlinearity; it may not do the physical violence of linearization methods".

This article is organized as follows. In the next section, the POD method is briefly presented, and the different means of computing this decomposition are described. Section 3 introduces two nonlinear extensions of the POD, namely, a global approach called *nonlinear principal component analysis* (*NLPCA*) and a local approach called *vector quantization principal component analysis* (*VQPCA*). Finally, reduced-order modeling and damage detection under varying environmental conditions are discussed in Section 4.

2 PROPER ORTHOGONAL DECOMPOSITION

2.1 Brief historical perspective

The POD, also known as the *Karhunen–Loève decomposition* (*KLD*), was proposed independently by several scientists including Karhunen, Kosambi, Loève, Obukhov, and Pougachev and was originally conceived in the framework of continuous second-order processes. When restricted to a finite dimensional case and truncated after a few terms, the POD is equivalent to principal component analysis (PCA) [6]. This latter methodology originated not only with the work of Pearson [7] as a means of fitting planes by orthogonal least squares but was also proposed by Hotelling [8]. It is emphasized that the method appears in various guises in the literature and is known by other names depending on the area of application, namely, PCA in the statistical literature, empirical orthogonal function in oceanography and meteorology, and factor analysis in psychology and economics. The reader can refer to [9, 10] for a detailed discussion about the equivalence of the POD, PCA, and KLD, and their connection with the singular value decomposition (SVD).

Because of the large amount of computations required to find the POD modes, the technique was virtually unused until the middle of the twentieth century. Radical changes came with the appearance of powerful computers. The POD has now gained popularity and is being used in numerous fields (e.g., biomedical engineering, forecasting in meteorology, classification of speech data, image processing, and chemical engineering). The first applications of the POD in the field of structural dynamics date back to the 1990s [11, 12].

The POD now enjoys various applications in structural dynamics, such as active control [13], dynamic characterization [14–16], finite element model updating [17, 18], modal analysis [19, 20], model order reduction [21–24], and stochastic structural dynamics [25]. Recently, the POD has also been used for damage detection [26–35] and sensor validation [36].

2.2 Mathematical formulation

The mathematical formulation of the POD presented here closely follows the one in [37]. Let $\theta(x,t)$ be a random field on a domain Ω. This field is first decomposed into mean $\mu(x)$ and time varying parts $\vartheta(x,t)$:

$$\theta(x,t) = \mu(x) + \vartheta(x,t) \tag{1}$$

At time t_k, the system displays a snapshot $\vartheta^k(x) = \vartheta(x,t_k)$. The POD aims at obtaining the most characteristic structure $\varphi(x)$ of an ensemble of snapshots of the field $\vartheta(x,t)$. This is equivalent to finding the basis function $\varphi(x)$ that maximizes the ensemble average of the inner products between $\vartheta^k(x)$ and $\varphi(x)$:

$$\text{Maximize} \quad \langle |(\vartheta^k, \varphi)|^2 \rangle \quad \text{with } \|\varphi\|^2 = 1 \tag{2}$$

where $(f,g) = \int_\Omega f(x)g(x)\,\mathrm{d}\Omega$ denotes the inner product in Ω; $\langle\cdot\rangle$ denotes the averaging operation; $\|\cdot\| = (\cdot,\cdot)^{1/2}$ denotes the norm; and $|\cdot|$ denotes the modulus. Expression (2) means that if the field ϑ is projected along φ, the average energy content is greater than if the field is projected along any other basis function.

The constraint $\|\varphi\|^2 = 1$, imposed to make the computation unique, can be taken into account by the use of a Lagrange multiplier

$$J[\varphi] = \langle |(\vartheta, \varphi)|^2 \rangle - \lambda \left(\|\varphi\|^2 - 1 \right) \tag{3}$$

The extremum is reached when the functional derivative is equal to zero. Holmes *et al.* [37] shows that this condition reduces to the following integral

eigenvalue problem:

$$\int_{\Omega} \langle \vartheta^k(x)\vartheta^k(x')\rangle \varphi(x')\,\mathrm{d}x' = \lambda\varphi(x) \tag{4}$$

where $\langle \vartheta^k(x)\vartheta^k(x')\rangle$ is the averaged autocorrelation function.

The solution of the optimization problem (2) is thus given by the orthogonal eigenfunctions $\varphi_i(x)$ of the integral equation (4), called the *proper orthogonal modes* (POMs) or POD modes. The corresponding eigenvalues λ_i ($\lambda_i \geq 0$) are the proper orthogonal values (POVs). The POMs may be used as a basis for the decomposition of the field $\vartheta(x,t)$:

$$\vartheta(x,t) = \sum_{i=1}^{\infty} a_i(t)\varphi_i(x) \tag{5}$$

where the coefficients $a_i(t)$ are uncorrelated, i.e., $\langle a_i(t)a_j(t)\rangle = \delta_{ij}\lambda_i$, and are determined by $a_i(t) = (\vartheta(x,t), \varphi_i(x))$.

The POM associated with the greatest POV is the optimal vector to characterize the ensemble of snapshots. The POM associated with the second greatest POV is the optimal vector to characterize the ensemble of snapshots but restricted to the space orthogonal to the first POM, and so forth. The energy ε contained in the data is defined as the sum of the POVs, i.e., $\varepsilon = \sum_j \lambda_j$, and the energy percentage captured by the ith POM is given by $\lambda_i / \sum_j \lambda_j$.

We note that a physical interpretation of the POMs in a structural dynamics context has been provided in [38, 39].

2.3 Practical computation

In practice, the data are discretized in space and time. Accordingly, n observations of an m-dimensional vector $\mathbf{x}$ are collected, and an $(m \times n)$ response matrix is formed:

$$\mathbf{X} = \begin{bmatrix} \mathbf{x}_1 & \dots & \mathbf{x}_n \end{bmatrix} = \begin{bmatrix} x_{11} & \cdot & x_{1n} \\ \cdots & \cdots & \cdots \\ x_{m1} & \cdots & x_{mn} \end{bmatrix} \tag{6}$$

The purpose of this section is to present several means of computing the POD.

2.3.1 Eigensolutions of the sample covariance matrix

Since the data are now discretized and do not necessarily have a zero mean, the averaged autocorrelation function is replaced by the covariance matrix $\boldsymbol{\Sigma} = E\left[(\mathbf{x}-\boldsymbol{\mu})(\mathbf{x}-\boldsymbol{\mu})^{\mathrm{T}}\right]$, where $E[\cdot]$ is the expectation, and $\boldsymbol{\mu} = E[\mathbf{x}]$ is the mean of the vector $\mathbf{x}$. Under the assumption that the process is stationary and ergodic and that the number of time instants is large, a reliable estimate of the covariance matrix is given by the sample covariance matrix

$$\boldsymbol{\Sigma}_{\mathrm{S}} = \frac{1}{n}\begin{Bmatrix} \left\{\sum_{j=1}^{n}\left(x_{1j} - \frac{1}{n}\sum_{k=1}^{n} x_{1k}\right)^2\right\} & \cdots & \left\{\sum_{j=1}^{n}\left(x_{1j} - \frac{1}{n}\sum_{k=1}^{n} x_{1k}\right)\left(x_{mj} - \frac{1}{n}\sum_{k=1}^{n} x_{mk}\right)\right\} \\ \cdots & \cdots & \cdots \\ \left\{\sum_{j=1}^{n}\left(x_{mj} - \frac{1}{n}\sum_{k=1}^{n} x_{mk}\right)\left(x_{1j} - \frac{1}{n}\sum_{k=1}^{n} x_{1k}\right)\right\} & \cdots & \left\{\sum_{j=1}^{n}\left(x_{mj} - \frac{1}{n}\sum_{k=1}^{n} x_{mk}\right)^2\right\} \end{Bmatrix} \tag{7}$$

The POMs and POVs are thus characterized by the eigensolutions of the sample covariance matrix $\mathbf{\Sigma}_S$. If the data have a zero mean, the sample covariance is merely given by the following expression:

$$\mathbf{\Sigma}_S = \frac{1}{n}\mathbf{X}\mathbf{X}^T \tag{8}$$

It should be noted that when the number of degrees of freedom is much higher than the number of snapshots (e.g., in turbulence theory), the computation of the sample covariance matrix may become expensive. In this context, the POD modes are most easily computed using the method of snapshots proposed by Sirovich [40].

2.3.2 Singular value decomposition of the response matrix

For any real $(m \times n)$ matrix $\mathbf{X}$ (i.e., for our purpose, the response matrix measured about its mean), there exists a real factorization called the *singular value decomposition* that can be written as

$$\mathbf{X} = \mathbf{U}\mathbf{S}\mathbf{V}^T \tag{9}$$

where $\mathbf{U}$ is an $(m \times m)$ orthonormal matrix containing the left singular vectors; $\mathbf{S}$ is an $(m \times n)$ pseudodiagonal and semipositive definite matrix with diagonal entries containing the singular values σ_i and $\mathbf{V}$ is an $(n \times n)$ orthonormal matrix containing the right singular vectors.

Reliable algorithms have been developed to compute the SVD. The SVD may also be calculated by solving two eigenvalue problems, or even one if only the left or the right singular vectors are required. Indeed,

$$\begin{aligned}\mathbf{X}\mathbf{X}^T &= \mathbf{U}\mathbf{S}^2\mathbf{U}^T \\ \mathbf{X}^T\mathbf{X} &= \mathbf{V}\mathbf{S}^2\mathbf{V}^T\end{aligned} \tag{10}$$

According to equation (10), the singular values of $\mathbf{X}$ are found to be the square roots of the eigenvalues of $\mathbf{X}\mathbf{X}^T$ or $\mathbf{X}^T\mathbf{X}$. In addition, the left and right singular vectors of $\mathbf{X}$ are the eigenvectors of $\mathbf{X}\mathbf{X}^T$ and $\mathbf{X}^T\mathbf{X}$, respectively. The POMs, defined as the eigenvectors of the sample covariance matrix $\mathbf{\Sigma}_S$ (8), are thus equal to the left singular vectors of $\mathbf{X}$. The POVs, defined as the eigenvalues of matrix $\mathbf{\Sigma}_S$, are the square of the singular values divided by the number of samples m.

The main advantage in considering the SVD to compute the POD instead of the eigenvalue problem described in Section 2.3.1 is that additional information is obtained through the matrix $\mathbf{V}$. The column $\mathbf{v}_i$ of matrix $\mathbf{V}$ contains the time modulation of the corresponding POM $\mathbf{u}_i$, normalized by the singular value σ_i. This information provides important insight into the system dynamics and plays a prominent role in the model updating of nonlinear systems [18].

2.3.3 A simple learning rule

Consider the following simple iterative scheme [41]:

$$\begin{aligned}y &= \mathbf{x}^T\mathbf{w} \\ \Delta\mathbf{w} &= \mathbf{w}_{(j+1)} - \mathbf{w}_{(j)} \\ &= \alpha\left(y_{(j)}\mathbf{x}_{(j)} - {y_{(j)}}^2\mathbf{w}_{(j)}\right)\end{aligned} \tag{11}$$

where $\mathbf{x}$ is the vector containing the inputs; $\mathbf{w}$ is the vector containing the weights; y is the output; α is the learning rate controlling the speed of convergence; and $\ldots_{(j)}$ refers to the result of the jth iteration.

After convergence, the expectation of the weight update $\Delta\mathbf{w}$ is equal to zero:

$$\begin{aligned}E[\Delta\mathbf{w}] &= E[\alpha(y\mathbf{x} - y^2\mathbf{w})] \\ &= \alpha E\left[\mathbf{x}\mathbf{x}^T\mathbf{w} - \mathbf{w}^T\mathbf{x}\mathbf{x}^T\mathbf{w}\mathbf{w}\right] \\ &= \alpha\left(\mathbf{\Sigma}\mathbf{w} - \mathbf{w}^T\mathbf{\Sigma}\mathbf{w}\mathbf{w}\right) = 0\end{aligned} \tag{12}$$

and,

$$\mathbf{\Sigma}\mathbf{w} = \left(\mathbf{w}^T\mathbf{\Sigma}\mathbf{w}\right)\mathbf{w} = \lambda\mathbf{w} \tag{13}$$

where $\mathbf{\Sigma} = E[\mathbf{x}\mathbf{x}^T]$ is the covariance matrix of $\mathbf{x}$ that is assumed to be zero mean. As can be seen from equation (13), the weights converge to an eigenvector of the covariance matrix; i.e., a POM. In fact, it can be shown that they approach the eigenvector with the largest eigenvalue. This scheme can easily be generalized to extract the first k POMs.

2.3.4 Autoassociative neural networks

The POD can also be computed using autoassociative neural networks (AANN). An artificial neural

network is a computational system inspired by the learning characteristics and the structure of biological neural networks [42]. The type of neural network considered here is composed of a series of parallel layers, each of which contains a number of processing elements analogous to neurons. The neurons are tied together with weighted connections that are analogous to synapses. The network has distinguished input and output neurons, and all other neurons are called *hidden neurons*. Each neuron computes a weighted sum of its inputs, and its resulting output is a well-defined function of the weighted sum. The outputs of the ith layer are used as inputs to the $(i+1)$th layer. If $y_j^{(i)}$ is the output of the jth neuron of the ith layer, then

$$y_k^{(i+1)} = \sigma^{(i+1)}\left(\sum_j w_{kj}^{(i+1)} y_j^{(i)} + b_k^{(i+1)}\right) \quad (14)$$

is the output of the kth neuron of the $(i+1)$th layer. The elements w_{kj} and b_k are referred to as *weights* and *biases*, respectively, and $\sigma(\cdot)$ is a linear or nonlinear transfer function.

AANNs are those in which the target output pattern is identical to the input pattern. The aim is thus to approximate, as closely as possible, the input data itself. When used with a hidden layer smaller than the input and output layers, a perfect reconstruction of all input data is generally not possible.

An AANN with linear activation functions performs a compression scheme equivalent to the POD [43]. To this end, let us consider an AANN with a single hidden unit and a linear activation function as shown in Figure 1. The sum of squares error (SSE) function for this network is given by the following equation:

$$\begin{aligned} SSE &= \tfrac{1}{2}(\mathbf{x}-\hat{\mathbf{x}})^{\mathrm{T}}(\mathbf{x}-\hat{\mathbf{x}}) \\ &= \tfrac{1}{2}(\mathbf{x}-y\mathbf{w})^{\mathrm{T}}(\mathbf{x}-y\mathbf{w}) \end{aligned} \quad (15)$$

The derivative of the error function is

$$\begin{aligned} \frac{\partial(SSE)}{\partial \mathbf{w}} &= -\left(\frac{\partial y}{\partial \mathbf{w}}\mathbf{w} + y\frac{\partial \mathbf{w}}{\partial \mathbf{w}}\right)(\mathbf{x}-y\mathbf{w}) \\ &= -\left(\mathbf{x}^{\mathrm{T}}\mathbf{w} + y\right)(\mathbf{x}-y\mathbf{w}) \\ &= -2y(\mathbf{x}-y\mathbf{w}) \end{aligned} \quad (16)$$

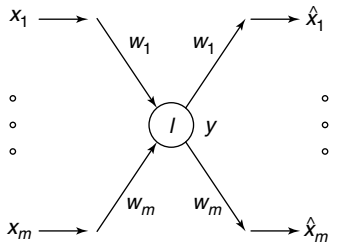

Figure 1. An autoassociative neural network with a single hidden unit with a linear activation function.

and the weight update becomes

$$\Delta\mathbf{w} = -\alpha\frac{\partial(SSE)}{\partial \mathbf{w}} = 2\alpha(y\mathbf{x} - y^2\mathbf{w}) \quad (17)$$

This latter expression is equivalent to learning rule (11), which demonstrates the ability of the neural network to perform the POD. Although neural networks offer no direct advantage over other means of computing the POD, they suggest an interesting nonlinear generalization, as detailed in the next section.

3 NONLINEAR GENERALIZATIONS OF PROPER ORTHOGONAL DECOMPOSITION

The linear nature of the POD may represent a restriction for some data sets. For instance, the covariance matrix of data sampled from a helix in $\mathbb{R}^3$ has full rank, and the POD requires the use of three variables for the description of the data. However, the helix is a one-dimensional manifold and can be smoothly parameterized with a single variable.

The POD can thus determine an appropriate embedding space for given data, but it cannot provide the most efficient description of a data set where nonlinear dependencies are present. To address this issue, researchers in the field of statistics and neural networks have developed alternatives to the POD that can take nonlinear correlations between the variables into account. NLPCA [44] and VQPCA [45] are two interesting alternatives that are briefly described in the following subsections.

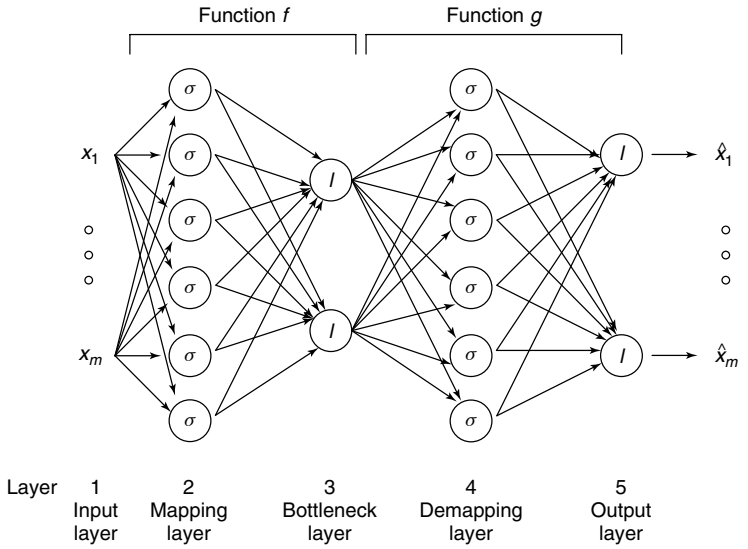

Figure 2. Network architecture for implementation of NLPCA (σ = sigmoidal transfer function, l = linear transfer function).

3.1 A global approach

Generally speaking, a dimension reduction technique provides an approximation to a data set, which is the composition of two functions f and g:

$$\mathbf{x} = \hat{\mathbf{x}} + \boldsymbol{\rho} = g(f(\mathbf{x}(t))) + \boldsymbol{\rho} \tag{18}$$

The projection function $f: \mathbb{R}^m \rightarrow \mathbb{R}^r$ projects the original m-dimensional data onto an r-dimensional subspace, whereas the expansion function $g: \mathbb{R}^r \rightarrow \mathbb{R}^m$ defines a mapping from an r-dimensional space back into the original m-dimensional space with $\boldsymbol{\rho}$ as the residue. Dimensionality reduction involves the determination of adequate functions f and g.

As the POD can be computed using AANNs with linear activation functions (Section 2.3.4), the most obvious generalization of the POD would be to consider nonlinear transfer functions in the hidden layer. However, a much better compression can be obtained by exploiting a theorem due to Cybenko [46]. It states that a three-layer neural network with m input neurons, nonlinear transfer functions in the second layer, and linear transfer functions in the third layer of r neurons can approximate to arbitrary accuracy any continuous functions from $\mathbb{R}^m$ to $\mathbb{R}^r$. This is true, provided that the number of neurons in the second layer is sufficiently large. This theorem suggests the use of a three-layer network to recover projection function f and the use of another three-layer network to recover expansion function g. The resulting five-layer network, which implements NLPCA, is shown in Figure 2.

A crucial step when using a neural network is the training phase. The neural network parameters (i.e., the weights and biases) are updated iteratively until the output of the network approximates the input as closely as possible. Eventually, this results in minimum information loss in the same sense as in the POD.

For further details about NLPCA, the reader can refer to [44]. In structural dynamics, NLPCA has been exploited for separating the structural changes from the changes caused by the environment in a damage detection context [47], for finite element model updating [48] and for sensor validation and reconstruction [49].

3.2 A local approach

The POD and NLPCA try to describe all the data using the same global features. An alternative paradigm is to capture data complexity by a combination of local linear POD projections. A local

model implementation of the POD involves a two-step procedure, i.e.,

1. a clustering of the data space into distinct regions by vector quantization;
2. the construction of separate low-dimensional coordinate systems in each local region using the POD.

The VQPCA algorithm is an extension of a standard vector quantizer [45]. VQPCA partitions the input space into a set of regions and approximates each region by a hyperplane defined by the POD, while a standard vector quantizer approximates each region by a codebook vector. The VQPCA algorithm is as follows:

1. Partition $\mathbb{R}^m$ into q disjoint regions $S_1, \ldots, S_q$ with a nearest neighbor approach using the Euclidean distance as the distortion function (other distortion functions can also be used [50]).
2. For each Voronoi cell S_j and its corresponding centroid $\boldsymbol{\mu}_j$, estimate the local covariance matrix

$$\boldsymbol{\Sigma}_j = \frac{1}{N_j} \sum_{\mathbf{x} \in S_j} (\mathbf{x} - \boldsymbol{\mu}_j)(\mathbf{x} - \boldsymbol{\mu}_j)^{\mathrm{T}} \qquad (19)$$

   where N_j is the number of vectors mapped to S_j. Next, compute the eigenvectors $(\mathbf{p}_{j1}, \ldots, \mathbf{p}_{jr})$ of each matrix $\boldsymbol{\Sigma}_j$.
3. To reduce the dimension of any m-dimensional vector $\mathbf{x}_i$, determine the cell S_j, which contains the vector and project $\mathbf{x}_i$ onto the r leading eigenvectors to obtain the local linear coordinates

$$\begin{aligned} \mathbf{z}_i &= f_j(\mathbf{x}_i) = [\mathbf{p}_{j1} \ldots \mathbf{p}_{jr}]^{\mathrm{T}} (\mathbf{x}_i - \boldsymbol{\mu}_j) \\ &= \begin{bmatrix} \mathbf{p}_{j1}^{\mathrm{T}} (\mathbf{x}_i - \boldsymbol{\mu}_j) \\ \vdots \\ \mathbf{p}_{jr}^{\mathrm{T}} (\mathbf{x}_i - \boldsymbol{\mu}_j) \end{bmatrix} \qquad \text{if } \mathbf{x}_i \in S_j \end{aligned} \qquad (20)$$

   The compressed representation of $\mathbf{x}_i$ consists of the index j of the Voronoi cell in which $\mathbf{x}_i$ lies and the r-dimensional vector $\mathbf{z}_i$. The data are reconstructed from this representation according to

$$\begin{aligned} \hat{\mathbf{x}}_i &= g_j(f_j(\mathbf{x}_i)) = g_j(\mathbf{z}_i) \\ &= \boldsymbol{\mu}_j + [\mathbf{p}_{j1} \ldots \mathbf{p}_{jr}] \mathbf{z}_i \end{aligned} \qquad (21)$$

   The accuracy of the compressed representation is assessed using the normalized mean square error (MSE):

$$MSE = \frac{E[\|\mathbf{x} - \hat{\mathbf{x}}\|^2]}{E[\|\mathbf{x} - E[\mathbf{x}]\|^2]} \qquad (22)$$

For further details about VQPCA, the reader can refer to [45]. In structural dynamics, VQPCA has been exploited for model reduction [51] and for separating the structural changes from the changes caused by the environment (e.g., temperature) for damage detection purposes [52].

4 APPLICATION EXAMPLES

4.1 Reduced-order modeling

A number of studies in the technical literature have shown that the POD provides a suitable basis for reduced-order modeling in structural dynamics (e.g., [14, 23]). We also aim to demonstrate herein the efficiency of a nonlinear dimensionality reduction technique such as VQPCA with respect to the classical POD. To this end, the reconstruction of the dynamical response of a nonlinear cantilever beam is taken as an example. As shown in Figure 3, the clamped beam is modeled with seven beam elements, and the local nonlinearity k_{nl} is a spring that exhibits a cubic stiffness. The free vibration of the beam is simulated with an initial displacement given by a static force F_0 applied at the end of the beam.

The data set consists of seven vertical accelerations measured along the beam. The POD, which is equivalent to VQPCA with a single Voronoi cell, is first applied to the data. In a second step, the data are reconstructed using VQPCA with a number of

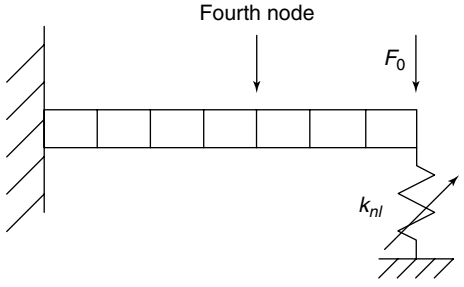

Figure 3. Model of the nonlinear beam.

Table 1. POD and VQPCA applied to the nonlinear beam example

Number of regions	MSE (%) 1 modes	MSE (%) 2 modes	MSE (%) 3 modes	MSE (%) 4 modes
1 (POD)	31.75	9.15	3.53	0.010
5	17.45	7.30	1.52	0.009
10	12.34	5.09	1.18	0.008
20	6.72	2.85	0.83	0.006
30	5.69	2.08	0.60	0.004

regions varying from 5 to 30. Table 1 summarizes the respective performance of the POD and VQPCA in terms of compression accuracy measured by the MSE. It is clear that VQPCA provides a more accurate representation of the system response than POD. For instance, for a unimodal representation, VQPCA with 20 cells attains about 80% lower error than POD and is still a better approximation than a bimodal POD representation.

4.2 Damage detection under varying environmental conditions

In addition to their dimensionality reduction capabilities, the POD and its nonlinear generalizations may also be used to eliminate the influence of environmental conditions in a damage detection context, and this without measuring the environmental variables. The basic idea of the methodology is to collect data on the healthy structure during a sufficiently long period of time, so that a reduced-order model capturing the environmental effects can be built. Eventually, this model can be used for a robust monitoring of the structural health under varying environmental conditions.

To illustrate the method, a geometric interpretation is presented in a two-dimensional case, i.e., when two features (e.g., the first two natural frequencies y_1, y_2 of a structure) are considered. As shown in Figure 4, the features collected on the healthy structure (represented by circles) are distributed around their geometric center (point O'). It is assumed that environmental variations are mainly responsible for the dispersion of the features. The application of the POD to this data set gives two POMs, namely, POM-I and POM-II. We note that the mean is not subtracted from the original data, for reasons explained in [31]. The first POM is associated with the highest singular value and is responsible for the largest variation of the features; it corresponds to the main environmental factor (or a combined effect of several factors). The second POM represents the effect of secondary factors. Considering point Y as an example, we first project this 2-D data onto the 1-D space spanned by the first POM. It results in a scalar equal to the length of segment $\overrightarrow{OX_1}$. Remapping this data point into the original 2-D space results in point Y_1, and

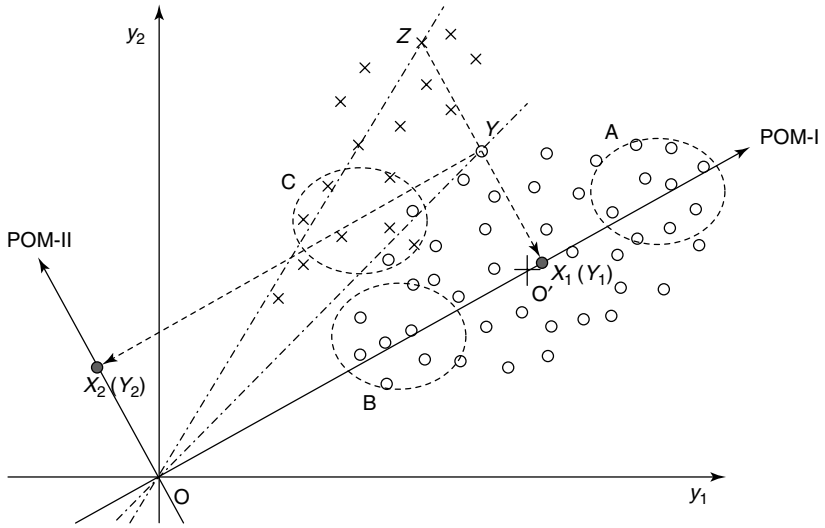

Figure 4. Geometric interpretation of the damage detection procedure under varying environmental conditions.

the corresponding residual error is measured by the length of segment $\overrightarrow{YY_1}$.

Let us now examine another set of identified features, indicated by the symbol X in Figure 4 and obtained from the damaged structure, still under varying environmental conditions. One inherent assumption of the proposed methodology is that the functional relationship between the features and damage is different from that between the features and the environmental factors. Considering point Z as an example, by using a similar projection process as for Y, the residual error $\overrightarrow{ZY_1}$ increases significantly with respect to $\overrightarrow{YY_1}$. In such a comparison between healthy and damaged states, the effect of the environmental factors has therefore been taken into account.

A damage indicator, the novelty index (NI), can be defined as the Euclidean norm of the computed residual error [53]. Defining $\overline{NI}$ and σ as the mean value and standard deviation of the NI for the prediction in the reference state, respectively, an X-bar control chart is constructed by drawing a centerline at $\overline{NI}$ and one additional horizontal line corresponding to the upper control limit, $UCL = \overline{NI} + 3\sigma$, which corresponds to a confidence interval of 99.7% in the case of a normal distribution. The presence of data above this control limit is potentially an indication of damage.

The POD and VQPCA algorithms were applied in [52] to experimental data resulting from 305 days of continuous monitoring of the Z24 bridge. During the monitoring period, accelerations were measured every hour on the structure, and modal parameters were identified automatically. From the first day of monitoring to the 268th day, the structure could be

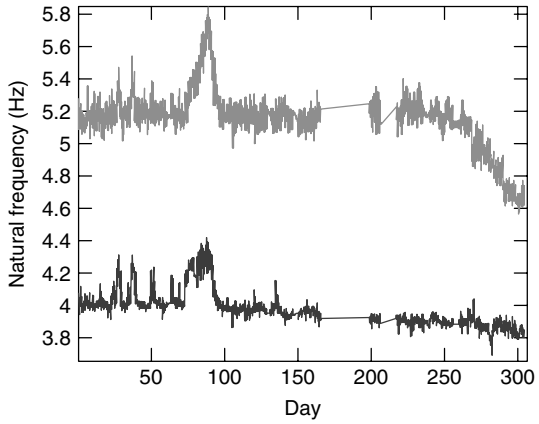

Figure 5. First two natural frequencies of the Z24 bridge during the monitoring period.

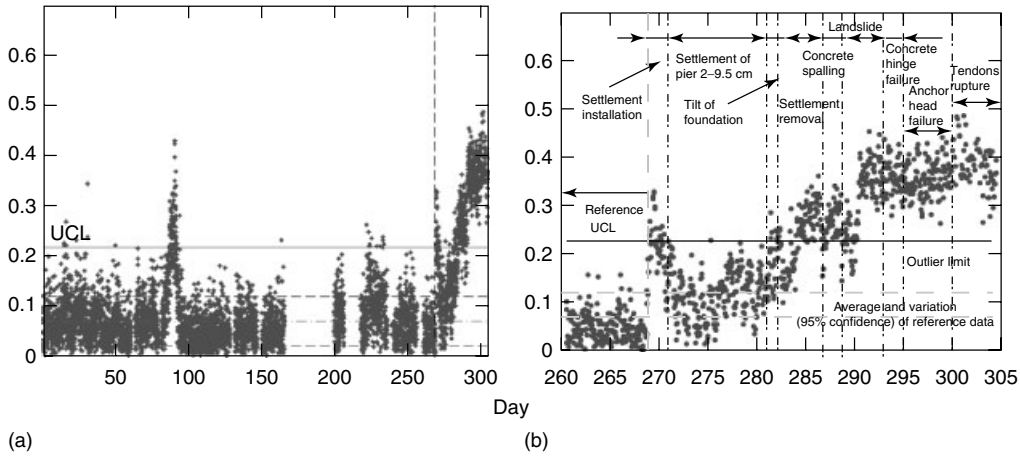

Figure 7. Damage detection results under varying environmental conditions. (a) POD; (b) close-up.

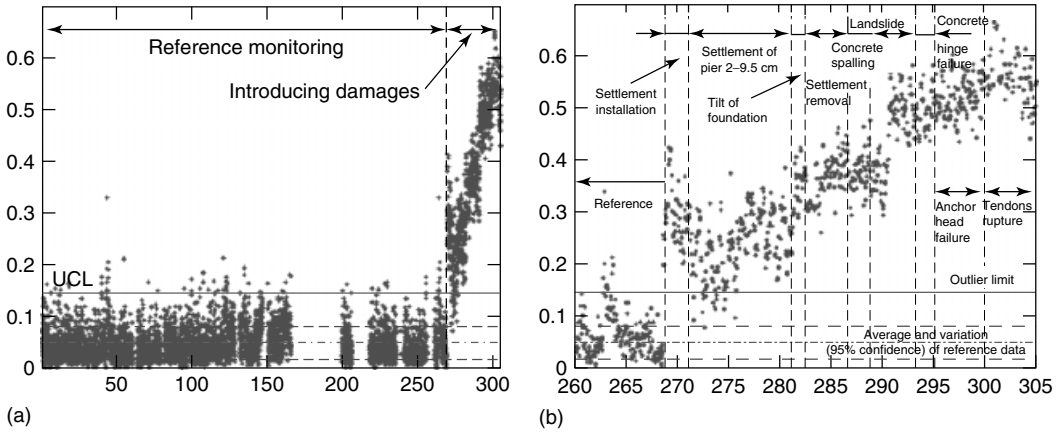

Figure 8. Damage detection results under varying environmental conditions. (a) VQPCA; (b) close-up.

assumed healthy; after the 268th day, the bridge was subjected to a series of realistic damage cases including pier settlement, concrete spalling, and tendons rupture.

One particularly challenging aspect of this application example is that the monitoring was performed under varying environmental conditions. A close look at the identified vibration features reveals that the natural frequencies of the first modes vary significantly with temperature (Figure 5). It was found that the asphalt layer on the bridge surface played a different role during warm and cold periods, which, in turn, caused the observed behavior. More precisely, the first four natural frequencies were shown to have a bilinear relation in function of the temperature, with a turning point at $0\,^{\circ}$C (Figure 6 for two-dimensional projections of this four-dimensional space).

The POD was first applied to the Z24 bridge data. The control chart together with a close-up is shown in Figure 7. A small incursion above the *UCL* is observed around the 270th day. The NI crosses the *UCL* for good after the 280th day, and the presence of a damage is detected. The results are therefore fairly satisfactory. However, outliers also appear between the 80th and 90th day, during which very cold weather caused freezing of the asphalt layer on the bridge surface.

To improve the results, VQPCA was then applied to the same data. Because of the bilinear relation between the first four natural frequencies, the space

was partitioned into two subregions, as indicated by the black solid lines in Figure 6. The comparison of the results obtained using VQPCA (Figure 8) and the POD (Figure 7) reveals two significant improvements:

- The abnormality between the 80th and 90th day disappears, because the nonlinear relation between the natural frequencies is effectively taken into account by the VQPCA method.
- The NI crosses the UCL after the 268th day, i.e., directly after the application of the damage and (aside from a few points) remains above this limit afterward. The VQPCA-based method is therefore more sensitive to damage.

5 CONCLUSION

With a clear trend toward very large data sets to analyze, dimensionality reduction has become an important step of structural health monitoring. In this context, the POD method is simple, fast, and efficient, which makes it a meaningful addition to the structural dynamicist's toolbox. This article has shown that when the linear nature of the POD is an important restriction, the VQPCA and NLPCA algorithms represent an interesting alternative to the POD for reduced-order modeling and feature extraction.

Chapter 29
Higher Order Statistical Signal Processing

Paul White
Institute of Sound and Vibration Research, University of Southampton, Southampton, UK

1 INTRODUCTION

Spectral analysis is one of the most powerful and widely used tools in engineering (*see also* **Statistical Time Series Methods for SHM**). Thus, it is not surprising that it is a key tool in structural health monitoring (SHM). For example, single-channel spectral analysis of vibration data can allow one to measure modal frequencies and estimate damping parameters under the assumption that the excitation is broadband. Monitoring such response data over a period of time can allow one to identify changes within a structure. Identification of such changes does not usually lead to an effective SHM methodology, since it can be difficult to ensure that changes observed are the consequence of damage and not the result of benign processes that do not affect a structure's integrity.

This article considers the extension of classical spectral analysis into the so-called higher orders. Such methods are referred to as HOS, which is an acronym taken to interchangeably mean either *higher order statistics* or *higher order spectra*. Similar to spectral analysis, HOS is concerned with the analysis of stationary random processes. Extensions to both spectral analysis (*see also* **Time–frequency Analysis**; **Wavelet Analysis**) and HOS [1] for nonstationary signals exist, but are not considered here.

Classical spectral (and correlation) analysis is based on an analysis of a signal's power; the power is equivalent to the signal's variance. For a zero mean signal,[a] the variance is the average of the square of the signal; see equation (1). It is because of this squaring operation that we refer to classical spectral analysis as being based on the signal's second-order statistics. HOS extends the principles of spectral and correlation analyses to orders higher than 2.

In dealing with second-order statistics, spectral analysis is intimately linked to stationary Gaussian random processes. A Gaussian random process is a signal whose amplitude is distributed according to a Gaussian, or normal, distribution. A jointly Gaussian process is a signal in which the joint probability density function for pairs of the signal points separated by a fixed interval is also Gaussian. One can construct examples of stationary processes

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

that are Gaussian, but not jointly Gaussian; however, such examples are pathological. We shall assume that Gaussianity implies joint Gaussianity.

Second-order statistics are important to stationary, zero mean, Gaussian random processes since such processes are completely described through knowledge of their second-order statistics. The implication of this is that if a process is Gaussian then the spectrum, evaluated with sufficient resolution, completely characterizes that signal. Hence, considering statistics of order greater than 2 is only valuable when applied to non-Gaussian processes. As an illustration of this: it is always possible to construct a Gaussian process with the same spectrum as a given non-Gaussian process. Such processes would be indistinguishable from each other using second-order statistics, but, in general, their HOS will be different.

Gaussian signals are examples of stable distributions [2], meaning that the output of any linear system excited by a Gaussian input is itself Gaussian. Thus, when analyzing response signals that are Gaussian, it is common to assume that the input was Gaussian and that the system is linear. If the response signal is non-Gaussian, it is common to model the signal in one of two ways. Firstly, the signal can be modeled as the output of a linear system whose input is non-Gaussian. Secondly, one might assume that the input is Gaussian and the system is nonlinear. Evidently, there is no physical reason why the input cannot be non-Gaussian and the system nonlinear, but, in practice, this combination leads to system problems that are ill-posed, which can only be solved if additional information is available.

One use of HOS in SHM is based on determining whether or not a signal is Gaussian. The distinction between Gaussian and non-Gaussian processes can become important in SHM because in many cases the presence of a fault within a structure may result in the response of the structure being nonlinear. Such nonlinearities produce responses that are, in almost all cases, non-Gaussian. By detecting and characterizing the non-Gaussianity, it may be possible to provide information regarding the presence/absence of a fault and some information regarding its nature. It may be possible to exploit such an approach when only naturally occurring excitations are available.

In addition, HOS also offer opportunities to solve signal-processing problems that are intractable using only second-order statistics. This advantage arises because phase information is discarded when using second-order statistics, which is retained in the HOS. To succeed, such methods require that the underlying signals be non-Gaussian, so that one needs to carefully consider whether such an assumption is reasonable for the particular application of interest.

2 SECOND-ORDER STATISTICS

We begin by recapping the important elements of second-order spectral analysis. The power, P, of a signal is defined as

$$P = E[x(t)^2] \tag{1}$$

where $x(t)$ is the signal and $E[]$ is the expectation, or averaging, operator. Accordingly, the correlation function, r, is defined as

$$\begin{aligned} r(\tau) &= E[x(t)x(t-\tau)] \\ &= E[x(t)x(t+\tau)] = r(-\tau) \end{aligned} \tag{2}$$

The variable τ is referred to as the *lag variable* and clearly $r(0) = P$. Alternatively, one definition of the power spectrum is

$$\begin{aligned} S(f) &= E[|X(f)|^2] = E[X(f)X(f)^*] \\ &= E[X(f)X(-f)] \end{aligned} \tag{3}$$

where * denotes complex conjugation and $X(f)$ denotes the Fourier transform of $x(t)$. This definition overlooks some theoretical issues associated with defining the Fourier transform of stationary random processes, which requires one to formally modify equation (3), but without changing its essence. The form in equation (3) conveys all of the salient aspects, so we choose to sacrifice rigor to enhance clarity; a fully rigorous treatment can be found in many standard texts including [3, 4].

The spectrum and the correlation function are related via the Wiener–Khintchine theorem

$$\begin{aligned} S(f) &= \int_{-\infty}^{\infty} r(\tau)\mathrm{e}^{-2\pi i f\tau}\,\mathrm{d}\tau \\ \Rightarrow r(\tau) &= \int_{-\infty}^{\infty} S(f)\mathrm{e}^{2\pi i f\tau}\,\mathrm{d}f \end{aligned} \tag{4}$$

so that the correlation function and the power spectrum form a Fourier transform pair. Further, the spectrum is a decomposition of the signal's power as a function of frequency, in the sense that the area under $S(f)$ is equal to the power of the signal P:

$$P = \int_{-\infty}^{\infty} S(f)\, \mathrm{d}f \tag{5}$$

In the following sections, we discuss how the above-mentioned familiar principles can be extended to higher orders.

3 HIGHER ORDER STATISTICS

3.1 Higher order moments and cumulants

According to equation (1), the power, P, is defined as the variance of the signal, which is the second-order moment[b] of the signal. The definition of the general nth order moment, M_n, is

$$M_n = E[x(t)^n] \tag{6}$$

Evidently, $P = M_2$ and the case $n = 1$ corresponds to the mean, which we assume to be zero.

If the probability density function for $x(t)$ is symmetric, then $M_n = 0$ for all odd values of n. A particular example of this is the Gaussian distribution. It is key to what follows to realize that, for a Gaussian process, these higher order moments can be expressed in terms of the second-order moments, reflecting the fact that for a Gaussian process all information is contained in the second-order statistics, for example, for a Gaussian process $M_4 = 3M_2^2 = 3P^2$ and $M_6 = 15M_2^3 = 15P^3$.

It is rather unsatisfying that the even numbered higher order moments of a Gaussian process are nonzero, although they contain no information other than that available at second order. To avoid this, one can work with a modified form of the moments, which enjoy further useful properties. These quantities are referred to as the *cumulants*. They are defined in a manner that ensures that for a Gaussian process the cumulants are zero for all $n > 2$, i.e., all higher orders. The cumulants C_k of a particular order are defined in terms of the moments of that and lower orders. The first four cumulants (for four is the highest order commonly considered in HOS analysis) are

$$\begin{aligned} C_k &= \mathrm{cum}\{x(t)^k\} = E[x(t)^k] = M_k \quad k = 1, 2, 3 \\ C_4 &= \mathrm{cum}\{x(t)^4\} = M_k - 3{M_2}^2 \end{aligned} \tag{7}$$

Note that, for the first three orders, the moments and cumulants are identical; it is not until the fourth order that one needs to distinguish between moments and cumulants.

The definition of a cumulant used in equation (7) is an example of a more general form. Specifically in the above definition, the fourth-order cumulant considers a product of $x(t)$ with itself four times. This generalizes to the case where we consider the so-called cross cumulants between four variables, say, y_k, $k = 1, \ldots, 4$, in which case

$$\begin{aligned} C_4 &= \mathrm{cum}\{y_1, y_2, y_3, y_4\} \\ &= E[y_1y_2y_3y_4] - E[y_1y_2]E[y_3y_4] \\ &\quad - E[y_1y_3]E[y_2y_4] - E[y_1y_4]E[y_2y_3] \end{aligned} \tag{8}$$

The above is equivalent to (7) when $y_k = x(t)$.

Higher order moments have been used for condition monitoring purposes for a significant period of time. In particular, the kurtosis, defined as a normalized fourth-order moment, is a well-known measure of the impulsiveness of a signal and can be used to indicate various forms of fault [5].

3.2 Higher order moments and cumulant functions

The concepts in the preceding section can be extended to generate higher order extensions of the correlation function, $r(\tau)$. The correlation function is simply the cross moment/cumulant between $x(t)$ and $x(t - \tau)$; see equation (2). Consequently, the nth order moment function can be defined as

$$\begin{aligned} M_n(\tau_1, \ldots, \tau_{n-1}) = E[&x(t)x(t - \tau_1) \\ &\times x(t - \tau_2) \ldots x(t - \tau_{n-1})] \end{aligned} \tag{9}$$

This is a function of the $n - 1$ lag variables, τ_k. For a Gaussian process, the moment function is only nonzero for even n. For even values of n, the higher

order moment function can be expressed in terms of the correlation function $r(\tau)$, for example, at fourth order

$$M_4(\tau_1, \tau_2, \tau_3) = r(\tau_1)r(\tau_2 - \tau_3) + r(\tau_2)r(\tau_1 - \tau_3) + r(\tau_3)r(\tau_1 - \tau_2) \quad (10)$$

If the lags are set to zero, $\tau_k = 0$, then equation (10) simplifies to the earlier result $M_4 = 3M_2^2$.

Cumulant functions of a given order can also be defined. As before, in the cases where $n < 4$, the cumulant and moment functions are identical. For $n = 4$, the definition given in equation (8) is used, leading to the fourth-order cumulant function being defined as

$$\begin{aligned} C_4(\tau_1, \tau_2, \tau_3) &= \text{cum}\{x(t), x(t - \tau_1), \\ &\quad x(t - \tau_2), x(t - \tau_3)\} \\ &= M_4(\tau_1, \tau_2, \tau_3) - r(\tau_1)r(\tau_2 - \tau_3) \\ &\quad - r(\tau_2)r(\tau_1 - \tau_3) - r(\tau_3)r(\tau_1 - \tau_2) \end{aligned} \quad (11)$$

3.3 Higher order moments and cumulant functions

Spectra can be defined on the basis of the moment and cumulant functions discussed in the previous section. This is realized by taking the multidimensional Fourier transforms of the functions $M_k()$ or $C_k()$ to yield the higher order moment or cumulant spectra respectively. Specifically, the higher order moment spectrum, $\overline{S}()$ is defined as

$$\overline{S}_n(f_1, f_2, \ldots) = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} M_n(\tau_1, \tau_2, \ldots, \tau_{n-1}) \times \mathrm{e}^{-2\pi i(f_1\tau_1 + f_2\tau_2 + \cdots + f_{n-1}\tau_{n-1})} \mathrm{d}\tau_1 \mathrm{d}\tau_2 \ldots \mathrm{d}\tau_{n-1} \quad (12)$$

and, for the higher order cumulant spectrum, $S()$, one has[c]

$$S_n(f_1, f_2, \ldots) = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} C_n(\tau_1, \tau_2, \ldots, \tau_{n-1}) \times \mathrm{e}^{-2\pi i(f_1\tau_1 + f_2\tau_2 + \cdots + f_{n-1}\tau_{n-1})} \mathrm{d}\tau_1 \mathrm{d}\tau_2 \ldots \mathrm{d}\tau_{n-1} \quad (13)$$

By extension of the principles discussed earlier, the higher order moment spectrum is zero for Gaussian processes only for odd n, whilst the cumulant HOS for Gaussian process is zero for all $n > 2$, for Gaussian signals. The moment spectra can also be expressed in a form equivalent to equation (3) as follows:

$$\overline{S}(f_1, f_2, \ldots, f_{n-1}) = E[X(f_1)X(f_2)\ldots X(f_{n-1}) \times X(f_1 + f_2 + \cdots + f_{n-1})^*] \quad (14)$$

The cumulant spectrum of third order (and all odd orders) is identical to the moment spectrum, whereas the fourth-order cumulant spectrum is as follows:

$$\begin{aligned} S(f_1, f_2, f_3) = \overline{S}(f_1, f_2, f_3) &- S(f_1)S(f_2)\delta(f_2 + f_3) \\ &- S(f_2)S(f_3)\delta(f_1 + f_3) \\ &- S(f_3)S(f_1)\delta(f_1 + f_2) \end{aligned} \quad (15)$$

where $\delta(f)$ is a Kronecker delta function, wherein $\delta(0) = 1$ and $\delta(f) = 0$ for all $f \neq 0$[d].

The higher order spectra of orders 3 and 4 are referred to using their own terminology. Specifically, the third-order spectrum is referred to as the *bispectrum*[e] [6, 7] and the fourth-order spectrum is the *trispectrum* [8, 9]. Note that there are cumulant and moment forms for the trispectrum, whereas the definition of the bispectrum remains unaffected whether one chooses to consider it as a moment or a cumulant spectrum.

Cumulant spectra or cumulant functions have two distinct advantages over their moment counterparts. The first advantage, which we have used to motivate the introduction of the cumulants, is the fact that Gaussian processes have cumulant spectra that are identically zero for all orders greater than 2 (all higher orders). The second is that cumulants are additive, in the sense that if two processes are statistically independent then the cumulant of a process formed when these two processes are added is the sum of the constituents' cumulants. These two facts combine to provide one of the key motivations for employing HOS, specifically, the observation that adding Gaussian noise to a signal does not alter its cumulant spectra or cumulant function. Since in many applications noise is regarded as obeying a Gaussian

distribution, then the use of HOS offers the potential to conduct processing, which is unaffected by the noise. This theoretical advantage can be undermined by some of the more practical issues associated with HOS analyses. Probably the most troublesome aspect comes from the fact that to construct robust estimates of HOS quantities one needs to use long data lengths. This requirement becomes more stringent as the order of the HOS increases or if one requires high resolution in the spectra. Such problems are exacerbated by the requisite increase in computer resources imposed by the use of HOS of higher order and/or high resolution.

3.4 The bispectrum

The bispectrum is a measure of the third-order statistics of a signal and as such is only nonzero if the signal has a skewed distribution. Being the first of the higher order spectra, it is easiest to deal with, requiring least memory and imposing the lowest computational burden. The bispectrum can be expressed in the particular form of equation (14) as follows:

$$\begin{aligned} S(f_1, f_2) &= E[X(f_1)X(f_2)X(f_1 + f_2)^*] \\ &= E[X(f_1)X(f_2)X(-f_1 - f_2)] \quad (16) \end{aligned}$$

Consider a low-pass signal, so that $X(f) = 0$ for $f > f_{\max}$. Then evidently $S(f_1, f_2) = 0$ if $f_1 + f_2 > f_{\max}$, so that the bispectrum of a low-pass signal can only be nonzero in a triangular region, as shown in Figure 1.

There are symmetries inherent within the bispectrum. Specifically, it is apparent from the definition in equation (16) that

$$\begin{aligned} S(f_2, f_1) &= S(f_1, f_2) \quad \text{and} \\ S(-f_1, -f_2) &= S(f_1, f_2)^* \end{aligned} \quad (17)$$

The full set of symmetries is depicted in Figure 2 for a low-pass signal. The bispectrum is completely specified only through its values in the triangular region, $f_1 \geq 0$, $f_1 \leq f_2$, called the *principal domain* and is shown as a chequered region in Figure 2.

From its definition in equation (16), it is apparent that the bispectrum will, in general, be complex valued. In many applications, it is adequate to only consider its magnitude.

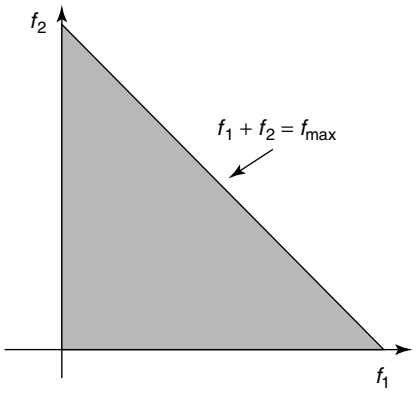

Figure 1. Possible nonzero values of the bispectrum of a low-pass signal.

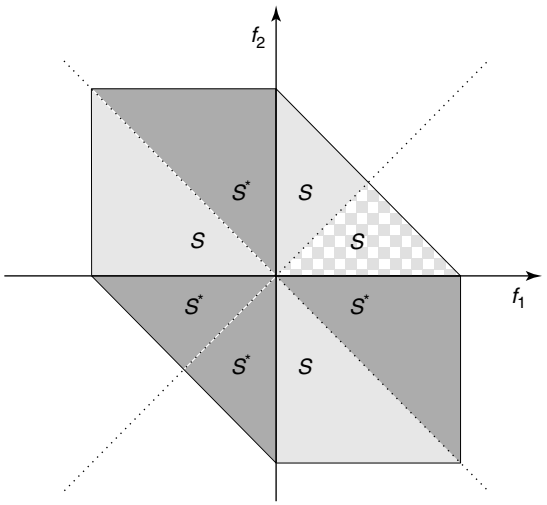

Figure 2. Symmetries in the bispectrum.

3.5 Computation of the bispectrum

The implementation of the bispectrum on a digital computer requires a formulation in terms of a digital signal. On the basis of equation (16), and assuming ergodicity, one method estimating the bispectrum is based on dividing the data into overlapping segments and applying a discrete Fourier transform (DFT) to

each segment [10]; specifically, one computes

$$\hat{S}(k_1, k_2) = \frac{1}{M} \sum_{m=1}^{M} X_m(k_1) X_m(k_2) X_m(k_1 + k_2)^* \tag{18}$$

where $X_m(k)$ is the DFT of the data in the mth segment. Each segment of data contains N consecutive samples; the blocks can be overlapped and maybe windowed. Such an estimation scheme is a natural extension of the segment averaging approach extensively employed in classical spectral estimation. The estimate in equation (18) can be scaled in various manners, as is the case with classical spectral estimation, but for simplicity we consider the unscaled form in equation (18).

The general form of bispectrum of a digital signal has additional properties that are not present in the analog formulation (16). Consider the principal domain as defined in the previous section, i.e., $k_1 \geq 0$, $k_1 \leq k_2$. Then this domain can itself be divided into two regions: the inner triangle (IT) and the outer triangle (OT), as shown in Figure 3 [11].

Inside IT, the arguments of the digital bispectrum k_1 and k_2 are such that $k_1 + k_2 < N/2$ and so all the terms in equation (18) are evaluated for frequencies between 0 and $f_s/2$, where f_s is the sampling frequency. Within the IT, for a properly sampled signal, the digital bispectrum can provide an unbiased estimate of bispectrum of the underlying analog process. In the OT, the digital bispectrum is zero assuming (i) that the signal is not aliased and (ii) that the signal is stationary [11, 12]. It has been proposed that examining the value of the bispectrum within this region provides a test for aliasing and/or stationarity [11, 13], whereas tests based in the IT have been used to test whether a signal is Gaussian or not [7, 14].

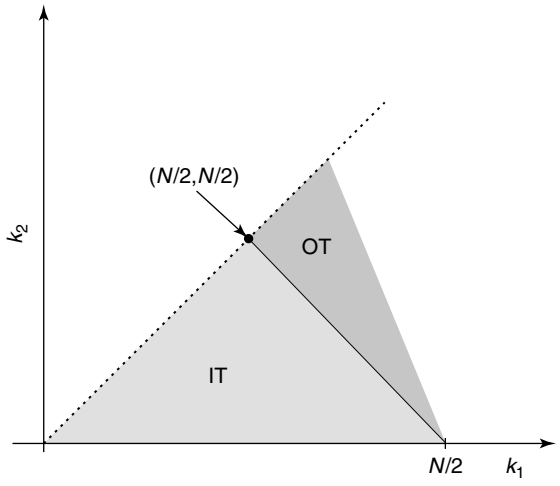

Figure 3. Regions in the digital bispectrum: inner triangle (IT) and outer triangle (OT).

Estimates of the bispectrum based on equation (18) are unbiased as long as an adequate block size, N, is used. The variance of this estimator has the following form [7, 15]:

$$\mathrm{var}\{\hat{S}(k_1, k_2)\} \propto S(k_1) S(k_2) S(k_1 + k_2) \tag{19}$$

Thus, the variance of the bispectrum estimate is dependent upon the spectrum of the signal. This can produce misleading results. Regions in the bispectrum can appear large simply because the variance of the estimate is large in that region, only as a consequence of the triple product of the spectrum, equation (19), being large. This effect can be mitigated by normalizing the bispectrum, $\tilde{S}(k_1, k_2)$, using

$$\tilde{S}(k_1, k_2) = \frac{\frac{1}{M} \sum_{m=1}^{M} X_m(k_1) X_m(k_2) X_m(k_1 + k_2)^*}{\sqrt{\hat{S}(k_1) \hat{S}(k_2) \hat{S}(k_1 + k_2)}},$$

$$\hat{S}(k) = \frac{1}{M} \sum_{m=1}^{M} |X_m(k)|^2 \tag{20}$$

where $\hat{S}(k)$ is an estimate of the power spectrum based on segment averaging. The quantity $\tilde{S}(k_1, k_2)$ is referred to as the *bicoherence* [6] and is a normalized form of the bispectrum. Other normalizations have been proposed for the bispectrum [10].

3.5.1 Example of the bispectrum for a simulated cracked beam

By way of example, consider data generated by randomly exciting a piecewise linear model of a cracked beam. This model is defined as [16, 17]

$$\frac{\mathrm{d}^2 y}{\mathrm{d}t^2} + c \frac{\mathrm{d}y}{\mathrm{d}t} + \kappa(y) y = x(t) \tag{21}$$

where c is the damping coefficient and $\kappa(y)$ is the displacement-dependent stiffness; note that equation (21) assumes a unit mass. This stiffness is defined such that $\kappa(y) = \kappa_1$ for $y < 0$ and $\kappa(y) = \kappa_2$ for $y > 0$, where κ_1 and κ_2 are constants. We assume that $\kappa_1 < \kappa_2$, i.e., the beam is stiffer when the crack is compressed (closed), and for $y < 0$, the crack opens and the beam is less stiff. The proportionate depth of the crack is approximately equal to the ratio of the stiffnesses κ_1/κ_2 for small crack depths [18, 19]. In this simulation, we assume a stiffness ratio of 30% and a damping coefficient of 0.1. The excitation is band-limited Gaussian noise. White Gaussian measurement noise is also added to the response data. For comparison purposes, we generate a surrogate signal based on this cracked beam response data. The surrogate signal consists of Gaussian noise, which is filtered so that its spectrum matches that of the response generated using equation (21). Both signals are constructed so that they are 100 000 samples in duration. This surrogate data, being Gaussian, has a bispectrum, which is theoretically zero for all frequencies.

Figure 4 shows the power spectra of the response and the surrogate data. The data consists of a resonance at a normalized frequency of 0.19. A harmonic component at double the resonance frequency can be seen in the noise-free data, shown as a dotted line in Figure 4(b), and this harmonic is a consequence of the nonlinear nature of the dynamics described in equation (21). The addition of measurement noise almost completely obscures the presence of this second harmonic in the simulated measured data set, as shown by the solid line in Figure 4(b). A key difference between the response and surrogate data is that, for the response data, the phase close to the harmonic frequency is related to the phase near the resonance [6], whereas in the surrogate data no such correlations exist. These interrelationships between different frequency bands are not evident in the power spectrum because second-order spectra fail to represent phase information.

Figure 5 depicts normalized and unnormalized bispectra computed for the surrogate and response data. These bispectra are computed using an fast Fourier transform (FFT) size (N) of 256 samples. For both the unnormalized bispectral estimates, shown in Figure 5(a) and (b), there are horizontal and vertical lines at a normalized frequency of 0.19. These features are present in the bispectra as consequence of the increase in the power spectrum at the resonance. It is important to recognize that these peaks are presented in both the surrogate data and the response data. Such structure can lead to one drawing misleading conclusions from the bispectrum. By normalizing the bispectrum, the spurious structure is eliminated. The normalized bispectrum of the surrogate signal is close to zero everywhere, whereas for the response data there is a strong peak, at the bifrequency (0.19, 0.19), indicating that, at frequency 0.38, there is a significant contribution from the normalized frequency 0.19 interacting with itself.

3.6 The trispectrum

The fact is that the bispectrum analyses of a signal in terms of its skewness limits its applicability. In most of the applications, the nonlinearities encountered are symmetric and give rise to response data, that is, they have a symmetric distribution. In such cases, the bispectrum is zero. In general, the trispectrum,

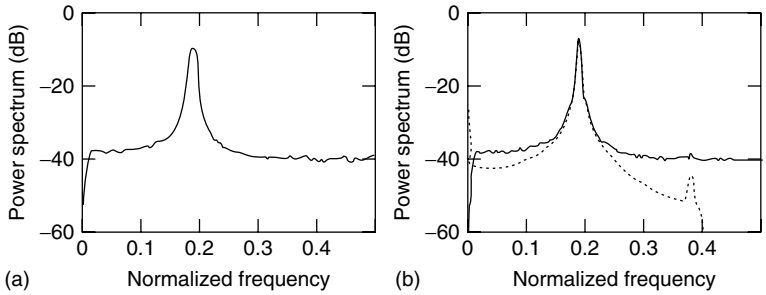

Figure 4. Spectral estimates: (a) spectrum of the surrogate Gaussian signal; (b) solid line: spectrum of the response signal with added noise and dotted line: spectrum of response signal in the absence of noise.

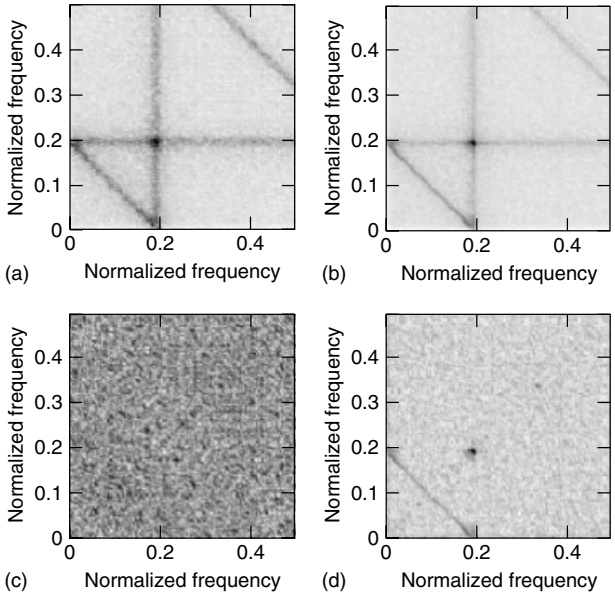

Figure 5. Bispectrum estimates, displayed on a logarithmic color axis with dark shades representing large values (each plot is individually scaled): (a) unnormalized bispectrum of the surrogate Gaussian signal, (b) unnormalized bispectrum of the response signal, (c) normalized bispectrum of the surrogate Gaussian signal, and (d) normalized bispectrum of the response signal.

the fourth-order HOS, is nonzero. It should be noted that the estimation of the trispectrum requires more data and imposes a greater computational burden than estimation of the bispectrum. As already discussed, there are definite theoretical advantages associated with the use of the cumulant, as opposed to the moment, form of the trispectrum and so it is only the cumulant form of the trispectrum that we consider in the following.

In general, the trispectrum exhibits a set of symmetries that parallel those of the bispectrum. The details of these symmetries can be found elsewhere [9]. The computation of the trispectrum can be performed in a manner that is a natural extension of the segmenting averaging approach described by equation (18).

The trispectrum is a function of three frequency variables, which makes displaying it problematic. There are several approaches that can be taken for representing the trispectrum; here we shall take the option of considering a specific subset of values, sometimes referred to as *a slice of the trispectrum*. Specifically, we consider the specific case of equation (15), where $f_1 = -f_2$, so that the cumulant trispectral slice, $T(f_1, f_2)^{\mathrm{f}}$, discussed here can be written as

$$T(f_1, f_2) = E[|X(f_1)|^2|X(f_2)|^2] - S(f_1)S(f_2) - S(f_1)^2\delta(f_1 - f_2) \tag{22}$$

This trispectral slice describes the correlations of the spectral amplitudes, $|X(f)|^2$, at the two frequencies f_1 and f_2. Since the slice is a subset of a cumulant HOS, by construction, it is zero for stationary Gaussian processes.

3.6.1 Example of the trispectrum for a simulated nonlinear spring

To illustrate the use of the trispectrum, we consider a simulated data set from a system with a nonlinear stiffness. This system can be regarded as a softening spring, i.e., a single degree of freedom system whose stiffness reduces as displacement away from equilibrium increases. The specific system modeled has the form:

$$\frac{\mathrm{d}^2 y}{\mathrm{d}t^2} + c\frac{\mathrm{d}y}{\mathrm{d}t} + k\sigma \tanh(y/\sigma) = x(t) \tag{23}$$

The hyperbolic tangent function ensures that for small displacements the spring stiffness is k. The scaling constant σ is included to control the linearity of the system; for large values of σ, the system behaves in a linear fashion, whilst for small values the system is highly nonlinear. The particular form of equation (23) ensures that the stiffness at small amplitudes remains unaffected by the value of σ.

The nonlinearity in the system means that, as the displacement is increased, the stiffness reduces. The consequence is that the response of this system has a larger fourth-order moment as the value of σ is reduced.

The excitation used for this simulation is band-limited Gaussian noise. The simulated response lasts for 100 000 samples. Results are shown for the system with the same stiffness parameter, $k = 160$, and damping, $c = 0.1$, but the value of nonlinearity parameter, σ, is varied. For large values of σ, the system has a resonance at a normalized frequency of 0.2. Four different values of σ are considered: 0.6, 0.3, 0.15, and 0.1. The largest value corresponds to a case where the system is very close to being linear, whereas for the smallest value there is a high degree of nonlinearity in the response. Figure 6 shows the spectra of the four response signals. Without explicit knowledge of the underlying system, these spectra provide no direct evidence of the nonlinearity. As the nonlinearity is increased, the peak at resonance broadens toward the lower frequencies, but this is not necessarily indicative of nonlinearity and could be explained by a change in the linear dynamics of the system. However, the slices of the normalized trispectrum, shown in Figure 7, betray the increasing levels of nonlinearity in the system. There is a peak in the slice of the trispectrum, indicating coupling between the spectral amplitudes at the different frequency pairs close to resonance.

4 OTHER USES OF HOS

In this discussion, we have considered the use of HOS for the limited problem of identifying the presence of a nonlinearity from response-only data. Such an application can be extremely useful if one only has output measurements under natural excitations. However, this is only one of the possible potential uses of HOS. There are several possible further uses of HOS. The most direct application is in situations where one has access to both input and response data. Then one can use the HOS spectra to construct estimates of the Wiener or Volterra kernels [20]

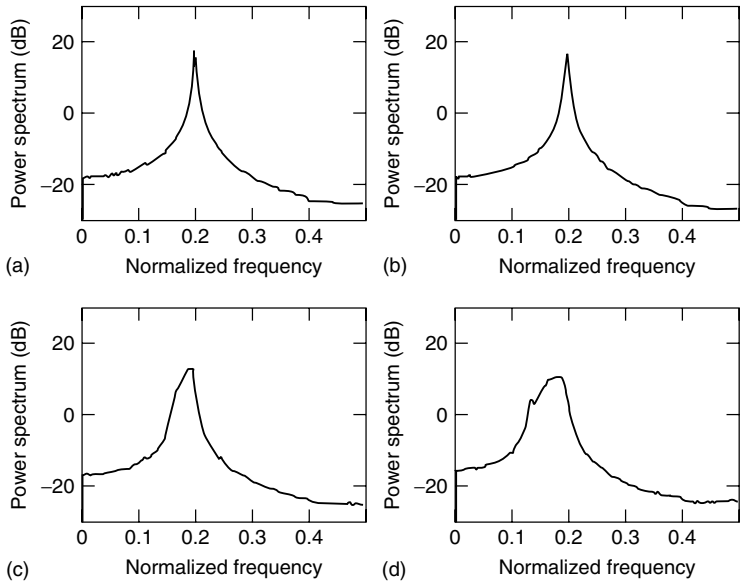

Figure 6. Power spectra of the simulated response form softening spring: (a) $\sigma = 0.6$, (b) $\sigma = 0.3$, (c) $\sigma = 0.15$, and (d) $\sigma = 0.1$.

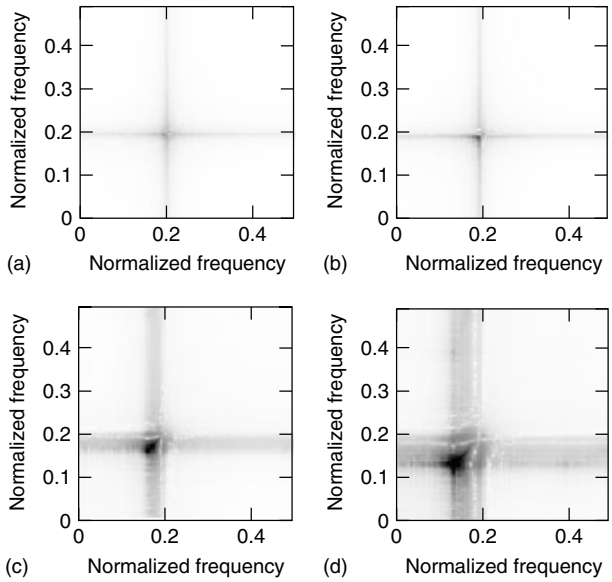

Figure 7. Estimates of the normalized slices of the trispectrum, displayed on a logarithmic gray scale with dark shades representing large values: (a) $\sigma = 0.6$, (b) $\sigma = 0.3$, (c) $\sigma = 0.15$, and (d) $\sigma = 0.1$.

that characterize the nonlinear system [21]. This is achieved using cross higher order spectra, in a manner analogous to the way that cross spectra are used to estimate transfer functions in linear systems.

Further to this, HOS can be used to solve at least two problems associated with linear systems excited by non-Gaussian processes. The first of these problems is the estimation of the parameters of a moving average (MA) system model (or by extension of the MA component of an autoregressive moving average (ARMA) system model) [22]. The second problem that HOS can be used to solve is blind source separation [23]. In both these problems, the fact is that using the spectrum to represent a signal discards phase information means that general solutions cannot be obtained, whereas the use of HOS, in which phase information is preserved, means that solutions can be formulated.

5 CONCLUSIONS

HOS can provide useful information that is not accessible through the spectrum (or correlation function). This information allows one a more complete description of non-Gaussian processes. These non-Gaussian processes are normally modeled as a result of non-Gaussian excitation of a linear system or Gaussian excitation of nonlinear system. In SHM, this can be of considerable benefit if the structure under investigation is such that nonlinearities are indicative of the presence of a fault.

END NOTES

[a.] Throughout we shall assume that signals of interest are zero mean.

[b.] Moments are commonly discussed in two forms: central and noncentral moments. The distinction being that the central moments are computed after the mean of the signal has been subtracted from the data. Since we assume the data to be zero mean, such a distinction is meaningless and we use the generic term "moment".

[c.] Note that the notation for spectrum and a higher order spectrum are both $S()$ and they are distinguished by the number of arguments in the function. This emphasizes the commonality between the concepts.

[d.] On a technical point: deriving (15) by Fourier transforming (11) yields a solution containing Dirac delta functions, rather than the Kronecker delta function appearing here. The reason for this difference is a consequence of relaxation of rigor in adopting (3), if

that rigor is applied throughout then no inconsistency occurs.

[e.] The prefix "bi" in the term bispectrum refers to the fact it is a function of two frequency variables and is not supposed to indicate that it is some measure of second-order properties.

[f.] It is necessary to adopt a notation for the trispectral slice, which is distinct from the bispectrum, so one cannot continue the convention of using S with different numbers of arguments.

Damage Detection Using the Hilbert–Huang Transform

Darryll J. Pines[1] and Liming W. Salvino[2]

[1] *Department of Aerospace Engineering, University of Maryland, College Park, MD, USA*
[2] *Structures and Composites, Carderock Division, Naval Surface Warfare Center, West Bethesda, MD, USA*

1 INTRODUCTION

Huang *et al.* [1] introduced a new adaptive method for nonlinear and nonstationary data analysis in 1998. This method consists of the combination of the empirical mode decomposition (EMD) and the Hilbert spectral analysis. Lin *et al.* [2] showed that the Hilbert–Huang transform (HHT) can be used to identify the structural parameters of a benchmark building and is quite accurate in detecting structural damage locations and severities. Quek *et al.* [3] illustrated the suitability of the HHT for damage detection problems, such as an aluminum beam with a crack, a sandwiched aluminum beam with an internal delamination, and a reinforced concrete slab with different degrees of damage. Crack and delamination in homogeneous beams can be located accurately and damage in the reinforced concrete slab can be identified if it has been previously loaded beyond first crack. Tua *et al.* [4] used the energy peaks in the Hilbert spectrum corresponding to crack-reflected waves to determine accurate flight times and also to estimate the orientation of the crack. Yang *et al.* [5] proposed two damage detection techniques based on the HHT. The first method based on the EMD extracted damage spikes due to a sudden change, whereas the second one based on the EMD and the Hilbert transform was capable of determining the damage time instants and determining the natural frequencies and damping ratios of the structure before and after damage. Pines and Salvino [6] showed the ability of the EMD to extract phase information from transient signals and used the results to infer damage in a structure. Salvino *et al.* [7–10] also compared the instantaneous phase detection approach with other data-driven damage detection methods, such as autoregressive modeling and nonlinear prediction approach using 2-D frame structure with multiple damages. Jha *et al.* [11] investigated the HHT to a multilevel structure. They showed that discontinuity in the intrinsic mode functions (IMFs) indicated the presence and location of

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

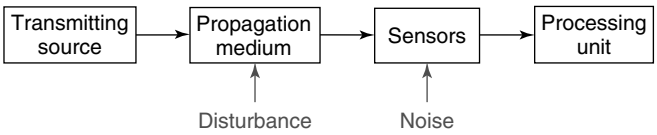

Figure 1. A common signal-processing system.

a damaging event in a structure monitored continuously. Bernal and Gunes [12] examined the instantaneous frequency of the IMFs provided by the EMD as a damage detection tool. Yu *et al.* [13] proposed a method for the fault diagnosis of roller bearings based on the HHT. The local Hilbert marginal spectrum is used to diagnose the faults in a roller bearing and to identify fault patterns. Quek *et al.* [14] compared the results obtained from the wavelet analysis with results from an EMD. The EMD was shown to provide a more direct method of extracting information needed for damage detection purposes.

This article demonstrates that the use of EMD coupled with Hilbert spectral analysis is an effective tool for locating and tracking progressive damage accumulation in a two-dimensional thin composite plate structure [15]. The next section introduces the concept of EMD as a new nonstationary time-series signal-processing approach (Figure 1).

2 THE HILBERT–HUANG TRANSFORM

The EMD and HHT method [12] addresses the limitations of the traditional Hilbert transform for signal analysis. The fundamental concepts of instantaneous frequency and time–frequency analysis are first described. The EMD and HHT method can be divided into two parts. In the first part, the data are decomposed into a collection of IMFs. This decomposition is viewed as an expansion of the data in terms of the IMFs. In other words, these IMFs are regarded as the basis of that expansion, which can be linear or nonlinear as dictated by the data. The IMFs, by definition, have well-behaved Hilbert transforms. In the second part, the corresponding instantaneous frequencies are calculated. The local energy and the instantaneous frequency derived from the Hilbert transforms of IMFs give us a full-energy–frequency–time distribution of the data, and such a representation is designated as the Hilbert–Huang spectrum. In this manner, the EMD and HHT method affords time–frequency analysis of a large class of signals.

2.1 Fundamental concepts

The Hilbert transform $H[x(t)]$ of a real-valued function $x(t)$ extended from $-\infty$ to $+\infty$ is a real-valued function defined by

$$\begin{aligned} H[x(t)] &= y(t) \\ &= \lim_{\varepsilon \to 0} \left[\int_{-\infty}^{0-\varepsilon} \frac{x(u)}{\pi(t-u)}\,\mathrm{d}u \right. \\ &\quad \left. + \int_{0-\varepsilon}^{\infty} \frac{x(u)}{\pi(t-u)}\,\mathrm{d}u \right] \end{aligned} \tag{1}$$

Assuming that $\int_{-\infty}^{\infty}[x(t)]^2\,\mathrm{d}t < \infty$, equation (1) can be rewritten as

$$H[x(t)] = y(t) = \frac{1}{\pi} P \int_{-\infty}^{\infty} \frac{x(u)}{t-u}\,\mathrm{d}u \tag{2}$$

where P indicates the Cauchy principal value. This transform exists for all functions of class L^p, i.e., the space of p-power integrable functions. With this definition, $y(t)$ forms the complex conjugate of $x(t)$ and we can define the analytical signal, $z(t)$, as

$$z(t) = x(t) + iy(t) \tag{3}$$

The advantage of this representation lies in the fact that the possibility arises of uniquely determining genuine time-variant variables. These are the instantaneous parameters with amplitude as $a(t) = \sqrt{x(t)^2 + y(t)^2}$ and phase $\theta(t) = \arctan(y(t)/x(t))$.

Finally, equation (3) can be rewritten as

$$z(t) = a(t)\,\mathrm{e}^{i\theta(t)} \tag{4}$$

In this equation, the polar coordinate expression further clarifies the local nature of this representation.

It is the best local fit of an amplitude- and phase-varying trigonometric function to $x(t)$. In this respect, the Hilbert transform expresses a signal as a harmonic with time-dependent amplitude and frequency. The instantaneous frequency is defined as the rate of phase change

$$\omega = \frac{\mathrm{d}\theta}{\mathrm{d}t} \quad \text{and} \quad f = \frac{1}{2\pi}\frac{\mathrm{d}\theta}{\mathrm{d}t} \tag{5}$$

The definition of the instantaneous frequency presented here is the most common form, but it is by no means unique. Ville [16] defined another estimator for the instantaneous frequency as the first moment of the distribution with respect to frequency. Cohen [17] defined the instantaneous frequency to be the average of the frequencies that exist in the time–frequency plane at a given time. A comprehensive discussion on the various proposed formulations may be found in Boashash [18]. Some limitations on the data are necessary, since the instantaneous frequency given in equation (5) is a single value function of time. The definition implies that at any given time, there is only one frequency value. This leads Cohen [19] to introduce the term *monocomponent function*, which has been loosely defined as narrow band. Finally, one reasonable and meaningful definition of the instantaneous frequency could be the representation of the frequency of the signal at one time, without any information about the signal at other times. For most multicomponent signals, the assumption of a single-frequency component at each time instant is no longer valid, leading to a meaningless instantaneous frequency. In order to obtain meaningful instantaneous frequency, restrictive conditions have to be imposed on the data as discussed by Gabor [20] and Cohen [19]: the frequency of the signal must be positive and the function must be symmetric locally with the respect to the zero mean level. These restrictions lead to the definition of a class of functions for which the instantaneous frequency can be defined everywhere. A new method needs therefore to be introduced in order to decompose any signal into a superposition of components with well-defined instantaneous frequency. The idea behind this decomposition method is to decompose a multicomponent signal into thesum of single-component functions. This new method has been introduced by Huang in 1998 [1] and is called the *empirical mode decomposition*.

2.2 The empirical mode decomposition

2.2.1 Intrinsic mode function

According to Huang, an intrinsic mode is a function that satisfies two conditions:

1. In the whole data set, the number of extrema and the number of zero crossings must either equal or differ at most by one;
2. At any point, the mean value of the envelope defined by the local maxima and the envelope defined by the local minima is zero.

An example of an IMF is given in Figure 2. IMFs represent oscillatory modes embedded within data where each IMF involves only one mode of oscillation. An IMF can be nonstationary and either be amplitude and/or frequency modulated. It has to be mentioned that, by definition, IMFs always have positive frequencies, because the oscillations in IMFs are symmetric with respect to the local mean.

2.2.2 The sifting process

The sifting process aims to decompose any data into a set of independent IMF components since most of the data are not naturally IMFs.

The decomposition is based on three assumptions:

1. the signal has at least two extrema, one maximum and one minimum;
2. the characteristic timescale is defined by the time lapse between the extrema; and
3. if the data were totally devoid of extrema but contained only inflection points, then it can be differentiated once or more times to reveal the extrema.

The sifting process to find the IMFs of a signal consists of several steps. We describe these steps using an arbitrary signal denoted $x(t)$.

1. Find the positions and amplitudes of all local maxima and minima in the input signal. These are marked by dots in Figure 3.
2. Create the upper envelope by spline interpolation of the local maxima and the lower envelope by spline interpolation of the local minima, denoted by $e_{\max}(t)$ and $e_{\min}(t)$. These are shown as curves in Figure 3.

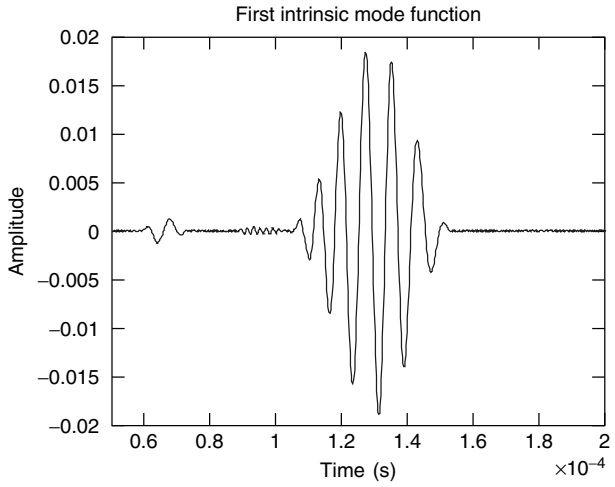

Figure 2. Intrinsic mode function (IMF) example.

3. For each time instant t, calculate the mean of the upper envelope and the lower envelope.

$$m_1 = \frac{e_{\max}(t) + e_{\min}(t)}{2} \tag{6}$$

This signal is referred to as the *envelope mean* and is shown as the black line in Figure 3.

4. Subtract the envelope mean signal from the input signal, yielding the results illustrated by dark grey in Figure 3.

$$h_1(t) = x(t) - m_1 \tag{7}$$

This is one iteration of the sifting process. The next step is to check if the signal $h_1(t)$ is an IMF or not. In the original work of Huang, the sifting process stops when the difference between two consecutive siftings is smaller than a selected threshold SD, defined by

$$SD = \sum_{t=0}^{T} \left[\frac{|(h_{1(k-1)}(t) - h_{1k}(t))|^2}{h_{1(k-1)}^2(t)} \right] \tag{8}$$

The choice of the stop criterion is crucial and is discussed further at the end of this section.

5. If $h_1(t)$ is not an IMF, iterate by repeating the process from step 1 with the resulting signal from step 4. If in the second sifting process, $h_1(t)$ is treated as the data, then

$$h_{11} = h_1 - m_{11} \tag{9}$$

We can repeat this sifting procedure k times, until h_{1k} is an IMF, that is,

$$h_{1k} = h_{1(k-1)} - m_{1k} \tag{10}$$

When the stop criterion is met, the IMF is defined as

$$c_1 = h_{1k} \tag{11}$$

After the IMF c_1 is found (illustrated by the dark grey curve in Figure 3), we define the residue r_1 as the result of subtracting this IMF from the input signal:

$$r_1 = x(t) - c_1 \tag{12}$$

The residue is illustrated by the dark grey curve in Figure 3.

6. The next IMF is found by starting over from step 1, now with the residue as the input signal.

Steps 1–6 can be repeated for all the subsequent r_j and the result is

$$r_1 - c_2 = r_2, \ldots, r_{n-1} - c_n = r_n \tag{13}$$

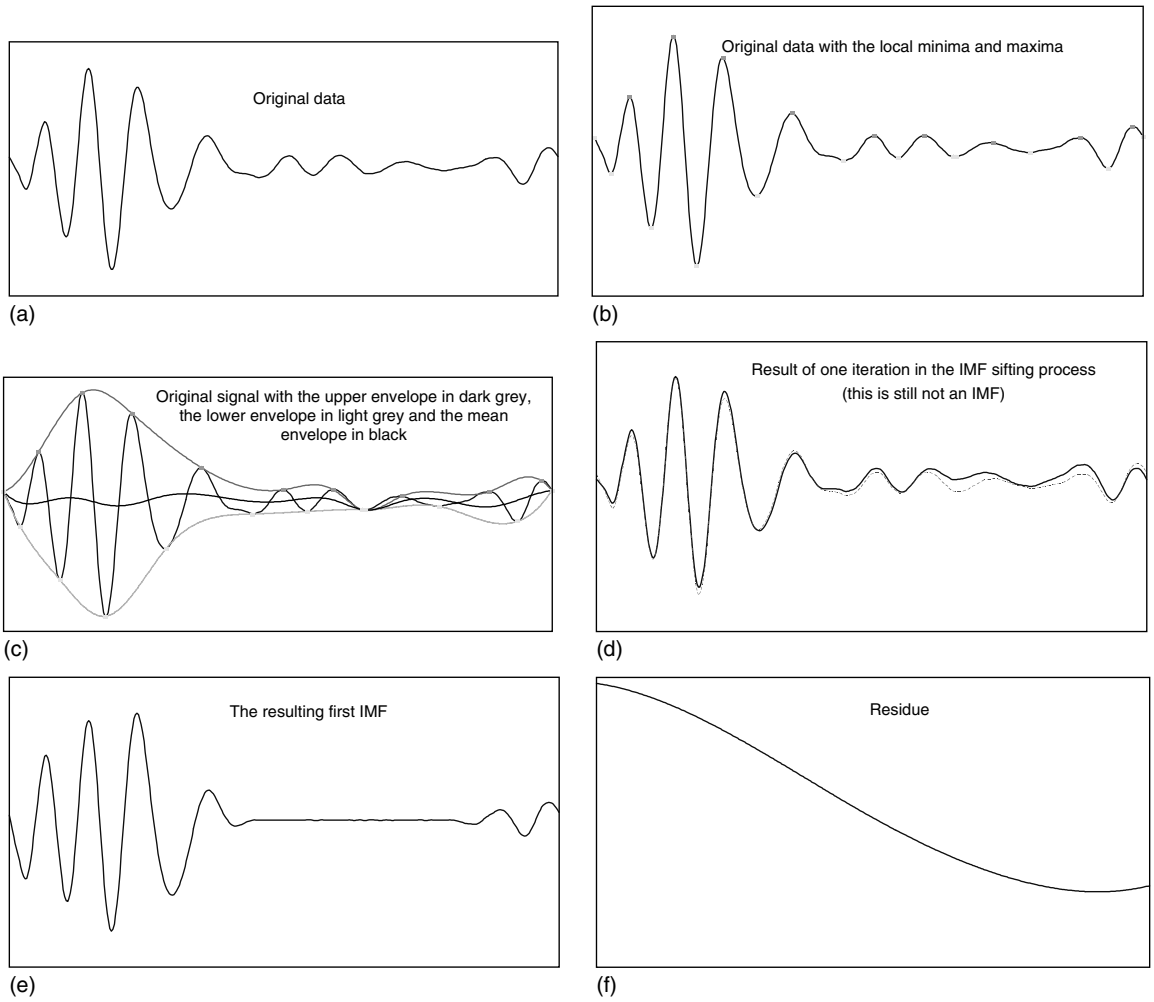

Figure 3. Sifting process illustration: (a) original signal; (b) localization of the local extrema; (c) spline fitting; (d) result of one iteration of the sifting process; (e) resulting first IMF; and (f) residue function.

The EMD is completed when the residue, ideally, does not contain any extrema points. This means that it is either a constant or a monotonic function. The signal can be expressed as the sum of IMFs and the last residue

$$x(t) = \sum_{i=1}^{n} c_i + r_n \tag{14}$$

The extracted IMFs are symmetric, have a unique local frequency, and different IMFs do not exhibit the same frequency at the same time. Another way of explaining how the EMD works is that it picks out the highest frequency possible that remains in the signal. The sifting process allows one to decompose the data into n-empirical modes and a residue. A brief summary of the EMD procedure is given in Figure 4.

It is important to note that certain features of IMFs are algorithm dependent. When more than one instantaneous frequency at a specified time exists for a complicated signal, its value can be uniquely assigned to an IMF component i. However, i can be different for a given time t, depending on the choice of computational parameters. In other words, there are different ways to decompose a given signal

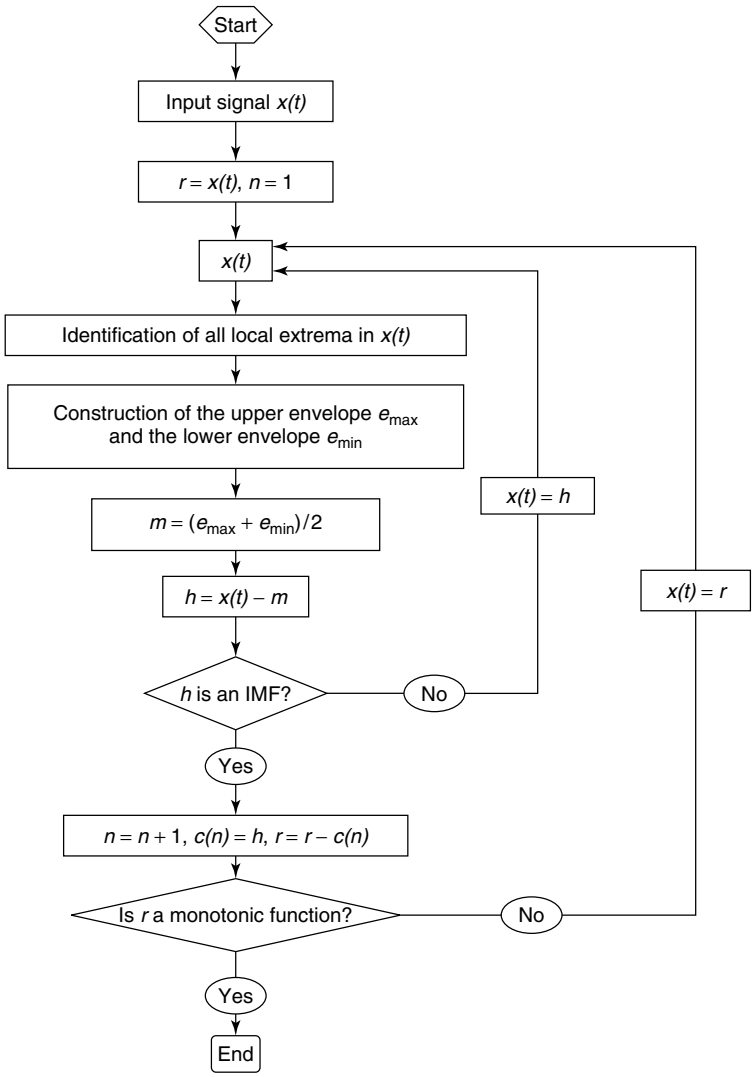

Figure 4. Flow chart of the EMD.

into IMFs. Different IMF sets can be generated using different sifting parameters such as stoppage criterion, maximum number of siftings, end-point boundary conditions, etc. The obvious, yet important question is which set of the many possible choices of shifting parameters gives a meaningful result and how to choose the sifting parameters to obtain the "best IMF set". A follow-on work of Huang *et al.* defines a confidence limit to find a stable range of stopping criteria for the sifting operation [9]. Within this stable parameter range, any IMF sets are good representations of the signal. This feature of EMD method can be used in a constructive way to examine data to achieve drastically improved robustness of the analysis results [10]. Further discussion about this is given in Section 2.5.

2.3 The Hilbert spectral analysis

The EMD gives us a set of independent IMF components with meaningful instantaneous frequencies.

Each of the IMF components can be therefore treated as a signal where the Hilbert transform can be applied.

$$c(t) = a_j(t) \exp\left(i \int \omega_j(t)\,\mathrm{d}t\right) \tag{15}$$

After performing the Hilbert transform on each IMF component, the original data $x(t)$ can be expressed as a real part (RE) of the complex expansion:

$$x(t) = RE\left[\sum_{j=1}^{n} a_j(t) \exp\left(i \int \omega_j(t)\,\mathrm{d}t\right)\right] \tag{16}$$

The residue r_n is omitted on purpose because it is either a monotonic function or a constant. Here, both amplitude $a_j(t)$ and instantaneous frequency $\omega_j(t)$ are functions of time t in contrast with the constant amplitude and frequency in the Fourier expansion.

$$x(t) = RE\left[\sum_{j=1}^{\infty} a_j \mathrm{e}^{i\omega_j t}\right] \tag{17}$$

The IMF represents a generalized Fourier expansion.

Equation (16) enables us to represent the amplitude and the instantaneous frequency as functions of time in a three-dimensional plot, in which the amplitude can be contoured on the frequency–time plane. This frequency–time distribution of the amplitude is designated as the Hilbert amplitude spectrum, $H(\omega, t)$, or simply Hilbert spectrum. Various forms of Hilbert spectra presentations can be made. The first one, the skeleton form, will emphasize frequency variations of each IMF and will be used if more quantitative results are desired. A second form, commonly used as a first look, is the smoothed Hilbert spectrum. If we apply a weighted spatial filter with large enough spatial averaging, we obtain a smoothed spectrum similar to what the wavelet analysis would give. Even if such a smoothing degrades both frequency and time resolutions, it could give a better physical interpretation. Hence, if more qualitative results are desired, the smoothed presentation is more appropriate. Both forms of the Hilbert spectrum are shown in Figure 5 for the example treated in the sifting process section.

2.4 Example of time–frequency response

To show the efficiency of the EMD and the Hilbert spectrum, a simple example has been studied and compared with the most common time–frequency methods. We consider the case of a simple sine wave with one frequency suddenly switching to another frequency and a Dirac-type impulse occurring at a certain time. This signal $s(t)$ is defined by equation (18)

$$\begin{cases} s(t) = \cos(2\pi f_1 t) & 0 < t \leq 0.125s \\ s(t) = \cos(2\pi f_2 t) + \delta(t = 0.1875s) & \\ & 0.125s < t \leq 0.25s \end{cases} \tag{18}$$

This signal has been chosen in order to demonstrate the ability of the EMD to separate the different

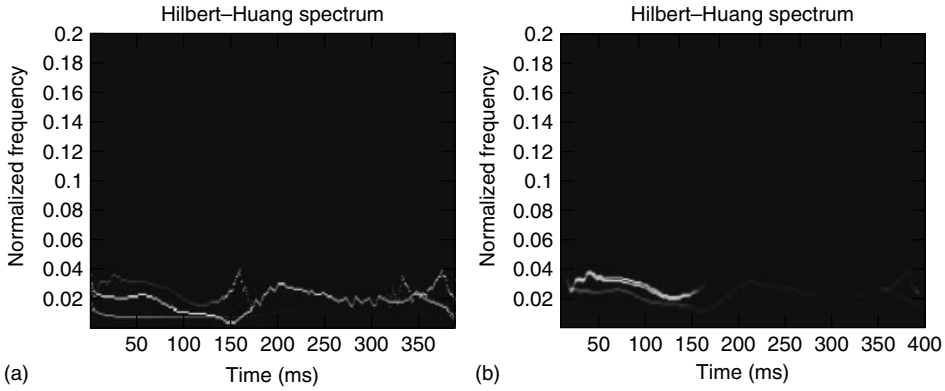

Figure 5. Hilbert–Huang spectrum: (a) skeleton form and (b) smoothed form.

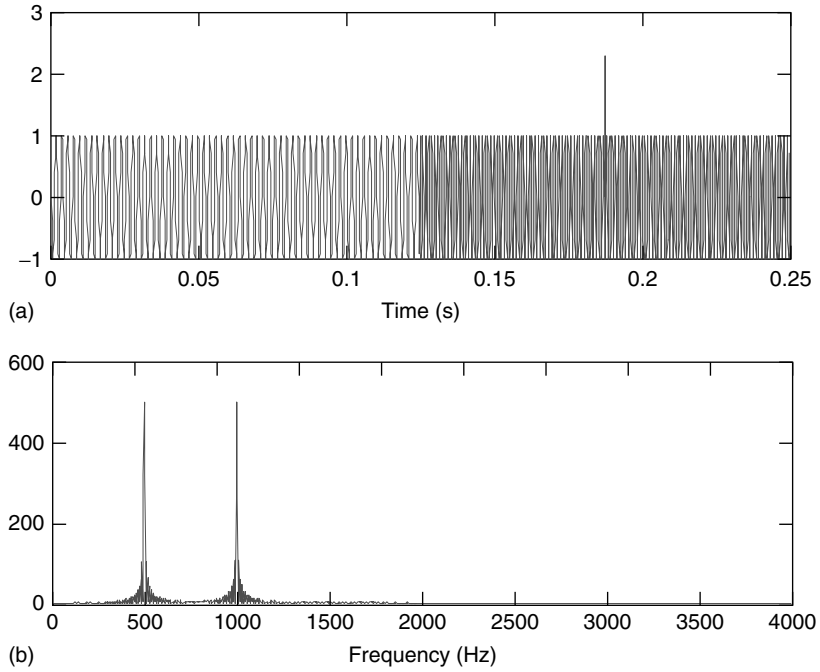

Figure 6. Example signal $s(t)$ (a) time-domain signal and (b) frequency spectrum.

frequency components as well as to identify irregularities in a signal. The time-domain representation of this signal along with its Fourier spectrum is given in Figure 6. As expected, the two frequencies present in the signal show up in the Fourier spectrum without any indication of when it is occurring and for how long these two frequencies are present. The spike in the signal is undetectable in Fourier spectrum.

The EMD with the Hilbert–Huang spectrum gives a high-resolution time–frequency representation. The 2-D plot provides fine details about the nature of the two sine waves as well as the impulse. The two frequencies can be accurately determined, as well as their time duration. Both frequency and time resolutions are excellent. Moreover, there is little, if any, leakage at the frequency switch point. The impulse appears as a discontinuity in the frequency band. This can be compared with a discontinuity for a mathematical function. This discontinuity is well localized in time and is spread out over the whole frequency range. This makes sense as an impulse in the time domain theoretically contains all frequencies. All these details can be seen in the three-dimensional plot in Figure 7.

After analyzing the signal $s(t)$ with the HHT, it is instructive to process the same signal through other time–frequency methods. A comparison with these methods will reveal the strengths and weaknesses of other time–frequency methods. The spectrogram of $s(t)$ corresponding to the short-time Fourier transform (STFT) and the scalogram corresponding to the wavelet transform are plotted in Figure 8. A random window size has been chosen for the STFT, that is, one-fourth of the signal length. A large time window implies a good frequency resolution and a poor time resolution. Indeed, we can notice that the two frequency components are overlapping in time around the switch point. Hence, we could believe that both frequencies are present in the signal during a short time period, which is not true. Furthermore, the impulse does not appear in the spectrogram. The main problem of the STFT is hence underlined. There is no guarantee that the window size adopted coincides with the stationary timescales. The impulse event being much localized in time, a narrow window must therefore be applied. However, this choice implies a poor frequency resolution, as shown in Figure 9(a). The impulse can now be seen but the spectrogram

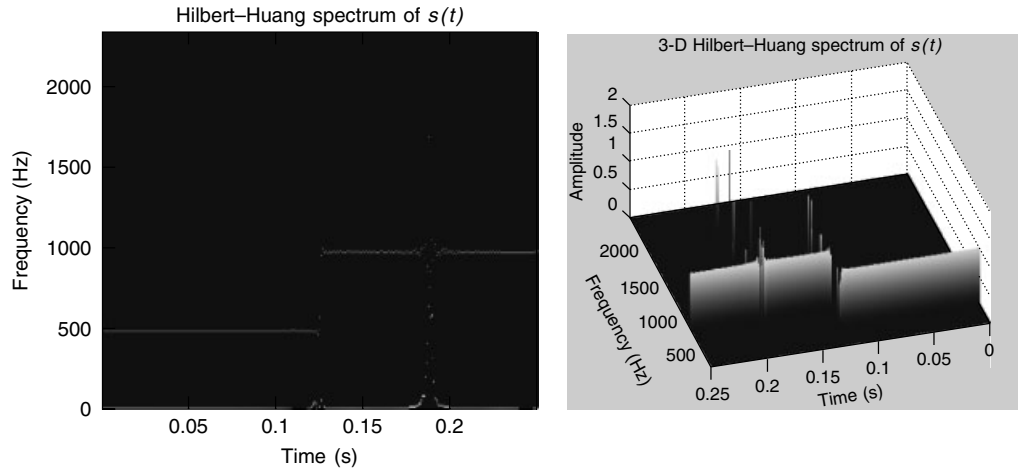

Figure 7. Hilbert–Huang spectrum of $s(t)$.

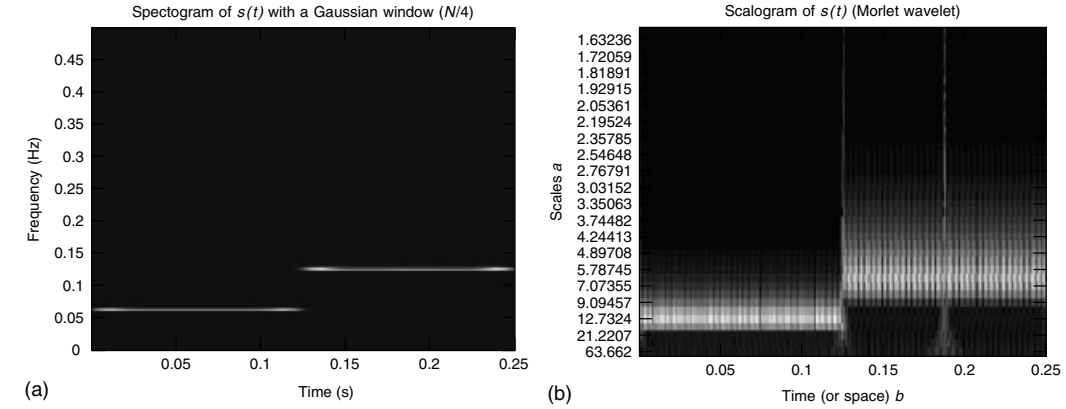

Figure 8. Spectrogram and scalogram of $s(t)$: (a) spectrogram ($N/4$) and (b) scalogram.

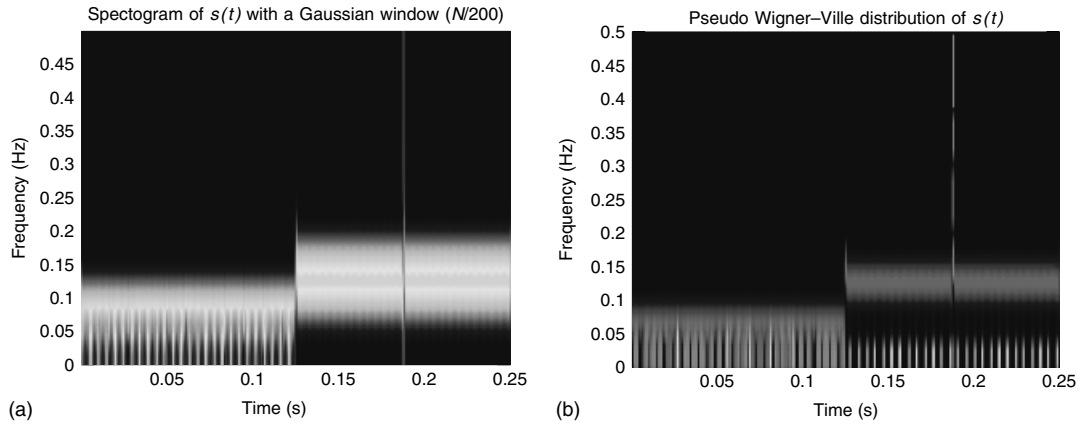

Figure 9. Similarity between the STFT and the PWVD: (a) spectrogram ($N/200$) and (b) pseudo Wigner–Ville distribution.

gives a smeared average frequency range over which the main wave energies reside. For the analysis of nonstationary data, the STFT turns out to be very limited compared to the HHT. Moreover, the pseudo Wigner–Ville distribution is plotted in Figure 9(b). In order to get rid of the cross terms and interferences, the time–frequency representation has been modified by smoothing in time and frequency. The result is, then, basically that of the STFT analysis. The Wigner–Ville distribution therefore suffers all the limitations of the STFT. The wavelet analysis is the best available nonstationary data analysis method prior to the development of HHT. The standard Morlet wavelet analysis identifies the local frequency before and after the frequency switch as well as the location of the frequency switch, which is shown in Figure 8(b). At the same time, the result also shows the leakage of energy to the neighboring modes. In the Hilbert–Huang spectrum (Figure 7), we can see much sharper frequency definitions and the time location of the frequency switch than those shown in the scalogram (Morlet wavelet). The range of variation is insignificant compared with the leakage in the wavelet analysis result. This suggests that the HHT is capable of providing a more crisp indication of the frequencies in the signal.

Another interesting observation is that the scalogram shows the smearing of the precise time location of the frequency switch event in the lower frequency range. If we only look in the low-frequency range, we cannot tell the exact time of the impulse, whereas it is well localized in the high-frequency range. More generally, to look for definition of a low-frequency event, we have to look at the high-frequency range in the wavelet spectrum. On the contrary, the energy of the impulse is well localized in both time and frequency domains in the Hilbert–Huang spectrum. This illustrates the unique property of the Hilbert spectrum in elimination of the spurious harmonic components to represent the nonstationary data. Another strength of the HHT is its ability to resolve the intrawave frequency modulation, while the wavelet can only describe the interwave frequency modulation. The analyzed signal $s(t)$ does not illustrate this property. Huang demonstrates it clearly through some examples [1].

This relatively simple example has been used to try to underline the strength as well as weaknesses of the basic wavelet transform, the STFT and the HHT. A comparative table (Table 1) summarizes the advantages and shortcomings of these different time–frequency methods based on the above simple observations. The STFT seems to be limited compared to the wavelet and the HHT in the analysis of nonstationary signals. The wavelet transform has been the best available nonstationary data analysis before the introduction of the HHT. However, the analysis of the signal $s(t)$ has proven that the HHT offers a better time and frequency resolutions than the basic wavelet transform used in this example and allows a better physical interpretation of the signal content. Section 3 is dedicated to the investigation of the HHT features that could be used to obtain robust and efficient metrics for damage detection in structures.

2.5 Summary, discussion, and recent development of EMD

EMD method has been proposed as an adaptive time–frequency data analysis method by decomposing a signal into a series of components known as *IMFs*. Each IMF contains only a single-frequency component at any instant in time. Instantaneous frequencies can be calculated using Hilbert transform for each IMF function. Taken collectively, the Hilbert spectra of the IMF set yield complete time–frequency information about the original signal. This approach, which has been termed the *Hilbert–Huang transform* (*HHT*), makes it possible to apply the Hilbert transform to an extremely general class of functions and signals. The HHT method has received considerable attention in a broad range of applications; many of these applications can be found in [21]. There are also many recent advancements in the EMD and HHT approach. For example, Flandrin *et al.* [22], and Wu and Huang [23] showed that the EMD algorithm is effectively an adaptive dyadic filter bank when applied to white noise.

One of the major drawbacks of the EMD algorithm is the frequent appearance of "mode mixing", which is defined as an IMF function either consisting of signals of different oscillation scales or a signal of a similar scale residing in different IMF components. Mode mixing is mainly due to time-series intermittency, which is a true physical phenomenon of measured systems. To overcome the scale mixed

Table 1. Comparison of time–frequency methods

	STFT	Wavelet	Hilbert–Huang
Strength	Easy to implement	Basis functions obtained by shifting and scaling a particular function	High time–frequency resolution
		Uniform resolution	Generalized Fourier analysis with variable amplitudes and frequencies
		Analytic form for the result	First local and adaptive method in frequency–time analysis
		Nonstationary data analysis	Can clearly define both inter- and intrawave frequency modulations
		Feature extraction	Robust nonlinear and nonstationary data analysis
			Feature extraction
Weakness	Piecewise stationarity of the data assumption not always justified	Uniformly poor resolution	End effects due to spline fitting and the Hilbert transform
	Time–frequency resolution limited by the Heisenberg principle	Leakage generated by the limited length of the basic wavelet function	Cannot separate signals with very close frequencies
	Nonadaptive nature	Nonadaptive nature	No physical meaning of some IMFs
	Feature extraction impossible	Cannot resolve intrawave frequency modulation	No mathematical formulation
		High-frequency range observation to define local events	

up between IMF components, a new approach is developed, termed *ensemble empirical mode decomposition* (*EEMD*) [24]. The EEMD utilizes important statistical characteristics of underlying scale separation principle of the EMD technique. It enables the EMD method to be a truly dyadic filter bank for general signal. By adding finite noise, the EEMD eliminates mode mixing in all cases automatically. This improvement is significant for real-world signal analysis.

3 EMD METRICS FOR DAMAGE DETECTION

The EMD with its associated Hilbert spectral analysis has shown promising results in the analysis of time-series data. This great potential could be applied to help the diagnosis and the prognosis of structures. The structural health monitoring aims at developing a damage identification method that provides complete damage information. Rytter [25] proposed a system of classification for damage identification techniques, which defined four levels of damage identification. The presence of damage, its location, its size, and the prediction of the remaining service life of the structure are the different hierarchical goals to reach for any damage detection scheme. An appropriate metric is an essential mechanism to validate the presence of a structural damage and the key tool to infer the size of the damage. From the measurement of a specific physical property of the structure (e.g., damping, stiffness, and energy), a metric will give the necessary information to quantify the severity of the damage. On the basis of the EMD method, we propose several metrics that can

be applied for damage detection and diagnostics of a structure.

3.1 The Hilbert instantaneous phase

Some researchers have recently suggested exploiting instantaneous phase features of the vibration signals combined with wave mechanics-based concepts for damage detection [26]. Compared to the other time–frequency methods, the Hilbert instantaneous phase is a unique feature that describes the traveling structural-wave propagation. Pines and Salvino [6] have indeed proved the dependency of the phase on the structural parameters as stiffness, mass, and damping. The Hilbert instantaneous phase has been shown to have an interesting feature for damage detection metrics.

3.1.1 Description

The Hilbert transform of a real-valued time-domain signal $x(t)$ is another real-valued time-domain signal, denoted by $H[x(t)]$, such that $z(t) = x(t) + iH[x(t)]$ is an analytic signal, where

$$H[x(t)] = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{x(u)}{t-u}\, \mathrm{d}u \tag{19}$$

We can define an envelope function $a(t)$ describing the instantaneous amplitudes of the original signal $x(t)$ and a phase function $\theta(t)$ describing the instantaneous phase of $x(t)$ versus time using $z(t) = x(t) + iH[x(t)] = a(t)\,\mathrm{e}^{i\theta(t)}$. These instantaneous parameters are hence defined as

$$a(t) = [x(t)^2 + H[x(t)]^2]^{1/2}$$
$$\text{and } \theta(t) = \arctan\left(\frac{H[x(t)]}{x(t)}\right) \tag{20}$$

The instantaneous Hilbert phase is therefore defined for the real-valued time-domain signal $x(t)$ in equation (20). Using superposition, the signal $x(t)$ can be decomposed into n-empirical modes $c_i(t)$ and can be expressed as

$$x(t) = \sum_{i=1}^{n} c_i(t) \tag{21}$$

The residue, which is a mean trend, has been left out on purpose. Then, the Hilbert transform is applied to each IMF and produces the instantaneous phase as functions of time,

$$\theta_i(t) = \arctan\left(\frac{H[c_i(t)]}{c_i(t)}\right) \tag{22}$$

The total instantaneous phase is the sum of the instantaneous phases corresponding to each IMF and is defined as

$$\theta(t) = \sum_{i=1}^{n} \arctan\left(\frac{H[c_i(t)]}{c_i(t)}\right) \tag{23}$$

Because the intrinsic modes have been restricted to be symmetrically local with respect to the mean zero level, the phase can be considered to be local and to increase monotonically as a function of time. The continuous phase function is represented using unwrapped radian phases with changing absolute jumps greater than π and their 2π complements. This unwrapped instantaneous Hilbert phase now needs to be investigated as a potential damage detection tool.

3.1.2 1-D finite element simulation

Before computing the phase for real undamaged and damaged data, a finite element model has been simulated in order to understand how the instantaneous phase can be used to detect damage in structures. A dynamic finite element model of a clamped-free rod was created in order to simulate the 1-D wave propagation. Damage was introduced by a loss of stiffness in an element and the excitation input was a sine burst signal. The simulation results are then processed through the EMD, and the phases for the undamaged case and the damaged case are then computed and compared.

First, we wish to analyze the response of an undamaged rod to a transient load. The problem will be that of a rod, fixed at $x = 0$ and subjected to a transient load $f(t)$ at $x = L = 30\,\mathrm{m}$. The goal of the dynamic finite element model (FEM) simulation is to plot the variation of the displacement $u(x, t)$ with time for any x along the rod. For the present study case, the transient load will be a sine burst at 10 kHz frequency applied at the tip, and the displacement at

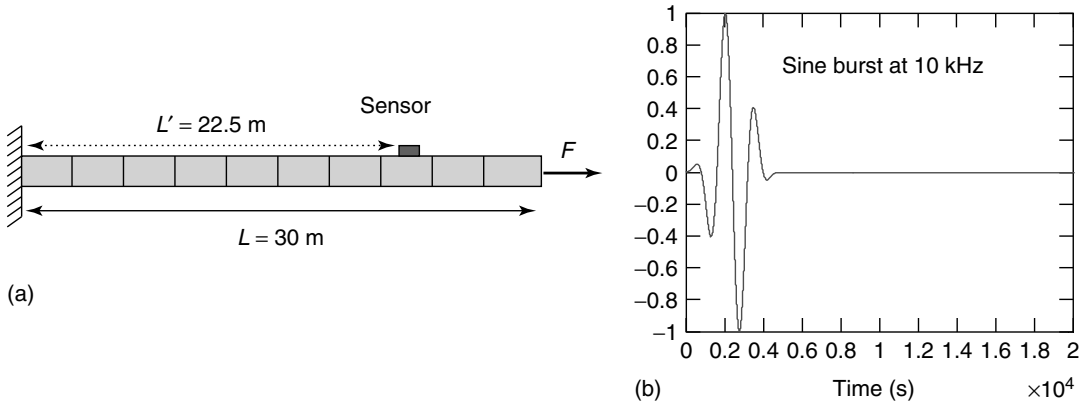

Figure 10. Forced vibrations model of a rod: (a) finite element model and (b) transient load.

$x = 22.5$ m is evaluated as shown in Figure 10. The wave-propagation solution of this kind of problem is very well known and can be found in Graff's book [27]. Waves in a rod are nondispersive. This means that their speed of propagation is constant, independent of frequency. The mathematical resolution of the wave propagation is therefore facilitated and the reflection from boundaries can be mathematically predicted. As shown in Graff's book [27], we will have a displacement reversal at the fixed boundary. This statement can be verified by the result of the simulation as seen in Figure 11. At first, the sensor detects the traveling wave generated by the tip excitation. The reflection from the clamped boundary is identified later and is reversed as predicted by the wave-propagation theory in a rod. The wave propagation in the undamaged rod is depicted in Figure 11.

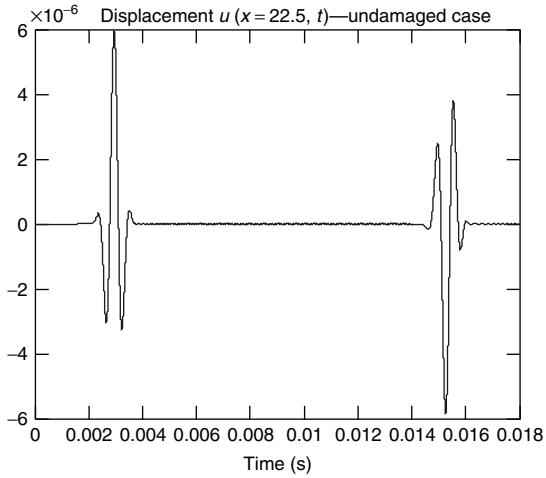

Figure 11. Response of an undamaged clamped-free rod to a transient load.

Reflections of waves may occur at discontinuities other than a boundary condition. One way to simulate damage in a computational model is to create a discontinuity in cross section, or material properties, or both, which is commonly referred to as an *impedance change*. A loss of stiffness in an element is hence introduced in the model, resulting in a damaged rod. The situation is shown in Figure 12.

Two damaged models have been created to introduce a loss of stiffness in the element located at $x = 7.5$ m such that (i) $E_{\text{dam}} = E_{\text{und}}/2$ for the first case, and (ii) $E_{\text{dam}} = E_{\text{und}}/4$ for the second case. Both wave-propagation simulation results are plotted in Figure 13. The reflections from the damage and the

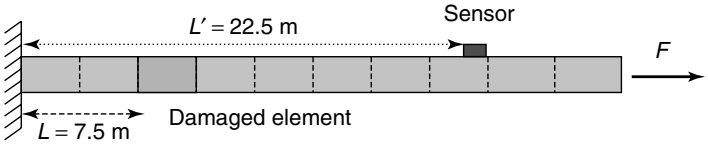

Figure 12. Damaged rod finite element model.

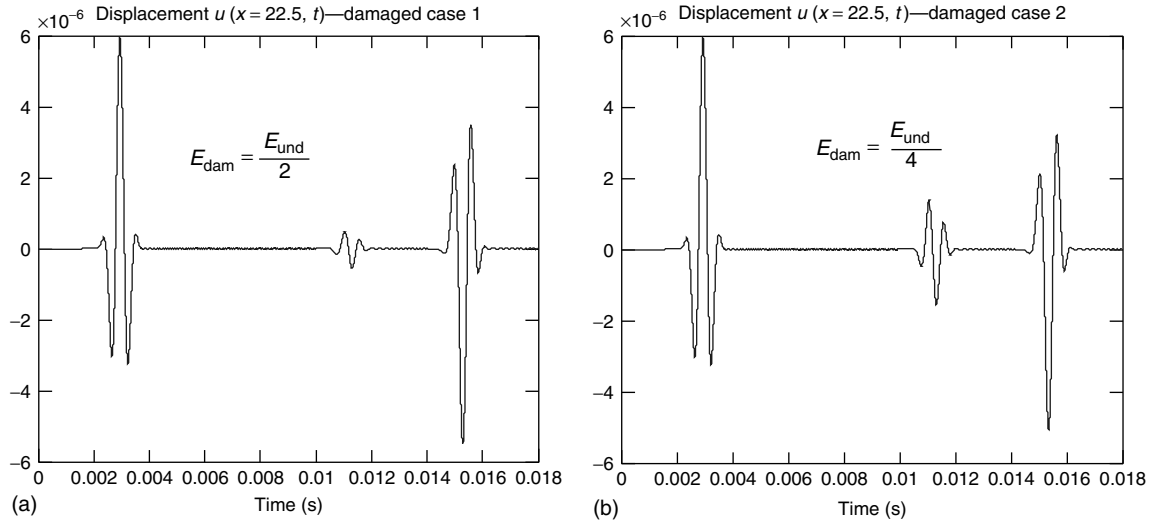

Figure 13. Response of a damaged clamped-free rod to a transient load: (a) damaged case 1 and (b) damaged case 2.

edge are clearly visible. The amplitude of these reflections increases with an increase in loss of stiffness in the element. A larger damage releases more energy in the structure, implying a greater magnitude in the waveform reflection.

A hamming window is applied in order to smooth the ends of the data to eliminate some aberrations and to allow a better spline interpolation in the EMD algorithm. The EMD along with the Hilbert transform can now be applied to these signals and the phase computed. The result for the Hilbert phase of the undamaged case and the damaged case is represented in Figure 14. From this plot, we can conclude that the reflection from the damage is interpreted by a slope change in the Hilbert phase. Physically, any damage in a structure alters the speed at which the energy traverses the structure. Once the wave passed through the damage, the energy speed is no more affected and the Hilbert phase behaves in the same manner for both undamaged and damaged cases as depicted in Figure 14. Furthermore, the slope change appears to be dependent on the size of the damage as seen in Figure 14. The energy speed propagation would be therefore altered in a different way depending on the

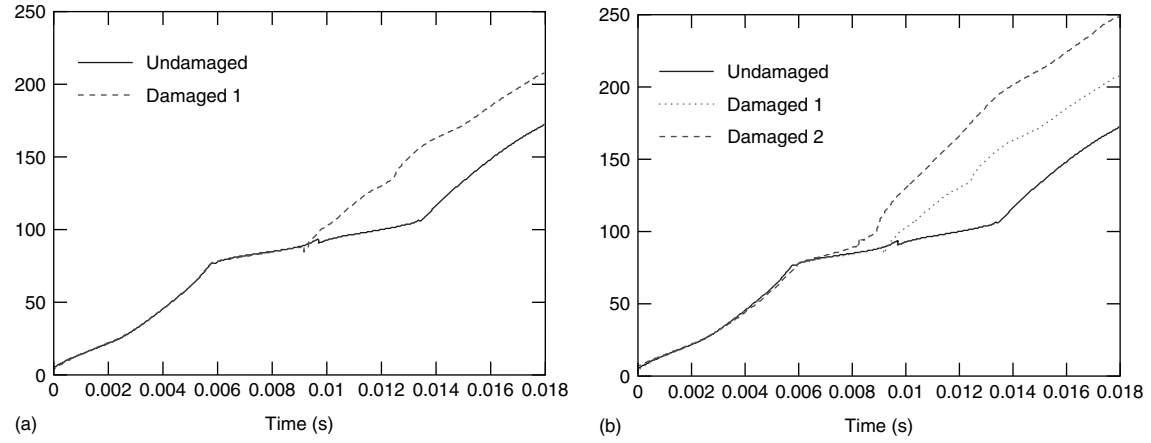

Figure 14. Hilbert phase: (a) damaged case 1 and (b) damaged case 2.

size of the damage. This implies that one can track increasing amount of damage as a function of phase. Thus, the Hilbert phase allows the size and location of damage to be determined. Even if the simulation results are not perfect and could be improved by augmenting the meshing and discretizing the rod by more elements, the damages are clearly localized by the slope change of the Hilbert phase.

3.2 The energy metric

One of the main advantages of the HHT is to provide a high-resolution energy–time–frequency representation. The Hilbert spectrum is capable of describing, with high precision, the frequency content of any nonstationary and nonlinear signals. The different features embedded in the time-domain signal can therefore be highlighted and better understood. For these reasons, the energy–time–frequency plot provided by the HHT could be used to identify and assess structural damage. A Hilbert energy spectrum describing the wave energy density can be created and the severity of the damage inferred from the reflected energy.

3.2.1 The Hilbert–Huang spectrum and the reflected energy

As seen earlier, after applying the EMD and the Hilbert transform on the IMFs, a real signal $x(t)$ can be expressed as $x(t) = \sum_{j=1}^{n} a_j(t) \exp\left(i \int \omega_j(t)\, \mathrm{d}t\right)$, where $a_j(t)$ are the instantaneous amplitudes and $\omega_j(t)$ are the corresponding instantaneous frequencies. Because both amplitude and frequency of each IMF are a function of time, they can be used to define a three-dimensional space or ordered triplet $[t, \omega(t), a(t)]$. This space is generalized by means of a function of two variables $H(\omega, t)$ to $[t, \omega(t), H(\omega, t)]$, where $a(t) = H(\omega(t), t)$. Therefore, we obtain a three-dimensional plot, in which the amplitude can be contoured on the frequency–time plane. The amount of energy carried by a wave is related to its amplitude. This transported energy is directly proportional to the square of the amplitude of the wave. Thus, the squared values of amplitude can be substituted in the Hilbert spectrum to represent the energy density and to produce the Hilbert energy spectrum. The idea behind this is that any reflection from damage can be quantitatively estimated through the energy transported by the reflected wave. The amplitude of the reflection increases with the size of the damage. This increase in amplitude should be revealed locally in the energy–time–frequency representation. We can, therefore, expect to infer the size of the damage through the Hilbert energy spectrum.

3.2.2 The Hilbert–Huang spectrum as a damage detection parameter

A damage index can be introduced in order to quantify the severity of the damage as a function of reflected energy:

$$E = \sum_{f} \sum_{t} |H_{\mathrm{e}}(t, f)| = \sum_{f} \sum_{t} |a(t)^2| \quad (24)$$

where $H_{\mathrm{e}}(t, f)$ is the energy density spectrum and $a(t)$ is the instantaneous amplitude.

This damage index is applied to the reflected waveform from the damage, and the result can be displayed next to each spectrum. As expected, this damage index increases with the size of the damage and a trend could be interpolated to infer the increasing damage.

In general, it will be difficult to identify the reflections from boundaries and other discontinuities. The EMD serves this purpose. The ability of the EMD to decompose any complicated data into a set of simple oscillatory functions would allow extracting embedded reflections.

To summarize, the objective is first to extract signal structures embedded in the data. The EMD is therefore the fundamental key to reveal the damage signatures that may otherwise remain hidden. The next step is to create the Hilbert energy spectrum for both undamaged and damaged cases. At this point, the energy density representation accurately describes the wave propagation in the structure. The presence of damage can hence be inferred and an estimation of the size predicted through the amount of reflected energy.

3.3 The phase shift metric

The high frequency and energy definitions provided by the HHT are used to locate and infer the size of

damage. Another interesting parameter to investigate is the high time resolution of the Hilbert–Huang spectrum. The time of flight is an important feature that is often used in damage detection schemes. The time of flight between the actuator and sensor in a structure is directly dependent on the wave-propagation properties in the structure.

The time resolution is therefore explored to obtain an accurate time of flight and, consequently, a precise position of the structural discontinuity. The track of increasing damage would be also possible as long as the initial size of the damage is known. A wave propagates at a certain speed in a structure. The time difference between the initial sensing actuation and the reflection from a discontinuity gives the time needed for the wave to travel. The basic formula length = speed × time locates the damage. When a wave encounters damage, part of the incident wave front is reflected back while the rest is transmitted through the damaged region. This reflection occurs at the beginning of the damage, which implies that a bigger damage would engender a sooner reflection than a smaller damage located at the same position. Hence, the times of flight would be different for damages with different sizes at the same location. Thus, if the time resolution of the HHT is powerful enough to perceive the small fluctuations of the different times of flight, an estimation of the severity of the damage would be possible.

Assuming that the size and the shape of the initial damage are known, simple geometric calculations would allow one to estimate the growth of the damage from the time difference between the initial and the new reflections. The severity of the damage can be thus quantified through the arrival time of the reflection as long as the initial damage is identified. Hence, the importance of an accurate signal processing for obtaining the flight times cannot be overemphasized. Accurate identification of localized events is required to determine the location of the damage, especially when complications due to the dispersive nature of waves in plates exist.

3.4 Summary

The EMD and the Hilbert spectrum offer a lot of possibilities for damage detection. First, the Hilbert phase represents a unique feature describing the energy propagation in a structure. The Hilbert phase as a damage detection parameter seems to work quite well for one-dimensional models with nondispersive wave propagation. The presence of damage is interpreted by a slope change in the Hilbert phase plot, which corresponds to a modification of the speed at which the energy traverses the structure. The finite element simulation as well as the civil building model analysis by Pines and Salvino [6] has shown promising results in the detection and evaluation of structural damage. Secondly, the energy metric relies on the high energy–time–frequency resolution of the Hilbert spectrum. This metric listens to the energy release in the structure upon defects growth. The amount of reflected energy is described and quantified with the Hilbert energy spectrum and an estimation of the severity of the damage can be deduced. Finally, a phase shift metric is developed on the basis of the arrival times of reflected waves from damage. Depending on the size of the damage, the wave will need a certain time to travel. This time of flight can be exploited along with geometric considerations to determine the defect growth from the knowledge of the initial damage properties.

Hence, the EMD along with the Hilbert transform seems to be the appropriate time–frequency analysis method for health monitoring of structures. The ability of the EMD to extract embedded oscillation, to reveal hidden reflections in the data, and to accurately describe the frequency content of a signal through the high-definition Hilbert spectrum make it an ideal tool for damage detection. The different damage detection schemes discussed in this article must now be investigated for two-dimensional structures where the waves are dispersive and thus more complicated to describe. The next section describes a low-velocity impact experiment on a cross-ply composite plate and an analysis of the results with the HHT.

4 LOW-VELOCITY IMPACT DAMAGE

A real-world application is now investigated to confirm the real potential of the HHT for a structural health monitoring system. The most commonly encountered type of damage is caused by impact due to the low interlaminar strength of composites. The mechanical properties can be severely degraded as

a result of a low-velocity impact even for barely visible damage. An impact on the structure can induce different type of damages such as matrix cracking, delaminations, and broken fibers. Such impact can occur in reality if a worker accidentally drops a tool or if a bird crashes into the aircraft during takeoff. A good way to experimentally simulate a low-velocity impact is to build a swinging pendulum mechanism. The energy of the impact could therefore be quantified through the potential energy and related to the damage growth.

4.1 Experimental setup

The experiment was conducted with an eight-ply composite plate [0/90]s, the setup of which is shown in Figure 15. The plate was instrumented with a piezoceramic actuator and a PVDF sensor array. A 0.635 cm × 0.635 cm PZT-5H patch actuator was bonded to the surface of the laminate at the left edge and used to excite the structure with interrogating A0 waves. A sensor array was bonded at a distance of 30.48 cm. from the actuation element. The array contained 19 circular sensor elements with a diameter of 0.3175 cm. and a spacing of 0.635 cm. The plate was 88.9 cm. long and 60.96 cm. wide. A tone burst signal of a 40 kHz frequency and five cycles was used to interrogate the plate and the resulting transient responses were observed and saved for each sensor of the array. The pendulum mechanism is shown in Figure 16. A hammer type of impactor was conceived and it was able to carry circular masses to increase the energy impact. The impactor was free to swing around a circular shaft introduced through the two columns. Instead of a bearing, shaft collars were used to avoid unwanted oscillations of the impactor. Thus, some frictional effects were neglected in this experiment and should be taken into account for a most accurate estimation of the energy released by the system. The experimental setup is pictured in Figure 17. The horizontal position of the plate was chosen in order to avoid any bending after the impact.

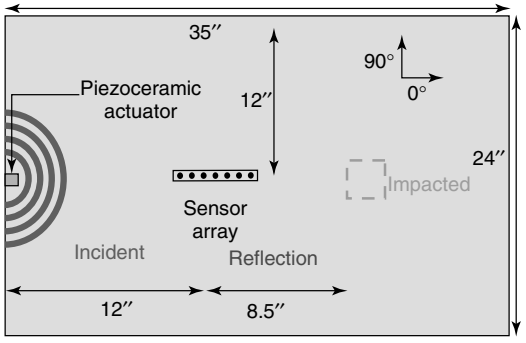

Figure 15. Experimental setup.

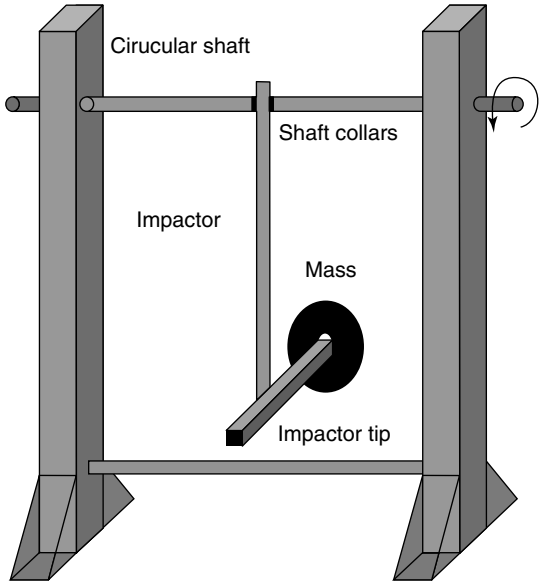

Figure 16. Swinging pendulum mechanism.

This experiment setup allows systematic impact as desired. For each impact, the response signals are gathered without removing the plate. The boundary conditions remain identical for every impact and thus will not influence the results. A picture of the impacted region is also taken after each impact. In this way, a correlation between the visual inspection (or local nondestructive evaluation (NDE)) of the plate and the signal-processing results will be possible. Each impact starts at zero initial velocity and at a certain initial angle. The impact energy comes from the gravitational potential energy. The experimental setup therefore makes pendulum impacts repeatable with only one varying parameter, the impact energy.

4.2 Impact energy quantification

Let us take the zero of potential energy to be at 90° angle of the swing, as shown in Figure 18. When the

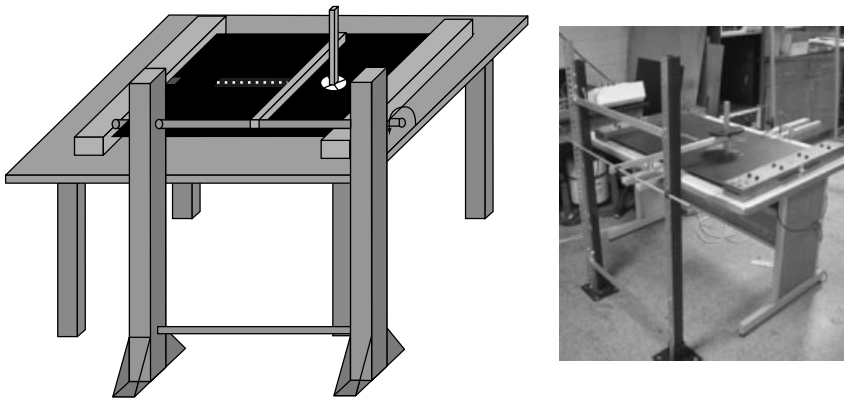

Figure 17. Low-velocity impact experimental setup.

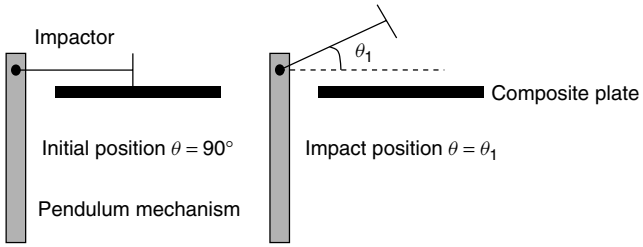

Figure 18. Potential energy calculation.

pendulum is brought to a certain height before being released, it is higher than at the initial position of the swing, and the potential energy is equal to the weight of the pendulum multiplied by the change in height. If the pendulum has length L, the change in height is $L \sin\theta$ and the potential energy becomes

$$E = mgL \sin\theta \tag{25}$$

In the study case, the pendulum is not limited at a single mass but at a hammer impactor with a significant weight. Thus, the impactor system will be replaced for the calculation by a single mass defined by its center of mass. The center of mass is defined as the average of the constituting element positions weighted by their masses. Each time a mass is added to the system, the center of mass changes.

The damage detection methodology follows these steps:

1. The plate is impacted. Each impact has more energy than the previous one. The initial angle is increased or a mass is added for this purpose.
2. A picture of the impacted region is taken.
3. The plate is interrogated by a tone burst at 40-kHz frequency with five cycles. The response signals are observed and saved on a disk.
4. This set of data is processed by using HHT.
5. Repeat the process.

The different impact cases with the corresponding potential energy are given in Table 2.

4.3 Transient signal analysis

A first undamaged set of data is taken as a baseline. The plate is then impacted and the middle

Table 2. Summary of the different impact cases

Case #	Mass m (kg)	Length L (m)	Initial angle θ (°)	Energy (J)
1	0.787	0.422	90	3.27
2	3.05	0.601	45	12.7
3	3.05	0.601	90	17.9
4	5.32	0.625	45	23.1

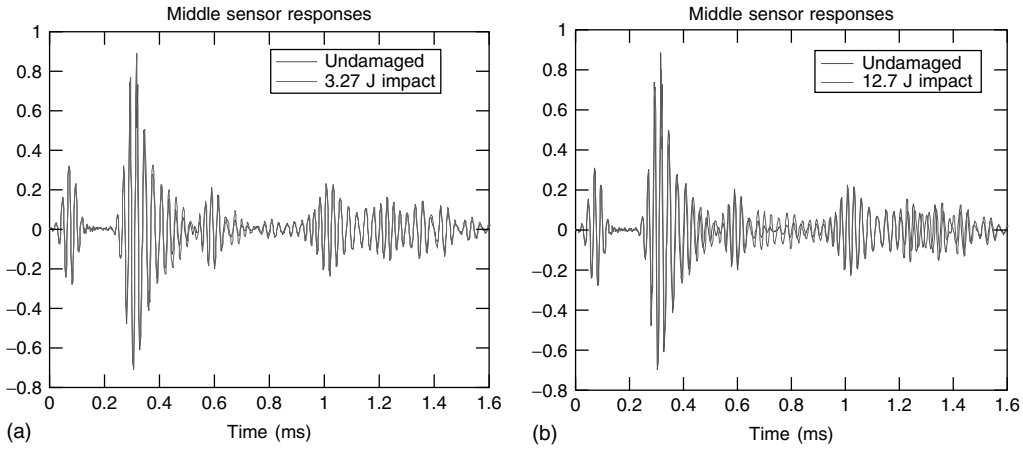

Figure 19. Middle sensor responses for the first two impact cases: (a) impact 1 and; (b) impact 2.

sensor responses are examined to infer the presence of damage in the plate. A first impact of 3.27 J is applied and the middle sensor signals for the undamaged and impacted plates are compared in Figure 19(a). The location of the impacted region was chosen in order for the reflected waveform to be visible in the transient signals. The pendulum mechanism was therefore impacted by the plate at a distance of 21.59 cm. from the middle sensor. If damage is created due to the impact, the reflected waveform should appear between the top/bottom edges and the right edge reflections. The observation of the transient signals in Figure 19(a) does not give any information about the presence of damage due to the first low-velocity impact. The impact energy was then increased by adding a mass to the impactor and the middle sensor responses are plotted in Figure 19(b). In this case, a difference can be seen between the undamaged and the impacted signals at ∼0.7 ms. A reflected waveform, though weak, shows up as expected in case of damage. The Lamb waves encounter a discontinuity through the thickness of the plate and part of the incident wavefront is reflected back. The middle sensor response is able to exhibit this reflection. An impact of 12.7 J damaged the composite plate. A C-scan examination would precisely determine the type of damage engendered by the impact. This NDE technique being unavailable, a visual inspection of the impacted region may provide some understanding of the impact consequence on the structure. A picture of both impacted region surfaces were taken and are shown in Figure 20. The observation of these pictures

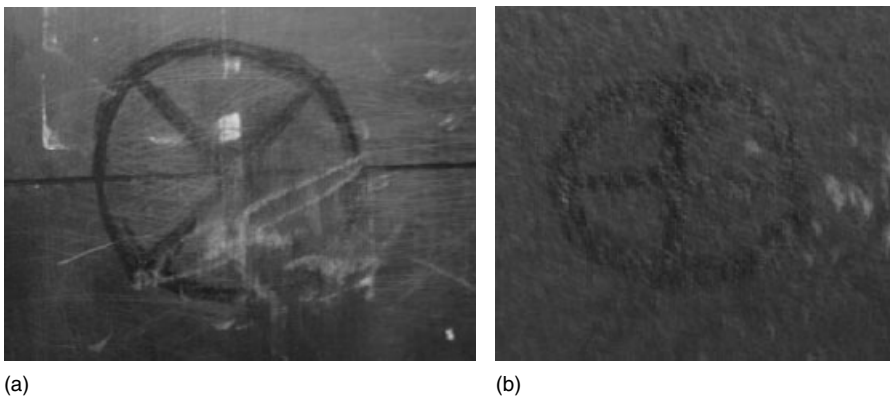

Figure 20. Impacted region pictures: (a) front surface and (b) back surface.

and a touch examination of the impacted region do not show the presence of any defects in the plate. The common visual inspection technique used for the structural health monitoring of composite structures would not detect the presence of damage in the plate. However, the transient response detects a discontinuity in the structure at the impact location. The reflected waveform localized by the sensor signal is, nevertheless, weak and needs to be effectively identified as a damage reflection. To accomplish this goal, the wavenumber filtering technique is applied to extract the leftward propagating waves. The damage reflection would be better characterized and quantified with this representation. The leftward propagating waves for the undamaged and the first two impacted cases are plotted in Figure 21. The first impact does not affect the health of the composite plate. However, the leftward propagating waves for the impact of 12.7 J of energy confirm the presence of damage with a new waveform detected between 0.6 and 0.8 ms. Although invisible on both surfaces of the impacted region, damage is present in the structure. The source of impact damage may include delamination between plies, matrix cracking, or broken fibers. The use of Lamb waves to interrogate composite structures enables subsurface damage that is invisible to the naked eye to be detected. A third impact is used to determine whether the damage region grows. The middle sensor response corresponding to this impact case 3 is plotted in Figure 22 along with the picture of the impacted region. Again, a weak reflection is visible for the impacted case around 0.7 ms that is not present for the undamaged case. In order to have a better idea of the magnitude of this reflection, the leftward propagation is also extracted and plotted in Figure 23. The picture of the front surface of the plate clearly shows that the composite structure is damaged. Broken fibers as well as matrix cracking can be seen. Compared to the previous impact, the damage is evident by visual inspection of the plate. However, the magnitude of the reflected waveform shown in Figure 24 slightly increases from the 12.7-J impact to the 17.9-J impact, whereas the difference between the shapes of the impacted region is obvious. From this observation, two theories can be assumed. The first theory is that the Lamb wave is not able to track the increasing damage. The second is that the structural properties of the plate have been equally affected by the impacts even though the visual inspection leads to different interpretations. A stronger impact analysis will confirm either of these assumptions. A mass of 10 lb is added to the hammer system and the swinging impactor is released at a 45° angle, producing a 23.1-J impact (case 4). The middle sensor response, along with the leftward propagation, is plotted in Figure 24. Both sensor signal and leftward propagating waves show that the magnitude of the damage reflection increases with the applied

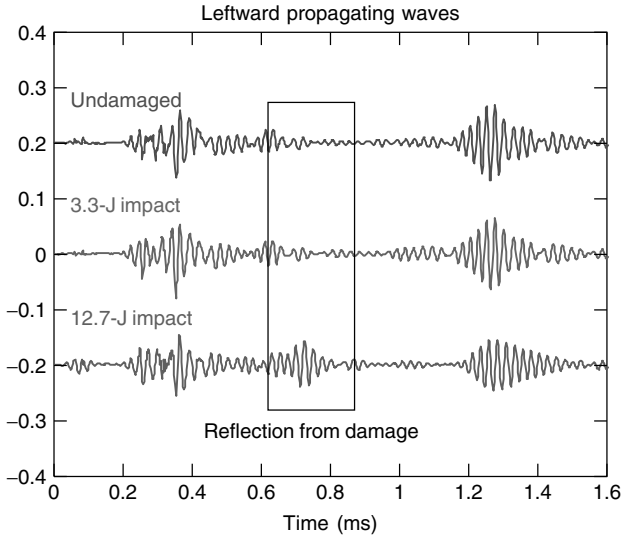

Figure 21. Leftward propagating waves—impacted cases 1 and 2.

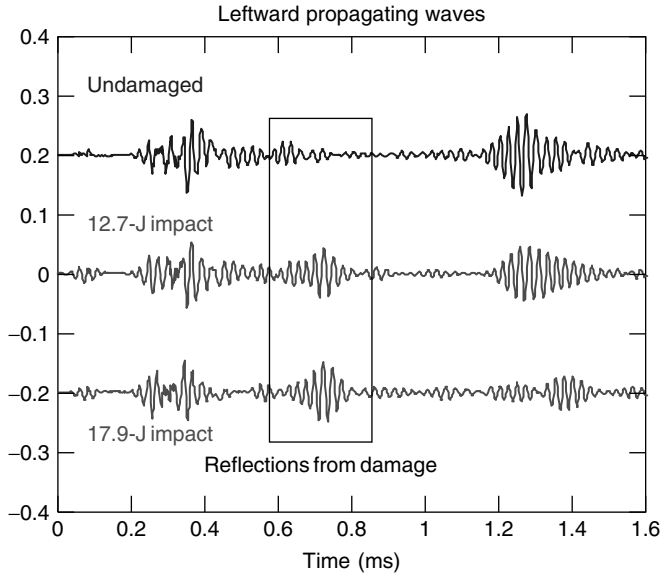

Figure 23. Leftward propagating waves—impacted cases 2 and 3.

impact energy and thus with the size of the damage. The second assumption is therefore the right one. The reflections from the right edge also decay with the increasing energy impact. Before applying the HHT to these signals, several conclusions can be drawn from the transient analysis:

- The Lamb waves are able to detect damage in a composite plate that is invisible to the naked eye.
- A composite structure can be seriously damaged without any physical signs being shown on the surfaces.
- The physical marks of damage and the real loss in mechanical properties are not related.
- The amplitude of the reflection from damage increases with the impact energy and therefore with the size of the damage.

4.4 Hilbert–Huang spectrum and energy metric

The EMD is then used to apply the Hilbert transform to the IMFs extracted and to plot the time–frequency representation of the data. Once the Hilbert–Huang spectrum is obtained, the energy released by the damage can be quantified and linked to the impact energy and the size of the damage. The energy metric is applied to the unfiltered set of data. The Hilbert–Huang spectra for the unfiltered undamaged and damaged (12.7-J impact) are given in Figure 25. The results of the Hilbert energy measurement of the reflected frequency band are given in Table 3. Assuming that each impact weakens the plate and contributes to the creation of damage in the next impact, a cumulative energy impact approach seems to be more representative of the effective energy involved in damaging the plate. The energy metric results can therefore be plotted to describe the growth of damage with respect to the energy impact, as seen in Figure 26. The energy released upon the damage growth perfectly fits a parabolic interpolation curve. The track of increasing damage is therefore possible for this experiment through the energy released by the damage and using only one sensor.

Table 3. Energy metric results for the unfiltered data

Potential energy	0	3.3	12.7	17.9	23.1
Released energy	0.0182	0.1172	0.4946	1.1773	2.8956

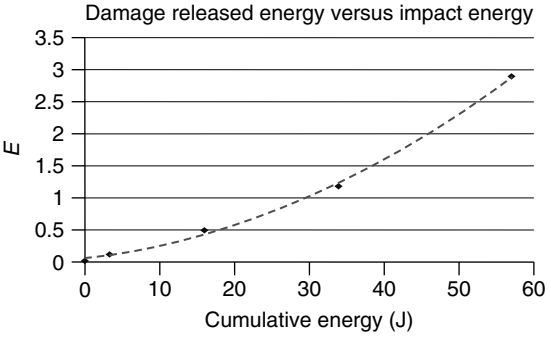

Figure 26. Growth of damage with impact energy.

4.5 Energy–time spectrum and phase shift metric

The energy–time spectrum aims to localize the damage through a precise determination of the time of flight and to quantify the size of the damage through the phase shift between the reflected waveforms. The energy–time spectrum for the low-velocity impact experiment described in the previous sections is given in Figure 27. For a better visibility and readability, the results have been separated in two distinct plots. As expected, the localization in time of the reflected waveform through the energy spectrum turns out to be very precise. A phase shift between the reflections from increasing damage can even be temporally quantified and related to the size of the damage. The amplitude of the reflected waveforms also increases with the energy impact. However, for case 4 corresponding to the 23.1-J impact energy, the reflection is spread out in time, has a weaker magnitude, and does not exhibit a clear peak. These characteristics can be explained by the fact that the addition of the 10-lb mass to the system along with a large initial angle deviated the point of impact and created a second damage in the plate. The reflected waveform represented in the energy spectrum therefore encloses two adjacent reflections. This assumption is confirmed by the picture of the impacted region in Figure 28 that shows two damages in the plate. Using the group wave velocity and the time of flight given by the energy spectrum, the location of the damage can be inferred.

In order to confirm that the plate has effectively been damaged by the impact, a cross section cut along the damage is realized. As we can see in Figure 29, the different impacts created matrix crackings, broken fibers, and a delamination.

4.6 The Hilbert phase

So far, the Hilbert phase turned out to be not only the most promising feature for delamination detection in composite structures using the HHT but also the most sensitive and difficult to apply. This real-world type of experiment aspires to confirm the capability of the Hilbert phase to describe the changes in the wave-propagation speed energy. The Hilbert phase results are plotted in Figure 30. For case 1, the transient analysis and the wavenumber filtering technique did not reveal the presence of damage even though the energy measurement showed a slight increase. The

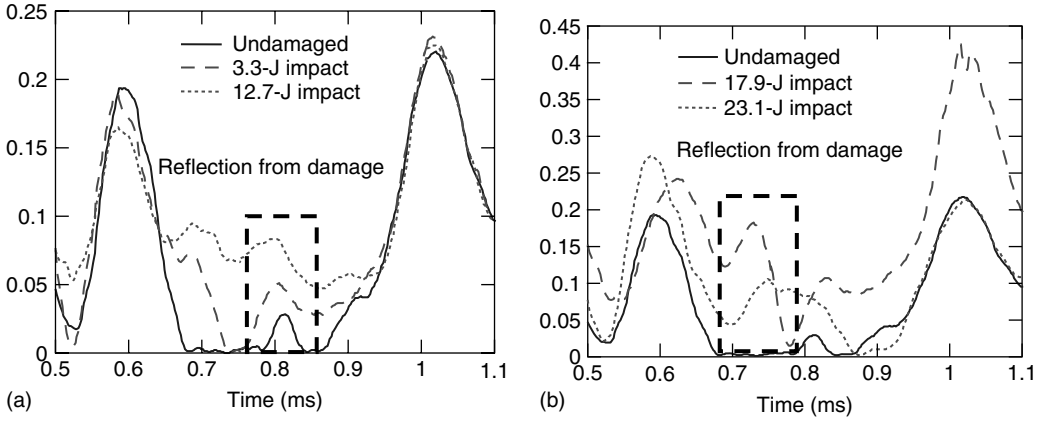

Figure 27. Energy–time spectra: (a) cases 1 and 2 and (b) cases 3 and 4.

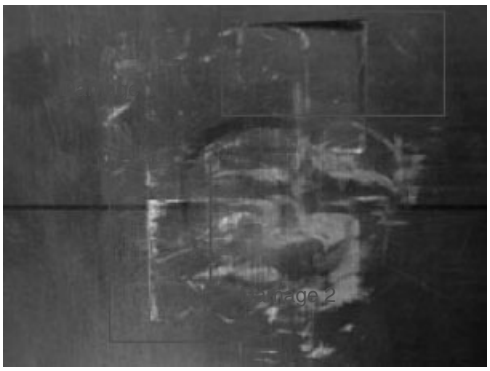

Figure 28. Front surface picture—case 4.

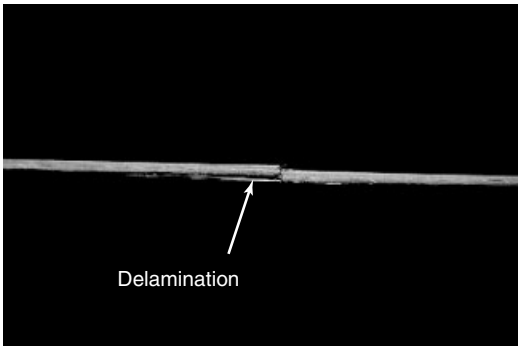

Figure 29. Cross-section picture of the impacted region.

Hilbert phase confirms these results. The phases for the undamaged case and the 3.3-J impact behave in the same way, indicating that there is no discontinuity encountered by the wave. In the case of damage, the wave propagation is altered, resulting in a slope change in the Hilbert phase. The Hilbert phase of cases 2 and 3 show these deviations. At around 0.7 ms, the undamaged and damaged phases start to diverge denoting the presence of damage in the composite plate as seen in Figure 30. The location of damage can be inferred from the time divergence and the amount of damage can be quantified by the mean phase error metric. The behaviors of both impacted phases are pretty close even if the 17.9-J impact appears to damage the plate more than the 12.7-J impact. The Hilbert phase is therefore consistent with all the previous conclusions and can perfectly describe the wave propagation and interaction with damage in the composite plate.

5 SUMMARY

This article has illustrated how the EMD method can be used to track damage in simple one-dimensional and thin two-dimensional composite structures. For thin plates, wave propagation is described in terms of Lamb waves. The antisymmetric fundamental transverse wave mode A_0 was able to describe the damage interactions in composite plates. The study has focused on developing and validating damage detection schemes based on the features of the EMD and the associated Hilbert spectral analysis. Three damage detection techniques were developed on the basis of the energy density, the time of flight, and the energy speed propagation. The instantaneous phase can be used as a damage detection tool. A finite

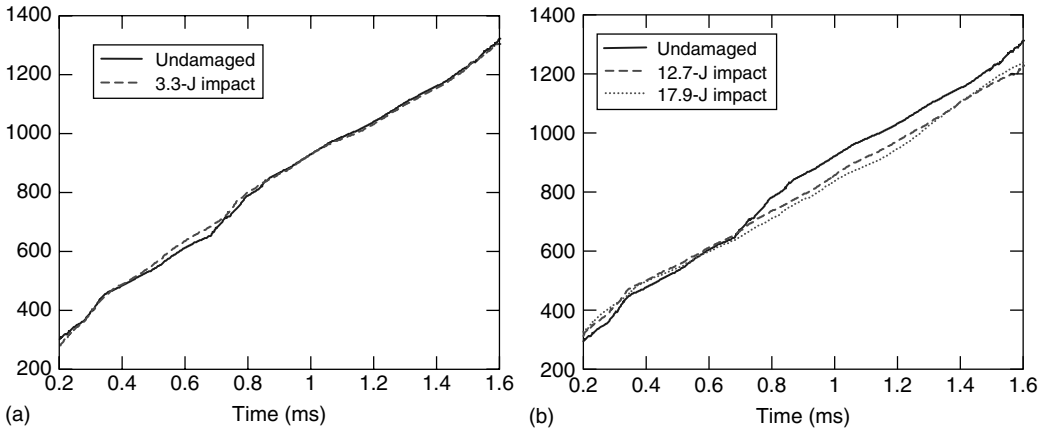

Figure 30. Hilbert phase plots: (a) case 1 and (b) cases 2 and 3.

element model of a rod was used to show the effect of a stiffness loss on the phase behavior. The principle is that any damage in a structure alters the speed at which the energy traverses the structure. The phase reflects this speed change by a slope deviation. As a result, the Hilbert phase can not only detect the presence of the defect in the structure but also quantify the extent of the damage. The Hilbert–Huang spectrum described the energy propagation in the structure. Any reflection is measurable by its energy density. The energy released upon defect growth can be therefore quantified and used to track the increasing damage. A larger reflection due to a larger damage will result in an increase of the energy in the Hilbert energy spectrum. The time of flight between the actuation waveform and a damage reflection can be accurately extracted from the energy–time spectrum provided by the HHT. The peaks on the energy–time spectrum for the IMF component, containing the highest energy, give the wave arrival times of interest. The wave group velocity combined with the time of flight locates the damage. If the initial shape and size of the damage is known, basic geometric considerations associated with the time of flight and wave-propagation characteristics provide a means to estimate the severity of the damage. A low-velocity impact was successfully experimented and tested. The repetitive impact system allowed a correlation of the visual inspection of the impacted region with the potential energy and the HHT results. Subsurface damage is detectable by examining the leftward propagating wave dynamics from the middle sensor. The energy–time spectrum could locate the damage, whereas the energy density spectrum was used to quantify the damage. The increasing damage was shown to follow a parabolic trend. The Hilbert phase also gave consistent results with the other damage detection techniques and was able to detect and quantify the amount of damage created by the pendulum impactor mechanism. This real-world application showed all the HHT potential as a damage detection tool.

Chapter 36

Model-based Statistical Signal Processing for Change and Damage Detection

Michèle Basseville
IRISA, Campus de Beaulieu, Rennes, France

1 INTRODUCTION

Detecting changes in signals and dynamical systems has been the topic of a number of both theoretical and practical investigations for about 30 years, as can be seen e.g., from the survey papers [1–3] and books [4–6] among many other references. Early investigations of statistical change detection took place in the area of quality control and trace back to the 1930s. More recent applications to industrial monitoring problems [7–11] have highlighted the relevance of statistical inference approaches to the problems of fault detection, isolation, and diagnosis. As for vibration-based structural health monitoring (SHM), a number of simulations, laboratory test beds, and real test cases [12–17] have also exhibited some interesting properties of algorithms based on a statistical change detection approach to damage detection and localization.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

1.1 Motivations for change detection

Many monitoring problems can be stated as the problem of detecting and isolating a change in the parameters of a static or dynamic stochastic system. The use of a model of the monitored system is reasonable, since many industrial processes rely on physical principles, which are written in terms of (differential) equations, providing us with (dynamical) models. Moreover, the use of (physical) parameters is mandatory when diagnostics is sought. In the sequel, we equally use the words deviation, change, fault, and damage, considering that all these events are reflected

by a change in the parameter vector of a model of the monitored structure or system.

The change detection framework and methodology is one way to approach the analysis of nonstationary phenomena. Statistical decision tools for detecting and estimating changes are useful for different purposes:

1. automatic segmentation of signals as a first step in recognition-oriented signal processing;
2. gain updating in adaptive identification algorithms for improving their tracking ability;
3. quality control;
4. monitoring complex structures and industrial processes (damage and fault detection and diagnosis) for fatigue prevention, aided control, and condition-based maintenance.

Even though this article focuses on the use of change detection for damage detection and isolation, the same methodology and tools apply to the other problems as well.

1.2 Motivations for statistical methods

It has been widely acknowledged that the fault or damage detection and isolation problem can be split into two steps: *generation of residuals*, which are ideally close to zero under no-fault conditions, minimally sensitive to noises and disturbances, and maximally sensitive to faults; and *residual evaluation*, namely, design of decision rules based on these residuals. The basic statistical approach to residual generation consists in deriving sufficient statistics, namely, transformations of the measurements, which capture the entire information about the fault contained in the original data. Residual evaluation is typically answerable to statistical methods, which are basically aimed at deciding if a residual discrepancy from zero is significant.

The main advantage of the statistical approach is its ability to perform the early detection of deviations with respect to a reference undamaged state of the monitored system (possibly *before* a deviation develops into a damage). Another major advantage is its ability to assess the level of significance of those deviations with respect to noises and uncertainties. Whereas the accuracy of parameter estimates provides us with the relative size of the estimation error with respect to the noises on the system measurements, the statistical tests described below can similarly tell us if the relative size of the parameter discrepancy in the monitored system with respect to the accuracy of the reference parameter value is significant or not. These are crucial issues when addressing real SHM problems.

1.3 Two types of changes

Let θ be the model parameter, and $y_1, y_2, \ldots, y_n$ a sequence of measurements. In most cases of interest for SHM, both θ and the y_i's are multidimensional. For both intuitive and mathematical reasons, it is useful to classify the change detection problems into two categories: *additive* changes, such as changes in the mean value of the measurements, and *nonadditive* (or spectral) changes, which basically affect the correlations in the data or the dynamics of the system and associated transfer functions.

The main issue is which function of the data should be handled for making a decision about the presence of a change. The main lesson is that, whereas the innovation is convenient for monitoring additive changes, the innovation is *not sufficient* for monitoring changes in the system dynamics.

1.4 Three types of change detection problems

From now on, we assume that we are given a reference value θ_0 of the model parameter. Generally, such a reference parameter is identified with data from the safe system. The monitored system is often subject to other types of nonstationarities than the parameter deviations of interest, typically changes in the functioning modes of a machine, nonstationarities in the environment of a structure, etc. In such cases, the reference value θ_0 should be identified on long data samples containing as many of these nuisance changes as possible. The detection problem may be solved on the basis of data samples of smaller size. Depending on the relative time constants of the system to be monitored, on the sampling of the data, and on the size, speed and rate of the deviations to be detected, three types of detection problems may

occur in practice, when processing real data, onboard or not.

- **Model validation**

Given, on the one hand, a reference value θ_0 of the model parameter and, on the other hand, a new data sample, the problem is to decide whether or not the new data are still well described by this parameter value. Of course, this problem may be stated either off-line (fixed sample size) or on-line (varying sample size). A fixed-size sliding window may be useful. Model validation may be a relevant issue for onboard processing: for example, batch processing is appropriate for onboard monitoring of aging.

- **Off-line change detection**

Given a data sample of size n, the problem is to decide whether a change in the parameter has occurred, from θ_0 to θ_1, at an unknown time υ in the sample.

- **On-line change detection**

At every time instant n, the problem is to decide whether a change in the parameter has occurred, from θ_0 to θ_1, at an unknown time instant $\upsilon < n$.

Of course, the most difficult problem is the third one, because in this problem the amount of information in the data about the new parameter value θ_1 is the least. Also, the criteria for designing the detection algorithms and analyzing their performances depend on the detection problem. These are mean time between false alarms, probability of wrong detection, mean delay to detection, probability of nondetection, and accuracy of the estimates of the change onset time and of the change magnitude. However, even though the decision functions for solving these three problems are not the same, they all can be viewed as different implementations of the same primary residual.

This article is organized as follows. First, in Section 2, the key detection tools, likelihood ratio and CUSUM (cumulative sum) tests, are introduced for the model validation and on-line change detection problems, respectively. Then, the on-line detection problem is addressed for changes in the mean of scalar signals, additive changes in multidimensional independent or dependent time series, and changes in the spectrum of scalar signals, in Sections 3, 4, and 5, respectively. Other tools useful for handling small changes are introduced in Section 6. Back to the model validation point of view, Section 7 addresses the problem of detecting changes in the dynamics of a linear state-space system, of which vibration-based monitoring is an important instance. Finally, in Section 8 some additional issues are addressed, such as damage or fault isolation and diagnostics, robustness in the decision, damage detectability, and sensor positioning.

2 LIKELIHOOD RATIO AND CUSUM TESTS

The key detection tools are first introduced for hypotheses testing, and then for on-line change detection, distinguishing between independent and dependent observed data.

2.1 Hypotheses testing

The measured data $y_1, y_2, \ldots, y_n$ are assumed to be random variables with probability distributions p_θ. Hypotheses about the parameter vector θ are stated, reflecting the *a priori* knowledge on the changes to be monitored. Typically, the null (no-change) hypothesis is $\mathbf{H}_0 : \theta \in \Theta_0$ and the alternative (change) hypothesis is $\mathbf{H}_1 : \theta \in \Theta_1$. Two types of hypotheses are distinguished. A *simple* hypothesis is reduced to one point in the parameter space; typically, the no-change hypothesis reduces to the reference value of the parameter vector: $\Theta_0 = \{\theta_0\}$, and the change hypothesis to a different value: $\Theta_1 = \{\theta_1\}$. A *composite* hypothesis is defined by a subset of the parameter space; typically the no-change hypothesis is defined by Θ_0, and the change hypothesis by Θ_1.

2.1.1 Independent observations

Assuming that the parameter is θ, the probability of observing the measurement y_i is $p_\theta(y_i)$ and is called the *likelihood*. First, consider the case of simple hypotheses. For deciding whether the parameter vector is more likely to be θ_1 than θ_0, it is natural to compute the *likelihood ratio* $p_{\theta_1}(y_i)/p_{\theta_0}(y_i)$. For computational purposes, it is also useful to handle the

log-likelihood function: $l_\theta(y_i) \stackrel{\text{def}}{=} \ln p_\theta(y_i)$ and the log-likelihood ratio:

$$s_i \stackrel{\text{def}}{=} \ln \frac{p_{\theta_1}(y_i)}{p_{\theta_0}(y_i)} = l_{\theta_1}(y_i) - l_{\theta_0}(y_i) \tag{1}$$

The basic feature of s_i, which makes it a good candidate for making the decision, is that

$$\mathbf{E}_{\theta_0}(s_i) < 0, \ \mathbf{E}_{\theta_1}(s_i) > 0 \tag{2}$$

In other words, s_i reflects the change in θ by a change in the sign of its expected value.

The likelihood of n independent observations $y_1, \ldots, y_n$, stacked into a vector $\mathcal{Y}_1^n$, is written as a product: $p_\theta(\mathcal{Y}_1^n) = \prod_{i=1}^n p_\theta(y_i)$. For making the decision between the two simple hypotheses, relevant functions of the data to deal with are the likelihood ratio [18]:

$$\Lambda_n \stackrel{\text{def}}{=} \frac{p_{\theta_1}(\mathcal{Y}_1^n)}{p_{\theta_0}(\mathcal{Y}_1^n)} = \frac{\prod_{i=1}^n p_{\theta_1}(y_i)}{\prod_{i=1}^n p_{\theta_0}(y_i)} \tag{3}$$

and the log-likelihood ratio, which is written as a CUSUM:

$$S_n \stackrel{\text{def}}{=} \ln \Lambda_n = \sum_{i=1}^n s_i \tag{4}$$

A typical behavior of S_n, reflecting the property in equation (2), is displayed in Figure 2 for the simple case of a change in the mean of a Gaussian sequence shown in Figure 1.

When the hypotheses are simple, the test comparing the likelihood ratio to a threshold,

$$\text{If } \Lambda_n < \varrho : \mathbf{H}_0 \text{ is chosen; If } \Lambda_n \geq \varrho : \mathbf{H}_1 \text{ is chosen}$$

or equivalently the log-likelihood ratio,

$$\text{If } S_n < h : \mathbf{H}_0 \text{ is chosen; If } S_n \geq h : \mathbf{H}_1 \text{ is chosen}$$

is optimal (Neyman–Pearson lemma). This means that for a given probability of wrong rejection of $\mathbf{H}_0$ (false alarm), this test minimizes the probability

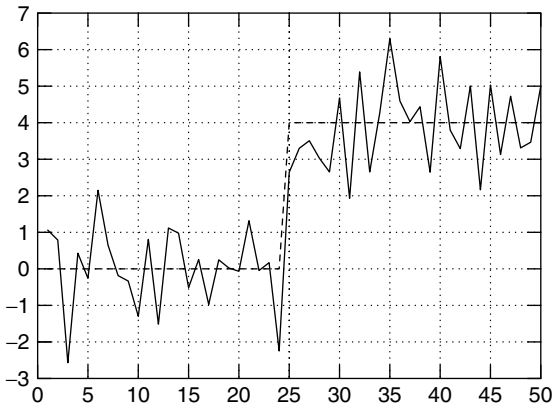

Figure 1. A change in the mean of a Gaussian sequence with constant variance.

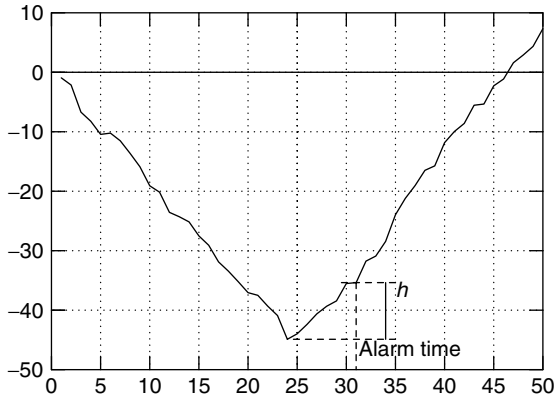

Figure 2. Typical behavior of the log-likelihood ratio S_n: negative drift before and positive drift after the change.

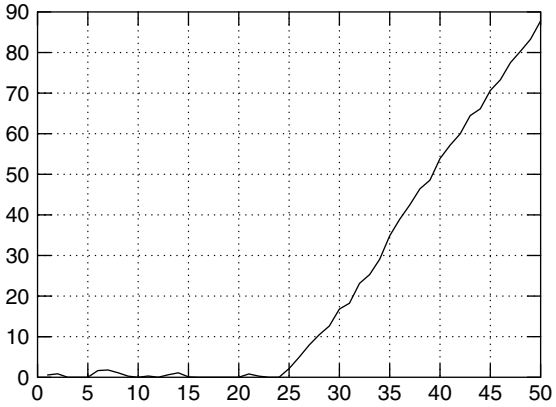

Figure 3. Typical behavior of the CUSUM decision function g_k.

of making a wrong acceptance of $\mathbf{H}_1$. The threshold (ϱ, or h) is determined from a fixed probability of false alarm.

When the hypotheses are composite, the decision is based on the generalized likelihood ratio (GLR), which consists in maximizing the likelihood functions with respect to the unknown parameter:

$$\widehat{\Lambda}_n = \frac{\sup_{\theta_1 \in \Theta_1} p_{\theta_1}(\mathcal{Y}_1^n)}{\sup_{\theta_0 \in \Theta_0} p_{\theta_0}(\mathcal{Y}_1^n)} \tag{5}$$

It is more tricky to precisely state in what ways this test is optimal.

2.1.2 Dependent observations

Assuming that the parameter is θ, one should use the *conditional likelihood* of y_i given the previous data $y_1, \ldots, y_{i-1}$, denoted by $p_\theta(y_i|\mathcal{Y}_1^{i-1})$ with the convention: for $i = 1$, $p_\theta(y_i|\mathcal{Y}_1^{i-1}) \stackrel{\text{def}}{=} p_\theta(y_1)$. The log-likelihood ratio is written as

$$s_i \stackrel{\text{def}}{=} \ln \frac{p_{\theta_1}(y_i|\mathcal{Y}_1^{i-1})}{p_{\theta_0}(y_i|\mathcal{Y}_1^{i-1})} \tag{6}$$

and has the same basic property as in equation (2). If n observations are recorded, the decision between two simple hypotheses is to be made with the aid of the likelihood ratio:

$$\Lambda_n \stackrel{\text{def}}{=} \frac{p_{\theta_1}(\mathcal{Y}_1^n)}{p_{\theta_0}(\mathcal{Y}_1^n)} = \frac{\prod_{i=1}^{n} p_{\theta_1}(y_i|\mathcal{Y}_1^{i-1})}{\prod_{i=1}^{n} p_{\theta_0}(y_i|\mathcal{Y}_1^{i-1})} \tag{7}$$

since, because of the Bayes rule, the joint likelihood is the product of conditional likelihoods:

$$p_{\theta_\ell}(\mathcal{Y}_1^n) = \prod_{i=1}^{n} p_{\theta_\ell}(y_i|\mathcal{Y}_1^{i-1}) \quad (\ell = 0, 1) \tag{8}$$

When using the log-likelihood ratio, the CUSUM property still holds true:

$$S_n \stackrel{\text{def}}{=} \ln \Lambda_n = \sum_{i=1}^{n} s_i \tag{9}$$

In case of composite hypotheses, the GLR test should involve the conditional probabilities as well.

2.2 On-line change detection

At the current time instant k, it is now assumed that there exists an unknown change time ν at which the parameter θ of the distribution p_θ changes.

The problem is stated as that of deciding between the two hypotheses:

$$\begin{aligned} \mathbf{H}_0 &: \forall\, i, 1 \le i \le k, \quad \theta_i = \theta_0 \\ \mathbf{H}_1 &: \exists\, \nu, 1 \le \nu \le k, \theta_i = \theta_0 \ (i < \nu) \\ &\text{and } \theta_i = \theta_1 \ (i \ge \nu) \end{aligned} \tag{10}$$

At time k, the null hypothesis $\mathbf{H}_0$ enforces observations $y_1, \ldots, y_k$ to have the same distribution p_{θ_0}, and the alternative (change) hypothesis $\mathbf{H}_1$ assumes that there exists an unknown change time ν such that $y_1, \ldots, y_{\nu-1}$ have the distribution p_{θ_0} and $y_\nu, \ldots, y_k$ have the distribution p_{θ_1}. The decision on the presence of a change is made with the aid of a stopping (alarm) time:

$$t_a = \min\{k \ge 1 : g_k \ge h\} \tag{11}$$

The parameter θ_0 is assumed to be known, up to an (on-line) estimation. The problem is to design the decision function g_k, namely, the function of the observations with which the decision will be made, to tune the threshold h, and to design a change time estimate $\widehat{\nu}_k$.

2.2.1 Independent observations

In the case of simple hypotheses, namely when both θ_0 and θ_1 are known, the key detection tool is, again, the likelihood ratio between the two hypotheses in equation (10):

$$\frac{\prod_{i=1}^{\nu-1} p_{\theta_0}(y_i) \cdot \prod_{i=\nu}^{k} p_{\theta_1}(y_i)}{\prod_{i=1}^{k} p_{\theta_0}(y_i)} = \frac{\prod_{i=\nu}^{k} p_{\theta_1}(y_i)}{\prod_{i=\nu}^{k} p_{\theta_0}(y_i)} \stackrel{\text{def}}{=} \Lambda_\nu^k \tag{12}$$

The change onset time is estimated by maximizing the likelihood under $\mathbf{H}_1$, that is,

$$\begin{aligned} \widehat{\nu}_k &\stackrel{\text{def}}{=} \arg \max_{1 \le j \le k} \prod_{i=1}^{j-1} p_{\theta_0}(y_i) \cdot \prod_{i=j}^{k} p_{\theta_1}(y_i) \\ &= \arg \max_{1 \le j \le k} \Lambda_j^k \end{aligned} \tag{13}$$

where

$$\Lambda_j^k = \frac{\prod_{i=j}^{k} p_{\theta_1}(y_i)}{\prod_{i=j}^{k} p_{\theta_0}(y_i)} \tag{14}$$

Equation (13) holds because the denominator in the left-hand side of equation (12) does not depend on ν. Let

$$S_j^k \stackrel{\text{def}}{=} \ln \Lambda_j^k \tag{15}$$

Then, because ln(.) is an increasing function, the estimated change time can be written as

$$\widehat{\nu}_k = \arg \max_{1 \le j \le k} S_j^k \tag{16}$$

Again, because of the products in equation (14), S_j^k defined in equation (15) and can be written as a *CUSUM*:

$$S_j^k = \sum_{i=j}^{k} \ln \frac{p_{\theta_1}(y_i)}{p_{\theta_0}(y_i)} \tag{17}$$

As a decision function g_k in equation (11), consider the following one, based on S_j^k

$$g_k \stackrel{\text{def}}{=} \max_{1 \le j \le k} S_j^k \tag{18}$$

Thanks to equation (15) and equation (16), this decision function can be also written as

$$g_k = \ln \Lambda_{\widehat{\nu}_k}^k \tag{19}$$

This is known as the *CUSUM algorithm* [19], first investigated by Page in the 1950s [20]. A typical behavior of g_k is displayed in Figure 3 for the simple case of a change in the mean of a Gaussian sequence shown in Figure 1.

The CUSUM algorithm can be interpreted as a repeated sequential probability ratio test (SPRT). It is optimal in the sense that it minimizes the mean delay to detection for a given probability between false alarms. Different definitions of the delay have been considered in the literature, and different optimality results have been proven, where some are asymptotic (infinite number of observations) [21] and some are not [22]. See also [2, 23, 24].

In the case of a composite alternative hypothesis $\mathbf{H}_1 : \theta_1 \in \Theta_1$, modified CUSUM algorithms can be designed, based either on a notion of minimum magnitude of change, or on a weighting of the likelihood with respect to the unknown values of θ_1. The GLR methodology can be used as well, resulting in a double maximization, with respect to the change time as above, and with respect to the change magnitude. This is further investigated in Section 3 for a simple case.

2.2.2 Dependent observations

Similar approaches can be used, replacing likelihoods $p_{\theta_\ell}(y_i)$ by conditional likelihoods $p_{\theta_\ell}(y_i|\mathcal{Y}_1^{i-1})$ for $\ell = 0, 1$. Again, the CUSUM property (equation 17) holds:

$$S_j^k = \sum_{i=j}^{k} \ln \frac{p_{\theta_1}(y_i|\mathcal{Y}_1^{i-1})}{p_{\theta_0}(y_i|\mathcal{Y}_1^{i-1})} \tag{20}$$

This is investigated in Section 5 for detecting changes in the spectrum of a signal.

A major issue is the computational complexity of the resulting algorithms in more sophisticated cases. Another key difficulty is the performance analysis of those algorithms. These are the main motivations for the approach described in Section 6.

2.2.3 Adaptive thresholds and windows

The decision function g_k in equation (18) can be easily written as the deviation of the CUSUM S_1^k with respect to its minimum value: $g_k = S_1^k - m_k$, with $m_k \stackrel{\text{def}}{=} \min_{1 \le j \le k} S_1^j$. The stopping rule, when written accordingly, namely,

$$t_a = \min \{k \ge 1 : S_1^k \ge m_k + h\} \tag{21}$$

appears to apply an *adaptive threshold* to the sum S_1^k. Note that the adaptation of the threshold involves m_k, and is thus based on the *entire past* of the sequence of observations.

The CUSUM algorithm also involves a *random size moving window* since g_k can also be written as

$$g_k = \left(S_{k-N_k+1}^k\right)^+ \tag{22}$$

with

$$N_k \stackrel{\text{def}}{=} N_{k-1} \cdot \mathbf{1}_{\{g_{k-1}>0\}} + 1 \tag{23}$$

3 ON-LINE DETECTION OF CHANGES IN THE MEAN

Consider now the problem addressed in Section 2 in the simple case where θ is the mean value of the distribution $p_\theta(y)$ assumed to be Gaussian, namely,

$$p_\theta(y) = 1/(\sigma\sqrt{2\pi})\mathrm{e}^{(y-\theta)^2/2\sigma^2} \tag{24}$$

Assuming that θ_1 is known after the change, the CUSUM S_j^k reduces to a data *integrator*:

$$S_j^k = \frac{\upsilon}{\sigma^2} \sum_{i=j}^{k} \left(y_i - \theta_0 - \frac{\upsilon}{2} \right) \stackrel{\text{def}}{=} S_j^k(\upsilon) \tag{25}$$

In equation (25), $\upsilon \stackrel{\text{def}}{=} \theta_1 - \theta_0$ is the *change magnitude* and $b \stackrel{\text{def}}{=} \upsilon/\sigma$ is the *change-to-noise ratio*, which is the relevant counterpart of the usual signal-to-noise ratio (SNR).

Because of equations (22) and 23), the CUSUM algorithm (11), (18), and (25) in this case can be seen as an *integration* of the observations *over a sliding window with adaptive size*. This algorithm is especially efficient for *small* change-to-noise ratio b [4].

When θ_1 is unknown and assumed to belong to a known set, $\theta_1 \in \Theta_1 \subseteq \mathbf{R}$, several approaches can be used. A weighting of the likelihood with respect to the unknown θ_1 may be introduced when some *a priori* information about the distribution of θ_1 is available [24, 25]. Another approach consists in introducing a minimum change magnitude υ_m in equation (25), and in running two CUSUM tests in parallel, since the change direction, namely increase or decrease in the mean, is not known either [4, Chapter 2]. This is summarized as

Decreasing mean

$$T_1^k \stackrel{\text{def}}{=} \sum_{i=1}^{k} \left(y_i - \theta_0 + \frac{\upsilon_m}{2} \right)$$
$$M_k \stackrel{\text{def}}{=} \max_{1\le j\le k} T_1^j$$
$$t_a = \min\{k \ge 1 : M_k - T_1^k \ge h\}$$

Increasing mean

$$S_1^k \stackrel{\text{def}}{=} \sum_{i=1}^{k} \left(y_i - \theta_0 - \frac{\upsilon_m}{2} \right)$$
$$m_k \stackrel{\text{def}}{=} \min_{1\le j\le k} S_1^j$$
$$t_a = \min\{k \ge 1 : S_1^k - m_k \ge h\}$$

Tuning two parameters υ_m and h might seem more tricky than tuning a single threshold. However, the two choices turn out to be easy since both parameters are well decoupled in practice. Because of equation (25), the threshold h should be of the form $\tilde{h}\sigma^2$. In case of unknown σ, involving a good estimate $\hat{\sigma}^2$ in the threshold may contribute to the performances of the algorithm. This approach has proven useful in many application cases.

The GLR approach maximizes the likelihood ratio with respect to the two unknown parameters (change time *and* magnitude):

$$g_k \stackrel{\text{def}}{=} \max_{1\le j\le k} \sup_{\upsilon} S_j^k(\upsilon) \tag{26}$$

The second maximization is explicit in the present Gaussian case, which results in a *quadratic* test:

$$g_k = \max_{1\le j\le k} \frac{1}{2(k-j+1)} \left(\frac{\sum_{i=j}^{k} (y_i - \theta_0)}{\sigma} \right)^2 \tag{27}$$

4 EXTENSION TO ADDITIVE JUMPS

These algorithms extend to the multidimensional case.

4.1 Changes in a vector mean

First consider the problem of detecting an additive change in a sequence of independent *vector* Gaussian variables $Y_1, \ldots, Y_k$, with mean $M\Upsilon$ and covariance Σ. The hypotheses can now be written as follows:

$$\begin{aligned} &\mathbf{H}_0 \ : \ \forall\, i, 1 \le i \le k, \Upsilon_i = 0 \\ &\mathbf{H}_1 \ : \ \exists\, \nu, 1 \le \nu \le k, \Upsilon_i = 0 \ (i < \nu) \\ &\quad \text{and } \Upsilon_i = \Upsilon \ (i \ge \nu) \end{aligned} \tag{28}$$

The GLR test for detecting such a deviation in Υ is written as

$$\begin{aligned} g_k &\stackrel{\text{def}}{=} \max_{1\le j\le k} \sup_{\Upsilon} S_j^k(\Upsilon) \\ &= \max_{1\le j\le k} \frac{k-j+1}{2} \end{aligned} \tag{29}$$

$$\overline{Y}_j^{k\,\mathrm{T}}\ \Sigma^{-1}\ M(M^{\mathrm{T}}\ \Sigma^{-1}\ M)^{-1}M^{\mathrm{T}}\ \Sigma^{-1}\ \overline{Y}_j^{k} \quad (30)$$

where $\overline{Y}_j^{k} \stackrel{\mathrm{def}}{=} \sum_{i=j}^{k} Y_i/(k-j+1)$. The test, equation (30), is the multidimensional counterpart of equation (27).

4.2 Additive jumps in state-space models

More generally, consider the case of additive jumps on linear Gaussian state-space systems:

$$\begin{cases} X_{k+1} = F\ X_k + G\ U_k + W_k + \Gamma\ \Upsilon_x(k,\nu) \\ Y_k = H\ X_k + J\ U_k + V_k + \Xi\ \Upsilon_y(k,\nu) \end{cases} \quad (31)$$

where X is the unknown state; U, Y are the measured input and output vectors, with dimensions s, m, r, respectively; $(W_k)_k$ and $(V_k)_k$ are independent Gaussian white noise sequences, with covariance matrices Q and R, respectively; Υ_x, Υ_y are the fault vectors, with compatible dimensions; and ν is the jump onset time. Sensor and actuator faults are important instances of equation (31).

As shown in [4, Chapter 7] and [26], this problem reduces to detecting a change in the mean vector of the *innovation* ε_k of system (31), computed with a Kalman filter, namely,

$$\begin{cases} \hat{X}_{k+1|k} = F\hat{X}_{k|k} + G\ U_k \\ \hat{X}_{k|k} = \hat{X}_{k|k-1} + K_k\ \varepsilon_k \\ \varepsilon_k = Y_k - H\ \hat{X}_{k|k-1} - J\ U_k \end{cases} \quad (32)$$

where the Kalman gain K_k is computed through

$$\begin{aligned} K_k &= P_{k|k-1}\ H^{\mathrm{T}}\ \Sigma_k^{-1} \\ P_{k+1|k} &= F\ P_{k|k}\ F^{\mathrm{T}} + Q \\ P_{k|k} &= (I_s - K_k\ H)\ P_{k|k-1} \end{aligned} \quad (33)$$

Under the hypothesis $\mathbf{H}_0$ $(k < \nu)$, the innovation ε_k is Gaussian with mean zero and covariance matrix $\Sigma_k = HP_{k|k-1}H^{\mathrm{T}} + R$. In the presence of a change, namely under $\mathbf{H}_1$, ε_k is Gaussian with mean vector $\rho(k,\nu)$ and covariance Σ_k. Actually, because of the assumption of additive changes in equation (31), the signature of the change on the innovation is also additive, and $\rho(k,\nu)$ can be computed recursively. Assuming a steady-state Kalman filter, a closed-form expression of $\rho(k,\nu)$ can be derived. Using the transfer function notation, $\rho(k,t_0) = \mathcal{K}_x(z)\Upsilon_x(k,t_0) + \mathcal{K}_y(z)\Upsilon_y(k,t_0)$, straightforward computations lead, asymptotically for large k, to

$$\begin{aligned} \mathcal{K}_x(z) &= H(zI_s - \bar{F})^{-1}\Gamma \\ \mathcal{K}_y(z) &= \left[I_r - H(zI_s - \bar{F})^{-1}FK\right]\Xi \\ \bar{F} &\stackrel{\mathrm{def}}{=} F(I_s - KH) \end{aligned} \quad (34)$$

When using the GLR methodology for detecting the change in the mean vector of ε_k, the double maximization with respect to the change time *and* "magnitude" in equation (29) reduces to a single maximization, since the maximization over the fault vector Υ is again explicit:

$$\begin{aligned} \sup_{\Upsilon} S_j^k = &\left(\sum_{i=j}^{k} \tilde{\rho}^{\mathrm{T}}(i,j)\Sigma_i^{-1}\varepsilon_i\right)^{\mathrm{T}} \\ &\times \left(\sum_{i=j}^{k} \tilde{\rho}^{\mathrm{T}}(i,j)\Sigma_i^{-1}\tilde{\rho}(i,j)\right)^{-1} \\ &\times \left(\sum_{i=j}^{k} \tilde{\rho}^{\mathrm{T}}(i,j)\Sigma_i^{-1}\varepsilon_i\right) \end{aligned} \quad (35)$$

(compare with equation 30). An estimate of the change onset time is provided by $\hat{\nu}_k = \arg\max_{k-\ell+1\le j\le k} S_j^k$. The information contained in the change time and magnitude estimates can be used for updating the Kalman filter after detection [4, Chapter 7] and [26].

5 CHANGES IN THE SPECTRUM

For detecting changes in the spectrum of a scalar signal, an intuitive approach is discussed and the application of the CUSUM and GLR methods is presented.

5.1 Monitoring one innovation

Assuming an AR (autoregressive) model, $y_k = \sum_{l=1}^{p} a_l\ y_{k-l} + \mathrm{e}_k$, the problem is to detect changes in the

parameter vector $\theta^{\mathrm{T}} \stackrel{\mathrm{def}}{=} (a_1 \ldots a_p)$. A natural idea is to compute the innovation:

$$\varepsilon_k(\theta) \stackrel{\mathrm{def}}{=} y_k - \sum_{l=1}^{p} \hat{a}_l \; y_{k-l} \tag{36}$$

and compare it with a threshold. From a statistical inference point of view, however, this type of residual suffers from two limitations. First, whenever $p > 1$, the dimension of ε in equation (36) is *smaller* than the dimension of the parameter vector.[a] This means that the innovation ε lives in a smaller dimensional space than the parameter θ, and thus might be unable to discriminate between, if not insensitive to, different changes in that vector. Stated otherwise, a statistics (function of the parameter vector and of the raw data) should have at least the same dimension as the parameter to be inferred and monitored.

Second, ε is a *linear* combination of the measured data. Stated otherwise, residual (equation 36) is a *first-order* statistic. When the changes of interest affect the dynamics (here the AR coefficients a_i's), using linear combinations of the data is *not* sufficient in the statistical sense: a nonnegligible set of spectral changes result in *no* change in either the mean or the variance of the innovation [27]. A more complex expression in ε, such as

$$\sum_i \left(\frac{\varepsilon_i^2(\theta)}{\sigma^2} - 1 \right) \tag{37}$$

shares the same type of limitations: the statistics in equation (37) is known to be poorly efficient in a number of cases [4, Chapter 8] and [27].

This does not mean, however, that the innovation should not play any role in detecting changes in spectra. Indeed, how to use the prediction error for parameter estimation is clearly stated in the system identification literature [28]: a parameter estimate should be updated with the aid of the *gradient* of the squared prediction error with respect to the parameter:

$$-\frac{1}{2} \; \partial / \partial \theta \left(\varepsilon_k^{\mathrm{T}}(\theta) \; \varepsilon_k(\theta) \right) \tag{38}$$

Note that the dimension of that gradient satisfies the above requirement. If the changes affect the dynamics of the system, a residual built on the vector in equation (38) is relevant. Note also that in the AR case it involves *second-order* statistics, namely covariances, which is mandatory.

More generally, a residual for detecting (parametric) changes in the dynamics of the system should build on a parameter *estimating function*. This is further described in Sections 6 and 7.

5.2 Monitoring two innovations

For detecting changes in the coefficients a_i's of an AR model, the CUSUM and GLR approaches can be used. Again, since the data are *dependent observations*, the computations should involve the conditional likelihoods $p_{\theta_\ell}(y_i | y_{i-1}, \ldots, y_{i-p})(\ell = 0, 1)$.

In the present scalar AR case, the CUSUM algorithm (11), (18), (20) runs with

$$S_j^k = \sum_{i=j}^{k} \frac{\varepsilon_i^2(\theta_0) - \varepsilon_i^2(\theta_1)}{2\sigma^2} \tag{39}$$

which involves *two innovations*, and not only one. The implementation in the (actual) case of unknown θ_0 and θ_1 consists in plugging in equation (39) estimates of $\widehat{\theta_0}$ and $\widehat{\theta_1}$ computed within a growing window and a fixed-size sliding window, respectively. Variations on this theme have resulted in a CUSUM test based on a function of two innovations different from equation (39) (but equivalent for small deviations) [27]. This algorithm has been shown to be useful for detecting small spectral changes.

This approach extends to scalar autoregressive moving average (ARMA) processes, although the likelihood and innovation computations are more involved in that case because of the MA part [4, Chapter 8].

5.3 Parameterized spectral distance measures

Comparing with a threshold the spectral distance between two models estimated on different data windows is a natural approach to detecting spectral changes. Some care should be taken for selecting a relevant spectral distance measure [29–31].

Of common use in speech processing, the family of log-spectral deviations between two spectral densities

s_0 and s_1 can be written as follows:

$$d_q(s_0, s_1) \stackrel{\text{def}}{=} \| \ln s_0 - \ln s_1 \|_q = \left\| \ln \frac{s_0}{s_1} \right\|_q \quad (40)$$

where, for a spectral density s, the q-norm is defined by

$$\|s\|_q \stackrel{\text{def}}{=} \left(\int_{-\pi}^{\pi} \frac{1}{2\pi} |s(\omega)|^q \, \mathrm{d}\omega \right)^{1/q} \quad (41)$$

Back to the linear prediction framework of the AR process above, namely, for s of the form

$$\frac{1}{s(\omega)} \stackrel{\text{def}}{=} \frac{|A(\mathrm{e}^{j\omega})|^2}{\sigma^2} \quad (42)$$

where $A(z) \stackrel{\text{def}}{=} \sum_{k=0}^{p} a_k \, z^{-k}$, the *cepstral coefficients* $(c_k)_k$ are defined as $\ln A(z) \stackrel{\text{def}}{=} \sum_{k=1}^{\infty} c_k \, z^{-k}$ and satisfy

$$\ln \frac{\sigma^2}{|A(\mathrm{e}^{j\omega})|^2} = \sum_{k=-\infty}^{\infty} c_k \, \mathrm{e}^{-jk\omega},$$
$$c_0 \stackrel{\text{def}}{=} \ln \sigma^2, \qquad c_{-k} \stackrel{\text{def}}{=} c_k \quad (43)$$

The *cepstral distance*, defined as *the mean quadratic distance* (d_q in equation (40) with $q = 2$), can be written as an Euclidean distance between the two collections of cepstral coefficients:

$$d_2^2(s_0, s_1) = \sum_{k=-\infty}^{\infty} \left(c_k^{(0)} - c_k^{(1)} \right)^2 \quad (44)$$

of which the finite sum

$$d^2(L) \stackrel{\text{def}}{=} \sum_{k=-L}^{L} \left(c_k^{(0)} - c_k^{(1)} \right)^2 \quad (45)$$

is a good approximation. It is important to note that equation (45) is *not* an Euclidean distance between the two collections of AR coefficients a_k. When written in terms of the poles z_i, equation (45) becomes

$$d^2(L) = \sum_{k=-L}^{L} \frac{1}{k^2} \left(\sum_{i=1}^{p} \left(z_i^{(1)\,n} - z_i^{(0)\,n} \right) \right)^2 \quad (46)$$

It is very important to realize that equation (45) is thus *not* an Euclidean distance between the two collections of poles z_i. Similarly it is *not* an Euclidean distance between the two collections of Fourier spectrum lines.

6 DETECTING SMALL CHANGES

Consider now more complex situations involving nonadditive changes in multidimensional dependent data (signals). For overcoming both computational and performance analysis issues associated with the likelihood ratio approach, a possible approach consists in assuming *small changes* and using basically a sensitivity analysis relative to various noise and uncertainty levels. This approach is known as the *statistical local approach*.

The capability of performing early detection and isolation of small deviations of a structure or a process, with respect to a reference behavior considered as normal, is most useful in condition-based and aging monitoring problems. This is why this approach is of interest for SHM.

The local approach is first introduced in the framework of the likelihood function, and then for other estimating functions. Indeed, some important monitoring problems cannot be addressed with the aid of the likelihood. This is the case of vibration-based SHM addressed in Section 7.

6.1 Likelihood: efficient score

A key concept turns out to be very useful for designing and analyzing hypotheses testing and change detection algorithms, under the assumption of a small change. This is the sensitivity of the log-likelihood function with respect to the parameter vector:

$$z_i^* \stackrel{\text{def}}{=} \left. \frac{\partial l_\theta(y_i | \mathcal{Y}_1^{i-1})}{\partial \theta} \right|_{\theta=\theta^*} \quad (47)$$

also called *efficient score*. It enjoys a basic sign change property:

$$\mathbf{E}_{\theta_0}(z_i^*) < 0 \quad \text{for } \theta_0 = \theta^* - \Upsilon,$$
$$\mathbf{E}_{\theta_1}(z_i^*) > 0 \quad \text{for } \theta_1 = \theta^* + \Upsilon \quad (48)$$

which again makes it a good candidate for making the decision about θ.

If n observations are recorded, the efficient score can be written as follows:

$$\mathcal{Z}_n(\theta^*) \stackrel{\text{def}}{=} \frac{1}{\sqrt{n}} \left.\frac{\partial \ln p_\theta(\mathcal{Y}_1^n)}{\partial \theta}\right|_{\theta=\theta^*} = \frac{1}{\sqrt{n}} \sum_{k=1}^{n} z_i^* \tag{49}$$

Again, the CUSUM property holds. The efficient score is characterized by the key identity:

$$\mathbf{E}_\theta(\mathcal{Z}_n(\theta^*)) = 0 \quad \Longleftrightarrow \quad \theta = \theta^* \tag{50}$$

The expectation of the score is zero if, and only if, the expectation is computed at the very point where the derivative is computed. The efficient score is thus the ML (maximum likelihood) parameter estimating function. *The efficient score is generically different from the innovation*.

The efficient score enjoys the following asymptotic property. Consider the hypotheses:

$$\begin{aligned} &\text{(Safe) } \mathbf{H}_0 : \theta = \theta_0 \\ &\text{(Damaged) } \mathbf{H}_1 : \theta = \theta_0 + \Upsilon/\sqrt{n} \end{aligned} \tag{51}$$

where vector Υ is unknown, but fixed. For large n, hypothesis $\mathbf{H}_1$ corresponds to *small* deviations.

Thanks to that assumption, the efficient score $\mathcal{Z}_n(\theta_0)$ behaves asymptotically as a Gaussian vector with the same covariance matrix under both hypotheses:

$$\mathcal{Z}_n(\theta_0) \rightarrow \begin{cases} \mathcal{N}(0, \mathbf{I}(\theta_0)) & \text{under} \quad \mathbf{P}_{\theta_0} \\ \mathcal{N}(\mathbf{I}(\theta_0)\ \Upsilon\theta, \mathbf{I}(\theta_0)) & \text{under} \quad \mathbf{P}_{\theta_0+\frac{\Upsilon}{\sqrt{n}}} \end{cases} \tag{52}$$

where $\mathbf{I}(\theta_0)$ is the covariance matrix of the efficient score:

$$\begin{aligned} \mathbf{I}(\theta_0) &\stackrel{\text{def}}{=} \lim_{n\to\infty} \mathbf{I}_n(\theta_0), \\ \mathbf{I}_n(\theta_0) &\stackrel{\text{def}}{=} \mathbf{E}_{\theta_0}\ \mathcal{Z}_n(\theta_0)\ \mathcal{Z}_n^{\mathrm{T}}(\theta_0) \\ &= -\frac{1}{n}\ \mathbf{E}_{\theta_0}\ \left.\frac{\partial^2 \ln p_\theta(\mathcal{Y}_1^n)}{\partial \theta^2}\right|_{\theta=\theta_0} \end{aligned} \tag{53}$$

and is known as *the Fisher information matrix*. The efficient score reflects the small change in θ as a change in its own mean value: $\mathcal{Z}_n$ has zero mean under $\mathbf{H}_0$, and mean $\mathbf{I}(\theta_0)\Upsilon$ under $\mathbf{H}_1$. Note that matrices $\mathbf{I}(\theta_0)$ and $\Sigma(\theta_0)$ depend on neither the sample size n nor the change vector Υ in the hypothesis $\mathbf{H}_1$. Thus the detection of a change in θ reduces to the detection of a change in the mean of the (asymptotically) Gaussian vector $\mathcal{Z}_n$. Exactly as in equation (30), the test is *quadratic* in $\mathcal{Z}_n$:

$$\mathcal{Z}_n^{\mathrm{T}}(\theta_0)\ \mathbf{I}^{-1}(\theta_0)\ \mathcal{Z}_n(\theta_0) \geq \varrho \tag{54}$$

This test is distributed as a χ^2-variable, with $\mathrm{rank}(\mathbf{I}(\theta_0))$ degrees of freedom (dof). From this, a threshold can be deduced, for a given false alarm probability. The noncentrality parameter under $\mathbf{H}_1$ is $\Upsilon^{\mathrm{T}}\ \mathbf{I}(\theta_0)\ \Upsilon$. This test is asymptotically optimum for testing the hypothesis of a small change [4].

6.2 Other estimating functions

The efficient score may not be the relevant function to base the decision on. Actually, there are many identification algorithms that do not build on the likelihood function, but on other parameter estimating functions instead [28, 32]. For such functions, a similar asymptotic Gaussianity result holds. Let $K(\theta, Y_k)$ be a function of the parameter vector and of the data, enjoying the property:

$$\mathbf{E}_{\theta_0}\ K(\theta, Y_k) = 0 \quad \Longleftrightarrow \quad \theta = \theta_0 \tag{55}$$

which makes it a good candidate for being the basis of a parameter estimation algorithm. Define

$$\zeta_n(\theta_0) = \frac{1}{\sqrt{n}}\ \sum_{k=1}^{n} K(\theta_0, Y_k) \tag{56}$$

which can be thought of as a generalized score. Also define the sensitivity and covariance matrices:

$$\begin{aligned} M(\theta_0) &\stackrel{\text{def}}{=} -\mathbf{E}_{\theta_0}\ \left.\frac{\partial K(\theta, Y_k)}{\partial \theta}\right|_{\theta=\theta_0}, \\ \Sigma(\theta_0) &\stackrel{\text{def}}{=} \lim_{n\to\infty} \mathbf{E}_{\theta_0}\ \zeta_n(\theta_0)\ \zeta_n^{\mathrm{T}}(\theta_0) \end{aligned} \tag{57}$$

Then, the asymptotic Gaussianity result holds for this residual [4, 7, 33–35]:

$$\zeta_n(\theta_0) \rightarrow \begin{cases} \mathcal{N}(0, \Sigma(\theta_0)) & \text{under} \quad \mathbf{P}_{\theta_0} \\ \mathcal{N}(M(\theta_0)\ \delta\theta, \Sigma(\theta_0)) & \text{under} \quad \mathbf{P}_{\theta_0+\frac{\Upsilon}{\sqrt{n}}} \end{cases} \tag{58}$$

This asymptotic property holds for a large class of (not necessarily Gaussian) random processes. Thus,

as the efficient score does, the residual reflects the small change in the parameter vector as a change in its own mean value. Hence the χ^2 test:

$$\chi_n^2 \stackrel{\text{def}}{=} \zeta_n^{\mathrm{T}}\, \Sigma^{-1}\, M\, \left(M^{\mathrm{T}}\, \Sigma^{-1}\, M\right)^{-1}\, M^{\mathrm{T}}\, \Sigma^{-1}\, \zeta_n \;\geq \varrho \tag{59}$$

where the dependence on θ_0 has been removed for simplicity.

This test is distributed as a χ^2 variable, with rank(M) dof and noncentrality parameter $\Upsilon^{\mathrm{T}} M^{\mathrm{T}} \Sigma^{-1} M\, \Upsilon$. Let $\mathbf{F}(\theta_0)$ be the asymptotic Fisher information on θ_0 contained in $\zeta_n(\theta_0)$:

$$\mathbf{F}(\theta_0) \stackrel{\text{def}}{=} M^{\mathrm{T}}(\theta_0)\; \Sigma^{-1}(\theta_0)\; M(\theta_0) \tag{60}$$

Note that if the estimating function K in equations (55) and (56) is the efficient score in equation (49), namely when using a likelihood-based approach, both matrices M and Σ in equation (57) equal the Fisher matrix $\mathbf{I}$ in equation (53), and the χ^2 test (equation 59) reduces to the test in equation (54).

7 CHANGES IN THE SYSTEM DYNAMICS AND VIBRATION-BASED SHM

Consider the multidimensional counterpart of the problem of detecting changes in a spectrum addressed in Section 5. This problem can be stated as that of detecting changes in the AR part of a multidimensional ARMA model, and is highly related to vibration-based SHM. More than the computational complexity of the likelihood function for vector ARMA processes, a tight coupling between the AR part (basically the structure) and the MA part (basically the excitation) prevents the use of a likelihood-based approach when the unknown excitation is nonstationary.

Another solution resorts to the equivalent representation of any vector ARMA model as a linear dynamical system [36]. The problem is then to detect changes in the pair (H, F) of

$$\begin{cases} X_{k+1} = F\; X_k + W_{k+1} \\ Y_k = H\; X_k \end{cases} \tag{61}$$

An important instance of this problem is the detection of changes in the observed eigenstructure of state-transition matrix F, namely, the $(\lambda, \varphi_\lambda)$'s, where $\varphi_\lambda \stackrel{\text{def}}{=} H\phi_\lambda$, and ϕ_λ is the eigenvector of F associated with the eigenvalue λ. It is well known that this is one relevant formulation of the vibration-based SHM problem [37, 38]. By stacking the modes and mode shapes $(\lambda, \varphi_\lambda)$'s into a vector parameter θ, damage detection reduces to the problem of detecting changes in θ. Assuming that a reference value θ_0 is available, identified on data recorded on the undamaged system, and given a new data sample, the problem is to decide whether or not this sample is still well described by θ_0.

A possible solution consists in using an estimating function, different from the likelihood, within the framework of small changes described in Section 6. The estimating function associated with the covariance-driven subspace identification algorithm is a good candidate, which exploits the following property. Let $R_i \stackrel{\text{def}}{=} \mathbf{E}(Y_k\; Y_{k-i}^{\mathrm{T}})$ be the theoretical covariance matrix for lag i, and

$$\mathcal{H}_{p+1,q} \stackrel{\text{def}}{=} \begin{pmatrix} R_0 & R_1 & \vdots & R_{q-1} \\ R_1 & R_2 & \vdots & R_q \\ \vdots & \vdots & \vdots & \vdots \\ R_p & R_{p+1} & \vdots & R_{p+q-1} \end{pmatrix} \tag{62}$$

be the theoretical output covariance and Hankel matrices, respectively. Introducing the cross-covariance between the state and the observed outputs, $G \stackrel{\text{def}}{=} \mathbf{E}(X_k Y_k^{\mathrm{T}})$, direct computations of the R_i's from (61) lead to $R_i = H F^i G$ and to the well-known factorization [39]:

$$\mathcal{H}_{p+1,q} = \mathcal{O}_{p+1}(H, F)\; \mathcal{C}_q(F, G) \tag{63}$$

where

$$\mathcal{O}_{p+1}(H, F) \stackrel{\text{def}}{=} \begin{pmatrix} H \\ HF \\ \vdots \\ HF^p \end{pmatrix}$$

$$\text{and} \qquad \mathcal{C}_q(F, G) \stackrel{\text{def}}{=} (G\; FG\; \cdots\; F^{q-1}G) \tag{64}$$

are the observability and controllability matrices, respectively. Note that the observed dynamics (H, F)

is found in the left-hand side term only. For estimating the reference θ_0, the covariance-driven subspace identification algorithm performs the singular value decomposition (SVD) of the empirical Hankel matrix $\widehat{\mathcal{H}}^0_{p+1,m}$ computed with data recorded on the undamaged system. Let θ_0 be the parameter vector resulting from this identification.

The subspace interpretation of the SVD provides the following characterization for θ_0:

$$N(\theta_0)^{\mathrm{T}}\ \widehat{\mathcal{H}}^0_{p+1,m} = 0 \tag{65}$$

where the orthonormal matrix N is subject to

$$N(\theta_0)^{\mathrm{T}} N(\theta_0) = I,\ \ N(\theta_0)^{\mathrm{T}} \mathcal{O}_{p+1}(\theta_0) = 0 \tag{66}$$

and matrix $\mathcal{O}_{p+1}(\theta_0)$ can be computed from θ_0. Matrix N depends implicitly on parameter θ and is not unique. However, it can be treated as a function of parameter θ, denoted by $N(\theta)$ [40].

Let $\widehat{\mathcal{H}}^1_{p+1,m}$ be the empirical Hankel matrix filled with the covariances of the *new measurements* collected on the (possibly damaged) system, and let n be the length of this new data set. Inspired by the left-hand side of equation (65), it is proposed to base the decision on the following residual in [40, 41]:

$$\zeta_n(\theta_0) \stackrel{\text{def}}{=} \mathrm{vec}\big(N(\theta_0)^{\mathrm{T}}\ \widehat{\mathcal{H}}^1_{p+1,m}\big) \tag{67}$$

where vec is the column stacking operator.

Thanks to the local approach in Section 6.2, vector $\zeta_n(\theta_0)$ in equation (67) has the asymptotic Gaussian behavior summarized in (58) [40]. A change in θ, namely in the system dynamics, is reflected as a change in its mean, which switches from zero under $\mathbf{H}_0$, to $M(\theta_0)\Upsilon$ under $\mathbf{H}_1$. Since the matrices $M(\theta_0)$ and $\Sigma(\theta_0)$ depend on neither the sample size n nor the fault vector Υ in the hypothesis $\mathbf{H}_1$, they can be estimated prior to testing, using data on the safe system (as the reference θ_0).

The global test χ^2_n in equation (59) to be used performs a *sensitivity* analysis of the residual to the damages, *relative to* uncertainties in the modal estimates and noises on the available data [41]. It is often necessary to select the threshold for χ^2_n experimentally. How to achieve this from histograms of empirical values obtained on data for undamaged cases is explained in [15]. This damage detection algorithm has been run successfully on a number of test cases [42]. A nonparametric version is described in [43].

In this section, we have considered a batch-wise computation of the residual and an off-line detection problem statement (equation 58). A sample-wise computation of ζ_n, together with a sample-wise CUSUM-like detection algorithm for solving an on-line detection problem as in (equation 28), is described in [8, 13]. Recent and ongoing research includes model-based statistical handling of the environmental effects in vibration-based monitoring of civil engineering structures [43, 44], and of the complex aeroservoelastic effects underlying the flutter phenomenon [8, 45].

8 FURTHER ISSUES

Several other issues relating to the above-mentioned statistical framework can be addressed.

8.1 Damage isolation and diagnostics

In a statistical framework, the fault or damage isolation problem can be addressed from different points of view. The first issue is to discriminate between the components of a Gaussian vector, using nuisance elimination methods. This problem is of wide interest, thanks to the asymptotic Gaussianity result underlying the design of change detection methods presented in Section 6. In practice, focusing the monitoring on some subsets of components of the parameter vector θ is of interest for many purposes. For example, in the vibration-based SHM problem in Section 7, it may be desirable to monitor a specific mode λ and the associated mode-shape φ_λ.

A more involved issue is multiple hypotheses testing, for which the definition of optimality criteria is tricky. A still more involved problem is online isolation: the design of both optimality criteria and optimal algorithms raises several questions and these are still not completely resolved.

Finally, in most SHM applications, a complex physical system, characterized by a generally nonidentifiable parameter vector Φ, has to be monitored using a simple model characterized by an identifiable parameter vector θ. A possible direct solution is sketched for the corresponding diagnostics problem expressed in terms of Φ.

8.1.1 Isolation as nuisance elimination

The fault or damage vector is now partitioned as follows: $\Upsilon = \begin{pmatrix} \Upsilon_a \\ \Upsilon_b \end{pmatrix}$, with Υ_a, Υ_b of known dimensions l_a, l_b, respectively ($l_a + l_b = l$). The matrices M in equation (58) and $\mathbf{F}$ in (60) are partitioned accordingly:

$$M = (M_a M_b), \mathbf{F} = \begin{pmatrix} \mathbf{F}_{aa} & \mathbf{F}_{ab} \\ \mathbf{F}_{ba} & \mathbf{F}_{bb} \end{pmatrix} = \begin{pmatrix} M_a^T \Sigma^{-1} M_a & M_a^{\mathrm{T}} \Sigma^{-1} M_b \\ M_b^T \Sigma^{-1} M_a & M_b^{\mathrm{T}} \Sigma^{-1} M_b \end{pmatrix} \quad (68)$$

Matrix M is assumed to be full column rank (fcr). Let notation $\mathbf{F}_a^{*-1}$ stand for the upper-left term of $\mathbf{F}^{-1}$, where $\mathbf{F}_a^* = \mathbf{F}_{aa} - \mathbf{F}_{ab}\, \mathbf{F}_{bb}^{-1}\, \mathbf{F}_{ba}$, and notation $p_{\Upsilon_a, \Upsilon_b}(\zeta)$ stands for the density of a Gaussian vector $\zeta \sim \mathcal{N}(M_a \Upsilon_a + M_b \Upsilon_b, \Sigma)$. The problem is to isolate changes either in Υ_a or in Υ_b, with the other component being unknown and considered as a nuisance parameter.

Isolation through projection A rather intuitive statistical solution to the isolation problem, called *sensitivity approach*, assumes Υ_b and consists in projecting the deviations in Υ onto the subspace generated by the components Υ_a to be isolated. The sensitivity test $\widetilde{t}_a$ for monitoring Υ_a is GLR test between $\Upsilon = (0, 0)$ and $\Upsilon = (\Upsilon_a, 0)$, where $\Upsilon_a \neq 0$, namely

$$\widetilde{t}_a \stackrel{\text{def}}{=} 2\, \ln \frac{\max_{\Upsilon_a}\ p_{\Upsilon_a, 0}(\zeta)}{p_{0,0}(\zeta)} = \widetilde{\zeta}_a^{\mathrm{T}}\, \mathbf{F}_{aa}^{-1}\, \widetilde{\zeta}_a \quad (69)$$

where the partial residual

$$\widetilde{\zeta}_a \stackrel{\text{def}}{=} M_a^{\mathrm{T}} \Sigma^{-1} \zeta \quad (70)$$

is nothing but the efficient score with respect to Υ_a. Under both hypotheses, test statistics $\widetilde{t}_a$ is distributed as a χ^2-variable with l_a dof, and noncentrality parameter $\Upsilon_a^{\mathrm{T}} \mathbf{F}_{aa} \Upsilon_a$ under $\Upsilon_a \neq 0$ *if* $\Upsilon_b = 0$ *actually holds*. Note that, for $a \neq b$, $\widetilde{\zeta}_a$ and $\widetilde{\zeta}_b$ are correlated, and $\widetilde{t}_a$ might be sensitive to a change in Υ_b [46]. The decision about the faulty or damaged component Υ_a or Υ_b is then taken according to the largest sensitivity test $\widetilde{t}_a$ or $\widetilde{t}_b$.

Isolation through rejection Another statistical solution to the problem of isolating Υ_a consists in viewing parameter Υ_b as a nuisance, and using an existing method for inferring part of the parameters while ignoring and being robust to the complementary part. This method is called *min–max approach* and consists in replacing the nuisance parameter component Υ_b by its least favorable value, namely the value that minimizes the power of test t, or equivalently the noncentrality parameter. This is equivalent to the GLR method:

$$t_a^* \stackrel{\text{def}}{=} 2\, \ln \frac{\max_{\Upsilon_a, \Upsilon_b}\ p_{\Upsilon_a, \Upsilon_b}(\zeta)}{\max_{\Upsilon_b}\ p_{0, \Upsilon_b}(\zeta)} \quad (71)$$

which consists in replacing the nuisance component Υ_b by its ML estimate. This can be written as follows:

$$t_a^* = \zeta_a^{*\mathrm{T}}\, \mathbf{F}_a^{*-1}\, \zeta_a^* \quad (72)$$

where $\zeta_a^* \stackrel{\text{def}}{=} \widetilde{\zeta}_a - \mathbf{F}_{ab} \mathbf{F}_{bb}^{-1} \widetilde{\zeta}_b$ is called *the effective score*. Note that ζ_a^* is the residual from regression of the partial residual in Υ_a on the (nuisance) partial residual in Υ_b. This is a fairly intuitive statistical approach, which actually traces back to Neyman's work in the 1950s [47]. Under both hypotheses, test statistics t_a^* is distributed as a χ^2-variable with l_a dof and, under $\Upsilon_a \neq 0$, noncentrality parameter $\Upsilon_a^T \mathbf{F}_a^* \Upsilon_a$ *for all* Υ_b. The isolation of the damaged component Υ_a or Υ_b is then performed according to the largest min–max test t_a^* or t_b^*.

The sensitivity (projection) and min–max (rejection) tests enjoy a nice relationship. Global test can be written as follows: $t = t_a^* + \widetilde{t}_b$, where the decomposition is orthogonal in the sense that the two terms are uncorrelated, namely, $\mathrm{cov}_0(t_a^*, \widetilde{t}_b) = \mathrm{cov}_1(t_a^*, \widetilde{t}_b) = 0$ under both safe and faulty hypotheses. This additive decomposition holds for general distributions and more than two faults, whereas the orthogonal decomposition holds in the Gaussian case for only two faults.

The min–max test can be used for designing damage detection tests insensitive to environmental effects. This has been done in [44], where a simplified model of the temperature effect on the structural dynamics has been plugged within the min–max rejection test. This approach has been tested on a simulated bridge deck and a laboratory test case within a climatic chamber.

8.1.2 Isolation as multiple hypotheses testing

The isolation of multiple (more than two) faults raises several issues. The first issue is to distinguish between embedded multiple faults with causality constraints and independent multiple faults, and to state the corresponding simultaneous multiple hypotheses testing problem. The second issue concerns optimality criteria, which are the relevant counterpart of the trade-off between false alarms and detection probabilities in the ordinary hypotheses testing (detection) problem. The third issue is to exhibit tests performing the isolation in an optimal manner. It turns out that the above sensitivity and rejection approaches are relevant, from both theoretical and experimental points of view. For example, the set of all the sensitivity tests monitoring each fault, or the set of all the rejection tests, solve different multiple hypotheses testing problem, optimally with respect to different optimality criteria [48–50].

8.1.3 On-line isolation

The on-line isolation problem requires both on-line detection of a change and on-line discrimination between multiple hypotheses. Several types of performance indexes can be defined: probabilities of wrong isolations, mean delay to detection/isolation, etc. For designing the on-line detection/isolation algorithms, different optimization problems can be defined, based on those criteria. A major issue, for which research investigations are still needed, is to define criteria and optimization problems, which admit an explicit, and not approximate, optimal solution [2, 51].

8.1.4 Damage diagnostics

Considering again the vibration-based SHM problem of Section 7, damage localization and diagnostics can be stated as a detection problem, and not an (usually ill-posed) inverse estimation problem. This problem is addressed by plugging aggregated sensitivities of the modes and mode shapes with respect to FEM structural parameters in the above setting of subspace-based residuals in equation (67) and partial residuals such as equation (70). This results in directional tests as in equation (69), which perform the same type of damage-to-noise sensitivity analysis of the residual as for damage detection. The computation, the analytical-to-experimental matching, and the aggregation of the sensitivities, are performed off-line at a design stage, whereas the directional tests may be computed onboard. See [41] for more details and [52] for an example.

8.2 Increasing the robustness of the test

The main idea for increasing the robustness of the tests with respect to operating conditions, for example, consists in using confidence ellipsoids for plugging the uncertainty in the reference parameter θ_0 and the *a priori* information on the changes in the shape of the hypotheses to be tested, instead of using a confidence interval for the decision function itself [7]. The hypotheses are then defined by

$$\begin{aligned}\Theta_0 &\stackrel{\text{def}}{=} \{\Upsilon | \Upsilon^{\mathrm{T}}\ M^{\mathrm{T}}\ \Sigma^{-1}\ M\ \Upsilon \leq \upsilon_0^2\} \\ \Theta_1 &\stackrel{\text{def}}{=} \{\Upsilon | \Upsilon^{\mathrm{T}}\ M^{\mathrm{T}}\ \Sigma^{-1}\ M\ \Upsilon \geq \upsilon_1^2\}\end{aligned} \tag{73}$$

In equation (73), $\Upsilon = \sqrt{n}(\theta - \theta_0)$ is the change vector, θ_0 is the reference parameter value, and the sizes υ_0 and υ_1 have to be chosen. Typically, υ_0 captures uncertainties on the reference value θ_0, and may be chosen by learning on the data while identifying θ_0. The other radius υ_1 reflects a minimum change magnitude to be detected and should be learned from the data based on the monitoring problem specifications. The GLR test for testing between the hypotheses in equation (73) consists in computing

$$\overline{\chi}_n^2 \stackrel{\text{def}}{=} \min_{\Upsilon \in \Theta_0} l_\Upsilon(\zeta_n) - \min_{\Upsilon \in \Theta_1} l_\Upsilon(\zeta_n) \tag{74}$$

where $l_\Upsilon(\zeta_n) \stackrel{\text{def}}{=} (\zeta_n - M\ \Upsilon)^{\mathrm{T}}\ \Sigma^{-1}\ (\zeta_n - M\ \Upsilon)$. This can be easily written as [4, 7]:

$$\begin{aligned}&\frac{1}{n}\ \overline{\chi}_n^2 \\ &= \begin{cases} -(\chi - \upsilon_1)^2 & \text{for} \quad \chi \leq \upsilon_0 \\ -(\chi - \upsilon_1)^2 + (\chi - \upsilon_0)^2 & \text{for} \quad \upsilon_0 \leq \chi \leq \upsilon_1 \\ +(\chi - \upsilon_0)^2 & \text{for} \quad \chi \geq \upsilon_1 \end{cases}\end{aligned} \tag{75}$$

where $\chi = \chi_n/\sqrt{n}$ and χ_n^2 is in equation (59).

Experiments on real applications have shown that this simple idea turns out to be a useful tool for

obtaining robustness against both changes in the functioning modes and undermodeling of the system to be monitored, which are often reported as being a crucial issue for model-based onboard fault or damage detection algorithms [9, 11].

8.3 Damage detectability and sensor positioning

There are two by-products of the statistical approach: information-based damage detectability and isolability definitions, and criteria for optimizing the sensor positioning for SHM.

Possible detectability definitions are of two types [53]. Intrinsic definitions capture the signature of the fault on the system. The signature may be defined in terms of the amount of information about the fault contained in the observed data. Performance-based definitions may capture, among other performance indexes, the signature of the fault on residuals. Again, the signature may be defined in terms of the amount of information about the fault contained in the residual.

The definition of a criterion for assessing the quality of a given sensor location for monitoring purposes can be based upon the power (probability of correct detection) of the statistical tests [54]. Such a criterion can be used in two ways. For a given sensor pool location (it is not always possible to choose), find the detectable and diagnosable faults; alternatively, for one given (set of) fault(s), find the sensor pools and locations with which their detection and diagnosis are possible.

9 CONCLUSION

In this article, the key elements in the design of change detection algorithms have been described. Basic concepts (likelihood ratio, estimation, innovation) have been introduced. They involve a number of familiar operations (integration, averaging, sensitivity, adaptive thresholds, and windows). It has been suggested that a statistical framework enlightens the meaning and increases the power of those operations.

One of the approaches in that framework is dedicated to the detection of small changes that is of interest for condition-based and aging monitoring problems, and thus for SHM. When applied to the case of vibration-based SHM, the small changes detection approach handles a residual that exploits the left null space of a particular matrix capturing the nominal (safe) state of the structure, and results in a damage detection algorithm proven useful on a number of test cases.

Handling nonlinear systems remains a challenging issue. Computing likelihood or other estimating functions may raise numerical and computational problems. Monte Carlo sequential simulation methods, of which a well-known instance is particle filtering, have been developed [55–57]. These types of methods can be used for e.g., efficient numerical approximation of the efficient score. Application of these methods to fault and damage detection problems is the topic of recent and ongoing works [58–60].

Finally, the methods described above have a limitation in terms of the number of sensors that can be handled at a time. This is especially true with the recent advances in sensors and wireless networking, which allow for a huge amount of synchronized distributed measurements. New SHM concepts, methods, and algorithms are necessary under such measurement setups.

END NOTES

[a.] The same situation occurs when the number of measured outputs is smaller than the order of the dynamics.

1 INTRODUCTION

The problem of searching for patterns in data has a long history. Statistical pattern recognition (SPR) is concerned with the discovery of regularities in data and subsequent actions such as classification [1]. Ample examples of pattern recognition are available. For instance, recognition of handwritten characters employs a machine-learning technique called *neural network* to take digital pixel images as inputs and to assign them into different characters. Although this is a nontrivial problem owing to the wide variations in handwriting, pattern-recognition techniques currently available can address such a classification problem. Thanks to their flexibility and diverse potential capacities, these pattern-recognition techniques have found a variety of applications.

One specific application of interest is structural health monitoring (SHM). SHM is a process of evaluating and assessing the integrity and safety of a structural system based on data autonomously and continuously collected from sensors [2]. The goals of SHM are (i) to identify the presence of damage (level I), (ii) to locate and quantify the damage (levels II and III), and (iii) finally, to predict the remaining useful life of the system (level IV) [2]. These objectives of SHM can be readily cast in the context of SPR. For instance, level I damage identification can be viewed as a classification problem where a binary output ($0 =$ undamaged and $1 =$ damaged) is assigned to the input data.

To achieve these goals, an SHM process involves the definition of potential damage scenarios for the system, observation of the system over a period

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

of time using periodically spaced measurements, extraction of features from these measurements, and statistical analysis of these features to determine the current state of the system's health [3]. For long-term SHM, the output of this process periodically updates information regarding the ability of the structure to perform its intended function in light of the inevitable aging and degradation resulting from operational environments. After extreme events, such as earthquakes or blast loading, SHM is used for a rapid condition screening and aims to provide, in near real time, reliable information regarding the current integrity of the structure.

Operational evaluation is the first step required before deploying an SHM system. Operational evaluation attempts to provide justifications for implementing an SHM system. In this stage, one should be able to answer the following questions: (i) What are the life-safety and economic motives for deploying an SHM system on the structure of interest? (ii) What are the definitions and types of damage that are of most concern for the system being monitored? (iii) Under what operational and environmental conditions does the system function? (iv) What are the costs and limitations on acquiring data in such operational environments? Once these questions are answered and the deployment of the SHM system is justified, we proceed to the second stage to design the data acquisition system.

The data acquisition process involves selecting the types of sensors to be used, choosing the location where the sensors should be placed, determining the number of sensors to be used, and defining the data acquisition/storage/transmittal hardware. This process is application specific, and economic considerations play a major role in these decisions. In this stage, additional questions such as how to improve the quality of data (data cleansing), how to compress the necessary data (data condensation), and how to alleviate undesirable variations of the data due to varying operational and environmental conditions (data normalization) should be addressed.

Feature extraction is a process of mining features that are sensitive to target damage from measured raw signals. Inherent in the feature selection process is the condensation of the data. The sensors employed to perform SHM typically produce a large amount of data. Therefore, data reduction is not only advantageous but also necessary, particularly if collection and comparison of data sets over the lifetime of the structure are envisioned (*see* **Dimensionality Reduction Using Linear and Nonlinear Transformation**). In addition, because data may be acquired from a structure over an extended period of time and in an operational environment, robust data-reduction techniques must retain the sensitivity of the chosen features to the structural damage of interest in the presence of environmental variability. Damage features that are used to distinguish damaged structures from undamaged ones have received the most attention in the technical literature.

Statistical model development is concerned with the implementation of the algorithms that operate on the extracted features to quantify the damage state of the structure. This statistical modeling can be done in either supervised or unsupervised learning mode. Unsupervised learning can be applied to data obtained from the undamaged structure, but this approach is often limited to level I or II damage classification, which identifies only the presence and locations of damage. When data are available from both the undamaged and damaged structure, the supervised learning approach can be taken to move forward to higher-level damage identification to classify and quantify the damage. Often, numerical simulations using an analytical model of a structure are employed to augment the scarce training data associated with the damaged structure.

Out of these four steps comprising the SHM process, the SPR approach is most relevant to feature extraction and statistical modeling processes. Therefore, the discussion in this article is mainly limited to these two steps of the SHM process. This article is organized as follows. First, it is discussed how various SPR techniques can be used in the feature-extraction process. Next, two distinctive statistical modeling approaches—unsupervised and supervised learning—are introduced. Finally, there is a separate section on data normalization because of its significance in the field deployment of an SHM system. The article concludes with a summary and a discussion on the scope for future work.

2 FEATURE EXTRACTION

For most SPR applications, it is advantageous to transform the raw data into some new form before

proceeding with statistical modeling; the feature-extraction process is one of the most important factors in determining the successful performance of the statistical modeling described in the next step (*see* **Data Preprocessing for Damage Detection**). Note that, feature extraction often involves signal preprocessing, data condensation, and data normalization. In the simplest form, feature extraction may take the form of a linear transform of the raw data as shown in Figure 1.

For the sake of discussion, let us assume that features 1 and 2 in Figure 1 denote the first two fundamental frequencies obtained from undamaged and damaged states of the system. In Figure 1, the data points in a lighter color are associated with the natural frequencies obtained from the undamaged state, and the darker data points correspond to the damaged state. These two-dimensional input data can be projected onto a one-dimensional feature space using various linear transforms. In particular, it is shown in Figure 1 that the separation (or damage sensitivity) of the data can be maximized by projecting the data using a projection technique called Fisher's linear discriminant. The description of Fisher's discriminant is provided later. In this process, the extraction of a damage-sensitive feature (the data after projection) and data reduction (from two-dimensional input data space to one-dimensional feature space) are accomplished simultaneously.

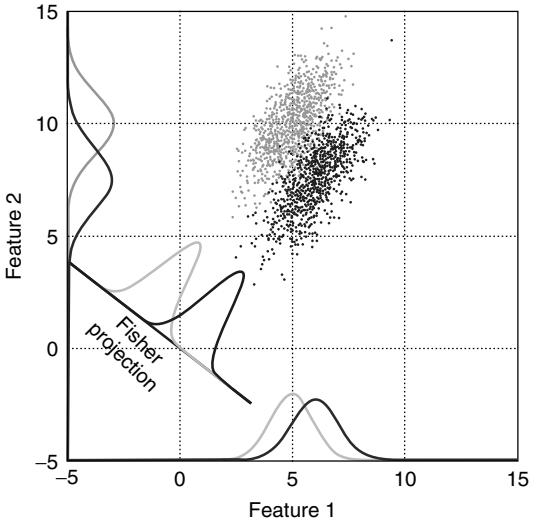

Figure 1. Simultaneous feature extraction and data condensation performed on the raw data.

The best features for damage detection are typically application specific. Numerous features are often identified for a structure and assembled into a feature vector. From a statistical discrimination perspective, a low-dimensional feature vector is desirable, and it is also desirable to obtain many samples of the feature vectors. There are no restrictions on the types or combinations of data contained in the feature vector. A variety of methods are employed to identify features for damage detection. Past experience with measured data from a system, particularly if damaging events have been previously observed for that system, is often the basis for feature selection. Numerical simulation of the damaged system's response to simulated inputs is another means of identifying features. The application of engineered flaws, similar to the ones expected in actual operating conditions, to laboratory specimens can identify parameters that are sensitive to the expected damage. Damage accumulation testing, during which significant structural components of the system under study are subjected to a realistic accumulation of damage, can also be used to identify appropriate features. A large number of features used for SHM are reported in [3, 4].

2.1 Curse of dimensionality

The need for low dimensionality in the feature vectors is referred to as curse of dimensionality and is discussed in general texts on density function estimation [5]. As discussed later in this article, statistical modeling requires statistical characterization of data, before any statistical inference can be reached. However, the difficulty of approximating local behavior of the data in a high-dimensional space is often reported. The problem is that to properly approximate a distribution of the data, the required sample size should grow exponentially with respect to the dimension of the sample space. This is called *curse of dimensionality*. This term was first coined by Bellman [6], when he observed the astronomical growth of computational effort in solving combinatorial optimization over many dimensions.

For one-dimensional feature space, 99.74% of the data will be inside $m \pm 3\sigma$ if the data have a normal distribution. Then, for two-dimensional feature spaces, only 66% of the data will be within

a circle of $m \pm 3\sigma$. Therefore, as the feature space expands to a higher dimension, more data are required to describe the distribution of the data, and it may impose serious limitations on how the unsupervised techniques can be used for SHM applications. Sometimes, it seems to be counterintuitive because we often feel that extraction of a higher-dimensional feature is better.

The true dimension of multivariate data in a high-dimensional space is almost always of dimension less than what it seems. Therefore, a parsimonious representation of the underlying structure can be obtained by eliminating a significant number of dimensions. The distinction between feature extraction and data reduction is not always clear cut. Feature extraction is the process of identifying damage-sensitive properties from the measured response signals, and this process often results in some form of data reduction. Data compression into feature vectors of small dimension is necessary if accurate estimates of the statistical distribution of the feature are to be obtained.

2.2 Multivariate analyses for dimensionality reduction

To avoid the curse of dimensionality, data are often projected onto a lower-dimensional feature space using specially designed mapping functions. This process is called *data reduction* or *data condensation*. In terms of data reduction, the main reason for using multivariate analysis is to analyze the simultaneous relationship among variables, to minimize the redundancy among them, and to obtain a parsimonious description of the structure underlying a set of multivariate data. Furthermore, data condensation is often done simultaneously as a part of feature extraction. For instance, the previously described illustrative example in Figure 1 can be seen as a feature-extraction process, but it is also conducting data reduction as well. Generally, this can be accomplished by constructing a linear/nonlinear combination of the original variables [7]. The choice of a multivariate technique for the analysis of interdependent variables is dependent on the nature of the data. Here, a few examples of multivariate techniques are introduced.

2.2.1 Principal component analysis

The primary goal of principal component analysis (PCA) is to construct a linear combination of the original variables so that the total variance (entropy) of the original variables can be kept as large as possible [8]. The variable projected onto the first principal component has the largest variance, and the variables projected using the subsequent projection components have successively smaller contributions to the total variables. These principal components are found by solving a singular-value problem of the covariance matrix among the original variables, and they are extracted in such a way that they are uncorrelated with each other.

Additional techniques often used for data reduction include canonical correlation analysis, multidimensional scaling, project pursuit, clustering analysis, and independent component analysis [1, 7, 9]. In particular, factor analysis and independent component analysis are similar to PCA in a sense that all of them explore the covariance structure for dimensionality reduction. For instance, factor analysis focuses on the common part of the total variance that a specific variable shares with the remaining variables.

2.2.2 Nonlinear principal component analysis

Multilayer neural networks such as autoassociative neural network (AANN) can be used to perform nonlinear dimensionality reduction, overcoming some of the limitation of linear techniques [10]

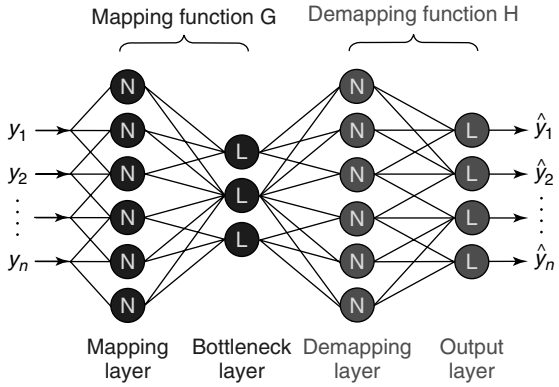

Figure 2. A schematic of an autoassociative neural network that performs nonlinear principal component analysis. [Reproduced with permission from Ref. 10. © Sage Publications, 2002.]

(*see* **Nonlinear Features for SHM Applications**). A typical AANN consists of three layers; mapping, bottleneck, and demapping layers as shown in Figure 2. The network is trained so that the outputs are simply the input vectors themselves. Because the network attempts to map each input vector onto itself, it is referred to as autoassociative network. In AANN, the dimension of the mapping and demapping layers (the number of neurons in each layer) are identical (m), but the dimension of the bottleneck layer (d) is designed to be less than those of the mapping and demapping layers ($m > d$). The first mapping layer projects the m-dimensional input space onto a d-dimensional subspace. Similarly, the demapping layer defines a mapping from the reduced subspace to the original input space. Owing to the reduced dimensionality of the bottleneck layer, AANN performs nonlinear PCA [11]. AANN has the advantage of not being limited to linear transforms, but nonlinear optimization techniques are needed to find the parameters of the network. Similarly, self-organizing maps can be also viewed as a nonlinear generalization of PCA.

2.3 Data preprocessing—standardization versus whitening

Typically, data from sensors are measured in different units and have significantly different variability. These different scaling and variability in data can cause the subsequent pattern-recognition algorithms to weigh input variables differently. To place equal importance for each variable, data can be standardized so that each variable has zero mean and unit variance, i.e., $z = (x - \overline{x})/\sigma$, where $\overline{x}$ and σ are the mean and the standard deviation of the data, respectively. Using PCA, the data can be further processed so that different variables become uncorrelated. This operation is called *whitening*.

$$z = \Lambda^{-\frac{1}{2}} U^T (x - \overline{x}) \tag{1}$$

where Λ and U represent diagonal matrices with elements of eigenvalues of the data covariance matrix and the orthogonal matrix with columns of eigenvectors, respectively.

3 UNSUPERVISED LEARNING

Unsupervised learning can be seen as one-class supervised learning, meaning that training is done using data only from one class. For SHM applications, this one class is most likely to be the pristine condition of the structure. On the basis of the training data sets obtained from the healthy condition of the structure, a statistical model of the healthy condition can be built. Once the statistical model of the healthy condition is constructed and a new set of data becomes available, typical unsupervised learning can be viewed as two-class hypothesis testing.

$$\begin{aligned} &\mathrm{H}_0 : \text{the system is not damaged} \\ &\mathrm{H}_1 : \text{the system is damaged} \end{aligned} \tag{2}$$

where H_0 is the null hypothesis stating that there is no defect in the system. If the new data set supports the null hypothesis, the null hypothesis is accepted. Otherwise, the null hypothesis is rejected. As can be seen from this example, hypothesis testing is a process of inferring whether a given null hypothesis is true or not based on the given data set. This dependency on the data can be explicitly expressed by employing the following conditional probabilities:

$$\begin{aligned} &\text{If } P(X|H_0) > P(X|H_1), \text{ accept } H_0 \\ &\text{otherwise reject } H_0 \end{aligned} \tag{3}$$

where $P(X|H_0)$ is a conditional probability of observing the data set X given that the null hypothesis is correct. $P(X|H_1)$ is defined in a similar manner. Most of unsupervised learning techniques can be viewed as variations of this hypothesis testing.

3.1 Type I error versus type II error

During hypothesis testing, there are two types of errors that need to be minimized: type I and II errors. Type I error is also referred to as a *false-positive error*, and this is the error of rejecting the null hypothesis when it is, in fact, correct. Type II error is the case where the null hypothesis is accepted even if it is incorrect and often called a *false-negative error*. In hypothesis testing, one needs to compromise between these two different types of

errors since it is not possible to simultaneously reduce both errors. Therefore, the users need to make conscious decisions as to which type of error is more critical for their applications. For instance, it might be more critical to minimize the false-negative error than to reduce the false-positive error for nuclear power plants because an unchecked defect (false-negative error) could lead to a catastrophic disaster. On the other hand, frequent false-positive alarms of a smoke detector in an ordinary house could lead to the deactivation of the device.

3.2 Fixed-sample test versus sequential test

On the basis of availability of data or how data are used, hypothesis testing can be classified into fixed-sample hypothesis testing or sequential hypothesis testing [12]. In fixed-sample hypothesis testing, that is, the conventional hypothesis testing, statistical inference is conducted after all necessary data are collected or the sample size is fixed. On the other hand, hypothesis testing is continuously (or sequentially) repeated in sequential hypothesis testing whenever a new set of data becomes available. For instance, an automobile company may want to examine the effectiveness of its newly designed air-bag system through actual car-crash tests. In this case, the null hypothesis could be that the newly designed air-bag system works properly with a certain confidence level. To verify this null hypothesis, the automobile company could have crashed 10 cars and performed fixed-sample hypothesis testing afterward. However, it would be more advantageous to repeatedly conduct hypothesis testing whenever another crash test is conducted, until one can arrive at a conclusion. For instance, if the air-bag system works properly five times in a row, probably there might be no reason to continue to crash the remaining cars. For continuous SHM, sequential testing may be more advantageous than fixed-sample testing.

3.3 Parametric approach versus nonparametric approach

As shown in equation (3), hypothesis testing requires statistical characterization of the data or extracted features, before the testing can be performed. This statistical modeling can be done in two different ways: parametric estimation versus nonparametric estimation [13]. In parametric estimation, the statistical distribution of the data is assumed in advance, and the corresponding parameters of the assumed distribution are estimated from the given data. For instance, the data can be often assumed to have a Gaussian distribution, and the parameters associated with the Gaussian distribution, the mean and standard deviation of the data, can be estimated from the given data sets. This type of parametric approach is advantageous when the available data are scarce because there are only a few parameters that need to be estimated. However, there is no guarantee that the selected distribution type properly captures the characteristics of the data, and it may impose unnecessary constraints on the data. For instance, a unimodal distribution such as a Gaussian distribution can be used, although the data, in fact, have a bimodal distribution. Therefore, it is important to verify the goodness of fit of the data.

On the other hand, nonparametric estimation techniques do not impose unnecessary constraints on the data and let the data define their own distribution. This nonparametric approach is more desirable when a plethora of training data is available. However, this nonparametric approach may fail to properly present the distribution of data when only a limited amount of data is available. Particularly, the nonparametric approach is more susceptible to the curse of dimensionality than the parametric approach. Examples of nonparametric approaches include but are not limited to: histogram, naive estimator, k-nearest neighbor method, and kernel estimator.

3.4 Normality test

As mentioned previously, the parametric approach assumes a known distribution type for an unknown data set. This can yield potential problems for later damage diagnosis. On the basis of available literature in SHM, most parametric techniques applied to SHM assume that the data have a Gaussian distribution without proper validation of such an assumption. There are techniques available for determining how close the data are to a normal distribution, such as a normal probability plot, skewness and

kurtosis tests, and the Kolmogorov–Smirnov test. It is recommended that users examine whether the normality assumption of the data is valid before using a normal distribution for their parametric estimation. When the data fail these normality tests, there are other types of distributions available.

3.5 Establishment of decision boundaries

The success of the hypothesis test not only depends on the proper characterization of the data's distribution but it also relies on the appropriate establishment of the decision boundary. A decision boundary or a threshold for damage diagnosis is often determined on the basis of the data distribution type and the given confidence level. For instance, when the training data have a normal distribution, a threshold for outlier analysis can be set to be at $m \pm 3\sigma$ with a 99.74% confidence. When a new data sample goes beyond this threshold value, it is likely that the null hypothesis is rejected with a 99.74% confidence.

3.6 Extreme value statistics

Often the decision boundary for SHM applications resides near the tail of the estimated distribution. Therefore, the errors of misclassification heavily depend on how well the tail of the distribution is modeled rather than the central population of the data. In fact, there is a large body of statistical theory that is explicitly concerned with modeling the tails of distributions, and these statistical procedures can be applied to damage-detection problems. The relevant field is referred to as extreme value statistics (EVS) [14], a branch of order statistics. EVS focuses on modeling those extreme points near the tails without prior knowledge of the parent distributions. It is shown that the extreme values can asymptotically follow one of only three possible extreme value distributions: Gumbel, Weibull, or Fréchet. Furthermore, a generalized extreme value distribution (GEV) can be employed to unify these three distributions, and a process to automatically estimate the associated parameters is available [15]. It has been demonstrated that false alarms resulting from unwarranted assumption of data distributions can be reduced by employing EVS [16].

3.7 Examples of unsupervised learning techniques

3.7.1 Outlier/novelty analysis

The idea of outlier/novelty analysis is to extract features from the data that characterize only the normal condition and these are used as a reference. During monitoring, data are measured, and the appropriate features are extracted and compared (in some sense) with the reference. Any significant deviation from the reference is considered to signal an outlier. Here, an outlier in a data set is an observation that is surprisingly different from the rest of the data in some sense, and therefore is believed to be generated by a different mechanism to the other data. The discordancy of a candidate outlier is some measure that can be compared against the corresponding objective criterion, and allows the outlier to be judged as statistically likely or unlikely to have come from the assumed generating model. For SHM applications, the discordancy should be evaluated with respect to a model constructed from a normal condition of the system of interest [17].

The case of outlier detection in univariate data is relatively straightforward in the sense that outliers will stick out from one end or the other of the data set. There are numerous discordancy tests. One of the most common, and the one whose extension to multivariate data is employed later, is based on deviation statistics given by [18]:

$$z_\zeta = \frac{x_\zeta - \overline{x}}{s} \tag{4}$$

where x_ζ is the potential outlier and $\overline{x}$ and s are the mean and standard deviation of the sample, respectively. The latter two values may be calculated with or without the potential outlier in the sample depending upon whether *inclusive* or *exclusive* measures are preferred. This discordancy value is then compared with a threshold value and the observation is declared to be an outlier or not.

The value of the threshold is critical; unfortunately, it is usually necessary to make some assumptions about the data to establish it. Suppose the normal condition data are assumed as Gaussian. In this case, there is a 95% probability that discordancy, z_ζ computed using equation (4) will lie in the range $[-1.96, 1.96]$. That is, there is only a 5% chance that

the point is a sample from the same normal condition distribution, but it lies outside this range.

3.7.2 Statistical process control

Statistical process control (SPC) is essentially similar to outlier/novelty analysis. For instance, control chart analysis, which is the most commonly used SPC technique and very suitable for automated continuous system monitoring, is applied for continuous SHM. When the system of interest experiences abnormal conditions, the mean and/or variance of the extracted features are expected to change. In [19], an X-bar control chart is employed to monitor the changes in the means of the selected features and to identify samples that are inconsistent with the past data sets. Application of the S control chart, which measures the variability of the structure over time, to the current test structure is presented in [20]. Several variations of the control charts can be found in [21].

3.7.3 Clustering

Cluster analysis is the grouping of sample data in a population to discover a structure in the data. In this article, it is considered as one of the unsupervised learning techniques since it explores natural groupings present in the data. For example, cluster analysis may find out that the data available are from two distinctive groups (one from an undamaged state and the other from a damaged state) without training. One approach of particular interest is a sum-of-squares method. The sum-of-squares method partitions a set of data samples into a prespecified number of clusters. This method finds partitioning of the data that minimizes within-class distances and maximizes between-class distances. There are several variations of the sum-of-squares method depending on the choice of the distance criteria and the optimization procedure adopted [22].

4 SUPERVISED LEARNING

Now, we turn our attention to supervised learning. The goal of supervised learning is to approximate a functional relationship between input and output variables using a set of input and output examples. For instance, a function $\mathbf{y} = f(\mathbf{x})$, which maps each input vector, $\mathbf{x}$, to an output vector $\mathbf{y}$, can be estimated using given training input and output data. Once the function is trained, it can be used for classification with discrete outputs or for regression when the outputs are continuous variables. Similarly, a conditional probability density function $p(\mathbf{y}|\mathbf{x})$ can be modeled using the training data set. Often this conditional probability is estimated using Bayes' theorem in the following form.

$$p(\mathbf{y}|\mathbf{x}) = \frac{p(\mathbf{x}|\mathbf{y})p(\mathbf{y})}{p(\mathbf{x})} \tag{5}$$

Note that the posterior probability $p(\mathbf{y}|\mathbf{x})$ can be directly determined and used for the subsequent decision stages. Approaches that model the posterior probabilities directly are called *discriminative models*. In generative models, the conditional probability $p(\mathbf{x}|\mathbf{y})$ and the prior probability $p(\mathbf{y})$ are computed first. Then, the posterior probability $p(\mathbf{y}|\mathbf{x})$ is estimated using the above form of Bayes' theorem. The relative merits of these alternatives are further discussed in [1].

4.1 Linear models for regression: polynomial curve fitting

Here, the basic concepts of the supervised learning are illustrated using a polynomial equation since it is one of the simplest forms of linear regression models used in supervised learning [1]. Note that this polynomial equation is linear in terms of the unknown parameters w_i. Here, the polynomial equation is used as a running example through this article to highlight a number of key concepts. Suppose that a training data set is composed of N observations of the input variable x together with corresponding observations of the target variable t. The goal is to exploit the training data set to make a prediction, y, of the target variable, t, for a new input variable, x_{new}, using the polynomial function of the form.

$$y = w_0 + w_1 x + w_2 x^2 + \cdots + w_d x^d = \sum_{i=0}^{d} w_i x^i \tag{6}$$

where d is the order of the polynomial and x^i denotes x raised to the ith power. The coefficients of the polynomial are collectively represented by

the coefficient vector $\mathbf{w}$. The coefficient values can be determined by minimizing an error function that measures the sum of the squares of the errors between the target outputs and the corresponding predictions:

$$J(\mathbf{w}) = \frac{1}{2}\sum_{n=1}^{N}(y_n - t_n)^2 \tag{7}$$

x_n and t_n denote the nth observations of x and t, and y_n represents the prediction corresponding to x_n. Because the error function is a quadratic function of $\mathbf{w}$, there exits a unique solution. This solution can be obtained by taking derivatives of the error function with respect to $\mathbf{w}$.

$$\mathbf{w} = (\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathrm{T}}\mathbf{T} \tag{8}$$

where

$$\mathbf{X} = \begin{bmatrix} 1 & x_1 & \cdots & x_1^d \\ 1 & x_2 & \cdots & x_2^d \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_N & \cdots & x_N^d \end{bmatrix} \quad \text{and}$$

$$\mathbf{T} = [\, t_1 \quad t_2 \quad \cdots \quad t_N \,]^{\mathrm{T}} \tag{9}$$

Using this linear prediction model in training, several issues need to be addressed. These issues are discussed below.

4.1.1 Model selection

The first issue is how to determine the order d of the polynomial. More generally, this issue is called *model selection*, and it is an issue common to most of the supervised learning techniques. In general, a lower-order polynomial gives poor fits to the data and does not fully capture the underlying structure of the data. As the order increases, the fitness of the model to the data improves. At some point, the polynomial passes exactly through all the data points and the error function becomes zero. However, as the model order keeps increasing, the fluctuation of the fitted model also increases and the model starts fitting the noises rather than the underlying function. That is, the prediction capability of the fitted model deteriorates as the model order increases. This behavior is known as overfitting. The behavior of the polynomial function also depends on the number of the available training data. For a fixed model order, the overfitting becomes less severe as data size increases. A rule of thumb for model selection is that the number of data points should be at least 5 or 10 times (or some multiple) larger than that of the free parameters in the prediction model.

4.1.2 Regularization

One approach often used to avoid overfitting is regularization [1, 23, 24]. Regularization introduces a penalty term in the error function to discourage a model with unnecessary complexity. A simple example of such a penalty term takes the form of a sum of squares of the coefficients, leading to a modified error function.

$$J(\mathbf{w}) = \frac{1}{2}\sum_{n=1}^{N}(y_n - t_n)^2 + \frac{\lambda}{2}\mathbf{w}^{\mathrm{T}}\mathbf{w} \tag{10}$$

where $\mathbf{w}^{\mathrm{T}}\mathbf{w} = w_0^2 + w_1^2 + \cdots + w_d^2$, and the Lagrange parameter $\lambda(\geq 0)$ controls the relative importance of the regularization term in comparison with the sum-of-squares error term. Note that the sum of squares of the coefficients typically increases as the model becomes more complex (or as the order of the polynomial model increases).

Another approach to avoid overfitting is to divide available data into training and validation data sets. The weight values of a range of models are estimated using the training data, and the prediction performances of the trained models are evaluated using the validation data. In theory, when the training is done properly, the prediction error level for the validation date should be roughly equivalent to that of the training data. This process can be repeated for an increasing order of the model, and the one having the best predictive performance is selected. Note that the use of validation data set is also commonly adopted when an iterative training of the prediction model is necessary, such as for neural networks. The prediction performance for the training and validation data sets can be evaluated and compared at each iteration step, and the training can be stopped when the prediction errors for the validation data start increasing during the iteration. Optionally, a third test set can be reserved so that the performance of the selected

model can be finally evaluated after completion of training. This process is called *early stopping*.

In many applications, the availability of data is scarce and the accessible data should be taken advantage of as much as possible for training. If the size of the validation data set is limited, it gives a poor estimate of predictive performance. One solution to this problem is to use cross validation. In cross validation, the data are partitioned into D groups. Then, data only from $D-1$ groups are used for training and the remaining data from the remaining group are used to evaluate the predictive capability. This process is repeated D times for all possible choices of the divided training and validation data sets, and the final predictive performance is averaged from the D runs.

4.2 Examples of supervised learning techniques

4.2.1 Linear discriminant function

The method using linear discriminant functions divides the given training data sets into the prescribed number of classes of different properties by determining linear separating boundaries. In case of binary classification where the prescribed number of classes is two, i.e., 0 or 1 for undamaged or damaged state of the structure, respectively, the linear boundary is defined as $f_1(\mathbf{x}) = 0$ using equation (11). This linear boundary is called a *hyperplane* whose unknown parameters such as weight vector $\mathbf{w}$ and bias w_0 are estimated through minimizing the training error, for example, the sum-of-squares error. The prediction is made for a new data $\mathbf{x}_{\text{new}}$ by assigning class C_1 if $f_1(\mathbf{x}_{\text{new}}) > 0$ or C_2 if $f_1(\mathbf{x}_{\text{new}}) < 0$. This can be easily extended to multiclass cases [23].

$$f_1(\mathbf{x}) = \mathbf{w}^{\mathrm{T}} \cdot \mathbf{x} + w_0 \tag{11}$$

Instead of using a linear combination, any monotonic function denoted by $g(\cdot)$ in equation (12) can be adopted. This function $g(\cdot)$ is called an *activation function*, and a specific choice is the logistic sigmoid function $g(x) = 1/(1+\exp(x))$.

$$f_2(\mathbf{x}) = g(\mathbf{w}^{\mathrm{T}} \cdot \mathbf{x} + w_0) \tag{12}$$

The separating boundary obtained by equation (12) is also linear, but it provides the probabilistic interpretation on outputs. There are, however, many SHM problems for which linear discriminant functions are insufficient, which leads to nonlinear classification methods presented next.

4.2.2 Neural networks

Neural networks, or artificial neural networks (ANN), were developed on the basis of biological neural networks and classified as two distinct groups, namely, *recurrent* and *feedforward* networks, depending on whether the form of networks is circled or not, respectively (*see* **Artificial Neural Networks**). The most commonly used feedforward network is the multilayer perceptron, which consists of the input, hidden, and output layers with weights that connect neurons in the layers.

A neural network is trained by using a given training data set to minimize a predefined cost function. This cost function is decided depending on the task; a popular choice is the mean-squared error between the given outputs in the training data set and the outputs generated from the network. Typically, there is one output node corresponding to each class, except in a binary classification where there is only one output node. The training procedure with a cost function of mean-squared error consists of the following steps: (i) to assign initial random weights and biases to nodes in the hidden and output layers; (ii) to generate outputs through the designed networks; (iii) to compare the outputs with the given values in the training data set; (iv) to go back to layers to modify the weights and biases if the discrepancy is larger than threshold (back-propagation algorithm); and (v) to iterate procedures (ii)–(iv) until the network outputs converge.

When designing neural networks, it is necessary to decide how many layers and neurons are used. Excessive number of layers or neurons causes an overfitting problem, while insufficient number of them causes an underfitting problem. In [25], Bayesian model class selection was adopted to overcome these problems by determining the most probable model class based on the given data set.

4.2.3 Radial basis function

The Radial basis function (RBF) is a real-valued function taking the form $\phi(\|\mathbf{x} - \mathbf{x}^n\|)$, where $\phi(\cdot)$ is a nonlinear function and $\|\cdot\|$ is a norm (usually

Euclidean norm). The most commonly used nonlinear function is the Gaussian, $\phi(\mathbf{x}) = \exp(-\mathbf{x}^2/(2\sigma^2))$, where σ controls the smoothness. The linear sum of M RBFs as shown in equation (13) forms the so-called RBF network.

$$f(\mathbf{x}) = \sum_{i=1}^{M} w_i \phi(\|\mathbf{x} - \mathbf{c}_i\|) + w_0 \qquad (13)$$

where $\mathbf{w}$, w_0, and $\mathbf{c}_i$ represent weight vector, bias, and center of the basis functions, respectively, and M is smaller than the number of training data.

In classification, RBF networks provide the distributions of separate classes instead of estimating separating boundaries. This distribution is approximated by RBF networks as a posterior probability for each class through Bayes' theorem in equation (5) [23].

4.2.4 Support vector machine

The support vector machine (SVM) is a recently developed state-of-art pattern-recognition method [24]. 0SVM determines the separating boundaries between data of different classes by maximizing the margin as well as minimizing the misclassification errors: margin is defined as the distance of the closest point to the hyperplane as shown in Figure 3. The SVM inherently considers regularization via this margin term to alleviate ill-conditioning, and the solution is computed by solving a convex optimization problem. The convex optimization has the advantage that if a local minimum is obtained, it is guaranteed to be a global minimum, and usually, there exists only one such minimum.

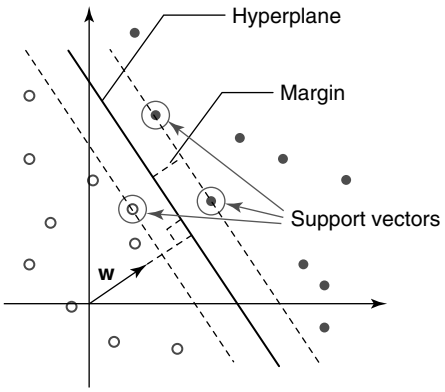

Figure 3. Illustration of SVM as a maximum margin classifier: SVM algorithm estimates a hyperplane to produce a maximum margin.

Nonlinear separating boundaries can also be computed by applying the kernel method. This method enables the same algorithm for the hyperplane evaluation to be applied for the nonlinear classification problems simply by replacing every dot product with any continuous, symmetric, and positive definite kernels, $k(\mathbf{x}, \mathbf{x}_i)$ [26]. The Gaussian kernel $k(\mathbf{x}, \mathbf{x}_i) = \exp(-\|\mathbf{x} - \mathbf{x}_i\|^2/(2\sigma^2))$ is one of the frequent choices and the corresponding boundary has the form

$$f(\mathbf{x}) = \sum_{i=1}^{N} \alpha_i y_i k(\mathbf{x}, \mathbf{x}_i) + \alpha_0 = 0 \qquad (14)$$

where α_i, y_i, and α_0 are Lagrangian multiplier, class label, and bias, respectively.

An illustrative example is presented in Figure 4(a). Classification is performed for 200 randomly generated data points from two mixtures of two Gaussian probability density functions (one shown as crosses and another as dots) using SVM. The circled data specify support vectors. Only these data play an important role in deciding the separating boundaries. The misclassification rate for SVM classification is 5.5% using 66 support vectors.

4.2.5 Relevance vector machine

The relevance vector machine (RVM) is a Bayesian classification methodology using an identical function form for separating boundary as the SVM described in equation (15) [27].

$$f(\mathbf{x}) = \sum_{i=1}^{N} w_i k(\mathbf{x}, \mathbf{x}_i) + w_0 \qquad (15)$$

RVM is known to overcome some of disadvantages of SVM, and a specific prior known as the *automatic relevance determination prior* gives a unifying framework to control model complexity, to overcome the overfitting problem, and to consider regularization as well [28].

The same dataset previously utilized for SVM classification is selected to perform RVM classification and relevance vectors to control a separating boundary are circled. As shown in Figure 4(b), RVM

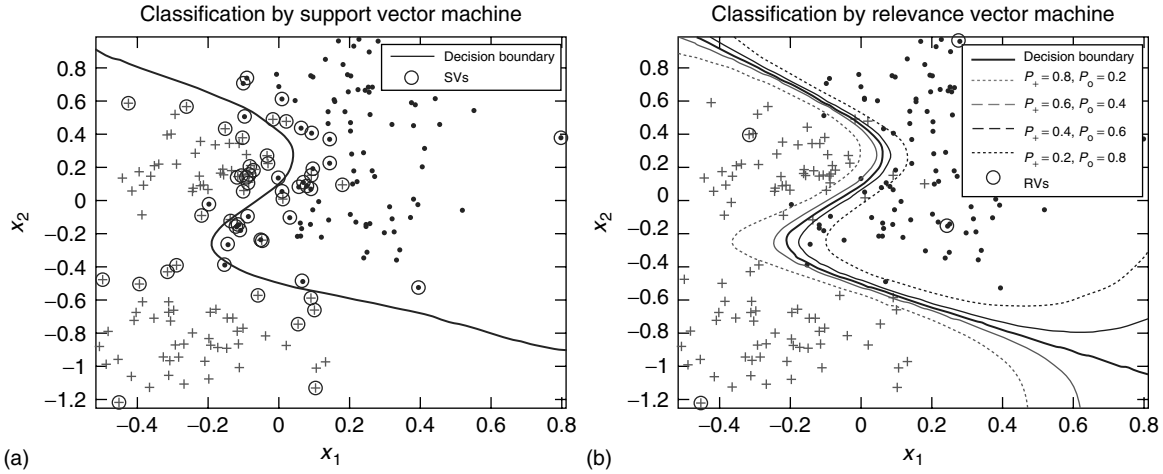

Figure 4. Comparison of classification results by SVM (a) and RVM (b) (RVM provides several separating boundaries according to the corresponding probabilities while SVM yields only one boundary. In Figure 4(b), P_+ and P_o denote the probabilities of crosses and dots, respectively. The misclassification rates for SVM and RVM are 5.5% identically but the number of support vectors and relevant vectors to control the separating boundary is 66 and 4, respectively.)

can provide a probabilistic description on results so that different separating boundaries can be obtained with the corresponding probabilities. Suppose that the crosses and dots in Figure 4 are data extracted from measurements representing undamaged and damaged states, respectively. If one wants to decide a separating boundary to reduce more critical false-negative alarm by imposing higher probabilities to an undamaged state, for example, probability for undamaged state $= 0.6$, the separating boundary with $P_+ = 0.6$ and $P_o = 0.4$ in Figure 4(b) can be estimated by RVM. The misclassification rate for RVM classification using the same data set is 5.5% using only four relevance vectors. Additional applications in SHM and comparison results with SVM are presented in [29].

5 DATA NORMALIZATION

Stated in its most basic form, the objective of SHM is to ascertain whether damage is present or not based on measured dynamic or static characteristics of a system to be monitored. Until now, damage diagnosis has been discussed by comparing the data collected from a healthy part of the structure with a new set of data obtained from a potentially damaged part of the system. The basic premise here is that any deviation from the healthy condition of the system is a result of damage. In reality, structures are subject to changing environmental and operational conditions that affect measured signals, and these ambient variations of the system can often mask subtle changes in the system's response signal caused by damage. It has been shown that these natural variations of the system could lead to false-positive indications of damage. This might be one of the biggest hurdles for deploying a reliable continuous SHM system to field applications. A procedure to normalize data sets so that signal changes caused by operational and environmental variations of the system can be separated from structural changes of interest, such as structural deterioration or degradation is called *data normalization* here. First, reviews of the effects of environmental and operational variations on real structures as reported in literature are presented. Then, research progresses that have been made in the area of data normalization are provided.

Many existing SHM techniques neglect the important effect of changing environmental and operational conditions on the underlying structure. For in-service structures, the variability in dynamic properties can be a result of time-varying environmental and operational conditions. Environmental conditions include wind, temperature, and humidity, while operational conditions include ambient loading conditions, operational speed, and mass loading. Note that data

normalization materials presented here are mainly taken from [30].

5.1 Temperature

The effects of temperature variability on the measured dynamic response of structures have been addressed in several studies. It is intuitive that temperature variation may change the material properties of a structure. Wood reported that the changes of bridge responses were closely related to the structure's temperature based on the vibration test of five bridges in the United Kingdom [31]. Analyses based on the data compiled suggested that the variability of the asphalt elastic modulus due to temperature effects was a major contributor to the changes in the structural stiffness. Temperature variation not only changes material stiffness but also alters the boundary conditions of a system. On the basis of a field test conducted on the Sutton Creek Bridge in Montana, USA, Moorty and Roeder reported that the movements obtained from both the analytical model and the measured values showed significant expansion of the bridge deck as temperature increased [32]. Rohrmann *et al.* noted that when a bridge structure was obstructed from expanding or contracting, the expansion joints could be closed, significantly altering the boundary conditions [33]. Finally, other studies on the influence of temperature variation on in-service structures have been reported in [30].

5.2 Boundary condition

Changes in the structure's surroundings or boundary conditions such as thermal expansion can produce more significant changes in dynamic responses than damage. Using an analytical model of a cantilever beam, Cawley compared the effect of crack formation on the resonant frequency to that of the beam's length [34]. In this study, the crack was introduced at the fixed end of the cantilever beam, and the length of the beam was varied. His results demonstrated that the resonance frequency change caused by a crack, which was 2% cut through the depth of the beam, was 40 times smaller than that caused by a 2% increase in the beam's length. Alampalli reported that, for a 6.76 m $\times$ 5.26 m bridge span that they tested, the natural frequency changes caused by freezing of the bridge supports were an order of magnitude larger than the variation introduced by an artificial saw cut across the bottom flanges of both girders [35]. In particular, the changing boundary conditions would impose difficulties on the implementation of SHM systems because it is often challenging to directly measure the boundary conditions of a structure.

5.3 Mass loading

Mass loading such as traffic loading would be another operational variable that is difficult to precisely measure, but might be important for data normalization. The researchers seem to agree that the mass loading effect of moving vehicles varies depending on the vehicles' mass relative to the magnitude of the bridge. Kim *et al.* reported that the measured natural frequencies of a 46-m-long simply supported plate girder bridge decreased by 5.4% because of heavy traffic [36]. However, for the medium- and long-span bridges, changes in the measured natural frequencies due to different types of vehicle loading (heavy vs light) were hardly detectable. Zhang *et al.* found the damping ratios are sensitive to the traffic mass, especially when the deck vibration exceeded a certain level [37]. It is believed that damping ratio increases because the energy dissipation capacity in the material and at the joint increases at higher traffic loading. In addition, it is speculated that the secondary structure–vehicle interaction effects could also influence the dynamic characteristics of bridge structures.

5.4 Wind-induced vibration

Wind-induced vibration plays an important role for long-span bridges. As a bridge vibrates in the wind, the energy input from the wind-induced vibration becomes larger than the energy dissipated by damping, causing flutter or buffeting. Fujino and Yoshida observed that the dynamic behavior of cable-stayed or suspension bridges is amplitude dependent [38]. For instance, the fundamental frequency of a suspension bridge reduced as the wind speed increased.

On the other hand, the modal damping increased when the wind velocity exceeded a certain level.

Mahmoud *et al.* utilized continuously measured vibration data from the Hakucho Suspension Bridge in Japan to study the dynamic behavior of a suspension bridge [39]. It was found that the vertical amplitude of the bridge response was almost a quadratic function of the wind speed, and the damping ratio was dependent on the vibration amplitude. In particular, the lower natural frequencies were significantly affected by wind speeds. However, the dependency of mode shapes on the vibration amplitude was mainly observed for higher modes and near the tower.

5.5 Data normalization techniques

Because data can be measured under varying conditions, the ability to normalize the data becomes very important to the SHM process. This section contains new technical developments that attempt to tackle the aforementioned environmental and operational issues of SHM. When the environmental or operating variability is an issue, there are three different situations for data normalization. First, when direct measurements of the varying environmental or operational parameters are available, various kinds of regression and interpolation analyses can be performed to relate measurements relevant to structural damage and those associated with environmental and operation variation of the system [17, 33, 40, 41]. For example, the dependency of two-dimensional features on some environmental variable T can be approximated by using regression analysis as shown in Figure 5(a) when a large set of extracted features and measured environmental variables are available. Note that there might be some damage cases that cannot be distinguished from the undamaged conditions unless the environmental variable is measured: for example, the damage case shown in Figure 5(a).

On the other hand, there are situations in which direct measurements of these operational and environmental parameters are impractical or difficult to achieve and damage produces changes in the extracted features, which are orthogonal to the

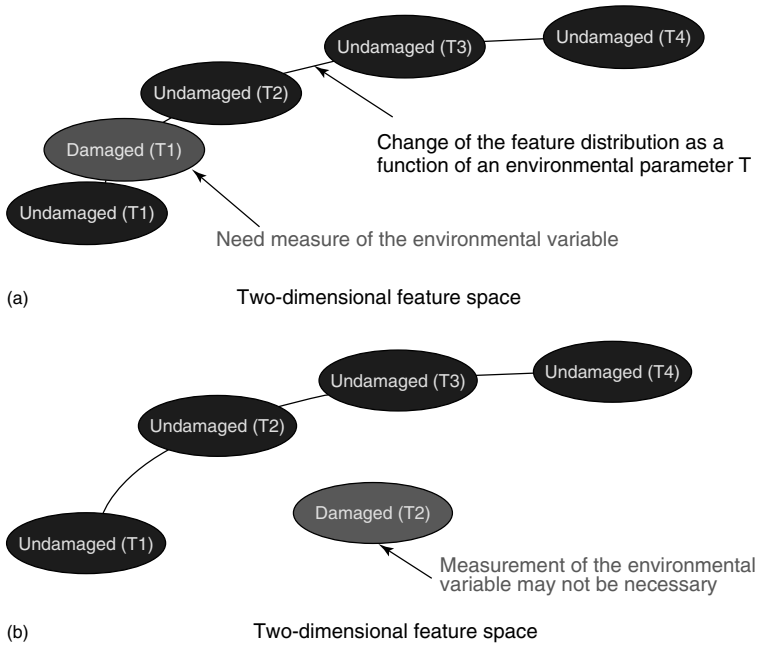

Figure 5. Three conceptional situations exist for data normalization: (a) direct measurements of the varying environmental or operational parameters are available, (b) direct measurements of these parameters are impractical or difficult to achieve, but damage produces changes orthogonal to changes caused by the operational and environmental variation, and (c) features that are mainly sensitive to damage but insensitive to operational and environmental variations can be extracted (not shown in the figure).

changes caused by the operational and environmental variation of the system as shown in Figure 5(b). For this situation, it may be possible to distinguish changes caused by damage from those caused by the operational and environmental variation of the system without measuring the operational and environmental parameters. Several researchers have tackled this situation by implicitly modeling the underlying relationship between the environmental variables and the damage-sensitive features [10, 42–44]. Others have attempted to divide baseline data sets into subsets, each corresponding to a different operational and environmental condition [45, 46].

Finally, there are other researchers who attempt to explicitly extract features that are mainly sensitive to damage but insensitive to operational and environmental variations. In particular, a suite of reference-free damage-detection techniques that do not require direct comparison with baseline data have been developed to address data normalization [47–49].

One of the reference-free approaches in [48] utilizes the polarization characteristics of the lead zirconate titanate (PZT) wafers attached on the both sides of the structure as shown in Figure 6. PZT materials develop an electrical charge or voltage when a mechanical pressure is applied. Conversely, they produce deformation (strain) when exposed to an applied electric field. PZTs are crystalline materials that are artificially polarized through a thermal poling process. The overall behavior of a piezoelectric material as well as its electrical characteristics is governed by the polarization direction of the material. That is, the "sign" of the output voltage depends on the bending of the PZT with respect to its poling direction.

PZTs A and D are collocated on either side of the plate, and PZTs B and C are placed in a similar manner. The arrows in Figure 6(a) show the positive poling direction of each PZT. When the plate is in a pristine condition and four identical PZTs are instrumented as shown in Figure 6(a), it is shown that signal AC becomes identical to signal BD as illustrated in Figure 6(b). Here, signal AC denotes the response signal measured at PZT C when a toneburst excitation is applied at PZT A, and signal BD is defined in a similar fashion. However, signal AC becomes no longer identical to signal BD when there is a crack between PZTs A and B (or PZTs C and D) as shown in Figure 6(c) and (d). Crack formation creates Lamb wave mode conversion due to a sudden thickness change in the structure. Note that, while the S_0 and A_0 modes in Figure 6(b) are in-phase, the S_0/A_0 and A_0/S_0 modes in signals AB and CD are fully out-of-phase as shown in Figure 6(d). (S_0, A_0, S_0/A_0, and A_0/S_0 are defined in Figure 6.) Therefore, the modes converted by the crack can be extracted simply by subtracting signal AC from signal BD.

Since this approach relies only on comparison of two signals instantaneously obtained at the current

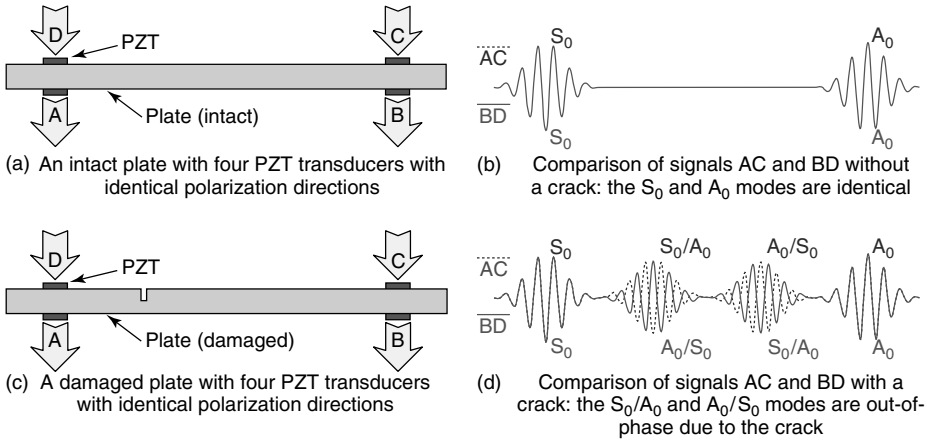

Figure 6. Extraction of the additional Lamb wave modes generated by a crack using the poling directions of the PZT transducers. (A_0 and S_0 denote the fundamental symmetric and antisymmetric modes. A_0/S_0 denotes an A_0 mode converted from an S_0 mode when it passes through a crack. S_0/A_0 is defined similarly. Signal AC denotes the response signal measured at PZT C when the excitation is applied at PZT A. Signal BD is defined similarly.)

state of the system, rather than on comparison with previously recorded reference data, it is experimentally and theoretically shown that this approach reduces false alarms of defect due to changing operational and environmental conditions of the system.

6 CONCLUSION

The problem of searching for patterns in data has a long history. SPR is concerned with the discovery of regularities in data and subsequent actions such as classification and regression. The introduction of this SPR paradigm to SHM has brought a new perspective to the SHM community, and together they have undergone substantial development over the past decade. In particular, the SPR approach of SHM problems has grown from being viewed as a special treatment of the SHM problems to becoming a mainstream. This article is intended to reflect these recent developments in SHM, while providing a brief introduction to the field of SPR. Many new concepts and novel SHM techniques based on SPR view points are constantly being developed and implemented in the SHM community. In addition, the practical applicability and benefits of the SPR approaches have been reported here through the illustrations of a range of numerical, experimental, and field examples.

Chapter 32
Artificial Neural Networks

Steve Reed
QinetiQ, Farnborough, UK

1 INTRODUCTION

The aim of this article is to describe the development and the key elements of artificial neural networks (ANNs) within the context of structural health monitoring (SHM). Chang [1] describes the essence of SHM technology as developing autonomous systems for the continuous monitoring, inspection, and damage detection of structures with minimum labor involvement. The characteristics of ANNs in their ability to learn from experience, generalize from examples, and identify underlying information from within noisy data mean that they have the potential to play a leading role in such SHM systems.

Within this article, the development of ANNs and the basic principles behind their functionality, training, and deployment are described. Emphasis is placed upon the multilayer perceptron (MLP), both as the workhorse of ANN methods and as a vehicle for describing the principles behind these methods; however, other frequently used techniques, including radial basis functions (RBFs) and self-organizing feature maps (SOFMs), are also detailed. Additionally, the application of ANN techniques, including examples of parameter-based structural usage models and damage detection methods using ANNs, are presented. The use of ANN techniques in novelty detection (*see* **Novelty Detection**), pattern-recognition applications (*see* **Statistical Pattern Recognition**), operational loads measurement (*see* **Operational Loads Monitoring in Military Transport Aircraft and Military Derivatives of Civil Aircraft**), and fixed-wing fatigue monitoring (*see* **Aerospace Applications of SMART Layer Technology**) are discussed elsewhere. Reference has been made throughout this article to a wide range of texts. Readers with a desire for further knowledge of ANNs are recommended to investigate [2–6] as introductory texts and [7–9] as more seminal works.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

2 ANN DEVELOPMENT

2.1 ANN definition

There is no universally accepted definition of what constitutes an ANN. However, a useful definition is provided by Gurney [2]:

> "... an interconnected assembly of simple processing elements, units or nodes, whose functionality is loosely based on the animal neuron. The processing ability of the network is stored in the interunit connection strengths, or weights, obtained by a process of adaptation to, or learning from, a set of training patterns."

2.2 Biological inspiration

The origins of ANNs lie primarily in the world of cognitive science. The human brain is an extremely complex system, capable of remembering, thinking, and problem solving. The neuron is the fundamental unit of the brain and receives and combines signals along input paths (dendrites) from other neurons. If the combined signal is sufficiently strong, the neuron "fires" and an output is transmitted via the axon to other neurons. Any signal entering a neuron passes through a synaptic junction. This is a minute gap in the dendrite, filled with neurotransmitter fluid that accelerates or retards the electrical flow [2]. Adjustment to the impedance of the synaptic gap is a critical process linked with memory and learning. Increasing the synaptic strengths allows the brain to learn or retain information (Figure 1).

2.3 McCulloch and Pitts neuron

While the inspiration may be biological, the development of ANNs has blossomed with the advances made in computing. The origins of ANNs are generally traced back to the work of McCulloch and Pitts [10]. They recognized that combining together many simple neurons was a potential source of increased computational power. The activation of their neuron was binary and it either fired (activation of 1) or did not fire (activation of 0) (Figure 2).

McCulloch–Pitts neurons were connected to other neurons by directed weighted paths. A connecting path excited the connection if the weight was positive;

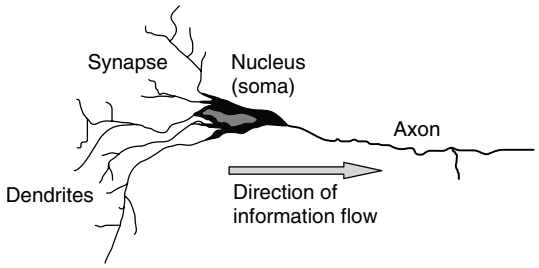

Figure 1. Illustration of a biological neuron.

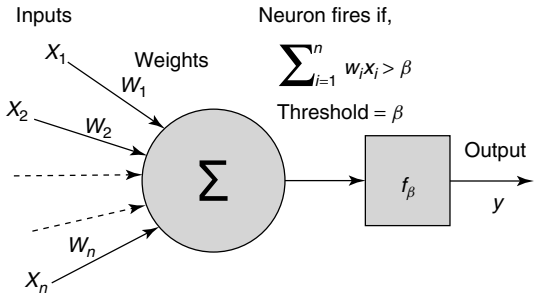

Figure 2. Representation of a simple McCulloch–Pitts Neuron.

otherwise it was inhibitory. All excitatory connections into a neuron had the same weight. Furthermore, each neuron had a fixed threshold, and if the net input was greater than the threshold, it fired. Also, it took one time step for a signal to pass over one connection link. As a single layer, the McCulloch–Pitts neuron was only able to solve linearly separable problems. However, McCulloch–Pitts neurons are still used widely in logic circuits today.

2.4 Hebb's learning rule

In the late 1940s, Hebb [11] developed the first learning rule for ANNs. Hebb stated that if two neurons were active simultaneously, then the strength of the connection between them should be increased. Hebb's rule was adapted by later researchers to allow it to be used in computer simulations.

2.5 Rosenblatt's perceptron

In the early 1960s, the McCulloch–Pitts neuron was developed further by Rosenblatt [12]. Rosenblatt's perceptron networks were composed of an input

layer (retina), a hidden layer (associative layer), and an output layer (decision layer). Rosenblatt's perceptron learning rule used a supervised iterative weight adjustment that used a learning coefficient, a more powerful form of the Hebb rule. Rosenblatt avoided the credit-assignment problem (i.e., how to update the weights between the input and hidden layers) by only allowing the connections between the decision nodes and the associative nodes to be adjusted. The connections between the inputs and hidden (associative) layer were fixed before learning commenced (Figure 3).

The early successes with perceptrons led to enthusiastic claims [6]. However, the problem was that the size of the network grew exponentially with the increased dimensions of the problem. Methods were developed to address this issue with restricted connections between nodes, referred to as *diameter-limited perceptrons*. Then, in the late 1960s, Minsky and Papert [13] published a rigorous investigation into the capabilities of perceptrons and concluded that they were of limited use. Possible solutions proposed included the use of several hidden layers within the perceptron but this approach failed over the credit-assignment problem that Rosenblatt had avoided. The result of Minsky and Papert's book was that nearly all ANN research was abandoned until Hopfield's paper [14] led to a rekindling of interest.

2.6 Hopfield's network

Hopfield [14] used a fully connected recurrent network of McCulloch–Pitts neurons to create a content-addressable memory system. Hopfield considered the output of the neurons as dynamical states and identified that a network could be used to store patterns that were the stable states of the network. A pattern can be retrieved from the network using only a subset of the pure pattern. Hopfield is also largely credited with reviving interest in neural network research.

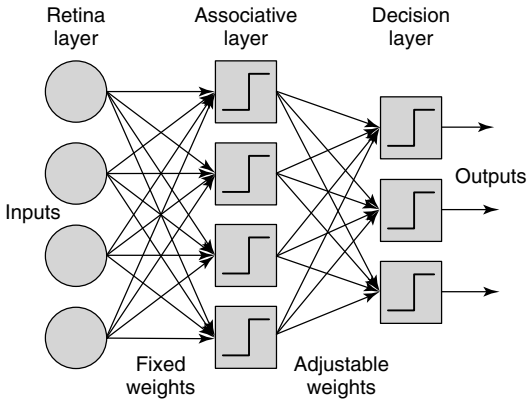

Figure 3. Rosenblatt's perceptron.

2.7 Development of the multilayer perceptron

The development of the MLP is generally attributed to Rumelhart and McClelland [7]. Interestingly, the backpropagation learning algorithm (or the generalized delta rule), the method of solving the credit-assignment problem, was outlined independently by Werbos in his 1974 doctoral thesis (published as [15]). Elsewhere in the literature, the independent development of the backpropagation method is also attributed to Parker [16] and LeCun [17].

3 SUPERVISED AND UNSUPERVISED LEARNING MECHANISMS

3.1 Supervised learning

ANNs can be subdivided by the methods they use to learn relationships. In supervised learning methods, the ANN is presented with inputs and examples of the required outputs, or targets. The inputs are multiplied by weights and biases, which are adjusted by iteration to reduce an error function. This error function is based upon the difference between the desired output and that predicted by the network. The concept is simple but the complexity is in the training algorithm that is required to converge the training to a minimum-error solution efficiently. Well-known examples of supervised learning ANNs include the MLP and RBF. Supervised learning is illustrated in Figure 4.

3.2 Unsupervised learning

Unsupervised learning allows the network to determine the characteristic relationships within the data

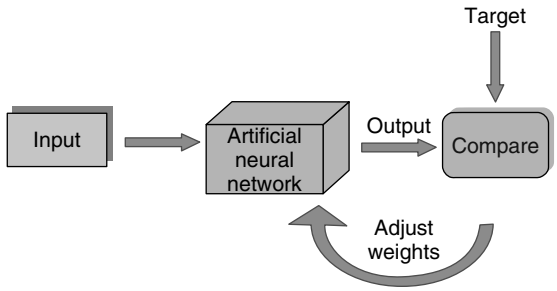

Figure 4. Supervised learning schematic for an ANN.

without reference to target examples. Information about the characteristic features of input data is created during the learning process and stored in the weights. Output signals describe relationships between the current input signals and the weight vectors. Well-known unsupervised techniques include SOFMs and learning vector quantization (LVQ) (incorporating both unsupervised and supervised learning).

4 MULTILAYER PERCEPTRON

4.1 Weights and biases

A simplified schematic of an MLP is illustrated in Figure 5. The normalized inputs are each linked to the hidden layer neurons by a weight vector ($\boldsymbol{w}$) and a bias vector ($\boldsymbol{b}$) is applied to each neuron. These weights and biases can be thought of as analogous to the equation used in linear regression ($y = mx + c$). The weight can be considered as the gradient (m) and the bias as the intercept (c). The network in Figure 5 has been illustrated with one output node; however, many output nodes can be used if required.

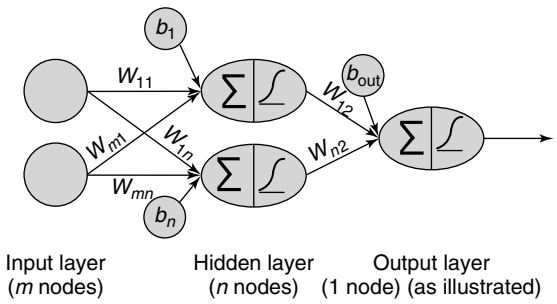

Figure 5. Schematic of simplified MLP–ANN.

4.2 Hidden layer activation functions

An MLP is a feed-forward network and the hidden layer contains a number of neurons that receive weighted data from each input node and pass it to the next layer node, via the activation function. The function of each of these nonlinear activation functions is akin to a mechanical nonlinear gearbox. The relationship between the input and output is nonlinear but constant. In the network illustrated in Figure 5, logistic sigmoid functions are used. Other shaped functions can be used as long as they are continuous, differentiable, monotonically nondecreasing functions. Being able to differentiate the activation function is the key element that separates an MLP from previous developments and the backpropagation of the error (solving the credit-assignment problem) is dependent upon this facet. Consequently, hard-limit functions cannot be used in an MLP.

4.3 Output layer

Data from each neuron in the final hidden layer are passed to the output layer. Here the output layer is a logistic sigmoid function (range 0–1), again with a bias. However, simple linear summation, again with a bias, is often used for an output without range restriction. The outputs of the two-layer network, illustrated in Figure 5, with both layers using logistic sigmoid activation functions would be calculated by using equation (1):

$$\mathbf{y} = \text{logistic}\left[\sum\left\{\boldsymbol{w}_2 \times \left[\text{logistic}\left\{\sum(\boldsymbol{w}_1 \times \mathbf{x} + \boldsymbol{b}_1)\right\}\right] + \boldsymbol{b}_2\right\}\right] \quad (1)$$

where, $\mathbf{y}$ is the output matrix, *logistic* describes the logistic sigmoid activation function (equation 2), $\mathbf{x}$ is the input matrix, $\boldsymbol{w}_1$ is the first-layer weight matrix, $\boldsymbol{w}_2$ is the second-layer weight matrix, $\boldsymbol{b}_1$ is the first-layer bias vector, and $\boldsymbol{b}_2$ is the second-layer bias vector.

4.4 Activation function derivatives

As already discussed, being able to differentiate the activation function is the key element of the

MLP and the importance of this becomes clear in the following sections. The activation functions and derivatives of the most widely used logistic sigmoid, tangent sigmoid, and linear functions are detailed in equations (2–4):

Logistic sigmoid

$$o_{\mathrm{pj}} = f\left(net_{\mathrm{pj}}\right) = \frac{1}{1+\mathrm{e}^{-k\cdot net}}$$
$$f'\left(net_{\mathrm{pj}}\right) = k\cdot o_{\mathrm{pj}}\left(1-o_{\mathrm{pj}}\right) \qquad (2)$$

Tangent sigmoid

$$o_{\mathrm{pj}} = f\left(net_{\mathrm{pj}}\right) = \frac{\mathrm{e}^{k\cdot net}-\mathrm{e}^{-k\cdot net}}{\mathrm{e}^{k\cdot net}+\mathrm{e}^{-k\cdot net}}$$
$$f'\left(net_{\mathrm{pj}}\right) = k\cdot\left(1-o_{\mathrm{pj}}^2\right) \qquad (3)$$

Linear

$$o_{\mathrm{pj}} = f\left(net_{\mathrm{pj}}\right) = net_{\mathrm{pj}}$$
$$f'\left(net_{\mathrm{pj}}\right) = 1 \qquad (4)$$

where w_{ij} is the output from pattern p at node j, f is the internal activation, k is the slope parameter, and $net_{\mathrm{pj}} = \Sigma w_{\mathrm{ij}}\cdot o_{\mathrm{pj}}$, where o_{pj} is the weight from node i to j. This formulation for the derivatives makes the computation of the gradient more efficient since the output has already been calculated in the forward pass. Plots of the logistic sigmoid function and its derivative, used in the MLP illustrated in Figure 5, are produced in Figure 6.

4.5 Backpropagation training algorithm

The aim of the training algorithm is to reduce the error function to a minimum. This error function is usually based upon the difference between the desired output (target) and that predicted by the ANN, sometimes with the addition of a regularization term to prevent weights from growing too large. Training the ANN can best be visualized by using a simplified two-dimensional error surface, illustrated in Figure 7. Here the aim is to reach the global minimum value in the error surface without getting stuck in local minima or saddle points.

There is insufficient space here to show the derivation of the backpropagation algorithm and hence the solution is merely stated using the notation reproduced by Beale and Jackson [3]. Firstly, the network output from the initialized weights and input values is calculated and compared with the desired output. Then the weights are adjusted starting from the output layer and working backward using equation (5):

$$w_{\mathrm{ij}}(t+1) = w_{\mathrm{ij}}(t) + \eta\delta_{\mathrm{pj}}o_{\mathrm{pj}} \qquad (5)$$

where $w_{\mathrm{ij}}(t)$ represents the weights from node i to node j at time t, η is the learning rate (0–1), which is

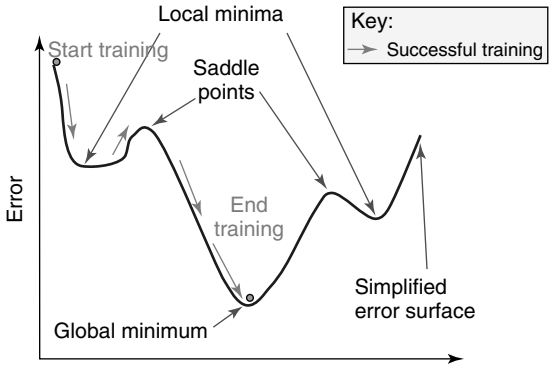

Figure 7. Simplified schematic of error surface.

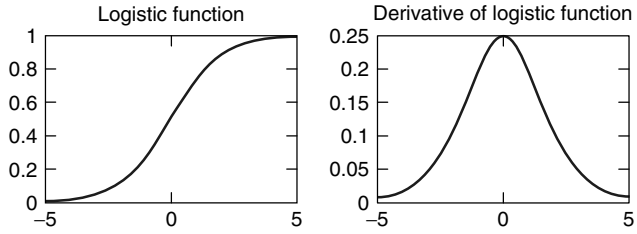

Figure 6. Logistic activation function and derivative.

effectively a gain term, δ_{pj} is an error term for pattern p on node j and o_{pj} is the output from pattern p at node j. For the output units the error term is expressed by equation (6):

$$\delta_{pj} = f'(net_{pj})(t_{pj} - o_{pj}) \tag{6}$$

For a logistic sigmoid activation function (equation 2), this would be represented by equation (7):

$$\delta_{pj} = k \cdot o_{pj}(1 - o_{pj}) \cdot (t_{pj} - o_{pj}) \tag{7}$$

For the hidden units, the error term is expressed by equation (8):

$$\delta_{pj} = f_j'(net_{pj}) \cdot \sum_k \delta_{pk} w_{jk} \tag{8}$$

where the sum is over the k nodes in the layer above node j. Again, for a logistic sigmoid activation function this would be represented by equation (9):

$$\delta_{pj} = k \cdot o_{pj}(1 - o_{pj}) \cdot \sum_k \delta_{pk} w_{jk} \tag{9}$$

The importance of being able to calculate the derivatives of the activation functions (equations 2–4) is now evident. Using these relationships, the network can either be trained in batch mode, where the weight updates are calculated after the entire training data set has passed through the network, or in sequential mode, where weight updates are carried out after the presentation of each training example.

4.6 Improvements to the backpropagation algorithm

There is a plethora of methods in the literature for improving the performance of the backpropagation algorithm. The addition of a momentum term is widely referenced; this allows previous updates to persist for a period of time. Hence, a large change of weights will occur if the changes are large and these will decrease as the changes become smaller. This means that the network is less likely to get stuck in local minima early in the training, as the momentum will push the changes over local increases in the error (or energy) function [8]. The inclusion of a momentum term modifies equation (5) to produce equation (10):

$$w_{ij}(t+1) = w_{ij}(t) + \eta \delta_{pj} o_{pj} + \alpha \Delta w_{ij}(t) \tag{10}$$

where α is the momentum coefficient and $0 \leq \alpha \leq 1$.

Other heuristic methods for improving the performance of MLPs with the backpropagation algorithm are described in the literature [6, 8, 9, 18, 19]; many of these are attributed to Jacobs [20] or seek to address the limitations identified by Jacobs and are based around adaptation of learning.

4.7 Second-order training algorithms

Although these developments, which are largely heuristic, have been shown to improve the speed of convergence, it is reported that the information provided by the first-order local error gradient can sometimes be an oversimplification of an often highly complex error surface [8]. Higher-order information may be required to produce significant improvements in the convergence performance of the MLP [9]. Here the problem becomes one of numerical optimization and the main methods used are based around conjugate gradient methods and quasi-Newtonian methods.

In the conjugate gradient algorithms, a search is performed along conjugate (i.e., not interfering with each other) directions. For most conjugate gradient algorithms, the length of weight update, or step size, is adjusted after each iteration of the algorithm. The initial step is taken in the steepest descent direction. Then a line search is performed to determine the optimum distance to move along the current search direction. The next search direction is then determined so that it is conjugate to previous search directions. The general procedure for determining the new search direction is to combine the new steepest descent direction with the previous search direction [8]. The various versions of the conjugate gradient method are distinguished by the way they calculate the step size and the step direction [18, 21].

The basis of Newtonian methods is that the change with the next step of the algorithm is equal to the product of the gradient of the error surface and the inverse Hessian matrix [9], where the Hessian matrix is the second derivative of the error

surface. However, calculation of the inverse Hessian matrix is extremely computationally expensive for large networks, and, in many cases, it may not be computable (as the Hessian must be nonsingular and positive definitive). Hence, in quasi-Newtonian (or secant) methods, an estimate of the Hessian matrix is calculated at each iteration of the algorithm, using the error surface gradient information. This estimation reduces the computational effort significantly and eliminates the risk of the inverse Hessian being incomputable [8].

Alternative approaches have also been suggested. These include the methods developed by MacKay [22]. In this method, a Bayesian framework is established and the weights and biases of the ANN are assumed to be random variables with specific distributions. The regularization parameters are related to the unknown variances associated with these distributions. Estimates of these parameters are produced using statistical techniques during training.

4.8 Limitations of MLP with backpropagation training

Although the network training may have arrived at a local minimum value, there is no guarantee that it is the absolute or global minimum (Figure 7). Consequently, the literature is brimming with detail on the risks of training halting in local minima and methods to avoid this, although, in practice, by training a reasonably large number of models and with the use of the large data sets typical of SHM applications, the risk of training halting in local minima is often found to be small [23].

Another curse of the MLP is overfitting. This occurs when the ANN no longer represents the underlying relationships in the data. The implication is that the ANN maps well the relationships within the training data, but fails to produce similar results on previously unseen data and fails to produce a generalized solution. This was illustrated by the now famous ANN tank detection photographic software that turned out to be a weather forecaster [24]. The literature is full of cautionary examples of the risks of overfitting and how to avoid it, such as early stopping (or test-error activation) techniques, regularization, or the addition of noise. In practice, the risk is very problem dependent, and where large training data sets and relatively small networks are used, the risk is often small [8].

4.9 Use of training, test, and validation data sets

Data are divided into training, test, and validation sets. Training data are used to optimize the weights and biases within the model. The statistically similar test data are used to ensure the solution is not overfitting to the training data (good generalization). Thereafter, the validation data are used for independent assessment of the performance of the model and to identify solution confidence limits.

5 RADIAL BASIS FUNCTIONS

Whereas the MLP applies a method of optimization by adjusting weights to vary the network response, the RBF is more of a curve-fitting approximation in high-dimensional space. The learning procedure involves finding a surface in multidimensional space that best approximates the training data. Considering the structure of a neural network in this case, the hidden units provide a set of functions that provide an arbitrary basis for the input patterns when they are expanded into the hidden-unit space. Hence these functions are termed *radial basis functions*.

In its most basic form, the RBF network consists of three entirely different layers—the input layer made up of source nodes (sensory units), the hidden layer (which serves a different purpose from that in an MLP), and the output layer (which supplies the response of the network). A schematic of an RBF network is shown in Figure 8. As for the MLP, the function contained within the RBF units can be varied. For example, these functions could be Gaussian, multiquadratic, inverse multiquadratic, thin plate spline, or r4 log r functions [9, 25].

The function of an RBF net can be understood directly by considering each of the nodes in the hidden layer. Each one contributes a "hump", possibly Gaussian, in n dimensions. This hump is weighted before being blended with others in the network at the output. Therefore, quite complex decision regions may be built up from relatively few nodes. An example is illustrated in Figure 9.

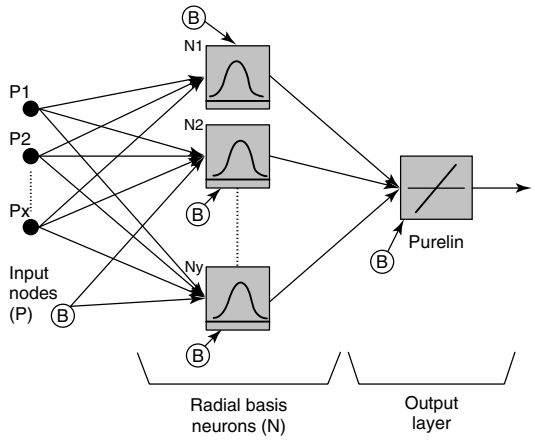

Figure 8. Example radial basis function network.

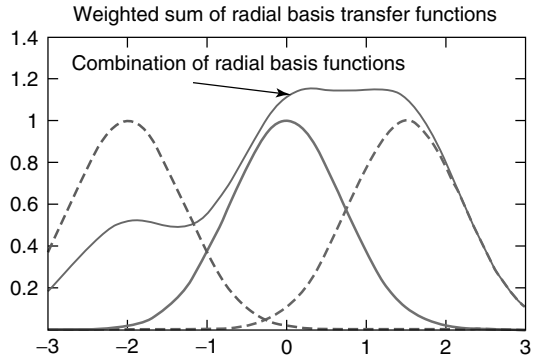

Figure 9. Creation of complex function from Gaussian distributions.

Training an RBF can be considerably faster than training MLP networks. The process usually consists of a two-stage training procedure. In the first stage, the parameters governing the basis functions are determined using relatively fast, unsupervised methods, i.e., without reference to target data. The second stage of the training then involves the determination of the final layer weights, which requires the solution of a linear problem and is therefore also fast. A set of vectors is applied to represent the input data, usually by minimizing the Euclidean distance. A set of weights is then simply adjusted to combine these vectors to represent the target. The Euclidean distance function is sometimes referred to as the *radial distance* and is the magnitude of the difference between the input vector and the locations of the centers of the radial functions. MLP and RBF networks play very similar roles in that they both provide techniques for approximating nonlinear relationships and both are feed-forward networks. They are also the most common forms of supervised networks in use.

6 AUTOASSOCIATIVE NETWORKS

An autoassociative network is a modified MLP whereby the network is trained to predict the inputs. However, the number of neurons in the hidden layer or layers is significantly less than the number of inputs (Figure 10—in this case, $\mathrm{N}y \ll \mathrm{P}x = \mathrm{M}x$). Hence, the network is forced to learn the key underlying relationships within the data.

When used as a data novelty detector [26] (*see* **Novelty Detection**), new input data are presented to this network and the inputs are predicted using the trained network. If the error in the prediction is significantly larger than the error seen in training, then this indicates that the new input data are outside of the experience of the network and are hence novel data.

7 SELF-ORGANIZING SYSTEMS

In self-organized or unsupervised learning, the purpose of the algorithm is to discover significant patterns in the input data without a target set. To achieve this, the algorithm applies rules of a local nature, meaning that changes applied to a neuron, in terms of weight variance, are confined to its immediate neighborhood.

A class of ANNs called *self-organizing feature maps* is based on this premise. These apply competitive learning, where the output neurons compete amongst themselves to be activated or fired. In an SOFM, neurons are placed at the nodes of a lattice that is one or two dimensional and these become tuned to various input patterns. These tuned neuron locations tend to become ordered in such a way that a meaningful coordinate system for different features is created over the lattice. Hence, an SOFM is characterized by the formation of a topographic map in which the spatial locations of the neurons correspond to intrinsic features of the input patterns.

One of the most well known SOFMs is the process developed by Kohonen [27]. The principal goal of

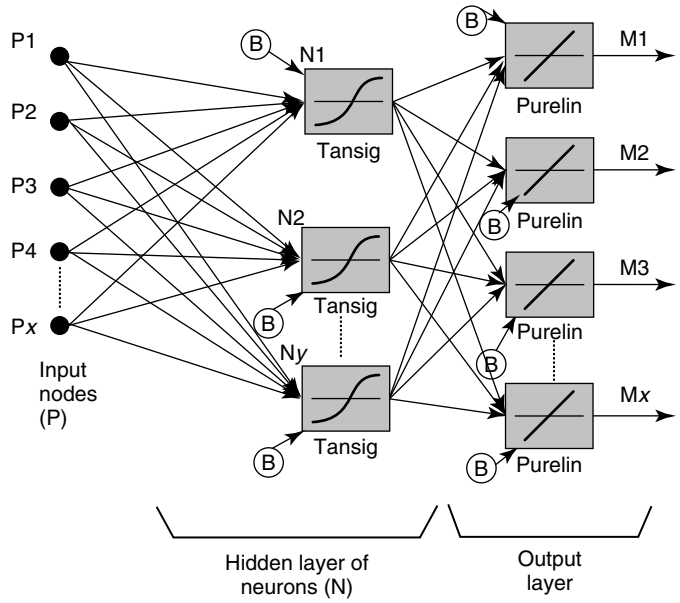

Figure 10. Schematic of an autoassociative network.

the Kohonen SOFM algorithm is to transform an incoming signal pattern of arbitrary dimension into a 1D or 2D discrete map.

8 LEARNING VECTOR QUANTIZATION

An LVQ combines supervised and unsupervised learning methods. The unsupervised competitive layer classifies the input data into a predetermined number of subclasses in the input multidimensional space. This activity is unsupervised, and the mapping is a result of the inherent clustering in the input data. Thereafter, these subclasses are mapped to the target classes, using a supervised learning algorithm. LVQ is a nearest-neighbor classification method that has been studied extensively in the field of pattern recognition [27]. Figure 11 is a simplified schematic of an LVQ.

9 PROBABILISTIC NEURAL NETWORKS

The probabilistic neural network (PNN) [28] is a Bayesian classifier contained within an ANN [5]. An input (feature) vector is used to identify a category and the network classifiers are trained by being shown data of known classifications. The PNN uses these training data to develop distributions that are used to estimate the likelihood of a feature vector being within several given categories. Ideally, this is combined with *a priori* knowledge such as the relative frequency of each category.

10 DYNAMIC NEURAL NETWORKS

Dynamic neural networks include an element of memory that allows the ANN to exhibit temporal behavior that is dependent not only on present inputs but also on prior inputs. There are two major classes of dynamic networks: recurrent neural networks (RNNs) and time delayed neural networks (TDNNs).

10.1 Recurrent neural networks

RNNs contain internal time delayed feedback connections. The two most common designs are the Elman network [29] and the Jordan network [30]. In an Elman network, the hidden-layer outputs are fed back

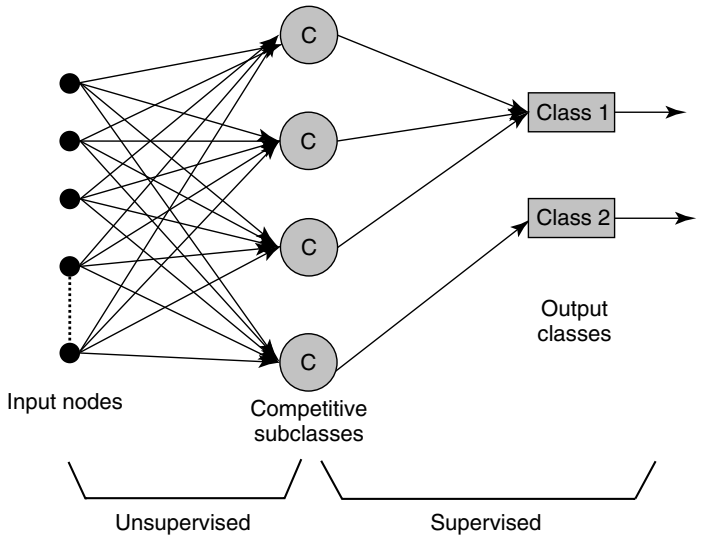

Figure 11. Simplified learning vector quantization example.

through a one-step delay to dummy input nodes. The Elman network can learn temporal patterns as well as spatial patterns because it can store information. The Jordan network is a recurrent architecture similar to the Elman network, but it feeds back the output layer rather than the hidden layer. RNN are more difficult to train than conventional networks because of the feedback connections.

10.2 Time delay neural networks

TDNNs can learn temporal behavior by using both present inputs and past inputs by simply delaying the input signal. The ANN is usually based upon a standard MLP, but it can also be an RBF, a PNN, or any other feed-forward network architecture. Since the TDNN has no feedback terms, it is easily trained with standard training algorithms [5].

11 ADAPTIVE AND NONADAPTIVE SYSTEMS

Adaptive prediction methods continue to train when it is in service, whereas for nonadaptive methods, the weight and bias coefficients are fixed after training. Without formal control over the training data set, currently, certification of such a mechanism for a safety-related application, such as an aircraft SHM system, would be most unlikely [31].

12 APPLICATIONS

ANNs can provide solutions to a variety of SHM-related problems including regression (mapping), classification, detection (abnormality), and autoassociation (reconstruction). This section contains some examples of the application of ANN technology within SHM systems.

12.1 Parametric-based aircraft structural loads and usage prediction

Several researchers in the aeronautical arena have published work using ANNs and similar mathematical techniques to predict stresses/strains or loads from flight parameters, to identify loading actions, or to supplement sparse flight test data. Smiths Aerospace are leading exponents of these techniques and Azzam *et al.* [32–34] and Wallace *et al.* [35] have described the use of a "mathematical network" to predict stresses/strains or loads in a cooperative work program involving Smiths Aerospace, the UK Ministry of Defence, and BAE SYSTEMS.

Successes reported included excellent correlation between measured strains and strains predicted from flight parameters. Cumulative fatigue damages from the predicted strains were reported as being within 3.6% of those calculated from measured strains for two wing locations, the fin, and taileron of the Tornado combat aircraft. These results were obtained from more than 1000 sorties, relating to data spread over 15 years of recording. Azzam [33] also described the development of methods to predict damage in helicopter components and the prediction of high-frequency events, or *rare events* as they termed them, such as buffet loading on the fin of a fixed-wing aircraft.

Reed and Cole [36] and Reed [23, 37, 38] reported the development of ANN-based fatigue monitors predicting strain from flight parameters for a wide range of fatigue critical locations for combat, transport, and trainer aircraft under both maneuver and buffet loading. An example plot comparing a measured strain time history with a predicted strain time history is presented in Figure 12. Fatigue damage calculated from predicted strains was within 6% of that calculated from the measured strains from unseen data.

Recent papers have illustrated the spread of this technology with the development of MLP–ANN parameter-based fatigue monitoring systems proposed for the Airbus A330-MRTT (Multi Role Tanker Transport) [39] and the Boeing F-18 combat aircraft, operated by the Finnish Air Force [40]. Other researchers have explored the use of this technology in discrete fields: the synthesis of helicopter loads was described by Hill *et al.* [41], in which a back-propagation ANN was used to synthesize strain and fatigue damage in several Lynx helicopter components. Manry and coauthors [42] also applied ANN to flight load synthesis, using Bell helicopter data. The prediction of strains in the empennage of a Cessna 172P General Aviation aircraft during discrete maneuvers, using a backpropagation ANN, was reported by Kim and Marciniak [43]. Additionally, Jacobs and Perez [44] used a hybrid cascade ANN to augment sparse buffet data by predicting the power spectral densities of surface pressures on the vertical tail of a fighter aircraft, from parametric data. Finally, Levinski [45] used ANN technology to synthesize loads on the vertical tail of an F/A-18 aircraft, using wind tunnel pressure data.

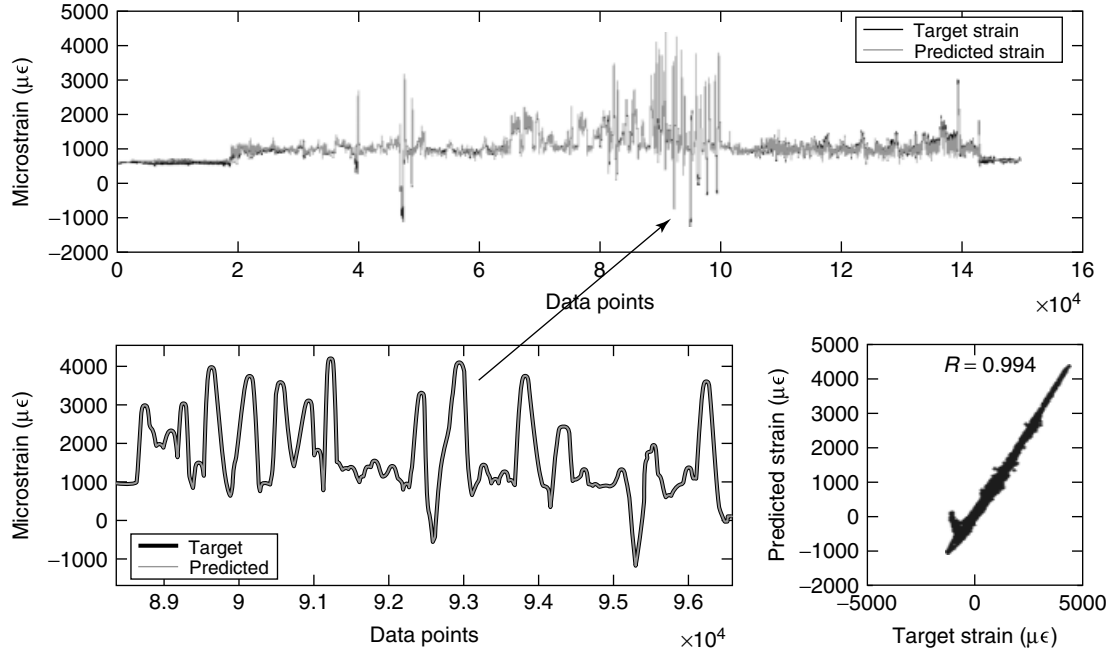

Figure 12. Example wing strain prediction for a trainer aircraft.

12.2 Damage detection in structures

There are a great many papers in the literature describing programs to develop or improve damage detection methods in both metallic and composite structures [46]. Advances in ultrasonic techniques, in particular, promise significant steps forward in this field [47]. ANN techniques are used within many of these techniques, primarily undertaking signal conditioning roles (*see* **Statistical Pattern Recognition**; **Novelty Detection**; **Data Fusion of Multiple Signals from the Sensor Network**).

For example, Lopes *et al.* [48] describe a nonmodel technique used to detect and locate structural damage using ANN. The method used piezoelectric sensors and actuators (*see* **Piezoelectricity Principles and Materials**; **Piezoelectric Wafer Active Sensors**; **Piezoelectric Paint Sensors for Ultrasonics-based Damage Detection**) with high-frequency structural excitation (typically $>30\,\text{kHz}$) to detect changes in structural point impedance caused by the presence of damage. The impedance-based technique was very sensitive to minor changes in the near field of the piezoelectric sensor. However, owing to the difficulties in developing analytical models at such high frequencies, the technique could not correlate a change in electrical impedance with a specific change in structural properties and hence only provided limited information on the nature of the damage. Therefore, a method was developed to combine the impedance-based technique with ANN. Two MLP–ANNs were used to detect, locate, and characterize the structural damage, having been trained upon experimental data. The first ANN was used to identify the presence of damage and a second network was trained to identify particular types of damage, using experimental data. The authors used this technique to locate and identify the damage in a four-bay structure with bolted joints.

Chetwynd *et al.* [49] described a program of work involving the damage detection in a curved carbon-fiber reinforced panel with two omega stiffeners; this was also investigated using ultrasonic Lamb waves. The statistical technique of outlier analysis was used here as a way of preprocessing experimental data, prior to damage classification. MLP–ANNs were used successfully for both classification and regression problems of damage detection. The authors highlighted that the most intensive aspects of creating this SHM system were the collection of the training data and the generation of the optimum MLP network. Compared with these, the time spent in investigating the sensor network with Lamb waves and generating the MLP response was considered negligible. Hence, they concluded that such a system could be effectively used for real-time SHM applications.

1 INTRODUCTION

Structural health monitoring (SHM) is somewhat like detective work to catch the *criminal*—the damage to a structure. We capture in-field signals using a sensor or sensor network, canvas signals with appropriate processing tools, and propose a suitable model that enables us to infer damage parameters based on extracted signal features. Such an inferential procedure is *data fusion*. Literately, *data fusion* is a *multilevel* and *multifaceted* process of combining *multiple* features extracted from a *multitude* of spatially distributed *independent* sources, so as to provide capabilities in automatic detection, classification, and identification [1]. An appropriate data fusion can provide a pathway to quantitatively describe a damage event (appearance, location, and severity) and further evaluate the health status of the structure under inspection.

Implied by the definition, extracting appropriate signal features is the prerequisite for correct data fusion. Though application specific, the basic principle in extracting signal features for data fusion is to select those that are most sensitive to the occurrence and alteration of structural health status. There are other relevant articles on this topic in this encyclopedia (*see* **Signal Processing for Damage Detection**; **Nonlinear Features for SHM Applications**; **Novelty Detection**).

2 DATA FUSION ARCHITECTURE

A single sensor performing local data acquisition may easily fail to provide sufficient information concerning structural health status because of uncertainty, imprecision, and/or incompleteness, thereby eroding confidence in the evaluation results. A number of spatially distributed sensors form a sensor network by *communicating* with each other or through a centralized controller, to render the

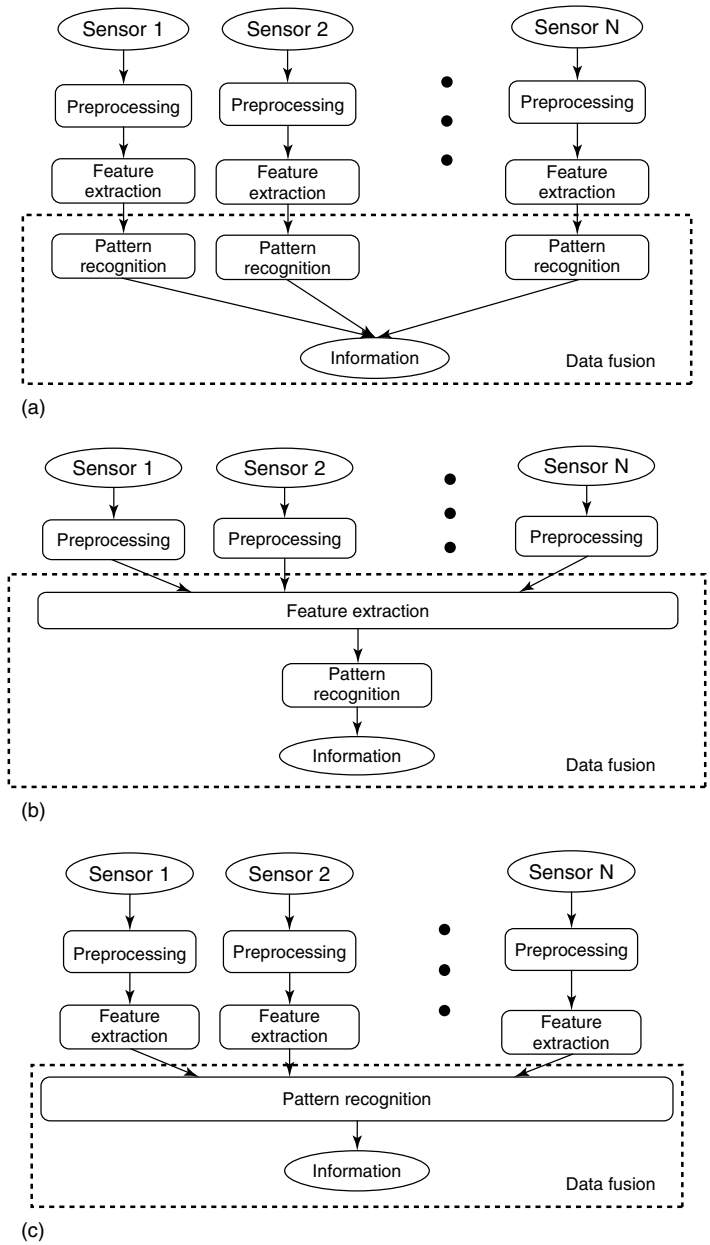

Figure 1. Major data fusion strategies: (a) independent sensor architecture; (b) centralized fusion architecture; and (c) decentralized fusion architecture [3].

possibility of aggregating and fusing all captured information. Basically, data fusion amalgamates redundant or/and complementary data from a multitude of sensors with the objective of making a robust and reliable decision. In general, the currently prevailing data fusion approaches for damage identification use one of three architectures, which are collated in Figure 1. The *independent sensor architecture* is the simplest scheme, where each sensor extracts signal features and carries out recognition independently; the *centralized fusion architecture* is used to fuse the information from data preprocessing and then extract features for future pattern recognition; and the *decentralized fusion architecture* executes feature extraction and selection for each sensor independently, and then the data are fused at the pattern recognition level to deliver a posterior recognition. In practice, various combinations of these three architectures such as the Waterfall and Omnibus strategies [2] are possible for different number of sensors.

3 DATA FUSION ALGORITHMS

Data fusion is implemented through a specific algorithm. A popular taxonomy for major data fusion algorithms currently available is displayed in Figure 2 [1], including mainly *physical models, feature-based inference techniques,* and *cognitive-based models*. In particular, the feature-based inference plays a dominating role and is widely adopted by the SHM community. It performs classification and identification by mapping data (such as statistical knowledge about an object or recognition of an object) into a declaration of identity, using either *parametric techniques* or *information theoretic techniques*. *Parametric techniques* directly map parametric data (such as signal features) into a declaration of identity, independent of a physical model. Some representative approaches under this category are *classical inference*, *Bayesian inference* (*BI*), *Dempster–Shafer inference*, and *generalized evidence processing*. On the other hand, *information theoretic*

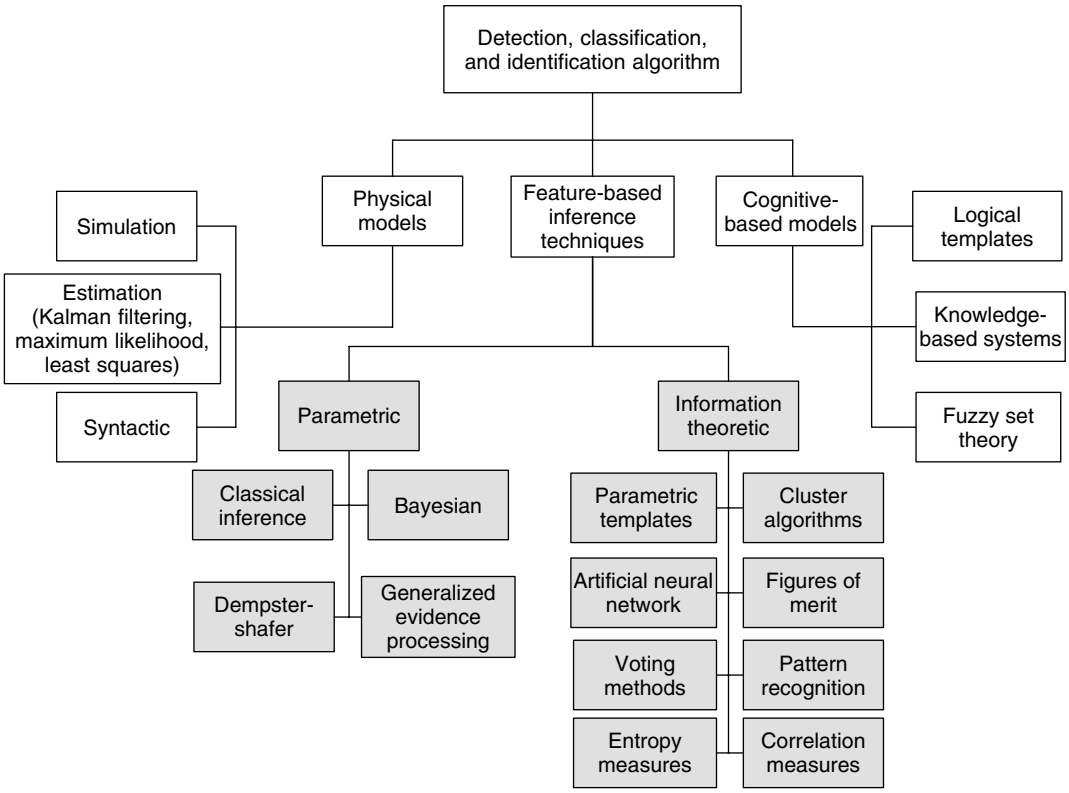

Figure 2. Taxonomy of detection, classification, and identification algorithms for data fusion [1].

Table 1. Comparison of major algorithms of detection, classification, and identification for data fusion

	Algorithm	Attributes
Parametric techniques	Classical inference (CI)	CI, based on a multitude of observations from different sources, gives the probability that an observation can be attributed to the presence of an object or event, given an assumed hypothesis. The major disadvantages of the algorithm include the difficulty in obtaining the probability density function that describes the observable used to classify the object, and complexities that arise when multivariate data are encountered. It has limitation in assessing multiple hypotheses and inability to take direct advantage of a prior likelihood probabilities. Examples can be referred to in [1].
	Bayesian inference (BI)	BI is a probability-based data fusion discipline. It uses prior knowledge to estimate and update the conditional posterior probability of a hypothesis or identify an event when given supporting evidence. As evidence accumulates, the degree of belief in the hypothesis becomes high or low, and it persistently modifies the perceptions when additional information becomes available. The hypothesis is accepted as true with a very high degree of belief or rejected as false when the degree of belief goes very low. Such a fusion algorithm can be used to assess more than two hypotheses. Its major disadvantages include the difficulty in defining prior probability functions, complexities when there are multiple potential hypotheses, mutual exclusivity required of competing hypotheses, and inability to account for general uncertainty. Examples can be referred to in [1, 4].
	Dempster–Shafer method (DSM)	DSM was developed under the *theory of evidence*, to deal with the degree of belief extracted from multiple evidence sources. Such a rule may represent both uncertainties and imprecision. The degree of belief on a hypothesis is described by a mass function. The fusion process takes a union of the mass of all similar beliefs among sensors through conjunction, also considering information conflict. The major disadvantages of the algorithm include the need to define the processes in each sensor that assign mass functions representing the degree of beliefs for a hypothesis. Examples can be referred to in [1, 3, 4].
Information theoretic techniques	Parametric templates (PT)	In this algorithm, multisensor data acquired over a period of time and multisource information are matched with preselected scenarios, models, or knowledge to determine if the observations contain evidence to identify an entity. The algorithm can be applied to event detection, situation assessment, and single object identification. Examples can be referred to in [1, 5].
	Artificial neural network (ANN)	ANN is a mathematical model or computational model based on biological neural networks, which is trained to map input data into selected output categories. The transformation of the input data into output classifications is performed by artificial neurons that attempt to emulate processes that occur in biological nervous systems. By fusing data from a multitude of sources, such an algorithm can be used to model complex relationships between inputs and outputs or to find patterns in data. Examples can be referred to in [3, 6, 7].
	Cluster algorithm (CA)	CA groups data into natural sets or clusters that are interpreted by an analyst to see if they represent a meaningful object category with similar characteristics or natures. All CAs need a similarity measure that described the closeness between any two feature vectors. A CA basically includes steps of sample selection, definition of features, computation of similarities among the data, use of a cluster analysis method to create groups of similar entities, and validation of resulting cluster solution. Examples can be referred to in [1].
	Voting method (VM)	VM fuses information from multiple sensors by weighting each sensor's belief as a vote to reach overall decision. The weight for each vote may be subjective. Examples can be referred to in [1, 4].

Table 1. (*continued*)

Algorithm	Attributes
Entropy measuring (EM)	EM measures the importance of an event by its probability of occurrence. Frequently occurring events or data are of low value while rare events or data are of higher values. By fusing all available information, EM can be used to measure the similarity of an event with regard to other similar events. Examples can be referred to in [1].
Figures of merit (FoM)	FoM is metrics derived from plausible or heuristic arguments that aid in establishing a degree of association between observations and object identity. It is often used to quantitatively characterize the probability of occurrence of an event or similarity with regard to other similar events, by fusing information concerning several variables. For damage identification, FoM is often used to indicate the probability that a damage event occurs, where, when FoM exceeds a critical value, damage is suspected. Examples can be referred to in [1, 8].
Pattern recognition (PR)	Pattern recognition is the identification of an individual object based on either *a priori* knowledge or on statistical information extracted from a series of patterns [7], and the term *pattern* is referred to as an entity to represent an abstract concept or a physical object. It is a field in the area of machine learning. Since diverse damage cases can be regarded as patterns that present various symptoms in a structure, identification of damage falls into the category of pattern recognition. Statistical and syntactic methods are two major implementations of pattern recognition. Statistical modeling is based on the statistical characterizations of patterns, generated by a probabilistic system using statistical density functions; syntactic recognition classifies data based on structural interrelationships of features and is not commonly used for damage identification. Examples can be referred to in [7].
Correlation measures (CMs)	In probability theory and statistics, correlation indicates the strength and direction of a linear relationship between two random variables. In general statistical usage, correlation reflects the independence of two variables. CMs can be used for detection, classification, and identification. Examples can be referred to in [3, 9].

techniques transform or map parametric data into an identity declaration based on the concept that similarity in identity is reflected by similarity in observable parameters, and no attempt is made to directly model the stochastic aspects of the observables [1]. Approaches under this category include *parametric templates*, *artificial neural network*s (*ANN*s) (*see* **Artificial Neural Networks**), *cluster algorithms, voting method, entropy measures, figures of merit, patter recognition*, (*see* **Statistical Pattern Recognition**) and *correlation measure*s (*CM*s). Attributes of the aforementioned major algorithms are compared in Table 1.

In addition, the cognitive-based models attempt to emulate the decision-making processes used by human analysts; representative approaches under this category include *logical templates, knowledge-based systems,* and *fuzzy set theory* [1].

4 EXAMPLES OF DATA FUSION FOR SHM

Various data fusion algorithms have been employed in different damage identification techniques. Four representative examples are presented here.

4.1 Fusion using independent sensor architecture

In this case study, each sensor independently extracts signal features (time-of-flight (ToF)) at the sensor level in the form of *independent sensor architecture* as illustrated in Figure 1(a). ToF is the time lag between two compositions in a signal, which is one of the most explicit and important features in a signal

for SHM. In terms of ToFs between the damage-scattered and incipient energy measured from a multitude of actuator–sensor pairs, the damage can be triangulated by referring to a benchmark. Pitch–catch and pulse–echo are two major implementations of ToF-based approaches, which measure forward and back scattering of incident energy from the damage, respectively [10]. Structural complication and noise often impairs the reliability and accuracy of the triangulation exercise. Data fusion by combining all available information from the sensor network provides an effective means of dealing with this problem.

Figure 3(a) [9] shows an example of a sensor network consisting of 12 lead zirconate titanate (PZT) elements and embedded in a composite laminate containing delamination and offering $12 \times 11 = 132$ sensing paths (*see* **Piezoceramic Materials—Phenomena and Modeling**; **Sensor Network Paradigms**; **Integrated Sensor Durability**

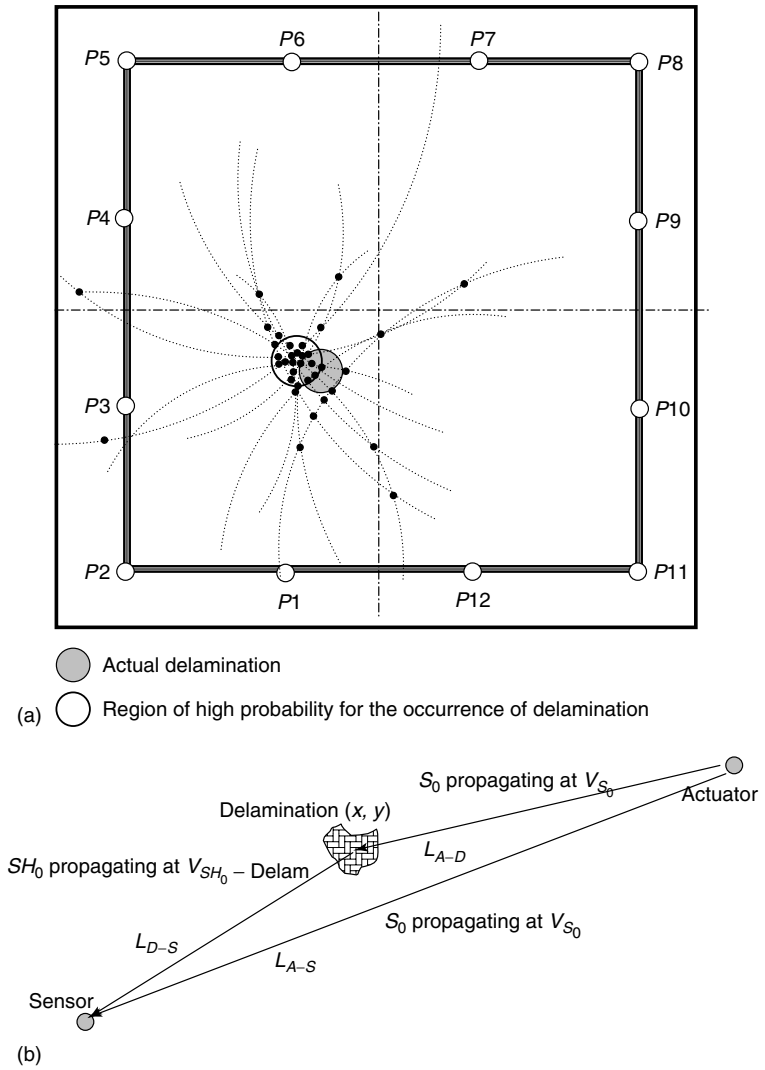

Figure 3. Damage triangulation in terms of ToF: (a) sensor arrangement and identification results and (b) spatial relationship of the actuator, sensor, and damage [9].

and Reliability). In the network, any one pair of PZT elements configures an actuator–sensor path, to generate and collect Lamb wave signals. A coordinate system is introduced for each path, where the actuator is at the origin. In the case that transducer $P1$ acts as the actuator and the damage center is presumed to be (x, y), it has

$$\frac{L_{A-D}}{V_{S_0}}+\frac{L_{D-S}}{V_{SH_{0\text{-Delam}}}}-\frac{L_{A-S}}{V_{S_0}}=T_{1-i},\ (i=2,3,\ldots,12)$$

$$L_{D-S}=\sqrt{(x-x_i)^2+(y-y_i)^2},\ \ L_{A-D}=\sqrt{x^2+y^2},$$

$$L_{A-S}=\sqrt{x_i^2+y_i^2}\ (i=2,3,\ldots,12) \qquad (1)$$

as elucidated in Figure 3(b), where L_{A-D}, L_{D-S}, and L_{A-S} represent the distances between $P1$ and the damage center (x, y), the damage center and the ith sensor, and $P1$ and the ith sensor, respectively. $V_{SH_0-\text{Delam}}$ and V_{S_0} are the velocities of the damage-induced fundamental shear-horizontal Lamb mode (SH_0) and the incipient fundamental symmetric Lamb mode (S_0), respectively. T_{1-i} denotes the ToF extracted from the signal acquired by sensing path $P1$-Pi; and (x_i, y_i) stands for the coordinates of the ith transducer.

Analogously, repeating the above analysis for all sensing paths in the sensor network, using equation (1), where each actuator, in turn, serves as the origin in its coordinate system, a nonlinear equation group is established. For each equation (quadratic) in the group, the solutions configure a circular root trajectory, indicating possible locations of the damage. Any two trajectories lead to an intersection and the region containing more interactions has a higher likelihood of occurrence of damage. Prediction results of the location of delamination in the composite laminate using several major actuator–sensor paths in the sensor network are shown in Figure 3(a).

In the above example, the procedure of two loci of roots leading to an intersection and indicating a possible damage location is considered as a low-level data fusion based on two pairs of actuator–sensor paths. As the number of sensors increases, a higher level data fusion is executed. In such a process, the prior beliefs or perceptions at low levels are fused into a posterior belief. As a consequence, the reliability of damage prediction is enhanced. Furthermore, the spatial distribution of the prior beliefs can become the basis for assessing the damage size and severity.

4.2 Fusion using correlation measures

In this case study, data fusion using CMs picks up the location of structural damage in terms of damage-induced singularity in the signals. The correlation coefficient, λ_{xy}, of two discretized signals in the same length, x_i and y_i $(i = 1, 2, \ldots, n)$, is defined as [9]

$$\lambda_{xy}=\frac{n\sum_{i=1}^{n}x_iy_i-\sum_{i=1}^{n}x_i\sum_{i=1}^{n}y_i}{\sqrt{n\sum_{i=1}^{n}x_i{}^2-\left(\sum_{i=1}^{n}x_i\right)^2}\cdot\sqrt{n\sum_{i=1}^{n}y_i{}^2-\left(\sum_{i=1}^{n}y_i\right)^2}}\leq 1 \qquad (2)$$

When composition in signal x_i is correlated (similar) with any in signal y_i, the correlation coefficient reaches a local extremum; and the more the similarity is, the closer to 1 is the value of the coefficient. In the case that $x_i = y_i$, the correlation is autocorrection. The autocorrelation curves of two signals acquired from a carbon fibre/epoxy (CF/EP) composite panel before and after the occurrence of delamination are compared in Figure 4 [9]. The time lag between the moment that singularity takes place and the moment that incipient energy is generated by the actuator, ΔT, can be exactly determined from the ratio curve, Figure 4(c). An exceptional advantage of the approach is the weakening of boundary effect, since the same boundary reflection remains in all signals, regardless of the existence of damage.

In such a procedure, signals captured by individual sensors are correlated with corresponding signals from the benchmark, considered as the prior beliefs. By taking into account all the prior beliefs from sensors in the network, an overall belief or a posterior belief about the difference between the structure under inspection and benchmark is depicted.

From the above two examples, it can be seen that, upon extraction of interested signal features such as ToF or correlation coefficients, distributed

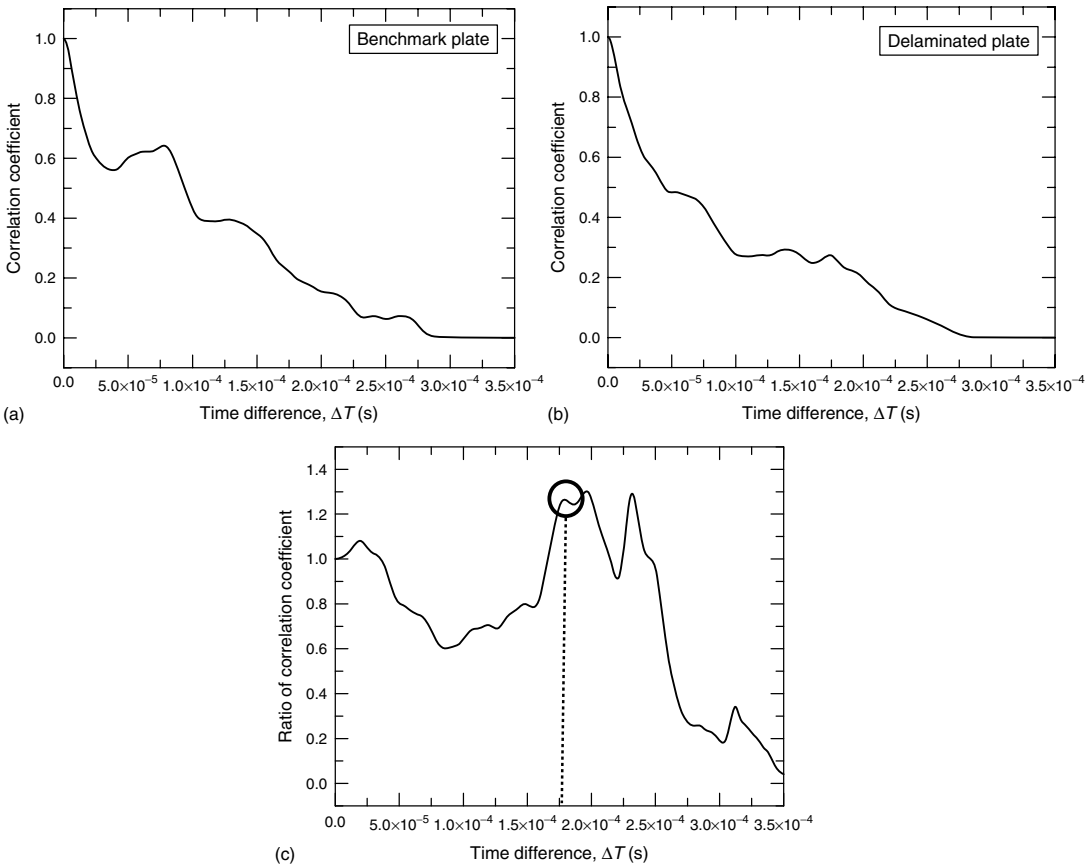

Figure 4. Correlation coefficient curves of Lamb wave signals acquired from (a) benchmark, (b) delaminated laminates, and (c) ratio of the curve in (b) to the curve in (a), where the delamination-induced singularity becomes pronounced [9].

sensors first figure out the individual beliefs that represent their own interpretation and perception on the damage event. A fusion process subsequently combines all these beliefs to form a consensus as to the overall view on the damage event and structural health status. During this procedure, fusion rules can be different for processing individual signals captured by distributed sensors. By this method, the fusion of multilevel decisions significantly reduces the risk caused by the inaccurate and even inappropriate judgment from an individual sensor or decision.

4.3 Fusion using artificial neural network (ANN)

The human nervous system consists of billions of small cellular units (*neurons*) connected by nerve fiber to form a neural net. ANN has been developed as a computational model to mimic such a way to process information based on a loose neural construction. ANN is able to explore the mathematical connection between a series of inputs (*conditions*) and outputs (*outcomes*) for a given system, whereby the consequence under an unknown stimulus can be predicted. A typical ANN is composed of one input layer, single or multiple processing (neural) layers, and one output layer, linked by transfer functions. Each neuron is weighted in parallel by an adjustable variable (*weight*) and offset by a constant (*bias*). One ANN developed for damage identification [6] is displayed in Figure 5(a).

In the ANN, the input, output, and two processing layers host m inputs, n outputs, J and K computing units (*neurons*), respectively; The ith neuron in the

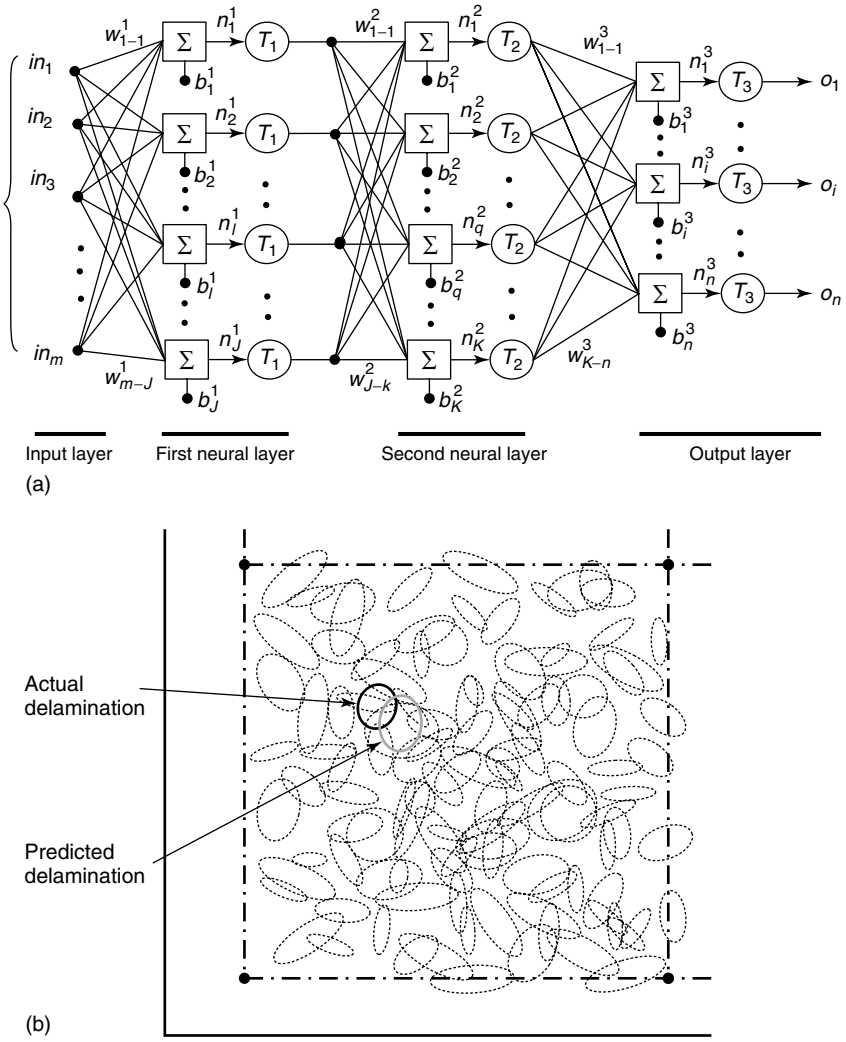

Figure 5. (a) An ANN designed for Lamb wave-based SHM and (b) prediction results (including location, shape, and size) of delamination in a CF/EP composite laminate using the well-trained ANN (dotted ellipses stand for the assumed pattern for ANN training) [6].

neural layer summates all the weighted inputs and biases to give the scalar output, which serves as the input for the next layer, in accordance with

$$o_i = T_3\left(\sum_{q=1}^{K} T_2\left(\left(\sum_{l=1}^{J} T_1\left(\left(\sum_{p=1}^{m} in_p \cdot w^1_{p-l} + b^1_l\right)\right.\right.\right.$$
$$\left.\left.\left.\cdot\, w^2_{l-q}\right) + b^2_q\right) \cdot w^3_{q-i}\right) + b^3_i\Bigg)$$
$$(i = 1, 2, \ldots, n) \qquad (3)$$

where o_i denotes the ith output element ($i = 1, 2, \ldots, n$). n^3_i is the output of the final output layer, and likewise, n^2_q and n^1_l are the outputs of two neural layers. in_p denotes the pth input element ($p = 1, 2, \ldots, m$); w^r_{p-q} represents the weight joining the pth input element (or neuron) in the rth layer with the qth neuron (or output) in the next layer; b^i_q is the bias for the qth element in the ith layer. T_i is the transfer function in the ith layer. A well-trained ANN is adept at inferring general rules or predicting

consequences from a specific example that has never been examined, making it possible to train an ANN using just a limited number of representative damage cases. Technically, an ANN network fuses all inputs to produce outputs as described above through a black box.

In one case study [6], up to 120 cases of delamination (with exclusive locations and geometric identities randomly selected in one-quarter of a quasi-isotropic CF/EP laminate (500 mm × 500 mm × 1.275 mm)) were simulated in terms of finite element method (FEM), respectively. For each damage case, signals were captured using a sensor network of nine piezoelectric elements surface mounted on the laminate, and signal features were extracted from the energy spectra. These extracted signal features were used to train the ANN shown in Figure 5(a). Without losing generality, the delamination was presumed elliptic, defined with six parameters: presence (0 or 1), location (ξ, ζ), semimajor/minor axes (α, β), and orientation of θ. The well-trained ANN was validated by quantitatively evaluating actual delamination in laminates of the same properties and dimension. Excellent prediction on all six damage parameters has been achieved (Figure 5b). The results predicted by the ANN do not superpose any damage pattern used for ANN training, implying that the results are ratiocinated rather than obtained by finding the fittest patterns from the training database.

In data fusion taking advantage of ANN, signals are acquired by different sensing paths for all the presumed structural health conditions and properly stacked to form a knowledge database. The training procedure of ANN in terms of the knowledge database is a kind of data fusion to achieve a belief on those concerned damage parameters (ANN outputs).

4.4 Fusion using Bayesian inference (BI)

BI is a probability-based data fusion discipline. It uses prior knowledge to estimate and update the conditional posterior probability of a hypothesis or to identify an event when given supporting evidence [1]. As evidence accumulates, the degree of belief in the hypothesis becomes high or low, and it persistently modifies the perceptions when additional information becomes available. The hypothesis is accepted as true with a very high degree of belief or rejected as false when the degree of belief goes very low, similar to the procedure of making judgments of human beings. The BI theorem is described by [4]

$$P(H_i|E_v)=\frac{P(E_v|H_i)P(H_i)}{P(E_v)}=\frac{P(E_v|H_i)P(H_i)}{\sum_i[P(E_v|H_i)P(H_i)]} \tag{4}$$

where $P(H_i|E_v)$ is the posterior probability that hypothesis H_i is true when given evidence E_v. $P(E_v|H_i)$ is the probability of evidence E_v given that H_i is true, defined as the likelihood function. $P(H_i)$ is the prior probability given that hypothesis H_i is true and satisfies $\sum_i P(H_i) = 1$. $\sum_i P(E_v|H_i)P(H_i)$ is the sum of the probability of evidence E_v when all mutually exclusive hypotheses H_i are true. The factor $P(E_v|H_i)/P(E_v)$ represents the impact of the new evidence on the degree of belief in the hypothesis; and if the hypothesis is true, this factor becomes large.

A two-level data fusion scheme using the BI algorithm was proposed for Lamb wave-based SHM [4]. In the approach, level-one decision fusion was based on signal features extracted from individual Lamb wave signals rendered by a sensor network to create perceptions of damage status and a knowledge database. H_i in equation (4) was the posterior probability for damage occurrence, and $P(E_v|H_i)$ estimated the confidence of individual sensor on the perception of damage existence. Subsequently, the perceptions from each sensor were integrated to represent decision fusion at the second level, to determine the detailed description for damage. The prediction results for through-hole damage in a composite laminate are displayed in Figure 6.

From the four examples aforementioned, it can be seen that whichever algorithms are used during data fusing, different criteria or methodologies can be adopted for processing individual signals captured by distributed sensors, so as to form an individual beliefs that represents their own interpretation and perception of damage status. All these beliefs or knowledge are further fused through one of the fusion strategies described in Figure 1 to deliver a comprehensive consensus on the entire

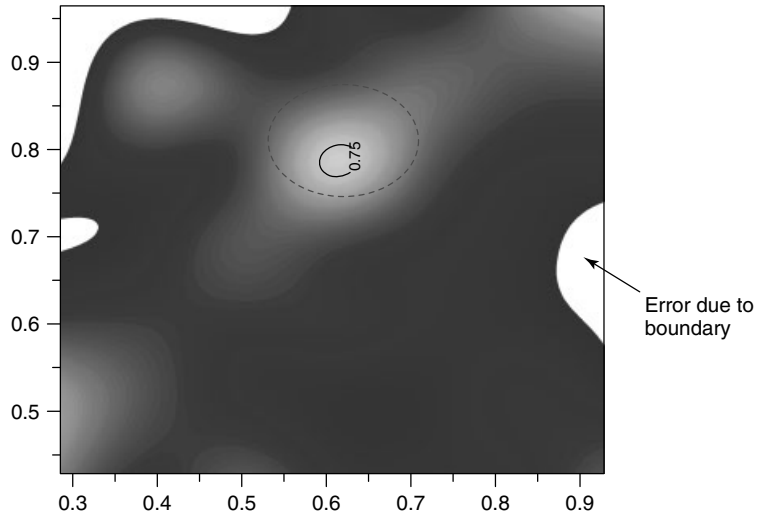

Figure 6. Damage prediction using BI (probability for the occurrence of damage is represented by grayscale—the lighter, the higher the possibility) [4].

damage event and health status of the structure under inspection.

5 CONCLUDING REMARKS

Data fusion is a *multilevel* and *multifaceted* process of combining *multiple* features extracted from a *multitude* of spatially distributed *independent* signal sources, so as to describe a damage event or health status of a structure under inspection. Triangulation of a damage site in simple structures can be fulfilled cost-effectively by using simple fusion schemes in terms of extracted signal features such as ToF or correlation. However, an SHM practice pertaining to quantitative evaluation of damage (including size assessment) is generally a highly complicated inverse procedure, which can only be implemented through appropriate inference-based data fusion. To this end, ANN and BI are two efficient solutions.

1 INTRODUCTION

Finding the optimum solution for a given problem is an important area of research and application in many engineering fields. A variety of different optimization problems can be identified in structural health monitoring (SHM); a number of different possible mathematical tools can be offered to find a solution. This article summarizes some of the most commonly used optimization techniques. The focus is on combinatorial methods, which are computationally efficient and widely used in many engineering areas. These methods are illustrated by examples related to the problem of determining the optimal location of sensors in damage detection.

In mathematics, optimization is related to finding the maximum and/or minimum value of a function $f(x_1, x_2, \ldots, x_n)$ of n (i.e., $x_1, x_2, \ldots, x_n$) variables. This function, often called *the objective function*, describes the optimization problem defined in engineering. Often *a priori* limitations (or constraints) are imposed on the solution leading to constrained optimization problems. For example, if optimal locations for transducers are sought, certain locations are not possible owing to design constraints. Within this context, optimization is the task of finding values of *variables* for which the *objective function* reaches the extreme value satisfying the *constraints*. This definition points out three important elements of any optimization problem, i.e., *variables, objective function*, and *constraints*. Since the objective function is not always required (for example, in feasibility analysis), variables form the only essential element for any optimization problem.

There exist a variety of different optimization methods used in practice. The method selected for a

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

given optimization method often depends upon four major criteria: (i) Is the problem one- or multidimensional? (ii) Are functions describing the problem efficiently differentiable? (iii) How noisy is the function describing the problem? (iv) Is the proposed optimization algorithm computationally efficient and cheap? Early optimization techniques, often known as *ad hoc* methods, are based on rough and ready ideas that do not have any theoretical background.

Altogether, optimization algorithms can be classified into various groups. These are (i) local and global, (ii) one-dimensional and multidimensional, (iii) constrained and unconstrained, (iv) deterministic and nondeterministic, and (v) linear and nonlinear. The entire classification is not trivial as there is substantial overlap between the various groups of methods. Local methods (e.g., gradient descent, Newton's method) are used to find local optimal values in a finite neighborhood of the analyzed space, whereas global methods (e.g., simplex method, simulated annealing (SA), genetic algorithms (GAs)) search for truly global extreme values. Optimization problems with only one variable can be solved using one-dimensional methods such as simple minimization techniques (e.g., golden section search, parabolic interpolation). Finding a number of parameters that optimize the problem is a much harder task and requires multidimensional methods (e.g., downhill simplex method, GAs). Deterministic optimization (gradient descent, simplex method) methods deal with problems formulated with all known parameters. In contrast, nondeterministic methods (e.g., Tabu search, SA, GAs) are applied to problems with uncertainties. Classical deterministic optimization techniques can be classified into unconstrained (e.g., gradient descent, nonlinear conjugate gradient methods, Newton's methods) and constrained optimization (e.g., method of Lagrange multipliers, GAs) where the latter involves limitations imposed on solutions. Classical constrained optimization has a great degree of complexity. When the objective function and constraints are linear, the methods involved are often referred to as *linear optimization* (e.g., simplex algorithm) or linear programming. In contrast, nonlinear optimization (e.g., branch and bound technique) involves a nonlinear objective function or constraints. Nonlinear programming is always associated with substantial computation.

A good theoretical background of various optimization techniques can be found in [1–3]. In the text that follows, a brief introduction to the most widely used techniques together with application examples is given.

2 CLASSICAL OPTIMIZATION TECHNIQUES

2.1 Gradient descent

The gradient descent optimization technique finds extreme values by following the gradient of the objective function. If the optimization space is represented as a surface, finding the maximum value is associated with "going up" with the gradient. Therefore, the method is often called *hill climbing* optimization.

The mathematical background of the method is very simple. If the objective function $f(x)$ is defined and differentiable, its gradient ∇f always indicates the direction of the steepest ascent. Thus, when a guess of x_0 for the local minimum is assumed initially, an improved estimation of the minimum value is achieved if the negative gradient is followed iteratively as

$$x_{n+1} = x_n - \gamma_n \nabla f \quad \text{for} \quad n = 0, 1, 2, \ldots \quad (1)$$

where the parameter γ_n is a value of step size and ∇ is the standard gradient operator. The step size value can change at every iteration. It follows that the sequence

$$f(x_0) \geq f(x_1) \geq f(x_2) \geq \cdots \quad (2)$$

converges and finally the minimum value is obtained. The method is illustrated graphically in Figure 1.

The gradient method is very simple since it requires only a few steps to find a minimum (or minimum) value. However, the major drawback is that the method can get trapped in local extremes and finding global values depends on the starting point. Also, often large jumps are observed when the gradient descent is performed. Smaller step sizes can reduce this effect.

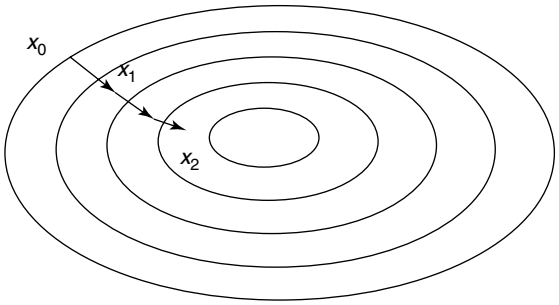

Figure 1. Graphical illustration of gradient descent optimization method.

2.2 Newton's method

Newton's optimization method originates from the iteration method for the approximate determination of zeros of a differentiable function. It is well known that the Taylor expansion of $f(x)$ given by

$$f(x + \Delta x) = f(x) + f'(x)\Delta x + \frac{1}{2} f''(x)\Delta x^2 + \cdots \tag{3}$$

leads to its extreme when $f''(x)$ is positive and Δx solves the following equation:

$$f'(x) + f''(x)\Delta x = 0 \tag{4}$$

Thus, for the multidimensional case and the initial guess x_0 for the minimum value, the optimization iterative scheme can be obtained as

$$x_{n+1} = x_n - \gamma_n [Hf(x_n)]^{-1} \nabla f(x_n) \quad \text{for} \quad n = 0, 1, 2, \ldots \tag{5}$$

where $Hf(x_n)$ is the Hessian matrix of the function $f(x_n)$ representing all its second-order partial derivatives. The convergence of Newton's method to the optimal value is much faster than for gradient descent. However, it is important to note that for multidimensional problems finding the inverse of the Hessian matrix is numerically expensive and can lead to instabilities.

2.3 Simplex method

The simplex algorithm is one of the most widely used linear optimization techniques. The algorithm is used to solve the linear programming problem, which aims to maximize a linear, real-valued objective function give in the form

$$f(x_1, x_2, \ldots, x_n) = a_1 x_1 + a_2 x_2 + \cdots + a_n x_n + a_0 \tag{6}$$

where $\boldsymbol{x}$ is the vector of variables and $\boldsymbol{a}$ is the vector of coefficients. The maximization is subjected to the constraint represented by the inequality

$$\boldsymbol{Ax} \leq \boldsymbol{b} \tag{7}$$

where $\boldsymbol{A}$ and $\boldsymbol{b}$ are the matrix and vector of coefficients, respectively.

The optimization algorithm used in the above problem utilizes the geometrical concept of a simplex. In geometry, a simplex is a higher-dimensional generalization of a triangle. More precisely, an n-simplex is a geometric figure called a *polytope* built from a set of $n + 1$ affinely independent points, i.e., a 1-simplex is a line segment, a 2-simplex is a triangle and a 3-simplex is a tetrahedron (shown in Figure 2) in Euclidean space. The simplex algorithm defines the objective function given by equation (6) on a polytope. The aim is then to find a geometrical point where the objective function has a maximum value. The process of searching through the polytope vertices leads to the maximum value. The simplex algorithm requires that the linear programming problem is converted into the so-called augmented form by replacing the inequalities with equalities in the constraints.

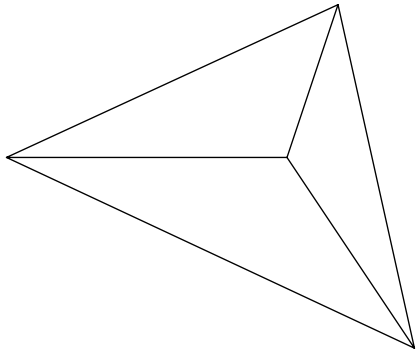

Figure 2. Example of simplex—tetrahedron.

3 SIMULATED ANNEALING

3.1 Basic theory

The SA algorithm is arguably the first and simplest of the heuristics inspired by physical and biological mechanisms and so it is described here first. It is based on an analogy with the physical process of annealing. Normal polycrystalline solids have a microscopic domain structure that is quite disordered; under equilibrium conditions, the solid is only at a *local* minimum of energy. However, if the solid is heated to a high temperature and then cooled slowly, it will arrive at a highly ordered state—the *global* minimum of energy. Consider a random search method for optimization—this attempts moves in random directions in the search space—accepting a trial move only if the objective function decreases. One can think of the method as moving downward gradually on the surface specified by the objective. Because the method accepts all downward moves, it will converge to a local minimum if the starting point for the algorithm is within the basin of attraction of that minimum. To escape from local minima, one can modify the algorithm by adding a certain amount of *thermal motion*, which allows the objective to sometimes increase. This is the basis of SA; the allowed upward movements are large in the early stages of the algorithm when local minima are to be avoided, corresponding to a high-temperature regime. In the later stages, the thermal motion is small to allow convergence, corresponding to low temperature. To decide whether an upward movement is allowed, Boltzman statistics are used. A probability

$$p = \exp\left(\frac{-\Delta E}{T}\right) \tag{8}$$

is computed, and if less than a uniform random deviate generated in parallel on the interval [0,1], the move is accepted. Here, ΔE is the change in the objective function (positive), and T is an external control parameter, the *temperature*, which decreases as the algorithm proceeds. Downward movements are always accepted. The origins of the method are in the Metropolis algorithm [4], although the serious development of the method is associated with Kirkpatrick *et al.* [5].

3.2 A case study: sensor placement

The algorithm is very simply described. It is also very straightforward to implement in computer code. The use of the algorithm is illustrated here via a case study—the optimal placement of sensors on a structure for damage localization. The structure considered here was a finite element (FE) model of a cantilever plate; the FE package used here was LUSAS. The plate was simulated to be of steel and having dimensions of 300 mm $\times$ 200 mm $\times$ 2.5 mm. The fixed edge of the plate was taken on one of the 200-mm edges. The FE mesh used 20×20 elements to produce results with appropriate accuracy. A coarser 4×4 cell mesh was used to place the sensors. Each node of the regular coarse mesh was considered as a candidate sensor location, except for those nodes on the fixed edge. This gave 20 candidate sensor locations indexed between 1 and 20 as shown in any of the figures from this section. Each of the cells of the 4×4 coarse mesh contained a 5×5 array of FE elements; damage was simulated in each of the coarse cells by "deleting" the 9 FE elements in the center of the cell. "Deletion", in this case, corresponded to setting the Young's modulus of the element in question to a very small value. The data generated from the FE model was the mode-shape data for the lowest natural frequencies for each possible damage condition of the plate, of which there were 16. The mode-shape data was then twice differentiated in both the x and y directions to obtain mode-shape curvature data (as described in **Modal–Vibration-based Damage Identification**). A centered-difference formula was used in each direction and the magnitude of the resulting vector was used as a scalar curvature measure. Only the curvature values on the coarse mesh (i.e., corresponding to sensor locations) were saved for damage identification purposes. The curvature data were used as training data to establish a neural network, which could locate the damage to within a cell of the coarse mesh. (Neural networks are described in some detail in **Artificial Neural Networks**.) To obtain sufficient data for the neural networks, multiple copies of each damage *pattern* (curvature vector) were made and each was corrupted with a low rms Gaussian noise vector to simulate the acquisition of real data with measurement noise. More details of this case study can be found in [6].

The neural network used here as a damage locator was a standard multilayer perceptron (MLP) trained using back propagation learning (*see* **Artificial Neural Networks**). In brief, the network was used as a learning machine that could be trained to indicate the position of damage within the structure when presented with a vector of modal curvature values. The number of input nodes to the network was fixed equal to the number of sensors chosen for the optimization and there were 16 outputs—each corresponding to a given damage location. The neural network training used a scheme—the 1 of M scheme—which basically generated the posterior probabilities of the 16 possible damage locations when presented with the curvatures. When a curvature pattern is presented, one chooses the highest output as the indicator of the damage location. The optimization problem illustrated here is simply to choose the best n sensor positions to provide data for the neural network diagnostic. The success of the neural network is judged by considering a set of curvature vectors corresponding to the different damage locations and simply counting the number of correct and incorrect diagnoses. These numbers are then converted into a single probability of misclassification. Optimization over the set of sensor distributions corresponds to minimizing this probability of error.

The implementation of the algorithm SA used here follows that in [3]. The objective function is the probability of misclassification described above. The initial temperature is chosen of the same order of magnitude as the probability of error for a randomly chosen sensor distribution. Each sensor distribution is encoded as a 20-bit binary vector where a 1 corresponds to the presence of a sensor and a 0 corresponds to the absence of a sensor. The bits of the distribution vector correspond to the position indices for the sensors indicated in the figures of this section. SA moves are made by operating on the bit vectors described previously. If a 10-sensor distribution is desired, an initial distribution is chosen randomly with 10 bits set to 1. Trial moves involve changing the position of a 1 randomly. Moves are accepted if they lead to a decrease of the objective function or—in the case of increase of the objective—the probability of acceptance leads to acceptance as described above. Fifty trial moves are taken at each temperature unless ten moves are accepted, and in each case, the temperature is decreased by a multiplicative factor of 0.9. Fifty temperature steps are taken.

The first run of the algorithm considered here was directed to find a 10-sensor distribution. The algorithm converged after 1350 iterations to a solution with a probability of error of 0.0014. In fact, during the run, the algorithm found three solutions with this error and they are given in Table 1.

The second of these distributions is depicted in Figure 3.

For the second illustration, the best three-sensor distribution was sought. In this case, it was actually feasible to find the optimum by exhaustive search as there were only 1140 possible candidate distributions.

Table 1. Best 10-sensor distributions from simulated annealing

10100001001101111001
10000100101101101011
11100000001111101010

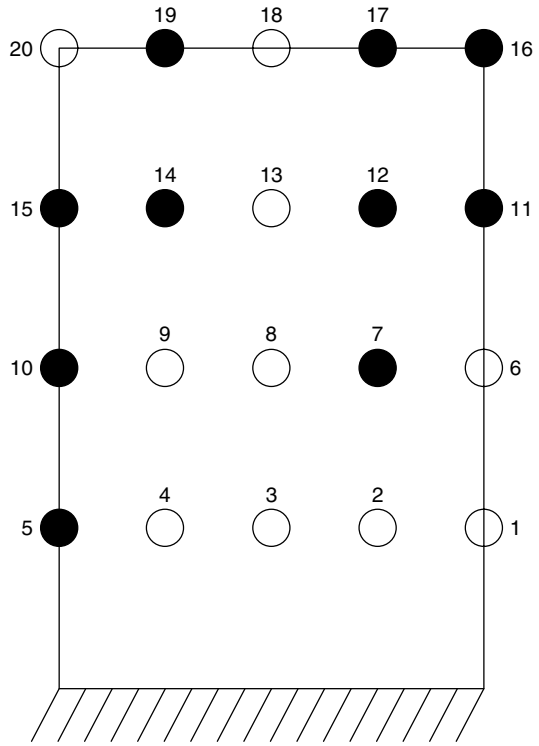

Figure 3. Best 10-sensor pattern for curvature diagnostic from simulated annealing.

Figure 4 shows the evolution of the objective function as the SA algorithm proceeded.

It can be seen that the algorithm found the minimum after approximately 700 iterations (although a fluctuation caused a temporary rise afterward). This is a considerable saving on exhaustive search. Figure 5(a) shows the sensor distribution found by the algorithm. Figure 5(b) shows the optimum distribution found by exhaustive search. It is found that the two distributions are mirror images of each other.

One issue that arises here, as it will with any optimization procedure that uses a neural network to determine the objective function, is that the objective is a random variable conditioned on the initial weights of the network. This means that the fitness of a given sensor distribution will actually be characterized by a distribution function. Now, in the case of sensor networks with a small number of sensors, one might expect that the distribution functions for near-optimal distributions will not overlap. This means that the probability of finding the true optimum is increased. In the three-sensor example shown here, the best SA distribution and that from exhaustive search actually have different objective function values so that it is the mirror image in the exhaustive search that actually corresponds to the SA optimum. It may be desirable to take into account the random nature of the fitness values. One way of doing this would be to use a different (randomly chosen) initial condition for the network every time a given sensor pattern occurs in the process. This was not done here.

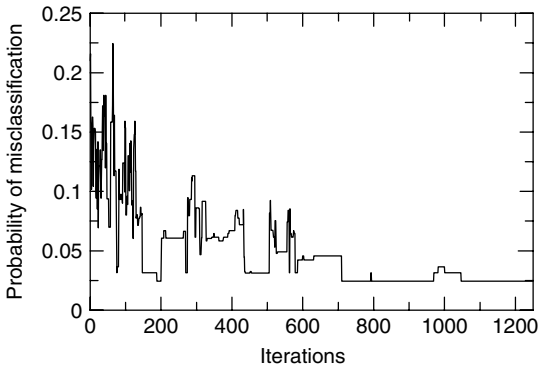

Figure 4. Progress of the SA algorithm toward the optimum three-sensor distribution.

The SA algorithm was initially formulated with combinatorial optimization in mind and that is how it has been used here. There are variants of the algorithm that can deal with real-valued optimization variables, and one example is discussed in [7]. A possible weakness of the algorithm is that it operates on a single point at each iteration and is thus more susceptible to getting trapped in a local minimum. Descriptions of population-based variants

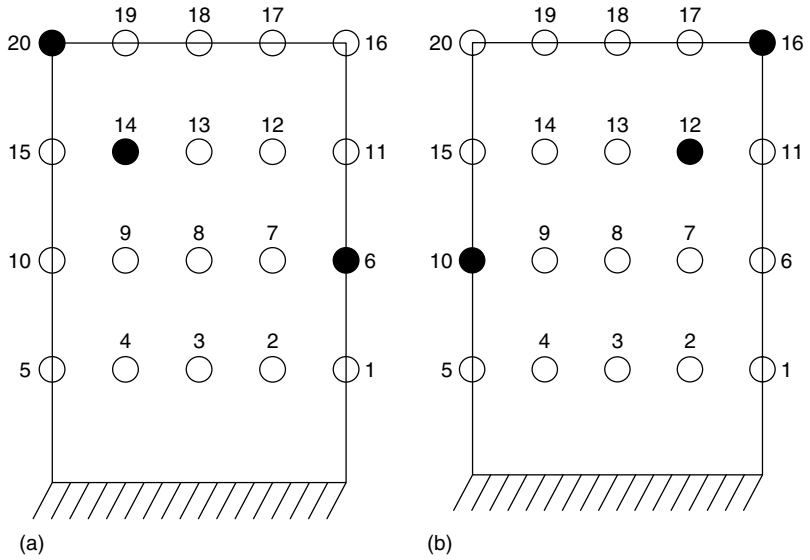

Figure 5. Best three-sensor patterns for curvature diagnostic: (a) SA and (b) exhaustive search.

of the algorithm that avoid this problem to an extent can be found in [8, 9].

4 GENETIC ALGORITHMS

4.1 Basic theory

GAs are a population-based algorithm motivated by biology. They were first introduced in their simplest form by Holland [10]; however, they have been the subject of considerable research since, and now form only one example of a broad class of *evolutionary algorithms* [11]. For the sake of brevity, only a short discussion of the simple GA is given here; for more detail, the reader is referred to the standard introduction to the subject [12].

GAs are optimization algorithms that evolve solutions in a manner analogous to the Darwinian principle of natural selection. They differ from the classical gradient-based optimization techniques in that they work on encoded forms of the possible solutions like the SA example of Section 3. Each possible solution i.e., each set of possible parameters in solution space is encoded as an *individual*. The most usual form for this individual is a binary string e.g., 00011010110. The first hurdle in setting up a problem for solution by GA methods is working out how best to encode the possible solutions as individuals. In the case of the sensor placement problem described earlier, a natural coding for the problem is provided by a bit-vector where the occurrences of a 1 signal the existence of a sensor, i.e., the individual 00100010000000001000 represents a solution in which transducers are placed at positions 3, 7, and 17.

Having decided on a representation, the next step is to generate, at random, an initial population of possible solutions. The number of individuals in a population depends on several factors, including the size of each individual, which itself depends on the dimension of the solution space. For example, if the problem of interest requires the optimization of three control parameters, the bit-vector will be in three segments; if each parameter is required to an accuracy of 1 part in 1000, 10-bits per parameter will be needed and the overall individual will need 30 bits. Larger initial populations will be required if the individuals are larger to have an appropriate initial level of diversity in the population.

Having generated a population of random individuals, it is necessary to decide which of them are fittest in the sense of producing the best solutions to the problem. This is the *selection* process. To do this, a fitness function is required, which operates on the encoded individuals and returns a single number that provides a measure of the suitability of the solution. In the SA example of Section 3, the objective function was the probability of misclassification; this was an object that required minimization; to get a fitness function, such an objective should be inverted to give a maximization problem. The fitter individuals are used for mating to create the next generation of individuals, which hopefully provides a better solution to the problem. Individuals are selected for mating based on their fitnesses. One way of implementing this is so-called roulette-wheel selection; the probability of a particular individual being chosen is equal to its fitness divided by the sum of the fitnesses of all the individuals in the population.

Once sufficient individuals have been selected for mating, they are paired up at random and their genes combined to produce two new individuals. The most common method of combination used is called *crossover*. Here, a position along the individuals is chosen at random and the substrings from each individual after the chosen point are switched. This is illustrated in Figure 6(a). This mechanism is termed *one-point crossover*. In a *two-point crossover*, a second position is chosen and the individual substrings switched again.

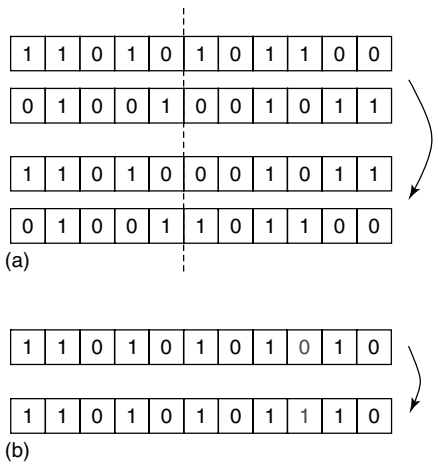

Figure 6. The basic genetic operations: (a) crossover and (b) mutation.

If an individual in a particular generation is extremely fit, i.e., is very close to the required solution, it is almost certain to be selected several times for mating. Each of these matings, however, involves combining the individual with a less fit individual, so the maximum fitness of the population may be lower in the next generation. To avoid this, a number of the most-fit individuals can be carried through unchanged to the next generation. These very fit individuals are called the *elite*.

To prevent a population from stagnating, it can be useful to introduce perturbations into the population. New entirely random individuals may be added at each generation. Such individuals are referred to as *new blood*. Also, by analogy with the biological process of the same name, individuals may be *mutated* by randomly switching one of their binary digits with a small probability. This latter process is one of the more important ones for the simple GA and is illustrated in Figure 6(b).

With genetic methods, it is not always possible to say what the fitness of a perfect individual will be. Thus the iterative process is usually continued until the population is dominated by a few relatively fit individuals. One or more of these individuals will generally be acceptable as solutions.

4.2 A case study: impact location

As in the case of SA, the simple GA is illustrated on a sensor placement problem. In this case, the best set of sensors is chosen to train an impact-locating neural network. The details of this case study can be found in [13].

The structure under examination consisted of a rectangular 530 mm × 300 mm composite plate and four aluminum channels. The top flanges of the channels were attached to the plate by a line of rivets, and the bottom flanges were fixed rigidly with screws to a pneumatic measuring table. This box structure was intended to simulate the skin panel of an aircraft. The composite plate was instrumented with 17 piezoceramics (*PZT Sonox P5*, 15 mm × 15 mm) fixed on the lower surface of the plate, the impacts being performed on the upper surface. The piezoceramics were used as strain sensors. Figure 7 shows the total distribution of sensors used.

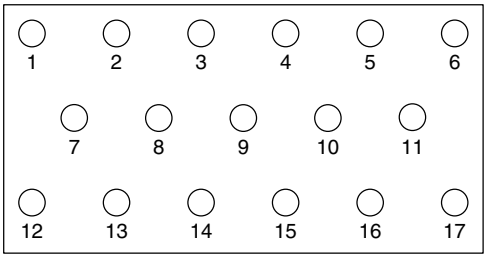

Figure 7. Schematic for sensor positions on a composite plate.

The impacts were applied using a *PCB* instrumented hammer. The levels of force applied were kept below 0.1 N in order not to damage the plate. Two sets of measurements were made. The first comprised 80 impacts at random positions on the plate and was intended for use as network training data. The second set of measurements contained 95 impacts placed on a regular grid and these were divided between the network validation and test sets: 48 in the former, and 47 in the latter.

The strain data were recorded using a DIFA SCADAS II 24 channel measuring system running the LMS 3.4.04 data-acquisition software. For each impact, 8192 samples were recorded at a frequency of 25 kHz.

To design a neural network that could predict the impact location, it was important to extract appropriate features that could be used as information-rich network inputs. A number of different candidates have been considered in the past [13]: (i) time after impact of maximum response, (ii) magnitude of maximum response, (iii) peak-to-trough range of the response, and (iv) real and imaginary parts of the response *spectrum*, integrated over frequency. The features were investigated alone and in combination, and it was found that the best results were obtained using features (i) and (ii) in tandem. This meant that each sensor contributed two features and that, if all sensors were used, the dimension of the pattern vectors for training was 34. This was the maximum, as the object of the exercise was to establish optimal subsets.

As for the SA case study, the neural network paradigm used for this study was the standard MLP trained with backpropagation. A principled approach to training demands the availability of three data sets. The first—the *training* set—is used to determine

the network weights. The second—the *validation* set—is used to investigate the optimum structure for the network and the final *testing* set is used to assess the effectiveness of the optimized network. The number of neurons in the input and output layers of the network was fixed by the number of measurement features and diagnostic outputs, respectively. In this case, the network needed up to 34 inputs; for impact location, the network was required to signal the location of damage and two outputs were required, namely, the x and y coordinates of the impact site. In principle, only one hidden layer is needed to approximate any function; therefore the strategy adopted here assumed a single hidden layer and optimized the performance by using all 34 inputs and varying the number of hidden neurons between 1 and 50. The network was also optimized over initial conditions and regularization was used (*see* **Artificial Neural Networks**). The MLP used hyperbolic tangent activation functions and a bias neuron was connected to all neurons. In all cases, the number of data presentations during training was equal to 100 000.

For the location problem using all sensor data, the optimization procedure produced a minimum error over the validation set when there were eight neurons in the hidden layer. When the corresponding network was evaluated on the testing set, the mean (modulus) of the x error was 23.1 mm and the mean y error was 25.7. This gave an area corresponding to 1.5% of the plate area. (The area error was used as the statistic for the evaluation of the networks, and the best value on the validation set was 1.1%.)

Despite the fact that the description above gave the simple GA as applied to a binary bit-vector representation for the data, it was shown in [6] that the binary representation is suboptimal for the sensor optimization problem. As a result, a modified GA is used, where the gene is a vector of integers, each specifying the position of a sensor; i.e., the gene (2,14,17) represents a three-sensor distribution, with sensors at locations 2, 14, and 17 on the candidate mesh. The operations of reproduction, crossover, and mutation for such a GA are straightforward modifications of those for a binary GA.

The initial population for the GA was generated randomly as standard. The individuals—in this case, sensor distributions—were propagated according to their fitness. For a given sensor distribution, a neural network was trained using the designated features and the area error on the validation set was obtained; this was inverted to give the fitness. Distributions with coincident sensors were penalized. The parameters used for the GA runs were as follows: population size of 50, number of generations 100, probability of crossover 0.8, and probability of mutation 0.1. A single member elite was used and two new blood were added at each iteration.

For the first example, the analysis was restricted to three-sensor distributions. The reason is that the number of candidate three-sensor distributions is 684, and it is feasible to compare the results with those from exhaustive search. Also three sensors are the minimum number that would be needed to locate the impact event from time-of-flight data using triangulation.

Recall that the error of the neural network depends on the starting conditions. To investigate this, the exhaustive search was carried out six times. In each case, different random numbers were used for initializing the networks and also for calculating the various probabilities required by the GA. The best distribution from each run is given in Table 2 together with the associated percentage error area.

The best three-sensor distribution is shown in Figure 8. It agrees strongly with engineering intuition: the sensors are placed in such a way as to effectively triangulate over a large area of the plate. Also, the degradation in performance over the full 17-sensor distribution is hardly significant: the area error is 2.0% instead of 1.1%.

When the GA was applied for the six network start-up conditions, it found the optimal solution in all cases. In most of the cases, it found them faster than the exhaustive search. Figure 9 shows the evolution of the fitness functions over the six runs. The solid lines are the maximum fitnesses of each generation and the dotted lines are the average fitnesses.

Table 2. Best three-sensor distributions from six exhaustive searches

Search number	Distribution	Area
1	3 : 12 : 17	2.16
2	8 : 11 : 12	2.15
3	1 : 3 : 17	2.15
4	3 : 12 : 14	2.19
5	3 : 7 : 11	2.13
6	3 : 10 : 12	1.99

5 DIFFERENTIAL EVOLUTION

5.1 Basic theory

The simple GA described in Section 4.1 used a binary form to encode the optimization parameters. Although this is quite general, it was almost immediately observed that a better encoding of the parameters for a particular problem was actually in terms of integers. This observation leads to the idea of evolutionary algorithms in general [11], where the objective is simply to generate the best approach to solving a given engineering problem. In the drive to find the best algorithm, it is accepted that one might move a distance away from the biological motivations of the algorithms. In the case of an optimization, which requires the search for a number of real parameters, a real-coded algorithm is clearly desirable. Although there are instances of real-coded GAs, the subject of this section is slightly different. The differential evolution (DE) algorithm was developed by Storn and Price [14] and has proved to be an extremely effective heuristic for optimization.

As in the case of the GA, the DE algorithm works with a population of candidate solutions or individuals. Figure 10 shows diagrammatically the procedure for evolving between subsequent populations. The process is repeated for each vector within the current population being the *target vector*. Each of these vectors has an associated cost value (or fitness value in maximization problems) obtained from the cost (or fitness) function. This target vector is pitted against a *trial vector* in a selection process with the vector with the lowest cost (or highest fitness) advancing to the next generation. The process for constructing the trial vector involves mutation and crossover, processes known from the GA to give fast, robust algorithms when used in conjunction. Mutation maintains diversity in the population while crossover builds new parameter combinations from the existing vector parameters.

The mutation procedure used here employs vector differentials. Two vectors (individuals) ($\mathbf{A}$ and $\mathbf{B}$) are randomly chosen from the current population to form a vector differential $\mathbf{A} - \mathbf{B}$. The *mutated vector* is then obtained by adding this differential, multiplied by a scaling factor, F, to a further randomly chosen vector $\mathbf{C}$ to give the overall expression for the mutated vector as $\mathbf{C} + F \cdot (\mathbf{A} - \mathbf{B})$. The scaling factor, F, will have an optimal value for most functions between 0.4 and 1.0.

The trial vector is the child of two vectors, the target vector and the mutated vector, and is obtained via the crossover process. In this work, the process of uniform crossover was used. Uniform crossover decides which of the two parent vectors contributes to each chromosome of the trial vector by a series of $D - 1$ binomial experiments. Each experiment, whose outcome is either success or failure, is mediated by a crossover constant, C, where $0 \leq C \leq 1$. If the random number is greater than C, the trial vector

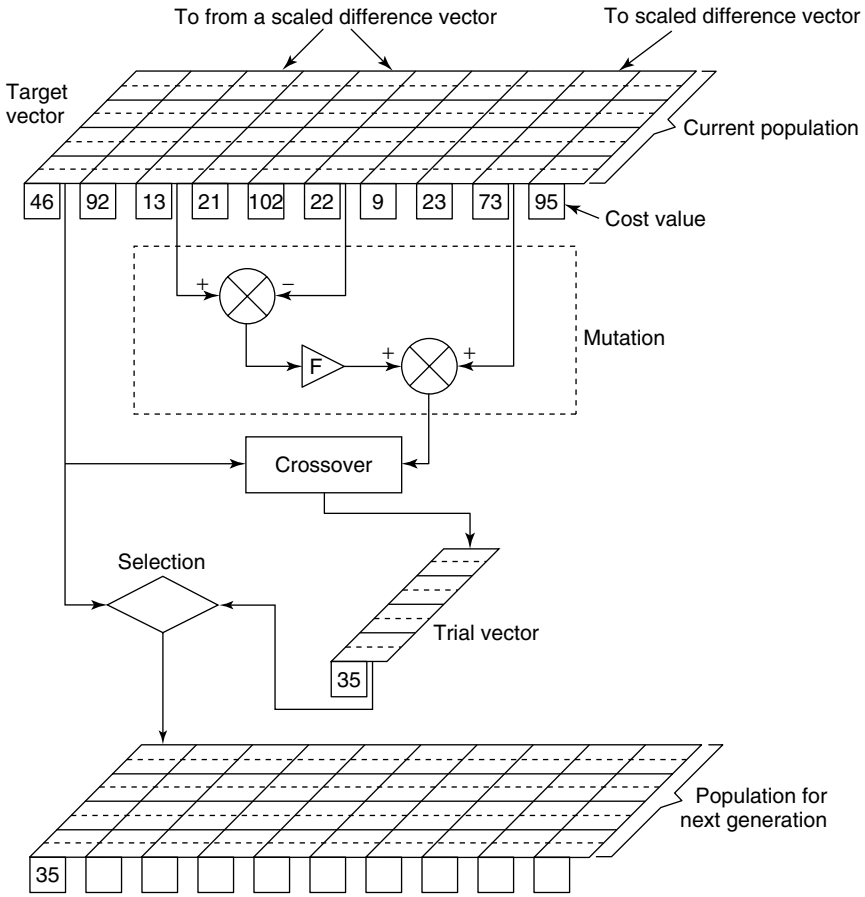

Figure 10. Schematic for differential evolution.

gets its parameter from the target vector; otherwise the parameter comes from the mutated vector.

This process of evolving through generations is repeated until the population becomes swamped by only a few low-cost (or high-fitness) solutions, any of which would be suitable. Now that the general procedure for the DE algorithm has been explained, a case study can be considered.

5.2 A case study: sensor placement for Lamb wave inspection

The case study presented here is based on the idea of inspecting plates using high-frequency Lamb waves. The idea is that waves will be launched from an emitter or actuator and recorded by a distant receiver or sensor. Once the wave profiles have been established for the normal condition of the plate, one can look for evidence of damage in the form of scattered and reflected waves in the wave profiles. As before, the optimization problem is the problem of placing emitters and receivers to best detect damage.

The method used to encode the problem variables as individuals in this case is remarkably straightforward; each chromosome of the gene is simply an x or y coordinate of one of the sensors. Figure 11 shows the situation for one possible arrangement of two emitters and two receivers on a $2\,\mathrm{m} \times 1\,\mathrm{m}$ plate. An eight-chromosome gene uniquely defines the sensor arrangement.

Once a procedure for the encoding of sensor locations has been devised, the next issue that arises

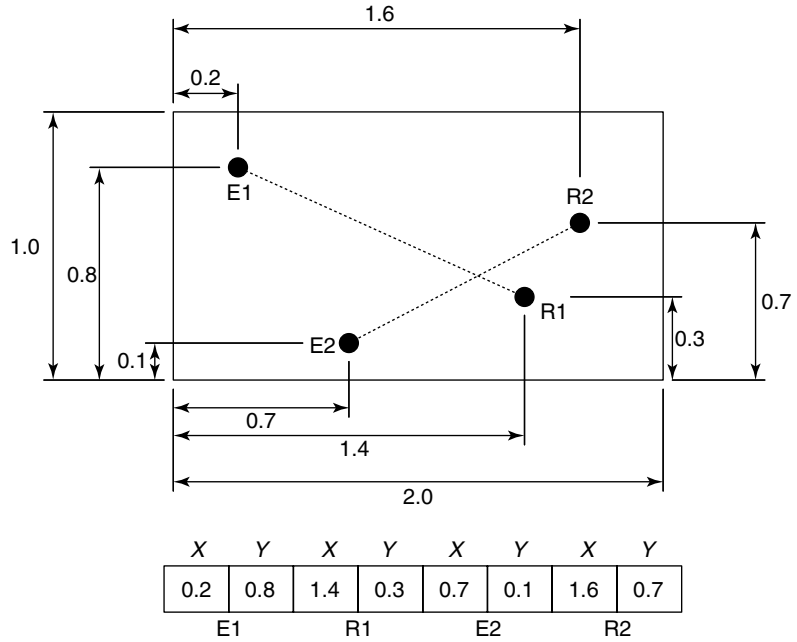

Figure 11. DE encoding for Lamb wave sensor placement problem.

concerns the objective function that is going to be optimized using the DE. For the problem at hand, the maximizing of damage detection coverage on a structure, the approach that will be taken is to try to minimize a cost function based upon angles between emitter, receiver, and damage locations. The reason for this is that the emitter considered here generates a directed wave and the receiver works on the same principles. This means that the greater the angle that a potential damage location makes with the emitter/receiver axis, the less likely that this sensor placement would be to detect said damage. However, if more than one pair of sensors is being used the situation should improve, with the best pair of sensors being used for each potential damage location. This may be easier explained by referring to Figure 12, which shows the situation for only one defect location and one possible placement of two pairs of emitters and receivers on a plate structure. The usefulness of the E1/R1 combination for the detection of the shown defect is dependent upon the greater of the two angles, R1E1D and E1R1D, with the ideal situation being that the defect is located on the axis between E1 and R1. In this case, there exists a second pair of sensors that may be more suitable for detecting the defect and

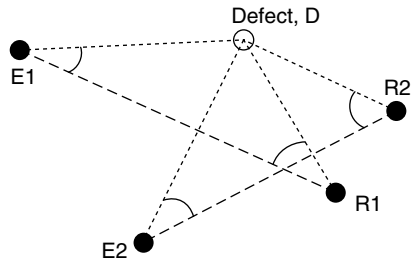

Figure 12. Schematic for Lamb wave inspection showing scattering of waves from a defect.

so the best pair of sensors is selected in each case. The process needs to be repeated over a mesh of all possible damage locations for this sensor placement to arrive at an overall cost value for the individual representing the emitter and receiver positions.

The cost function for the two pairs situation may be obtained as the maximum scattering angle between a sensor pair and a defect, with the maximum taken over all possible defect positions and over the two sensor pairs. The extension to different numbers of sensor pairs is clearly straightforward.

The optimization was carried out for a square plate with numbers of sensor pairs between one and

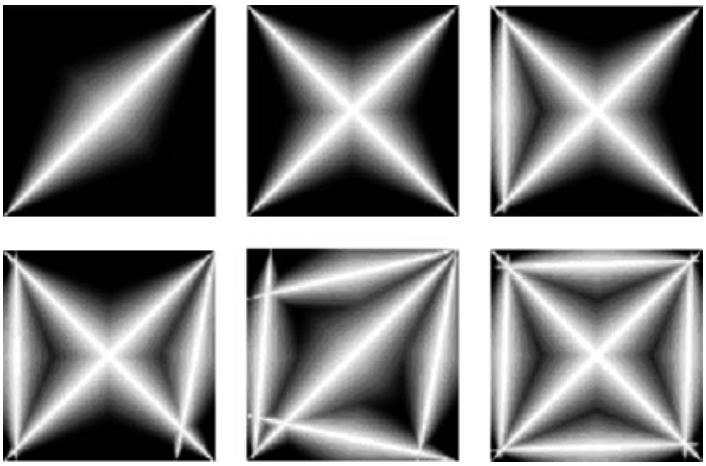

Figure 13. Optimized plate coverage for Lamb wave sensing.

six. Figure 13 shows the solutions obtained from the DE algorithm for the square plate with directional emitters and sensors; the grey-scale plots use white to indicate areas where damage is more likely to be detected and the darker areas indicate areas where detection may be a problem. As expected, in all cases, the algorithm has placed the sensors at the outer edge of the plate. The emitters and receivers associated with one another are obvious from the white paths. The range for the scattering angle in the plots in Figure 13 are between 0° and 25°. Any location shown in black indicates an angle of 25° or more. For the square plate, the cases for between one and four pairs of sensors show little surprise with sensors being located at opposite corners of the plate to begin with and subsequent pairs trying to remove "black spots". It is only the five-pair case that shows some departure from this process, only to return to the high level of symmetry in the six-pair case.

6 MORE METHODS INSPIRED BY BIOLOGY

6.1 Ant colony metaphors

Algorithms based on *ant colony metaphors* are a comparatively recent addition to the group of heuristic optimization algorithms. These are based on the cooperative interaction of simple computational agents termed *ants*. The basic forms of the algorithms—ant-density, ant-quantity, and ant-cycle—were introduced in [15]. Of these basic forms, the ant-cycle algorithm proved to be the most effective, and this was renamed *ant system* and discussed in more detail in [16]. Originally, the algorithms were applied to the travelling salesman problem (TSP), but were then shown to apply to other hard combinatorial optimization problems like the quadratic assignment problem and job-shop scheduling problem. Modifications soon appeared, which could deal with continuous design spaces [17] and constrained problems [18]. The ant algorithms have proved to be a useful addition to the armory of methods, combining aspects of greedy search with population-based cooperative search.

Real ants are well known to be capable of finding the shortest path to a food source from their nest without using visual clues [19–21]. This is done by exploiting *pheromone* information. Ants deposit pheromone as they move and follow pheromone trails deposited by previous ants. If a trail has higher pheromone information, an ant will follow it in preference to other trails with less pheromone. In other words, an ant will follow a trail with higher pheromone, with higher probability.

Consider Figure 14. Initially the ants leave the nest and have no preference as to which path they will follow and they will choose a path with equal probability. Assuming that all ants travel with equal speed, the ants taking the lower path will reach the food before those taking the upper one. When

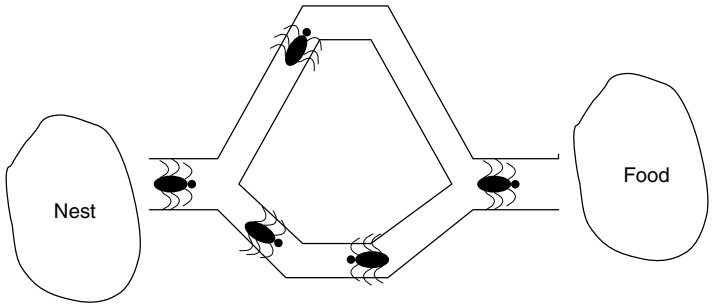

Figure 14. Schematic for ant foraging activity.

returning to the nest, they will choose the lower path with higher probability because the upper path ants have not arrived yet to lay trail. This reinforces the pheromone path on the lower trail. When the lower path ants arrive back at the nest, new ants will initially see twice as much trail on the lower path and choose it with higher probability. It is not difficult to see that a positive feedback mechanism emerges, which reinforces the desirability of the lower trail. Eventually, all ants will follow the shorter path.

This simple example illustrates the idea behind ant algorithms, which is that simple agents can communicate using distributed memory about the problem—pheromone—to cooperate and solve an optimization problem.

Because the aim here and elsewhere in the engineering literature is to solve an engineering problem and not to model real ant colonies, various simplifications are assumed. Artificial ants differ from real ants in the following ways:

1. They are completely blind.
2. They have some memory.
3. They live in a discrete-time environment.

To explain the original ant system algorithm, it is convenient to do so in the context of the TSP, which provided the original motivation for the algorithms. The basic TSP is formulated as follows: Given N cities distributed randomly within the plane, find the shortest tour that visits each city once only and returns to the original city. The distance $d(i, j)$ between cities i and j with coordinates (x_i, y_i) and (x_j, y_j) is computed using the standard Euclidean norm. One can think of the problem in terms of a graph, where each pair of cities is potentially joined by an edge (i, j). The ants move around in this graph laying a pheromone trail with intensity $\tau(i, j)$ for each edge (i, j) they traverse. This trail can be updated locally as the ants move or can be updated globally at the end of an iteration when all ants have completed a tour. The global updating rule, which forms the basis of the *ant system* algorithm, was shown to be superior to local rules [13]. The ants are forced to complete a tour by maintaining a *tabu list* for each ant; this simply contains a list of the cities that the ant has already visited, and the ant is forbidden to revisit any city in the tabu list.

Given a state of the system at time t in a specific iteration, each ant k is at one of the cities. The probability that an ant will make the journey from city i to city j is assumed to be

$$P_k(i, j) = \frac{[\tau(i, j)]^\alpha [\eta(i, j)]^\beta}{\sum_{j \in J_k(t)} [\tau(i, j)]^\alpha [\eta(i, j)]^\beta} \qquad (9)$$

where $J_k(t)$ are the allowed cities for ant k at time t i.e., the complement of the tabu list. If j is not in $J_k(t)$, the transition is forbidden by setting $P_k(i, j) = 0$. In equation (3), $\tau(i, j)$ is the trail intensity associated with the edge (i, j). The *visibility* $\eta(i, j)$ is the inverse of the distance between cities i and j. This is included to allow a degree of greediness in the algorithm; the ants are more likely to move to a nearer city at a given step. This is not guaranteed to lead to a tour with overall minimum length as at step $N - 1$; the ant may be very far from its starting city. The parameters α and β control the relative importance of trail and visibility. Note that the inclusion of visibility means that the ants are not

totally blind in this variant of the algorithm. After N steps when the ants have completed a tour, the pheromone levels for each edge are updated using the rule

$$\tau(i, j) \longrightarrow \rho\tau(i, j) + \sum_{k=1}^{m} \tau_k(i, j) \qquad (10)$$

where

$$\tau_k(i, j) = \frac{Q}{L_k} \qquad (11)$$

if edge (i, j) is in the tour of the kth ant and $\tau_k(i, j) = 0$ otherwise. Q is a user-defined constant and L_k is the total tour length for ant k in that iteration. The total number of ants is m. The parameter ρ is also user defined. A number between 0 and 1, this represents the trail persistence between iterations; $1 - \rho$ is a measure of trail *evaporation*.

This is how the ant system algorithm is used to solve the TSP. To illustrate an optimization problem here, the algorithm was applied to a known TSP problem—the Oliver30 problem. This was chosen as it was the problem used in the original paper on the ant system algorithm [11]. Overall, 25 runs of the ant system algorithm were carried out. The agreement between the runs was impressive. By 500 iterations, 16 of the runs had arrived at the best previously known solution, and this had a tour length of 423.74 (Figure 15). The remaining nine runs had arrived at a local minimum with tour length 423.91. After 1000 iterations, 22 of the runs had arrived at the best solution, with 3 runs remaining at the local minimum. After 1500 runs, only two of the local minima persisted and after 2000 iterations all 25 runs had arrived at the "optimum". The fastest run hit the best solution at 27 iterations and the slowest run took 1981 iterations. The best tour obtained using a greedy nearest neighbor heuristic had a length of 473.33, substantially worse than that from the ant algorithm.

Having established that the ant algorithm works well on a difficult problem, it is straightforward to apply to problems of engineering interest. Elsewhere in this encyclopedia (*see* **Sensor Placement Optimization**), an application to the sensor placement described above in Section 3 is given. The algorithm is shown to outperform a GA.

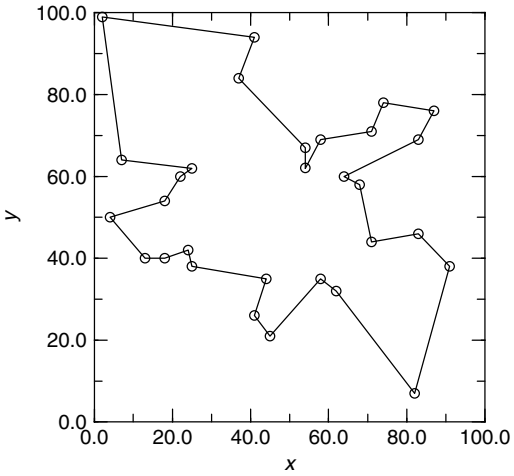

Figure 15. Ant algorithm solution to Oliver30 TSP problem.

6.2 Immune system metaphors

Algorithms based on immune system metaphors are another comparatively recent addition to this group of algorithms. Unlike GAs or SA, the immune system has inspired a diverse range of algorithms designed to address a number of problems including (but not restricted to) pattern recognition, anomaly detection, data analysis, scheduling, machine learning, and optimization. Analogies with the biological immune system have enabled the development of the field of *immune engineering* [22], which encompasses a number of algorithms motivated by more or less detailed aspects of the actual immune system that can be used for the solution of real engineering problems. The field has developed to the point where the first pedagogical treatment has appeared [23]. In the field of SHM, the main applications of immune engineering have been in anomaly or novelty detection, examples of which can be found in [24–26]. The object of this section is to consider an optimization algorithm motivated by the immune system—the clonal selection algorithm (CSA).

The biological immune system is very complex and it would be inappropriate to discuss it in detail here; instead, a brief discussion will explain the motivation of the algorithm, which is the subject of this article. Much of this section is a précis of [22] and the interested reader can refer to the original reference for far more detail.

The human body has two interrelated components for its protection from foreign material. The first of these systems is the *innate immune system*. The body is born with the basic ability to recognize certain invaders and to destroy them. However, this part of the immune system is not relevant for motivating the optimization algorithm required here. The relevant mechanism is the *adaptive immune system*, which is able to optimize its response to microbial agents by modifying certain cells to maximize their ability to recognize chemicals on the surface of the invading cells (called *antigens* here). The adaptive immune system allows the body to learn to recognize any given antigen and mobilize the body's defenses even if it has never seen it before.

The adaptive immune system mainly acts through agents (cells) called *lymphocytes*. These are a heterogeneous set of cells, their numbers being of the order of 10^{12}. The complexity of the immune system thus rivals that of the brain, which typically contains 10^{10} neurons. The lymphocytes can be divided into *B cells* and *T cells*.

The B cells, when activated, differentiate into plasma cells, which can secrete *antibodies*. Each B cell can secrete only one type of antibody. The antibodies are proteins that bind to the antigens and signal other cells to kill, or otherwise deactivate, the invading body. T cells are also vital to the biological immune system; however, one can argue that they play a secondary, regulatory role in motivating the engineering algorithm needed for optimization problems.

The antibodies are composed of *constant regions* and *variable regions*. The constant regions are responsible for a number of functions that are necessary for the effective functioning of the immune system; however, they are again secondary in motivating the optimization algorithm. The variable regions are those that are subject to frequent mutation and can therefore adapt to maximize their ability to bind to the antigen. The actual computational agents or individuals of the optimization routine really represent only the variable regions of the antibodies.

The principle that motivates the optimization routine is the *clonal selection principle*. When exposed to antigens, the B cells respond by producing antibodies. The antigen stimulates the B cells to divide and proliferate into the antibody secreting plasma cells. Only the B cells that recognize the antigen proliferate by cloning. High levels of mutation—*hypermutation*—allow the system to adapt by maximizing the affinity of the antibodies for the antigen. The initial population of B cells has sufficient diversity to effectively adapt to the attack of any antigen. The final result of the adaption is a population of cells adapted to the removal of the antigen; this population endures in the body in the form of *memory cells*, which can then form the defense against a secondary attack involving the same antigen. Another important ingredient of the process, which will not be pursued here, is *self–non-self discrimination*, which ensures that the antibodies do not evolve into forms that may attack the host cells. This is important in motivating algorithms for novelty detection [24–26].

The engineering version of the adaptive immune system is basically constructed by analogy, with the objective of generating the population of memory cells that are optimized for a given antigen. The idea is to begin with an initial population of individuals and then iterate by a process of selection and mutation in much the same way as standard evolutionary algorithms. In fact, the algorithm here—the *CSA*—can broadly be regarded as a type of GA without crossover. The individuals in the algorithm will be identified as the antibodies, essentially ignoring the distinctions between the real entities, the B cells, plasma cells, and biological antibodies. The quantity that is optimized in the real immune system is the affinity between the antibodies and the antigens; the affinity in the CSA is therefore defined as the value of the objective function, which must be maximized. As in the binary GA, the individuals of the population here are binary strings that encode the parameters to be optimized. The steps in the CSA can be summarized as follows (see also Figure 16):

1. Define the problem—objective function and encoding.
2. Generate random initial population of antibodies—$\mathbf{Ab_1}$. The population number of individuals is set at P.
3. Calculate the affinities. This is the standard process of decoding the individuals and substituting into the objective function.
4. Choose the N best individuals—based on their affinities.
5. Cloning by taking C copies of each of the best individuals; these clones form the set $\mathbf{Ab_2}$. The

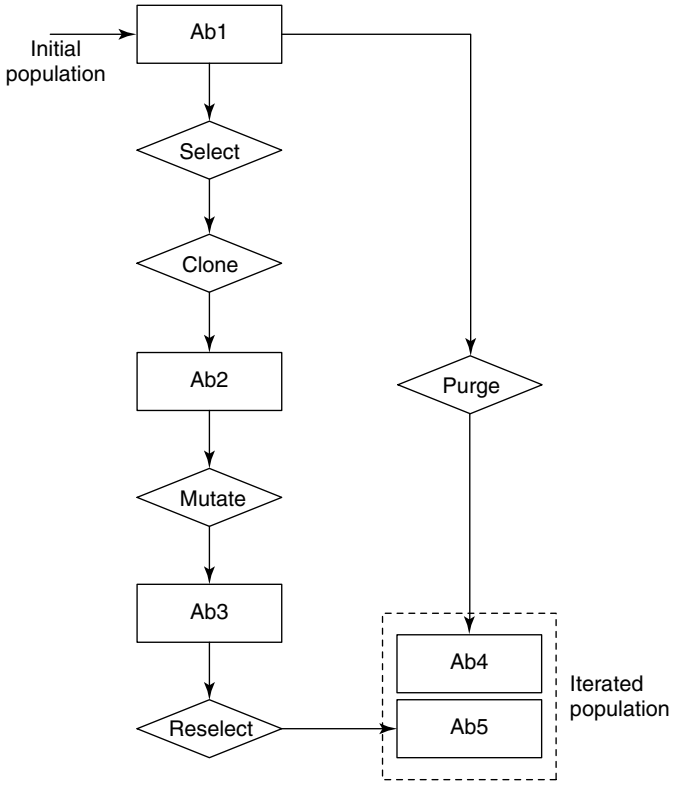

Figure 16. Schematic for the CSA algorithm.

number of clones of an individual can also be proportional to its affinity.

6. The clones are now subjected to mutation—applied in the same way as the binary GA by flipping bits of the binary string that represents the individual. A high mutation probability is used. This forms the set $\mathbf{Ab_3}$.
7. Remove a percentage of the individuals with lowest affinity from $\mathbf{Ab_1}$—this forms the set $\mathbf{Ab_4}$. This step represents the death of the least-stimulated cells, which is a feature of the biological immune system. Alternatively, one can replace the least-stimulated cells with random individuals to maintain diversity.
8. Reselect a proportion of the cells with highest affinity from $\mathbf{Ab_3}$ to form the set $\mathbf{Ab_5}$ (these are the memory cells), which is added to $\mathbf{Ab_4}$ to form the new population.
9. The process is iterated until some performance criterion is satisfied.

The various parameters are balanced to maintain a constant population size, which gets successively better (has higher average affinity) as the algorithm progresses.

An illustration of the use of the CSA algorithm on the sensor placement problem considered in Section 3 of this article can be found in [27].

7 A FINAL CASE STUDY—DAMAGE DETECTION

In this section, the previously discussed SA algorithm and the GA are applied in two cases: first when data obtained from an FE beam simulation with multiple cracks are analyzed; second, when experimental data measured from three cantilever steel beams with two cracks are examined to estimate depth and positions of their cracks. The results obtained with these optimization techniques are discussed to highlight the relative merits and drawbacks.

7.1 Optimization approach

The basis for the damage detection method is to establish a model of the system and then to compute the parameters of the model that gives the best (in some sense) correspondence with experimental data. As usual, one first formulates an objective function, $F(\cdot)$, which gives a scalar measure of the difference between measured and calculated dynamic characteristics of the structure under consideration, $\mathbf{D}^{(\mathrm{m})}$ and $\mathbf{D}^{(\mathrm{c})}$, respectively. An estimate $\mathbf{R}^{(\mathrm{s})}$ of the state of damage is the value $\mathbf{R}$ for which the function $F(\cdot)$ is a minimum, where

$$F(\mathbf{R}) = \|\mathbf{D}^{(\mathrm{m})} - \mathbf{D}^{(\mathrm{c})}(\mathbf{R})\| \tag{12}$$

$\mathbf{R}^{(\mathrm{s})}$ can be estimated using various optimization procedures, but one should be aware that the estimate of the state of damage given by the numerical procedure may be quite different from the correct value. This is usually the case in which the objective function has many local minima and each one is related to an incorrect state of damage. In general, one would hope that just the global minimum provides an accurate estimate of the actual state of damage of the structure.

As an example of damage identification as an optimization problem, Shen and Taylor [28] utilized a min–max optimization to assess the damage in a simply supported beam; they used a cost function with both the natural frequencies and the mode shapes of the structure,

$$\left(\sum_{i=1}^{n_f} \left(\left(f_i^{(\mathrm{c})}(r_0, a) - f_i^{(\mathrm{m})} \right)^2 + \sum_{j=1}^{n_\mathrm{p}} \left(\phi_{ij}^{(\mathrm{c})}(r_0, a) - \phi_{ij}^{(\mathrm{m})} \right)^2 \right) \right)_{\min} \tag{13}$$

where n_f is the number of considered modes, r_0 gives the position of the crack, a its depth, n_p the number of measurement points, and ϕ_{ij} is the ith mode shape at the point j; the superscript (c) refers to the calculated and the superscript (m) to the measured dynamic characteristics of the structure. According to this method, and assuming a known location r_0, the authors obtained a good estimate for the crack depth, while they found very poor results trying to evaluate both the location and the size of the crack, probably due to the presence of local minima.

For maximum generality, it was decided here to use an FE model of the beam in which each element is potentially cracked [29, 30]; in this way the number of cracks in the structure is not limited. As a consequence, the stiffness matrix of the structure can be written as follows:

$$\mathbf{K} = \mathbf{K}(\mathbf{R}) \tag{14}$$

where $\mathbf{R}$ is a vector representing the state of damage,

$$\mathbf{R} = [r_1 r_2 r_3 \ldots r_n]^{\mathrm{T}} \tag{15}$$

n indicates the number of elements into which the structure is subdivided, and $r_i = a_i / h$ with a_i being the depth of the crack in the ith element and h the height of the beam.

In general, the problem of local minima can be avoided to an extent if more knowledge of the structure physical properties is introduced into the objective function and some boundary conditions are included to limit the state-of-damage domain [28]. To compare the performance of GA with SA the following formulation, derived from [29], is used:

$$F(\mathbf{R}) = \frac{1}{\alpha g_1(\mathbf{R}) + v(\mathbf{R})} \tag{16}$$

Table 3. Simulated damage scenarios

Case	First cracked element			r_i			Second cracked element			r_i		
	True	GA	SA	True	GA	SA	True	GA	SA	True	GA	SA
1	5	5	5	0.20	0.197	0.197						
2	3	3	3	0.20	0.197	0.197						
3	1	1	1	0.15	0.150	0.151	4	4	4	0.10	0.102	0.090

where

$$g_1(\mathbf{R}) = \sum_{i=1}^{N} \left(1 - \frac{f_i^{(\mathrm{m})}/f_i^{*(\mathrm{m})}}{f_i^{(\mathrm{c})}(\mathbf{R})/f_i^{*(\mathrm{c})}} \right) \qquad (17)$$

with N being the number of natural frequencies.

$$v(\mathbf{R}) = \sum_{i=1}^{n} r_i \qquad (18)$$

denotes the global damage of the structure as the sum of damage affecting n elements making up the mathematical model.

7.2 Numerical results

The procedure for damage assessment described here was applied to identify the damage in a beam, cracked in one or two locations (Table 3), with the following properties: elastic modulus $E = 2.06 \cdot 10^{11}\,\mathrm{N\,m^{-2}}$, mass density $\rho = 7850\,\mathrm{kg\,m^{-3}}$, length $L = 0.7\,\mathrm{m}$, and cross-sectional area of $0.020 \times 0.020\,\mathrm{m^2}$. The beam was discretized in 10 elements. Both GAs and SA were applied to maximize the objective function, in which α was set equal to 80 000; the relative results are also shown in Table 3 and the evolution of the objective function during the optimization has been plotted in Figure 17, where it is evident that with 10 000 evaluations of the cost function, it is possible to reach the global maximum using both SA and the GA. Furthermore, it may be stated that it is necessary to run the GA several times (five times here) to properly account for the random initializations of the algorithms. This consideration can be important in assessing damage in more complex structures, where a greater number of objective function evaluations is potentially needed to reach an accurate estimate of the state of damage.

7.3 Experimental results

To validate the damage assessment procedure, data obtained by performing tests on three cantilever steel beams have been analyzed. These beams were tested both in the undamaged and in the cracked states, so it was possible to update their FE models in which accelerometer mass, stiffness of the clamping device, and elastic modulus of the beam were assumed as variables. On completion of the updating task, values

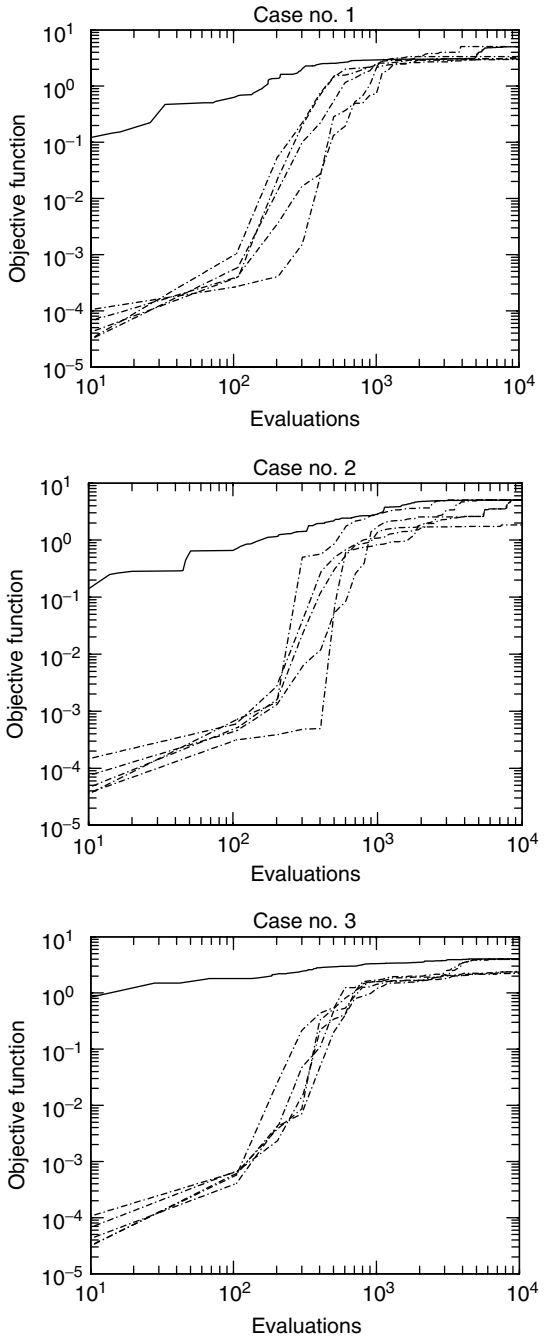

Figure 17. GA fitness evolution (dashed) and SA fitness evolution (solid).

Table 4. Experimental cantilever beams

Case	First cracked element			r_i			Second cracked element			r_i		
	True	GA	SA	True	GA	SA	True	GA	SA	True	GA	SA
C1	4	4	4	0.20	0.207	0.213	8	8	8	0.20	0.207	0.206
C2	4	3	3	0.20	0.127	0.174	8	8	8	0.30	0.367	0.349
C3	4	4	4	0.30	0.267	0.267	8	8	8	0.20	0.258	0.255

for $f_i^{(c)}$ were computed and introduced into the objective function formulation. The results obtained by running both SA and genetic algorithms are shown in Table 4. This table highlights that both the procedures identify the correct state of damage except for beam C2 (where the estimate for the location of one crack is wrong) and give sufficiently accurate results.

8 CONCLUSIONS

Only the briefest of conclusions is warranted here. It is clear that SHM inspires a number of important and complex optimization problems. It is fortunate that the mathematical discipline of optimization provides a battery of powerful techniques that can address these problems. Amongst the most powerful, particularly for combinatorial optimization problems, are the heuristics which have been inspired by physical and biological metaphors and several of these techniques have been illustrated in this article.

1 INTRODUCTION

Future engineering will rely increasingly on computer simulations and modeling for a wide range of processes in the design-to-decommissioning life cycle—from design and prototyping, through production planning, manufacture, and in-service monitoring and ending with a safe decommission. This "virtual" approach usually offers clear financial and/or environmental advantages. However, a fundamental concern is that the modeling process must be robust to uncertainty: a high-fidelity model can become worthless if there is no understanding of how uncertainty is propagated through it. To elaborate on the concept of uncertainty propagation, consider a complex component incorporating inelastic materials, contacts, friction, etc. The model requires an initial specification of material properties, clearances, and friction coefficients. The response of the model will only be as accurate as these initial values, yet the values may be subject to large uncertainty; consider the difficulty in the mechanical characterization of biomaterials or viscoelastic polymers. In a worst-case analysis, the predictions of the model may prove highly sensitive to variations in the input parameters.

In 1999/2000, members of the Engineering Analysis group, amongst others, at Los Alamos National Laboratories (LANL), carried out arguably the most ambitious calculation in the (short) history of structural dynamics. Using one of the most powerful computers in the world at the time, the platform *Blue Mountain*, the computation essentially attempted

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

to quantify the propagation of uncertainty through a nonlinear finite element (FE) model of a weapon component under blast loading [1]. The calculation made use of 3968 processors from the available 6000 and used concurrently 4000 ABAQUS/Explicit licenses. The analysis took over 72 h and would have required 17.8 years of equivalent single-processor time.

The scale of this calculation is testimony to the importance that uncertainty quantification and propagation (UQP) is inevitably going to assume in the immediate future of structural dynamics and also in the long term. One of the reasons for the LANL interest in UQP is that current test bans in the field of nuclear weaponry forbid the type of experimentation which would usually be used to validate physical and computational models. Another compelling reason for UQP is the fact that the environmental and operational conditions for certain engineering projects are unknown and cannot be estimated with certainty. Alternatively, conditions can be estimated, but cannot be recreated exactly in validation experiments. Consider the design and manufacture of an in-orbit facility. In this case, aspects of the true environment, such as weightlessness and absence of drag, can be reproduced to an extent in terrestrial experiments. However, consider the design of an exploration module intended to operate on the surface of Venus. Such systems are extremely expensive and will often have only one chance to succeed. The performance of the Hubble telescope or the Mars Lander Beagle 2 is an object lesson here.

Another prime motivator for uncertainty analysis is the need for risk assessment in safety-critical systems. In fact, one might argue that the modern origins of the subject are here with projects like the Nuclear Reactor Safety Study [2]. One of the main regulators in the design of structural health monitoring (SHM) systems for say, a civil aircraft, will be the need to eliminate false assertions of damage as a result of environmental and operational variations. Such false positives and the ensuing "no fault found" inspections would substantially increase the cost of ownership of the aircraft. Even more critical is the possibility of a false negative as a result of environmental uncertainty, with potential loss of life being the result.

The purpose of this article is to introduce the issue of uncertainty analysis in general and also its relevance to SHM. In the next section, brief descriptions of the most popular of the many frameworks for uncertainty representation are given. Section 3 discusses the three main uncertainty-related problems of relevance to structural dynamics, namely, quantification, fusion, and propagation. In order to illustrate the ideas of the preceding two sections in a realistic scenario, two case studies conducted on an aerospace structure, namely the wing of a Gnat trainer aircraft, are provided. The first case study, in Section 4, considers the issue of attaining certification for artificial neural network (ANN) damage classifiers through the assessment of the network's robustness to uncertainty. This case study involves the propagation of intervals through the network structure and examines whether the networks, which would be considered as optimal, in the traditional sense, are also most robust to uncertainty. In Section 5, the second case study considers evidence-based classifiers as an alternative to probabilistic classifiers for the problem of damage location. The Dempster–Shafer (DS) theory is employed to construct neural network classifiers with the potential to admit ignorance, rather than misclassify. The section considers issues of propagation and fusion in an evidence-based framework and compares the performance of DS neural networks with their probabilistic counterparts. The article ends with some brief conclusions.

2 THEORIES OF UNCERTAINTY

There are many frameworks available through which uncertainty may be represented and this section examines some of the more common theories, considers their pros and cons, and looks for applications in the literature of structural dynamics. It is not the intention to give an exhaustive review of the literature and, in particular, the large body of work in the high-frequency/Statistical Energy Analysis (SEA) arena is ignored.

2.1 Classical probability theory

The classical probability theory is well known. In fact, if the variations in a parameter are random, there is no better specification of the uncertainty than a probability distribution. However, in practice, this is often not available. Engineering analysis is routinely

based on small samples and one might only be able to estimate the low-order moments of a distribution—mean and variance—with any confidence. Arbitrarily imposing a known distribution shape e.g., Gaussian, on the basis of this information is perilous. In particular, the use of such central statistics may result in a distribution radically different in the tails from the true distribution. In risk analysis, where one is concerned with extreme events, the results of such a strategy will probably be meaningless. Another problem, in general, is that a specification of a problem will necessarily include a region of ignorance, and classical probability theory cannot accommodate this. In particular, a statement of the probability of an event automatically fixes the probability that it will not occur. The evidence for the occurrence of the event is essentially the same as the evidence for nonoccurrence.

2.2 Evidence theory

This can be regarded as an extension of the theory of probability (although this interpretation is contested). The main theory of this sort is DS theory [3, 4], although generalizations exist [5]. Essentially, the single probability is replaced here with two quantities. The *belief, Be*, associated with an event is the sum of the evidence in favor of the event. The *plausibility, Pl*, is the complement of the evidence against the occurrence of the event. By the fact that these quantities can be different, DS theory accommodates the idea of ignorance. DS theory thus replaces the single probability with an interval [*Pl, Be*], and these quantities are sometimes called *lower and upper probabilities. Be* can be regarded as the best-case estimate of the probability of an event, corresponding to the case when all the missing evidence (ignorance) turns out to be in support of the event. Applications in engineering of DS theory are rather few and far between, [6] cites 12 application references in total, but interestingly exclude [7, 8] and those that specifically consider problems of SHM.

2.3 Possibility theory

Similar to DS theory, the possibility theory makes use of two complementary uncertainty measures—possibility and necessity [9]. Essentially, some proposition e is mapped into the interval [0,1], which may be divided into the three intervals: necessity $N(e)$, necessity of the contrary proposition $N(e')$, and ignorance $\theta(e)$. Possibility of the proposition is given by $P(e) = N(e) + \theta(e) = 1 - N(e')$. Applications of the possibility theory are even rarer than applications of DS, [6] cites only three. In some ways, the possibility theory can be interpreted in terms of fuzzy sets [10].

2.4 Fuzzy logic

This is one of the elder statesmen of contenders with probability theory [11]. This extends the classical probability theory by relaxing one of the fundamental set-theoretic properties on which it is based. In the classical set theory, an element x is either a member of a set A or a member of its complement A^c. In fuzzy set theory, x may be associated (with given weight) with a number of different sets. Fuzzy logic encodes uncertainty by associating linguistic descriptors with a variable x like *large* or *small*. x may be a member of both sets, large and small, but it is associated to each by a membership function that mediates the likelihood of its membership. There are analogs of all the basic mathematical operations for such fuzzy variables (often based on interval arithmetic) and it is possible to construct fuzzy analogs of many *crisp* theories. The most intensive use of fuzzy logic in engineering is associated with control, although the interesting studies [12–14] construct a fuzzy version of modal analysis. The same authors have also formulated a fuzzy version of FE analysis [15].

2.5 Interval methods

Rather simply stated, the interval method replaces *crisp* numbers and variables with intervals $[\underline{x}, \overline{x}]$ [16]. Uncertainty in a parameter is encoded in the statement that it lies somewhere between two given bounds $\underline{x}$ and $\overline{x}$ with certainty. Note that this information could be incorporated in a probabilistic analysis by giving a distribution for the parameter on the interval, e.g., a uniform distribution. However, interval analysis makes no use of such additional

assumptions. There are again analogs of all the expected arithmetical operations, which thus allow the propagation of interval quantities through various types of models. There are numerous uses of interval arithmetic documented in the literature. In terms of structural dynamics, the previously cited study on fuzzy modal analysis, [13], made extensive use of interval arithmetic. In [17], there is an independent attempt to formulate a fuzzy FE analysis in terms of interval arithmetic. The paper [18] is of interest in that it considers a problem of damage detection. The problem with interval arithmetic is that it is conservative in nature and that the bounds on the calculations expand considerably in practical computations. An attempt to improve on this behavior is under development in the form of *affine arithmetic* [19]. An application to the structural eigenvalue problem can be found in [20].

2.6 Convex models

In a sense, the convex models can be regarded as a generalization of the interval concept of uncertainty (although they are more than this). A given parameter p is associated with a convex set, which may be said to contain the parameter. For example, an *ellipsoidal-bound* convex model takes the form

$$\Im(\alpha, p) = \{p : (p - \overline{p})^T W (p - \overline{p}) < \alpha\} \quad (1)$$

where W specifies the axes of the ellipsoid containing the data and $\overline{p}$ is the mean of the data set. This is a convex set. This approach to uncertainty was pioneered by Ben-Haim and has been applied by him and coworkers in numerous contexts [21]. It is possible to prove numerous theorems such as: if the input to a linear system is a convex model, then so is

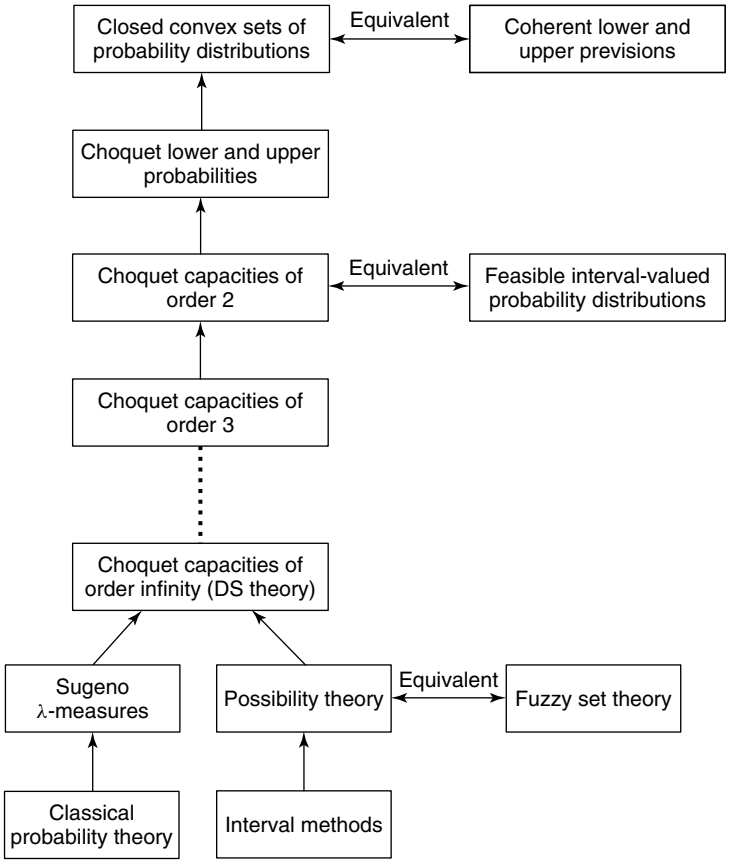

Figure 1. Klir and Smith's hierarchy of theories of uncertainty.

the output. This property does not hold for a nonlinear system, but by relaxing the constraints one obtains an *information-gap* model and recovers the property of invariance under a nonlinear operator [22]. An interesting formulation of an information-gap model on a problem of structural dynamics can be found in [23].

2.7 Klir and Smith's hierarchy of uncertainty theories

In a sense, the approaches described above are lower-level approaches to modeling uncertainty. In the survey [24], Klir and Smith identify a hierarchy of theories of uncertainty as shown in Figure 1.

As one moves up the diagram, one encounters more general representations of uncertainty. In practice, none of the theories above DS theory have so far been applied to engineering problems; however, they have potential for the future. All the theories above the classical probability theory are based on a more general form of measure—*capacity* [25]. The classical probability theory has, for disjoint events A and B, that

$$p(A \cup B) = p(A) + p(B) \tag{2}$$

i.e., the measure p is *additive*. Choquet's capacities g allow

$$g(A \cup B) >< g(A) + g(B) \tag{3}$$

i.e., they account for the possibility of mutual cooperation or inhibition between events. As discussed above, this freedom has so far been neglected in terms of engineering applications.

3 QUANTIFICATION, FUSION, AND PROPAGATION OF UNCERTAINTY

In terms of uncertainty, structural dynamics has arguably three main concerns, which are discussed briefly in this section.

3.1 Quantification

Given a parameter a, associate with this a meaningful uncertainty measure with the framework of a given uncertainty model. For example, assign a probability in the classical probability theory or a basic probability assignment (BPA) in DS theory. The process of quantification may involve several steps, each refining the measure. For example, in [26], the following process is described within the context of the Bayesian probability theory. A prior distribution is defined, for example, for a given model parameter. If it exists, expert opinion data are used to update/refine the priors to obtain a posterior distribution for the parameter. This posterior then becomes the prior for stage 2 whereby the results of computer simulation are used to update. Finally, the posterior from stage 2 becomes the prior for stage 3 where experimental data are used to update. The multistage process may also be thought of as a precursor to fusion.

3.2 Fusion

Given a parameter a, which has a set of uncertainty measures $m(a)_i$ associated with different uncertainty models U_i, how does one refine each measure in the light of the others? For example, if one is given a classical probability 0.75 for an event, and lower and upper probabilities [0.6, 1.0] from DS theory, how can one refine each measure given the other? Associated with this problem is that of *normalization* i.e., which uncertainty measure in the convex model theory corresponds to a given probability or BPA? Or is it even possible to make a quantitative comparison? This is largely an open problem, although some preliminary results are available; [27] sketches a relationship between fuzzy set theory and the classical probability theory.

3.3 Propagation

If a parameter a, with a given uncertainty measure $m(a)$, forms the input to a given physical process, which uncertainty measure should be associated with the output, or a given aspect of the output? As an example, consider the discussion in [28] a control problem. The aim is to establish, given a system with uncertain parameters, the probability that the derived

controller will be stable. An associated problem here is the question of *sensitivity*, i.e., which parameters, with their associated uncertainties, are the main cause of variation in the model/system response.

4 CASE STUDY 1: ASSESSMENT OF NEURAL NETWORK ROBUSTNESS FOR DAMAGE CLASSIFICATION

The first case study considers the application of ANN classifiers to the interpretation of data for the purposes of damage location. ANN classifiers have found diverse applications in many fields including aircraft wing damage detection [29, 30]. Conventional network training can be viewed within a framework of the global optimization (minimization) of the error function between the network output prediction and the true target data. There exist a number of strategies to locate this minimum, the most common being variants of gradient descent such as scaled conjugate gradients [31, 32]. These techniques make use of the local gradient information of the error surface to ascertain the optimum search direction but are susceptible to the danger of locking a solution into a local minimum rather than locating the true global minimum. A number of strategies have been devised to counter this problem [31–33], and new techniques of searching the error function space are currently active areas of research, for example, using genetic algorithms (GAs) [32].

An additional complication to network performance lies in the capability of a network to generalize its classification performance to previously unseen data. There exists the widely recognized problem of overtraining that can occur such that a network starts to learn the noise present in data rather than the underlying data structure. The use of cross-validation and early stopping [33] using an independent validation data set are often used as termination criteria for training to help avoid this problem.

The problems of network overtraining and lack of generalization are central to understanding the inertia to the practical application of ANNs, especially to safety-critical applications. If, for example, one envisages an ANN classifier being used to assess the condition of a major structural airframe component, it is imperative that the performance of the classifier to the most diverse range of inputs is well understood. Poor classifier performance could result in catastrophic failure and possible loss of life. Although a range of techniques have been developed for output confidence interval predications [32, 34–37], they all adopt a probabilistic standpoint and therefore suffer from the common drawback that since the probability distributions are usually estimated from the low-order moments of the data (typically mean and standard deviation), there is often no representation associated with the extremes of the distributions. Unfortunately, it is often the extreme events of the data that are likely to be associated with the unpredictable failure events of greatest interest.

This case study comprises a novel nonprobabilistic approach applied to predicting extreme network outputs in the presence of uncertainty in the input data. This technique is based on the theory of convex models and information-gap uncertainty as pioneered by Ben-Haim [38–41]. Interval-based [42] techniques are extended to investigate the response of a simple multilayer perceptron (MLP) network used for a classification problem to locate damage sites on the wing of a Gnat trainer aircraft. A comparison with conventional network training based on cross-validation is presented. It is shown that the use of interval-based network propagation allows a new criterion for network selection to be established. This technique allows the identification of an ANN classifier, which is intrinsically more robust to noise on the input data than network solutions obtained by conventional maximum likelihood training. Furthermore, by virtue of the conservative nature of interval sets, the reliance on probabilistic-based estimates of confidence bounds on network predictions is obviated. The interval-based worst-case error predictions represent an inclusive bounded solution set given a specified degree of input noise to the classifier.

4.1 Experimental data acquisition and signal processing

The work concerns an SHM strategy to the problem of damage location on an aircraft (Gnat) wing located at DSTL Farnborough, as shown in Figure 2. The wing was instrumented with an array of 12 accelerometers to measure the response to forced

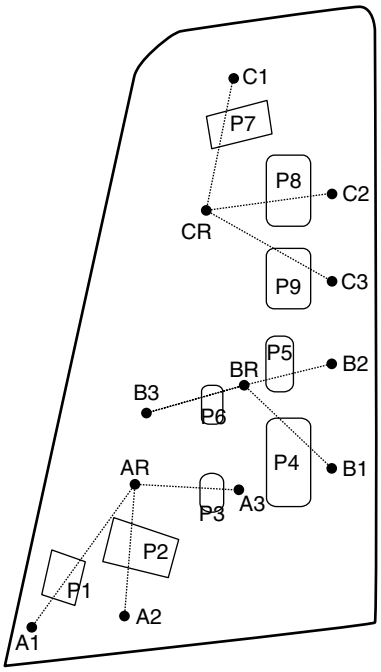

Figure 2. Detail of Gnat wing, showing position of sensors and removable panels.

vibration induced from a shaker mounted to the underside of the wing. The wing had a series of nine removable panels (P1–P9), which could be removed and replaced to provide a reproducible and reversible representation of changing conditions on the wing structure. In this fashion, damage represented by a local change in stiffness properties could be simulated.

Data were collected from all 12 accelerometers for a variety of undamaged (normal condition with all panels in place) and simulated damage data. Note from Figure 2 that the accelerometers were positioned in three distinct groupings (A, B, C) across the plate. Rather than record the individual acceleration responses, the experiment was configured to record the ratio of measured accelerations between transducer pairs AR/A1, AR/A2, AR/A3, etc. in such a way that the transmissibilities between transducer pairs formed the base measurement [29, 30]. In this fashion, there were a total of nine measurement variables recorded. Figure 3 illustrates a typical raw transmissibility measurement with 1024 spectral lines recorded with 1 Hz width in the frequency range 1024–2048 Hz.

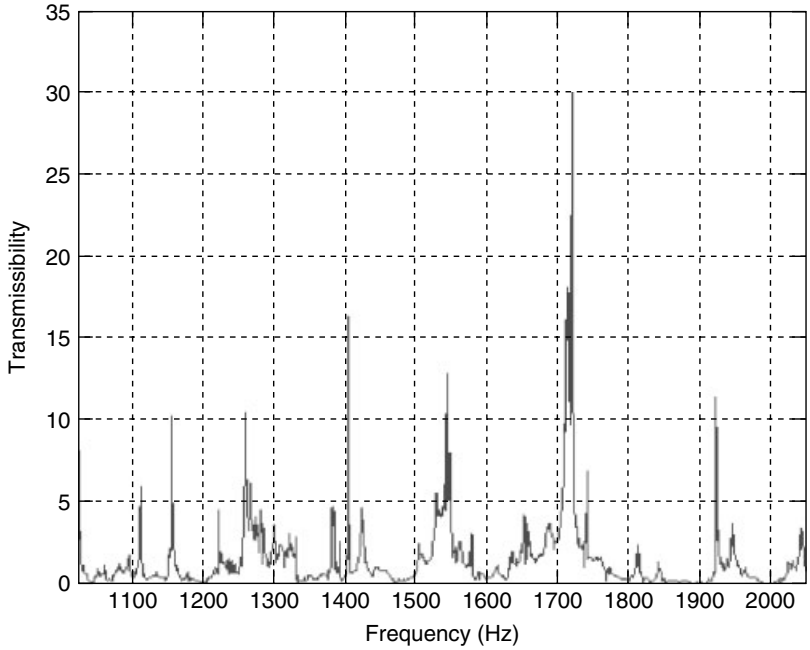

Figure 3. Example of a transmissibility plot spectrum.

By systematic removal of panels P1–P9, the effect of simulated damage on the spectral response of the transmissibility functions could be observed. For each panel removed, 100 individual measurements were recorded for each of the nine separate transmissibilities (labeled T1 through T9) corresponding to removal of panels P1–P9. Two complete runs through the set were completed making a total of 18 runs each with 9 transmissibilities each with 100 measurements; giving a total of 16 200 results. Additionally, 7 normal condition (undamaged) cases were recorded for each of the 9 transmissibilities, again taking 100 individual measurements for each, thus giving a total of 6300 results representing normal condition.

The data were inspected manually to select features (spectral line windows) from the T spectra (transmissibility spectra) that corresponded to particular damage events. This problem was simplified by using a nonlocal argument with respect to the transducer groups [29, 30]. For removal of panels P1–P3, only the T spectra from T1, T2, T3 (corresponding to the accelerometers A1–A3 and AR) were considered relevant, and the spectra from transducer groups B and C were ignored. Similarly, for the removal of panels P4–P6, only measurements from the B set of transducers were considered and likewise only measurements from the C set of transducers for the removal of P7–P9.

From a total of 77 individual features [29, 30], a single feature was selected (by inspection) to correspond to the removal of a single panel. In this fashion, the feature set was reduced to nine individual features (F1–F9). For each individual feature, the data comprised 700 normal condition measurements, and 1800 test measurements. An outlier (novelty) analysis was then performed [43] by computing the Mahalanobis squared distance of the data points with respect to the normal condition data.

$$\Delta^2 = (x - \mu)^T \mathbf{\Sigma} \Sigma^{-1} (x - \mu) \tag{4}$$

where Δ is the Mahalanobis distance, x is the data, μ is the mean of the normal condition data, and $\mathbf{\Sigma}$ is the covariance matrix of the data.

By performing the novelty analysis for each of the nine features, a data matrix of size [1800 by 9] was obtained. This was divided into three equal parts to form separate *training, validation*, and *test* data sets for subsequent network evaluation. Finally, the data sets were logarithmically compressed and normalized to -1 to $+1$ before presentation to the network.

4.2 Network topology and training

The MLP network implementation and training was undertaken in MATLAB™ using the NETLAB toolbox developed by Nabney [32]. The data were presented to a series of MLP networks with different numbers of hidden nodes. Each network had nine input nodes corresponding to the features F1–F9, and nine output nodes corresponding to the classes P1–P9 (Figure 4). The input values were x_i, $i = 1, \ldots, d$. The outputs from the second layer were given by

$$a_k^{(2)} = \sum_{j=1}^{M} w_{kj}^{(2)} \tanh \left[\sum_{i=1}^{d} w_{ji}^{(1)} x_i + b_j^{(1)} \right] + b_k^{(2)} \quad \text{for } j = 1, \ldots, M \quad \text{and} \quad k = 1, \ldots, C \tag{5}$$

where w is the weight matrix, b is the bias matrix, M is number of input nodes, and C is number of output nodes.

The network output was given by transformation of the second layer activations by the output activation function. Since there were a series of C independent output classes, it was appropriate to utilize the *softmax* function [32]:

$$y_k = \frac{\exp[a_k^{(2)}]}{\sum_{k'} \exp[a_{k'}^{(2)}]} \tag{6}$$

The choice of the softmax activation function ensured that the outputs always summed to unity, and thus could be directly interpreted as class conditional probability values.

The number of hidden nodes in the second layer was varied between 1 and 15 hidden units. Each individual network structure was trained with 100 independent training sessions starting at differently randomly chosen points on the error surface so that a total of 1500 independent networks were evaluated. Up to 1000 iterations of a scaled conjugate gradient optimization were implemented within a maximum likelihood training framework using a small hyperparameter $\alpha = 0.001$ to control weight decay.

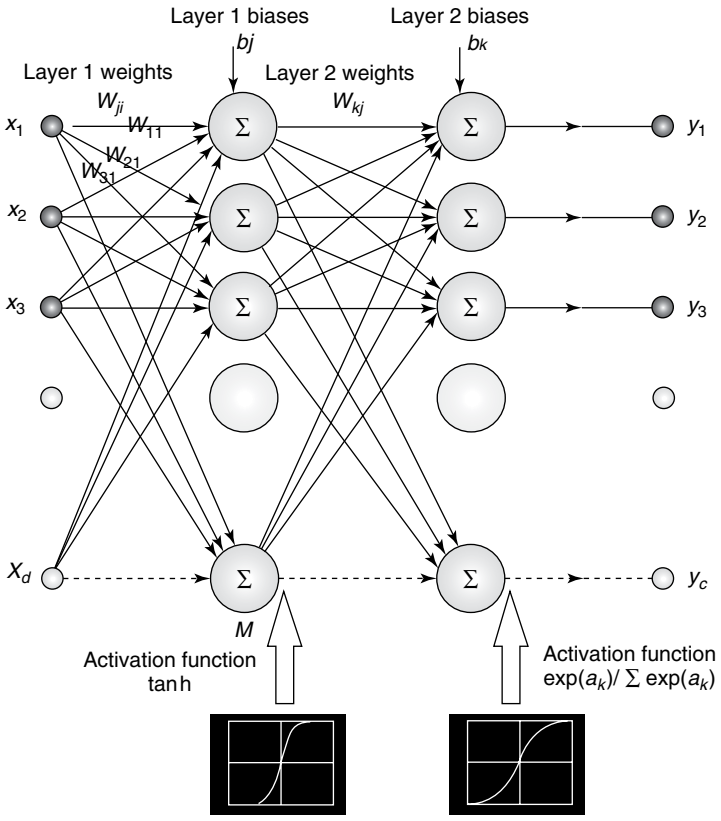

Figure 4. Multilayer perceptron network structure.

4.3 Conventionally trained network results

Traditional network selection was implemented by dividing the data into three equal portions designated the training, validation, and test data sets. The training data were used to train the networks; the best network was then selected from the 1500 possibilities by finding the best classification rate on the validation data set. Finally, the performance of this selected best network was assessed using the test data set. It was found that a network with eight or nine hidden nodes produced an excellent classification performance for a relatively compact network structure.

However, considering that an eight-hidden-node network structure has 161 independent weight and bias components and the total number of training examples was 594 (66 examples of each class), it is very likely that the network structure with eight hidden nodes was likely to possess poor generalization performance. It was for this reason that the maximum network size considered in the present analysis was four hidden nodes, which have 22 independent weight and bias components. This choice of network provides reasonable classification performance on the validation data, whilst maintaining a relatively simple network structure. Using a cross-validation [33] approach to network selection, the best-performing network (with four hidden nodes) from the validation set was selected. This network gave a classification rate of 92.9% when applied to the test data set.

4.4 Interval-based classification networks and network robustness

Having established the network performance to *crisp* (i.e., single-valued) input data, the next step was

to devise a method to investigate the sensitivity of the classification performance of the network to fluctuations in its input data. Quantification of this performance would allow an estimate of the network robustness to be evaluated. Perhaps the most obvious way of performing this analysis would be to use a Monte Carlo approach, randomizing the input data (within certain predefined bounds) and monitoring the associated changes in the output classification performance. This technique has a significant drawback, especially when applied to nonlinear MLP networks, in that it is impossible to be sure of mapping all possible combinations of variation in input space to output space unless an unfeasibly large number of sample points are used. Since interest lies in understanding the worst possible performance of the classifier in the presence of input data uncertainty, a Monte Carlo approach would therefore not provide certainty of behavior under all possible input data conditions. Similarly, the other techniques discussed in the introduction have a similar flaw in that they generate a probabilistic view of the likelihood of the classifier performance with respect to input data fluctuation. It was to circumvent this problem that the input data set was redefined as a series of interval number inputs. Interval numbers [42] occupy a bounded range of the number line, and can be defined as an ordered pair of real numbers $[a, b]$ with $a < b$ such that

$$[a, b] = \{x | a \leq x \leq b\} \tag{7}$$

Interval numbers have specific rules for the standard arithmetic operations of addition, subtraction, multiplication, and division [40].

The MATLAB™ compatible toolbox INTLAB [44] was used to implement the interval calculations required to calculate forward propagation through the MLP networks. This toolbox incorporated a rigorous approach to rounding, which was critical when using finite precision calculations in order to preserve the true conservative interval bounds. Formally, with each network, we associated an input set $I(\beta)$ composed of all possible inputs to the network, the size of the uncertainty was governed by the β parameter. Having defined the input set $I(\beta)$, the output response set $R(\beta)$ of all network outputs was computed. It was then possible to quantify the network reliability in terms of how large a β parameter could be tolerated before a point in the failure set (defined by choosing an appropriate threshold for a performance governing parameter, for example, the worst-case error) was just reached; at this point, β attained a critical value β_{CR}. A large value of β_{CR} was desirable as the network would then be more robust [41].

Each input value x_i of the test data set was intervalized by a parameter β such that

$$[x_{ia}, x_{ib}] = [(x_i - \beta), (x_i + \beta)] \tag{8}$$

Propagation of interval sets through a crisp-valued ANN weight matrix gives rise to interval number outputs. For a regression problem, this is manifest as a set of upper and lower bounds around the true output prediction. However, for a classification problem, it is necessary to introduce some new definitions for the concepts of the confusion matrix and classification rate to be valid.

4.4.1 Defining interval classification rates

For crisp-valued outputs, the designation for a correct classification is if the class with the highest class conditional probability output (the winning class) belongs to the correct target class. If this is not the case, then a misclassification is assigned. The overall classification rate is just the percentage of classifications to total number of data presentations. For an intervalized network output with sufficiently small interval bounds, it would be expected that the classification rate would be the same as in the crisp data situation. The class with the highest bound output remains the winning class (correct or incorrect), and its lower bound is greater than any of the other classes upper bounds. However, as the interval size increases, a point is reached where one (or more) of the losing class upper bounds becomes equal to or greater than the lower bound of the winning class. (The lower bound of the winning class is defined as the *threshold value* for interval-based classification.) At this critical point, it becomes impossible to distinguish between the two (or more) classes, and either (or any) of the classes could be the winner. The best-case classification rate is defined as the percentage of correct classifications, regardless of whether these classifications were unambiguous (only one class identified) or ambiguous (more than one class identified). The worst-case classification rate is

defined as the percentage of unambiguous, correct classifications. In keeping with the framework of Ben-Haim [39, 41], opportunity is defined as the best classification rate minus the crisp classification rate. It is clear that, as the interval size increases, the worst-case classification rate decreases, whilst the best-case classification rate and the opportunity increase.

4.4.2 Interval propagation through conventionally trained network

The network with four hidden nodes, which was previously chosen via the cross-validation approach, was then subjected to the propagation of intervalized data in order to investigate its robustness to data uncertainty. The behavior of this network is shown in Figure 5.

This is a typical information-gap style plot [40, 41], where the opportunity is a measure of how much performance headroom is available to the system if we are prepared to tolerate the presence of uncertainty in the input data. However, for safety-critical systems, we are more likely to be interested in the worst-case classification rate. From such a figure, it is possible to decide on a minimum acceptable classification rate (for example 80%) and then infer the corresponding interval size, which in turn relates to the spread in the input data. For the case of Figure 5, the 80% minimum worst-case classification rate corresponds to an uncertainty in the input data of $\beta_{CR} = 0.01$. Since the interval output set is conservative, we can then guarantee that, if the input set remains within the bound specified by β_{CR}, the output classification rate cannot fall below the minimum specified rate of 80%. In this fashion, the interval forward propagation routine can be used to assess the robustness of an individual network to uncertainty in the input data [45].

4.5 Interval-based network selection

Having established the basis for the definition of classification rates, worst-case error, opportunity, and best-case error applied to interval outputs from an individual network [28], the technique was extended to investigate propagation through multiple networks to appraise the capability of using interval results as a basis for network selection. The same networks trained using the conventional maximum likelihood approach detailed above were investigated. For each particular value of the number of hidden nodes (1–15), the interval forward propagation was evaluated for all 100 individual networks. The range of interval outputs for the worst-case error, opportunity,

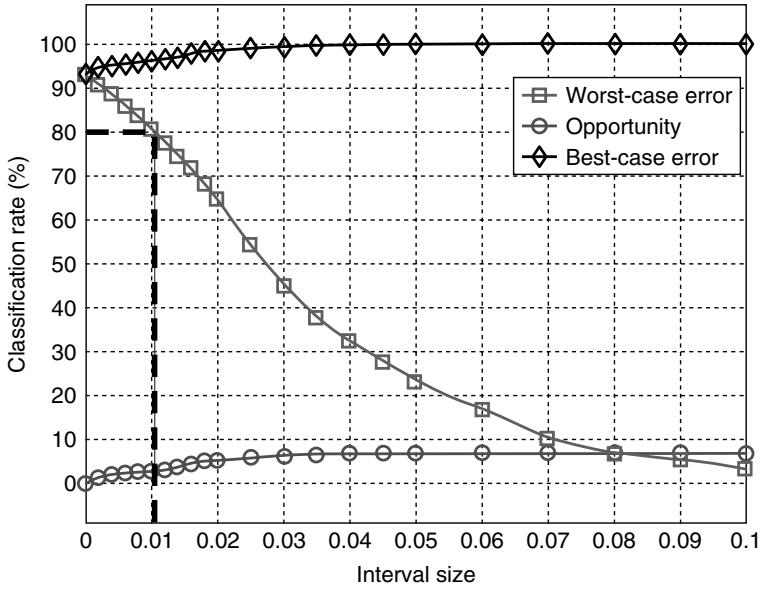

Figure 5. Classification rate as a function of interval size for four hidden node network chosen using cross-validation.

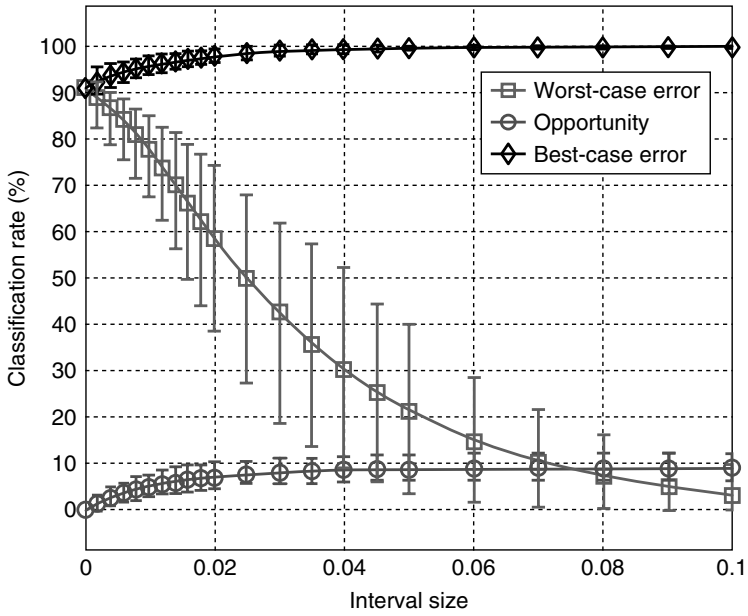

Figure 6. Interval output classification rates as function of interval size for all 100 of the 4 hidden node networks.

and best-case error were then calculated. The results for all 100 of the 4 hidden node networks are shown in Figure 6, where the markers indicate the mean values and the error bars show the range (i.e., the maximum and minimum values) of the three functions.

The most interesting feature of Figure 6 is the large spread in the values of the worst-case error function. For example, at an interval size of 0.02, the worst-case error falls between classification rates of 38.7 and 74.6%. The best-performing network using conventional cross-validation on crisp data, whilst not the worst-performing network, was certainly not the best. The best-performing network in terms of highest worst classification rate varied, depending upon the interval size but a few networks performed consistently well over the entire interval range.

In general, to select the best network in an interval tolerant sense, it is required to set a sensible upper limit on the input uncertainty (the interval size. The best network would then be the one giving the highest worst-case error at this uncertainty level. It is imperative to then check to ensure that this network also provides good performance at lower interval values. In this fashion, when considering interval input data, it is possible to determine a more appropriate choice of network selection criteria than is available using the conventional maximum likelihood training applied to crisp input data.

The merit of the interval-based forward propagation technique lies in two distinct areas. Firstly, it allows the definition of a critical size of uncertainty in the input data set that guarantees that the output classification performance does not fall below a predefined level. This is useful to apply to a single network structure (which could be obtained from any general training technique) to evaluate the robustness of that particular network to uncertainty or noise in the input data. Secondly, and more importantly, an extension of the first technique can be used as an alternative criterion for network selection. It was demonstrated that the worst-case interval output classification rates from conventional MLP networks can be used to find network structures with significantly improved classification performances over their conventional crisp-output counterparts in the presence of input uncertainty or noise. In general, it seems that prior knowledge of the maximum size of the input uncertainty is required to select the optimum network structure.

5 CASE STUDY 2: EVIDENCE-BASED DAMAGE CLASSIFICATION FOR AN AIRCRAFT STRUCTURE

The recent past has seen considerable use of machine learning techniques for SHM. The basic idea of the approach is to use data measured from undamaged and damaged structures in order to train a learning machine to assign a condition label to previously unseen data. The simplest problem of SHM is arguably *damage detection*. This is most easily carried out in the machine-learning context by using a novelty detector [46]. Novelty detection involves the construction of a model of the normal condition of a system or structure, which can then be used in a hypothesis test on unseen data to establish whether the new data corresponds to normal condition or not. The advantage of the novelty detection approach is that it can be carried out using unsupervised learning, i.e., with only samples of undamaged data. If a more detailed diagnosis of a system is required, e.g., if it is necessary to specify the type or location of damage in a structure, this can still be done using machine-learning methods. For higher levels of diagnostics, algorithms based on classification or regression are applicable; however, these must be applied in a supervised learning context and examples of data from both the undamaged and damaged conditions can be used [47].

The most popular classifiers for damage location and quantification so far have been those based on MLP neural networks [31] (although there is growing popularity for classifiers based on the concepts of statistical learning theory—like support vector machines [47]). Training of MLP networks as classifiers is usually accomplished by using the 1 *of M* strategy [31], which implicitly assumes a Bayesian probabilistic basis for the classification. Whilst probability theory is only one (but arguably the most important) of a group of theories that can quantify and propagate uncertainty, other theories of uncertainty, perhaps with the exception of fuzzy set theory, have been largely unexplored in the context of damage identification. The object of this case study is to design a classifier for damage location based on DS theory of evidence [3, 4]. The reason for exploring the possibilities of DS theory is that it *extends* probability in a number of ways, which are potentially exploitable in an SHM context. The current case study is looking only to demonstrate that the method is competitive with the probability-based MLP approach on an experimental case study of an aircraft wing. The DS classifier here is also implemented using a neural network structure [48].

5.1 Dempster–Shafer reasoning

DS theory is a means of decision fusion, which is formulated in terms of probability-like measures but extends probability theory in a number of important respects. The basic idea of *belief* was introduced by Dempster in [3] and extended in Shafer's treatise [4].

The basic model is formulated in similar terms to probability. In the place of the sample space is the *frame of discernment* Θ, which is the set spanning the possible events for observation A_i, where $i = 1, \ldots, N$. On the basis of sensor evidence, each event or union of events is assigned a degree of probability mass or *basic belief assignment* (*BBA*) m such that,

$$0 \leq m(A_i) \leq 1 \quad \forall A_i \subseteq \Theta \tag{9}$$

$$m(\phi) = 0 \tag{10}$$

$$\sum_{A_i \subseteq \Theta} m(A_i) = 1 \tag{11}$$

where ϕ is the empty set. (Note that normalization, as in equation (11), is not always required in belief function theory.) The difference between this *evidential* theory and probability theory is that the total probability mass need not be exhausted in the assignments to individual events. There is allowed to be a degree of *uncertainty* or *ignorance*. This is sometimes denoted by a probability mass assignment to the *whole* frame of discernment $m(\Theta)$ or $m(A_1 \cup \ldots A_N)$.

The *belief* in an event B is denoted by $Be(B)$ and is defined by

$$Be(B) = \sum_{A_i \subseteq B} m(A_i) \tag{12}$$

and this is the total probability, which is committed to the support of the proposition that B has occurred.

The *doubt* in the proposition B is denoted by $Dou(B)$ and is defined by

$$Dou(B) = Be(\sim B) \tag{13}$$

i.e., the doubt is the total support for the negation of the proposition B (negation is denoted by a tilde).

One of the fundamental differences between the DS and probability theory is that the belief and doubt *do not necessarily sum to unity* i.e., it is not certain that $B \cup \sim B$ is true. This is illustrated diagrammatically in Figure 7.

The uncertainty Un in the proposition B is that portion of the probability mass which does not support B *or* its negation. If further evidence were provided, some of the uncertainty could move in support of B but the mass assigned to the doubt *cannot* move. This means that the possible belief in B is bounded above by the quantity $Be(B) + Un(B) = 1 - Dou(B)$ and this quantity is termed the *plausibility* of B and is denoted by $Pl(B)$. The plausibility can also be defined by

$$Pl(B) = \sum_{A_i \cap B \neq \phi} m(A_i) \tag{14}$$

A concrete example will be useful at this point.

Example *Consider a composite structure which may have sustained damage at one of two internal sites A and B which are indistinguishable. It is known that the only possible damage mechanism at site A is delamination (denoted D), but site B may fail by delamination or fiber fracture (denoted F) and the relative probabilities of the damage mechanisms are unknown. It is further known that failure at A is twice as likely as failure at B. What can one say about the likely damage type if a fault is found?*

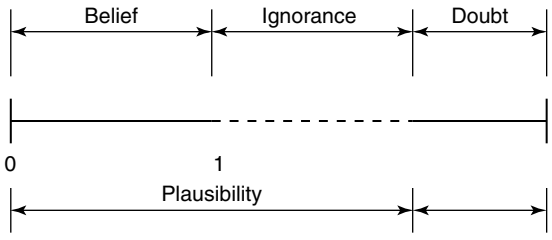

Figure 7. The Dempster–Shafer uncertainty interval.

First of all, if damage occurs at A, it is certainly by delamination and this forces the mass assignment,

$$m(D) = \frac{2}{3} \tag{15}$$

the remaining mass cannot be assigned with certainty, so it is assigned to the frame of discernment,

$$m(\Theta) = m(D \cup F) = \frac{1}{3} \tag{16}$$

The belief in the delamination is simply $Be(D) = 2/3$ *as this is the only basic mass assignment to B. There is no such assignment to F so the belief* $Be(F) = 0$. *The plausibility in D is given by*

$$Pl(D) = m(D) + m(D \cup F) = 1 \tag{17}$$

and the plausibility of F is similarly calculated as 1/3. *The uncertainty interval for D is* [2/3,1] *and that for F is* [0,1/3].

Note that it is not possible to use probability theory here directly as the relative probabilities at site B are not known. It is possible to construct bounds on the probabilities though. Suppose delamination were impossible at site B, then the overall probability of delamination would be 2/3 *and this would be a lower bound. If delamination were certain at B, the overall probability would be* 1. *Note that these quantities are the belief and plausibility respectively. For this reason, the belief and plausibility are sometimes termed the lower and upper probabilities.*

The interpretation of some common instances of the uncertainty interval for a proposition B is as follows:

[0,0] B is impossible.
[1,1] B is certain.
[0.75,0.75] There is no uncertainty. B has a true probability of 0.75.
[0,1] There is total ignorance regarding B.
[0.25,1] B is plausible, there is no support for $\sim B$.
[0,0.75] $\sim B$ is plausible, there is no support for B.
[0.25,0.75] Both B and $\sim B$ are plausible.

All this suffices to establish terminology, to explain how to compute belief functions, and how to interpret the results. It does not provide a means of data

fusion—that requires the use of *Dempster's combination rule* [49].

Suppose that one has two sensors 1 and 2. BPAs are possible on the basis of either sensor alone, denoted m_1 and m_2. Belief functions Be_1 and Be_2 can be computed. Dempster's rule allows the calculation of an overall probability assignment m_+ and a corresponding overall belief function Be_+, where this *direct sum*,

$$Be_+ = Be_1 \oplus Be_2 \tag{18}$$

is induced by m_+. Suppose that sensor 1 makes assignments $m_1(A_i)$ to the proposition A_i (which can, and usually does, include the frame of discernment), and sensor 2 makes assignments $m_2(B_j)$, then Dempster's rule makes assignments as follows.

Consider a matrix with row entries labeled by i and column entries j, then the (i, j)th element of the matrix is an assignment of probability mass $m_1(A_i) \times m_2(B_j)$ to the proposition $A_i \cup B_j$.

This is best understood by an example:

Example *Suppose a classifier is required which can assign a damage type to data from a composite structure. The possible damage types are delamination D, fiber fracture F, matrix cracking M, or fiber pullout P. Two different classifiers are trained, A and B, which produce different probability mass assignments. Classifier A makes the assignments,*

$$m_A(D) = 0.25, \quad m_A(F \cup M) = 0.5, \quad m_A(\Theta) = 0.25 \tag{19}$$

and classifier B returns,

$$m_B(D \cup M) = 0.3, \quad m_B(D \cup F) = 0.4, \quad m_B(\Theta) = 0.3 \tag{20}$$

Dempsters rule induces a mass assignment matrix,

	$m_A(D)$	$m_A(F \cup M)$	$m_A(\Theta)$
$m_B(D \cup M)$	$0.25 \times 0.3 = 0.075$	$0.25 \times 0.4 = 0.1$	$0.25 \times 0.3 = 0.075$
$m_B(D \cup F)$	$0.5 \times 0.3 = 0.15$	$0.5 \times 0.4 = 0.2$	$0.5 \times 0.3 = 0.15$
$m_B(\Theta)$	$0.25 \times 0.3 = 0.075$	$0.25 \times 0.4 = 0.1$	$0.25 \times 0.3 = 0.075$

to the propositions,

	$m_A(D)$	$m_A(F \cup M)$	$m_A(\Theta)$
$m_B(D \cup M)$	D	M	$D \cup M$
$m_B(D \cup F)$	D	F	$D \cup F$
$m_B(\Theta)$	D	$F \cup M$	Θ

and the direct sum m_+ assigns support to the propositions D, M, F, $D \cup M$, $D \cup F$, $F \cup M$, and $\Theta = D \cup M \cup F \cup P$.

The belief in delamination is $Be_+(D) = 0.075 + 0.15 + 0.075 = 0.3$; similarly, $Be_+(M) = 0.1$, $Be_+(F) = 0.2$, and $Be_+(P) = 0$. The plausibility of delamination D is given by

$$Pl_+(D) = m_+(D) + m_+(D \cup M) + m_+(D \cup F) = 0.3 + 0.075 + 0.15 = 0.525 \tag{21}$$

similarly,

$$Pl_+(M) = 0.275, \; Pl_+(F) = 0.45 \; \text{and} \; Pl_+(P) = 0.075 \tag{22}$$

In summary, the uncertainty intervals for the fused belief function are

D	[0.3,0.525]
M	[0.1,0.275]
F	[0.2,0.45]
P	[0,0.075]

The most plausible diagnosis is clearly delamination.

In mathematical terms, Dempster's combination rule is expressed as

$$m_+(C) = \sum_{A_i \cap B_j = C} m_1(A_i) m_2(B_j) \tag{23}$$

and

$$Be_+(C) = \sum_{\substack{i,j \\ A_i \cap B_j = C}} m_1(A_i) m_2(B_j) \qquad (24)$$

Unfortunately, things are not quite as straightforward as this. Problems arise in using Dempster's rule if the intersection between supported propositions A_i and B_j is empty. In this circumstance, a nonzero mass assignment is made to the empty set ϕ and this contradicts the basic definition of the mass assignment, which demands that $m_+(\phi) = 0$. In order to preserve this rule, Dempster's rule *must* assign zero mass to nonoverlapping propositions. However, if this is the case, the probability mass is lost and the total mass assignment for m_+ is less than unity, contradicting another rule for probability numbers. A valid mass assignment is obtained by *rescaling* m_+ to take account of the lost mass. If the mass lost on nonoverlapping propositions totals k, the remaining mass assignments should be rescaled by a factor $K = 1/(1-k)$. The combination rule (23) is modified to

$$m_+(C) = K \sum_{A_i \cap B_j = C} m_1(A_i) m_2(B_j) \qquad (25)$$

Example *Consider the last example. Suppose the assignments made by sensor A were as before, but those of sensor B were now,*

$$m_B(D \cup M) = 0.3, \quad m_B(P \cup F) = 0.4,$$
$$m_B(\Theta) = 0.3 \qquad (26)$$

Dempster's rule gives the same assignments,

	$m_A(D)$	$m_A(F \cup M)$	$m_A(\Theta)$
$m_B(D \cup M)$	$0.25 \times 0.3 = 0.075$	$0.25 \times 0.4 = 0.1$	$0.25 \times 0.3 = 0.075$
$m_B(P \cup F)$	$0.5 \times 0.3 = 0.15$	$0.5 \times 0.4 = 0.2$	$0.5 \times 0.3 = 0.15$
$m_B(\Theta)$	$0.25 \times 0.3 = 0.075$	$0.25 \times 0.4 = 0.1$	$0.25 \times 0.3 = 0.075$

but this time to the propositions,

	$m_A(D)$	$m_A(F \cup M)$	$m_A(\Theta)$
$m_B(D \cup M)$	D	M	$D \cup M$
$m_B(P \cup F)$	ϕ	F	$P \cup F$
$m_B(\Theta)$	D	$F \cup M$	Θ

and a total mass of 0.15 *is lost on the empty set. This means that the assignments should be rescaled by a factor* $K = 1/0.85 = 1.1765$ *(to four decimal places). The mass matrix becomes,*

	$m_A(D)$	$m_A(F \cup M)$	$m_A(\Theta)$
$m_B(D \cup M)$	0.0882	0.1176	0.0882
$m_B(P \cup F)$	0.1765	0.2353	0.1764
$m_B(\Theta)$	0.0882	0.1176	0.0882

and the calculation for the belief functions and uncertainty intervals proceeds exactly as before.

The differences between the DS approach and the probabilistic are now manifest. First of all, probabilistic—or rather Bayesian—approaches are unable to accommodate ignorance. All probability must be assigned to the set of propositions under consideration. Secondly, the Bayesian approach is unable to meaningfully assign probabilities to the union of propositions. If the uncertainty for all propositions is zero and the mass assigned to unions is zero, DS is reduced to Bayesian probability reasoning.

There are other frameworks that seek to extend Bayesian methods in a similar manner to DS such as the generalized evidence processing (GEP) approach of [5] and those proposed in [50, 51].

5.2 The DS neural network

The object of this section is to briefly describe the neural network implementation of the DS-based

classifier. More detail can be found in the original reference [46].

The basic idea is to assign one of M classes $C_1, \ldots, C_M$ (these form the frame of discernment) to a feature vector $\underline{x}$ on the basis of a set of N training examples $\underline{x}_1, \ldots, \underline{x}_N$. Suppose the vector $\underline{x}$ is close to a training example $\underline{x}_i$ with respect to an appropriate distance measure d ($d_i = \|\underline{x} - \underline{x}_i\|$). It is then appropriate that the class of the vector $\underline{x}_i$ influences ones beliefs about the class of $\underline{x}$. One has evidence about the class of $\underline{x}_i$. The approach to the classification taken in [48] is to allocate belief to the event C_q (the class of $\underline{x}_i$, according to the distance d_i).

$$m^i(C_q) = \alpha\phi_q(d_i) \tag{27}$$

where $0 < \alpha < 1$ is a constant and ϕ_q is an appropriate monotonically decreasing function. Each training vector close to $\underline{x}$ contributes some degree of belief. For each training vector, a degree of belief is also assigned to the whole frame of discernment Θ as follows:

$$m^i(\Theta) = 1 - \alpha\phi_q(d_i) \tag{28}$$

The function ϕ used here is the basic Gaussian,

$$\phi_q(d_i) = \exp(-\gamma_q(d_i)^2) \tag{29}$$

where γ_q is a positive constant associated with class q. To simplify matters, one confines the construction of the belief assignment for the vector $\underline{x}$ to a sum of the beliefs induced by its nearest neighbors. The sum is computed using Dempster's combination rule as described in the previous subsection. Actually, a further simplification is made to speed up the processing. Rather than summing over the nearest neighbors from the whole training set in order to assign the belief, one sums over a set of *prototypes* constructed from the training set by a clustering algorithm. Each prototype $\underline{p}_i$ is assigned a degree of membership to the class q denoted by u_q^i with the constraint $\sum_{q=1}^{M} u_q^i = 1$. These are used to compute the belief in the class q for $\underline{x}$ given the distances d_i from the prototypes

Although it is a gross simplification, the algorithm can be summed up as follows:

1. Construct the prototypes $\underline{p}_i$ from the training data using a clustering algorithm.
2. Given a vector $\underline{x}$, compute the distances from the vector to the prototypes. Using the parameters d_i and u_q^i, assign a degree of belief for each class q.
3. Use Dempster's combination rule to compute the total belief in each class from all the contributing prototypes.

The algorithm extends the probabilistic classifier by also making an assignment to the frame of discernment and this quantifies the degree of uncertainty of the classification. Reference [48] explains how the algorithm can be implemented in terms of a four-layer neural network. Unlike an MLP, the network is not a simple feed-forward structure.

In order to assign a class to the vector $\underline{x}$, one selects that with the largest overall belief assignment induced by the training data.

5.3 Damage location example

The same problem that was investigated in the first case study, namely damage location on a Gnat aircraft wing (Figure 2), is revisited in order to compare the evidence-based approach to damage classification with the probabilistic approach. The only significant difference between the data acquisition and signal processing methodology outlined in the previous case study and that used in the current study related to the number of features used. In the previous study, the candidate features were reduced to form a feature set comprising of nine features. In the current study, the candidate features were reduced to form a feature set of four individual features. The best four features were selected from the initial set using a GA to optimize the classification error of an MLP classifier [52]. The reduction to four features was made to ensure that the MLP network used for comparison with the DS network later was unlikely to suffer from overtraining.

By performing the novelty analysis for each of the four features, a data matrix of size $[1800 \times 4]$ was obtained. As before, this was divided into three equal parts to form separate *training, validation*, and *test* data sets for subsequent network evaluation. Finally, the data sets were logarithmically compressed and normalized to -1 to $+1$ before presentation

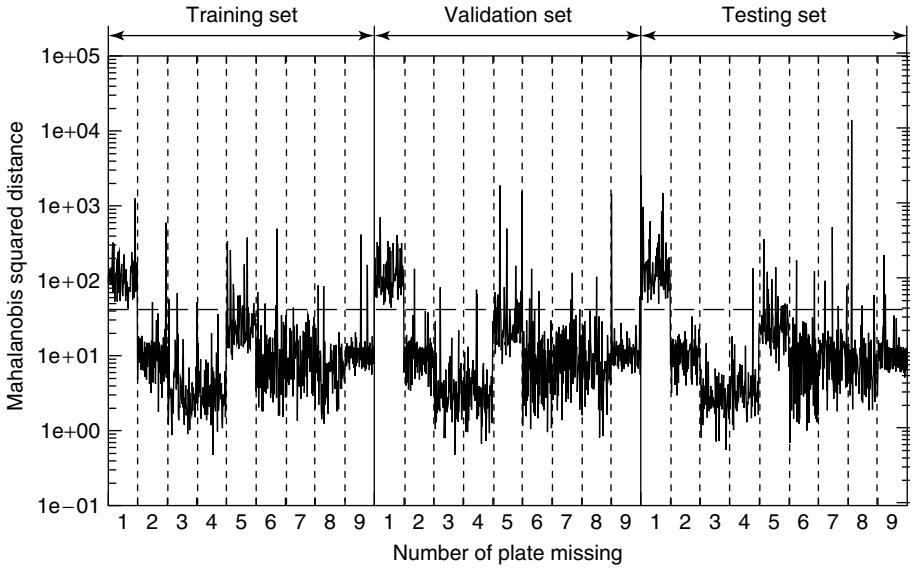

Figure 8. Outlier statistic for all damage states for the novelty detector trained to recognize panel 1 removal.

to the network. Figure 8 shows the results of the outlier analysis for a feature that was clearly able to recognize the removal of inspection panel 1.

The plot in Figure 8 shows the discordancy (novelty index) values returned by the novelty detector over the whole set of damage states. The horizontal dashed lines in the figures are the thresholds for 99% confidence in identifying an outlier; they are calculated according to the Monte Carlo scheme described in [53]. The novelty detector substantially fires only for the removal of panel for which it has been trained. The outputs from the four novelty detectors are then used to form the data with which the damage location classifiers are trained.

5.4 DS network results

The final stage of the analysis was to produce a classifier based on the DS neural network algorithm, which could serve as a damage location system. As with a standard MLP network, the specification of the DS network structure requires hyperparameters; in this case, the number of prototypes (analogous to the number of hidden units in the first layer of the network) and the starting values of the weights before training. These were computed by a cross-validation procedure as for the MLP [54]. Many neural networks were trained with the same training data but with differing numbers of prototypes and initial weights. Up to 30 prototypes were considered, and in each case 10 randomly chosen initial conditions were used. The best network was selected by observing which of them produced the minimum misclassification error on the validation set. The final judgment of the network capability was made by using the independent testing set.

The results for the presentation to the classifier are summarized in the confusion matrix given in Table 1. The best DS network used 29 prototypes. The probability of correct classification was 89.7%. There were four events associated with the frame of discernment, corresponding to a probability mass of 0.007. This means that, allowing for the fact that the network indicates when it has insufficient evidence to make a classification, the classification error is 9.6%. The main source of confusion is in locating damage to the two smallest panels, 3 and 6, which was anticipated.

In order to make a comparison with the standard approach, the algorithm chosen was a standard MLP neural network. The neural network was presented with the same four novelty indices at the input layer and required to predict the damage class at the output layer. The procedure for training the neural

Table 1. Confusion matrix for the best DS network using four log features–testing set

Prediction	1	2	3	4	5	6	7	8	9	Θ
True class 1	54	5	5	0	0	0	2	0	0	0
True class 2	0	63	0	0	2	0	0	0	0	1
True class 3	6	1	56	2	0	0	0	0	0	1
True class 4	5	0	1	55	0	3	0	2	0	0
True class 5	0	0	0	0	65	0	0	1	0	0
True class 6	2	2	2	4	0	54	1	0	0	1
True class 7	0	1	1	0	0	0	61	2	1	0
True class 8	0	0	1	0	1	0	0	62	1	1
True class 9	0	0	0	0	0	0	0	3	63	0

network again followed the guidelines in [54]. The training set was used to establish weights, whilst the network structure and training time etc. were optimized using the validation set. The testing set was then presented to this optimized network to arrive at a final classification error. For the network structure, the input layer necessarily had four neurons, one for each novelty index, and the output layer had nine nodes, one for each class. The training phase used the same 1 of M strategy as in the previous case study.

The best neural network had 19 hidden units and resulted in a testing classification error of 0.108 i.e., 89.2% of the patterns were classified correctly. This means that the misclassification probability is 10.8%. The confusion matrix is given in Table 2. Again, the main errors were associated with the two small panels P3 and P6.

The main conclusion here is that the DS approach to classification implemented as a neural network gives comparable results to the standard analysis using an MLP neural network. The data used are from a full-scale experimental test on an aircraft wing and is therefore a stringent test of algorithms from the point of view of SHM. In fact, the DS network shows a slight improvement, giving a classification probability of 89.7% compared to 89.2% for the MLP. One possible advantage of the DS approach is the fact that it can assign patterns to the frame of discernment and thus indicate to the analyst that there is insufficient evidence to make a classification. Another advantage of using the DS approach might be to provide methodological diversity in order to use data fusion. In this case, the errors made by the DS network and the MLP network are slightly different and therefore there is some advantage to fusion—this is considered in [55].

6 CONCLUSIONS

The purpose of this article was to introduce the many frameworks for the representation of uncertainty and the three uncertainty-related issues of interest in the field of structural dynamics. In order to put these ideas into context, and to showcase the merits of nonprobabilistic treatments of uncertainty, within the area of SHM, two SHM-related case studies were discussed.

Table 2. Confusion matrix for best MLP neural network using four log features–testing set

Prediction	1	2	3	4	5	6	7	8	9
True class 1	61	1	0	0	0	0	1	0	0
True class 2	0	63	0	0	3	0	0	0	0
True class 3	1	0	48	8	0	5	7	2	0
True class 4	0	1	3	56	0	2	0	4	0
True class 5	0	0	0	0	66	0	0	0	0
True class 6	4	1	0	9	0	52	0	0	0
True class 7	1	0	0	0	0	0	59	5	1
True class 8	1	0	0	0	1	0	1	59	4
True class 9	0	0	0	0	0	0	0	5	61

The first case study illustrated how, by taking an alternative approach to the convention technique of neural network selection via cross-validation, the robustness of a network to data uncertainty could be drastically improved. This finding should have implications related to the issue of certification of neural network classifiers and regressors for the purpose of monitoring safety-critical structures. The second case study illustrated that the use of an evidence-based classifier, with its ability to admit ignorance, could reduce the likelihood of misclassifications within an SHM system. This will clearly have both economic and safety-related benefits.

Piezoceramic Materials—Phenomena and Modeling

Jayabal Kaliappan and Srinivasan M. Sivakumar

Department of Applied Mechanics, Indian Institute of Technology, Chennai, India

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

1 INTRODUCTION

Transducers such as piezoceramics play the core role in structural health monitoring (SHM) applications where a sensing cum actuating element that can be embedded to the structure could help. Piezoceramics convert mechanical energy into electrical energy, called the *direct effect*, and electrical to mechanical energy, called the *converse effect* [1]. Their superiority in being tunable to very high rates of loading and being shapeable to any arbitrary shape dominates the transducer market today, which is billing over $10 billion worldwide. The awareness in the requirement of monitoring a structure for its health for both safety and longevity assessment makes these a much sought after material today.

This article deals with piezoceramics focusing on the behavior characteristics, the phenomena realized by these characteristics, the various available forms of the material, and modeling such phenomena. The effects of different loading conditions and varieties of models to describe the reversible and irreversible effects are also presented. Important parameters pertaining to piezoceramics that play a role in design and how they are computed for various shapes of piezoceramics for various applications are explained.

Finally, the article closes with throwing some light on a few critical issues that mar piezoceramics and the research and development efforts that are going on in addressing these issues.

2 BEHAVIOR CHARACTERISTICS—PHENOMENA

In piezoceramics, the piezoelectric property is realized because of the crystal structure the material exhibits. In general, the ABX_3–perovskite structure is observed, where A and B represents cations alkaline earth (Ca, Ba, Sr, etc.) and transition metals (Fe, Ti, Ni, etc.), respectively, and X is oxide halide ion: for example, $BaTiO_3$–Ti^{4+} at the center, Ba^{2+} at the corners and O^{2-} at the center of faces (Figure 1).

The centrosymmetric structure with the transition metal ion present at the center balances the polarization effects that may occur otherwise. For example, at higher temperatures, it exhibits, for example, a cubic structure that is of a high symmetry (centrosymmetry) and exhibits no polarization since the positive metal ion (charge center) coincides with the center of the structure. Such a zero polarization phase is called a *paraelectric phase*. In general, these materials exhibit paraelectric state above a certain temperature called the *Curie temperature*, T_C. Below Curie temperature, the cubic structure becomes unstable giving way to another crystal structure (for e.g., tetragonal structure) of lower symmetry, which is more stable at such temperatures. These structures are typically noncentrosymmetric. The more stable state (maximum entropic state) is achieved in these structures by slight movement away from the center of positive and negative charges leading to remnant polarization. For example, in the barium titanate crystals, at low temperatures, a tetragonal structure becomes more stable and at its natural state, the O^{2-} ions assume a slightly downward position while the Ti^{4+} assumes an upward position. The separation that occurs in the two charge centers (for example, O^{2-} ion charge center and Ti^{4+}, Ba^{2+} ions charge center are separated in the tetragonal state as shown in Figure 1) leads to a spontaneous polarization in the crystal and, therefore, the unit cell. This also induces an associated spontaneous strain. An extensive review of the underlying materials science of piezoceramic materials is available in [2, 3].

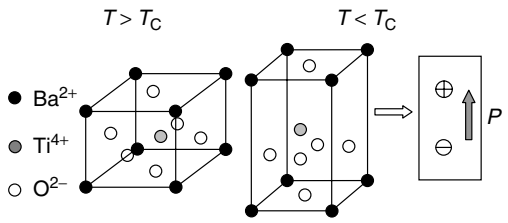

Figure 1. Perovskite structure unit cell—paraelectric and ferroelectric phases.

In the example shown in Figure 1, the lattice length of each side of the cubic structure above the Curie temperature, T_C, is given by a_o, while the lattice lengths of the tetragonal structure that is stable below T_C, are given by a and c. Assuming that the total strain is in the small strain range, the strain that occurs due to spontaneous transformation from the cubic to the tetragonal stage can be written as spontaneous strain $= (c - a_o)/a_o$.

Such a spontaneous strain is realizable only if all the unit cells are aligned along a single direction. In a polycrystal material (described in a later part in this article), the cumulative sum of the spontaneous strains achievable by means of poling (the process of poling is explained in a later section) is less than the spontaneous strain. Such a strain in the polycrystal after poling is called the *remnant strain*. The most popular commercially available piezoelectric ceramic is the lead Zirconate Titanate (PZT) i.e., $Pb(Zr,Ti)O_3$ in which the composition with Zr and Ti components vary in percentage [2]. Depending on the Zr/Ti ratio, the crystal structure of the ceramic, the Curie temperature, and the piezoelectric coupling coefficient, i.e., maximum strain to electrical voltage ratio, vary.

Apart from the PZT ceramics, there are other compositions that show piezoelectric effect and are used in specific applications or for understanding the characteristics of the piezo/ferroelectric phenomena. A lanthanum doping is found to improve the piezo coupling in PZT and such materials are referred to as *PLZT* (lead lanthanum zirconate titanate). One of the main problems with these materials is the lead content, which may prevent its application in biocompatibility applications. The stability of the composition in terms of lead erosion in these materials is important in such applications. One such composition is $BaTiO_3$ (barium titanate).

3 PHENOMENA REALIZED BY THE ABOVE CHARACTERISTICS OF THE FERROELECTRIC MATERIAL

The above description of characteristics provides an understanding of the various ways in which the material could be stimulated for a particular response. In the following, specific effects that come into play at various stimuli conditions and states of material are described. The significant ones are the electrostriction, direct and converse piezoelectric effect, domain switching, etc. While the electrostriction effect is prominent in the paraelectric phase, the other effects such as direct and converse piezoelectricity and domain switching take place in the ferroelectric phase.

3.1 Direct piezoelectric effect

One of the important effects that has significant role in the applications is the direct piezoelectric effect. The first demonstration of the direct piezoelectric effect was done by the brothers Pierre Curie and Jacques Curie. They demonstrated the effect using crystals of tourmaline, quartz, and Rochelle salt. Later, artificial piezoelectric materials were developed to improve the piezoelectric constants many folds and they are called *ferroelectric materials*.

Piezoelectric effect occurs primarily in the ferroelectric phase in which the remnant polarization is present in the lattice structure as shown in Figure 1. The tensile or compressive stress brings about a shift in the charge center (either in terms of further shift for the tensile stress case or closer shift for the compressive stress case). This shift, in turn, alters the polarization in the material (Figure 2). Macroscopically, a charge accumulation occurs at the surface of the material as in the dielectric material, resulting in an electric field. The phenomenon is called the *direct piezoelectric effect*. When the surfaces of positive and negative charges are connected to a potentiometer, a transient potential change is observed. This change per unit separation of the surfaces is a measure of the average electric field produced due to the applied stress. The higher the stress, the higher is the potential change observed. Upon removal of the stress, the charge centers are brought back to their original equilibrium positions. Thus, this effect is reversible. However, in a later section, we have dealt with a critical situation of high stress during which this reversibility could be lost resulting in domain switching. This effect is best understood as a linear and reversible response, i.e.,

$$P = h\,\varepsilon \quad \text{(or)} \quad P = d\,\sigma \tag{1}$$

where h and d are piezoelectric constants. Invoking the relation between stress, σ, and strain, ε, a relationship between the constants h and d can be obtained. This direct piezoelectric effect is used in force/pressure sensor applications owing to noticeable and measurable change in polarization.

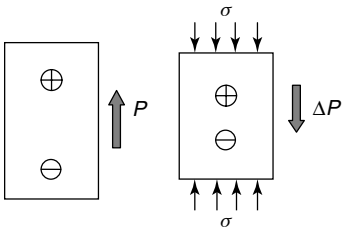

Figure 2. Direct piezoelectric effect.

3.2 Converse piezoelectric effect

As noted earlier, the converse of the above effect is also observed in these materials. When an electric field is applied on a ferroelectric material in its poled ferroelectric phase, a strain is produced because of increased or decreased charge separation that occurs owing to the field (Figure 3). This effect is often referred to as *converse piezoelectric effect*. Depending on the direction of remnant polarization in the ferroelectric phase due to poling, the electric field applied may produce positive or negative strain. It should be noted here that this is a reversible effect meaning that once the field is removed, the strain produced goes to zero. There is, however, a

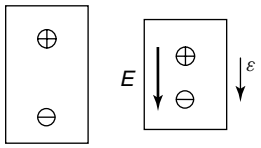

Figure 3. Converse piezoelectric effect.

critical value of strain or stress beyond which the reversibility may be lost. Such a situation is discussed separately as domain switching phenomenon in a forthcoming section. This reversible effect, for a first approximation, can be mathematically expressed as

$$\varepsilon = dE \tag{2}$$

where d is the piezoelectric constant. The linear relationship between the stain, ε, and electric field, E, is found sufficient in most of the situations to describe the converse piezoelectric effect since the strains involved are in the small strain regime. For a detailed treatment of classical linear piezoelectricity, the reader is referred to [4–7].

This effect occurs in the ferroelectric phase, i.e., when there is a spontaneous polarization in the unit cell (due to an existing separation in the charge centers). This charge separation is important in this effect since a nearly linear and reversible effect is realized. Depending on the direction of the forcing electric field, the strain is either positive or negative. However, this effect is quite different from another effect commonly known as the *electrostrictive effect* encountered in these materials in their paraelectric phase. In the electrostrictive effect, which is described in the next section, strains are always positive, since there is no directional effect found in that phase unlike the directional effect produced by the spontaneous polarization in the ferroelectric phase. Converse effect is used in many actuator applications.

3.3 Electrostriction

Electrostriction is noticed prominently in the paraelectric phase where charge centers coincide even without external field. The deformation induced is due to the separation of the positive and negative charge centers from each other that happens owing to an external electric field under equilibrium conditions. It is interesting to note that the reverse phenomenon does not occur here, i.e., upon application of a deformation, no electric displacement is produced.

When the electric field, E, is applied in one direction, the positive and the negative charge centers separate and this separation causes strain in the material to maintain equilibrium. When the electric field is removed, the configuration reverts back to the original one where the charge centers coincide. Thus, this effect is reversible even for fairly large electric fields. Since the reversal of electric field also produces charge separation from zero separation, the resulting configuration due to the applied electric field is always of one sign as shown in Figure 4. Thus, deformation is the same in both cases for a given magnitude of electric field, E. This effect can be expressed by

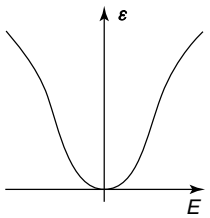

Figure 4. Electrostrictive effect.

$$\varepsilon = qE^2 \tag{3}$$

where q is the *electrostrictive constant.* This can be directly derived from the Coulomb's law of electrostatics.

Though the electrostrictive effect is observed in most of the materials, they are too weak for technical applications. In some applications, electrostrictive transducers are preferred over piezoelectric transducers owing to their minimal hysteresis and aging effects. However, their temperature-dependent and nonlinear saturation effects are to be taken into account while designing control systems.

3.4 Domain switching

The phenomenon of domain switching described here plays a major role in the nonlinear and hysteretic behavior of the material. When the temperature falls below the Curie temperature, the material transforms from cubic crystallographic structure to another structure such as tetragonal, orthorhombic, and rhombohedral, depending on the temperature and the composition of the material. While the cubic state is stable above the Curie temperature, the other less-symmetric state is stable below the Curie temperature. During this transition, the material transforms from a paraelectric phase to a ferroelectric phase as described in the introductory section. In general,

a single cubic unit cell can transform into any of multiple configurations of the other less-symmetric state that is energetically motivated [8]. One such example involving cubic to tetragonal transformation is discussed below. In the absence of any forcing field, electrical and stress, during the transition, every one of the configurations of the less-symmetric state formed is a preferred configuration and, therefore, this leads to the formation of equal proportions of each of these configurations leading to a net zero polarization although each of the configurations or the variants exhibit a spontaneous polarization. Such a state of the material is usually referred to as a *thermally depoled ferroelectric state*. The group of unit cells with the same polarization direction is referred to as a *domain*.

We use the transition from a cubic to a tetragonal state as an example to explain this. When the cubic structure transforms to tetragonal structure, it can assume any of the six orientations as shown in Figure 5. Since there is no preference to any one of the orientations under the purely thermal cooling, equal proportions of the six orientations are expected. Generally, as noted earlier, groups of unit cells of the same polarization (domains) form separated by domain walls. Domain walls separating two orientations of opposite polarizations and domain walls separating domains with polarization 90° apart are shown in Figure 6. Application of a forcing field large enough will induce a domain to switch to another. This can also be thought of as movement of the domain wall in the crystal. Such a phenomenon is called *domain switching*. This domain switching brings about permanent irreversible change in the net polarization and net strain of a group of domains

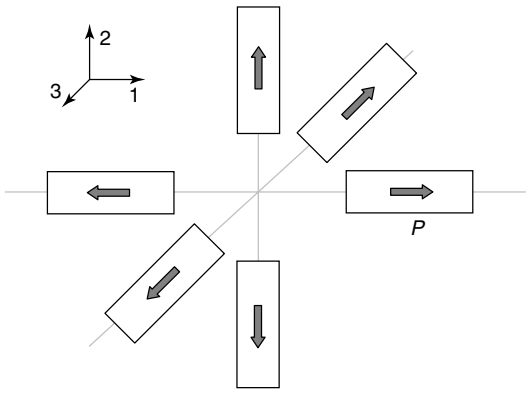

Figure 5. Domain switching for a tetragonal lattice.

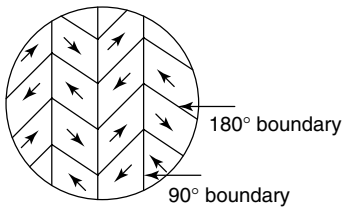

Figure 6. Domains and their boundaries.

in question. During this process of switching, some amount of energy is dissipated in the movement of the domain walls and related mechanisms.

When the domain switching is induced by the electric field, a domain may switch to any of the other five domains such that the polarization direction of the switched domain is the most favorable to the external electric field. Hence, an electric field can induce either a 90° switching or a 180° switching in a unit cell depending upon the direction of the electric field and the orientation of polarization in the unit cell. The electric field at which domain switching is initiated in a ferroelectric material from a poled state is referred to as *coercive electric field* and it is a material-dependent property. However, the electric field producing zero net polarization that is easily obtainable without ambiguity from the experimental plots is often referred to as the *coercive electric field* in some of the literature [9]. The other way to induce domain switching in a ferroelectric material is the application of stress. The stress sufficient enough will force the domains to reorient in such a way that their polarization direction is normal to the direction of stress. Hence, unlike the electric field, stress can produce only 90° domain switching and for any given domain all the four 90° switching are equally probable on application of stress. The compressive stress at which domain switching starts occurring in the ferroelectric material is called the *coercive stress*. This coercive stress is an important property of the material that should be paid enough attention to while designing the transducers.

The crystallographic orientation of tetragonal unit cell remains the same and only the polarization direction inside the unit cell reverses during 180° switching. Hence, 180° switching is associated with only polarization change and the strain due to switching is zero. However, during 90° switching, since both the crystallographic orientation and the polarization direction of the unit cell change, 90°

switching causes both strain and polarization change [10]. Domain switching is primarily responsible for nonlinear behavior of ferroelectric material.

4 BEHAVIOR UNDER DIFFERENT LOADING CONDITIONS

Response of ferroelectric materials under different loading conditions assumes significance from a design point of view. When the material is in a completely depoled state, it can be considered to be macroscopically, though not microscopically, isotropic. As discussed before, an electric field can pole the material in a specific direction from a depoled state. The response of ferroelectric materials under cyclic electric fields with superimposed constant stresses are reported in the literature [10–12] and one such behavior in terms of electric displacement versus electric field is shown in Figure 7. For small electric fields, the ferroelectric material behaves linearly and as the electric field reaches the coercive electric field, nonlinearity is introduced through microscopic domain switching. Once the domain switching saturates, the linear relationship is retained again where the increment in polarization is very small with respect to electric field. During unloading, the ferroelectric material reaches the remnant polarization at zero electric field. In this state, the ferroelectric material can be treated to be a transversely isotropic material since the plane normal to the remnant polarization direction of the ferroelectric material is the plane of symmetry or the transverse plane. Reversing the electric field

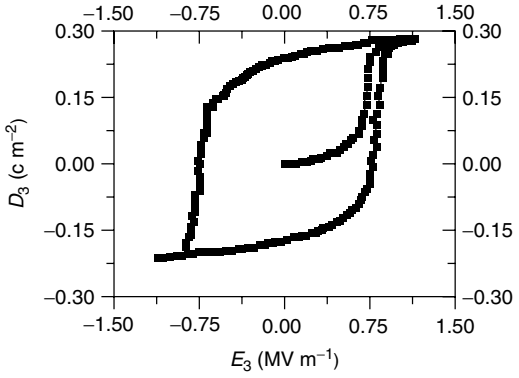

Figure 7. Response regimes and the related switched domains in hysteresis response [11].

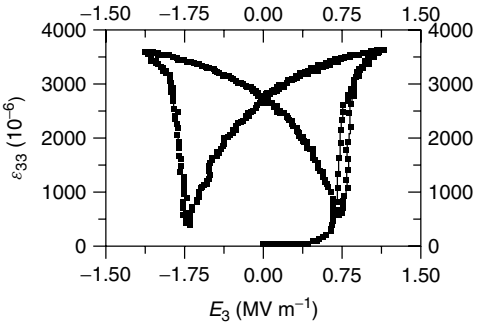

Figure 8. Response regimes and the related switched domains in the butterfly curve [11].

causes the domains to switch in the opposite direction causing a macroscopic polarization change. Remnant polarization obtained during reversal of negative electric field equals the magnitude of the positive remnant polarization but with opposite sense. Hence, the piezoelectric constants determined at the positive and negative remnant polarization states will have the same magnitude but opposite sense.

During cyclic electric field, the dependence of the normal strain on the applied field is shown in Figure 8 [11]. The virgin state of the material is taken as the reference state and the subsequent change in dimensions are measured with respect to that reference state. For small increments in the field, the strain is negligible. As the electric field crosses the coercive electric field, appreciable strain is observed. The increment in the normal strain is due to two reasons: irreversible reorientation of unit cells in the direction of the electric field and the reversible piezoelectric effect of the switched domains. After the switching reaches the saturation state, only reversible strain is present in the material and this is realized during unloading. The strain present in the material after unloading represents the remnant strain and the ferroelectric material behaves linearly in this state for small magnitudes of electric field. This property has widely been exploited for transducer applications.

5 EFFECT OF GRAIN SIZE, TEMPERATURE, AND FREQUENCY

With the advancement that has taken place in the manufacturing process, ferroelectrics possessing

a variety of grain sizes can be developed. It is observed that the ferroelectric property depends also on the grain size. The domains become smaller with decrease in grain size and the width of the domains is roughly proportional to the square root of the grain size for a specific range (between 1 and 10 μm). As the grain size decreases, the multiple domain state may become a single domain state. Finer grain ferroelectrics produce decreased hysteresis and the maximum strain value decreases monotonically with reduction in grain size for the same electric field [13, 14]. This may be due to the pinning effect by the grain boundaries that prevents the easy movement of domain walls. It has been observed in pure $BaTiO_3$ at room temperature that when the particle size decreases below a critical value, about 0.2 μm, c/a ratio of the tetragonal structure falls drastically and the tetragonality is lost at about 0.12 μm [15]. With reduction in grain size, the electrostrictive strain also decreases in relaxor ferroelectrics (discussed later in this section) for the same applied electric field [16]. Hence, the grain size is an important determinant that would influence the electrical and mechanical properties of the ferroelectric and efforts are made to control it depending upon the requirement. Particle size, chemical composition, and heating process are primarily responsible for controlling grain size and the optimum conditions are to be experimentally determined.

As mentioned before, Curie temperature of ferroelectrics vary depending upon its composition. Below Curie temperature, with the ferroelectric phase, the material has appreciable hysteresis and as it moves closer to the paraelectric phase, the hysteresis decreases. On reaching Curie temperature, the hysteresis completely disappears as shown in Figure 9. Hence, when the ferroelectric phase is used in the transducer design for a specific application, considerable care is to be taken to ensure that the operating temperature does not reach the Curie temperature. Otherwise, the ferroelectric will lose its piezoelectric behavior resulting in the failure of the device. Increase in the rate of application of electric field results in a higher coercive electric field. With the loading rate, the hysteresis loop between the polarization and the electric field widens and the butterfly loop between the strain and electric field gets broader with a decreased strain [17]. The reason for the ferroelectrics experiencing lesser strain under higher loading rate than the quasi-static loading is due to the less availability of time for the domains to switch completely in the former case. Even with the mechanical stress, the response is rate dependent, i.e., faster the loading rate bigger is the hysteresis in the stress–strain loop [17].

For most compositions of piezoceramics, the dielectric properties do not vary greatly with frequency, but a special type of ferroelectrics called the *relaxor ferroelectrics* has the tendency to vary the permittivity as a function of temperature and frequency [18]. The composition of a widely used relaxor ferroelectric is $Pb(Mg_{1/3}Nb_{2/3})O_3$ (PMN). Relaxor ferroelectrics have high permittivity and are hence primarily used in compact chip capacitors. Their high electrostriction coefficient with less hysteretic dissipation renders them more attractive to actuator applications.

6 MODELS FOR FERROELECTRIC MATERIALS

The response of ferroelectric materials under different loading conditions should be accurately predictable to incorporate them in the measurement type devices and precision instruments. Among the many models proposed for describing the behavior of the material, linear models suffice for most of the applications. For low-to-moderate input fields, the dielectric and strain relations with the electric field and mechanical stress can be considered to be practically linear. The

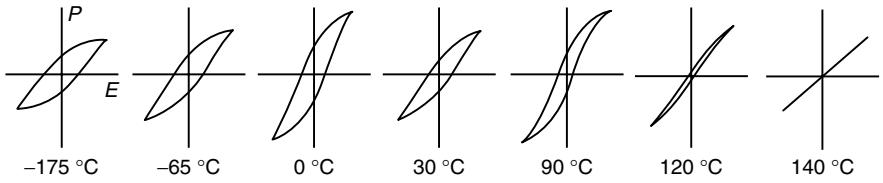

Figure 9. Variation of the size of the hysteresis curve with temperature [Courtesy: DoITPoMS, University of Cambridge].

linear model representing the piezoelectric behavior is represented by

$$P_k = d_{kij}\sigma_{ij} + \kappa_{km}E_m$$
$$\varepsilon_{ij} = S_{ijkl}\sigma_{kl} + d_{mij}E_m \tag{4}$$

$$\begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \varepsilon_4 \\ \varepsilon_5 \\ \varepsilon_6 \\ \hline P_1 \\ P_2 \\ P_3 \end{bmatrix} = \left[\begin{array}{cccccc|ccc} S_{11} & S_{12} & S_{13} & 0 & 0 & 0 & 0 & 0 & d_{31} \\ S_{12} & S_{11} & S_{13} & 0 & 0 & 0 & 0 & 0 & d_{31} \\ S_{13} & S_{13} & S_{33} & 0 & 0 & 0 & 0 & 0 & d_{33} \\ 0 & 0 & 0 & S_{44} & 0 & 0 & 0 & d_{15} & 0 \\ 0 & 0 & 0 & 0 & S_{44} & 0 & d_{15} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & S_{66} & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & d_{15} & 0 & \kappa_{11} & 0 & 0 \\ 0 & 0 & 0 & d_{15} & 0 & 0 & 0 & \kappa_{11} & 0 \\ d_{31} & d_{31} & d_{33} & 0 & 0 & 0 & 0 & 0 & \kappa_{33} \end{array}\right] \times \begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \sigma_4 \\ \sigma_5 \\ \sigma_6 \\ \hline E_1 \\ E_2 \\ E_3 \end{bmatrix} \tag{5}$$

where $\boldsymbol{S}$ is the elastic compliance tensor, $\boldsymbol{d}$ the piezoelectric coupling tensor, and $\boldsymbol{\kappa}$ the dielectric susceptibility tensor. As can be seen in equation (4), the number of constants involved in the material properties is high and they can be considerably reduced by invoking elastic and electric symmetries. For the lowest macroscopic symmetry, i.e., a thermally or electrically depoled state, there are 21 elastic constants, 18 piezoelectric constants, and 6 dielectric constants considering a tetragonal crystal structure. Since the ferroelectric materials are primarily used in their piezoelectric region, i.e., after poling is done in a specific direction, they can be considered to be transversely isotropic, which is a higher symmetry state macroscopically. Hence, the total number of constants required in the piezoelectric linear analysis can be reduced to just 10 consisting of 5 elastic constants, 3 piezoelectric constants, and 2 dielectric constants. Thus, the linear relationship for piezoelectric ceramics described in equation (4) can be represented in a compact form as given in equation (5).

As discussed earlier, the ferroelectric material behaves nonlinearly under higher electric field and stress. Owing to complex geometry requirements in the design of ferroelectric devices and operating conditions, the material may be exposed to electric field and stress, beyond their critical values, affecting the performance of the devices. In addition, owing to lack of fracture resistance, the ferroelectric ceramic experiences cracks at electrode interfaces, within the ceramic layers, and near the electrode tips. In linear analysis, the effect of switching on the fracture toughness of the material is ignored [19]. Hence, the electromechanical fields that are determined using linear analysis are considerably different from those of nonlinear analysis since the latter includes the switching process happening near the crack tip [20–23]. Hence, the nonlinear models are necessary to capture the ferroelectric behavior more realistically in order to design the ferroelectric devices more accurately.

To capture the nonlinearity, many models have been proposed and reported in literature [9, 24, 25]. They can broadly be classified as phenomenological models and micromechanical models. Phenomenological models are generally derived within the framework of irreversible thermodynamics. The state of the material is defined by internal variables at any given time and the evolution of these internal variables is determined by the kinetic equations [26–30]. Remnant strain and remnant polarization are the generally used internal variables in this approach and they define the irreversible state of the material. Some of the phenomenological models use plasticity approach in which the electric yield surface and stress yield surface are developed and the material's macroscopic reversible behavior occurs within these surfaces. When domain switching takes place in the material, the switching surface displays an irreversible change due to variation in the remnant strain and remnant polarization. During switching, the switching surface expands or moves depending upon the hardening rule that determines the evolution of the new surfaces. The phenomenological models are computationally effective and the implementation of these into the finite element formulation is simple. These finite element formulations are then used to predict the performance of ferroelectric devices and to analyze the fracture process in the material. The flip side of the phenomenological models is that they need experiment-dependent constants as

they do not involve microscopic mechanism of the material.

The other classification of models, micromechanical models, is based on the internal microstructure and the microscopic switching mechanisms [10, 31–35]. In these models, each grain with a single domain or multiple domains is considered for modeling and is allowed to switch when the ferroelectric grain meets some switching criterion. The criterion may be based on work done, total potential, Gibb's energy, and internal energy density [10, 32, 36–39]. The driving force for each increment of electric field and stress is calculated and checked for the switching criterion and on satisfying the criterion, the existing domains are converted to another set of domains that are favorable to the external forcing fields. The macroscopic material behavior is obtained by microscopic averaging of the individual grains or domains. Though it is computationally costly preventing it from being as popular as phenomenological models, it has some advantages over the latter models. Since the material constants are related to the microstructure of the ferroelectric materials, the microscopic models are independent of the experiments. The material response under loading conditions that are difficult to conduct in the lab can be predicted through these models. A combination of phenomenological and micromechanical models may deliver the advantages of both, for instance, the saturation strain and saturation polarization of the ferroelectric materials under specific loading conditions are calculated using micromechanical models and are given as input to the phenomenological models to gain the computational edge.

However, in general, as discussed earlier, the piezoceramics are employed within their linear region only. When unconstrained, the piezoceramic produces strain in all the directions under the influence of electric field, and hence, the material experiences no stress; however, as the deformation of the material is constrained, it exhibits enormous force on the constraining element, which is used for actuation purposes. By rearranging the linear relationship discussed in the preceding section, the stresses developed in the piezoceramic can be determined as follows:

$$\sigma_{ij} = S^{-1}_{ijkl}\varepsilon_{kl} - \boldsymbol{e}_{ijk}E_k \tag{6}$$

Table 1. Material constants of a few ferroelectric materials widely studied in literature [43]

	PZT-4	PZT-5H	PZT-6B	$BaTiO_3$

where, $\boldsymbol{e} = \mathrm{S}^{-1}d^T$, the modified piezoelectric coupling tensor. From equation (6), the stress developed in the piezoceramic can be determined when a specific quantity of strain is restrained. Also, it is apparent from equation (6) that the stress in the piezoceramic becomes zero when the deformation is allowed to take place freely. Some typical properties of various parameters involved in the constitutive models are given Table 1.

7 IMPORTANT DESIGN PARAMETERS IN PIEZOCERAMICS

Many parameters defining the piezoelectric properties relevant to practical applications play an important role in the piezoelectric devices. A few of those figures of merit are discussed here [40]. For the given applied electric field, E, the value of strain, ε, produced is determined by *piezoelectric strain constant*, d, which is an important property for actuator applications.

$$\varepsilon = dE \tag{7}$$

The electric field developed in the material due to external stress, σ, is represented by *piezoelectric voltage constant*, g, which is used for sensor

applications.

$$E = g\sigma \tag{8}$$

The relationship between the piezoelectric strain and piezoelectric voltage constants can be obtained as $g = d/\kappa$, where κ is called *dielectric permittivity*.

Another important figure of merit is the *electromechanical coupling factor*, f, which is defined as the ratio of the stored mechanical energy in the piezoelectric material to the given input electrical energy. It can also be defined as the ratio between the stored electrical energy and the given mechanical energy input. For mathematical ease, the electromechanical coupling factor is taken as

$$f^2 = \text{stored mechanical energy/input electrical energy} \tag{9}$$

$$\text{Mechanical energy stored} = \frac{1}{2}\varepsilon\sigma = \frac{1}{2S}\varepsilon^2 = \frac{1}{2S}(dE)^2 \tag{10}$$

$$\text{Input electrical energy} = \frac{1}{2}\kappa E^2 \tag{11}$$

$$f^2 = \frac{\frac{1}{2S}(dE)^2}{\frac{1}{2}\kappa E^2} = \frac{d^2}{\kappa S} \tag{12}$$

Electromechanical coupling factor indicates only the energy stored in the material and not the useful work done by it. Hence, another figure of merit is required to denote the amount of actual work done for the given input energy and that is referred to as the *energy transmission coefficient*, λ.

$$\lambda = \text{output mechanical energy/input electrical energy (or)} = \text{output electrical energy/input mechanical energy} \tag{13}$$

The relationship between the electromechanical coupling factor (f) and the energy transmission coefficient (λ_{max}) can be obtained as

$$\lambda_{max} = \left[\frac{1}{f} - \sqrt{\frac{1}{f^2} - 1}\right]^2 \tag{14}$$

Mechanical quality factor, Q, is an important parameter to evaluate the resonant strain and resonance spectrum of the given ceramic. The off-resonance strain can also be determined using the mechanical quality factor at the resonance frequency and the inverse of mechanical quality factor defines the *mechanical loss*. The mechanical quality factor is defined with the resonance frequency, ω_0, as

$$Q = \frac{\omega_0}{2\Delta\omega} \tag{15}$$

When the wave energy is transferred between two mediums, a part of it is transmitted and the rest is reflected back. The ratio of reflected energy to transmitted energy depends upon an important parameter called *acoustic impedance*, Z, and the transmission is complete if the acoustic impedance of the materials is matching.

$$Z = \sqrt{\rho M} \tag{16}$$

where ρ is the density and M is the elastic stiffness of the material.

A simple application of piezoelectric ceramic is the gas igniter. When force is applied on piezoelectric material, it produces very high voltage that is sufficient to ignite the gas. Given the resonance time period of the piezoelectric material considered for the igniter, its required length can be determined by a simple calculation as follows. The resonance frequency, ω_r, and the length, L, are related by $\omega_r = 1/L$, where ω_r is expressed in kilohertz and L in meter. For example, if the resonance time period, t_r, is 20 μs, then

$$\omega_r = \frac{1}{t_r} = \frac{1}{20\,\mu s} = \frac{1}{20 \times 10^{-6}\,s} = 50\,\text{kHz} \tag{17}$$

$$L = \frac{1}{\omega_r} = \frac{1}{50} = 0.02\,\text{m} = 20\,\text{mm} \tag{18}$$

When the electric field is applied, the piezoelectric ceramic experiences a strain, and on alternating the

field, the material vibrates. As the frequency of the driving electric field matches the resonance frequency of the device, the magnitude of the strain of the ceramic becomes very large and this phenomenon is known as *piezoelectric resonance*. This phenomenon is exploited in vibrators. Piezoelectric resonance is understood due to the accumulation of the input energy in the material. The internal energy, U, of the piezoelectric vibrator is the addition of mechanical and electrical energies.

$$\begin{aligned} U_{\text{Total}} &= U_{\text{M}} + U_{\text{E}} \\ &= \frac{1}{2}\varepsilon\sigma + \frac{1}{2}PE \end{aligned} \tag{19}$$

Using the linear relationship of ε and P on E and σ as discussed before,

$$U_{\text{Total}} = \frac{1}{2}[S\sigma^2 + dE\sigma] + \frac{1}{2}[d\sigma E + \kappa E^2] \tag{20}$$

where, pure mechanical energy, U_{M}, and pure electrical energy, U_{E}, are represented by

$$U_{\text{M}} = \frac{1}{2}S\sigma^2 \quad \text{and} \quad U_{\text{E}} = \frac{1}{2}\kappa E^2 \tag{21}$$

and the energy transduced, U_{trans}, from mechanical to electrical or vice versa is represented by

$$U_{\text{trans}} = \frac{1}{2}dE\sigma \tag{22}$$

The electromechanical coupling factor for piezoelectric vibrator is defined as

$$f = \frac{U_{\text{trans}}}{\sqrt{U_{\text{M}}U_{\text{E}}}} \tag{23}$$

For example, the electromechanical coupling factor with certain elastic boundary conditions for the resonator shape shown in Figure 10 can be derived as follows. The displacement of the ferroelectric material along the axis 1 is used for actuation as the electric field is applied along the axis 3. The ceramic exhibits strain in all the directions, but the stress will be developed only along the axis 1, since the actuation is done in that direction. Hence, the electromechanical coupling factor for this specific actuation or vibration mode can be obtained as

$$f_{31} = \frac{\frac{1}{2}d_{31}E_3\sigma_1}{\sqrt{\frac{1}{2}S_{11}\sigma_1^2 \times \frac{1}{2}\kappa_{33}E_3^2}} = \frac{d_{31}}{\sqrt{S_{11}\kappa_{33}}} \tag{24}$$

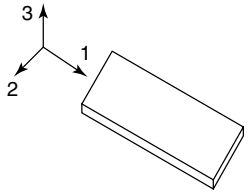

Figure 10. Piezoelectric resonator shape.

The electromechanical coupling factor for various resonator shapes under different elastic boundary conditions are listed in [40]. In piezoelectric vibrators, the size and shape of the device are also significant in addition to the piezoelectric material and the vibration mode at which the resonance is produced. In general, the piezoelectric ceramic with higher mechanical quality factor is desirable for vibrators and hence, the harder piezoelectric materials.

Current trends in the actuator applications are in exploring and using the electrostrictive effect of high permittivity materials since they have specific advantages over piezoelectric actuators. As discussed earlier, the strain produced by the electrostrictive effect is always positive irrespective of the direction of the electric field applied. The electrostrictive actuators, operating above Curie temperature, do not contain domains and hence, return to their original position after the removal of the electric field and do not suffer from aging problems. Hence, the materials showing strong electrostrictive effects are gaining more interest despite the fact that their electrostrictive effect is not as strong as the piezoelectric effect.

8 APPLICATIONS

The piezoelectric behavior of ferroelectric ceramics, i.e., generation of high voltage and detection of acoustic and ultrasonic energy, are widely exploited in developing electromechanical actuators and sensors [8, 40, 41]. A piezoelectric solid-state ceramic actuator converts the electrical energy directly into a linear motion. A piezoelectric ceramic sensor converts the mechanical energy directly into an electrical charge. Large force actuation, microsecond

range response, and insensitivity to magnetic field are some of the major advantages of piezoceramic transducers. High-resolution ferroelectric ceramic actuators can provide incremental motion ranging from a few microns to subnanometers with almost negligible backlash. Micro- and nanopositioning are the key factors in semiconductor industry and in medical diagnostics. Another important characteristic of PZT actuators is that they exhibit consistent performance even after a large number of cycles. Ferroelectric ceramics are used from simple gas igniters to complex scanning microscopy and precision machining. The ultimate usage of piezoceramics lies in *SHM,* which is a nondestructive evaluation technique. The recent developments in the piezo devices and piezo composites cause a remarkable improvement in SHM systems [42].

The main challenge in incorporating the piezoelectric or electrostrictive materials in the actuator devices is the small displacements produced by them on application of low or medium electric fields. For example, 1 kV applied across a poled ferroelectric strip of 1 mm thickness with a piezoelectric coupling coefficient of 0.5×10^{-9} C/N will produce only 0.5-μm displacement. Hence, with these small displacements, the ferroelectric actuator devices should be able to produce the required actuation strain. One way of achieving the more demanding strain is through stacking of ferroelectric materials by connecting the alternate layers without allowing a short circuit between the adjacent layers as shown in Figure 11. The main advantage of this multilayer arrangement, which is widely used in actuator devices, is the generation of high displacement with low driving voltage and high electromechanical coupling.

Except for some applications, even this summed up displacement is not sufficient to produce the required strain. Also, the stack actuation results in larger size of the device, which is undesirable in some applications like MEMS (micro-electromechanical systems) where the size of the device counts. To overcome the drawback of the low actuation strain in multilayer actuators, the piezoelectric plates are bonded with the elastic plates to produce large strains utilizing the bending displacement. In such a bimorph, the ferroelectric beams may be poled in the same direction or in the opposite direction and the placement of electrodes in between the beams and the measurement of voltage through them depends on the way the ferroelectric beams are poled. Bimorph actuators produce more strain than the stack actuators, but with low response time and generative forces. A compromise between stack actuation and bimorph is obtained through the composite actuator structure called *Moonie*, which develops the strain that is one magnitude higher than that of stack actuators and larger generative forces in less response time when compared to bimorphs.

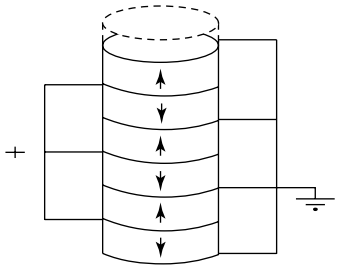

Figure 11. Stack actuation.

When the ferroelectric ceramics are used as sensors, they are generally brought under two major classes as passive and active sensing/sampling. In passive sampling, the ferroelectric sensors detect the perturbations due to ambient conditions that are not introduced artificially. These measurements may be for a single value that occurs as maximum during the operation like the maximum strain or a continuously varying data like acceleration and ambient frequency response of dynamic systems. Active-sensing systems require the externally supplied energy that is generated specifically for sensing purpose.

An important field effectively using ferroelectric ceramics both as sensors and actuators is *nondestructive evaluation techniques*. Owing to the impurities present in the material and the manufacturing process, flaws are likely to occur in the materials and it is mandatory to check for the magnitude of defects before the material is put in use. Also, when the material or structure is in service, it is essential to check for any possible degradation of its performance to avoid drastic failure of the system. The manufacturing process of the material can be optimized and the quality of service of the structure can be ensured through nondestructive techniques. Nondestructive techniques involving ferroelectric materials make use of different concepts like ultrasonic, eddy current, and radiography to examine the state of the structure. The piezoceramic transducers may be

pasted on the surface of the material or embedded within the material through complex manufacturing process. When the embedded piezoceramic is driven by an electric pulse, it transmits ultrasonic waves in a wide range of frequency. A conventional scanning probe receives the signal from the structure to check for flaws developed owing to environmental and operational reasons. This way, not only the condition of the materials under probe but also the piezoceramic actuators can be checked. In case of radiography, a harmonic excitation is given to the piezoceramic and the thermal field output is visualized through an infrared camera. In eddy-current method, the actuator, driven by a harmonic electric source, produces electromagnetic field, which is detectable by external sensors.

SHM is the extension of nondestructive evaluation techniques and is the process of implementing active damage-detection strategy for aerospace, civil, and mechanical engineering infrastructures. SHM involves the measurements of inputs to and the response of the structure using piezoelectric transducers in order to predict the onset of damage and deterioration in the structural condition. This provides a path for the transition from a schedule-based maintenance practice to condition-based maintenance.

9 CONCLUSIONS

The wide range of applications of piezoelectric ceramics in sensing and actuation devices demands more usage of them, especially the *PZT*. The main challenge in employing piezoceramics for actuation over other smart materials like shape memory alloys lies in the quantity of strain they produce under external loads. A simple way to overcome this concern is through stack actuation, but at the cost of the size of the device. Also, there is an increasing demand for the restricted use of piezoceramics containing lead owing to the growing awareness on health and environmental problems associated with lead content in materials. One possible solution that addresses both problems lies with the utilization of the nonlinear range that enhances greater potential for their use in applications that demand higher performance. To deal with the nonlinearity in the design of the devices in the applications, models that are capable of predicting the piezoelectric ceramics more precisely and accurately in their nonlinear region, under variety of loading conditions, becomes necessary. This also helps in overcoming the hesitation in designer's approach to dealing with the nonlinear behavior, providing a new dimension to the usage of piezoceramic materials.

Chapter 41

Constitutive Modeling of Magnetostrictive Materials

Srinivasan Gopalakrishnan

Department of Aerospace Engineering, Indian Institute of Science, Bangalore, India

1 INTRODUCTION

Some magnetic materials show elongation and contraction in the magnetization direction owing to an induced magnetic field. This is called *magnetostriction*, which is due to the switching of a large amount of magnetic domains caused by spontaneous magnetization below the Curie point of temperature. Thus, magnetostrictive materials have the ability to convert magnetic energy into mechanical energy and vice versa. This coupling between magnetic and mechanical energies represents the transudation capability and this allows a magnetostrictive material to be used in both actuation and sensing devices. Owing to magnetostriction and its inverse effect (also called *Villery effect*) [1], magnetostrictive materials can be used both as an actuator and as a sensor. The theoretical and experimental study of magnetostrictive materials has been the focus of considerable research for many years. However, only with the recent development of giant magnetostrictive materials (e.g., Terfenol-D), it is now possible to produce sufficiently large strains and forces to facilitate the use of these materials in actuators and sensors. This has led to the application of magnetostrictive materials to devices such as micropositioners, vibration controller, sonar projectors and insulators, etc. Magnetostrictive material has found its way in many structural applications such as vibration control, noise control, and structural health monitoring.

The constitutive relationship of magnetostrictive materials consists of a sensing and an actuation equation. In the sensing equation, magnetic flux density is a function of applied magnetic field and stress, whereas, in actuation equation, strain is a function of applied magnetic field and stress. Both sensing and actuation equations are coupled through applied magnetic field and mechanical stress level. The compliance matrix in the actuation law depends on the magnetic field, while the permeability matrix in the sensing law depends on the measured stress.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

Hence, unlike the piezoceramic material, both the sensing and actuation law cannot be uncoupled. For evaluating all the material constants in the constitutive law, both sensing and actuation laws have to be solved simultaneously. For each magnetic field, there are different stress–strain curves and for each stress level, there are different magnetostriction–magnetic field curves, which are highly nonlinear. There are very few works reported in the literature toward this direction. Small sets of data provided by the manufacturer [2] are highly inadequate for modeling and analysis of structures with built-in magnetostrictive sensors. Hence, there is need to numerically characterize the constitutive model so that the material data can be generated for all magnetic fields and stress levels. This is the main focus of this article.

Analysis of smart structures with magnetostrictive material is generally performed using uncoupled models. Uncoupled models are based on the assumption that the magnetic field within the magnetostrictive material is proportional to the electric coil current times the number of coil turns per unit length (Ghosh and Gopalakrishnan, 2002). Owing to this assumption, the actuation and the sensing equations get uncoupled. For the actuator, the strain due to magnetic field (which is proportional to coil current) is incorporated as the equivalent nodal load in the finite element model for calculating the block force. Thus, with this procedure, analysis can be carried out without taking the smart degrees of freedom in the finite element model. Similarly, for sensor, where generally coil current is assumed as zero, the magnetic flux density is proportional to mechanical stress, which can be calculated from the finite element results through postprocessing. This assumption on magnetic field leads to the violation of flux line continuity, which is one of the four Maxwell's equations in electromagnetism. On the other hand, in the coupled model, it is considered that magnetic flux density and/or strain of the material are functions of stress and magnetic field, without any additional assumption on magnetic field, like the uncoupled model. Benbouzid *et al.* modeled the static [3] and dynamic [4] behavior of the nonlinear magnetoelastic medium for magnetostatic case using finite element method. Magnetomechanical coupling was incorporated considering both permeability and elastic modulus as functions of stress and magnetic field. However, all these works do not provide a convenient way for analysis of magnetostrictive smart structure considering coupled magnetomechanical features. This article deals with the numerical characterization of the constitutive relationship considering the coupled features of magnetostrictive materials, which can be directly used in any mathematical/numerical formulation such as finite element method for structures with magnetostrictive material considering both magnetic and mechanical degrees as unknown degrees of freedom. In addition, it is shown that the magnetic field is not proportional to applied coil current (which is the assumption of the uncoupled model) and depends on the mechanical stress on the magnetostrictive material. This study here also demonstrates how the coupled model preserves the flux line continuity, which is one of the drawbacks of the uncoupled model.

The constitutive relations of magnetostrictive materials are essentially nonlinear [2]. The prediction of the behavior of magnetostrictive material, in general, is extremely complicated owing to its hysteretic nonlinear character. In structural application, owing to these nonlinear material properties, modeling of the system becomes nonlinear, for which exact nonlinear constitutive relationships are essential. Toupin [5] and Maugin [6] had done extensive work related to electrostrictive and piezoelectric phenomena, which have similarities in form with the magnetostriction phenomena. Earlier study to model uncoupled nonlinear actuation of magnetostrictive material was done by Krishnamurty *et al.* [7] by considering a fourth-order polynomial of magnetic field for each stress level. In this approach, for the stress level for which the curve is not available, the coefficients of the curve have to be interpolated from the coefficients of the nearest upper and lower stress level curves.

The numerical characterization of the nonlinear-coupled constitutive model can be performed by expanding the magnetic flux density and strain variations as higher order polynomials, the constants of which can be computed from the data supplied by the manufacturer [2] for different magnetic fields and stress levels through an iterative procedure. Alternatively, the numerical characterization of the constitutive law can be performed using a back propagation (BP) artificial neural network (ANN) and this uses the data supplied by the manufacturer. This procedure completely avoids the nonlinear iteration, and is readily amenable for implementation alongside any finite element code. Here, one three-layer ANN is

trained using the data supplied by the manufacturer, to get this nonlinear mapping directly. ANN is a universal approximator, which can give a nonlinear parameterized mapping from a given input data to an output data. In this study, ANN is used to get the direct mapping for the constitutive relationship of magnetostrictive materials, where inputs in the network are magnetic field and applied stress level and outputs in the network are the strain and the magnetic flux density. Hence, nonlinearity in elastic modulus and permeability is replaced by this trained network. Both these approaches are demonstrated in this article.

The article is organized as follows. In the next section, the complete architecture of the ANN developed for this work is explained, which includes the process of training and validation of network. This is followed by a detailed section on the numerical characterization of linear and nonlinear coupled and uncoupled constitutive models. Finally, the developed models are validated with each other and also with available results.

2 ARTIFICIAL NEURAL NETWORK (ANN)

ANNs can provide nonlinear parameterized mapping between a set of inputs and a set of outputs with unknown function relationship. A three-layer network (Figure 1) with the sigmoid activation functions can approximate any smooth mapping. A typical supervised feedforward multilayer neural network is called as a *back propagation* neural network. The structure of a BP neural network shown in Figure 1 mainly includes an input layer for receiving the input data; some hidden layer for processing data; and an output layer to indicate the identified results. In this study, the task of identifying nonlinear magnetostriction through ANN is performed by training the neural network using the known samples.

2.1 Training of the network

The training of a BP neural network is a two-step procedure [8]. In the first step, the network propagates input through each layer until an output is generated. The error between the output and the target output is then computed. In the second step, the calculated error is transmitted backward from the output layer and the weights are adjusted to minimize the error. The training process is terminated when the error is sufficiently small for all training samples. In practical applications of the BP algorithm, learning is the result from many presentations of these training examples to the multilayer perceptron. One complete presentation of the entire training set during the learning process is called an *epoch*. The learning process is maintained on an epoch-by-epoch basis until the synaptic weights and bias levels of the network stabilize and the averaged squared error over the entire training set converges to some minimum value. For a given

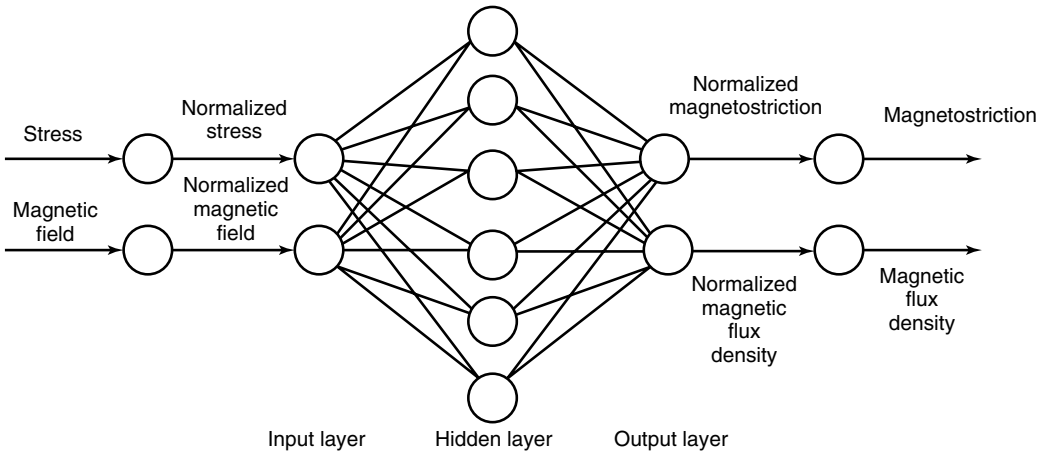

Figure 1. Artificial neural network architecture.

training set, BP learning can be done in a sequential or batch mode.

2.2 Validation of trained network

To validate the trained network, the data set is separated into two parts, one for training and the other for testing the network performance. The network is trained using training sample and the trained network is validated with the test sample. A network is said to generalize well when the input–output mapping computed by the network is corrected with the test data that was never used in creating or training the network. Although the network performs useful interpolation, because of multilayered perceptrons with continuous activation functions, it leads to output functions that are also continuous.

3 ANHYSTERETIC-COUPLED CONSTITUTIVE MODEL

Here, experimental data is taken from Etrema manual [2] for Terfenol-D, a giant magnetostrictive material to verify the proposed model. Experimental data of the magnetostriction versus magnetic field for different stress level given in the manual is reproduced in Figure 2 and the stress versus strain curves for different magnetic field level are reproduced in Figure 3.

The application of magnetic field causes strain in the magnetostrictive material (Terfenol-D) and hence the stress, which changes magnetization of the material. As described by Butler [2], Moffett *et al.* [9], and Hall and Flatau [10], the three-dimensional coupled constitutive relationship between magnetic and mechanical quantities for magnetostrictive material is given by

$$\{\varepsilon\} = [S^{(H)}]\{\sigma\} + [d]^T\{H\} \tag{1}$$

$$\{B\} = [\mu^{\sigma}]\{H\} + [d]\{\sigma\} \tag{2}$$

where $\{\varepsilon\}$ and $\{\sigma\}$ are strain and stress, respectively. $[S^{(H)}]$ represents elastic compliance measured at constant $\{H\}$ and $[\mu^{(\sigma)}]$ represents the permeability measured at constant stress $\{\sigma\}$. Here, $[d]$ is the magnetomechanical coupling coefficient, which provides a measure of the coupling between the mechanical strain and magnetic field. In general, $[S]$, $[d]$, and $[\mu]$ are nonlinear as they depend upon $\{\sigma\}$ and $\{H\}$. Equation (1) is often referred to as the *direct effect* and equation (2) is known as the *converse effect*. These equations are traditionally used for actuation and sensing purpose, respectively. It should be noted that the elastic constants used correspond to

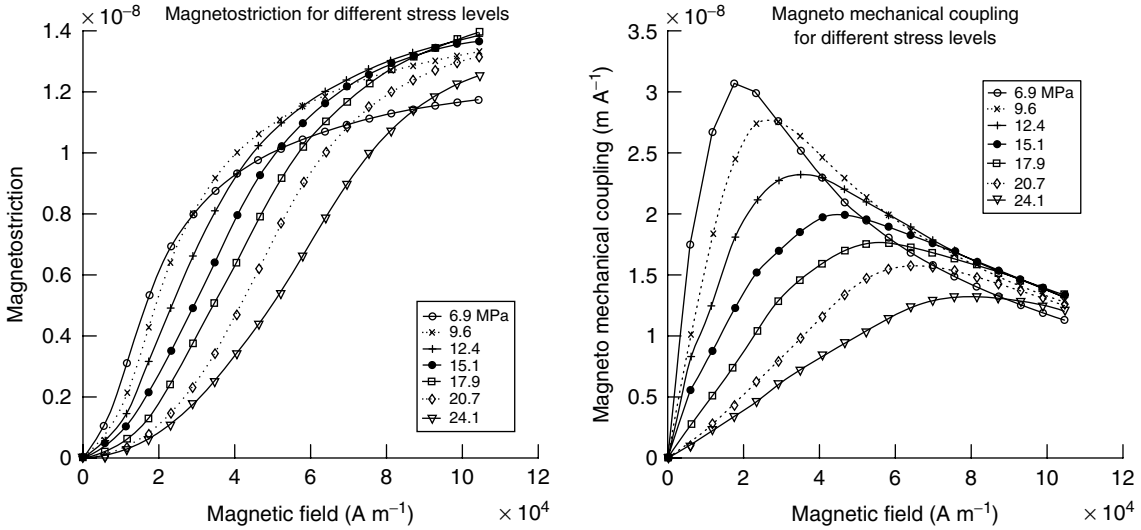

Figure 2. Magnetostriction and magnetomechanical coupling as a function of magnetic field data plotted from Etrema data.

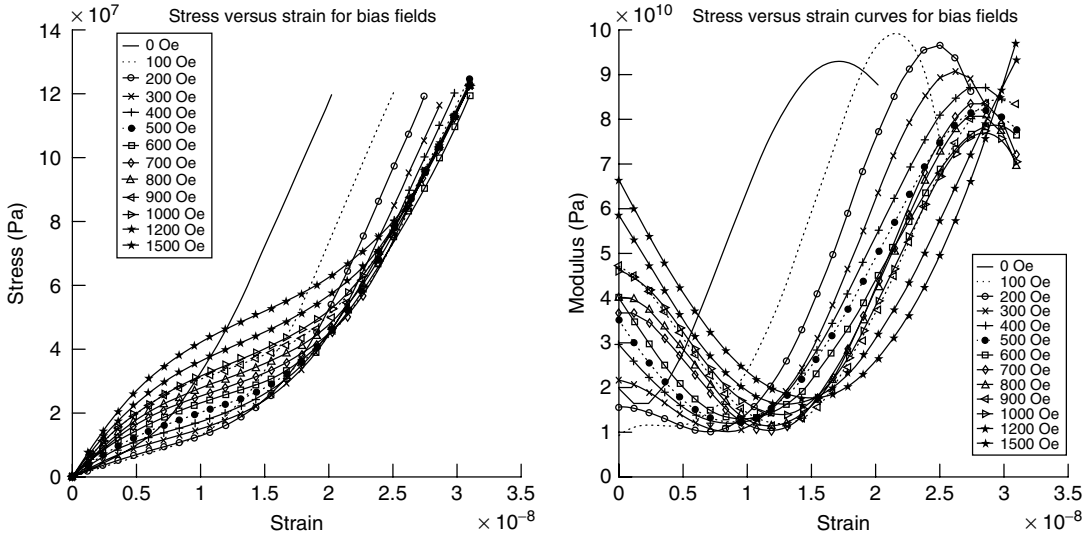

Figure 3. Stress–strain relationship for different magnetic field data plotted from Etrema data.

the fixed magnetic field values and the permeability corresponds to the fixed stress values.

3.1 Coupled constitutive model

Analysis of smart structures using magnetostrictive materials as either sensors or actuators has traditionally been performed using uncoupled models. Uncoupled models make the assumption that the magnetic field within the magnetostrictive material is constant and proportional to the electric coil current times the number of coil turns per unit length [11]. Hence, actuation and sensing problems are solved by two uncoupled equations, which are given by the last part of equations (1) and (2), respectively. This makes the analysis relatively simple; however, this method has its limitations. It is quite well known that $[S]$, $[d]$, and $[\mu]$ all depend on the stress level and magnetic field. In the presence of mechanical loads, the stress changes and so does the magnetic field. Estimating the constitutive properties using the uncoupled model in such cases gives inaccurate predictions. Hence, the constitutive model should be represented by a pair of coupled equations given by equations (1) and (2) to predict the mechanical and magnetic response. It is therefore necessary to simultaneously solve for both the magnetic response and the mechanical response, regardless of whether the magnetostrictive material is being used as a sensor or an actuator. Owing to in-built nonlinearity, the uncoupled model may not be capable of handling certain applications such as (i) modeling passive damping circuits in vibration control and (ii) development of self-sensing actuators in structural health monitoring. In these applications, the coupled equations require to be solved simultaneously. The simultaneous solution of coupled equations is a necessity for general-purpose analysis of adaptive structures built with magnetostrictive materials.

In general, the errors that result from using uncoupled models, as opposed to coupled ones, are problem dependent. There are some cases where very large differences exist in situations where an uncoupled model is used over a coupled model [11]. In this work, the coupled case is analyzed with both linear and nonlinear models. In the linear-coupled model, magnetomechanical coefficient, elasticity matrix, and permeability matrix are assumed as constants. In the nonlinear-coupled model, mechanical and magnetic nonlinearity are decoupled in their respective domains. The nonlinear stress–strain relationship is generally represented by the modulus of elasticity and the nonlinear magnetic flux–magnetic field relationship is represented by the permeability of the material. Magnetomechanical coupling coefficient is assumed as constant in this case.

3.1.1 Linear model

From equation (1) and equation (2), the 3-D constitutive model for the magnetostrictive material can be written as

$$\{\sigma\} = [Q]\{\varepsilon\} - [e]^T\{H\} \tag{3}$$

$$\{B\} = [e]\{\varepsilon\} + [\mu^\varepsilon]\{H\} \tag{4}$$

where $[Q]$ is elasticity matrix, which is the inverse of compliance matrix $[S]$, and $[\mu^\varepsilon]$ is the permeability at constant strain. $[\mu^\varepsilon]$ and $[e]$ are related to $[Q]$ through

$$[e] = [d][Q] \tag{5}$$

$$[\mu^\varepsilon] = [\mu^\sigma] - [d][Q][d]^T \tag{6}$$

For ordinary magnetic materials, where magnetostrictive coupling coefficients are zero, $[\mu^\varepsilon] = [\mu^\sigma]$, the permeability.

Consider a magnetostrictive rod element of length L, area A, with Young's modulus Q. If a tensile force F is applied, the rod develops a strain ε, and hence stress σ. Total strain energy in the rod is

$$V_s = \frac{1}{2}\int \varepsilon\sigma \,\mathrm{d}v = \frac{1}{2}\int \varepsilon\{Q\varepsilon = e\mathbf{H}\}\,\mathrm{d}v$$
$$= \frac{1}{2}(ALQ\varepsilon^2 = ALe\varepsilon\mathbf{H}) \tag{7}$$

Magnetic potential energy in the magnetostrictive rod is

$$V_M = \frac{1}{2}\int B\mathbf{H}\,\mathrm{d}v = \frac{1}{2}\int \{e\varepsilon + \mu\mathbf{H}\}\mathbf{H}\,\mathrm{d}v$$
$$= \frac{1}{2}AL\mathbf{H}e\varepsilon + \frac{1}{2}AL\mu^\varepsilon\mathbf{H}^2 \tag{8}$$

The magnetic and mechanical external work done for N number of coil turns with coil current I is

$$W_m = IN\mu^\sigma\mathbf{H}A, \tag{9}$$

$$W_e = F\varepsilon L \tag{10}$$

The total potential energy of the system is $T_p = -(V_e - W_e) + (V_m - W_m)$

$$T_p = -\frac{1}{2}ALQ\varepsilon^2 + \frac{1}{2}ALe\varepsilon\mathbf{H} + \frac{1}{2}AL\mathbf{H}e\varepsilon$$
$$+ \frac{1}{2}AL\mathbf{H}\mu^\varepsilon\mathbf{H}^2 - IN\mu^\sigma\mathbf{H}A + F\varepsilon L \tag{11}$$

Using Hamilton's principle, two equations in terms of $\mathbf{H}$ and ε can be written as

$$-ALQ\varepsilon + ALe\mathbf{H} + FL = 0 \tag{12}$$

$$ALe\varepsilon + ALe\mathbf{H} + FL = 0 \tag{13}$$

Dividing both equations by AL, the equations will become

$$-Q\varepsilon + e\mathbf{H} = -\frac{F}{A} \tag{14}$$

$$e\varepsilon + \mathbf{H}\mu^\varepsilon = -\frac{F}{A} \tag{15}$$

As the right-hand side of equation (15) is not a function of ε and the left-hand side is magnetic flux density (equation 4), the magnetic flux density in this model is not a function of ε. Hence, it is preserving the flux line continuity. Eliminating $\mathbf{H}$ from equation (14) and substituting this in equation (15), stress–strain relationship of the magnetostrictive material can be written as follows:

$$\mathbf{H} = (Q\varepsilon - F/A)/e \tag{16}$$

$$\varepsilon = \frac{IN\mu^\sigma Ae + L\mu^\varepsilon F}{ALe^2 + AL\mu^\varepsilon Q} = \frac{IN\mu^\sigma eA + F\mu^\varepsilon L}{AL\mu^\sigma Q} \tag{17}$$

From equation (17), the total strain for applied coil current I and tensile stress F/A can be written as

$$\varepsilon = \lambda + \varepsilon\sigma \tag{18}$$

where λ is the strain due to coil current, which is called the *magnetostriction* and ε_σ is the strain due to tensile stress (elastic strain).

$$\lambda = \frac{IN\mu^\sigma Ae}{AL\mu^\sigma A} = \frac{INd}{L} \tag{19}$$

$$\varepsilon_\sigma = \frac{L\mu^\varepsilon F}{AL\mu^\sigma Q} = \frac{F}{AQ^*} \tag{20}$$

Let Q^* be the modified elastic modulus, and substituting the value of e and μ^ε from equation (5)

and equation (6), Q^* will be

$$Q* = \frac{Q\mu^\sigma}{\mu^\varepsilon} = \frac{Q\mu^\sigma}{\mu^\sigma - d^2 Q} = Q + \frac{e^2}{\mu^\varepsilon} \quad (21)$$

If the value of μ^σ is much greater than d^2Q, μ^ε can be assumed as equal to μ^σ and $Q*$ can be assumed as equal to Q. If the value of μ^σ is much greater than d^2Q, the total strain of the rod is the same as for the uncoupled model. The first term in the above expression is the strain due to magnetic field, and the second term is the strain due to the applied mechanical loading. However, for Terfenol-D [2], the value of d^2Q is comparable with μ^σ. Substituting the value of strain from equation (17) in equation (16), the value of magnetic field is

$$\mathbf{H} = \frac{F}{Ae}\left(1 - \frac{\mu^\varepsilon}{\mu^\sigma}\right) + \frac{IN}{L} \quad (22)$$

Note that although the magnetostriction value (INd/L) in equation (19) is the same for coupled and uncoupled cases, the value of magnetic field is different. Let r be the ratio of two permeabilities or two elastic modulii. From equation (21), r can be written as

$$r = \frac{\mu^\sigma}{\mu^\varepsilon} = \frac{Q^*}{Q} \quad (23)$$

If the value of r is 1, the results of coupled analysis are similar with uncoupled analysis. In Figure 4, the value of r is shown in contour plot for different values of constant strain permeability and modulus of elasticity for coupling coefficient of $15 \times 10^{-9}\,\mathrm{m\,A^{-1}}$. In Figure 4(a), the value of r is shown for different values of permeability and elastic modulus. In Figure 4(b), the value of r is shown for different values of permeability and modified elasticity. In these plots, it is clear that for a particular value of elasticity, if the value of permeability increases, the value of r will decrease. However, for a particular value of permeability, if the value of elastic modulus increases, the value of r will increase. In Figure 5, the value of r is shown in contour plot for different value of permeabilities and coupling coefficient, considering the modulus of elasticity as 15 GPa. In Figure 5(a), value of r is given for different values of constant strain permeability and coupling coefficient. In Figure 5(b), the value of r is shown for different values of constant stress permeability and coupling coefficients. In these plots, it is clear that for a particular value of permeability, if the value

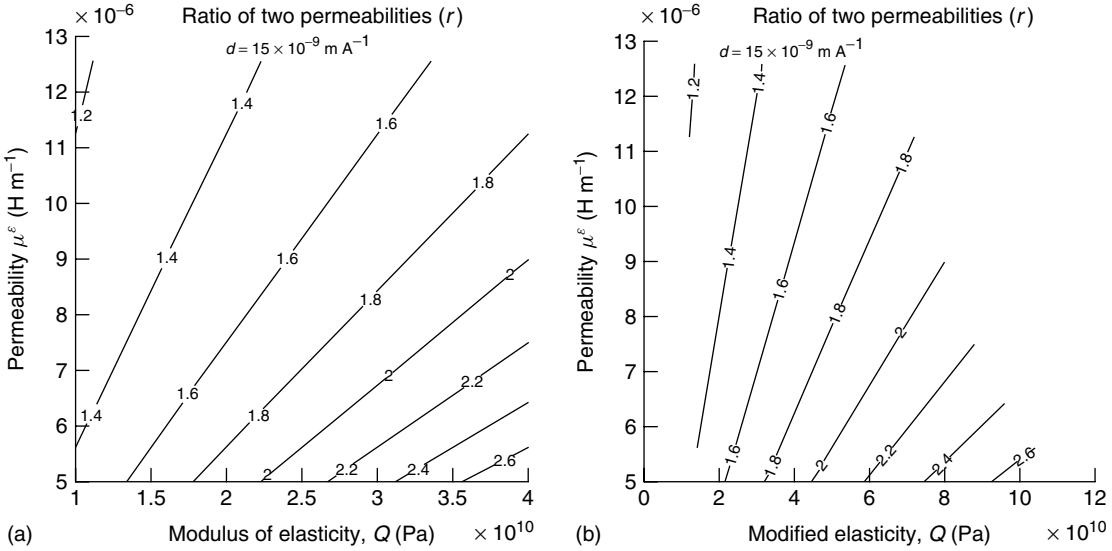

Figure 4. Ratio of two permeabilities (r): permeability versus modulus of elasticity (a) and permeability versus modified elasticity (b), for $d = 15 \times 10^{-9}\,\mathrm{m\,A^{-1}}$.

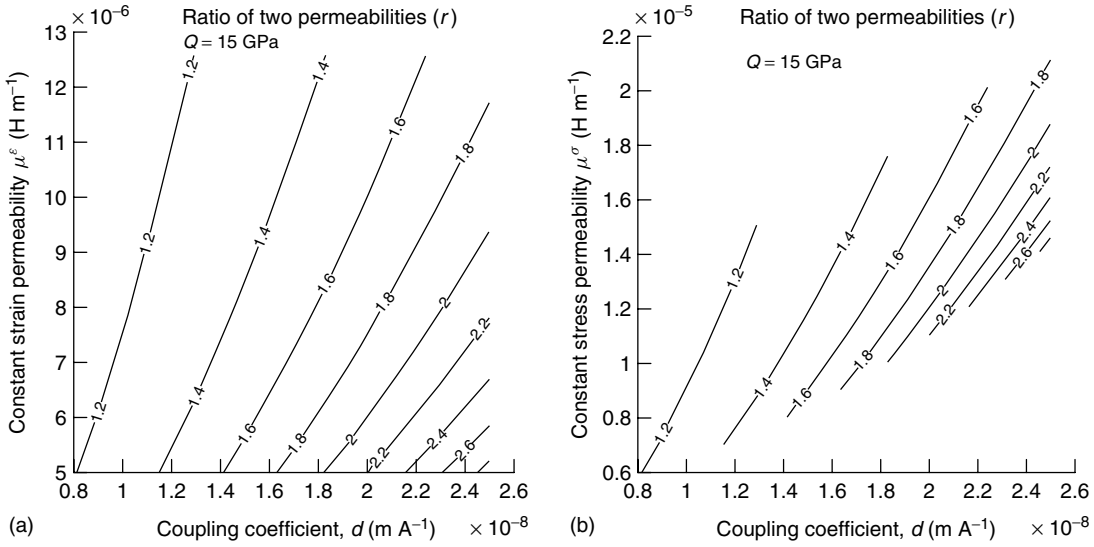

Figure 5. Ratio of two permeabilities (r): permeability versus coupling coefficients (a) and constant stress versus coupling coefficients (b), for $Q = 15$ Gpa.

of coupling coefficient increases the value of r will increase. However, for a particular value of coupling coefficient, if the value of permeability increases the value of r will decrease.

In Figure 6, the value of r is shown in contour plot for different value of elastic modulus and coupling coefficient considering constant strain permeability as $7 \times 10^{-6}\,\mathrm{H\,m^{-1}}$. In Figure 6(a), the value of r is

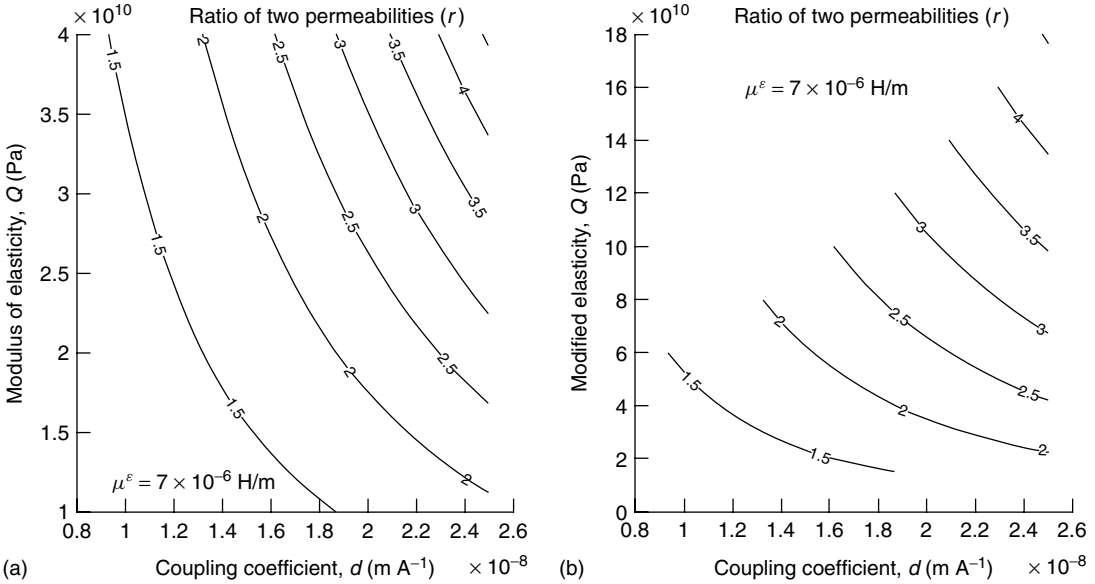

Figure 6. Ratio of two permeabilities (r): modulus Q versus coupling coefficient (a) and modulus Q^* versus coupling coefficient (b), for $\mu = 7 \times 10^{-6}\,\mathrm{H\,m^{-1}}$.

given for different values of modulii of elasticity and coupling coefficients. In Figure 6(b), the value of r is shown for different values of modulii of elasticity and coupling coefficients. In these plots, it is clear that for a particular value of elastic modulus, if the value of coupling coefficient increases, the value of r will increase. Similarly, for a particular value of coupling coefficient, if the value of elastic modulus increases, the value of r will increase.

From the experimental data given in Etrema manual [2], the best value of Q, μ^{σ}, and d is calculated by minimizing the difference between the experimental data and the data according to equation (17), by least square approach. In the first set of experimental data, only magnetostriction values were reported, which is given in equation (19). The value of coupling coefficient is calculated by minimizing the total square error λ_{error} as given by

$$\lambda_{\text{error}} = \sum \left(\lambda_{\text{exp}} - \lambda\right)^2 \tag{24}$$

Similarly, in the second set of experimental data, the strain due to compressive stress (ε_{σ}) was reported. The expression for the value of elastic strain ε_{σ} is given in equation (20). In this expression, the value of Q^* is calculated by minimizing the total square error $\varepsilon_{\sigma}^{\text{error}}$:

$$\varepsilon_{\sigma}^{\text{error}} = \sum \left(\varepsilon_{\sigma}^{\text{exp}} - \varepsilon_{\sigma}\right)^2 \tag{25}$$

From equation (24), using the first set of experimental data (plotted in Figure 2), the value of d was calculated as 14.8×10^{-9} (m A^{-1}). From equation (25), using the second set of experimental data (plotted in Figure 3), the value of Q^* *is* 33.4 GPa. Assuming that the constant strain permeability (μ^{ε}) of the material is $7 \times 10^{-6}\,\text{H m}^{-1}$, the value of r is 1.6, constant stress permeability (μ^{σ}) is $11.2 \times 10^{-6}\,\text{H m}^{-1}$, and Q is 20.8 GPa. From these studies, it is clear that for a giant magnetostrictive material, like Terfenol-D, the coupled analysis gives better result than the uncoupled analysis. However, for a magnetostrictive material with low coupling coefficient, the uncoupled analysis gives a similar result as the coupled analysis.

The coupled-linear model cannot model the high nonlinearity of magnetostriction λ, which is required for the design of actuators. Even considering nonlinear magnetic (magnetic field–magnetic flux) and mechanical (stress–strain) relationships with linear-coupling coefficient, nonlinear relationships of magnetostriction cannot be modeled, as it is a function of coil current, coil turns per unit length of actuator, and magnetomechanical coefficient (equation (19)). In the next section, we introduce a nonlinear model with a constant coupling coefficient, which can model the nonlinear constitutive model exactly for constant magnetic coupling.

3.1.2 Nonlinear-coupled model

The model developed in this section is based on a coupled magnetomechanical formulation, which allows accurate prediction of both the mechanical and magnetic responses of a magnetostrictive device with nonlinear magnetic and mechanical properties. Nonlinearity in this model is introduced using two nonlinear curves, one for the stress–strain relationship and the second for magnetic field–magnetic flux relation, which enables to decouple the nonlinearity in the mechanical and magnetic domains. Magnetomechanical coefficient is considered as a real parameter scalar value. Two-way coupled magnetomechanical theory is used to model magnetostrictive material. The formulation starts with the constitutive relations.

In the earlier linear-coupled model, stress (σ) and magnetic flux density (**B**) were expressed as a function of the components of strain (ε) and magnetic field (**H**) as per equation (3) and equation (4), respectively. A main drawback with such an approach is that the nonlinearity between magnetic domains (μ) and mechanical domains (Q) is not uncoupled. Hence, it is difficult to model nonlinearity in earlier representations. To address these issues, a different approach is used in which equation (3) and equation (4) are rearranged in terms of the mechanical strain (ε) and the magnetic flux density (**B**). In doing so, the mechanical nonlinearity is limited to the stress–strain relationship and the magnetic nonlinearity is limited to magnetic field and magnetic flux relationship. One-dimensional nonlinear modeling is again studied using one-dimensional experimental data from Etrema manual. The constitutive equation can now be rewritten in terms of magnetic flux density (**B**) and strain (ε), as

$$\sigma = E\varepsilon - f^T\mathbf{B} \tag{26}$$

$$H = -f\varepsilon + g\mathbf{B} \tag{27}$$

where

$$g = (\mu^{\varepsilon})^{-1}$$
$$f = gdQ = e/\mu^{\varepsilon}$$
$$E = Q + Qdf = Q^{*} \tag{28}$$

Like the linear case, considering a magnetostrictive rod element of length L, area A, applied tensile force F, strain ε, stress σ, and elastic modulus E, the total strain energy in the rod is

$$V_e = \frac{1}{2}AL\varepsilon\sigma = \frac{1}{2}\varepsilon(E\varepsilon - f\mathbf{B})$$
$$= \frac{1}{2}ALE\varepsilon^2 - \frac{1}{2}AL\varepsilon f\mathbf{B} \tag{29}$$

Magnetic potential energy in the magnetostrictive rod is

$$V_m = \frac{1}{2}AL\mathbf{B}\mathbf{H} = \frac{1}{2}AL(-F\varepsilon + b\mathbf{B})\mathbf{H}$$
$$= -\frac{1}{2}AL\mathbf{B}f\varepsilon + \frac{1}{2}ALg\mathbf{B}^2 \tag{30}$$

Magnetic external work done for N coil turns with coil current I is

$$W_m = IN\mathbf{B}A \tag{31}$$

Mechanical external work done is

$$W_E = F\varepsilon L \tag{32}$$

Total potential energy of the system is equal to $T_p = -V_e - V_m + W_m + W_e$, which in expanded form becomes

$$T_p = -\frac{1}{2}ALE\varepsilon^2 + ALf\mathbf{B} - \frac{1}{2}ALg\mathbf{B}^2$$
$$+ IN\mathbf{B}A + F\varepsilon L \tag{33}$$

Using Hamilton's principle, we get two equations for $\mathbf{B}$ and ε as

$$-ALE\varepsilon + ALf\mathbf{B} + FL = 0 \tag{34}$$

$$ALE\varepsilon f + ALg\mathbf{B} + INA = 0 \tag{35}$$

Dividing by volume AL, equations (34) and (35) become

$$E\varepsilon - f\mathbf{B} = \frac{F}{A} \tag{36}$$

$$-f\varepsilon + g\mathbf{B} = \frac{F}{A} \tag{37}$$

Eliminating $\mathbf{B}$ from equation (36) and substituting this in equation (37), the stress–strain relationship for the magnetostrictive material can be obtained as

$$\mathbf{B} = \frac{E\varepsilon - F/A}{f} \tag{38}$$

$$\varepsilon = \frac{F/A + INf\,(gL)}{E - f^2/g} \tag{39}$$

Assuming E^* as the magnetically free elastic modulus

$$E^* = E - f^2/g - Q \tag{40}$$

Total strain for applied coil current I and tensile force F is given as

$$\varepsilon = \frac{INf}{(gLE^*)} + \frac{F}{AE^*} \tag{41}$$

Here $E = Q^*$ is the elastic modulus for a magnetically stiffened rod and $Q = E^*$ is for magnetically flexible rod. Magnetically stiffened means that the magnetic flux $\mathbf{B} = \mathbf{0}$ inside the rod as the rod is wound by short-circuited coils. Magnetically flexible means the rod is free from any coil. E–Q relation can be obtained form equation (28). To model the one-dimensional nonlinear magnetostrictive stress–strain and magnetic field–magnetic flux relationships, equations (26) and (27) can be written as

$$E(\varepsilon) - f\mathbf{B} = \sigma \tag{42}$$

$$-f\varepsilon + g(\mathbf{B}) = \frac{IN}{L} \tag{43}$$

where f is the real parameter of scalar value and $\varepsilon - E\ (\varepsilon)$, $\mathbf{B} - g(\mathbf{B})$ are two real parameter nonlinear curves. The basic advantage of this model is that only two nonlinear curves are required for representing nonlinearity reported in different stress levels. As

opposed to this approach, in straightforward polynomial representation of magnetostriction [7], one requires single nonlinear curve for every stress level. To get the coefficients of two nonlinear curves and the value of real parameter f, experimental data from Etrema manual [2] is used. From strain, applied coil current, and stress level available in the manual, these coefficients are evaluated. Considering modulus elasticity as 30 GPa, and f as $75.3 \times 106\,\mathrm{m\,A^{-1}}$ as an initial guess, the values of magnetic flux density $\mathbf{B}$ are calculated from equation (42). Similarly, from equation (43), values of $g(\mathbf{B})$ are evaluated. From these values of $\mathbf{B}$ and $g(\mathbf{B})$, the curve of $\mathbf{B} - g(\mathbf{B})$ is computed.

This curve is used to get the mechanical relationship. Here, the value of $\mathbf{B}$ is computed from the $\mathbf{B} - g(\mathbf{B})$ relationship. From this value of $\mathbf{B}$, using equation (42), value of $E(\varepsilon)$ is calculated. From the $E(\varepsilon)$ and ε values, the mechanical nonlinear curve of $\varepsilon - E(\varepsilon)$ relationship is computed. In summary, first the magnetic nonlinear curve is evaluated from the mechanical nonlinear curve and the mechanical nonlinear curve is evaluated from the magnetic nonlinear curve with the help of experimental data given in the Etrema manual [2]. This iteration continues till both the mechanical curve and magnetic curve converge. Thus, with the help of experimental data given in the Etrema manual [2] and equations (42) and (43), nonlinear mechanical and magnetic relationships are evaluated. Initial values of modulus of elasticity and f are computed on a trial and error basis.

For sensor device, where coil current is assumed as zero, strain and the value of magnetic flux due to the application of stress are given by

$$\mathbf{B} = \frac{E(\varepsilon) - \sigma}{f} \tag{44}$$

$$\varepsilon = \frac{g(\mathbf{B})}{f} \tag{45}$$

The magnetic field is approximated by a sixth-order polynomial of magnetic flux density and the modulus is approximated by a sixth-order polynomial of the strain, which is given by

$$g(\mathbf{B}) = c_5 \times \mathbf{B}^5 + \cdots + c_1 \times \mathbf{B} + c_0 \tag{46}$$

$$\mathbf{B} = d_5 \times g(\mathbf{B})^5 + \cdots + d_1 \times g(\mathbf{B}) + d_0 \tag{47}$$

$$E(\varepsilon) = a_6 \times \varepsilon^6 + \cdots + a_1 \times \varepsilon + a_0 \tag{48}$$

$$\varepsilon = b_6 \times E(\varepsilon)^6 + \cdots + b_1 \times E(\varepsilon) + b_0 \tag{49}$$

These curves are shown in Figure 7. Coefficients of these polynomial curves are given in Table 1, where

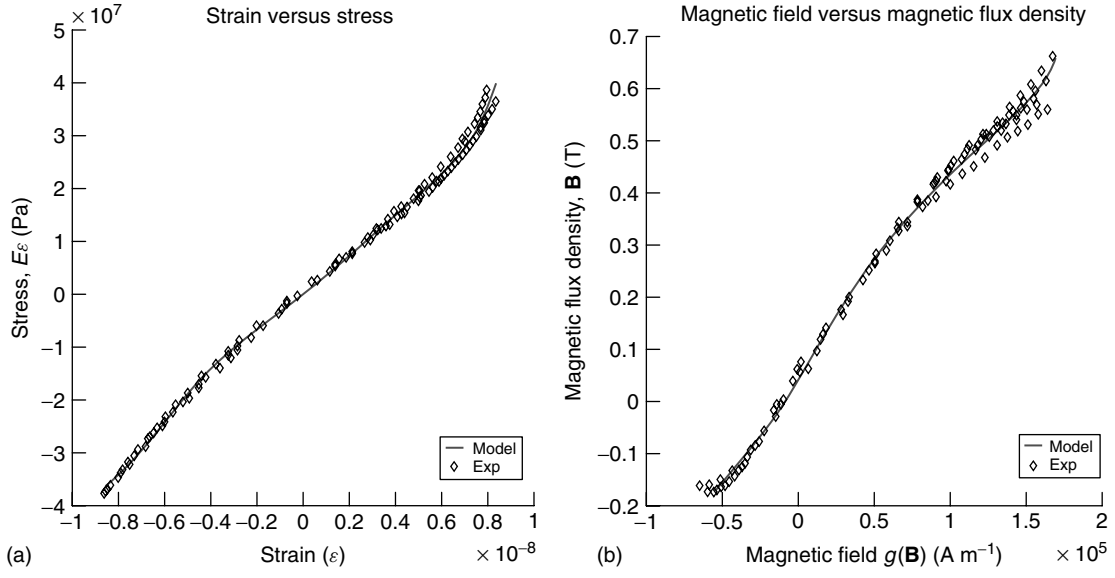

Figure 7. Nonlinear stress–strain curves (a) and magnetic flux and magnetic field curves (b).

Table 1. Coefficients for sixth-order polynomial

	c	*d*	*a*	*b*
6	0	0	4.5419e+28	1.5853e−50

4	1.5211e+06	1.1589e−21	−4.2662e+22	−1.0355e−34
3	3.5828e+05	−2.0047e−16	−6.6788e+19	−4.0508e−27
2	−2.1062e+05	2.0096e−12	2.3911e+16	1.0806e−27
1	2.2754e+05	4.7789e−06	1.2539e+13	2.7977e−11
0	−8.8129e+03	4.4239e−02	3.3893e+10	−1.9704e−05

the unit of **B** is T, $g(\mathbf{B})$ is $\mathrm{A\,m^{-1}}$, and $E(\varepsilon)$ is Pa. The value of magnetomechanical coupling parameter (f) is $75.3 \times 106\,\mathrm{m\,A^{-1}}$, which is the reciprocal of $13.3 \times 10^{-9}\,\mathrm{A\,m^{-1}}$.

On the basis of the two curves given by equations (46) and (48) and parameter (f), strain and magnetostriction versus applied magnetic field for different stress levels are plotted in Figure 8. The experimental data of strain–magnetic field relationships for different stress levels almost match with this model. Similarly, strain-compressive force and elastic modulus for different magnetic field levels are plotted in Figure 9. Elastic modulus initially decreases and then increases for each magnetic field level, which is also reported in Butler [2]. The magnetic flux, strain, stress, and coil current are computed as follows. As two nonlinear curves are related in these relationships, the calculation of magnetic flux and strain from stress and coil current is an iterative procedure. Initially, the value of magnetic flux **B** is assumed as a certain value. From curve $\mathbf{B} - g(\mathbf{B})$, the value of $g(\mathbf{B})$ is evaluated. From equation (37), the value of strain is evaluated considering the magnetic field as coil current times coil turns per unit length of the actuator. Using this strain, from the $\varepsilon - E(\varepsilon)$ curve the value of $E(\varepsilon)$ can be found. From equation (36), the value of **B** can be determined. If this **B** value is not the same as assumed, this iteration will be continued until the value converges.

3.1.3 ANN model

To avoid the iterative procedure mentioned for the nonlinear model, one three-layer ANN is developed,

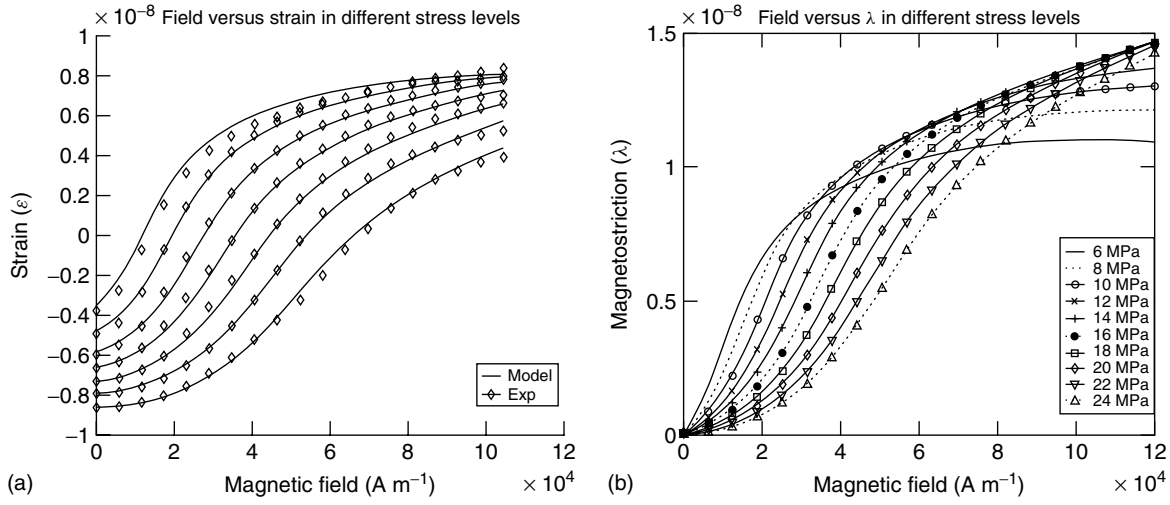

Figure 8. Nonlinear strain–magnetic field curves (a) and magnetostriction–magnetic field curves (b).

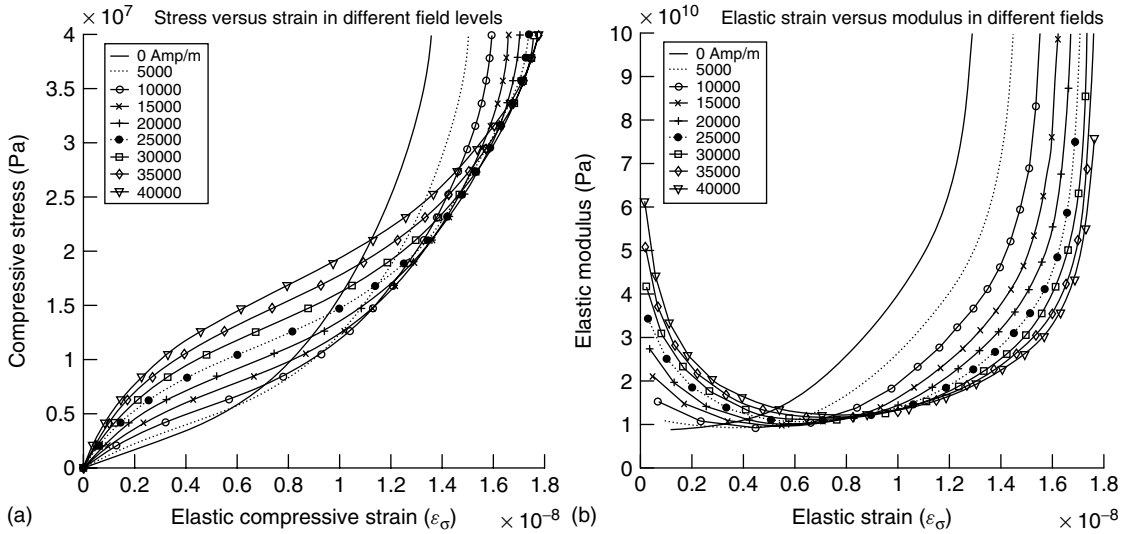

Figure 9. Nonlinear stress–strain curves (a) and elastic modulus–elastic strain curves (b).

which gives direct nonlinear mapping from magnetic field and stress to magnetic flux density and strain. Standard logistic function $y = 1/(1 + e^{-1.7159v})$ is used in hidden layer as activation function with linear output layer. Input (stress and magnetic field) and output (strain and magnetic flux density) data is normalized for a better performance of network.

$$\sigma_n = \frac{(\sigma - \sigma_{\text{mean}})}{(\max|\sigma| - \sigma_{\text{mean}})} \tag{50}$$

$$\mathbf{H}_n = \frac{(\mathbf{H} - \mathbf{H}_{\text{mean}})}{(\max|\mathbf{H}| - \mathbf{H}_{\text{mean}})} \tag{51}$$

$$\varepsilon_n = \frac{(\varepsilon - \varepsilon_{\text{mean}})}{(\max|\varepsilon| - \varepsilon_{\text{mean}})} \tag{52}$$

$$\mathbf{B}_n = \frac{(\mathbf{B} - \mathbf{B}_{\text{mean}})}{(\max|\mathbf{B}| - \mathbf{B}_{\text{mean}})} \tag{53}$$

The normalized stress, σ_n, is calculated using equation (50). The value of σ_{mean} and $(\max|\sigma| - \sigma_{\text{mean}})$ are -1.57966×10^7 and 0.830345×10^8 Pa, respectively. Similarly, $\mathbf{H}^n$, the normalized magnetic field, is calculated from equation (51). The values of $\mathbf{H}_{\text{mean}}$ and $(\max|\mathrm{H}| - \mathbf{H}_{\text{mean}})$ in equation (51) are both 750 Oe. Normalized strain ε_n is the output of network, from which strain is calculated using equation (52). The value of $\varepsilon_{\text{mean}}$ and $(\max|\varepsilon| - \varepsilon_{\text{mean}})$ are 0.203245×10^{-3} and 0.106504×10^{-2}, respectively. In equation (53), the value of $\mathbf{B}_{\text{mean}}$ is 0.385126 T and the value of $(\max|B| - \mathbf{B}_{\text{mean}})$ is 0.319818 and 0.499656 T, respectively. To train this network, some training and validation samples are generated through the iterative process stated earlier. Weight and bias parameter of the trained network are given in Tables 2 and 3. Different validation studies are also carried out.

Table 2. Connection between input layer and hidden layer

Input layer Neurons	Hidden Node 1	Hidden Node 2	Hidden Node 3	Hidden Node 4
$\mathbf{H}_n$	4.6187	−2.1241	−0.15066	0.38726

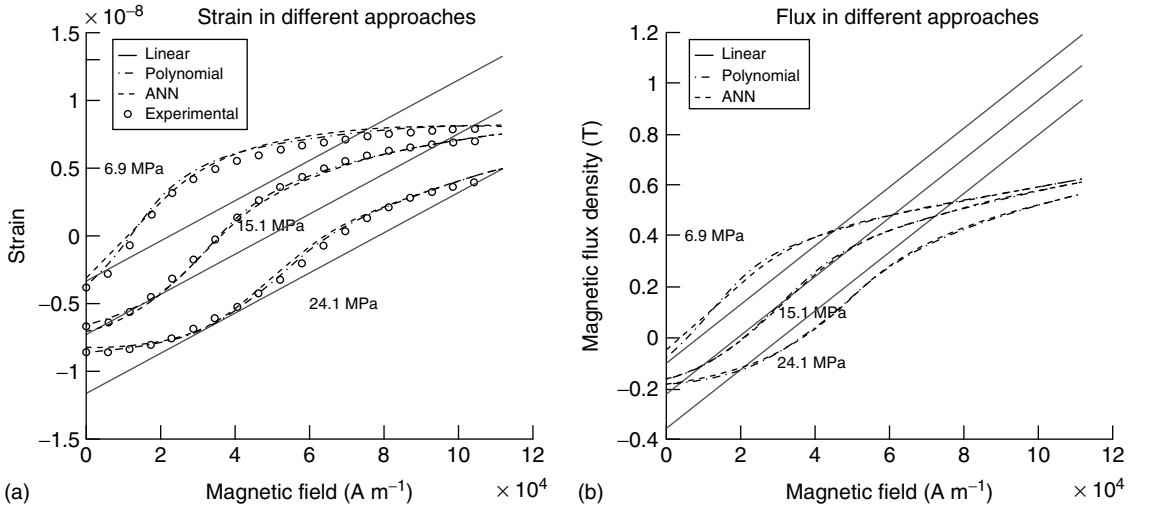

Figure 10. Comparison of different models: strain–magnetic field curves (a) and flux density–magnetic field curves (b).

3.2 Comparison between different coupled models

A comparative study of different models is done using a magnetostrictive rod with varying magnetic field and stress level. Three different stress levels (6.9, 15.1, and 24.1 MPa) are used to compute the total strain and magnetic flux density in the rod for varying magnetic field levels and shown in Figure 10. In Figure 10(a), total strain is shown according to linear, polynomial, ANN, and experimental approaches. Both polynomial and ANN approaches show close results with the experimental data throughout the magnetic field range. As in the case of the linear model, the results do not match with the experimental data throughout the magnetic field range. However, this model can be used in low magnetic field level for medium stress level, and in medium field level for high stress level. For a low stress level, the linear model can be used on an average sense. In the absence of experimental data (Etrema manual) of magnetic flux density, only computational results are shown in Figure 10(b). Magnetic flux density is shown according to linear, polynomial, and ANN approaches. Similar to the strain results, the results of the ANN model and polynomial model are in excellent agreement. However, the results of the linear model do not match throughout the magnetic field range. In the linear model, for medium stress level in low magnetic field level, magnetic flux density matches with the nonlinear model. For high and low stress level, the linear model can be used in the average sense.

4 SUMMARY

This article is mainly intended for anhysteretic linear and nonlinear, coupled constitutive relationships of magnetostrictive material. The coupled model is studied without assuming any direct relationship of magnetic field unlike the uncoupled model. In the linear-coupled model, the elastic modulus, permeability, and magnetoelastic constant are considered as constants. However, this model cannot predict the highly nonlinear properties of magnetostrictive material. In the nonlinear-coupled model, nonlinearity is decoupled in the magnetic and the mechanical domain using two nonlinear curves for stress–strain and magnetic flux density and magnetic field intensity. In this model, the computation of magnetostriction requires the value of magnetic flux density, which is obtained through an iterative process for nonlinearity of curves. To avoid this iterative computation, one three-layer ANN is developed, which will give nonlinear mapping from stress level and magnetic field to strain and magnetic flux density. Finally, a comparative study of linear, polynomial, and ANN

approaches is done, which shows that the linear-coupled model can predict the constitutive relationships in an averaged sense only. The nonlinear models are shown to predict experimental results exactly throughout the magnetic field range.

ACKNOWLEDGMENTS

The author wishes to thank his graduate student Dr Debiprasad Ghosh for performing the numerical simulation addressed in this article.

Finite Elements: Modeling of Piezoceramic and Magnetostrictive Sensors and Actuators

Srinivasan Gopalakrishnan

Department of Aerospace Engineering, Indian Institute of Science, Bangalore, India

1 INTRODUCTION

Finite element (FE) is a powerful numerical tool to model any complex system that is governed by a partial differential equation. Modeling and analysis of structures through FE procedures are now quite well established and matured to such an extent that there are many general-purpose FE codes, commercially available, that satisfy most industrial standards specified for modeling, analysis, and design. With increasing emphasis on incorporating health monitoring concepts at the design stage itself for the present-day systems, it is necessary to build a new or modify the existing FE code to handle this additional complexity. One of the ways or means to incorporate the health monitoring concepts at the design stage itself is by introducing smart material patches anywhere in the structures (if the structure is of laminated composite construction), or select a proper location to surface bond these smart material patches. This article deals with the FE modeling of such structures with built-in smart material patches. However, this article only gives a brief outline of how some FEs are formulated with smart degrees of freedom. Mathematical aspects of FEs, detailed method of formulation of FEs, method of solution of FE equations, etc. can be obtained from many classic text books in [1–3]. Some aspects of modeling of smart sensors and actuators using FEs can also be found in [4].

The main function of the smart material patches is to introduce additional functionalities, namely, the sensing and actuation functions. Sensing function is normally used in the health monitoring application, whereas in applications such as vibration or noise control, actuation mechanism is used. Such functionalities are possible using smart material patches due to the presence of coupling parameter in their constitutive model. Some of the smart materials

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

have two different constitutive laws: one is used for sensing while the other is used for actuation purpose. In piezoceramic material, for example, which is a class of smart material used extensively in structural application, the constitutive law couples the mechanical motion and the electrical field through an electromechanical coupling coefficient. Some of the elementary concepts of behavior of smart materials in relation to structures are given in [5–7]. From FE point of view, this additional complexity arising owing to this coupling results in additional degrees of freedom and hence increased size of the system matrices. However, the general procedure for the formulation of FEs and their synthesis remains the same and these are covered extensively in many classic text books in [1–3].

The general procedure for the formulation of FEs involves the following:

- Develop a suitable constitutive model for the combined material consisting of the host material (say metallic or laminated composite structure) and the smart material patch. The constitutive matrix for metallic isotropic structure is quite well known. A laminated composite normally exhibits anisotropic behavior due to arbitrary orientation of the fiber. The constitutive law for composites can be found in [8, 9]. When the composite constitutive law is coupled with the constitutive law of the smart material (say piezoceramic), the resulting matrix, not only couples the different mechanical motions but also the smart degrees of freedom.
- Formulate the weak form of the governing differential equation. This will involve the energy expressions due to elasticity, inertia, surface and body forces, and external forces. When smart material patches are introduced (say piezoceramic or magnetostrictive material), then the energy due to electrical or magnetic motion should also be included in the weak form of the equations.
- Decide on the number of degrees of freedom and assume a suitable interpolating function for each of the degrees of freedom. Note that if the structure has smart material patches, then the smart degree of freedom (say electrical degree of freedom for piezoceramic material) also needs to be introduced and interpolated over an element using a suitable function, as is done for the other degrees of freedom.
- These interpolating functions are then substituted for the different field variable in the weak form of the equation and the resulting equation is minimized to obtain the discritized equation of motion, which involves computing the stiffness, the mass, and the damping matrices. The discritized governing equations are solved using many standard methods, the details of which can be obtained from many standard FE text books.

This article is organized as follows. The next section explains briefly the constitutive law for two different classes of smart materials, namely, the piezoceramic material and magnetostrictive materials. Although the detailed treatment of their constitutive models are dealt in detail in earlier articles (*see* **Piezoceramic Materials—Phenomena and Modeling**; **Constitutive Modeling of Magnetostrictive Materials**), here, only those details that are required for FE formulation are given. This section is followed with a detailed derivation of constitutive law for a laminated composite with embedded piezoelectric material patch. This method then extends to piezo fiber composites (PFCs). Next, the detailed 1-D and 2-D FE formulation with embedded smart senor/actuator patches are outlined, which is followed by some numerical examples.

2 CONSTITUTIVE MODELS FOR SMART SENSORS AND ACTUATORS

2.1 Piezoelectric sensors/actuators

Piezoelectric or magnetostrictive materials have two constitutive laws, one of which is used for sensing and the other for actuation purposes. For 2-D state of stress, the constitutive model for the piezoelectric material is of the form

$$\{\sigma\}_{3\times1} = [C]^{(E)}_{3\times3}\{\varepsilon\}_{3\times1} - [e]_{3\times2}\{E\}_{2\times1} \quad (1)$$

$$\{D\}_{2\times1} = [e]^{\mathrm{T}}_{2\times3} + [\mu]^{(\sigma)}_{2\times2}\{E\}_{2\times1} \quad (2)$$

The first of this constitutive law is called *the actuation law*, while the second is called *the sensing law*. Here, $\{\sigma\}^{\mathrm{T}} = \{\,\sigma_{xx} \quad \sigma_{yy} \quad \tau_{xy}\,\}$ is the stress vector; $\{\varepsilon\}^{\mathrm{T}} = \{\,\varepsilon_{xx} \quad \varepsilon_{yy} \quad \gamma_{xy}\,\}$ is the strain vector;

$[e]$ is the matrix of piezoelectric coefficients of size 3×2, which has a unit of N/V-mm; and $\{E\}^{\mathrm{T}} = \{E_x \quad E_y\} = \{V_x/t \quad V_y/t\}$ is the applied field in two coordinate directions, where V_x and V_y are the applied voltages in the two coordinate directions, and t is the thickness parameter. It has a unit of V/mm. $[\mu]$ is the permittivity matrix of size 2×2, measured at constant stress and has a unit of N/V/V and $\{D\}^{\mathrm{T}} = \{D_x \quad D_y\}$ is the vector of electric displacement in two coordinate directions. This has a unit of N/V-mm. $[C]$ is the mechanical constitutive matrix measured at constant electric field. Equation (1) can also be written in the form

$$\{\varepsilon\} = [S]\{\sigma\} + [d]\{E\} \tag{3}$$

In the above expression, $[S]$ is the compliance matrix, which is the inverse of the mechanical material matrix $[C]$ and $[d] = [C]^{-1}[e]$ is the electromechanical coupling matrix, where the elements of this matrix have a unit mm/V and the elements of this matrix are direction dependent. In most analyses, it is assumed that the mechanical properties will change very little with the change in the electric field and, as a result, the actuation law (equation 1) can be assumed to behave linearly with the electric field, while the sensing law (equation 2) can be assumed to behave linearly with the stress. This assumption will considerably simplify the process of analyses.

The first part of equation (1) represents the stresses developed due to mechanical load, while the second part of the same equation gives the stresses due to voltage input. From equations (1) and (2), it is clear that the structure is stressed due to the application of electric field even in the absence of mechanical load. Alternatively, when the mechanical structure is loaded, it generates an electric field. In other words, the above constitutive law demonstrates the electromechanical coupling, which is exploited for a variety of structural applications, such as vibration control, noise control, shape control, or structural health monitoring. Piezoceramic materials are a class of piezoelectric materials, which are available in different forms, namely, ceramic, polymer, or crystal forms. The most commonly used piezoceramic material is the PZT (lead–zirconate–titanate) material, which is extensively used as bulk actuator material as they have high electromechanical coupling factor. Owing to the low electromechanical coupling factor, piezo polymers polyvinylidene fluoride (PVDF) are extensively used only as sensor material. With the advent of smart composite structures, a new brand of material called *piezofiber composite* is found to be a very effective actuator material for use in vibration/noise control applications. The form of the constitutive model of this material is very similar to that of the piezoelectric material and since this is always a part of the composite structure, its constitutive model is established in this context at a later part of this article.

2.2 Magnetostrictive sensors/actuators

Some magnetic materials (magnetostrictive) show elongation and contraction in the magnetization direction due to an induced magnetic field. This is called *the magnetostriction*, which is due to the switching of a large amount of magnetic domains caused by spontaneous magnetization, below the Curie point of temperature. Thus, magnetostrictive materials have the ability to convert magnetic energy into mechanical energy and vice versa. This coupling between magnetic and mechanical energies represents what is called *the transudation capability*, which allows a magnetostrictive material to be used in both actuation and sensing applications. The most extensively used magnetostrictive material for structural applications is the Terfenol-D. The constitutive laws (both actuation and sensing) for magnetostrictive materials such as Terfenol-D are much more complex than the piezoelectric materials. They are highly nonlinear and have the similar form as that of the piezoelectric material, which is given by

$$\{\varepsilon\} = [S]^{(H)}\{\sigma\} + [d]^{\mathrm{T}}\{H\} \tag{4}$$

$$\{B\} = [d]\{\sigma\} + [\mu]^{\{(\sigma\}}\{H\} \tag{5}$$

Here, $[S]$ is the compliance matrix measured at constant magnetic field H; $[d]$ is the magnetomechanical coupling matrix, the elements of which has units of meter per ampere; and $\{B\}$ is the vector of magnetic flux density in the two coordinate directions. It has a unit called *tesla*, which is equal to weber per cubic meter. $\{H\}$ is the magnetic field intensity vector in the two coordinate directions and it has a unit called *oersted,* which is equal to *Ampere per meter.* It is related to the ac current $(I(t))$ through the relation $H = nI$, where n is the number of turns in the actuator. $[\mu]$ is the matrix of magnetic permeability

measured at constant stress and it has a unit of weber per ampere-meter. As in the case of piezoelectric material, the first equation (equation 4) is the actuation constitutive law, while the second equation (equation 5) is the sensing law. The stress–strain relations are different for different magnetic field intensities. The strain is linear to stress only for small magnetic field intensities. For higher magnetic field intensities, both sensing and actuator equations require to be simultaneously solved to arrive at the correct stress–strain relation. This is because change in the magnetic field changes the stress, which changes the magnetic permeability. Hence, characterization of material properties of Terfenol-D is more difficult compared to the piezoelectric material. These aspects were clearly highlighted in the previous article on constitutive model for magnetostrictive material. The reader is also encouraged to refer [8, 9] for the constitutive model of the above material.

In this article, we assume only the linear behavior of these materials and proceed with FE modeling of these smart sensors and actuators based on this assumption. Here, the FE modeling of some of the 1-D and 2-D structures with both piezo and magnetostrictive material patches embedded in a composite material is given.

3 CONSTITUTIVE MODEL FOR A COMPOSITE MATERIAL WITH EMBEDDED PIEZOELECTRIC SENSORS/ACTUATORS

Fundamental to any FE modeling is to first establish the constitutive model and this also holds true for a 3-D laminate with embedded piezoelectric sensors/actuators. Here, we can take the same approach as undertaken to establish the constitutive model for conventional composite structure. That is, we first establish the constitutive model at the lamina level in the fiber coordinate system, which is then transformed to the global coordinate system. These relations are then synthesized for all the laminae to establish the constitutive model of the laminate. However, additional matrices arise in this case due to the presence of electromechanical coupling. Consider a lamina with the piezoelectric layer as shown in Figure 1. The constitutive model in directions 1, 2, and 3 for such a lamina is given by equations (1) and (2), respectively. In matrix form, it is given by

$$\begin{Bmatrix} \{\sigma\} \\ \{D\} \end{Bmatrix} = \begin{bmatrix} [C] & -[e] \\ [e]^{\mathrm{T}} & [\mu] \end{bmatrix} \begin{Bmatrix} \{\varepsilon\} \\ \{E\} \end{Bmatrix} \tag{6}$$

$$\text{or } \{\overline{\sigma}\} = [\overline{C}]\{\overline{\varepsilon}\} \tag{7}$$

Expanding the above relation, we get

$$\begin{Bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sigma_{23} \\ \sigma_{31} \\ \sigma_{12} \\ D_1 \\ D_2 \\ D_3 \end{Bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 & 0 & 0 & -e_{31} \\ C_{12} & C_{22} & C_{23} & 0 & 0 & 0 & 0 & 0 & -e_{32} \\ C_{13} & C_{23} & C_{33} & 0 & 0 & 0 & 0 & 0 & -e_{33} \\ 0 & 0 & 0 & C_{44} & 0 & 0 & 0 & -e_{24} & 0 \\ 0 & 0 & 0 & 0 & C_{55} & 0 & -e_{15} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & C_{66} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & e_{15} & 0 & \mu_{11} & 0 & 0 \\ 0 & 0 & 0 & e_{24} & 0 & 0 & 0 & \mu_{22} & 0 \\ e_{31} & e_{32} & e_{33} & 0 & 0 & 0 & 0 & 0 & \mu_{33} \end{bmatrix} \begin{Bmatrix} \varepsilon_{11} \\ \varepsilon_{22} \\ \varepsilon_{33} \\ \varepsilon_{23} \\ \varepsilon_{31} \\ \varepsilon_{12} \\ E_1 \\ E_2 \\ E_3 \end{Bmatrix} \tag{8}$$

Here, $E_i = -\nabla\Phi$, where Φ is the electric potential vector. The above constitutive model is then transformed to the global $x-y-z$ coordinate system using

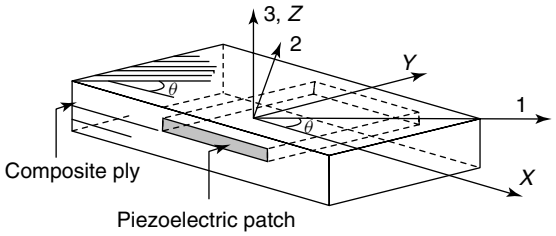

Figure 1. Local and global coordinate system for a lamina with embedded piezoelectric patch.

the transformation matrix, which is given by

$$[T] = \begin{bmatrix} [T_{11}] & [0] \\ [0] & [T_{22}] \end{bmatrix} \tag{9}$$

where

$$[T_{11}] = \begin{bmatrix} C^2 & S^2 & 0 & 0 & 0 & -2CS \\ S^2 & C^2 & 0 & 0 & 0 & 2CS \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & C & S & 0 \\ 0 & 0 & 0 & S & C & 0 \\ CS & -CS & 0 & 0 & 0 & C^2 - S^2 \end{bmatrix} \tag{10}$$

$$[T_{22}] = \begin{bmatrix} C^2 & S^2 & 0 \\ S^2 & C^2 & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{11}$$

$$C = \cos(\theta),\ S = \sin(\theta) \tag{12}$$

Here θ is the fiber orientation of the lamina. The constitutive model in the global $x-y-z$ direction is then given by

$$\begin{aligned} \{\sigma\} &= [T]^{\mathrm{T}} \begin{bmatrix} [C] & -[e] \\ [e]^{\mathrm{T}} & [\mu] \end{bmatrix} [T]\{\varepsilon\} \\ &= \begin{bmatrix} [\overline{\overline{C}}] & -[\overline{\overline{e}}] \\ [\overline{\overline{e}}] & [\mu] \end{bmatrix} \{\varepsilon\} \end{aligned} \tag{13}$$

In expanded form, the above equation becomes

The elements of $[\overline{\overline{C}}]$ and $[\overline{\overline{e}}]$ are given by

$$\begin{aligned}
\overline{\overline{C}}_{11} &= 4C_{66}C^2S^2 + C^2(C_{11}C^2 + C_{12}S^2) \\
&\quad + S^2(C_{12}C^2 + C_{22}S^2) \\
\overline{\overline{C}}_{12} &= -4C_{66}C^2S^2 + S^2(C_{11}C^2 + C_{12}S^2) \\
&\quad + C^2(C_{12}C^2 + C_{22}S^2), \\
\overline{\overline{C}}_{13} &= C_{13}C^2 - C_{23}S^2 \\

\end{aligned} \tag{15}
$$

For 2-D analysis, we normally employ either plane stress or plane strain assumptions. For plane stress assumption in the $x-z$ plane, we substitute $\sigma_{yy} = \sigma_{xy} = \sigma_{yz} = D_x = D_y = 0$ in equation (14). Simplifying this, we can write the constitutive model for a 2-D piezoelectric composite as

$$
\begin{Bmatrix} \{\sigma\} \\ D_z \end{Bmatrix} = \begin{bmatrix} [\hat{C}] & -[\hat{e}] \\ [\hat{e}]^{\mathrm{T}} & \hat{\mu} \end{bmatrix} \begin{Bmatrix} \{\varepsilon\} \\ E_z \end{Bmatrix} = \begin{Bmatrix} \sigma_{xx} \\ \sigma_{zz} \\ \sigma_{xz} \\ D_z \end{Bmatrix}
$$
$$
= \begin{bmatrix} \hat{C}_{11} & \hat{C}_{12} & 0 & -\hat{e}_{31} \\ \hat{C}_{13} & \hat{C}_{33} & 0 & -\hat{e}_{32} \\ 0 & 0 & \hat{C}_{55} & 0 \\ \hat{e}_{31} & \hat{e}_{32} & 0 & \hat{\mu}_{33} \end{bmatrix} \begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{zz} \\ 2\varepsilon_{xz} \\ E_z \end{Bmatrix} \tag{16}
$$

where,

$$
\begin{aligned}
\hat{C}_{11} &= \overline{\overline{C}}_{11} + \frac{1}{\Delta}\Big[\overline{\overline{C}}_{12}\Big(\overline{\overline{C}}_{26}\overline{\overline{C}}_{16} - \overline{\overline{C}}_{66}\overline{\overline{C}}_{12}\Big) \\
&\quad + \overline{\overline{C}}_{16}\Big(\overline{\overline{C}}_{26}\overline{\overline{C}}_{16} - \overline{\overline{C}}_{22}\overline{\overline{C}}_{16}\Big)\Big] \\

&\quad + \overline{\overline{e}}_{32}\Big(\overline{\overline{C}}_{29}\overline{\overline{C}}_{66} - \overline{\overline{C}}_{26}\overline{\overline{C}}_{69}\Big)\Big]
\end{aligned} \tag{17}
$$

In the next subsection, we derive the constitutive of the PFCs, wherein the piezo fibers together with the interdigital electrodes (IDEs) are embedded in the composite structures to perform a variety of applications.

3.1 Constitutive model for piezofiber composite (PFC) structures

PFC sensors and actuators are a class of multifunctional composites, wherein the piezo fibers, the associated IDEs are embedded in the composites at the manufacturing stage as shown in Figure 2. In this section, we outline the derivation of the constitutive model of PFC sensors and actuators.

The constitutive model can be derived by considering a rectangular representative volume element (RVE) shown in Figure 2. The rectangular cross section of the fibers can provide maximum volume fraction of ceramic, which is preferable for actuation. The configuration can be obtained using fibers that have been tape-cast and diced, extruded, or cast into a mould. Figure 3 also shows an actuator element (say qth) with its host composite structure and having local coordinate system (X_a^q, Y_a^q, Z_a^q). The RVE of the two-phase ceramic–matrix composite system is described by one quadrant axisymmetric model about the x_3 axis. Here, h is the total depth of a single PFC layer, p is the uniform spacing of the IDEs spanning along x_1, and b is the width of each electrode. The constitutive relations for orthotropic active ceramic bulk form [10] can be represented as

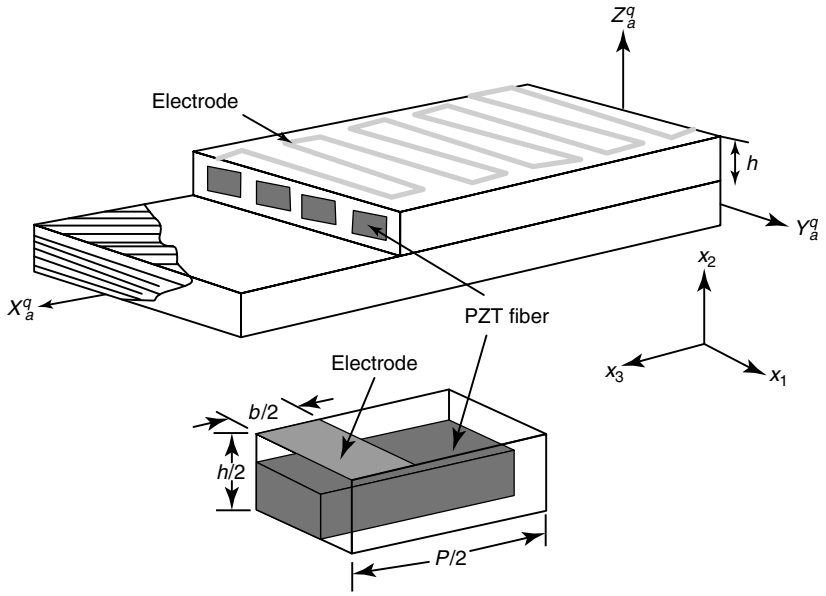

Figure 2. Configuration of piezoelectric fiber composite (PFC) for composite beam actuation.

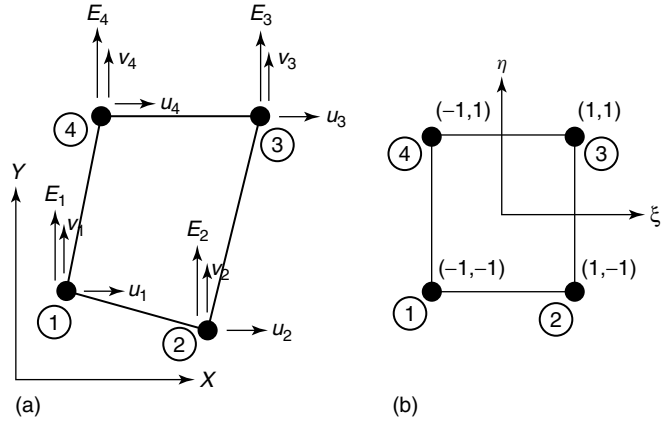

Figure 3. Element degrees of freedom and the isoparametric coordinate system.

$$\begin{Bmatrix} \sigma_{xx} \\ \sigma_{zz} \\ \tau_{xz} \\ D_z \end{Bmatrix} = \begin{bmatrix} C^E{}_{11} & C^E{}_{12} & C^E{}_{13} & -e_{31} \\ C^E{}_{12} & C^E{}_{22} & C^E{}_{23} & -e_{32} \\ C^E{}_{13} & C^E{}_{23} & C^E{}_{33} & -e_{33} \\ e_{31} & e_{32} & e_{33} & \mu^s{}_{33} \end{bmatrix} \begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{zz} \\ \gamma_{xz} \\ E_z \end{Bmatrix} \tag{18}$$

This relation is of a very similar form as that of PZT sensor/actuator. This relation can be directly used in equation (41) by substituting equation (18) for matrices $[\hat{C}]$ and $[e]$. For 1-D analysis, this requires reduction into single equivalent constitutive law by considering the volume fraction of the piezo fiber (PZT) to the total volume of the laminate. For pure piezoceramic material, $C_{11}^E = C_{22}^E$, $C_{23}^E = C_{13}^E$, $e_{32} = e_{31}$. For matrix phase, all e_{ij} are zero, and their mechanical and dielectric properties are represented without superscripts. Assuming negligible distortion of the equipotential lines and electric fields beneath the electrodes, and imposing proper field continuity between the ceramic and matrix phases, the effective unidirectional constitutive law for a PFC

beam structure can be expressed as

$$\sigma_{zz} = C^{eff}{}_{33}\varepsilon_{zz} - e^{eff}{}_{33}E_z \tag{19}$$

where,

$$C_{33}{}^{eff} = \left(\overline{\overline{C}}_{33}V_1{}^p + C_{22}V_1{}^m\right) - \frac{V_1{}^pV_1{}^m\left(C_{12} - \overline{\overline{C}}_{13}\right)^2}{C_{22}V_1{}^p + \overline{\overline{C}}_{11}V_1{}^m} \tag{20}$$

$$e^{eff}{}_{33} = \overline{\overline{e}}_{33}V_1{}^p + \frac{\overline{\overline{e}}_{31}V_1{}^pV_1{}^m\left(C_{12} - \overline{\overline{C}}_{13}\right)}{C_{22}V_1{}^p + \overline{\overline{C}}_{11}V_1{}^m} \tag{21}$$

$$\overline{\overline{C}}_{11} = \left(\overline{C}_{33}V_2{}^p + C_{11}V_2{}^m\right) - \frac{V_2{}^pV_2{}^m\left(C_{12} - \overline{C}_{23}\right)^2}{C_{11}V_2{}^p + \overline{C}_{22}V_2{}^m} \tag{22}$$

$$\overline{\overline{e}}_{31} = \overline{e}_{31}V_2{}^p + \frac{\overline{e}_{32}V_2{}^pV_2{}^m\left(C_{12} - \overline{C}_{12}\right)}{C_{11}V_2{}^p + \overline{C}_{22}V_2{}^m} \tag{23}$$

$$\overline{\overline{e}}_{33} = \overline{e}_{33}V_2{}^p + \frac{\overline{e}_{32}V_2{}^pV_2{}^m\left(C_{12} - \overline{C}_{23}\right)}{C_{11}V_2{}^p + \overline{C}_{22}V_2{}^m} \tag{24}$$

$$\overline{C}_{jk} = C_{jk}{}^E + \frac{V_3{}^me_{3j}e_{3k}}{V_3{}^m\mu_{33} + V_3{}^m\mu^s{}_{33}} \tag{25}$$

$$\overline{e}_{3j} = \frac{\mu_{33}e_{3j}}{V_3{}^p\mu_{33}V_3{}^m\mu^s{}_{33}} \tag{26}$$

Here, v_i^p and v_i^m, for $i = 1, 2$ represents the length fraction of ceramic and matrix phase along direction i, respectively, and

$$V_3{}^p = \frac{\dfrac{p}{h}}{\dfrac{p}{h} + \left(1 - V_2{}^p\right)} \quad b \ll p \tag{27}$$

represents the volume fraction of ceramic phase in RVE. The details of the above derivation can be found in [11]. Similar models for uniform packing circular fiber can be found in [12]. Essentially, these models provide dominant electromechanical coupling in direction 3, which can be aligned along the local host beam axis during bonding or embedding. This is unlikely in uniformly electroded PZT plate structure.

4 FINITE ELEMENT MODELING

In this section, FE modeling of laminated composite structures with embedded/surface-bonded smart sensors/actuators is given. First, a 2-D FE model for a composite beam with embedded piezoelectric sensor/actuator is given. Since the FE formulation of PFCs is very similar to the piezoelectric laminate case, we will not repeat the formulation here. This is later followed by the modeling of composites with embedded magnetostrictive sensors/actuators. Some numerical examples are also given to demonstrate the use of the formulated element.

4.1 Four-noded isoparametric finite element formulation

Isoparametric FE formulation is a class of FE formulation, wherein an arbitrary element shape is mapped onto a square of dimension 2 units. Hence, in such formulation, in addition to mapping the field variables (displacements and electric field), the geometry is also mapped using the same functions.

Let us consider a 2-D composite laminate under plane stress in the $x-z$ plane. Let $u(x, y, t)$ and $w(x, y, t)$ be its displacement components. The strong form of the governing equation essentially gives the governing partial differential equation for the given problem. This form of the governing equation is not readily amenable for numerical solution and, in addition, the exact analytical solution is available only for a few simple problems. On the other hand, the weak form of solution is readily amenable for numerical solution. Both forms can be derived using the Hamilton's principle. First the strong form of the governing differential equation is derived. This requires that the energy associated with the problem be written in terms of displacements. The kinetic, strain, and the electrical energy for the smart laminated having a volume V is given by

$$T = \frac{1}{2}\int_V \rho\{\dot{u}\}^{\mathrm{T}}\{\dot{u}\}\,\mathrm{d}V \tag{28}$$

$$U = \frac{1}{2}\int_V \{\sigma\}^{\mathrm{T}}\{\varepsilon\}\,\mathrm{d}V \tag{29}$$

$$U_e = \frac{1}{2}\int_V E_z\mu_z\,\mathrm{d}V \tag{30}$$

where

$$\{u\}^{\mathrm{T}} = \{u \;\; v\} \tag{31}$$

$$\{\sigma\}^{\mathrm{T}} = \{\sigma_{xx} \;\; \sigma_{zz} \;\; \sigma_{xz}\} \tag{32}$$

Here, ρ is the density of the smart composite. The stresses are related to strain using equation (16), which can be expressed in terms of displacement using strain–displacement relationship. Using these energies in the Hamilton's principle, we get the following strong form of the governing equation and its associated boundary conditions

$$\rho\frac{\partial^2 u}{\partial t^2} - \hat{C}_{11}\frac{\partial^2 u}{\partial x^2} - \hat{C}_{13}\frac{\partial^2 w}{\partial x \partial z} - \hat{C}_{55}\left(\frac{\partial^2 u}{\partial z^2} + \frac{\partial^2 w}{\partial x \partial z}\right) + \hat{e}_{31}\frac{\partial E_z}{\partial x} = F_{sx} + \hat{e}_{31}\frac{\partial E_s}{\partial x}$$

$$\rho\frac{\partial^2 w}{\partial t^2} - \hat{C}_{33}\frac{\partial^2 w}{\partial z^2} - \hat{C}_{13}\frac{\partial^2 u}{\partial x \partial z} - \hat{C}_{55}\left(\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 u}{\partial x \partial z}\right) + \hat{e}_{33}\frac{\partial E_z}{\partial z} = F_{sz} - \hat{e}_{33}\frac{\partial E_s}{\partial z}$$

$$\hat{e}_{31}\frac{\partial u}{\partial x} + \hat{e}_{33}\frac{\partial w}{\partial z} + \overline{\overline{\mu}}_{33}E_z = -D_s - \overline{\overline{\mu}}_{33}E_s \tag{33}$$

where $\{F_s\}^{\mathrm{T}} = \{F_{sx} \;\; F_{sz}\}$ is the surface force vector in the two directions and E_s, D_s are the residual electrical field and the electrical displacement in the smart composite. In the above equation, the first two represent the force equilibrium in the x and z directions, while the third equation represents the equation for electrical field equilibrium. The associated force boundary conditions on the edge parallel to z axis are

$$\hat{C}_{11}\frac{\partial u}{\partial x} + \hat{C}_{13}\frac{\partial w}{\partial z} - \hat{e}_{31}E_z = F_{cx} + \hat{e}_{31}E_s \quad \text{or} \quad u \text{ prescribed} \tag{34}$$

$$\hat{C}_{55}\left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x}\right) = F_{cz} \quad \text{or} \quad w \text{ prescribed} \tag{35}$$

Similarly, the force boundary conditions on the edge parallel to x-axis are

$$\hat{C}_{13}\frac{\partial u}{\partial x} + \hat{C}_{33}\frac{\partial w}{\partial z} - \hat{e}_{33}E_z = F_{cz} + \hat{e}_{33}E_s \quad \text{or} \quad w \text{ prescribed} \tag{36}$$

$$\hat{C}_{55}\left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x}\right) = F_{cx} \quad \text{or} \quad u \text{ prescribed} \tag{37}$$

where F_{cx} and F_{cz} are the sum of all point loads in x and z directions, respectively. The main goal here is to solve equation (33). These are very difficult to solve exactly. Hence, it is necessary to recast the above equilibrium equation in its weak form and best fit an approximate solution using FE procedure.

The weak form of the governing differential equation is obtained next. This is obtained by performing a variational minimization (Hamilton's principle) of the total energy, which can be written as

$$\delta\left(\frac{1}{2}\int_{t_1}^{t_2}\int_V \{\dot{u}\}^{\mathrm{T}}\rho\{\dot{u}\}\,\mathrm{d}V\,\mathrm{d}t + \frac{1}{2}\int_{t_1}^{t_2}\int_V \{\sigma\}^{\mathrm{T}}\{\varepsilon\}\,\mathrm{d}V\,\mathrm{d}t + \frac{1}{2}\int_{t_1}^{t_2}\int_V E_z D_z\,\mathrm{d}V\,\mathrm{d}t + \int_{t_1}^{t_2}\{u\}^{\mathrm{T}}\{F_c\}\,\mathrm{d}t + \int_{t_1}^{t_2}\int_{S_1}\{u\}^{\mathrm{T}}\{F_s\}\,\mathrm{d}S_1\,\mathrm{d}t + \int_{t_1}^{t_2}\int_{S_2} E_z D_s\,\mathrm{d}S_2\,\mathrm{d}t\right) = 0 \tag{38}$$

where S_1 and S_2 are the surfaces in the structure where the surface forces and residual displacements act. Substituting for stresses and electrical displacements from equation (16), the weak form of the differential equation becomes

$$\int_{t_1}^{t_2}\int_V \{\delta\dot{u}\}^{\mathrm{T}}\rho\{\dot{u}\}\,\mathrm{d}V\,\mathrm{d}t + \int_{t_1}^{t_2}\int_V \{\delta\varepsilon\}^{\mathrm{T}}[\overline{\overline{C}}]\{\varepsilon\}\,\mathrm{d}V\,\mathrm{d}t - \int_{t_1}^{t_2}\int_V \delta E[\overline{\overline{e}}]^{\mathrm{T}}\{\varepsilon\}\,\mathrm{d}V\,\mathrm{d}t + \int_{t_1}^{t_2}\int_V \delta E_z[\overline{\overline{e}}]^{\mathrm{T}}\{\varepsilon\}\,\mathrm{d}V\,\mathrm{d}t + \int_{t_1}^{t_2}\int_V \delta E_z\mu E_z\,\mathrm{d}V\,\mathrm{d}t + \int_{t_1}^{t_2}\{\delta u\}^{\mathrm{T}}\{F_c\}\,\mathrm{d}t$$

$$+\int_{t_1}^{t_2}\int_{S_1}\{\delta u\}^{\mathrm{T}}\{F_s\}\,\mathrm{d}S_1\,\mathrm{d}t$$
$$+\int_{t_1}^{t_2}\int_{S_2}\delta E_z D_s\,\mathrm{d}S_2\,\mathrm{d}t=0 \tag{39}$$

The above equation is the weak form of the governing equation (equation 33) for a composite laminate with piezoelectric smart sensors. This is the starting point for the FE formulation.

Next, we outline the procedure for formulating a four-node isoparametric plane stress smart composite FE. The element configuration is shown in Figure 3. This element will have two mechanical degrees of freedom, namely, the two displacement components $u(x, y, t)$ and $w(x, y, t)$, respectively, and a single electrical degree of freedom $E_z(x, y, t)$ in the z direction. The electric field in this direction will induce stresses in the x direction. Thus, this element will have a total of 12 degrees of freedom. Here, we adopt isoparametric formulation. Since the proposed element is four noded, the bilinear shape functions for the mechanical displacements will be required, which can be written as

$$u(x, y, t)=\sum_{i=1}^{4}N_i(\xi,\eta)u_i(t),$$
$$w(x, y, t)=\sum_{i=1}^{4}N_i(\xi,\eta)w_i(t) \tag{40}$$

where ξ and η are the isoparametric coordinates and $u_i(t)$ and $w_i(t)$ are the nodal mechanical degrees of freedom. The four bilinear shape functions are given by

$$N_1=\frac{1}{4}(1-\xi)(1-\eta),\quad N_2=\frac{1}{4}(1+\xi)(1-\eta),$$
$$N_3=\frac{1}{4}(1+\xi)(1+\eta),\quad N_4=\frac{1}{4}(1-\xi)(1+\eta) \tag{41}$$

Now to choose the interpolating polynomial for the electrical degrees of freedom, we look at the strong form of the governing equation (equation 33). By substituting linear variation for the mechanical degrees of freedom, we find that for consistency of the displacement field, we also require a bilinear variation of the electrical field. Hence, we assume the electric field to vary as

$$E_z(x, y, t)=\sum_{i=1}^{4}N_i(\xi,\eta)E_{zi}(t) \tag{42}$$

where the same shape function given in equation (41) is also used here, and E_{zi} are the nodal electrical degrees of freedom at the four nodes.

In isoparametric formulation, we map the actual geometry of the element to a square of size 2 defined in the generalized coordinate system (ξ, η) through a Jacobian transformation. This requires the variation of the coordinate system in the generalized coordinates in terms of the nodal coordinates of the actual element geometry. Hence, one can use the same displacement shape functions to describe this variation and can be written as

$$x(x, y)=\sum_{i=1}^{4}N_i(\xi,\eta)x_i \tag{43}$$

$$z(x, y)=\sum_{i=1}^{4}N_i(\xi,\eta)z_i \tag{44}$$

The strains are evaluated by using strain–displacement relationship. That is,

$$\begin{Bmatrix}\varepsilon_{xx}\\ \varepsilon_{xx}\\ 2\varepsilon_{xz}\\ E_z\end{Bmatrix}=\begin{bmatrix}\partial/\partial x & 0 & 0\\ 0 & \partial/\partial z & 0\\ \partial/\partial z & \partial/\partial x & 0\\ 0 & 0 & 1\end{bmatrix}\begin{Bmatrix}u\\ w\\ D_z\end{Bmatrix} \tag{45}$$

Using equations (40) and (42) in the above equation enables expressing the strains in terms of nodal displacement vector $\{u\}_e=\{u_1\ \ w_1\ \ u_2\ \ w_2\ \ u_3\ \ w_3\ \ u_4\ \ w_4\}^{\mathrm{T}}$ and electric field vector $\{E_z\}_e=\{E_{z1}\ \ E_{z2}\ \ E_{z3}\ \ E_{z3}\}^{\mathrm{T}}$. That is, strain can be written as

$$\{\varepsilon\}=[B]\{u\}=\begin{bmatrix}[B]_{u(3\times 8)} & 0\\ 0 & [B]_{E(1\times 4)}\end{bmatrix} \tag{46}$$

where $[B]$ matrix is given by

$$[B] = \begin{bmatrix} \frac{\partial N_1}{\partial x} & 0 & \frac{\partial N_2}{\partial x} & 0 & \frac{\partial N_3}{\partial x} & 0 & \frac{\partial N_4}{\partial x} & 0 & 0 & 0 & 0 & 0 \\ 0 & \frac{\partial N_1}{\partial z} & 0 & \frac{\partial N_2}{\partial z} & 0 & \frac{\partial N_3}{\partial z} & 0 & \frac{\partial N_4}{\partial z} & 0 & 0 & 0 & 0 \\ \frac{\partial N_1}{\partial z} & \frac{\partial N_1}{\partial x} & \frac{\partial N_2}{\partial z} & \frac{\partial N_2}{\partial x} & \frac{\partial N_3}{\partial z} & \frac{\partial N_3}{\partial x} & \frac{\partial N_4}{\partial z} & \frac{\partial N_4}{\partial x} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & N_1 & N_2 & N_3 & N_4 \end{bmatrix} \tag{47}$$

Using equations (46) and (42) in the weak form of the equation (equation 24), and performing variational minimization, we get

$$\begin{aligned} &\{\delta u\}_e^{\mathrm{T}} \left(\int_V [N]^{\mathrm{T}} \rho [N] \, \mathrm{d}V \right) \{\ddot{u}\}_e \\ &\quad + \{\delta u\}_e^{\mathrm{T}} \left(\int_V [B_u]^{\mathrm{T}} [\hat{C}] [B_u] \, \mathrm{d}V \right) \{u\}_e \\ &\quad - \{\delta u\}_e^{\mathrm{T}} \left(\int_V [B_u]^{\mathrm{T}} [\hat{e}] [B_E] \, \mathrm{d}V \right) \{E_z\}_e \\ &\quad - \{\delta E_z\}_e^{\mathrm{T}} \left(\int_V [B_E]^{\mathrm{T}} [\hat{e}]^{\mathrm{T}} [B_u] \, \mathrm{d}V \right) \{u\}_e \\ &\quad - \{\delta E_z\}_e^{\mathrm{T}} \left(\int_V [B_E]^{\mathrm{T}} \hat{\mu}_{33} [B_E] \, \mathrm{d}V \right) \{E_z\}_e \\ &\quad - \{\delta u\}_e^{\mathrm{T}} \{F_c\} - \{\delta u\}_e^{\mathrm{T}} \int_{S_1} [N]^{\mathrm{T}} \{F_s\} \, \mathrm{d}S_1 \\ &\quad - \{\delta E_z\}_e^{\mathrm{T}} \int_{S_2} [B_E]^{\mathrm{T}} D_s \, \mathrm{d}S_2 = 0 \end{aligned} \tag{48}$$

Since $\{\delta u\}_e$ and $\{\delta E_z\}_e$ are arbitrary, the above expression can be written in a concise matrix form as

$$\begin{aligned} &\begin{bmatrix} [M_{uu}] & [0] \\ [0] & [0] \end{bmatrix} \begin{Bmatrix} \{\ddot{u}\}_e \\ \{\ddot{E}_z\}_e \end{Bmatrix} \\ &\quad + \begin{bmatrix} [K_{uu}] & [K_{uE}] \\ [K_{uE}]^{\mathrm{T}} & [K_{EE}] \end{bmatrix} \begin{Bmatrix} \{u\}_e \\ \{E_z\}_e \end{Bmatrix} = \begin{Bmatrix} \{F\}_e \\ \{q\}_e \end{Bmatrix} \end{aligned} \tag{49}$$

The above equation is the elemental equilibrium in the discritized form, where $[M_{uu}]$ is the mass matrix, $[K_{uu}]$ is the stiffness matrix corresponding to mechanical degrees of freedom, $[K_{uE}]$ is the stiffness matrix due to electromechanical coupling, and $[K_{EE}]$ is the stiffness matrix due to electrical degrees of freedom alone. Note that all these matrices require the volume integral to be evaluated. Since the exact integration of these is most difficult to achieve, we resort to numerical integration (see [1–3] for more details). Here, $\{F\}_e$ is the elemental nodal vector and $\{q\}_e$ is the elemental charge vector. These matrices are given by

$$\begin{aligned} [M_{uu}] &= t \int_{-1}^{1} \int_{-1}^{1} [N]^{\mathrm{T}} \rho [N] |J| \, \mathrm{d}\xi \, \mathrm{d}\eta, \\ [K_{uu}] &= t \int_{-1}^{1} \int_{-1}^{1} [B_u]^{\mathrm{T}} [\hat{C}] [B_u] |J| \, \mathrm{d}\xi \, \mathrm{d}\eta, \\ [K_{uE}] &= -t \int_{-1}^{1} \int_{-1}^{1} [B_u]^{\mathrm{T}} [\hat{e}] [B_E] |J| \, \mathrm{d}\xi \, \mathrm{d}\eta, \\ [K_{EE}] &= t \int_{-1}^{1} \int_{-1}^{1} [B_E]^{\mathrm{T}} \hat{\mu}_{33} [B_E] |J| \, \mathrm{d}\xi \, \mathrm{d}\eta \end{aligned} \tag{50}$$

The elemental load and charge vectors are given by

$$\{F\}_e = \{F\}_c + \int_{S_1} [N]^{\mathrm{T}} \{F\}_s \, \mathrm{d}S_1 \tag{51}$$

$$\{q\}_e = -\int_{S_2} [N]^{\mathrm{T}} D_s \, \mathrm{d}S_2 \tag{52}$$

The matrices in equation (49) are then assembled to obtain their global counterparts and solved for obtaining solutions for displacements and electric field. Note that it has a zero diagonal block in the mass matrix. The method of solution for sensing and actuation problem is quite different. For sensing problem, for a given mechanical loading, we need to determine the voltage developed across the smart patch. This is done by first obtaining the mechanical displacement due to the given mechanical load, which is then used to obtain the electric field and hence the voltage developed in the sensor patch. In order to solve this, the global matrix equation can be expanded

and written as

$$[M_{uu}]\{\ddot{u}\} + [K_{uu}]\{u\} + [K_{uE}]\{E_z\} = \{F\}$$
$$[K_{uE}]^{\mathrm{T}}\{u\} + [K_{EE}]\{E_z\} = \{q\} \quad (53)$$

We can write the second part of the above equation as

$$\{E_z\} = [K_{EE}]^{-1}\{q\} - [K_{EE}]^{-1}[K_{uE}]^{\mathrm{T}}\{u\} \quad (54)$$

Using the above equation in the first of equation (53) and simplifying, we get

$$[M_{uu}]\{\ddot{u}\} + [\overline{K}_{uu}] = \{\overline{F}\} \quad (55)$$

where

$$[\overline{K}_{uu}] = [K_{uu}] - [K_{uE}][K_{EE}]^{-1}[K_{uE}]^{\mathrm{T}} \quad (56)$$
$$\{\overline{F}\} = \{F\} - [K_{EE}]^{-1}\{q\} \quad (57)$$

Note that equation (55) is only in terms of mechanical displacements, which is solved. Using this solution, electrical fields are obtained using equation (54), from which voltages can be obtained. This procedure is adopted for sensing problem, which is used in the health monitoring studies. For actuation problem, the voltages and hence the electric field goes as input. That is, the second part of equation (49) is not required. Hence, the equation that requires solution becomes

$$[M_{uu}]\{\ddot{u}\} + [K_{uu}]\{u\} = \{F\} - [K_{uE}]\{E_z\} = \{F^*\} \quad (58)$$

More details on this formulation can be obtained from [13].

4.2 Numerical example

4.2.1 Actuation example

The main objective of this example is to demonstrate the actuation capability of the formulated FE with piezoelectric actuators and validate the formulated element in the process by comparing the results obtained from the standard published results. Here, a piezoelectric bimorph composite beam is considered for analysis. Chen [14] presented the comparative study of the bending of a bimorph beam due to external applied voltage as a part of verifying the accuracy of the piezoelectric FE solution and this bimorph beam configuration was adopted from Hwang [15]. In this study, the same configuration of the bimorph beam is considered. The bimorph beam consists of two identical PVDF beams laminated together with opposite polarities. The schematic diagram of the bimorph beam is as shown in Figure 4. The dimensions of the beam are taken as 100 mm × 5.0 mm × 0.5 mm. The material properties of the PVDF bimorph beam are taken same as that of Chen [14] and are as follows: Young's modulus E_{11} is equal to $0.2e^{10}$ N m^{-2}, shear modulus G_{12} is equal to $0.775e^{10}$ N m^{-2}, Poisson's ratio ν_{12} is equal to 0.29, piezoelectric constant e_{31} is equal to 0.046 C m^{-2}, and piezoelectric constant e_{32} is equal to e_{31}. The theoretical solution for transverse displacement for the above problem is given in [14], which

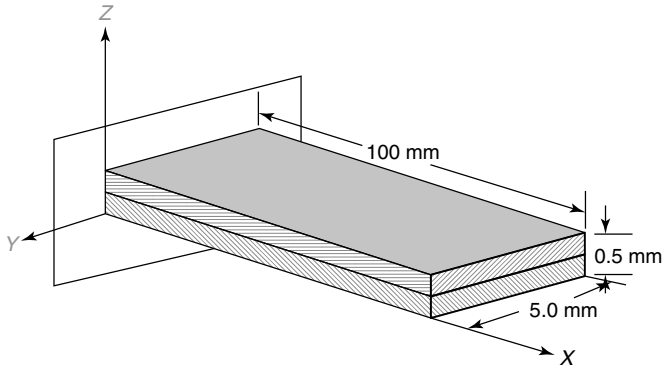

Figure 4. Schematic diagram of the piezoelectric PVDF bimorph cantilever beam.

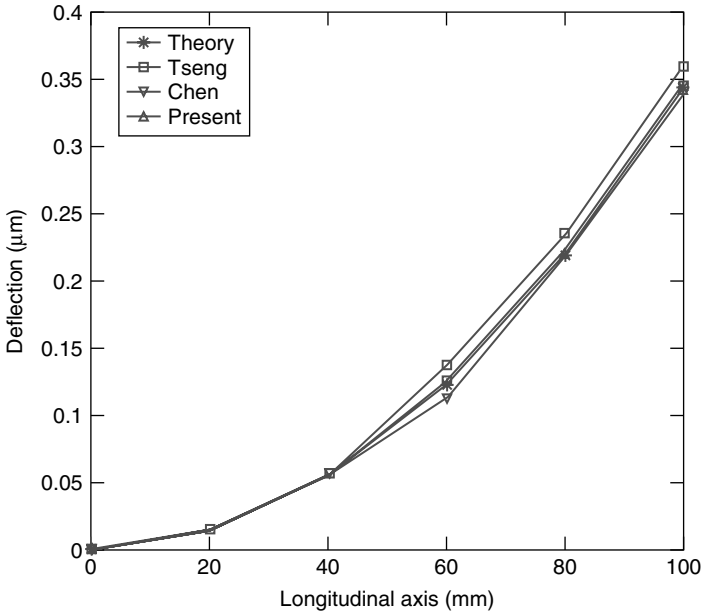

Figure 5. Centerline deflections for a PVDF bimorph beam under a unit voltage.

is given by

$$w(x) = 0.375\frac{e_{31}}{E}V\left(\frac{x}{t}\right)^2 \tag{59}$$

where V is the applied voltage and t is the thickness of the beam. This beam is modeled using 200 formulated elements along the $x-z$ plane. When an external active voltage is applied across the thickness, the induced strain generates control forces that bend the bimorph beam. A unit voltage is applied across the thickness and the deflections at the nodes are computed. The deflection of the beam along the central longitudinal axis obtained from the present formulation is compared with the theoretical value and the works of Chen [14], and Tzou and Tseng [16], respectively. Figure 5 shows the comparison of deflection along the length of the beam for unit voltage applied across the thickness.

Next, the deflection of the beam is calculated for different applied voltage in the range of 0–100 V. The objective here is to actuate the beam to the extent so as to make the tip deflection, due to applied load, negligible. This is shown in Figure 6. From the figure, we can clearly see that with increase in voltage, the tip deflection reduces gradually toward zero value.

5 FINITE ELEMENT MODELING OF MAGNETOSTRICTIVE SENSORS AND ACTUATORS

Analysis of structures with magnetostrictive sensors/actuators is generally performed using uncoupled models. Uncoupled models are based on the assumption that the magnetic field within the magnetostrictive material is proportional to the electric coil current times the number of coil turns per unit length. Owing to this assumption, actuation and sensing equations get uncoupled. For actuator, the strain due to magnetic field (which is proportional to coil current) is incorporated as the equivalent nodal load in the FE model for calculating the block force. Thus, with this procedure, analysis is carried out without taking smart (magnetic) degrees of freedom in the FE model. Similarly for sensor, where generally coil current is assumed zero, the magnetic flux density is proportional to mechanical stress, which can be calculated from the FE results through post-processing. This assumption on magnetic field, leads to the violation of flux line continuity, which is one of the four Maxwell's equations in electromagnetism.

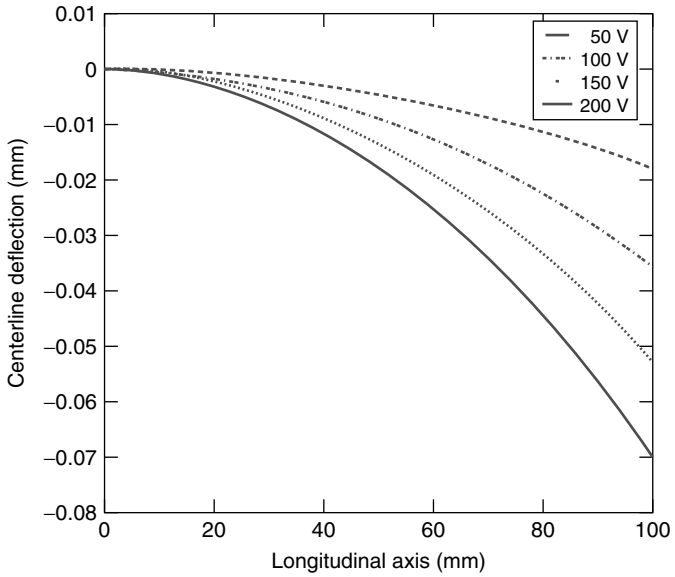

Figure 6. Deflection profile for a PVDF bimorph beam for various voltages.

On the other hand, in coupled model, it is considered that magnetic flux density and/or strain of the material are functions of stress and magnetic field, without any additional assumption on magnetic field, like in uncoupled model. The procedure to obtain the constitutive model for a composite with magnetostrictive sensors/actuators is very similar to what was derived for the piezoelectric sensors/actuators and hence is not repeated here. We directly go to the FE formulation.

The FE formulation of structures with embedded magnetostrictive patches differs depending upon whether the constitutive model is coupled or uncoupled. For the uncoupled model, the magnetic field is assumed proportional to the coil current and, as a result, the sensing and actuation constitutive relations are solved independently. That is, there is no need to have magnetic field as independent degrees of freedom. However, in a coupled model, both the sensing and actuation constitutive laws need to be solved simultaneously, since no explicit variation of the magnetic field with respect to magnetostrictive patch parameters are available. This requires that the magnetic field be taken as independent degrees of freedom. Here, we outline the procedure of modeling magnetostrictive sensors/actuators for both uncoupled and coupled constitutive law.

FE formulation begins by writing the associated energy in terms of nodal degrees of freedom by assuming the displacement and magnetic field variation in three coordinate directions over each element. That is, the displacement field can be written as

$$\{U\} = \{\, u \quad v \quad w \,\} = [N_u]\{U\}_e \tag{60}$$

Here, $u(x, y, z, t)$, $v(x, y, z, t)$, and $w(x, y, z, t)$ are the displacement components in the three coordinate directions, $[N_u]$ is the shape functions associated with mechanical degrees of freedom, and $\{U\}_e$ is the nodal displacement vector. If isoparametric formulation is used, then the conventional isoparametric shape functions in natural coordinate could be adopted. The strains can be expressed in terms of displacement through strain–displacement relationship. That is,

$$\begin{aligned}\{\varepsilon\} &= \{\varepsilon_{xx} \quad \varepsilon_{yy} \quad \varepsilon_{zz} \quad \gamma_{yz} \quad \gamma_{xz} \quad \gamma_{xy}\}^{\mathrm{T}} \\ &= [\overline{B}]\{U\}_e \end{aligned} \tag{61}$$

where $[\overline{B}]$ is the strain–displacement matrix. For coupled analysis, we need to take magnetic field as independent degrees of freedom. In such cases, the magnetic field in the three coordinate directions can

be written as

$$\{H\} = \{H_x \quad H_y \quad H_z\} = [N_H]\{H\}_e \tag{62}$$

where $\{H\}_e$ is the nodal magnetic field vector and $[N_H]$ is the shape function associated with magnetic field degrees of freedom.

The strain energy in a structure with magnetostrictive patches over a volume V is given by

$$V_e = \frac{1}{2}\int_V \{\varepsilon\}^{\mathrm{T}}\{\sigma\}\,\mathrm{d}V \tag{63}$$

Substituting for $\{\sigma\}$ from equation (4), we can write the above equation in terms of strains and magnetic field vector. In this equation, the strains are expressed in terms of displacement using equation (61) and magnetic field in terms of nodal magnetic field vector using equation (62).

The resulting expression for the strain energy becomes

$$V_e = \frac{1}{2}\{U\}_e{}^{\mathrm{T}}[K_{uu}]\{U\}_e - \frac{1}{2}\{U\}_e{}^{\mathrm{T}}[K_{uH}]\{H\}_e \tag{64}$$

where

$$[K_{uu}] = \int_V [\overline{B}]^{\mathrm{T}}[Q][\overline{B}]\,\mathrm{d}V,$$

$$[K_{uH}] = \int_V [\overline{B}]^{\mathrm{T}}[e]^{\mathrm{T}}[N_H]\,\mathrm{d}V \tag{65}$$

where $[K_{uu}]$ is the stiffness matrix associated with mechanical degrees of freedom and $[K_{UH}]$ is the coupling stiffness matrix, which couples the mechanical and magnetic degrees of freedom. Kinetic energy is given by

$$T_e = \frac{1}{2}\int_V \{\dot{U}\}^{\mathrm{T}}\rho\{\dot{U}\}\,\mathrm{d}V \tag{66}$$

Here, $\{\dot{U}\}$ is the velocity vector and ρ is the average density of the host material. Using equation (60) in the above equation, we can write the kinetic energy as

$$T_e = \frac{1}{2}\{\dot{U}\}^{\mathrm{T}}[M_{uu}]\{\dot{U}\} \tag{67}$$

where $[M_{uu}]$ is the mass matrix associated only with mechanical degrees of freedom and is given by

$$[M_{uu}] = \int_V [N_u]^{\mathrm{T}}\rho[N_u]\,\mathrm{d}V \tag{68}$$

The magnetic potential energy for the system can be written as

$$V_m = \frac{1}{2}\int_V [B]^{\mathrm{T}}\{H\}\,\mathrm{d}V \tag{69}$$

Substituting for $[B]$ from equation (4), and $\{H\}$ from equation (62), we can write the magnetic potential energy as

$$V_m = \frac{1}{2}\int_V \{[e]\{\varepsilon\} + [\mu^{\varepsilon}]\{H\}\}^{\mathrm{T}}\{H\}\,\mathrm{d}V \tag{70}$$

Substituting for strains from equation (61), we get

$$V_m = \frac{1}{2}\{U\}_e{}^{\mathrm{T}}[K_{uH}]^{\mathrm{T}}\{H\}_e + \frac{1}{2}\{H\}_e{}^{\mathrm{T}}[K_{HH}]\{H\}_e \tag{71}$$

where,

$$[K_{HH}] = \int_V [N_H]^{\mathrm{T}}[\mu^{\varepsilon}]\left[N_H\right]\,\mathrm{d}V \tag{72}$$

When an applied current I ampere (ac or dc) is fed to the patch having N number of coils, it creates a magnetic field, which, in turn, introduces an external force in the patch. The external work done over a magnetostrictive patch of area A due to this field is given by

$$W_m = IN\int_A [\mu^{\sigma}]\{H\}\,\mathrm{d}A \tag{73}$$

Here, $[\mu^{\sigma}]$ is the permeability matrix measured at constant stress. It is necessary to convert this area integral into a volume integral. If n is the number of coil turns per unit length and $\{l_c\}$ is the direction cosine vector of the coil axis, the above area integral can be converted into volume integral by replacing N by $n\{l_c\}^{\mathrm{T}}$. Substituting for the magnetic field from equation (62), equation (73) becomes

$$W_m = \{F_H\}^{\mathrm{T}}\{H\}_e,$$

$$\{F_H\} = In\{l_c\}^{\mathrm{T}}\int_V [\mu^{\sigma}][N_H]\,\mathrm{d}V \tag{74}$$

The external mechanical work done owing to body force or surface traction vector can be written in the form

$$W_e = \{R\}^{\mathrm{T}}\{U\}_e \tag{75}$$

Using Hamilton's principle, $\delta \int_{t_1}^{t_2} (T_e - V_e + V_m + W_m + W_e)\,\mathrm{d}t = 0$ gives the necessary FE governing equation. This takes a varied form for uncoupled and coupled models, which are given below.

In uncoupled model, the magnetic field is assumed proportional to the coil current and hence a variation with respect to magnetic field is not performed. That is, the magnetic field is normally equal to $H = nI$, where n is normally the coil turns per unit length of the magnetostrictive material patch. With this assumption, the Hamilton's principle gives the equation of motion as

$$[M_{uu}]\{\ddot{U}\}_e + [K_{uu}]\{U\}_e = [K_{uH}]\{H\}_e - \{R\} \quad (76)$$

where $\{\ddot{U}\}_e$ is the elemental acceleration vector and the magnetic field in the above equation is obtained by $\{H\}_e = n_e I$ with n_e being the elemental coil turns per unit length.

In the case of coupled model, one has to also take a variation on the magnetic field as there is no explicit relation of this with respect to any of the parameters. Hence, both mechanical and magnetic degrees of freedom are considered as unknown. The Hamilton's principle gives the following coupled set of equation.

$$\begin{bmatrix} [M_{uu}] & [0] \\ [0] & [0] \end{bmatrix} \begin{Bmatrix} \{\ddot{U}\}_e \\ \{\ddot{H}\}_e \end{Bmatrix} + \begin{bmatrix} [K_{uu}] & -[K_{uH}] \\ [K_{uH}]^{\mathrm{T}} & [K_{HH}] \end{bmatrix} \begin{Bmatrix} \{U\}_e \\ \{H\}_e \end{Bmatrix} = \begin{Bmatrix} -\{R\} \\ \{F_H\} \end{Bmatrix} \quad (77)$$

Note that the stiffness matrix is not symmetric and have a block zero diagonal matrix in the mass matrix as magnetic field does not contribute to the inertia of the composite. For effective solution, the above equation is expanded and the magnetic degrees of freedom are condensed out. The reduced equation of motion can be written as

$$[M_{uu}]\{\ddot{U}\}_e + [K^*{}_{uu}]\{U\}_e = \{R^*\} \quad (78)$$

where,

$$[K^*{}_{uu}] = \left[[K_{uu}] + [K_{uH}][K_{HH}]^{-1}[K_{uH}]^{\mathrm{T}}\right] \quad (79)$$

$$\{R^*\} = [K_{uH}][K_{HH}]^{-1}\{F_H\} - \{R\} \quad (80)$$

Before solution of equation (78), all the matrices are formed for each element and assembled.

After the computation of nodal displacement and velocities, we can compute the sensor open circuit voltage. This is particularly of great interest in structural health monitoring studies. The process of computing this for coupled and uncoupled models is quite different. Using Faraday's law, open circuit voltage V_v in the sensing coil can be calculated from magnetic flux passing through the sensing patch.

In uncoupled model, nodal magnetic field is assumed constant over the element and with zero sensor coil current. To get open circuit voltage, magnetic flux density can be expressed in terms of strain from sensing equation (equation 5), which is given by

$$\{B\} = [d]\{\sigma\} = [d][Q]\{\varepsilon\} = [e]\{\varepsilon\} = [e][\overline{B}]\{U\}_e \quad (81)$$

Now using Faraday's law, open circuit voltage of the sensor having N_S turns and area A can be calculated from the expression

$$V_v = -N_S \int_A \frac{\partial}{\partial t}\{[e]\{\varepsilon\}\}\,\mathrm{d}A \quad (82)$$

The above integral can be converted to volume integral as before by multiplying it with the direction cosine vector, and the open circuit voltage can now be written as

$$V_v = \{F_v\}^{\mathrm{T}}\{U_e\} \quad (83)$$

$$\{F_v\}^{\mathrm{T}} = -n_s\{l_c\}^{\mathrm{T}} \int_V [e][\overline{B}]\,\mathrm{d}V \quad (84)$$

Here, n_s is the coil turns per unit length of the sensor.

In the case of coupled model, the magnetic flux density is computed from nodal magnetic field, which is obtained from FE analysis. Thus, open circuit voltage in the sensor takes a different expression and can be calculated from the expression

$$V_v = -N_s \int_A \frac{\partial}{\partial t}[\mu^\sigma]\{H\}\,\mathrm{d}A \quad (85)$$

This can again be converted into volume integral as before. Substituting for $\{H\}$ from equation (62), in terms of nodal magnetic degrees of freedom, for

which the second part of equation (77) is used and finally after simplification, the open circuit voltage can be written as

$$V_v = \{F_v\}^{\mathrm{T}}\{U_e\} \tag{86}$$

$$\{F_v\}^{\mathrm{T}} = -n_s\{l_c\}^{\mathrm{T}}\left[\int_V [\mu^{\sigma}][N_H]\,\mathrm{d}V\right] \times [K_{HH}]^{-1}[K_{uH}]^{\mathrm{T}} \tag{87}$$

The above formulation is a general 3-D composite structure with embedded/surface-bonded magnetostrictive patches. In the next subsection, we generalize this to a beam structure.

5.1 Modeling of laminated composite beam with embedded Terfenol-D patch

The displacement field for the beam based on first-order shear deformation theory (FSDT) is given by

$$u(x, y, x, t) = u_0(x, t) - z\phi(x, t) \tag{88}$$

$$v(x, y, z, t) = 0 \tag{89}$$

$$w(x, y, x, t) = w(x, t) \tag{90}$$

As before, the magnetic field (H) is only in the axial direction. Next, we need to assume the necessary polynomials for the mid-plane axial displacement u_0, lateral displacement w_0, and the slope ϕ. Since the slopes are independent and not derivable from the lateral displacement, C^0 continuous formulation is sufficient and hence, we can use linear polynomials. All the formulated matrices are numerically integrated. However, this formulation is prone to exhibit what is called the *shear locking* problem. That is, when this element is used for a beam that is very thin, then the shear strains should go to zero. Since this element is based on FSDT, this does not happen, and in the process produces results that are many orders smaller than the actual result. More details on shear locking problems and their alleviation can be obtained in [17–20]. One of the simplest ways to eliminate locking is to reduce the integrated part of the mechanical stiffness matrix contributed by the shear stress. This is undertaken in this formulation.

The approach is very similar to the formulation of the quadrilateral element in the previous section. First, using the assumed polynomial for axial, transverse, and rotation degrees of freedom, the shape functions are constructed. Using these, the strain–displacement matrix is constructed, which relates the strains to the nodal displacements. The stiffness and mass matrix is then evaluated using equations (65) and (68), respectively. Note that while evaluating the stiffness matrix, isoparametric shape function is used and the matrix is numerically integrated. In addition, to alleviate the shear locking problem, the matrix is reduced integrated. We write down only the final form of elemental matrices involved. The mechanical stiffness matrix $[K_{uu}]$ is 6×6 and is given by

$$[K_{uu}] = \begin{bmatrix} \frac{A_{11}}{L} & \frac{A_{15}}{L} & \left(\frac{A_{15}}{2} - \frac{B_{11}}{L}\right) & -\frac{A_{11}}{L} & -\frac{A_{15}}{L} & \left(\frac{A_{15}}{2} + \frac{B_{11}}{L}\right) \\ & \frac{A_{55}}{L} & \left(\frac{A_{55}}{2} - \frac{B_{15}}{L}\right) & -\frac{A_{15}}{L} & -\frac{A_{55}}{L} & \left(\frac{A_{55}}{2} + \frac{B_{15}}{L}\right) \\ & & \left(\frac{A_{55}L}{4} - B_{15}\right) & \left(-\frac{A_{15}}{2} + \frac{B_{11}}{L}\right) & \left(-\frac{A_{55}}{2} + \frac{B_{15}}{L}\right) & \left(\frac{A_{55}L}{4} - \frac{D_{11}}{L}\right) \\ & & & \frac{A_{11}}{L} & \frac{A_{15}}{L} & \left(-\frac{A_{15}}{2} - \frac{B_{11}}{L}\right) \\ & sym & & & \frac{A_{55}}{L} & \left(-\frac{A_{55}}{2} - \frac{B_{15}}{L}\right) \\ & & & & & \left(\frac{A_{55}L}{4} + B_{15} + \frac{D_{11}}{L}\right) \end{bmatrix} \tag{91}$$

where,

$$[A_{ij}, B_{ij}, D_{ij}] = \int_A Q_{ij}[1, z, z^2]\,\mathrm{d}A \qquad (92)$$

The magnetomechanical coupling matrix is given by

$$[K_{uH}]^{\mathrm{T}} = \frac{1}{2}\begin{bmatrix} -e^0{}_{11} & 0 & e^1{}_{11} & e^0{}_{11} & 0 & -e^1{}_{11} \\ -e^0{}_{11} & 0 & e^1{}_{11} & e^0{}_{11} & 0 & -e^1{}_{11} \end{bmatrix} \qquad (93)$$

where,

$$[\, e^0{}_{11} \quad e^1{}_{11}\,] = \int_A e_{11}[\,1 \quad z\,]\,\mathrm{d}A \qquad (94)$$

Matrix $[K_{HH}]$ is given by

$$[K_{HH}] = \frac{L\mu^0}{6}\begin{bmatrix} 2 & 1 \\ 1 & 2 \end{bmatrix} \qquad (95)$$

$$\mu^0 = \int_A \mu^{\varepsilon}\,\mathrm{d}A \qquad (96)$$

In the case of coupled model, we require force vector $\{F_H\}$, which is given in equation (74). This vector becomes

$$\{F_H\} = \frac{In\mu^0 L}{2}\begin{Bmatrix} 1 \\ 1 \end{Bmatrix} \qquad (97)$$

The mass matrix is given by

$$[M_{uu}] = \begin{bmatrix} 2I_0 & 0 & -2I_1 & I_0 & 0 & -I_1 \\ & 2I_0 & 0 & 0 & I_0 & 0 \\ & & 2I_2 & -I_1 & 0 & I_2 \\ & & & 2I_0 & 0 & -2I_1 \\ & sym & & & 2I_0 & 0 \\ & & & & & 2I_2 \end{bmatrix} \qquad (98)$$

where,

$$[I_0, I_1, I_2] = \int_A \rho[1, z, z^2]\,\mathrm{d}A \qquad (99)$$

5.2 Numerical examples

A composite magnetostrictive bimorph beam shown in Figure 7 is analyzed to verify the effectiveness of the formulated element. A dynamic response analysis is performed on this beam to bring out the effects of coupling in the constitutive model. Note that the coupling aspects were addressed in detail on the article on constitutive model of magnetostrictive materials. In this beam example, length and width of the beam are 500 and 50 mm, respectively. The beam is made of 12 layers with thickness of each layer being 0.15 mm. Surface-mounted magnetostrictive patches at the top and bottom layers are considered as sensor and actuator, respectively. Elastic modulus of composite is assumed as 181 and 10.3 GPa in parallel (E_1) and perpendicular (E_2) direction of fiber. Density (ρ) and shear modulus

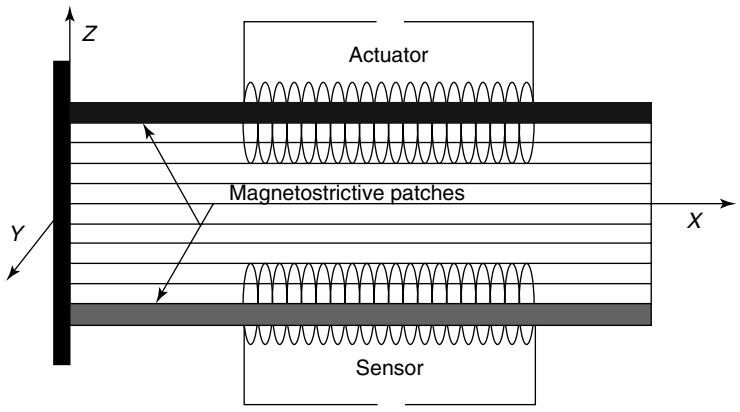

Figure 7. Cantilever magnetostrictive bimorph beam.

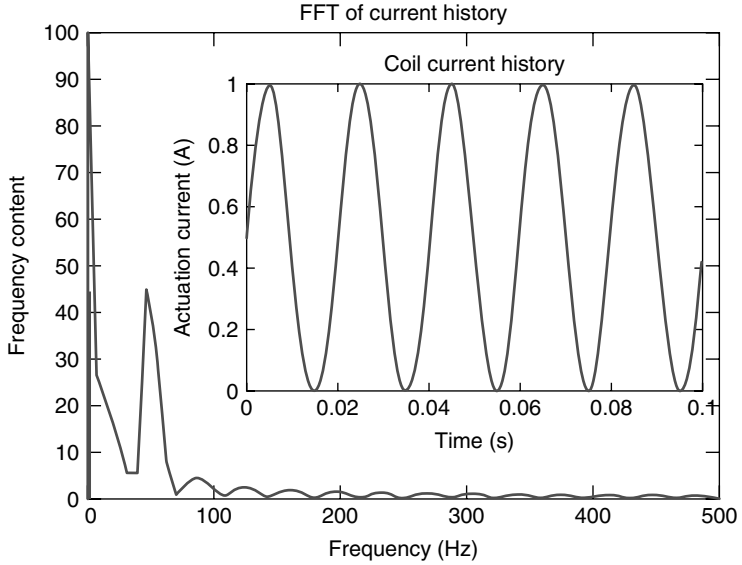

Figure 8. Sinusoidal input force (50 Hz) of in-time and frequency domain.

(G_{12}) of composite are $1.6\,\mathrm{g\,cm^{-3}}$ and 28 GPa, respectively. Elastic modulus (E_m), shear modulus (G_m), and density (ρ_m) of the magnetostrictive material are taken as 30 GPa, 23 GPa, and $9.25\,\mathrm{g\,cm^{-3}}$, respectively. Magnetomechanical coupling coefficient is taken as 15E-09 $\mathrm{m\,A^{-1}}$. Permeability at vacuum or air is assumed to be 400 π $\mathrm{nH\,m^{-1}}$. Constant stress relative permeability for magnetostrictive material is assumed to be equal to 10. The number of coil turns per meter (n) in sensor and actuator is assumed to be 20 000.

To observe the effects of coupled analysis on structure with magnetostrictive material, time-domain analysis is carried out for both low- and high-frequency actuation for the same cantilever composite beam. Here, the structure is actuated through time-domain signal with sinusoidal actuation current I of 0.5-A ac current (I_0) and 0.5-A bias current (I_{dc}) at 50-Hz frequency. The equation of current is of the form

$$I = I_0 \sin(\omega t) + I_{\mathrm{dc}} \tag{100}$$

Figure 8 shows the time and frequency-domain representation of a 50-Hz sinusoidal signal.

Direct transient dynamic analysis is performed for 200 time steps to calculate open circuit voltage of the sensor and beam-tip velocity. The time step considered is equal to 50 ms. Figure 9(a) and (b) shows the tip velocity for unidirectional laminate (0° ply angle) and 90° cross ply laminate, respectively. The figures show the responses for both coupled and uncoupled constitutive models for magnetostrictive material. Following are the observations that can be made from these figures: (i) for 0° laminate, the effect of coupling in the constitutive model is not very significant, while in the 90° laminate, we see significant difference; (ii) coupled models tend to give lower amplitudes; and (iii) the coupled model, in addition to the given lower amplitudes, also shifts the phase. Next, we compute the open circuit voltage developed across the sensor patches and this is shown in Figure 10(a) and (b), respectively. These figures show that the effect of coupling on the voltages is significant for 90° composite. One important aspect to be noticed is that the voltage developed is significant (of the order of millivolts) considering that a small amplitude current was only fed into the actuator.

6 SUMMARY

In this article, FE modeling of composite structures with embedded smart sensors/actuators is presented. Three different smart sensors/actuators, namely, the

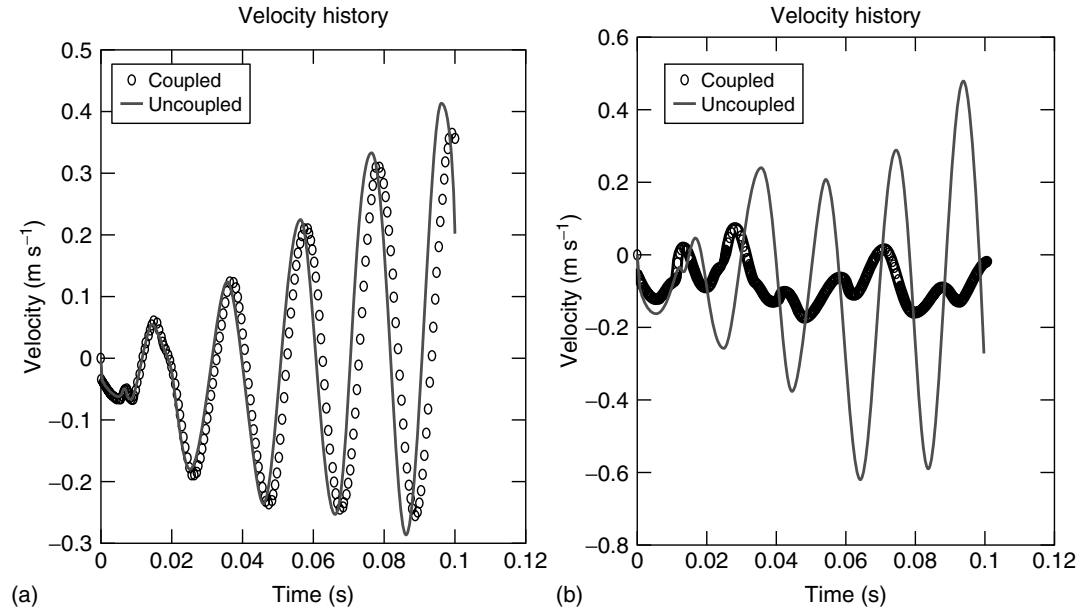

Figure 9. (a) Tip velocity for 0° laminate, (b) tip velocity for 90° laminate.

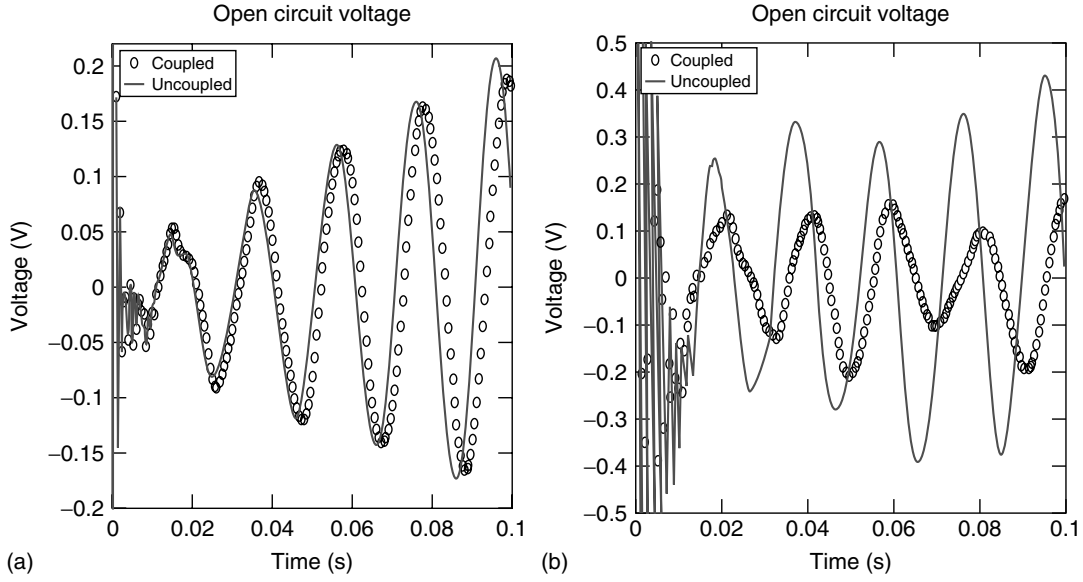

Figure 10. (a) Open circuit voltage for 0° laminate and (b) open circuit voltage for 90° laminate.

PZT, Terfenol-D, and PFCs are considered for FE modeling. The general FE procedure is outlined and specialized to a few specific cases such as the quadrilateral element for the PZT sensor/actuator case and the beam element formulation for the Terfenol-D sensor/actuator. The efficiency of the formulated element is demonstrated using some numerical examples.

Chapter 42
Modeling Aspects in Finite Elements

Srinivasan Gopalakrishnan
Department of Aerospace Engineering, Indian Institute of Science, Bangalore, India

1 INTRODUCTION

Modeling is one of the key elements in structural health monitoring (SHM) studies. Proper mathematical models are required to postprocess the measured output to predict the damage location and its extent. Some of the commonly used mathematical models are the finite element methods (FEMs), spectral element methods, and boundary element methods. Some of these techniques are highlighted in articles **Finite Elements: Modeling of Piezoceramic and Magnetostrictive Sensors and Actuators**; **Modeling for Detection of Degraded Zones in Metallic and Composite Structures**; **Damage Detection Using Piezoceramic and Magnetostrictive Sensors and Actuators**; **Modeling of Lamb Waves in Composite Structures**. Among them, FEM is the most powerful method and has great ability to model complex geometries with relative ease.

FEM is a powerful numerical technique to solve problems governed by partial differential equations over complex domains. It is normally adopted to solve forward problems in structures, that is, for a given a loading (input), one can easily determine the deformations the structures undergo (output). SHM, however, requires estimating the state of the structure from the measured output (deformation, velocities, acceleration, voltages, etc.) for a given predefined input (force) [1]. Hence, SHM falls under the realm of system identification problem. Such problems are also called the *inverse problems*.

Many researchers have used FEM to model flaws. For example, Yang *et al.* [2] used FEM to study the Lamb wave propagation in composite plates. Powar

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

and Ganguli [3] used FEM to model matrix cracks in composites beam and to study the performance of a rotating helicopter blade. FEM was used to obtain crack parameters in [4]. A new method to model cracks under the finite element (FE) framework using the Heaveside function is proposed in [5]. Many researchers have used FEs to model cracks to perform fracture mechanics studies. The related literature is very large and hence is not covered in this article.

Performing inverse problems using finite elements is not straightforward. This requires the determination of frequency response functions (FRFs) directly from the analysis. FEM, being predominantly a time domain method, is a time-consuming process for the estimation of FRF. Frequency domain methods, such as spectral FEMs [6, 7], are ideally suited for solving inverse problems since FRF, also called the *system transfer function* (STF), which directly relates the input and the output, is a direct by-product of such an analysis. Hence, for studying SHM problems through FE, one cannot employ methods requiring the determination of STF.

Alternatively, one can perform an SHM study by treating the problem as a forward problem and study the signature of the output to a set of predefined inputs to characterize the flaw.

Use of modal methods is one such example. There are quite a few works in this area [8–10], wherein the damage was predicted on the basis of the change in the natural frequencies. However, for very small damages, the change in stiffness is so insignificant that the changes in the first few natural frequencies are hardly noticeable. In such a case, one has to find different signatures that are sensitive for small stiffness changes. One such signature is to see the change in the curvature modes [11, 12]. These modes are very difficult to determine from the measured responses. Hence, modal analysis–based methods as such are not recommended for predicting very small damages.

Damage prediction is successful only if one can see a significant change in the output of the structure in a damaged state compared to the output of the structure in a healthy state. To entice a change in the output, especially in structures having very small damage, one has to fine-tune the frequency content of the predefined input signal. This is required to make the wavelengths comparable to the damage sizes. A change in the frequency content of the signal requires a change in the FE mesh. If all these are performed in an ad hoc manner, the process of analysis of a damaged structure takes significant amount of time. This article basically gives some ideas as to how to choose the mesh size for a given flaw size or for a given frequency content of the input signal.

Another factor that makes the interpretation of the signatures obtained from a cracked structure due to a predefined input difficult is the scattering of waves due to boundary reflections.

Although techniques such as time reversal methods [13, 14] are available for identifying the scattered components of wave response due to boundaries, these methods are difficult to apply under the FE computational frame work. Hence, for the damage detection to be successful, it is necessary to differentiate between the reflections arising due to the damage and the reflections from the boundary so that the boundary reflections are filtered out. Knowing the speed of the medium, it is possible to locate the flaw location from the filtered measured responses. This is the most difficult operation to accomplish especially for the short-duration broadband input signal on short finite structures. The problem gets amplified if the medium is dispersive wherein the wave forms of the input signal change its profile as it propagates, making it difficult to identify any reflections. If the medium is nondispersive, reflection also retains the input profile and makes identification of these a lot simpler. A tone burst signal, which is essentially a sine wave modulated over a small time window and travels nondispersively even in a dispersive medium, helps alleviate this problem to a little extent and hence is extensively used in SHM studies. Therefore, the choice of the type of the predefined input signal also plays a significant role in the SHM studies [7].

Failure modes in composites are many compared to metallic structures. The common failure mechanisms in composites are the delamination of the plies, the fiber breakage, and the matrix cracks. In built-up composite structures, debonds are also a common type of failure. Modeling these flaws efficiently is very crucial for their detection using the measured responses. The most common way of modeling flaws, such as cracks in FEM, is to introduce duplicate nodes along the crack front, which have the same nodal coordinates but a different node number. This procedure ensures discontinuity in the medium arising due to the presence of a crack. Such modeling procedures are extensively used in modeling fracture mechanics

problems. Although such models can very accurately model the flaw, the huge model size limits its use in real-time health monitoring. One of the important differences in the response behavior of the cracked structure as compared to the uncracked structures is the presence of a phenomenon of mode conversion [15, 16] present in the former. If such a phenomenon can be built in a simpler model, one can use such models effectively in SHM studies. One such model is the kinematics-based model, wherein the damaged structure is split up into multiple waveguides along the crack front. This process reduces the cracked structure into multiply connected framed structures. By enforcing kinematic relationship among the nodes of the waveguides, one can eliminate the intermediate nodes of the frame structure, thereby obtaining an FE-type model with a built-in damage. References 17 and 18 use such models under a spectral FE environment to study the wave propagation responses in delaminated beams and beams with fiber breakage. This method can be readily extended to model structures with such damage under an FE environment. This is discussed in detail under the modeling section of this article.

This article is organized as follows. First the relationship between the flaw size, frequency content of the signal, and the FE mesh is established. This is followed by a detailed section on different flaw models available under FEM. A number of numerical examples are given to highlight the importance of mesh size, frequency content of the input signal, and the type of forcing function in the SHM studies.

2 RELATIONSHIP BETWEEN MESH SIZE, FLAW SIZE, AND FREQUENCY CONTENT OF THE INPUT SIGNAL

SHM requires a powerful modeling tool to post-process the experimentally measured responses, due to a predefined input (forcing), to predict the location, extent, and severity of the flaws present in the structure. The predefined input is normally triggered through a piezoceramic actuator either statically or dynamically. To rapidly assess the health of the structure, the chosen mathematical model should be of smaller size and, in addition, it should be able to predict the location and extent of the flaws using a smaller number of measured sensor responses. The choice of the method depends upon the structure geometry, size of the flaw, and the frequency content of the input.

FE is a powerful modeling tool to solve structure problems defined by a partial differential equation over any complex domain. Although modeling flaws such as cracks or delamination are straightforward in FEs (which is addressed in the next section), the stress singularity near the crack tip requires a very fine mesh near the crack tip even for a static loading, which makes the model sizes enormously large. If the loading is dynamic, the mesh sizes required are even larger and it depends on the frequency content of the predefined input.

Frequency content of the predefined input is yet another parameter that should be carefully chosen, depending upon the flaw sizes. When the flaw sizes are larger compared to the dimension of the structure, then even static loading is sufficient. However, such flaws will be visible to the naked eye and as such SHM is not needed. However, if the flaws sizes are reasonably small compared to the smallest dimension of the structure, then one requires that the predefined input loading be dynamic in nature and the frequency content be of the order of few hundred hertz. Such low-frequency content problem comes under the category of structural dynamics. On the other hand, if the flaw sizes are very small (not visible to the naked eye), then the frequency content of predefined input signal should be of the order of few hundred kilohertz. These problems come under the category of wave propagation. The main difference between these two is that the latter is a multimodal phenomenon, wherein phase information becomes very important. Cracks in structures act like a boundary and induce a very small impedance mismatch at the crack boundary, which will induce reflections for a high-frequency input signal. These reflected signals can be effectively used to characterize, predict, and locate the cracks in a structure and also its extent. Hence, the choice between the structural dynamics or wave propagation analysis to be adopted depends upon the frequency content of the input signal, which in turn depends on the flaw size. All these have a bearing on the mesh sizes to be chosen for the FE analysis.

Now, two questions need to be answered: what should be the mesh size for a given input loading

and what should be the frequency content of the input signal for a given flaw size? For a given input loading, the mesh sizes should be chosen such that they are comparable to the wavelength. When the frequency content of the signal is high, the wavelengths are very small and hence the mesh sizes have to be small, which in turn increases the problem of sizes enormously. To determine the mesh sizes, first the predefined input signal is transformed into a frequency domain using fast Fourier transform (FFT), and a plot of the amplitude (in the frequency domain) and the frequency gives the frequency content of the signal. Let us denote this by ω (radian per second). If C_0 is the wave speed of the given wave mode, then the wavelength λ is given by

$$\lambda = \frac{2\pi C_0}{\omega} \tag{1}$$

Typically, the mesh sizes should be of the order of $\lambda/8$ [19]. If the mesh sizes are larger than what is given in equation (1), then the mesh boundaries start reflecting the input signal, thereby giving spurious indication of the presence of the crack.

Mesh sizes depend on the speed of the medium in which the signal is propagating. In order to make this statement clear, let us consider two mediums namely aluminum and composite. The wave speed in composite is approximately $3850\,\mathrm{m\,s^{-1}}$, while in aluminum it is $6000\,\mathrm{m\,s^{-1}}$. Let these mediums be subjected to an input pulse having a frequency content of 50 kHz. From equation (1), the wavelength in composites is about 77 mm, while in aluminum it is about 120 mm. Hence, for a given input, composite requires a more dense mesh.

Now, the second question is what should be the frequency content of the predefined input signal for a given flaw size for such a signal to induce an impedance mismatch at the crack boundary and induce a reflection. For this to happen, the wavelengths should be comparable to the flaw sizes. For example, we again consider the same example considered previously, that is, aluminum and composites with damage. The wave speed in composite is approximately $3850\,\mathrm{m\,s^{-1}}$, while in aluminum it is $6000\,\mathrm{m\,s^{-1}}$. Let us assume that both these mediums have a small crack of size 20 mm. Equation (1) can be rewritten as

$$f = \frac{C_0}{a} \tag{2}$$

where f is the frequency in hertz and a is the size of the flaw. From equation (2), substituting the speed of the composite and the aluminum medium, we see that, for inducing a reflection from the damage in composites, the frequency content of the input signal should be 192.5 kHz, while in aluminum medium the frequency content of the predefined input signal should be 300 kHz. In addition, if one needs the signal to travel nondispersively, one can create a tone burst signal created using a sine wave of the above-calculated frequencies. From the above discussion, it is clear that the frequency content of the input pulse and the mesh size are highly dependent upon the medium in which the waves are propagating.

The success of this analysis requires that the speed of the medium be known. The calculation of speed, especially for a dispersive system, is an involved process. The calculation of speed requires a deep understanding of the spectral analysis. References 6 and 7 give a good account of deriving the dispersion relation (speed vs frequency plots) for metallic and composite structures for both 1-D and 2-D waveguides. In most second-order systems, the waves are usually nondispersive and the speeds do not vary with the frequencies. However, for fourth-order systems like beams, the waves are highly dispersive and hence, at different speeds, the speeds will be different. Then the question that arises is, at what frequency should the speed be used in equation (1) to compute the mesh sizes? To answer this question, let us consider the dispersion plot of a composite beam for different ply orientations [6] shown in Figure 1. The plot shows the group speeds for axial and bending waves for different ply orientations of a laminated composite beam. The parameter r is the bending–axial coupling factor [6] for the beam. The speeds are normalized with the axial speed of an isotropic rod ($C_0 = \sqrt{E/\rho}$). The three horizontal lines are the axial wave speeds for three different ply orientations. One can clearly see that the axial speeds are constant for all frequencies and hence they are nondispersive. The figure also shows three nonlinear curves for the bending wave for three different ply orientations. These waves are highly dispersive in nature and hence their speeds are different at different frequencies. If the input signal is broadbanded, then the choice of wave speeds to be used in equation (1) becomes very difficult. In such cases, modulated signals are very useful since their active energies are

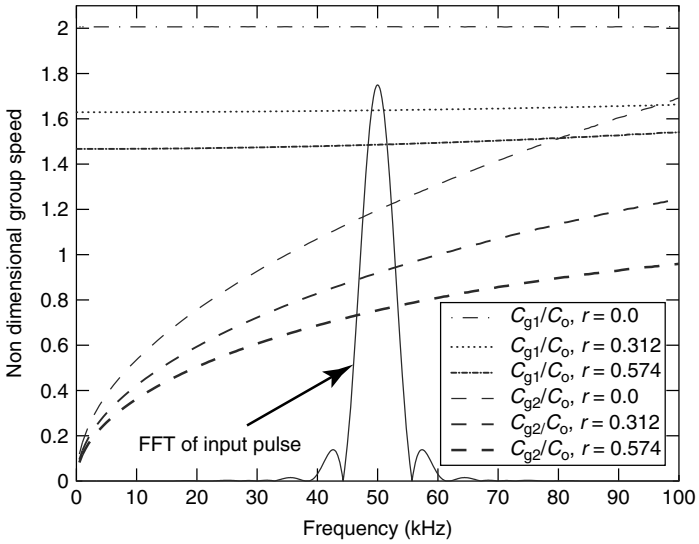

Figure 1. Dispersion plot for an elementary composite beam.

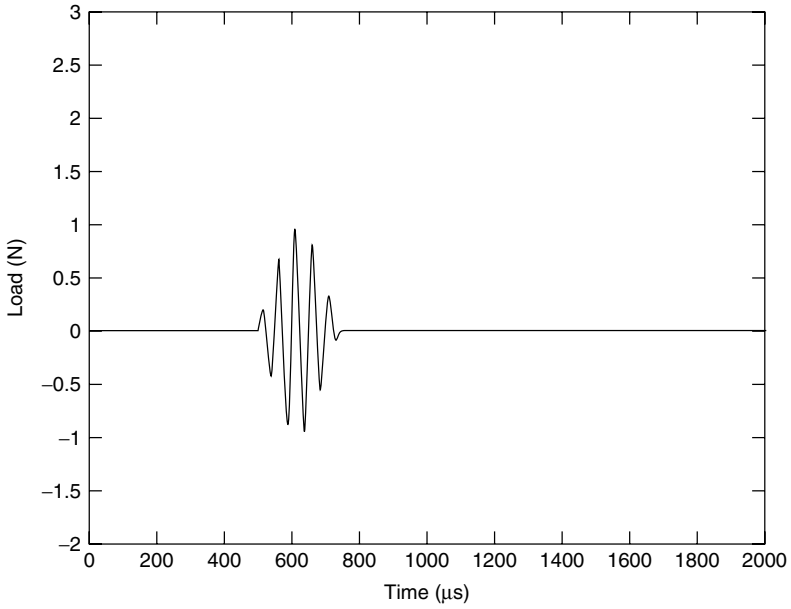

Figure 2. A tone burst signal modulated at 50 kHz frequency.

band limited over a small frequency band. One such modulated signal, also called the *tone burst signal*, is shown in Figure 2. This signal is created using a sine wave of frequency 50 kHz and modulated using a Hanning window. The FFT amplitude of this signal is superimposed in Figure 1 along with the dispersion plots. Through this superimposition, the wave speeds corresponding to 50 kHz can be easily computed for various propagating modes and this value can be used in equation (1) for calculating the wave speeds. In addition, modulated input pulse can force the wave to be nondispersive even in a dispersive medium. It can

be seen from Figure 1 that the modulated frequency of the input signal is 50 kHz. That is, such a pulse excites only those modes that are lying very close to 50 kHz and all other modes do not participate in the response. As a result, the group speeds of the wave are a function of only a small set of frequencies close to the modulated frequency, which forces the response to be nondispersive even in a dispersive medium.

An alternate way of fixing the mesh sizes is by looking at the stiffness of the structure. It is well known that the presence of a flaw reduces the stiffness of the structure. This stiffness reduction depends on the size of the flaw. If the flaw size is small, it causes an insignificant change in the stiffness of the structure and hence an insignificant change in the first few natural frequencies of the structure. However, for large flaw sizes, the stiffness change is significant, and hence the modal frequencies. This is shown in Figure 3 for a laminated composite beam of 20 cm length with two different delamination sizes, where the bending stiffness is plotted as a function of the frequency. For a delamination of 1 cm, one can notice the frequency change only beyond 14 kHz, while for a delamination of 5 cm one can see that the frequency change happens much earlier at 3 kHz. That is, for small flaw sizes, only higher modes get excited and hence, to capture all higher modes accurately, one needs a very fine mesh. Therefore, for such small flaw sizes, modal methods, which are extensively used in SHM studies, are not suitable. One needs wave propagation analysis.

Accuracy of the response to high-frequency input depends on the density of the FE mesh. For a reasonably dense mesh, the wave response predicted may be accurate; however, it may show period error. To reinforce these ideas better, let us consider a simple aluminum rod of 2.0 m length and 0.01 m^2 cross section, with Young's Modulus (E) of 70 GPa and a density (ρ) of 2600 kg m^{-3}. The wave speeds in the aluminum can be calculated from the formula $C_0 = \sqrt{E/\rho} = 5189$ m s^{-1}. This rod is subjected to an input signal, as shown in Figure 4 (inset), which has a frequency content of 46 kHz. From equation (1), the wavelength can be calculated, which is equal to 0.11 m. In order to capture the wave behavior accurately, at least eight elements per wavelength are required, that is, an element length of 0.014 m. Hence, for a length of 2.0 m, at least 145 1-D FEs are required for modeling. Figure 5 shows the axial wave responses at the cantilever tip for different number of elements. We have used 250 1-D rod elements to get a fully converged solution, which shows an initial pulse at around 100 μs and a reflected pulse from the boundary at around 420 μs. Figure 5 also shows (in the inset) the period error when the mesh sizes are inadequate. Inadequate FE mesh for a high-frequency input pulse results in mass or inertial

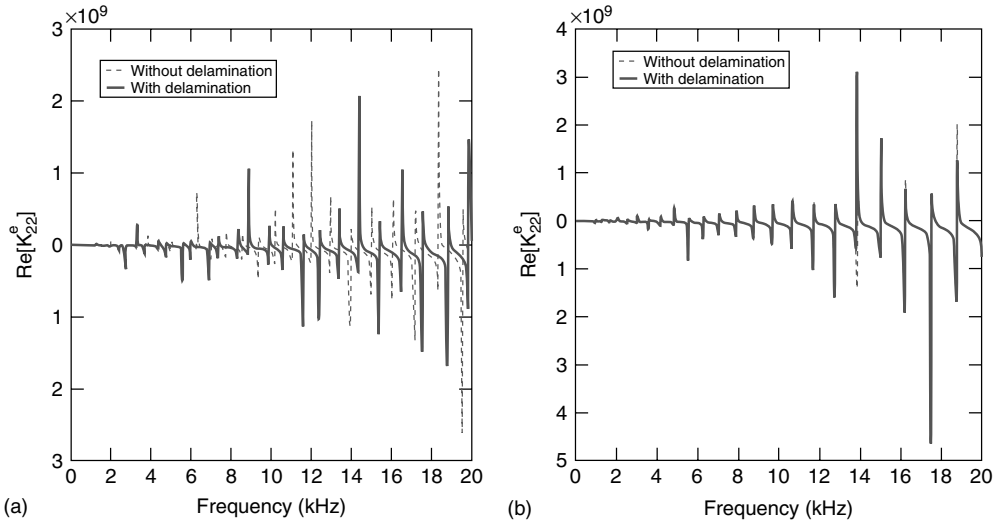

Figure 3. Stiffness changes as a function of frequency for different delamination sizes: (a) 5 cm and (b) 1 cm.

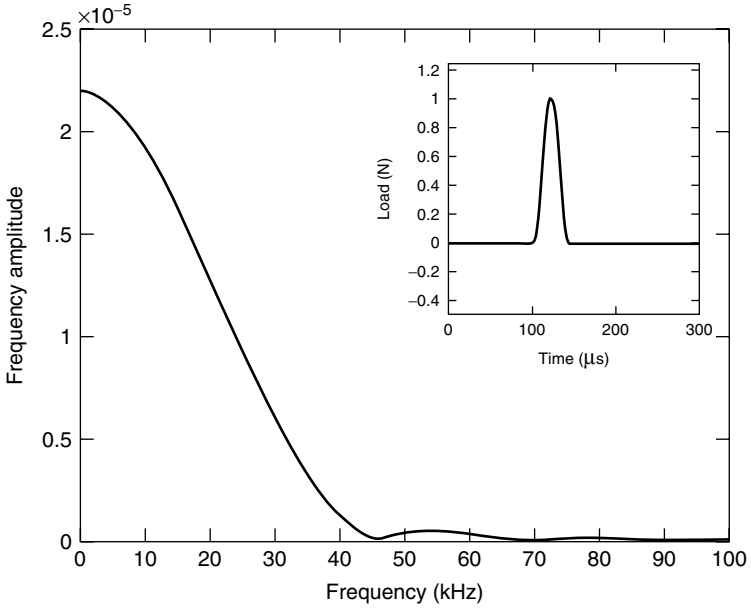

Figure 4. High-frequency input load with its Fourier transform.

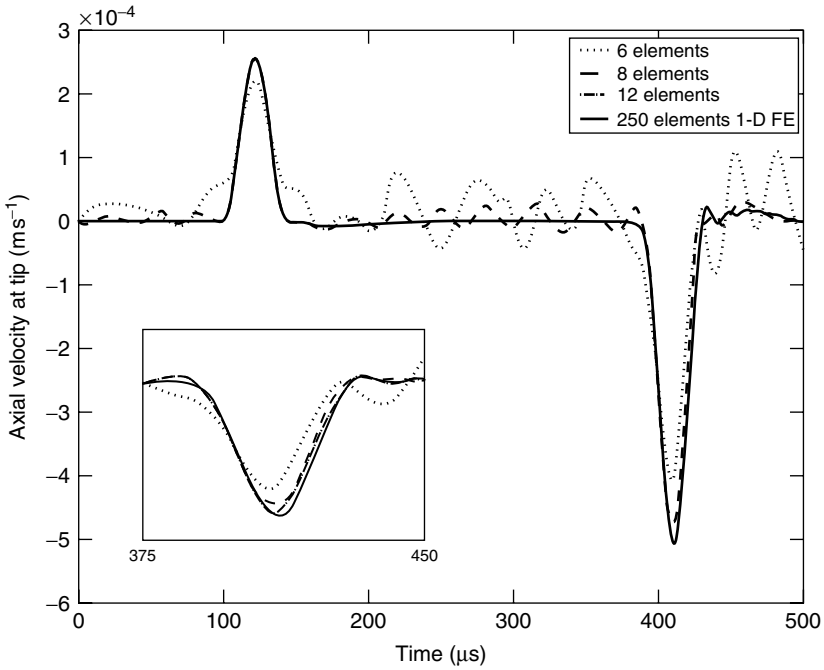

Figure 5. Longitudinal wave responses in a rod for different element discretizations.

distribution not being accurate. As a result, the wave speeds predicted by FE analysis are highly inaccurate, resulting in period error. In addition, if the mesh sizes are much smaller than what is required, then the mesh boundaries act as a fixed boundary and start reflecting responses from these boundaries. These are clearly seen in Figure 5 for very small mesh density. Hence, for very high frequency content input pulse, which is normally the case for most SHM problems, a fine mesh is an absolute necessity.

3 MODELING OF FLAWS IN FINITE ELEMENT METHOD

Materials such as composites have many modes of failures. Among these, delamination and fiber breakages are the important modes of failure. These failure modes correspond to horizontal and vertical cracks in metallic structures. Modeling of these is quite different in some of the methods. This section outlines some of the methods adopted to model the above failure modes in composites and metallic structures under an FE environment. These methods can be classified as follows:

1. stiffness reduction method (SRM),
2. duplicate node method (DNM), and
3. kinematics-based method (KBM).

These methods are explained in detail in the subsequent paragraphs.

1. Stiffness reduction method

It is quite well known that the presence of flaws causes the reduction of stiffness in the structure. A simple way of modeling flaws is to incorporate the stiffness loss in the region of the flaw by modifying the material properties P (where P can signify Young's modulus, shear modulus, density, etc.) to αP where, $\alpha < 1$. This concept is demonstrated in Figure 6.

Figure 6(a) shows the actual model of a laminated beam with a through-width delamination and Figure 6(b) shows the equivalent stiffness-reduced model. This procedure could be adopted to model any number of flaws in the structure. However, such a modeling, although good in estimation of the remaining life of the structure, is not suitable for determining the extent of damage, which is paramount in SHM studies. In [20], such a model was used to perform SHM studies on large civil structures.

2. Duplicate node method

A better way of modeling flaws in FE is to completely model the entire crack front. This can be performed in the following way. Modeling can be done using either the 1-D beam element or the 2-D plane stress/strain FEs using the concept of duplicate nodes. In the case of beams, the modeling of a flawlike delamination is done by keeping the two nodes in the same place, one for the elements above the flaw and the other for those below it. This is shown in Figure 7(a). Here, elements 1 and 2 are at the left part of the flaw,

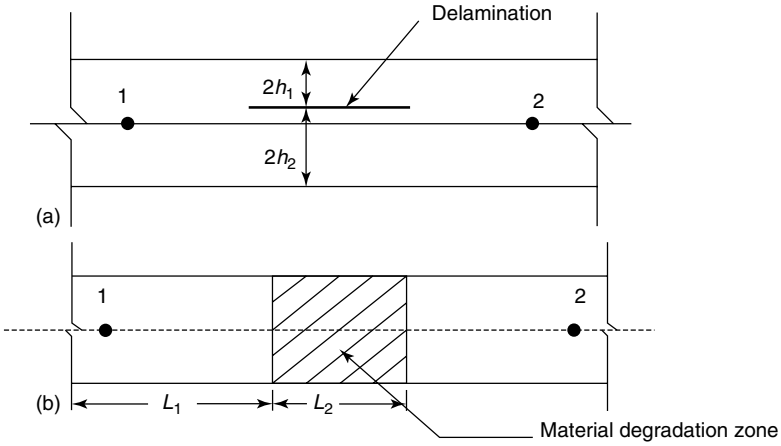

Figure 6. Modeling of flaws using the stiffness reduction method: (a) actual model and (b) stiffness-reduced model.

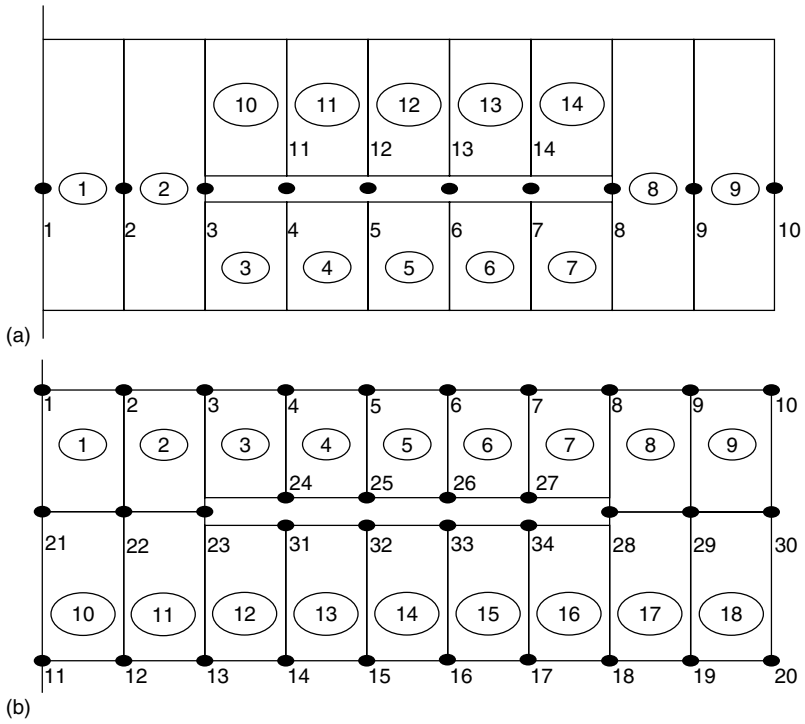

Figure 7. Modeling of flaws using the duplicate node method: (a) using beam elements and (b) using plane stress/strain elements.

while elements 8 and 9 are to the right part of the flaw. All other elements are in the flawed zone, either above or below the flaw. The zone below the flaw is modeled with elements 3–7 and the one above by elements 10–14. The flaw is modeled through proper nodal connectivity of these elements. That is, for the healthy zone, element 1 is connected with nodes 1 and 2 and element 9 is connected with nodes 9 and 10. All these nodes are in the midplane of the corresponding beam elements. For elements below the flaw, say, element 3 is connected with nodes 3 and 4, where nodes 3 and 4 are not in the midplane of this element. This may create high bending–stretching coupling, which is the objective of the modeling process to induce mode conversion. Similarly, for elements above the delamination, say, element 10 is connected through nodes 3 and 11, where nodes 3 and 11 are not in the midplane of this element. As mentioned earlier, nodes 4 and 11 are in the same place and are not connected with any direct element. These are termed as *duplicate nodes*. Similarly, nodes 5 and 12, nodes 6 and 13, and nodes 7 and 14 are duplicate nodes. In the flaw zone, the lower part of the elements connects with nodes 4, 5, 6, and 7 and the upper part of the elements connects nodes 11, 12, 13, and 14. If these nodes are merged with their corresponding duplicate nodes, the beam will be healthy. In addition, with these duplicate nodes, different kinds of contact or gap elements can be used in FE analysis to prevent interpenetration of the crack front.

A similar procedure could be adopted in modeling a flaw using 2-D plane stress/strain elements, which are shown in Figure 7(b) using duplicate nodes. The figure is self-explanatory. The extending of this procedure to model fiber breakages and multiple delaminations in composites is quite similar and straightforward.

3. Kinematics-based method

This is quite a powerful method for modeling delaminations, fiber breakage, and multiple delaminations.

This approach was used under the spectral FE environment for modeling and detection of different types of damages in 1-D waveguides (see [17, 18, 21]). In this article, we extend this method to work with FEM. Its use in SHM studies till now has been explored only to model delaminations and fiber breakages in 1-D laminated composite structures. This method of modeling is limited to through-width straight-line cracks.

The main idea behind this modeling approach is to cut the beam structure into multiple elements (domains) along the crack front. The stiffness and mass matrices for each of the subdomains is generated. The intermediate nodes away from the crack front arising due to this splitting are then connected to the nodes along the crack front through rigid links in order create a coupling between the axial and transverse displacements. The procedure for modeling delaminations and fiber breakage are quite different and hence described separately.

1. Modeling of single and multiple delamination

Here, let us consider a composite beam with a delamination, the dimensions of which are shown in Figure 8(a). This delaminated beam is split into base laminates and sublaminates, as shown in Figure 8(b). The equivalent beam model with eight nodes makes up this delaminated beam. Each subdomain (element) is indicated by a number within a circle. Let each node support three degrees of freedom, namely the axial deformation $\boldsymbol{u}$, the transverse deformation $\boldsymbol{w}$, and the slope φ. These are represented by a vector $\{\mathbf{u}\}_i$, where $\boldsymbol{i}$ represents the domain (element) of interest. Note that the through-width delamination lies between nodes 4 and 7. It is assumed in this modeling that there is no contact action between

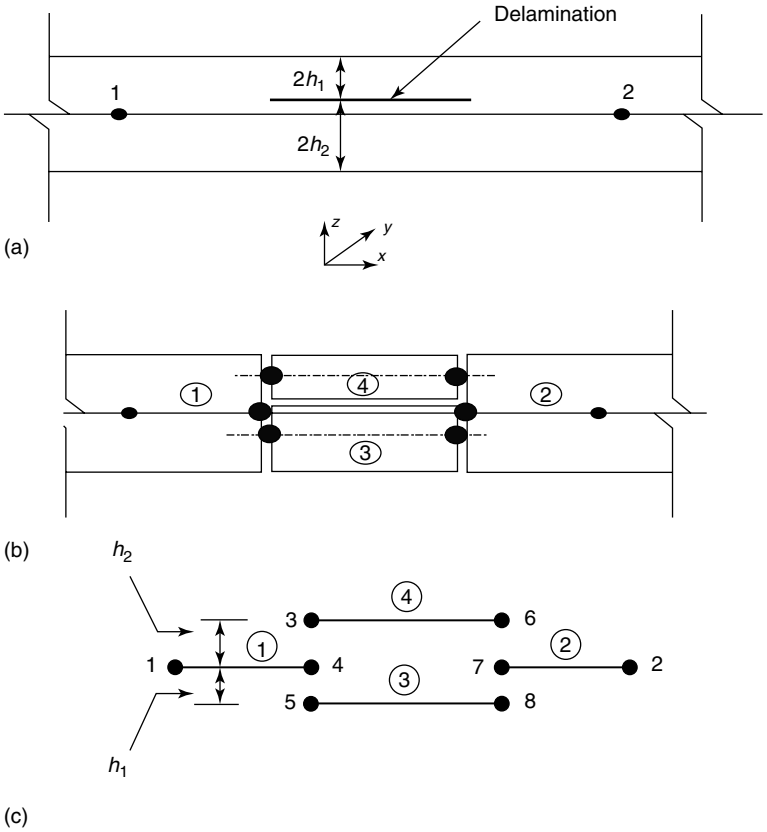

Figure 8. (a) Original delaminated beam, (b) splitting of the damaged beam into base and sub laminates, and (c) equivalent beam models.

the sublaminates at the plane of delaminations and the cross sections are perfectly straight at the interfaces. The connections between nodes 3-4, 4-5, 6-7, and 7-8 are made with the help of the rigid links to simulate the bending–axial coupling. This model does not take care of crack tip stress singularity as it is not of importance in the context of damage detection. A similar approach can be adopted when the laminated composite structures has multiple delaminations. Some examples on the use of this model in the context of SHM are given in the next section.

2. Modeling of fiber breakage

Here, we have adopted the same procedure that was used for modeling delamination. Let us consider a beam with a fiber breakage represented in Figure 9(a). The split-up model is shown in Figure 9(b) and the

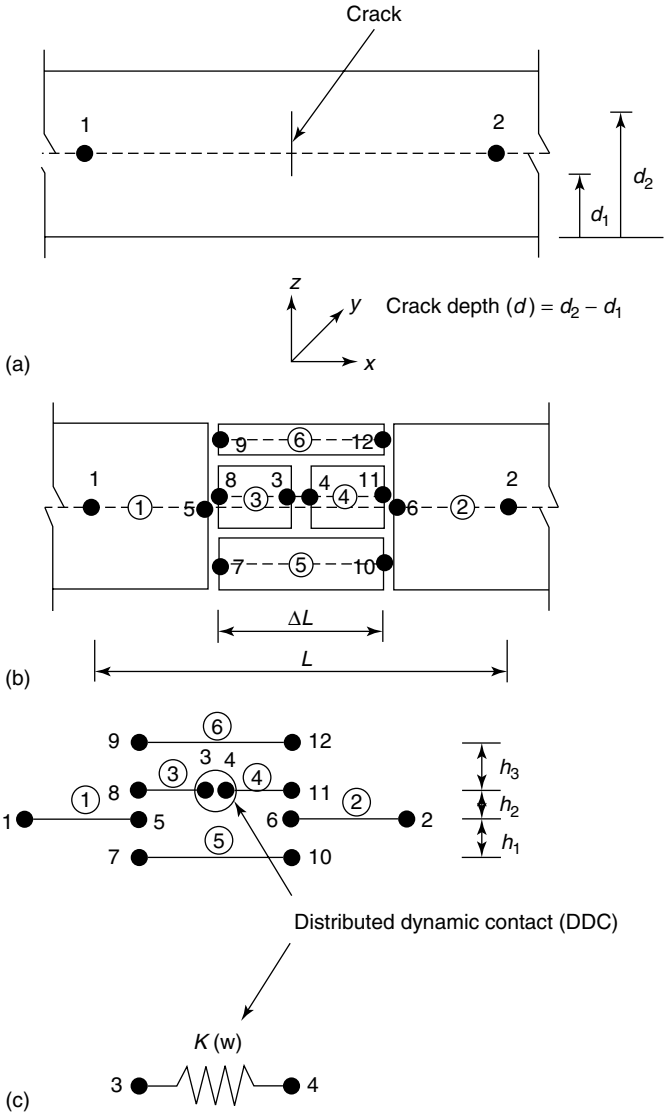

Figure 9. (a) Original beam with fiber breakage, (b) splitting of the damaged beam into base and sub laminates, and (c) equivalent beam models.

beam model representation is shown in Figure 9(c). In this model, we assume that there exists a distributed dynamic contact at crack surfaces and the crack surface remains perfectly straight. The nodes along the left and the right side of the crack are connected by rigid links to simulate the bending–axial coupling behavior. That is, nodes 9-8, 8-5, 5-7, 10-6, 6-11, and 11-122 are connected by a rigid link. Unlike the previous case of delamination, there is a hanging interface between nodes 3 and 4, which are connected by a nonlinear spring to simulate the distributed dynamic contact. The spring constant had to be chosen in such a manner that this simplified beam model simulates the actual waveguide behavior at high frequencies. As before, the effects of crack tip stress singularity is ignored in this model. Some examples of this model usage are given in the next section.

4 NUMERICAL EXAMPLES

A few numerical examples are given in this section, wherein some of the modeling methods described in the previous section are used in the context of SHM. The main objective of any SHM analysis is to determine the presence of damages and their extent and severity from the measured responses. For the above analysis, the SRM method may not be useful. If one is required to predict the location and also the extent of damage, then the method based on duplicate nodes is very useful. In addition, if the flaw is 2-D in nature, the KBM method is not useful. There are many situations wherein the designer wants to estimate the overall life of the structure due to the presence of a number of damages, in which case, the SRM method is quite sufficient for modeling. Hence, the choice of the model entirely depends upon the level of sophistication required for the analysis. The next few paragraphs describe numerical examples related to static, free vibration, and wave propagation in the context of SHM using the models described above.

4.1 Static and free vibration analysis of a cantilever beam using DNM

Here, two different studies are performed. In the first case, the results from two different DNM models (1-D beam and 2-D plane stress models) are compared to see the effectiveness of each of these models for SHM studies. In the next case, the results from the DNM- and KBM-based models are compared.

Here, a unidirectional 12-layer laminated composite beam of total depth 1.8 mm and length 500 mm is considered for the study. A through-width delamination is symmetrically placed with respect to both top and bottom and the sides. The lamina is assumed to be orthotropic with the Young's Modulus in the two perpendicular directions being E_1 equal to 181 GPa, E_2 equal to 10.3 GPa, and the shear modulus G_{12} equal to 28 GPa. The FE model details are as shown in Figure 7 and Table 1 gives the percentage increase in the tip deflection for a tip unit load. From the results, we find that the agreement between the two DNM models is closer for large delaminations.

Next, a free vibration study is performed to assess the performance of the two different DNM models. These are plotted in Figure 10. Both the models (beam and 2-D) show more or less similar results. When the delamination is 10% of the length of the cantilever, the 15th natural frequency reduces 20%, corresponding to the corresponding frequency

Table 1. Comparison of static results for two different DNM models

Delamination (%)	Beam DNM model (% increase in tip deflection)	Plane stress DNM model (% increase in tip deflection)
10	0.39	0.08
20	0.91	0.61
30	2.35	2.03
40	5.15	4.80
50	9.77	9.37
60	16.63	16.24
70	26.13	25.75
80	38.90	38.32

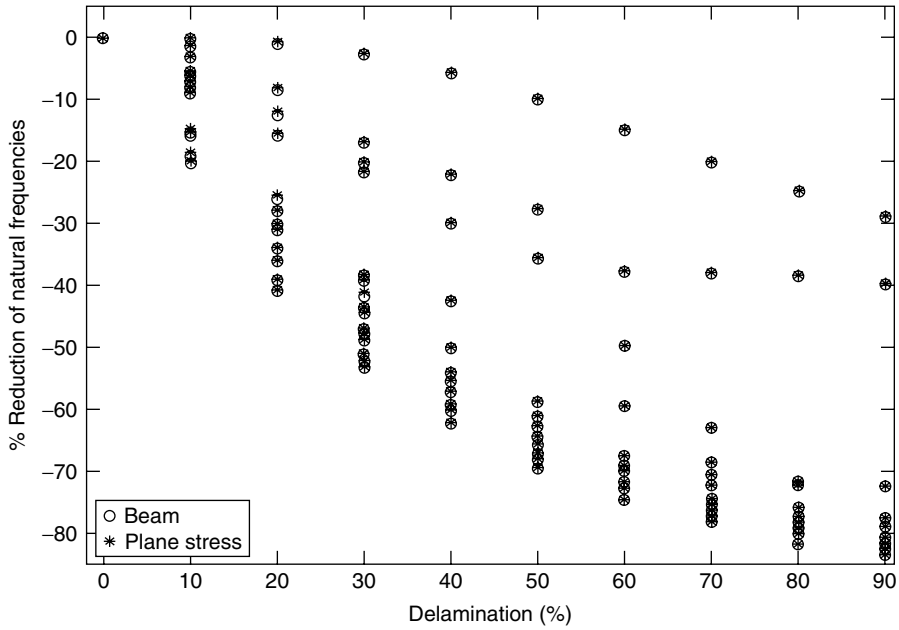

Figure 10. Comparison of free vibration results for two different DNM models.

of the healthy beam. Similarly, for 90% delamination, the first natural frequency reduces 29%, the second natural frequency reduces 40%, and the third natural frequency reduces 72%. From these studies, it is quite clear that beam DNM models can give comparable results with the plane stress DNM models. This has huge implications in SHM studies as beam models can give substantially smaller problem sizes, which is one of the key requirements for SHM simulations.

In the next exercise, the static analysis is performed using the DNM (plane stress model) and the KBM model on a metallic cantilever beam of length 635 mm, width 25.4 mm, depth 25.4 mm, the Young's modulus of the beam assumed to be 70 GPa, and shear modulus 27 GPa. The results are generated for a given crack length of $L/10$ located at a different location along and across the beam. The DNM model has 100 elements with due care taken to have a finer mesh near the crack tip. The KBM model has only four elements, as shown in Figure 8(c). The beam is subjected to a load of 5000 N. The results of these two models are tabulated in Table 2. From Table 2, it is clear that the four-element KBM model is able to capture the damaged behavior of the cantilever metallic beam quite accurately. This again results in substantial reduction in problem sizes. However, most SHM problems require high-frequency content loads for damage detection, which needs wave propagation analysis. This is addressed in the next subsection.

4.2 Response analysis of a delaminated cantilever composite beam

The aim of this numerical example is to bring out the differences in the responses predicted by the KBM model as opposed to the DNM model (2-D plane stress model). Here, we consider a delaminated AS/3505-6 graphite epoxy composite cantilever beam of length 800 mm, with a midplane delamination of size 50 mm, introduced at 400 mm from the root. The beam is 16 mm thick and 10 mm wide. The beam is subjected to a transverse tone burst signal of 20 kHz frequency content. The flexural group speed in composites is around 3850 m s^{-1}. As per equation (1), the wavelengths at 20 kHz frequency is around 192.5 mm, which is more than the size of the damage of 50 mm. Hence, in order to induce an impedance mismatch at the crack tip, the frequency content of the pulse needs to be increased. Alternatively, the mesh size can be computed by assuming the wavelength as 50 mm, which is the size of the

Table 2. Comparison of static results for DNM and KBM models for different crack locations

Location of the crack of size $L/10$ in the cantilever beam	Tip deflection based on plane stress DNM model (mm)	Tip deflection based on four-element KBM (mm)	% difference
Crack located symmetrically lengthwise and depthwise	1.78×10^{-4}	1.804×10^{-4}	1.37
Crack located symmetrically lengthwise and 17.78 mm from the bottom	1.778×10^{-4}	1.90×10^{-4}	5.92
Crack located symmetrically depth wise and 228.6 mm from the fixed end	1.786×10^{-4}	1.77×10^{-4}	1.02
Crack located symmetrically depth wise and 342.9 mm from the fixed end	1.773×10^{-4}	1.84×10^{-4}	3.78

damage. For accurate modeling, we require eight elements per wavelength, which requires the element size to be approximately equal to 6.25 mm. In order to model 800 mm, one requires a total of 128 beam elements to model this problem. The KBM model is simulated using 250 elements, while the DNM model contains 2560 plane stress triangular elements. A small portion of the 2-D DNM model mesh near the crack tip is shown in Figure 11(a). The KBM model near the crack tip is simulated using rigid connections, as explained in the previous section. Figure 11(b) shows the transverse velocities predicted by these two models. One can clearly see two reflections: the first from the damage and the second from the fixed boundary. It can be clearly seen that the KBM model predicts the reflections from the crack tip as accurately as the DNM model at a fraction of the computational cost.

In this last example, all the three models, namely the SRM, DNM, and KBM, are compared on a composite cantilever beam that was considered in the last example, and subjected to a transverse broadband impact load shown in Figure 4. Two different damage types, namely the delamination and fiber breakage, both of which are of 20 mm size, are considered on this beam and are symmetrically placed as shown in Figure 12. The beam with 20-mm delamination is modeled by the DNM model, while the beam with 20-mm fiber breakage is modeled using the KBM model. The results from these are compared with the 1-D beam FE model with stiffness reduced by 50% in the small region close to the damage. The main objective of this example is to not only to compare the responses predicted by these models but to also look at the possibility of substituting the detailed KBM model with the SRM model for SHM analysis.

The damage is modeled as a horizontal crack (delamination) using the DNM model, where a total of 3500 2-D triangular elements are used. The vertical crack or the fiber breakage is modeled using the KBM method, while the SRM model is obtained from the healthy beam 2-D model by reducing the stiffness (composite modulus $\overline{Q}_{11}$) by around 50%. This input has a frequency content of 44 kHz. For this force, with a wave speed of 3850 m s^{-1}, it requires nearly 320 beam elements. However, this simulation is performed using 500 elements for the SRM and KBM models, respectively. The hanging interface in case of the KBM model of the spring is simulated with a spring constant of 1×10^{-3} times the $\overline{Q}_{11}$. The different beam configurations with the associated damages are shown in Figure 12 and the transverse response histories are shown in Figure 13.

From Figure 13, we can clearly see that each of these models pick up the reflection from the damage at around 0.5 ms and the responses show very little change between different damage types of the same size and location. Hence, it can be concluded that the SRM model, which is the easiest to model, can indeed be used to get the response estimates on a damages structure. However, if one needs to further predict the location and extend of damage, more local models such as the DNM method may be required.

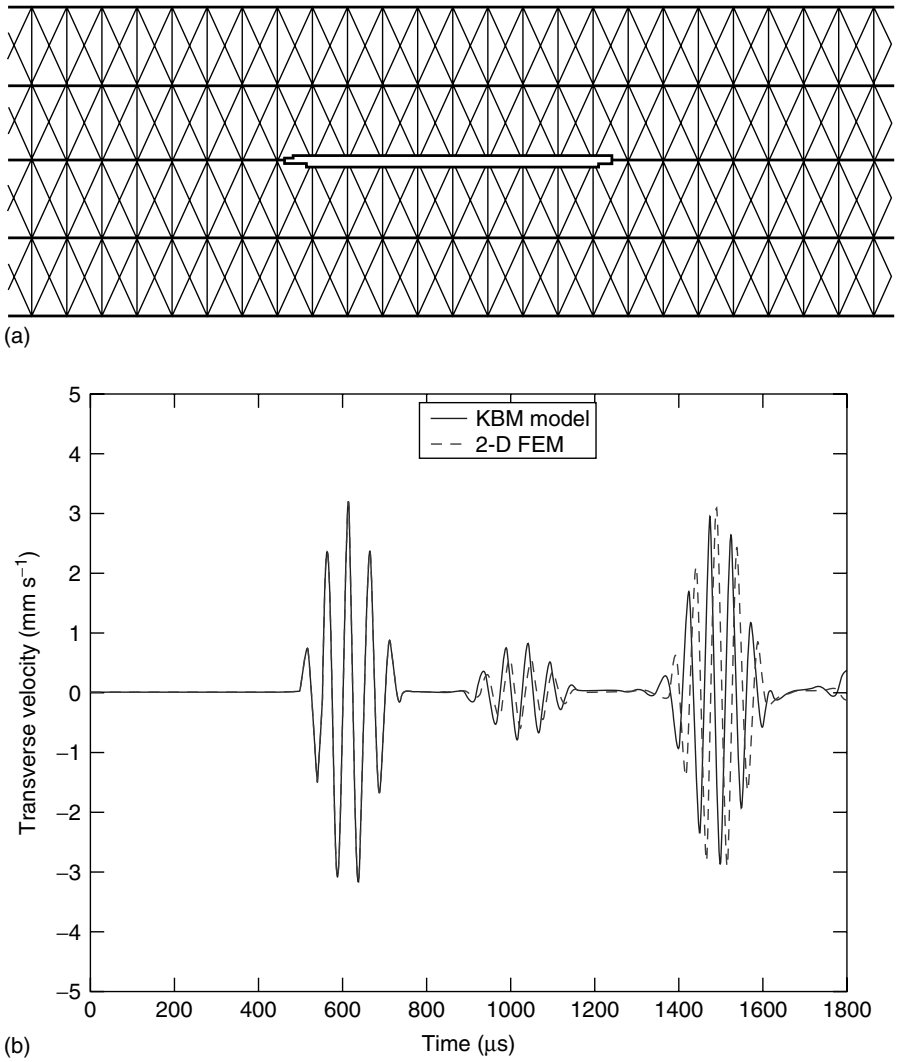

Figure 11. Comparison of wave propagation responses for DNM and KBM models for a delaminated composite beam. (a) DNM model near the crack tip and (b) transverse response history at the tip.

5 MODELING SUGGESTIONS FOR 2-D AND 3-D STRUCTURES

All the examples shown so far dealt with 1-D waveguides. This is because the modeling concepts outlined are better understood with 1-D waveguides. However, most practical structures are either two or three dimensional in nature. Here we outline some suggestions for modeling flaws in general and in 2-D and 3-D structures in particular:

1. The procedure for deciding mesh sizes and the frequency content of the input signal for 2-D and 3-D structures is the same as that outlined in Section 2 of this article. However, the mesh size obtained from equation (1) should be applied for all the dimensions of the structure.
2. For modeling 1-D, straight-line cracks for SHM studies, the KBM method is quite sufficient for damage detection purposes. However, a more detailed DNM model will be required if one needs to perform life estimation studies.

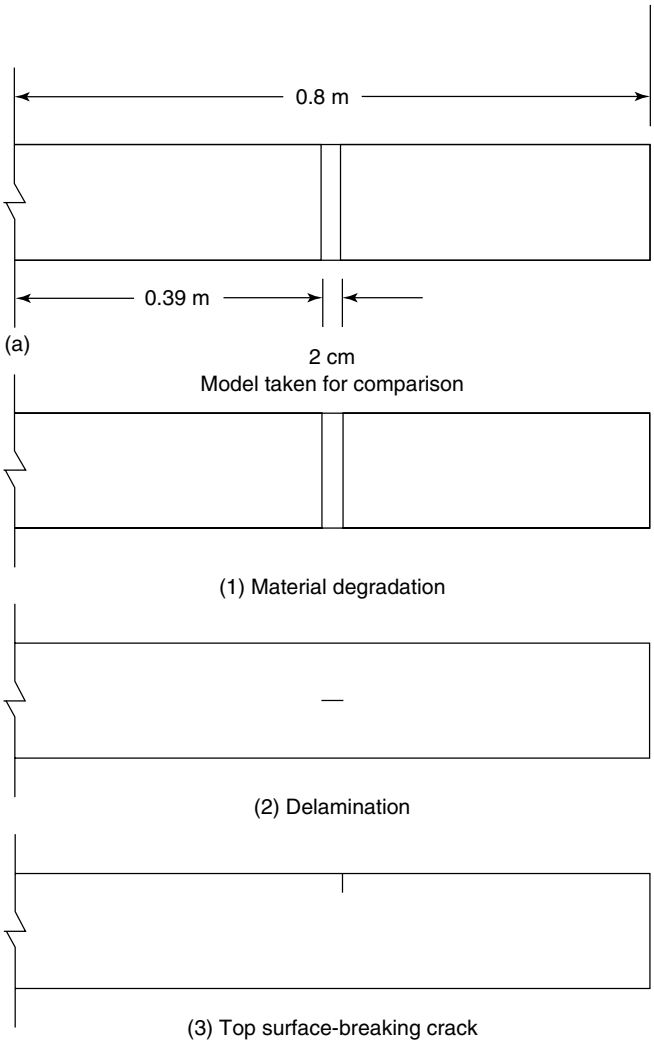

Figure 12. (a) Basic model showing the damage: (1) SRM model with 50% stiffness reduction in the cracked region, (2) delamination modeled using DNM, and (3) vertical surface breaking crack modeled using KBM with a spring constant of 1×10^{-3} of $\overline{Q}_{11}$.

3. Deriving FEs based on KBM is not straightforward and hence this method is seldom used in 2-D or 3-D structures with flaws. However, for certain crack orientations, some crack functions are derived, which capture the mode coupling aspects in 2-D structures. These functions can be readily incorporated into the FE formulation to obtain a simplified damage model. This is outlined in [22].
4. If the frequency content of the signal is large, that is, if the mesh sizes are very small, then we seldom use a graded mesh as used in static analysis of a cracked structure. We normally choose very small but equal mesh sizes as dictated by equation (1). This was used in some of the numerical simulations in the last section (see Figure 11a).
5. All the examples demonstrated the use of various modeling methods for either perfectly horizontal or perfectly vertical cracks, which is normally the case in composites. However, in metals, the commonly occurring cracks are inclined in

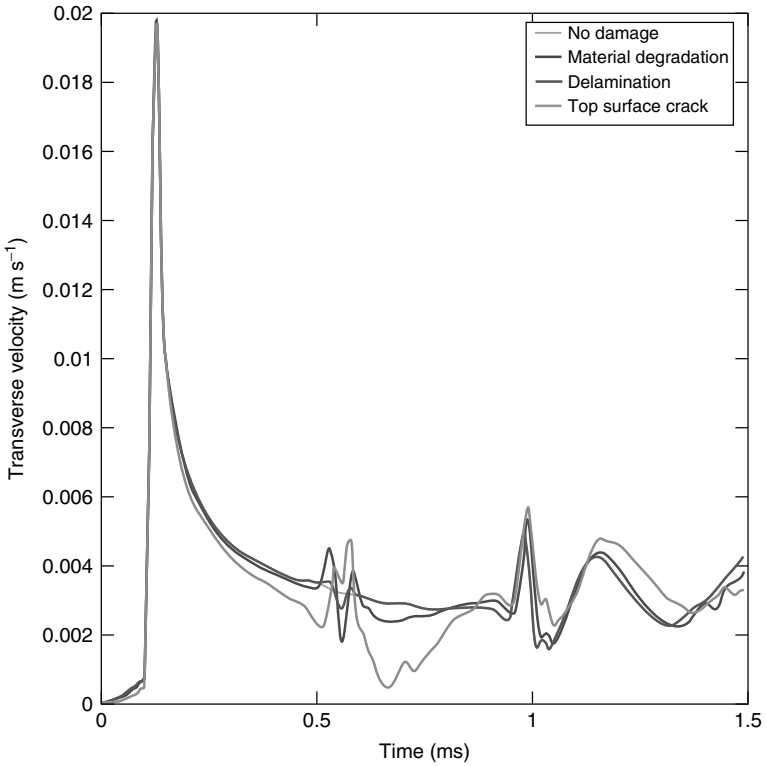

Figure 13. Comparison of wave propagation responses for different models.

nature. For such structures with inclined cracks, the DNM method is normally used, although the SRM method may also be employed. However, for matrix cracking type in damages, where the determination of the location is not that important, the SRM method is ideally suited.

6 MODELING PITFALLS IN FEM FOR SHM AND THEIR REMEDIES

One of the fundamental objectives of the SHM is to rapidly obtain the state of the structure. It was mentioned earlier that the FE model sizes depend on the size of the flaw. For very small flaw sizes, the frequency content of the signal should be large, which leads to enormously large problem sizes, which takes many hours to obtain the solution. This aspect defeats the very purpose of SHM. This is one of the bottlenecks in SHM modeling.

Unlike in a beam, wherein most damages are through-width, single-dimension cracks, in most 2-D and 3-D structures, the damages have an area. For modeling these type of flaws, the DNM method is ideal, although the mesh sizes will be very large. One way to reduce the size of the model is to adopt reduced-order FE models. Reduced-order FE models have only a few nodes retained, which correspond to either sensor locations or the locations where forces are applied, while all other nodes are condensed out. For static analysis, simple static condensation as outlined in [23] is sufficient. For dynamic loading, many reduced-order models are available, which are outlined in [24]. The procedure to model and its application to SHM studies are reported in [25].

Spectral FEM [6] can model very large structures with very limited model sizes irrespective of the frequency content of the input signal. However, modeling arbitrary geometries in spectral FEM is practically impossible. The solution to such problems is to marry these two methods. For example, in the

region very close to the crack, FE modeling can be used and, in the region far away from the crack, spectral FEM [6] could be used. This is because spectral FEM can model long and straight edge surfaces with only one element. Such an approach was adopted in [26] to model cracks in isotropic beams. Alternatively, a new FE formulation based on "partition of unity" [27] can be used to model the zone near the crack and, far away, one can use spectral FEM. Such a method will be very useful for SHM analysis of large-scale structures.

A complete SHM analysis requires modeling of flaws, their detection from the measured responses, and their location, extent, and severity. Today, many general-purpose modeling tools such as NASTRAN, ANSYS, ABAQUES, and ALGOR are available for modeling cracks using any of the above methods described in this article and also for assessing its severity. Some of these software can also perform optimization studies to decide on the number of sensors required and their locations. However, most of these tools cannot perform SHM-centric analysis as they do not have the other components of SHM, namely the damage-detection algorithms and the signal-processing algorithms. Since SHM concepts are built in the design of today's civil, aerospace, mechanical, and ship structures, the need of the hour is to develop SHM-centric FE software that integrates many different modules and new modeling concepts. Such an effort will go a long way toward taking SHM development to a higher level.

7 CONCLUSIONS

This article presents some of the modeling concepts for analysis of SHM-related problems. The work presented here can serve as a useful guideline for those involved with SHM modeling. It clearly brings out the relationship that exists between the predefined input, its frequency content, the wavelength, and mesh size. The article describes various modeling methods available under the FE environment and clearly brings out the situation wherein such models can be used. A number of numerical examples are provided to elucidate the concepts brought out in this article.

The aim of this article is to help the analyst in obtaining fast and accurate damage estimates, location, extent, and severity. These guidelines are not complete by themselves. There are many other rules that govern the accuracy of FE solutions under dynamic loading, and these are not covered here. For example, in situations where the gradients of the field variables such as strains are steep, as in the case of structures with cracks, one needs to have finer mesh discretization near the crack tip. Although one can use a graded mesh for solving such problems under static loading, for wave propagation problems, it is preferred to have a very small size uniform mesh so that response distortions do not occur at the mesh boundaries. For structural dynamics and wave propagation problems involving defects, the choice of mass matrix also plays a very important part in obtaining accurate damage estimates. If the frequency content of input loading is high, as in the case of wave propagation problems, the use of lumped mass matrix as opposed to consistent mass matrix is recommended. This would not only reduce the matrix storage requirement but would also accelerate the convergence of the solution. Modal methods are seldom used to obtain time histories for problems involving high-frequency content input. This is because, for such problems, one has to obtain main eigen frequencies for response estimation, which will be highly time consuming. Instead, we use time integration methods. In addition to the above, other FE rules for node numbering, element numbering, treatment of boundaries, choice of solvers, etc. should be rigorously followed in modeling.

Chapter 46
Fatigue Life Assessment of Structures

Thomas Bruder

Fraunhofer Institute for Structural Durability and System Reliability (LBF), Darmstadt, Germany

1 INTRODUCTION

Fatigue refers to the effect due to which a component fails under repeated or cyclic loading, with the maximum loads not reaching static strength criteria. Even today, components and systems fail because of fatigue cracks. Failures often happen due to misinterpretation of service loading/usage, the component-related material strength, or environmental conditions (e.g., corrosion).

Evaluating the fatigue life of structures experimentally typically takes a lot of time. Sometimes, components exist only once and fatigue testing prior to service is impossible, e.g., for structures of big power plants. Numerical fatigue analyses, load and structural health monitoring, as well as non-destructive testing techniques help to prevent failure of components and systems due to fatigue.

This article focuses on engineering approaches to fatigue life assessment based on finite element (FE) results. Anyhow, by applying these basic methods, many applications of interest in the context of structural health monitoring (SHM) can be covered, such as

- detecting fatigue critical areas, which may be the subject of monitoring;
- assessing fatigue impact of the loading applied; and
- deriving a relationship between fatigue impact at a location, which is difficult to access and locations where stress or strain data can be acquired.

A general introduction into fatigue and fatigue damage models is given in **Damage Evolution Phenomena and Models**, which outlines "Fatigue Damage Models" in Section 3 and "Load History Effects" in Section 4. For more detailed information, see Refs. 1–6. Corrosion, creep, buckling, as well as global yielding of the component's net section is not covered in this article. **Static Damage Phenomena and Models** describes static damage phenomena.

Fatigue damage is especially sensitive to actual usage and is difficult to analyze without detailed knowledge of the service loading experienced by the

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

component of interest. For a typical notched component manufactured from medium-strength steel, an increase in the loading amplitude by 15% leads to a reduction in fatigue life by 50%. Since loading plays an important role in components' fatigue life assessment, this article describes how to deal with loading without loosing the fatigue-relevant content. In this context, fatigue-relevant loads are determined by the number, amplitude (size), and mean value (position) of load cycles.

In general, for deriving service loading, extensive full system tests or simulations should be avoided owing to time and cost constraints. A common method to reduce efforts is to perform measurements at various specific conditions/events only. Typically, the time histories are transformed to more abstract histograms, which allow efficient data handling as well as durability-focused visualization. The final testing target is then derived by mixing various load scenarios and extrapolating to longer usage. Such a target statistically represents the usage of the component during a certain lifetime. Nondamage relevant parts of the load-time histories are removed and the remaining signal can be used for numerical analyses or be replayed on a test rig system.

Since fatigue is a local phenomenon, finite element or boundary element methods (FEMs/BEMs) are powerful tools that are used to derive stresses and strains at fatigue-relevant locations.

Generally, various methods are used for numerical fatigue life analysis. Stresses derived by the "Theory of Elasticity" are regarded as a relevant criterion in stress–life methods such as

- nominal stress approach,
- structural stress approach and
- local stress approach.

The basis for the first three of the above-mentioned approaches is the so-called S–N curve (Figure 1).

Such a curve is derived by subjecting specimens or components to constant-amplitude (CA) loading at various load levels. Failed specimens are plotted in a double logarithmic diagram, displaying load or stress amplitude versus the number of cycles to failure.

Local elastic–plastic stresses and strains ("true" stresses and strains) are taken into account in the strain–life method, often called the local strain approach.

Further approaches describes fatigue life by growth and coalescence of initial cracks like linear elastic fracture mechanics (LEFM) and elastic–plastic fracture mechanics (EPFM).

The definition of "damage" depends on the approach used. For example, the damage D at a certain load level may be defined as the ratio between the

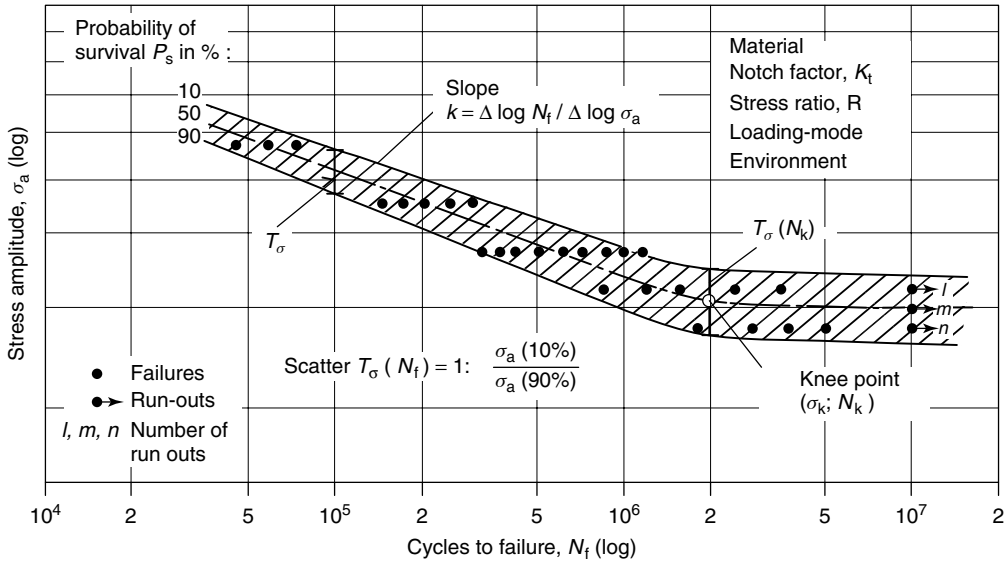

Figure 1. Parameters describing the S–N curve.

number of applied cycles and the number of cycles to failure $D_i = n_i/N_i$ as well as an increase in crack length.

The most suitable approach for a given application depends on the aim of a structural durability analysis and the information that is available. The "local" approaches as well as fracture mechanics typically use FE results.

2 PARAMETERS DETERMINING FATIGUE LIFE

Figure 2 shows the main parameters influencing a structure's fatigue life:

- component's shape
- loading and
- material and manufacturing.

Since the component's shape can be described well using FE methods, the following sections focus on effects due to loading and material.

2.1 Loading

Most often, data acquisition is done as time history recording. Although this type of data contains all the necessary information, it is inconvenient to handle because of its size. Furthermore, a fatigue-related comparison of miscellaneous time histories is difficult. Therefore, other data representations have been developed. They contain only that part of the original information, which is important for the actual analysis. Generally, these representations are called *diagrams or histograms*. Figure 3 shows a time history and the related level crossing and range pair diagrams. The level crossing diagram shows how often the load-time signal passes by a certain load level in one direction (upwards or downwards). The range pair diagram shows how often cycles exceeding a certain load level or amplitude occur within the load sequence.

One of the most important histogram types for fatigue-related analysis is the "rainflow matrix", which contains cycles resulting from a so-called rainflow counting [7–9]. Rainflow counting reveals fatigue-relevant events—the closed hysteresis loops providing amplitude and mean level—in the load-time signal and stores them in an efficient way. A graphical representation of a rainflow matrix is shown in Figure 4.

The rainflow matrix belongs to two-dimensional (2-D) histograms since it contains two pieces of information for every cycle: "from" and "to" level. A 1-D histogram like the "range pair histogram" contains only the amplitude of the cycles. Range pair and level crossing histograms as well as some other 1-D histograms can be easily derived from the rainflow matrix.

For deriving a rainflow matrix, the total load range of the time signal is divided equally into a certain number of "bins" (typically 64 or 100 bins are used). Monotonous parts of the signal are removed and a series of reversal points remain. From this signal, the closed hysteresis loops are identified and stored in the rainflow matrix; small loops may be dropped (hysteresis filtering). In the counting procedure, every closed loop is described by its two anchor points: the load level (bin) where it starts ("from") and the load level (bin) where it ends ("to"). Thus, the "from–to" representation contains information on amplitude, mean, and orientation ("standing" and

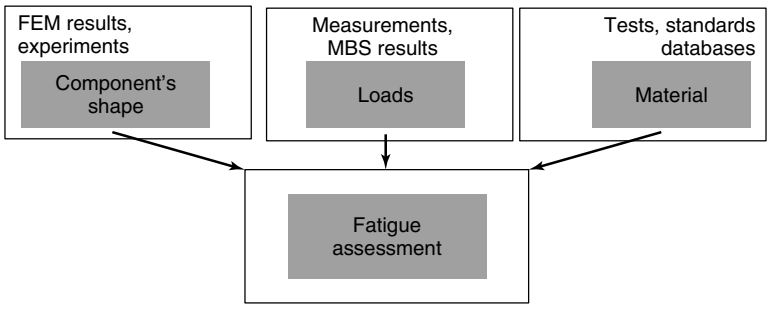

Figure 2. Describing fatigue test results with a S–N curve, important parameters.

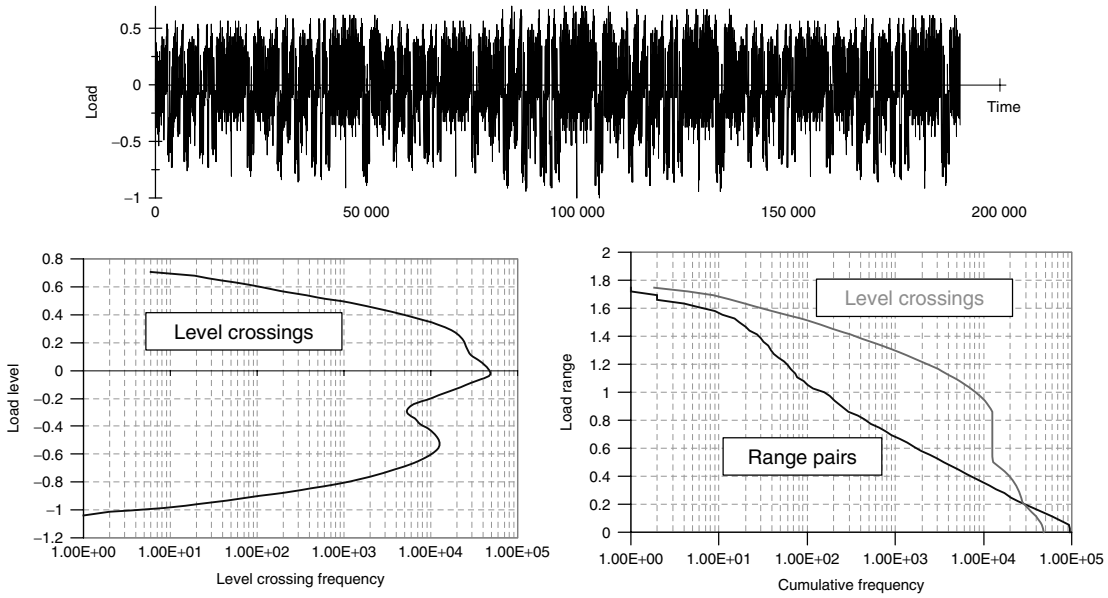

Figure 3. Service loading—Load-time history and representation by level crossing and range pair diagrams.

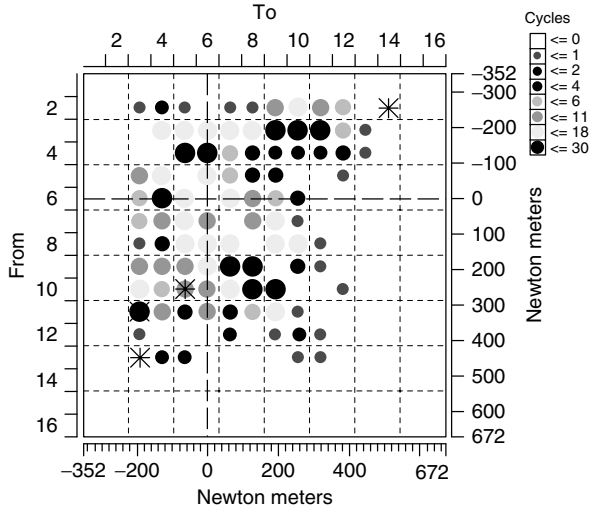

Figure 4. Graphical representation of a rainflow matrix in "from–to" form.

"hanging" inside a bigger hysteresis loop) of the closed hysteresis loops. At the end of the counting, the remaining reversal points that have not formed a closed loop are stored in a so-called residue. The residue may become important in further analysis steps like superposition of rainflow matrices.

The coordinates of the matrix in Figure 4 are the "from" (vertical axis) and "to" (horizontal axis) bins. Additional physical units, e.g., at the centers of bins are displayed. The matrix is divided into two triangular parts by the empty main diagonal. On lines parallel to this main diagonal, cycles with same amplitude but varying mean load are located. The amplitude varies on lines perpendicular to the main diagonal. The bubbles in different gray tones and sizes represent the number of cycles collected in

the corresponding cell. The half-cycles that form the residue are represented by asterisk markers.

Often, load histories (or stress histories derived with respect to a certain location on the component) are analyzed and counted with the rainflow algorithm.

For car body and chassis applications, designing a durability test based on rainflow matrix methods is well accepted. Here, typically time histories reflecting service loading of a vehicle are recorded on proving grounds or public roads. Proving ground tests are the result of many years of experience and contain a mix of test drives (e.g., driving on highway-like as well as rough roads under various vehicle-loading conditions) and especially designed tests.

For durability analyses, axial forces, moments, displacements, or strains are of interest. Data consolidation, e.g., removing spikes and drifts is done in time domain. Transferring load-time histories into (sets of) rainflow matrices reduces the amount of data and simplifies comparisons and further manipulation. Rainflow matrices are edited (e.g., small cycles are removed) and extrapolated to longer measurements or to extreme usage. The final target for a durability analysis consists of a superposition of rainflow matrices [10]. Superposition is, roughly speaking, an addition of the different matrices, which takes the residues into account. The weighting of different events can be accomplished by specifying individual repetition factors. For a rig test, the target in the rainflow domain has to be transformed back in time domain. In case of single channels, this can be achieved by "rainflow reconstruction" [11]. In case of multiaxial loading, the final time histories consist of a number of measured short events (time series). Selecting events and adjusting their repetition factors appropriately allows matching the target.

Using rainflow-based data analysis and synthesis methods, a fatigue test can be setup, which preserves the fatigue-relevant content but leads to a time reduction compared to using the originally measured time histories.

2.2 Material's fatigue properties

Often, CA loading tests are performed to derive the component's S–N curve or material's σ–N curve, respectively. These curves form the basis for the stress–life approach, in which the material behavior is assumed to be linear elastic.

$$\sigma_{\mathrm{a}} = \sigma_{\mathrm{a},k}\left(\frac{N}{N_k}\right)^{-\frac{1}{k}}, \quad \text{for } N \le N_k \tag{1}$$

Parameters are stress amplitude σ_{a}, number of cycles to failure N, and inverse slope k; the index k denotes the knee point of the curve in a double logarithmic diagram. Instead of stresses σ_{a}, loads L_{a} or nominal stresses S_{a} may be used. In the case of a notched rod under axial load F_{ax}, nominal stresses are often defined as $S = F_{\mathrm{ax}}/A$, where A denotes the net area of the cross section.

In the strain–life approach, the cyclic material behavior is described by both the cyclic stress–strain curve (CSSC) (according to Ramberg–Osgood [12]) and the strain–life curve (according to Manson–Coffin–Morrow [13–16]). Typically, strain-controlled tests are carried out on unnotched samples at various strain ranges. Stresses, strains, as well as the associated number of cycles are recorded during each test.

Ramberg and Osgood have suggested a method for describing the CSSC. The total strain amplitude ε_{a} is divided into elastic ($\varepsilon_{\mathrm{a,e}}$) and plastic ($\varepsilon_{\mathrm{a,p}}$) portions and is described by material parameters like Young's modulus E, cyclic strength coefficient K', and cyclic strain hardening exponent n'.

$$\varepsilon_{\mathrm{a}} = \varepsilon_{\mathrm{a,e}} + \varepsilon_{\mathrm{a,p}} = \frac{\sigma_{\mathrm{a}}}{E} + \left(\frac{\sigma_{\mathrm{a}}}{K'}\right)^{\frac{1}{n'}} \tag{2}$$

In the strain–life curve, the endurable strain amplitude σ_{a} is plotted against the number of cycles to crack initiation of technical size N_{i}. The subscript i denotes initiation. Often this failure criterion may be defined by a crack length $2c$ at the surface of $2c \approx 0.5$–1 mm. Plotting strain–life curves for the elastic and the plastic portion on a double logarithmic scale results in straight lines for each, which can be described according to Manson, Coffin, Morrow with Young's modulus E and further material parameters: fatigue ductility coefficient $\varepsilon'_{\mathrm{f}}$, fatigue strength coefficient σ'_{f}, fatigue strength exponent b, and the fatigue ductility exponent c.

$$\varepsilon_{\mathrm{a}} = \varepsilon_{\mathrm{a,e}} + \varepsilon_{\mathrm{a,p}} = \frac{\sigma'_{\mathrm{f}}}{E}\cdot(2N_i)^b + \varepsilon'_{\mathrm{f}}\cdot(2N_i)^c \tag{3}$$

The cyclic parameters of both the Manson–Coffin–Morrow and the Ramberg–Osgood equations are determined using regression analyses of experimental results. The parameters K' and n' can be derived from the data set using the compatibility conditions [12]:

$$K' = \frac{\sigma_f'}{(\varepsilon_f')^{n'}} \tag{4}$$

and

$$n' = \frac{b}{c} \tag{5}$$

Besides deriving cyclic material data from experiments, they can be found in data books or synthetic data may be used, e.g., from Uniform Material Law (UML) proposed by Bäume1 [17].

The stress–strain and strain–life curves are not solely sufficient for fatigue assessment because they do not consider the important effect of mean stresses. A widely spread and accepted parameter to consider mean stresses in the local strain approach is the damage parameter P_{SWT} proposed by Smith, Watson and Topper [18]

$$P_{SWT} = \sqrt{(\sigma_a + \sigma_m)\varepsilon_a E} \tag{6}$$

with stress amplitude σ_a, mean stress σ_m, and strain amplitude ε_a. The endurable damage parameter values are characterized by the P_{SWT}–life curve, which can be derived from strain–life curve

$$P_{SWT}(N) = \sqrt{\sigma_f'^2 \cdot (2N)^{2b} + \sigma_f'^2 \varepsilon_f'^2 E \cdot (2N)^{b+c}} \tag{7}$$

To be able to compare results from stress- and strain-controlled CA tests, even if mean stresses σ_m are slightly different, the damage parameter P_{SWT}—calculated assuming elastic material behavior—is used:

$$P_{SWT,e} = \sqrt{(\sigma_a + \sigma_m)\cdot\varepsilon_a \cdot E} = \sqrt{(\sigma_a + \sigma_m)\cdot\sigma_a} \tag{8}$$

3 FATIGUE STRENGTH ASSESSMENT

A numerical fatigue strength analysis consists of two major steps: the FE analysis of the component behavior when external cyclic load is applied, and a postprocessing step, which interprets the FE results in order to derive the number of load cycles, which the component will endure under a defined loading with a certain probability (Figure 5).

3.1 Determination of local stresses using FEM

Often, the numerical fatigue life assessment is based on FE analyses, assuming the linear behavior of materials and components. The nonlinearity, like nonlinear

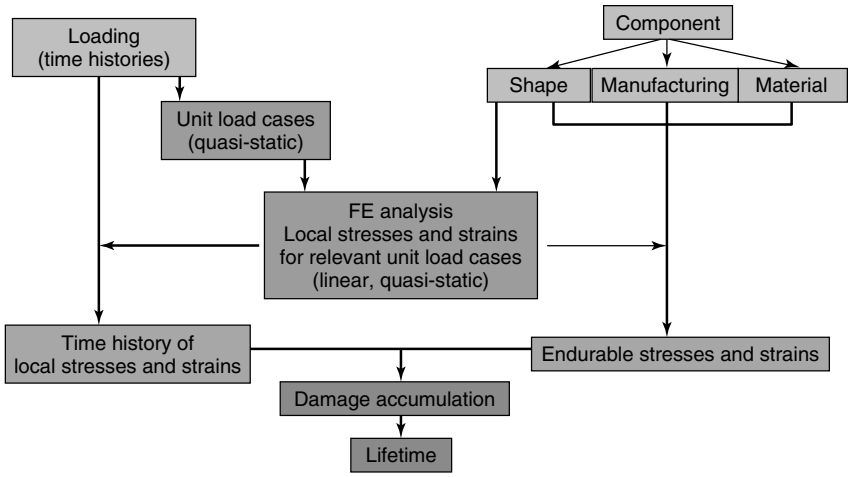

Figure 5. Workflow for fatigue life assessment based on FE results.

material behavior, contact, or large deformations, is neglected. Local stresses derived by the "Theory of Elasticity" are referred to as *elastic* stresses.

For relatively solid components, a static FE analysis can be applied because the lowest eigenfrequency typically lies far above the frequency range of the load-time histories relevant for structural durability. In case a single load $L(t)$ varying in time acts on a component the local "elastic" stresses, σ_e can be computed using the load influence factor c as follows:

$$\sigma_e(t) = c \cdot L(t) = (c \cdot L_{max}) \times \left(\frac{L(t)}{L_{max}}\right) = \sigma_{e,max} \cdot f(t) \tag{9}$$

If multiaxial loading is applied, the basic static load cases (so-called unit load cases) ${}^{s}\sigma_{e,i}$ (hyperscript s denotes static) multiplied with the normalized load-time histories $f_i(t)$ are superposed quasi-statically (Figure 6):

$$\sigma_e(t) = {}^{s}\sigma_{e,1} \cdot f_1(t) + {}^{s}\sigma_{e,2} \cdot f_2(t) + \cdots + {}^{s}\sigma_{e,n} \cdot f_n(t) \tag{10}$$

For thin-walled structures, such an assumption may be invalid. Resonances may be excited with the lowest eigenfrequency lying within the frequency range of the loading. In the numerical analyses, eigenmodes ${}^{m}\sigma_{e,i}$ are determined, starting with the lowest one. In a transient FE analysis, participation factor-time histories $p_i(t)$ are derived on the basis of the given eigenmodes and time histories of all loads acting on the structure. The participation factor-time histories $p_i(t)$ describe the influence of each eigenmode i on the local stresses at a certain point in time t.

The elastic stresses σ_e are computed from the linear combination

$$\sigma_e(t) = {}^{m}\sigma_{e,1} \cdot p_1(t) + {}^{m}\sigma_{e,2} \cdot p_2(t) + \cdots + {}^{m}\sigma_{e,n} \cdot p_n(t) \tag{11}$$

It is also possible to derive "elastic" stresses σ_e based on a combination of basic static modes and eigenmodes, as in the Craig–Bampton approach [19].

$$\sigma_e(t) = {}^{s}\sigma_{e,1} \cdot g_1(t) + {}^{s}\sigma_{e,2} \cdot g_2(t) + \cdots + {}^{s}\sigma_{e,n} \cdot g_n(t) + {}^{m}\sigma_{e,n+1} \cdot g_{n+1}(t) + {}^{m}\sigma_{e,n+2} \cdot g_{n+2}(t) + \cdots + {}^{m}\sigma_{e,n+k} \cdot g_{n+k}(t) \tag{12}$$

The latter approach has the main advantage that typically less modes are needed compared to a solution using eigenmodes only, which—depending on structure and type of loading—may require a high number of modes in order to describe the stresses with sufficient accuracy.

In an FE-based modal analysis, choosing appropriate damping can be challenging. Adjusting damping, based on the results of an experimental modal analysis, helps in improving the numerical analysis. For further information on modal analysis, reference is made to **Modal–Vibration-based Damage Identification**.

Furthermore, the workflow of the fatigue post-processing in the superposition approaches described in equations (11) and (12) is the same as for the quasi-static superposition, equation (10), which

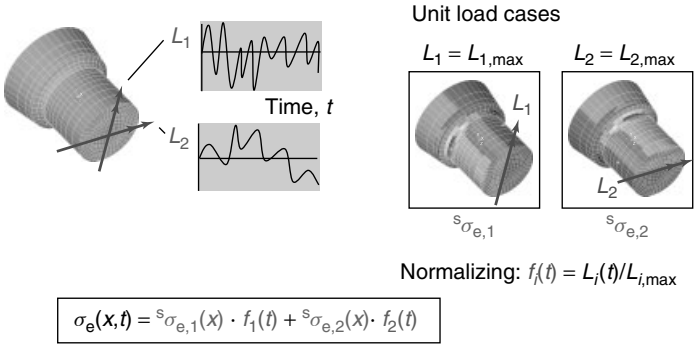

Figure 6. Quasi-static superposition of FE unit load cases (load frequency range below first eigenfrequency).

is supported by commercial fatigue analysis software packages, such as ABAQUS fe-safe, LMS Virtual.Lab Durability, MSC Fatigue, and nCode FE-Fatigue.

Apart from the approaches described in equations (10–12), a transient FE analysis applying all the loads acting on the structure in time domain may be performed. Thus, typically only relatively short events are analyzed due to the effort of calculating all the stresses and strains of a component for each time step. On the other hand, it is advantageous that in a transient analysis even complex contact situations can be handled.

For FE analyses with nonlinear material behavior, the elastic–plastic behavior may be described by the bilinear kinematic hardening rule of Prager–Ziegler [20]. Bilinear stress–strain curves approximate the interpolated Ramberg–Osgood stress–strain curves. More advanced material laws for fatigue analysis were proposed, e.g., by Mróz [21] and Jiang [22, 23].

3.2 Postprocessing of FEM results

For the prediction of the fatigue life of components under a high cycle fatigue (HCF) regime, the "concept of the local fatigue limit" can be applied, in which a purely elastic material behavior is assumed.

Typically in finite life design, elastic–plastic stresses and strains arise at the critical locations of a component. In the more general "local strain approach", elastic and elastic–plastic stresses are computed, and evaluated with regard to the criterion of crack initiation of technical size.

An analysis requires the following input data:

1. A sequence of reversal points of external load or a sequence of local stresses and strains, respectively: assuming that all loads acting on a structure are proportional ($L_i/L_j = \text{const}$) or only a single load is acting (uniaxial loading), a sequence of reversal points of the loading or a rainflow matrix is sufficient. In general, for multiaxial loading, time histories of all loads have to be provided in order to maintain the phase information.
2. Materials data for cyclic loading.
3. Relation between load and local strain.
4. Local macroscopic residual stresses.
5. Selection of a damage parameter P.
6. Modification factor for consideration of the size effect.
7. Modification factor for surface topography, e.g., following Siebel and Gaier [24].

In the following, some of these topics are addressed in more detail:

Materials data for cyclic loading: The material's data for cyclic loading, the stabilized CSSCs, and the strain–life curves can be determined using strain-controlled CA tests on residual-stress-free smooth specimens.

For notched specimens with a homogeneous cyclic material behavior over the cross section, Neuber's rule allows to derive the *relationship between load and local strains* in the notch for many applications with sufficient accuracy.

On the basis of the CSSC,

$$\varepsilon = g(\sigma) \tag{13}$$

Neuber's Rule can be simplified as

$$\sigma \cdot \varepsilon = K_t^2 \cdot S \cdot e \tag{14}$$

where K_t is the stress concentration factor, S is the nominal stress, and e is the nominal strain. The relationship between nominal strain and nominal stress is given by the CSSC $e = g(S)$.

Assuming the elastic behavior of the net section, equation (14) can be further simplified:

$$\sigma \cdot \varepsilon = \frac{\sigma_e^2}{E} \tag{15}$$

Equation (15) can then be directly applied to elastic stresses derived by FE analysis.

The more complex load-notch strain relationship following Seeger [25] has proved to be more accurate, as shown by a very good correlation with the results of the FE analysis.

Size effects: For notched bars with identical cyclic $\sigma-\varepsilon$ behavior of the surface layer and bulk material, the modification factor for consideration of the size effect may be determined according to Siebel–Stieler [26] or the weakest link approach. When using the Smith–Watson–Topper damage parameter P_{SWT} [18], both the modification factors for size and surface

roughness are taken into consideration by shifting the $P-N$ curve in the P direction by the respective factors.

3.3 Surface-strengthened components

Often, residual stresses can be observed at the surface of components, e.g., due to manufacturing processes like turning or grinding. Furthermore, surface strengthening techniques such as shot-peening or gas nitriding are applied in order to improve fatigue strength in the HCF regime [27].

If the local residual stresses are known, they may be considered in the fatigue life assessment using the "thin surface layer model" [28]. This model assumes that the surface layer of a component is of a negligible thickness with regard to its load-bearing capabilities. The thin surface layer model describes the release of initial residual stress through deformation; and, in a generalized form, the cyclic hardening or softening of the material (through using stabilized CSSC). The model does not, however, cover the continuous release of residual stresses arising after 1000 or more load cycles. Under CA loading, the second cycle is already stabilized in the calculation model. The influence of residual stresses upon the deformation behavior of the component as a whole is assumed to be negligible.

The surface layer can have cyclic material data and initial residual stresses that diverge from those of the bulk material. Owing to its negligible thickness, the deformation behavior of the component is not significantly influenced by the layer and the bulk material remains almost free of residual stress. Under these conditions, the total strain of the surface layer when the component is loaded results from the addition of the residual strain ε_{RS} plus the strain ε_B that a component without a surface layer would have. Figure 7 schematically illustrates the determination of local stresses and strains in a component with a thin surface layer of higher strength than the bulk material subjected to compressive residual stresses.

Subsurface crack initiation can be observed under an HCF regime [29], especially with thermochemically surface-strengthened components with low stress gradients at the site of maximum stress and strain.

4 SIZE EFFECTS

In the context of this text, size effect means that—assuming geometrically similar components—the allowable nominal stresses S (respectively the stresses based on the theory of elasticity σ_e at the critical location) decrease with increasing component size. Kloos [30, 31] introduces a systematic, which classifies size effects as

- technological
- stress gradient dependent
- statistical and
- surface treatment related.

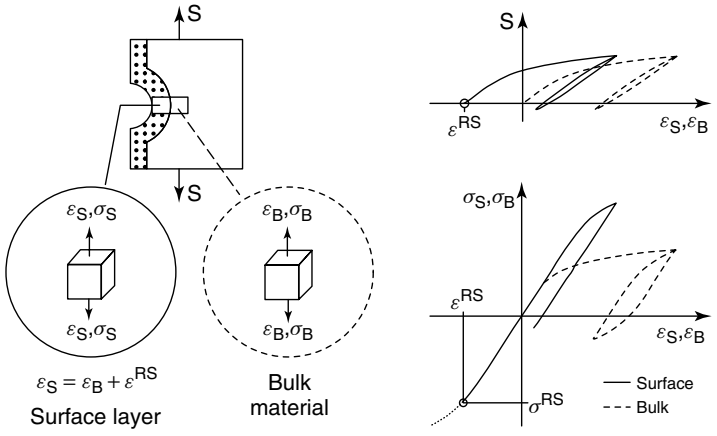

Figure 7. Thin surface layer model: stress-strain behavior in the notch root.

The technological—through use of corresponding component data—and the surface treatment–related size effect can be taken into account to a large extent in the local strain approach. Usually, the transferability of the $P-N$ or $S-N$ curve derived from unnotched specimen to the fatigue critical location of a component has to be ensured. If the highly stressed component area is very small, e.g., in a sharply notched component, the statistical possibility of finding a failure-causing material defect in the highly stressed component area is lower compared to an unnotched specimen with same net section diameter (statistical size effect) and type of loading. A variety of methods exist to take into account the so-called statistical size effect, as well as the structure mechanical size effect. The latter effect describes that stresses derived by the "Theory of Elasticity" are reduced, owing to microscopic and macroscopic yielding in the notch root. In notched components made from mild steels, such yielding leads to true stresses below the elastic stresses even at stress levels close to the knee point of the $S-N$ curve and thus to a better fatigue performance than those that would be expected from the elastic stress level.

Owing to their ease of use, empirically derived factors (so-called size factors) are often applied for the consideration of the size effect. In the HCF regime, e.g., at the knee point of the S–N curve, these size factors n are put in relation to the local fatigue strength of the component (calculated by the "Theory of Elasticity") $K_t \cdot S_\mathrm{k}$ and the material's fatigue strength σ_k (subscript k denotes the knee point):

$$n = \frac{K_t \cdot S_\mathrm{k}}{\sigma_\mathrm{k}} = \frac{\sigma_\mathrm{e,k}}{\sigma_\mathrm{k}} \tag{16}$$

For components with uniform cyclic $\sigma-\varepsilon$ behavior at the fatigue critical location, the size factor can be determined using the approaches proposed by Siebel–Stieler [26]. Similar formulae are given in the (FKM) Forschungskuratorium Maschinenbau Guideline [32], published by the Research Association for the Mechanical Engineering Industry (FKM). Here, the size factor is derived from diagrams or a formula in dependence from the normalized stress gradient χ^* and the material's strength, e.g., the yield strength R_e.

$$n_\chi = f(\chi^*, R_\mathrm{e}) \tag{17}$$

The normalized stress gradient χ^* is defined as follows:

$$\chi^* = \left| \frac{1}{\sigma_\mathrm{e,max}} \cdot \frac{\mathrm{d}}{\mathrm{d}x} \sigma_\mathrm{e} \right| \tag{18}$$

where x denotes a coordinate normal to the surface.

All purely empirical approaches, which describe the size effect on fatigue properties with a size factor based on the normalized stress gradient χ^* only and which neglect the dimensions of both the reference specimen used to derive the material's fatigue strength and the component considered, have a disadvantage. They are somewhat limited to the dimensions and fatigue properties, which are contained in the data set used for their derivation.

Another possibility of describing the size effect is based on the "weakest link" model proposed by Weibull [33–35]. Experiencing the scatter of the fatigue resistance for a constant fatigue life, respectively the scatter of fatigue life for constant load amplitudes, it is assumed that the distribution of internal defect sizes of a material (e.g., length of microscopic cracks) or the local strength corresponds to a Weibull distribution. The largest defect determines the component strength; the subcritical crack growth or coalescence of cracks is of minor importance. Furthermore, it is assumed that the components compared have the same distribution of internal defect sizes (e.g., scatter) and show the same failure mode.

Thereafter, the ratio of the fatigue strength of two components can be determined by comparing the probability to find an internal defect that causes failure in each of the individual components. This probability increases with the size of the highly stressed component area.

5 EXAMPLES

5.1 Uniaxial loading

Fatigue tests were performed on notched, axially loaded specimens. Cyclic material data determined from strain-controlled constant-amplitude loading, residual stress measurements, and FE analyses provided the input data for the calculation.

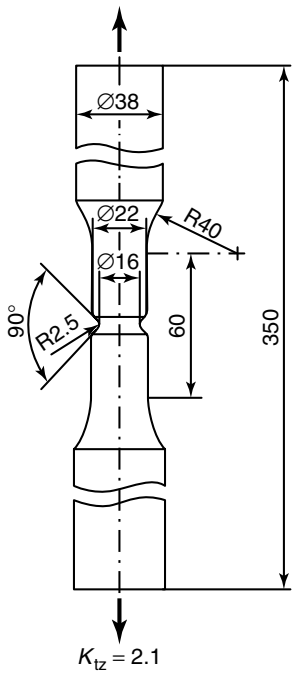

Figure 8. Shape and dimensions of specimen.

The experiments were performed with German grade 42CrMo4 steel (AISI 4040H), quenched and tempered at $T_A = 620\,^{\circ}\mathrm{C}/2.5\,\mathrm{h}$ (ultimate tensile strength $R_m = 1075\,\mathrm{MPa}$, 0.2% offset yield stress $R_{p0.2} = 980\,\mathrm{MPa}$, hardness 330 HV 0.3).

Figure 8 shows the shape of the notched, axially loaded specimen; the axial stress concentration factors is $K_{tz} = 2.1$, and the equivalent stress concentration factor (von Mises criterion) is $K_{tq} = 1.9$.

Tests with constant-amplitude ($R = -1$) and variable-amplitude loading were performed. In the variable-amplitude tests, a random sequence with Gaussian level crossing distribution, a spectrum block size $H_0 = 10^4$ cycles, and a nearly equal number of mean crossings and turning points was used. For all samples (with crack initiation at surface), the criterion of failure was the reaching of a crack length at a surface of $2c = 0.5\,\mathrm{mm}$.

Cyclic material data were determined with strain-controlled CA tests with axially loaded unnotched specimens. The description of the thus-received experimental results for calculation uses relationships following Ramberg–Osgood and Manson–Coffin–Morrow (Figure 9).

Figures 10 and 11 show graphs of the numerically and experimentally determined crack initiation lives of residual-stress-free specimens. The computed curves are shown with solid or dashed lines—these correlate well with the experimental results.

The relation between predicted and experimental results under a Gaussian load sequence corresponds to the general experience made with such comparisons in the literature: If the calculation results fit well with the experimentally determined S–N curve, then the use of the damage parameter according to Vormwald [36] P_J leads to a slightly conservative prediction of the fatigue life curve, while the calculation with the P_{SWT} parameter in conjunction with a P_{SWT}–N curve based on the Manson–Coffin–Morrow relationship and ignoring the endurance limit tends to be somewhat on the unsafe side. Typically, this is adjusted by choosing an allowable damage value for variable amplitude (VA) loading D_{VA} lower than 1.

For analyzing the life of shot-peened specimens with stress concentration factor $K_{tz} = 2.1$, the thin surface layer model is used. As the comparison between the S–N_i curves of untreated and shot-peened samples shows (Figure 12), the influence of residual stress is predominant in the region of low loads, while with higher load levels a release of residual stresses is forced and only the life-reducing influence of surface roughness remains. For the fatigue life curve, the above statements concerning the P_{SWT} parameter apply accordingly.

Applying the stress–life approach based on experimentally determined S–N curves may lead to even better accuracy. Please keep in mind that in the strain–life approach based on cyclic material data, an S–N curve is already a first calculatio result.

5.2 Multiaxial loading

An assessment of a component under multiaxial loading is illustrated using a forged aluminum knuckle of a car's front suspension as an example (Figure 13), [37].

The knuckle is manufactured by forging a wrought aluminum alloy. The material's cyclic properties were derived using the UML [17].

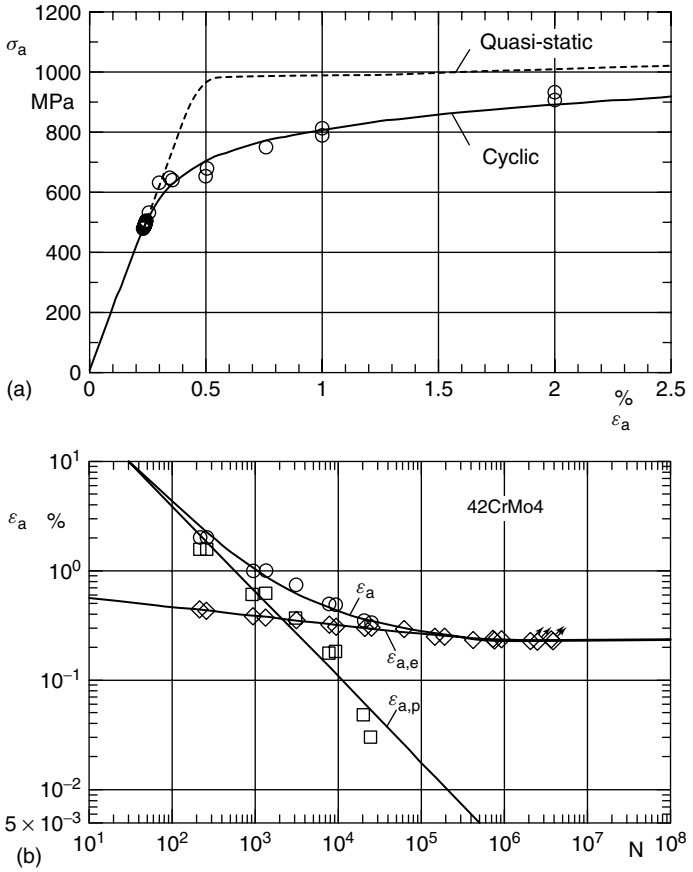

Figure 9. Stabilized CSSC (a) and strain–life (b) curves for steel 42CrMo4.

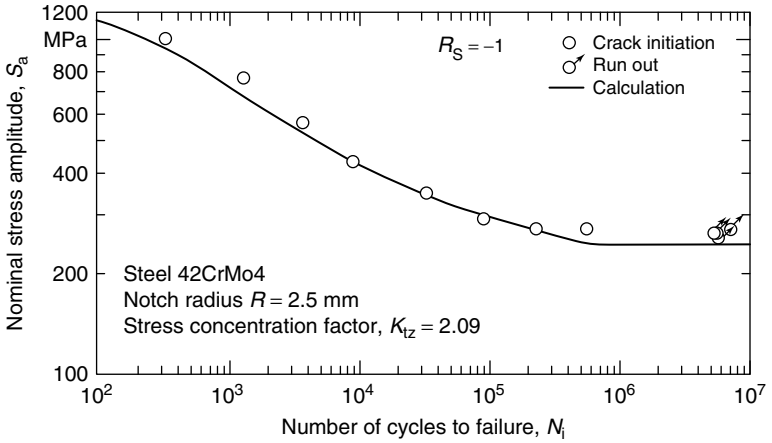

Figure 10. Comparison of numerically and experimentally determined crack initiation life under constant-amplitude loading. $S-N$ curve ($R_S = -1$) of untreated notched specimens.

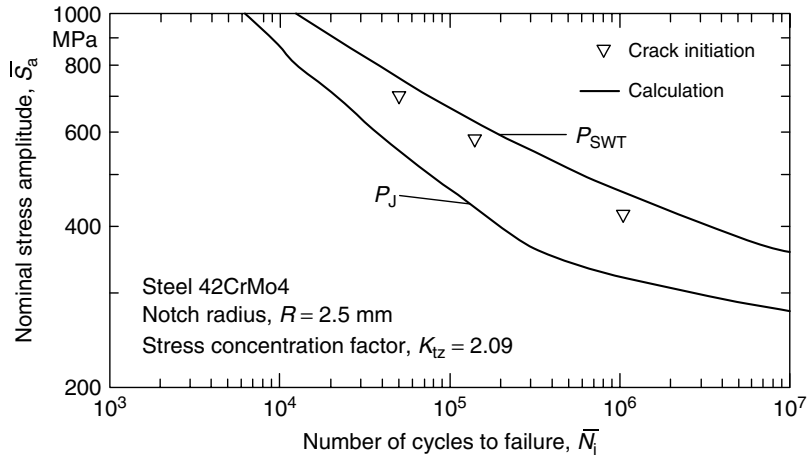

Figure 11. Comparison of numerically and experimentally determined crack initiation life: VA loading (Gaussian load spectrum, ($R_S = -1$) of untreated notched specimens.

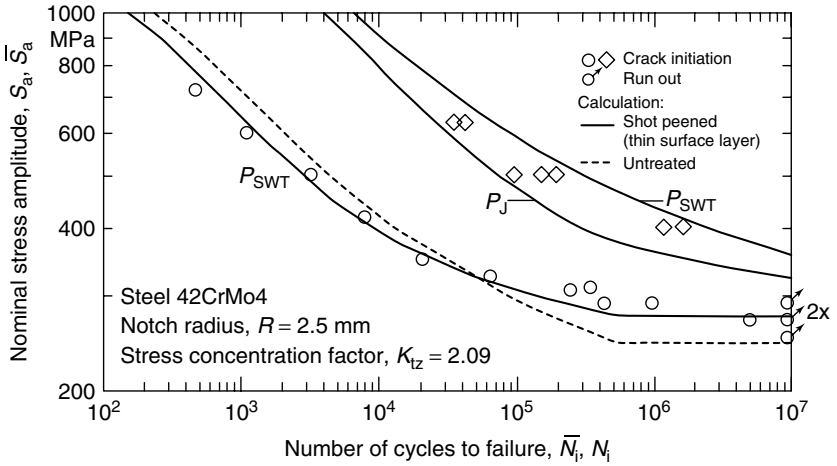

Figure 12. Comparison of numerically and experimentally determined crack initiation life: CA and VA loading ($R_S = -1$) of shot-peened notched specimens (axial residual stresses $\sigma^{R_S} = -700$ MPa).

The standardized load-time history "CARLOS multi" [38] is chosen as a nonproportional load input, which consists of four load channels (longitudinal, lateral, and vertical load vectors acting at the spindle and braking/accelerating forces acting at the tire contact patch) (Figure 14).

The calculation is based on elastic stresses. On the basis of the CAD geometry, an FE mesh with quadratic tetrahedral elements was created and a skinning with membrane elements was applied at the surface. Stresses close to the areas of load application depend strongly on the modeling of this area. Owing to the simplifications made (e.g., rigid element spiders connecting the input points with the solid elements of the component), load input areas are excluded from further analyses. The stiffness of the brake caliper, which is mounted to the knuckle at two points, affects the input of brake loads (and subsequently

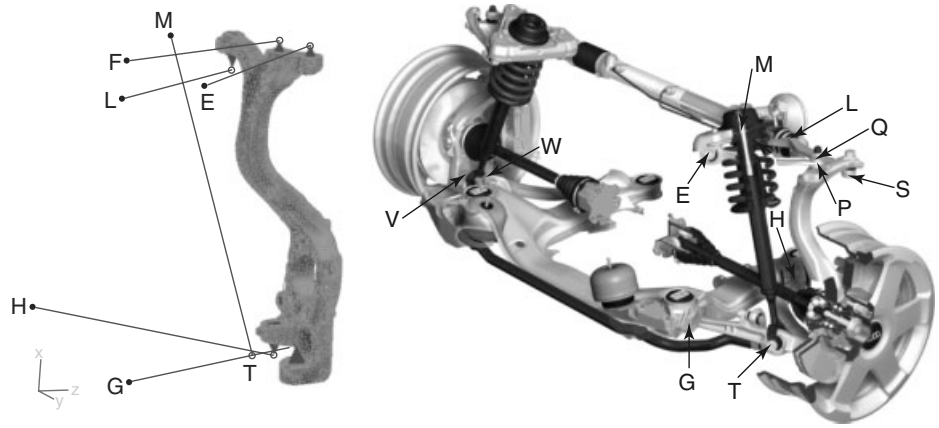

Figure 13. Forged aluminum knuckle and front suspension. [Reproduced from Ref. [37]. © Elsevier, 2004.]

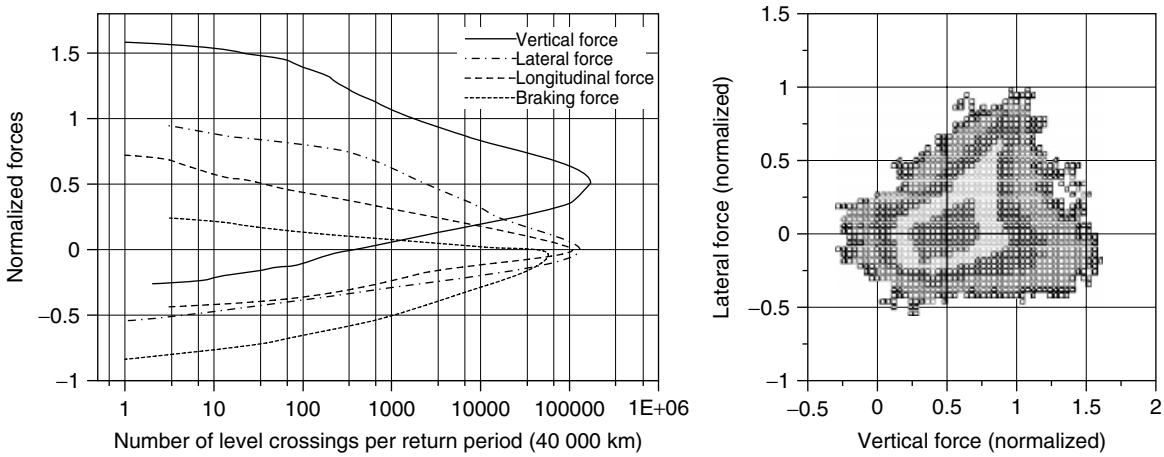

Figure 14. Standardized load-time history CARLOS multi—level crossing distributions and an example for statistical correlations between two channels. [Reproduced from Ref. 38. © Fraunhofer-Institut für Betriebsfestigkeit, 1994.]

the stress distribution in the neighboring area). The caliper is modeled with beam elements representing the appropriate stiffness (Figure 15).

Figure 16 shows the von Mises stress plots for the four unit load cases applying the respective maximum load levels of the corresponding CARLOS multi-load-time histories. For all plots, the same scaling is applied for the stresses. It is obvious that some locations exhibit high stress levels due to several load cases, whereas others exhibit these stress levels only due to a single load case.

For the fatigue life assessment, the critical plane approach is chosen. Local stresses are computed by quasi-static superposition (equation 10). On the basis of the elastic normal stresses in the various planes, the local strain approach is applied [39] in combination with the load–notch strain relation proposed by Seeger–Beste [25], the damage parameter P_{SWT} [18] and the damage accumulation according to Palmgren and Miner. For the sake of simplicity, other influences such as surface roughness, statistical size effects, and changes in local material properties due to the manufacturing process are neglected.

The results of the fatigue life assessment, which has been performed with the software package LMS FALANCS [40], are given as damage plots displaying potentially critical locations (Figure 17).

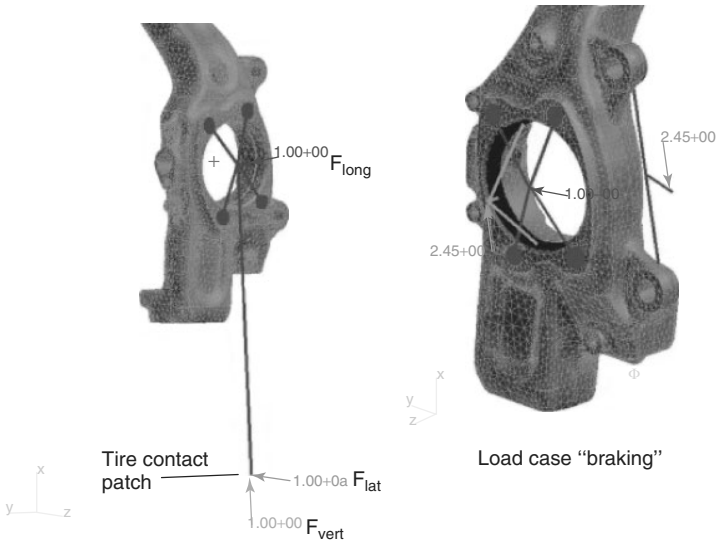

Figure 15. Load input at the knuckle.

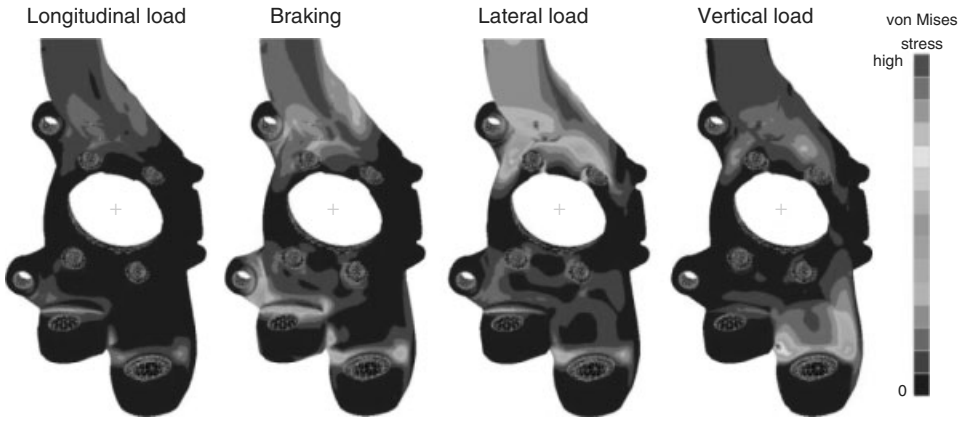

Figure 16. von Mises stresses at the inner side of the knuckle for each unit load case.

Please note that the displayed range of fatigue life covers four decades. Numbers 1 and 2 designate the two most critical locations examined at the knuckle side pointing to the car center.

Figure 18 describes the local biaxial stress state at the two locations. For the evaluation, the maximum principal stresses at the surface were defined as follows: $|\sigma_1| > |\sigma_2|$; $\sigma_3 = 0$. In the histograms, all principle stresses are normalized by the absolute maximum principle stress, which occurs at location 1. The biaxiality ratio is defined as ratio between minimum and maximum principal stress. The behavior at location 1 is strongly influenced by the vertical loading. The local stress state can be described as nearly uniaxial. The direction of the maximum principal stress changes only at very low loads. Location 2 lies in a relatively sharp notch, which is loaded mainly during braking. The constraint caused by the notch leads to a ratio between minimum and maximum principal stress slightly below Poisson's Ratio. With high stress values, no significant variation in the angle of the maximum principal stress can be observed.

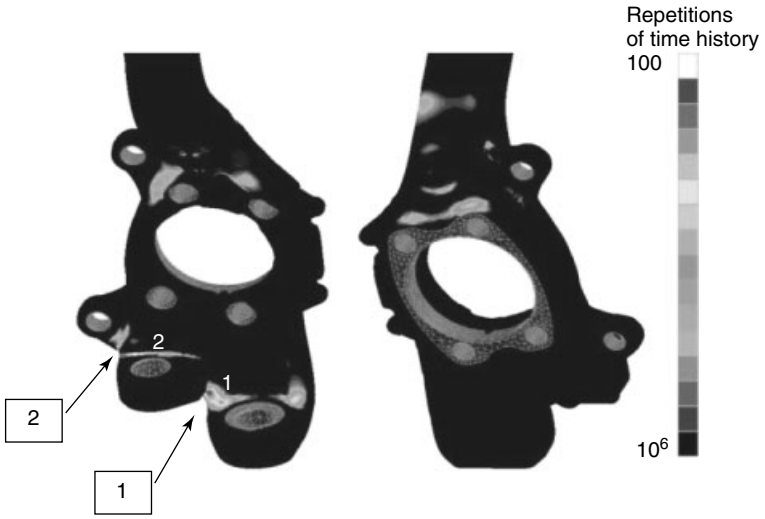

Figure 17. Damage plots.

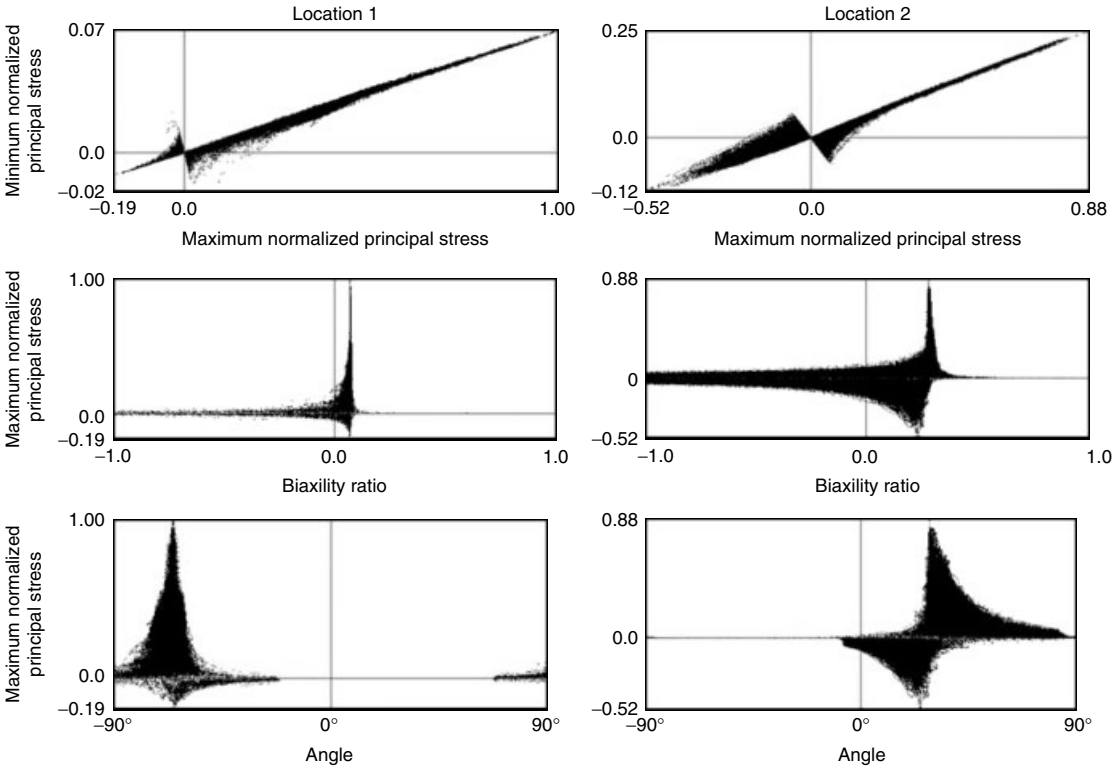

Figure 18. Local elastic stress states at locations 1 and 2 of the aluminum knuckle under loading with CARLOS multi.

In the present example, the structure—a part of multilink car suspension—and the design of the knuckle leads to a separation of the load-transferring functions, thus limiting nonproportional local stress states. The stress state at the locations analyzed turns out to be proportional in spite of the external nonproportional load input, especially with higher loads. For sign-off testing of a single critical location, therefore, a simplified test would be sufficient. If all critical locations on a component or subsystem have to be detected and analyzed, the full set of multiaxial load input has to be taken into account.

The example shows

- how to detect fatigue critical areas, which may be the subject of monitoring and
- how to assess the fatigue damage caused by the loading applied.

Furthermore, knowing the fatigue-relevant locations of a component, actuators and sensors of a structural health monitoring system can be optimally placed on the component in order to detect an occurrence of fatigue cracks.

6 CONCLUSIONS

A broad range of fatigue life assessment methods exists. The most efficient approach depends strongly on the input available.

It has to be pointed out that—compared to relative fatigue strength analyses—a quantitative fatigue life assessment of a component requires profound knowledge of the service loading applied. Load monitoring is important for achieving more reliable input data or to verify assumptions taken in the design phase of structures. It has been shown that numerical fatigue life assessment allows

- detecting fatigue critical areas, which may be the subject of structural health monitoring and
- assessing the fatigue impact of the loading applied.

On the basis of combined load monitoring and fatigue life assessment, an evaluation of the remaining service life is possible.

1 INTRODUCTION

Fatigue cracking and delamination are particularly dangerous and are, at the same time, the most common kinds of damages in elements of machines and structures. It is of great importance for the safe operation of the elements of machines and structures to ensure that they are free of any fatigue cracks and delaminations and to determine the extent of fatigue cracks and delaminations in case they are present. Since existing nondestructive methods for the detection of fatigue cracks and delaminations have failed in many practical cases, vibration methods have been continually used for nearly 20 years for the diagnosis of such damage. These methods are based on diagnostic relations between the size and location of failures and changes in some dynamic characteristics of construction elements. In order to establish such relations, and to identify changes of the dynamic characteristics, efficient models that facilitate the assessment of the influence of fatigue cracks and delaminations must be established. In this work, a review of the existing models used for analyses of the influence of fatigue cracks and delaminations on changes in dynamic characteristics of construction elements has been presented.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino ISBN: 978-0-470-05822-0.

2 CONTINUOUS MODELS

Historically, the oldest method, proposed by Hetenyi [1], is applied for modeling fatigue cracks in construction elements made of isotropic materials, in which a crack in a construction element is represented by some additional external equivalent loads (Figure 1a). This method was originally developed to determine the line of static deflection for beams of a nonconstant

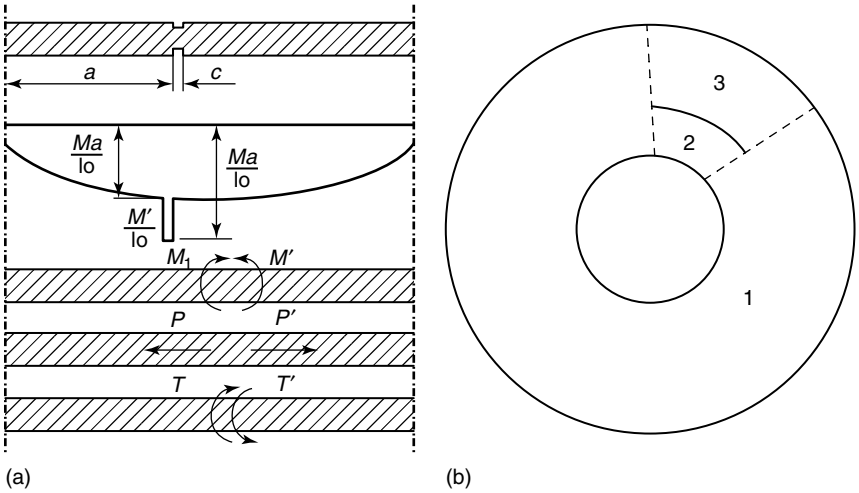

Figure 1. Continuous models of (a) a beam with a transverse fatigue crack (by Thomson [3]) and (b) a thin circular plate with an internal fatigue crack (by Lee [5]).

cross section. Modifications introduced by Kirsmer [2] and Thomson [3] enhanced the method and it is being successfully used for studies of natural frequencies of beams with fatigue cracks. In the following years, models based on the concept of equivalent external loads were further developed by Petroski and Glazik [4]. The principal limitation of these models was the fact that their mathematical description was based on partial differential equations and then they enabled studies and investigation and provided results of sufficiently high accuracy only in the case of construction elements of very simple geometry. Therefore, these models were mainly used for studies of static and dynamic behavior of beams of constant cross sections. On the other hand, the lack of an explicit relation between the size of a fatigue crack and the magnitude of its external equivalent load made it practically inapplicable for the sensitivity analysis of dynamic characteristics of construction elements. Another shortcoming of these models was also the fact that a singular character of the stress and strain fields around the crack tip was omitted. Owing to the above facts, these methods are practically not in use anymore.

Another method used in the analysis of continuous models of construction elements with fatigue cracks or delaminations is the one in which the investigated element is divided into subdomains constrained by its boundaries and the line of a discontinuity (Figure 1b). In order to connect the subdomains, additional boundary conditions are introduced. This approach is applied for isotropic and composite structures. The method was commonly and successfully used to study natural vibrations of thin rectangular plates. Lynn and Kumbasar [6] used the Green's function approach to obtain the Fredholm integral equation of the first kind. Stahl and Keer [7] and Aggarwala and Ariel [8] have solved the eigenvalue problem of simply supported plates by using homogeneous Fredholm integral equations of the second kind. The methods presented in [6–8] were limited to such locations of the crack that enabled the problem to be reduced to a dual series equation. Hirano and Okazaki [9], Neku [10], and Solecki [11] applied fast Fourier transform to the differential equations governing the problem. They obtained a system of integral equations possessing the unknown discontinuities of the deflection and slope across the crack. Lee [5] used a method based on the Rayleigh principle, subsectioning the plates in the determination of the fundamental natural frequency of the circular plate.

The model of delaminated beam, based on the approach described above, is presented in Figure 2. Through-width delamination is parallel to the beam surface located arbitrarily in both the spanwise and thicknesswise directions. The delamination divides the beam into four regions. A Euler beam theory is applied to each region. Apart from the usual

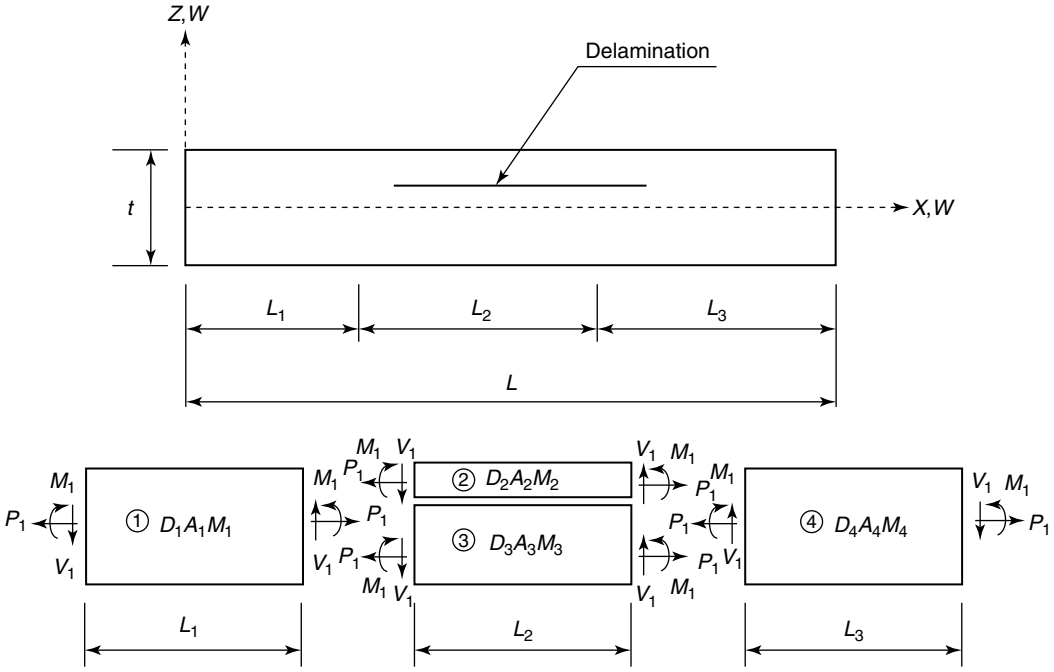

Figure 2. Continuous model of delaminated beam (by Tracy and Pardoen [13]).

conditions of continuity of transverse displacements, slopes, bending moments, and shear forces, two additional conditions were considered (the continuity of axial displacements and forces). This model gives good results for determining the modal parameters of composite laminate. Zou *et al.* [12] presented a review of papers in which models of delaminated beams are described.

The effects of delamination on buckling and postbuckling deformation and delamination growth with various geometrical parameters and loading conditions were studied extensively by Chai *et al.* [14], Botega and Maewal [15], Whitcomb [16], Yin *et al.* [17], and Chen [18]. Natural vibrations of delaminated beams were studied by Ramkumar *et al.* [19] on the basis of the Timoshenko beam theory. The authors, however, did not take into account the effect of coupling of the transverse vibration with the longitudinal wave motion in the upper and lower split layers. Their analytical results predicted significant reduction in the fundamental frequency. Wang *et al.* [20] used the classical beam theory, but, in contrast to Ramkumar *et al.* [19], they considered the coupling effect. With the inclusion of coupling, the calculated fundamental frequency was not appreciably reduced by the presence of a relatively short delamination, and the results were in close agreement with experimental measurements.

Also, results obtained by Christidis and Barr [21] and by Wauer [22] are of great importance in the development of continuous models of construction elements with fatigue cracks. Applying the variational formula of Hu–Washizu, they derived differential equations governing vibrations of beams [21] and turbine blades [22] with fatigue cracks. In order to model changes in their stiffness due to the cracks, they assumed that the stress field along the length of a beam can be approximated by an exponential function. However, limitations of this approach are concerned with the fact that the exponent of the function describing the stress field must be determined experimentally. A singular character of the stress function around the crack tip is also not maintained. It should be noted that such a model does not describe precisely a fatigue crack but rather represents a notch or slot.

The restrictions of the above-mentioned models allow one to analyze the vibration of structures

only in some particular cases. Real engineering constructions are more complex, and the application of other techniques follows naturally.

3 DISCRETE–CONTINUOUS MODELS

Discrete–continuous models as well as discrete models are the most commonly used models to study the dynamic behavior of construction elements with fatigue cracks. In the discrete–continuous models (see Figure 3), a fatigue crack in a construction element is represented by additional springlike elements, compliance of which is calculated according to the laws of fracture. In this manner, a system consisting of an undamaged element and springlike elements modeling the crack is created. The undamaged element and the elements modeling the fatigue crack are connected together by introduction of special boundary conditions. This method can be successfully used for modeling fatigue cracks in one-dimensional construction elements (rods, beams, shafts, columns, and pipes) or in constructions made of such elements (frames and trusses) and plates. In the general case, compliance of springlike elements modeling a fatigue crack in a one-dimensional construction element can be expressed by a 6×6 compliance matrix.

Particular elements of this matrix were studied by many investigators. Liebowitz *et al.* [24] and Okamura *et al.* [25] found the compliance of a springlike element related to longitudinal deformation of a column of a rectangular cross section. Rice and Levy [26] determined the compliance related to the bending and compression modes as well as a coupling term for a thin membrane. Dimarogonas and Massouros [27] derived a formula to calculate compliance of a springlike element related to the torsional mode of a beam of a circular cross section. Anifantis and Dimarogonas [28] showed the form of the compliance matrix of springlike elements modeling a fatigue crack in a beam of a circular cross section except for the term connected to torsion. The full form of this matrix for a beam of a circular cross section can be found in the work of Dimarogonas and Papadopoulos [29] and that of a beam of a rectangular cross section in the work of Krawczuk [30]. The form of the compliance matrix for a beam of a rectangular cross section made of unidirectional composite material was presented in the work of Nikpour and Dimarogonas [31]. The influence of a single transverse fatigue crack on the stability of composite pillars was analyzed by Nikpour [32] who showed that, with increasing slenderness ratio of the columns and depth of the crack, the value of the critical force decreases. Recently, Papadopoulos [33] presented a review of papers in which discrete–continuous models based on strain energy release are described.

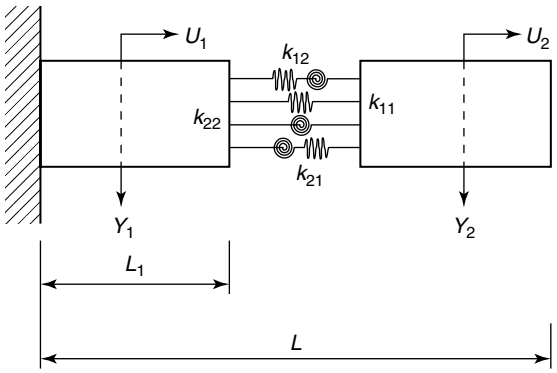

Figure 3. A discrete–continuous model of a shaft (by Papadopoulos and Dimarogonas [23]).

This approach was used in the past in studies of static and dynamic behavior of one-dimensional construction elements. Liebowitz *et al.* [24], Okamura *et al.* [25], and Anifantis and Dimarogonas [34] applied the discrete–continuous model of fatigue damage to investigate the influence of the size and location of fatigue cracks on changes in the critical load and stability of columns made of isotropic material, while Nikpour [32] enhanced these studies by investigation of columns made of composite material. Results on changes in the natural frequencies and mode shapes of beams calculated by the use of this discrete–continuous method can be found in the work of Gudmundson [35], Adams *et al.* [36], Ju *et al.* [37], Springer *et al.* [38], Cuntze and Hajek [39], Papaeconomu and Dimarogonas [40], Liang *et al.* [41], Ostachowicz and Krawczuk [42], Rajab and Al–Sabeeh [43], Rytter *et al.* [44], and Kisa and Arif [45]. However, this method was applied in studies of dynamic behavior of rotors with fatigue cracks most extensively and successfully. The most important studies in this area were carried out by Gash *et al.* [46], Grabowski [47], Ignaki *et al.* [48], Schmied and Kramer [49], Bachschmid *et al.* [50], Dentsoras

and Dimarogonas [51], Papadopoulos and Dimarogonas [23], Wauer [52], Jun *et al.* [53], and Lee *et al.* [54]. This method was also successfully applied in studies of fatigue cracking rings by Dimarogonas [55], as well as in cylindrical shells by Anifantis and Dimarogonas [56].

This method was used by Khadem and Rezaee [57] and Mateev and Boginich [58–60] for the analysis of modal parameters of rectangular cracked plates based on the Kirchoff approach.

It should be noted that, apart from the already mentioned restrictions, this approach is also limited because it is based on partial differential or integral equations. Similar to the method of external equivalent loads, this approach enables one to study, investigate, and obtain results of sufficiently high accuracy only in the case of construction elements of simple geometry like rods, beams, columns, shafts, or rectangular plates with typical boundary conditions.

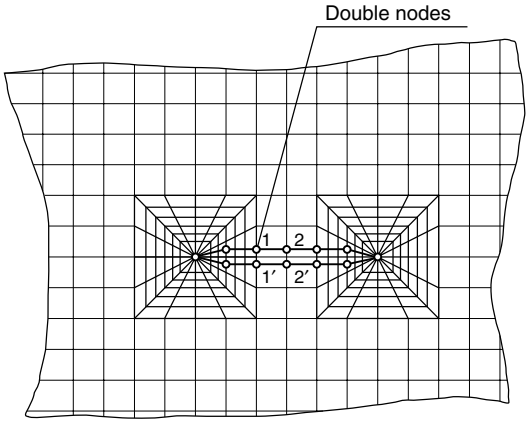

Figure 4. Modeling of a fatigue crack by separation of finite-element nodes and by condensation of the mesh around the crack tip.

4 DISCRETE MODELS

In general, discrete models of fatigue damage are not restricted geometrically, whereas restriction is one of the biggest disadvantages of the continuous or discrete–continuous models. In order to create a discrete model of a construction element with a fatigue crack, the finite-element method is applied most of the times. Other methods such as the boundary element method, graph method, transition matrix method, and the analog method are also used, but these methods are not as popular and commonly used as the finite-element method.

4.1 Finite-element method

The simplest method applied to model construction elements with fatigue damage is based on the use of classical finite elements. In this case, a fatigue crack in the finite element is modeled by reduction of elastic coefficients of the element [61], by reduction of its Young's modulus [62], and by reduction of the cross section area of the element in the crack position [50]. The main disadvantage of these approaches is the fact that the reduced parameters describing a fatigue crack are chosen arbitrarily. Generally, their values are not directly related to the actual size of a crack and therefore a precise study of the influence of the crack depth on changes in dynamic characteristics cannot be made. A singular character of the stress and strain fields around the crack tip is also neglected in these methods.

Another method applied in modeling of fatigue cracks in construction elements based on the finite-element method is the one in which the nodes of finite elements are separated along the crack surface and a condensed mesh of finite elements around the crack tip is used (Figure 4). The condensed mesh of finite elements enables to model properly a singular character of the stress and strain fields around the crack tip. Models based on this approach were successfully applied by Zastrau [63]. This approach gives good results and the existing finite-element software can be effectively used for these studies. Calculating dynamical parameters of construction elements is considerably time consuming.

The methods discussed above can be easily modified by the use of finite elements with singular shape functions around the crack tip [64]. Shen and Pierre have demonstrated that, for an eight-node quadrilateral element, by moving the midside nodes near the crack tip to the quaterside position (Figure 5a), strain singularities are produced. However, for such an element, the singularity conditions prevail only along the edges, and not on an arbitrary ray emanating from the crack tip. This problem was later resolved by collapsing the nodes 1 and 4 of the eight-node quadrilateral element in Figure 5(a), resulting in the

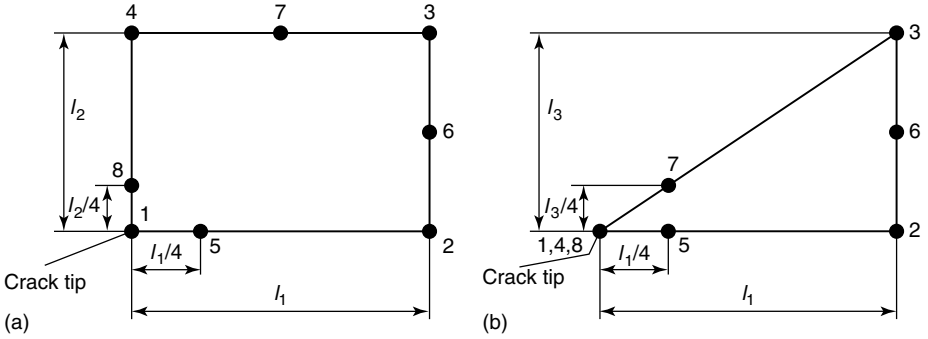

Figure 5. (a) Rectangular finite element with midside nodes at quarter points and (b) triangular element with midside nodes at the quarter points (by Shen and Pierre [64]).

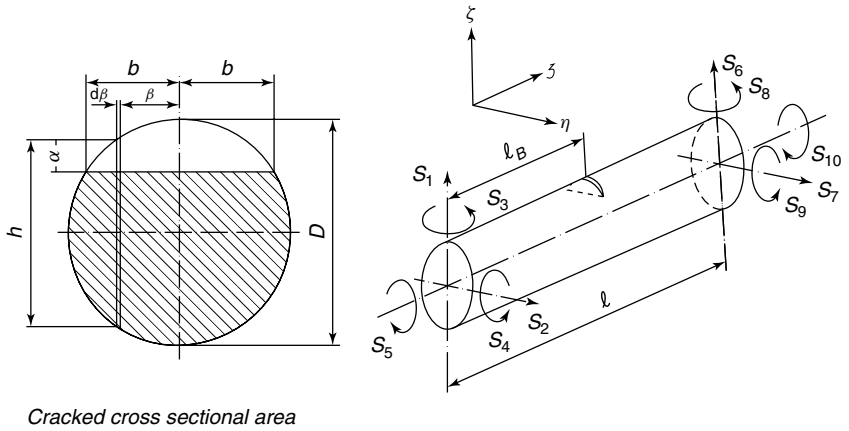

Figure 6. Fragment of shaft with single-sided crack (by Ostachowicz and Krawczuk [70]).

triangular element in Figure 5(b). Then the singularity prevails on all rays emanating from the crack tip. Application of such elements does not require condensation of the finite-element mesh around the crack tip and, consequently, the time required for numerical calculations is significantly shorter.

In the last decade, new finite-element method (FEM)-based models were formulated. Researchers assumed that a failure appears inside the special finite element. A model of a truss finite element with an open one-sided transverse crack was developed by Krawczuk [65]. Models of beam finite elements with fatigue cracks of different types can be found in the work of Haisty and Springer [66], Gounaris and Dimarogonas [67], and Chen and Chen [68]. Krawczuk and Ostachowicz [69] investigated a mathematical, FEM-based model of a beam with a crack, loaded at the end with a constant tensile axial force. The authors assumed that the crack does not propagate and remains open during the beam's vibrations. Admission of a complete opening of the crack in this case was correct because the beam was subjected to the action of a constant axial force.

Ostachowicz and Krawczuk also developed a model of a shaft of constant cross section with a crack. The shaft was modeled by finite elements. The crack was considered to be open. The stiffness matrix for the element with a crack was formulated. The model takes into consideration the torsional–bending interaction in rotor vibration (Figure 6).

The curved beam finite element with a transverse, one-edged, nonpropagating, open crack (Figure 7) was investigated by Krawczuk and Ostachowicz [71]. The authors presented an analysis of the effect of the crack position, and of its location, on the changes in the in-plane natural frequencies and mode shapes of

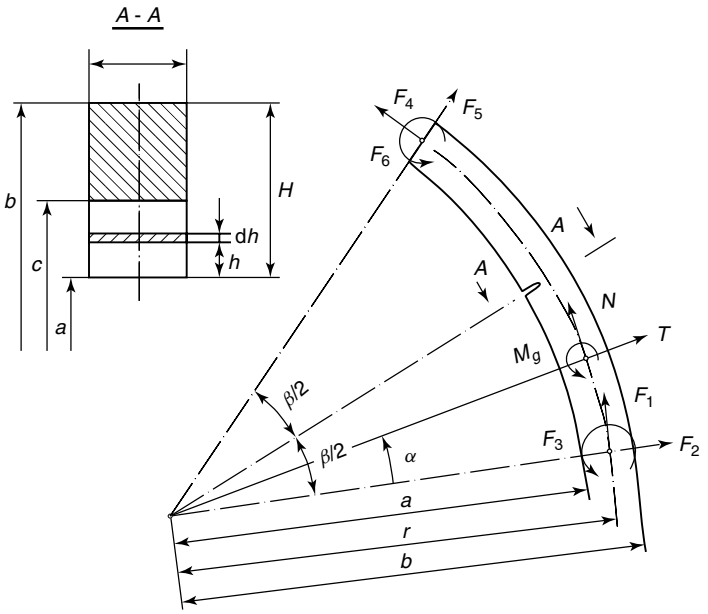

Figure 7. A curved beam finite element with transverse, one-edged, nonpropagating open crack (by Krawczuk and Ostachowicz [71]).

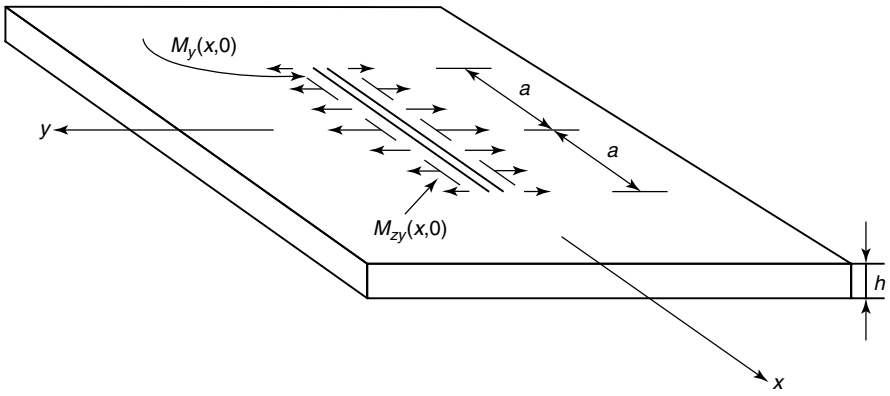

Figure 8. A plate finite element with a fatigue crack (by Qian *et al.* [73]).

the clamped–clamped arch. The authors assumed that the crack only changes the stiffness of the element, with the mass of the element remaining unchanged. The investigated model of the cracked element is restricted to curved beams with a rectangular cross section.

A cracked beam finite element, which is based on elastoplastic fracture mechanics, was formulated by Krawczuk *et al.* [72]. Crack-tip plasticity, at the cracked cross section, was included in the model of the local flexibility. The inertia and stiffness matrices take into account the effect of flexural bending deformation due to the crack presence. They are formulated in closed forms.

Along with one-dimensional models, special models of two- or three-dimensional construction elements (see Figure 8) with fatigue cracks were also investigated. The cracks occurring in a plate can be modeled by the finite-element method in various ways. Plate finite elements with fatigue cracks were used by

Qian *et al.* [73], Krawczuk [74], and Krawczuk and Ostachowicz [75], while a solid finite element with a fatigue crack was developed by Krawczuk and Ostachowicz [76], and a shell element by Krawczuk [77].

Krawczuk and Ostachowicz presented a method of creating the stiffness matrix of a finite plate element with a nonpropagating, internal, open crack (Figure 9). The method is similar to that described by Qian *et el*. [73] but, contrary to their approach, the stiffness matrix of the cracked element was given in a closed form. The additional flexibility matrix was calculated by taking into account the additional elastic stress energy due to the occurrence of the crack in the plate. The method is restricted to cracks whose length is smaller than the dimensions of the element. It has been assumed that the crack changes only the stiffness of the element, whereas the mass of the element remains unchanged.

A method of creating the stiffness matrix of a hexahedral eight-node finite element with a single, nonpropagating, transverse, one-edged crack at half of its length was investigated by Krawczuk and Ostachowicz [76] Figure 10. The crack was modeled by adding an additional flexibility matrix to that of the noncracked element. The terms of the additional matrix were calculated by using an approximated model of the stress intensity factor.

Damage models in composite structures have been studied extensively by many researchers. Krawczuk *et al.* proposed [78] the formulation of a finite

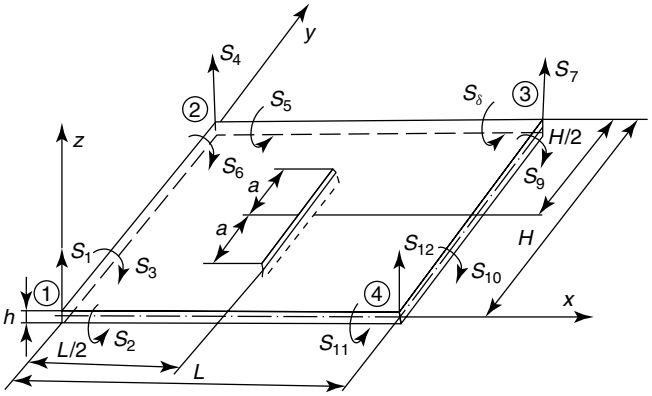

Figure 9. A four-node plate finite element with a crack (by Krawczuk and Ostachowicz [75]).

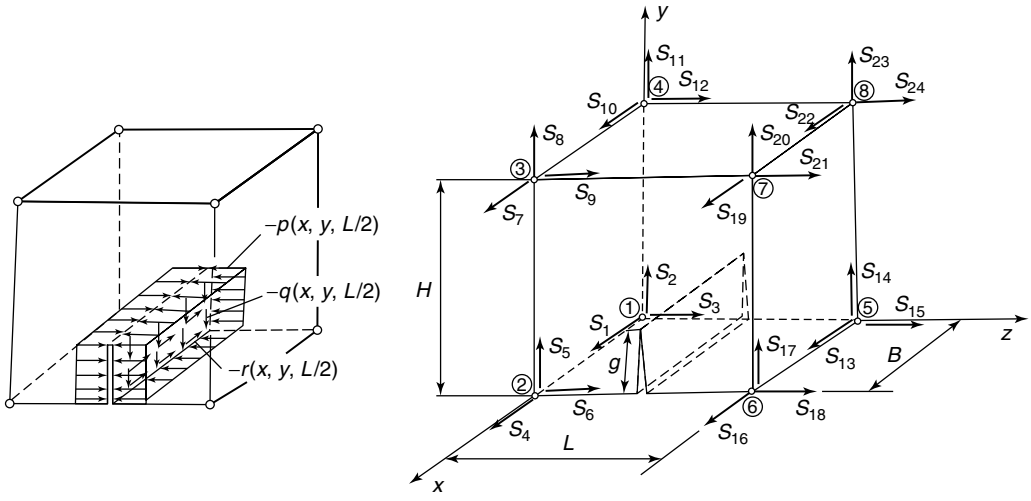

Figure 10. Hexahedral finite element with an open crack (by Krawczuk and Ostachowicz [76]).

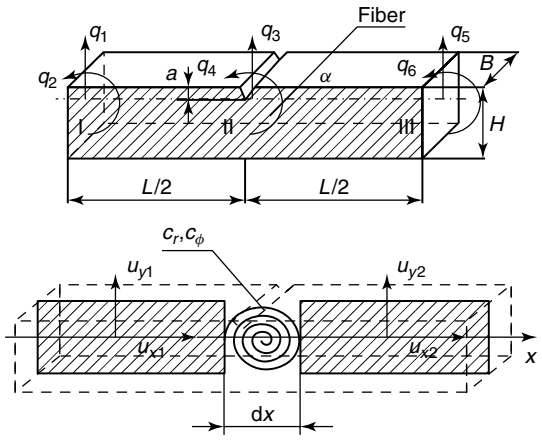

Figure 11. The finite composite beam element with an open crack (by Krawczuk *et al.* [78]).

composite beam element with an open crack. The damaged part of the beam was modeled by a special finite element with a crack (Figure 11), while the undamaged part was substituted by a three-noded beam element. The crack was placed in the middle of the element and remained open. The angle between the fiber and the axis of the element was α. The element had three nodes. Each of them had two degrees of freedom: transverse displacements and rotations. In the paper [78], only the case of flat bending was considered.

Krawczuk *et al.* [79] investigated a model of a layered, delaminated composite beam. The beam was modeled by beam finite elements with three nodes and three degrees of freedom per node (Figure 12). In the delaminated region, additional boundary conditions were applied. It was assumed that the delamination is open (i.e., the contact forces between lower and upper parts are neglected).

The delaminated region is modeled by three finite elements, which are connected at the delamination crack tip where additional boundary conditions are applied. Each element has three nodes with three degrees of freedom, which are axial displacements, transverse displacements, and the independent rotations. In addition to general conditions of beams theory, two different assumptions were used. One was that the extensional and bending stiffnesses are uncoupled.

A model of a finite delaminated plate element was developed by Żak *et al.* [80]. Figures 13 and 14 present a way of modeling the delaminated region in a composite plate with delamination. The delamination is modeled by three-plate finite elements and, to connect them, additional boundary condition are applied at the delamination front. Each finite element has eight nodes with five degrees of freedom.

4.2 Spectral finite-element method

The spectral element method (SEM) is a technique that combines the geometric flexibility of finite

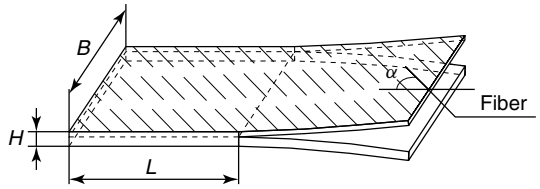

Figure 13. The multilayer composite plate with delamination (by Żak *et al.* [80]).

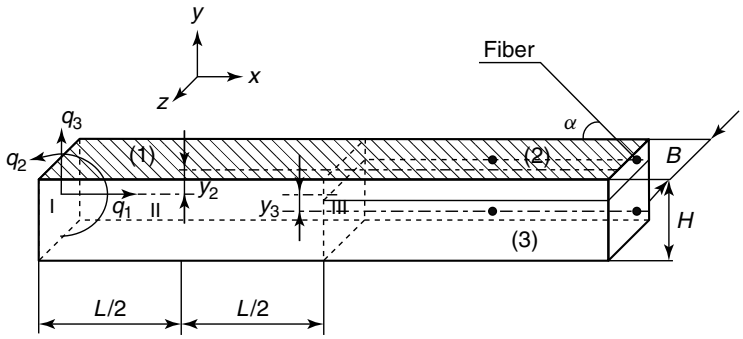

Figure 12. Delamination of a beam modeled by finite elements (by Krawczuk *et al.* [79]).

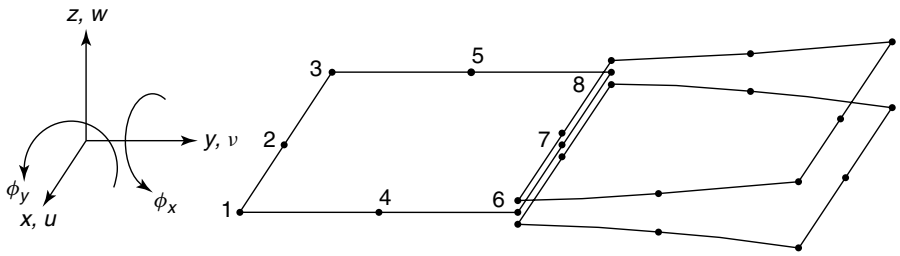

Figure 14. The region of the delamination modeled by finite elements (by Żak *et al.* [80]).

elements with the high accuracy of spectral methods. This method is widely applied for damage detection based on analysis of anomalies in elastic waves propagation. In the literature, two main versions of the method are reported.

The first formulation, called the *forward Fourier transformation (FFT)-based spectral element method*, was proposed by Doyle [81] and developed (especially for damage detection) by Gopalakrishnan *et al.* [82]. This technique is very similar to the technique of the FEM as far as the assembly and the solution of the equation of motion are concerned. Firstly, the excitation signal is transformed into a number of frequency components using the FFT. Next, as a part of a big frequency loop (as opposed to a loop overtime in the conventional finite element (FE) formulation), the dynamic stiffness matrix is generated, transformed, and then a solution is found for each unit impulse at each frequency. This directly yields the frequency response function (FRF) of an analyzed problem. The calculated frequency-domain responses are then transformed back to the time domain using the inverse fast Fourier transformation (IFFT). It proves that this technique is well suited for simple one-dimensional problems but is inefficient when the geometry becomes complex or when two- or three-dimensional problems must be analyzed. This method was applied for analysis of wave propagation in one-dimensional structures with different kinds of damages like cracks [83–85] or delaminations [86–90].

The second formulation of the method, called the *time-domain-based spectral element method*, was proposed by Patera in 1984 [91]. This version is much more versatile for the analysis of elastic wave propagation in structures of complex geometry. The method originates from the use of spectral series for solution of partial differential equations. The

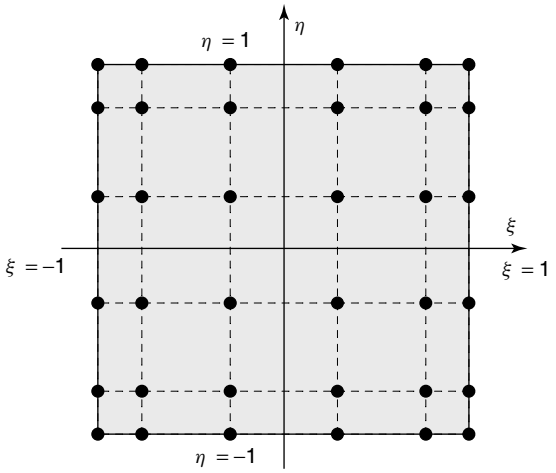

Figure 15. Location of nodes in the spectral finite element (time domain formulation) of the sixth order.

idea of SEM is very similar to the FEM, except for specific approximation. The element interpolation nodes are placed at the zeros of an appropriate family of orthogonal polynomials (Legendre or Chebyshev) Figure 15. A set of local shape functions consisting of Lagrange polynomials, which go through this point, are used. As a consequence, in conjunction with the Gauss–Lobatto–Legendre integration rule, the diagonal mass matrix is obtained. In this way, the cost of numerical calculation is much less than in the case of the classic FE approach. Moreover, the numerical error decreases faster than any power of $1/p$ (spectral convergence), where p is the order of the polynomial expansion. The analysis of the influence of different kinds of damages on elastic wave propagation in one-dimensional structures are presented in papers [92], whereas two-dimensional problems are described in the following works [93, 94].

4.3 Boundary element method

The boundary element method is still not being commonly used in studies of the influence of fatigue damage on dynamic behavior of construction elements. Despite this, this method is being very successfully used in studies of static behavior of construction elements with cracks such as determination of stress intensity factors, strain or stress fields around the crack tip, and similar studies. Also, existing software developed for the boundary element method can be effectively used.

4.4 Transition matrix method

An application of the transition matrix method in modeling and studies of natural frequencies of a beam with a fatigue crack can be found in the work by Sato [95] (Figure 16). This is the only example available in the literature on the use of this method for the investigation of the dynamic behavior of construction elements with fatigue cracks. In the model presented by Sato, only a change of the beam cross section in the place of a crack was considered and therefore, similar to the continuous models, in this model a singular character of the stress and strain fields around the crack tip was not maintained. Thus, mathematical models elaborated by the use of the transition matrix method like the model developed by Sato describe changes in the stiffness of the beam caused by a notch rather than by a real fatigue crack.

4.5 Graph method

The graph method, similar to the boundary element method and the transition matrix method, is not commonly used in studies relating to the influence of fatigue damage on the dynamic behavior of construction elements. This method was used to investigate vibrations of beams with cracks by Ibrahim [96] and Ismail *et al.* [97]. The advantage of this method is that the existing software for the graph method can be very effectively used. An example of a beam with a fatigue crack modeled by the use of the graph method is presented in Figure 17. In this case, the damage is modeled by substitution of the crack by equivalent stiffness. Similar to the continuous models and the transition matrix method, the discussed approach does not take into account a singular character of the stress and strain fields around the crack tip with all the consequences already discussed.

4.6 Analog method

The analog method was applied in modeling of beams and frames with fatigue cracks by Tsyfansky and Beresnevich. [98] and Akgun and Ju [99]. A fatigue crack in this method is modeled by the decrease in the electrical resistance representing the bending stiffness of the beam. Also, in this approach, a singular character of stress and strain fields around the crack tip is neglected. An example of an analog system modeling a cantilever beam with several fatigue cracks is presented in Figure 18.

5 CONCLUSIONS

In this paper, a number of typical models of cracked and delaminated structures have been described. There are many challenges in the development of models of structural stiffness loss due to damage. Typical ones are those that have the ability to identify minor changes of stiffness in composite structures.

Analytical methods to predict changes in the stiffness parameters become dubious with complex structures. The difficulties lie in restrictions described in

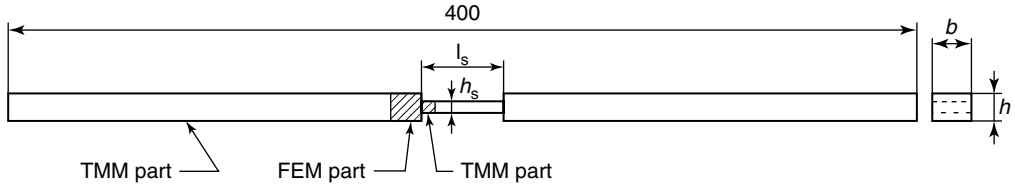

Figure 16. A beam with a fatigue crack modeled by the transition matrix method (by Sato [95]).

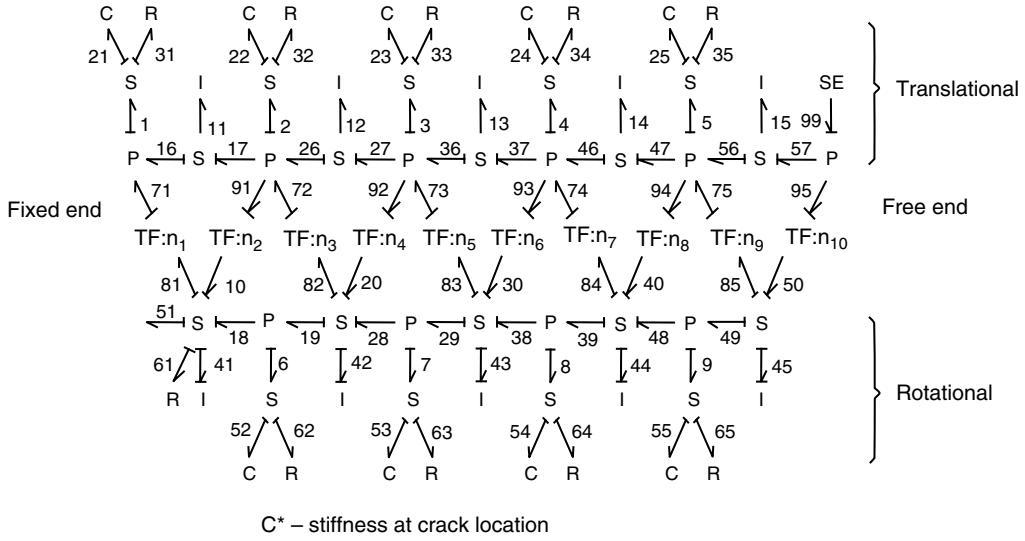

Figure 17. A cantilever beam with a fatigue crack modeled by the graph method (by Ismail *et al.* [97]).

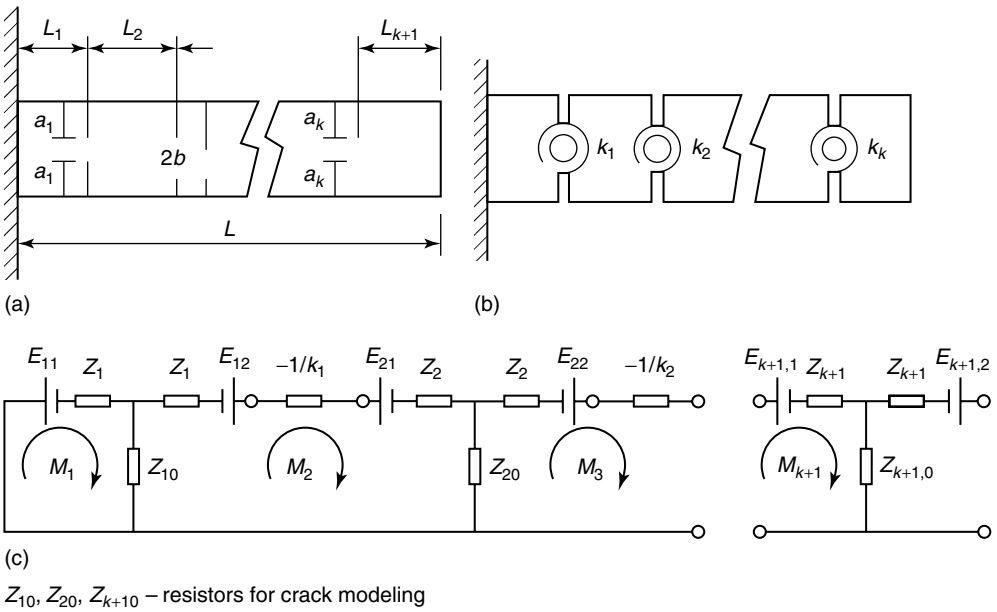

Figure 18. An analog system modeling a cantilever beam with a fatigue crack (by Akgun and Ju [99]).

detail in Section 2. So far, the FEM-based methods have been more realistic for application in engineering constructions.

Laboratory experiments are often conducted to ensure the reality of analytical and numerical models. Therefore, to develop practical and capable detection of stiffness, a large amount of work is still to be done.

Current and future work is concentrated on the integration of various models into a uniform system. Studies are also being carried out on other failures that appear in the composite structure.

1 INTRODUCTION

Wave propagation phenomena in solids have received a great deal of attention due to their manifestation in various engineering problems. For instance, the mechanisms of Lamb waves have been rigorously examined over the years for their application to damage identification or structural health monitoring (SHM) (*see* **Ultrasonic Methods**; **Guided-wave Array Methods**; **Modeling of Lamb Waves in Composite Structures**). Applications of various numerical approaches or numerical modeling in this field can be mainly categorized into the following three areas: (i) characterization of Lamb waves, e.g., the dispersion nature; (ii) investigation on Lamb wave scattering by damage; and (iii) direction application of numerically simulated Lamb wave signals in damage identification or damage evaluation (*see* **Modeling of Lamb Waves in Composite Structures**). We review these three application areas one by one as follows.

The nature of dispersion Lamb waves can provide a lot of important information for SHM or damage identification, such as mode selection, nondispersive zone for optimizing the excitation frequency, and wave propagation speed, etc. There are numerous analytical studies on the dispersion nature of Lamb waves, one of them being the well-known transfer matrix approach. They are not reviewed here since our focus is on numerical modeling for complex media. Owing to the complexity of Lamb waves in composites, such as the different wave velocities

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

for different laminate layouts, the finite element method (FEM) has been developed in parallel for this purpose. For example, FEM models that allow particle displacement to vary as cubic polynomials in the z direction (through-thickness direction) and to vary harmonically in the x direction (span direction) were developed to evaluate the dispersion nature of Lamb waves in carbon fiber/resin composite laminates [1, 2]. The models are able to simulate horizontal shear mode (Love wave).

There have also been a number of studies in the second area of Lamb wave scattering by damages in structures, which can provide some fundamental information for damage identification, such as reflection intensity from damage. For instance, for isotropic materials, Karim *et al.* [3] studied Lamb wave scattering from cracks and inclusions in a plate due to a vertical Gaussian beam load using a hybrid FEM and normal function expansion method. Mal and Chang [4] investigated the scattering of Lamb waves from rivet holes and cracks in plates by using hybrid frequency-domain FEM and normal mode expansion (called *global–local FEM technique*) followed by inverse fast Fourier transformation (FFT) to obtain the scattered field in time domain. Hu *et al.* [5] employed a 3-D hybrid FEM to study the Lamb wave scattering caused by a circular hole in metallic plate, and obtained the relationship between the reflection intensity and wave incident angle. In the above studies [3–5], because of the employment of the conventional FEM for whole structures or at least for damaged regions, in general, very fine meshes should be used, especially in the damaged zones. For composite materials, Liu and Achenbach [6] employed the strip element method to model wave propagation in composite laminates containing matrix cracks. Aberg and Gudmundson [7] proposed a higher-order beam theory to analyze the transient waves in laminated beams containing matrix cracks and fiber breakage. The interaction between Lamb waves and delaminations has also been investigated numerically by the conventional 2-D FEM [8] and 3-D FEM [9]. For instance, the detailed position of a delamination in a laminated beam, where the strongest reflection takes place, was identified for S_0 mode [9], which facilitates a more accurate identification of location of the delamination. Further, some recent studies were focused on the improvement of the spectral element method for matrix cracks [10] and delaminations [11, 12] in beam structures. The spectral element method utilizes the exact solution to the strong form of the elastodynamics for finite element (FE) interpolation at discrete frequencies. Computationally, it is a very efficient and powerful method for analyzing the high-frequency responses.

In the third area, tremendous efforts [13–16] have been directed to solve the damage identification problem as an inverse pattern-recognition problem through comparison between numerical analysis results and experimentally captured signals, including artificial neural networks. With the use of numerical models, most of these techniques do not need the experimental *baseline* data of intact structures, although they may be referred to, e.g., as in [14]. Techniques of this kind, which provide detailed information of damage shape or extent, need a careful verification of the effectiveness of the numerical models by comparing them with the experimental data to increase the reliability and accuracy (*see* **Modeling of Lamb Waves in Composite Structures**).

As stated above, owing to the extreme importance of numerical modeling or numerical characterization of elastic waves (e.g., Lamb waves) in the field of damage identification and SHM, over the years, many numerical techniques have been developed for dealing with elastic wave problems. Such methods include: the finite difference method (FDM) [17], the conventional FEM [1, 2, 5, 8, 9, 18–20] and the boundary element method (BEM) [21, 22]. These methods can deal with most complex situations, especially the complex geometry, arbitrary time history of excitation, and the nonlocal properties. However, computational solvability and accuracy based on these approaches deteriorate dramatically as the spatial domain becomes larger and as the time duration of the excitation becomes shorter. For instance, among the versatile computational methods developed till date, the standard *hp*-FEM can deal with most complex situations. However, in the context of the wave propagation problem, the main disadvantage of such *hp*-FEM with polynomial interpolation is that, the higher the frequency, the greater the number of elements required for obtaining accurate results, and, consequently, high computational costs.

Parallel to the above general approaches, there have been quite remarkable progresses on exact or seminumerical methods, which rely upon the

strong form of the boundary value problem (BVP) as opposed to its weak form as in the FEM. For simple 1-D geometry with general boundary conditions and for 2-D or 3-D geometries with periodic or semi-infinite boundary conditions, asymptotic solutions have been employed to develop various numerical methods, namely, the transfer function matrix method [23], dynamic stiffness matrix method [24], space–time FEM [25], strip element method [6], spectral FEM for beams [10–12, 26, 27], and Levy-type plate [28]. In general, these methods that are constructed in the frequency domain need much less memory storage space for necessary data due to a lower level of discretization and application of the exact solution in one direction, which is very effective for the computation of forced wave motion under much higher frequencies. However, it is very difficult to use them for problems with complex geometries. In general, almost all of above exact or seminumerical approaches are built up in the frequency domain and the responses in the time domain should be obtained through inverse FFT.

Another important approach is a spectral or pseudospectral method in the time domain, which may have been first proposed by Patera [29], based on trial functions of the Chebyshev series, for the solution of partial differential equations of laminar flow problems. Despite the terminology, this method in the time domain is completely different from the spectral element methods [10–12, 26–28] in the frequency domain. An important advantage of this method is that the numerical errors decrease more quickly than any power of $1/p$, i.e., the so-called spectral convergence, where p is the order of the polynomial used [30]. At present, the main application fields of this pseudospectral method include: fluid dynamics, heat transfer, acoustics, seismology, and so on. Despite its wide application, the available literature suggests that the use of this pseudospectral method has been quite limited in the fields of elastic wave propagation in 2-D plate structures, e.g., as described only in [31, 32], to the best of the authors' knowledge. The idea of the pseudospectral element method is quite similar to that of FEM except for the specific piecewise interpolation functions such as the orthogonal Chebyshev or the Legendre polynomials that it uses within elements.

From the above brief review of some limited previous studies, it can be seen that successful numerical simulation of elastic wave propagation, especially the wave scattering of structures containing damages, is a key issue for developing highly reliable and applicable SHM techniques or damage identification techniques. Some new numerical approaches are still needed to tackle this problem more efficiently and with greater flexibility. Keeping this in mind, the main objective of this work is to construct a highly accurate element to simulate elastic wave propagation in 2-D problems of metallic and composite materials containing damages. Two different types of interpolation bases are used in two orthogonal directions: (i) the superposed harmonic wave-type solution using wave vector (**k**) from an assumed kinematic theory (e.g., first-order shear deformation theory (FSDT) for the present beam problem) and (ii) the Lagrangian family of interpolation. While dealing with the wave propagation problem in complex geometry, the above description of the displacement field has definite advantage over the exact spectral interpolation. As a consequence of the hybrid interpolation using (i) and (ii), a weak formulation of the BVP becomes necessary. Therefore, we employ a frequency-domain variational approach and derive the frequency-dependent dynamic stiffness matrix, the mass matrix, and the consistent load vector. Compared with many previous studies for wave scattering with the conventional FEM [3–5, 8, 9], by using a coarse mesh, this element can effectively model the region having various damages, i.e., the "interior region", in metallic and composite materials with high flexibility. Ordinary spectral elements are used to model the "exterior regions" or far-field regions for enhancing computational efficiency. Displacement continuity and equilibrium of forces between the "interior region" and the "exterior region" are modeled using the global–local approach [3, 4, 7]. Numerical examples are used to demonstrate the effectiveness of this new element and to study the behavior of wave propagation in cracked or delaminated beams.

2 FIELD INTERPOLATION

2.1 Solution to one-dimensional wave dispersion

In this section, the authors give a brief outline of the steps involved in obtaining the spectral family of

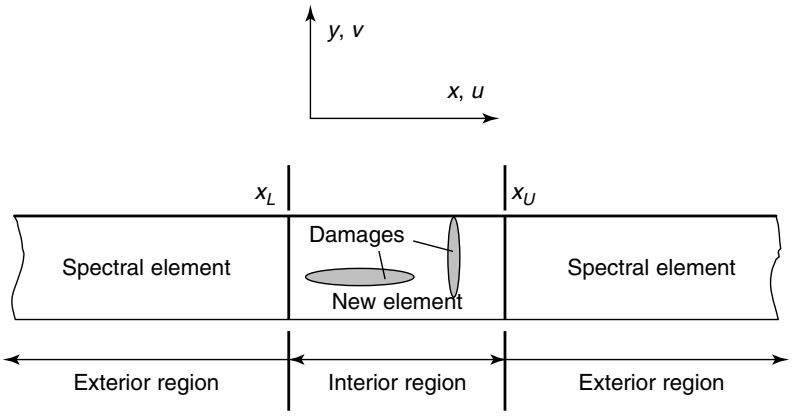

Figure 1. A schematic diagram of the problem geometry.

interpolation functions by solving the characteristic system in terms of the wavenumber (k). These functions are then used to interpolate the displacements along the longitudinal direction (x) of the beam (see Figure 1). In this article, while arriving at the wave dispersion model, the authors apply FSDT for the beam considered as an equivalent single layer. The formulations given by Mahapatra and Gopalakrishnan [27] are employed.

First, cross-sectional stiffness and inertial coefficients of the beam are defined as follows [27]:

$$[A_{kl}, B_{kl}, D_{kl}] = \sum_i \int_{y_i}^{y_{i+1}} \overline{\boldsymbol{Q}}^i_{\boldsymbol{kl}} [1, y, y^2] b_w \, \mathrm{d}y \quad (1a)$$

$$[I_0, I_1, I_2] = \sum_i \int_{y_i}^{y_{i+1}} \rho [1, y, y^2] b_w \, \mathrm{d}y \quad (1b)$$

where y is the thickness coordinate perpendicular to the beam reference plane, b_w the width of the beam, ρ the mass density, and $\overline{\boldsymbol{Q}}^i_{\boldsymbol{kl}}$ the elastic constitutive tensor of the ith layer. In addition, the following parameters are introduced:

$$k_a = \frac{\omega_m}{c_a}, \quad k_b = \frac{\omega_m}{c_b}, \quad k_r = \frac{\omega_m}{c_s} \quad (2a)$$

$$c_a = \sqrt{\frac{A_{11}}{I_0}}, \quad c_b = \sqrt[4]{\frac{D_{11}\omega_m^2}{I_0}}, \quad c_s = \sqrt{\frac{A_{55}}{I_0}} \quad (2b)$$

$$r = \sqrt{\frac{B_{11}^2}{(A_{11}D_{11})}}, \quad s_1 = \omega_m \sqrt{\frac{I_2}{A_{55}}}, \quad s_2 = \sqrt{\frac{I_1^2}{(I_0 I_2)}} \quad (2c)$$

For the coupled axial–flexural shear deformation, without the thickness contractional modes, the wavenumbers (k_j) associated with the individual wave modes at frequency ω_m are determined by solving the following equation:

$$\begin{vmatrix} (k_j^2 - k_a^2) & 0 & \left(\dfrac{s_1 s_2 k_a^2}{k_r} - \dfrac{r k_a k_j^2}{k_r^2}\right) \\ 0 & (k_j^2 - k_r^2) & -ik_j \\ \left(\dfrac{r k_r^2 k_j^2}{k_a k_b^2} - s_1 s_2 k_r\right) & -ik_j & \left(s_1^2 - 1 - \dfrac{k_r^2 k_j^2}{k_b^4}\right) \end{vmatrix} = 0 \quad (3)$$

The characteristic system given by equation (3) can be expressed as follows:

$$a k_j^6 + b k_j^4 + c k_j^2 + d = 0 \quad (4)$$

where

$$a = 1 - r^2 \tag{5a}$$

$$b = \frac{2rs_1s_2k_a k_b^2}{k_r} - (1 - r^2)k_r^2 - \frac{s_1^2 k_b^4}{k_r^2 - k_a^2} \tag{5b}$$

$$c = k_a^2 k_r^2 - 2rs_1s_2k_a k_r k_b^2 - (1 - s_1^2)k_b^4 + \frac{s_1^2(1 - s_2^2)k_a^2 k_b^4}{k_r^2} \tag{5c}$$

$$d = [1 - s_1^2(1 - s_2^2)]k_a^2 k_b^4 \tag{5d}$$

The six roots of equation (4) are given by

$$k_{1,2} = \pm\sqrt{\sqrt[3]{-\frac{q}{2} + \sqrt{\left(\frac{q}{2}\right)^2 + \left(\frac{p}{2}\right)^3}} + \sqrt[3]{-\frac{q}{2} - \sqrt{\left(\frac{q}{2}\right)^2 + \left(\frac{p}{2}\right)^3}} - \frac{b}{3a}} \tag{6a}$$

$$k_{3,4} = \pm\sqrt{\mu_2\sqrt[3]{-\frac{q}{2} + \sqrt{\left(\frac{q}{2}\right)^2 + \left(\frac{p}{2}\right)^3}} + \mu_1\sqrt[3]{-\frac{q}{2} - \sqrt{\left(\frac{q}{2}\right)^2 + \left(\frac{p}{2}\right)^3}} - \frac{b}{3a}} \tag{6b}$$

$$k_{5,6} = \pm\sqrt{\mu_1\sqrt[3]{-\frac{q}{2} + \sqrt{\left(\frac{q}{2}\right)^2 + \left(\frac{p}{2}\right)^3}} + \mu_2\sqrt[3]{-\frac{q}{2} - \sqrt{\left(\frac{q}{2}\right)^2 + \left(\frac{p}{2}\right)^3}} - \frac{b}{3a}} \tag{6c}$$

where

$$p = \frac{(27ca^2 - 9ab^2)}{27a^3},$$

$$q = \frac{(27da^2 - 9abc + 2b^2)}{27a^3} \tag{7a}$$

$$\mu_1 = \frac{-1 + i\sqrt{3}}{2}, \quad \mu_2 = \frac{-1 - i\sqrt{3}}{2} \tag{7b}$$

The three pairs of wavenumbers in equation (6a–c) are distinct (except at few frequencies where crossover may occur), since they represent the axial, the flexural, and the shear modes, respectively. The axial mode must strictly have real wavenumbers. The reason can be explained as follows: first assume that the wavenumbers for axial modes are complex. Then they should exist in conjugate form, i.e., $k_1 = a + ib$, $k_2 = a - ib$. Since the bulk wave equations are of second order, even when they are coupled with flexural waves, they propagate with forward and backward wave components. Hence, the associated wave vector, whose amplitude is the wavenumber, must have an opposite sign. The real part of the wave number must have an opposite sign (the imaginary part is attenuation). Therefore, one must have: $\mathrm{Re}[k_1] = \mathrm{Re}[a + ib]$, $\mathrm{Re}[k_2] = \mathrm{Re}[a - ib] = -\mathrm{Re}[k_1] = -\mathrm{Re}[a + ib]$. The last equation is a contradiction. Consequently, the assumption that the bulk wavenumbers are complex is not true.

Depending on the material configuration and geometry, the other modes may have complex wavenumbers. Note that the shear mode starts propagating only for frequencies greater than the cutoff frequency [27], where the term of cutoff frequency means the frequency below which a specified wave fails to propagate in media.

$$\omega_{\text{cutoff}} = \sqrt{\frac{A_{55}}{I_2(1 - s_2^2)}} \tag{8}$$

When $\omega_m < \omega_{\text{cutoff}}$, the shear waves are evanescent in nature. Usually, if there are unsymmetrical damages in beams, the components in the reflected waves contain the axial wave mode. However, in this article, the authors deal with the damages, which are only symmetric with respect to the middle plane of the beam of a symmetric stacking sequence. It is proper to consider flexural and shear waves only.

2.2 Enriched interpolation of the displacement field

After transforming the longitudinal displacement $u(x, y, t)$ and the transverse displacement $v(x, y, t)$

(see Figure 1) from the time domain to the frequency domain, their frequency-domain counterparts are expanded as linear combinations of orthogonal basis functions. The bases for interpolation parallel to the x axis are the four wave modes ψ_i, $i = 1, 2, 3, 4$ (the forward and the backward propagating flexural wave modes, and the forward and the backward propagating/evanescent shear wave modes). The bases for interpolation parallel to the y axis are the Lagrangian family of interpolation functions. Thus, the displacement components of u and v in the frequency domain are expressed as

$$\overline{u}_m(x, y, \omega_m) = \sum_{j=1}^{n} \sum_{l=1}^{NW} N_j(x, y)\psi_l(x)A_j^l \quad (9a)$$

$$\overline{v}_m(x, y, \omega_m) = \sum_{j=}^{n} \sum_{l=1}^{NW} N_j(x, y)\psi_l(x)B_j^l \quad (9b)$$

where A_j^l and B_j^l are the boundary-dependent coefficients for each of the wave modes $l = 1, \ldots, 4; n$ is the number of elemental nodes; NW is the number of used wavenumbers (k_1, k_2, k_3, and k_4); and N_j are the standard FE Lagrangian interpolation functions, i.e., the "old shape functions". In other words, ψ_l are the spectral enrichment functions over N_j. For the present beam problem, they are described as

$$\psi_1 = \mathrm{e}^{-\mathrm{i}[k_1(x-x_L)]}, \quad \psi_2 = \mathrm{e}^{\mathrm{i}[k_2(x_U-x)]} \quad (10a)$$

$$\psi_3 = \mathrm{e}^{\mathrm{i}[k_3(x-x_L)]}, \quad \psi_4 = \mathrm{e}^{-\mathrm{i}[k_4(x_U-x)]} \quad \forall\omega < \omega_{\text{cutoff}} \quad (10b)$$

$$\psi_3 = \mathrm{e}^{-\mathrm{i}[k_3(x-x_L)]}, \quad \psi_4 = \mathrm{e}^{\mathrm{i}[k_4(x_U-x)]} \quad \forall\omega \geq \omega_{\text{cutoff}} \quad (10c)$$

where k_1 and k_2 are the wavenumbers of flexural waves, which are positive real, and negative real numbers, respectively. k_3 and k_4 are wavenumbers of shear waves, which are positive imaginary and negative imaginary numbers when the frequencies are smaller than ω_{cutoff}. x_L and x_U denote the x coordinates of the left and the right cross sections of the interior region, respectively as shown in Figure 1. Generally, it is convenient to define them in the local coordinate system.

The enrichment functions ψ_l in equation (10) occur in pairs, where one member of the pair is the "mirror image" of the other. In fact, the origin of this idea for the displacement field in equation (9) can be traced to a new and general numerical methodology in recent times, namely, the partition of unity finite element method (PUFEM), for solving Helmholtz equations [33–35], where at each of the FE nodes, the potential is expanded into one or multiple discrete series of plane waves. However, no work has been reported for elastic waves in bounded media. The present element is also termed as *PUFEM* in the following content.

To prevent transverse shear locking while applying FSDT, the order of approximation has to be at least quadratic along the y axis. Therefore, 8- or 12-noded isoparametric shape functions are used as the "old shape functions". Rewriting the enriched interpolation functions as $P_{j,l} = N_j\psi_l$, the displacement field can be expressed as

$$\begin{Bmatrix} u(x, y, t) \\ v(x, y, t) \end{Bmatrix} = \sum_{m=1}^{M} \aleph\overline{\mathbf{u}}\mathrm{e}^{-i\omega_m t} \quad (11)$$

where M is the number of sampling points in the frequency domain, and

$$\aleph = \begin{bmatrix} \Re_1 & \mathbf{0} & \Re_2 & \mathbf{0} & \cdots & \Re_n & \mathbf{0} \\ \mathbf{0} & \Re_1 & \mathbf{0} & \Re_2 & \cdots & \mathbf{0} & \Re_n \end{bmatrix} \quad (12)$$

where

$$\Re_j = [\, P_{j,1} \quad P_{j,2} \quad \cdots \quad P_{j,NW} \,] \quad (13)$$

$\overline{\mathbf{u}}$ is a vector consisting of unknown nodal coefficients,

$$\overline{\mathbf{u}} = \{\, \boldsymbol{\alpha}_1 \quad \boldsymbol{\beta}_1 \quad \cdots \quad \boldsymbol{\alpha}_n \quad \boldsymbol{\beta}_n \,\}^T \quad (14)$$

where

$$\boldsymbol{\alpha}_j = \{\, A_j^1 \quad A_j^2 \quad \cdots \quad A_j^{NW} \,\} \quad (15a)$$

$$\boldsymbol{\beta}_j = \{\, B_j^1 \quad B_j^2 \quad \cdots \quad B_j^{NW} \,\} \quad (15b)$$

In equation (15a and 15b), for the different boundary conditions, careful definition of parameters A_j^n and B_j^n is needed. For example, for the energy absorbing boundary condition in the following examples, the parameters in A_j^n and B_j^n corresponding to the backward propagating modes should be set to be zero.

3 WEAK FORMULATION IN FREQUENCY DOMAIN

With the above description of the enriched displacement field, the Hamiltonian for the two-dimensional elastodynamics is given by

$$\Pi_P = \int_{t_1}^{t_2} \left[\frac{1}{2} \iint_\Omega \boldsymbol{\varepsilon}^T \mathbf{D} \boldsymbol{\varepsilon} \, \mathrm{d}x \, \mathrm{d}y - \int_S \mathbf{q}^T \boldsymbol{\delta} \, \mathrm{d}s - \sum_{k=1}^{K} \mathbf{P}_k^T \boldsymbol{\delta}_k - \frac{1}{2} \iint_\Omega \frac{\mathrm{d}\boldsymbol{\delta}^T}{\mathrm{d}t} \boldsymbol{\vartheta} \frac{\mathrm{d}\boldsymbol{\delta}}{\mathrm{d}t} \, \mathrm{d}x \, \mathrm{d}y \right] \mathrm{d}t \tag{16}$$

where t_1 and t_2 are the starting time and ending time, respectively, $\mathbf{D}$ is the elasticity matrix for the plane stress model adopted here, $\boldsymbol{\delta}$ is a vector containing the two displacement components and is defined as

$$\delta = \begin{Bmatrix} u \\ v \end{Bmatrix} \tag{17}$$

The diagonal matrix $\boldsymbol{\vartheta}$ for mass density ρ can be expressed as

$$\boldsymbol{\vartheta} = \begin{bmatrix} \rho & 0 \\ 0 & \rho \end{bmatrix} \tag{18}$$

The terms $\mathbf{P}_k$ and $\mathbf{q}$ in equation (16) are the applied concentrated loads and applied distributed loads, respectively. The strain vector $\boldsymbol{\varepsilon}$ in equation (16) is defined in the following form

$$\boldsymbol{\varepsilon} = \begin{Bmatrix} \varepsilon_{\mathrm{xx}} \\ \varepsilon_{yy} \\ \varepsilon_{\mathrm{xy}} \end{Bmatrix} = \begin{Bmatrix} \dfrac{\partial u}{\partial x} \\ \dfrac{\partial v}{\partial y} \\ \dfrac{\partial u}{\partial y} + \dfrac{\partial v}{\partial x} \end{Bmatrix} = \sum_{m=1}^{M} \boldsymbol{\Theta} \overline{\mathbf{u}} \mathrm{e}^{-\mathrm{i}\omega_m t} \tag{19}$$

where

$$\boldsymbol{\Theta} = \begin{bmatrix} \dfrac{\partial \Re_1}{\partial x} & \mathbf{0} & \dfrac{\partial \Re_2}{\partial x} & \mathbf{0} & \cdots & \dfrac{\partial \Re_n}{\partial x} & \mathbf{0} \\ \mathbf{0} & \dfrac{\partial \Re_1}{\partial y} & \mathbf{0} & \dfrac{\partial \Re_2}{\partial y} & \cdots & \mathbf{0} & \dfrac{\partial \Re_n}{\partial y} \\ \dfrac{\partial \Re_1}{\partial y} & \dfrac{\partial \Re_1}{\partial x} & \dfrac{\partial \Re_2}{\partial y} & \dfrac{\partial \Re_2}{\partial x} & \cdots & \dfrac{\partial \Re_n}{\partial y} & \dfrac{\partial \Re_n}{\partial x} \end{bmatrix} \tag{20}$$

To obtain the strain–displacement matrix $\boldsymbol{\Theta}$, the derivatives in equation (20) are calculated as follows:

$$\frac{\partial P_{j,l}}{\partial x} = \left[\frac{\partial N_j}{\partial x} + i k_l N_j \right] \psi_l \tag{21a}$$

$$\frac{\partial P_{j,l}}{\partial y} = \left[\frac{\partial N_j}{\partial y} \right] \psi_l \tag{21b}$$

The kinetic energy term in equation (16) can further be expanded as

$$\begin{aligned} \Gamma &= \int_{t_1}^{t_2} \frac{1}{2} \iint_\Omega \frac{\mathrm{d}\boldsymbol{\delta}^T}{\mathrm{d}t} \boldsymbol{\vartheta} \frac{\mathrm{d}\boldsymbol{\delta}}{\mathrm{d}t} \, \mathrm{d}x \, \mathrm{d}y \, \mathrm{d}t \\ &= \frac{1}{2} \iint_\Omega \frac{\mathrm{d}\boldsymbol{\delta}^T}{\mathrm{d}t} \boldsymbol{\vartheta} \boldsymbol{\delta} \, \mathrm{d}x \, \mathrm{d}y \Big|_{t_1}^{t_2} \\ &\quad - \int_{t_1}^{t_2} \frac{1}{2} \iint_\Omega \boldsymbol{\delta}^T \boldsymbol{\vartheta} \frac{\mathrm{d}^2 \boldsymbol{\delta}}{\mathrm{d}t^2} \, \mathrm{d}x \, \mathrm{d}y \, \mathrm{d}t \end{aligned} \tag{22}$$

where

$$\begin{aligned} \frac{\mathrm{d}^2 \boldsymbol{\delta}}{\mathrm{d}t^2} &= \begin{Bmatrix} \dfrac{\mathrm{d}^2 u}{\mathrm{d}t^2} \\ \dfrac{\mathrm{d}^2 v}{\mathrm{d}t^2} \end{Bmatrix} = -\sum_{m=1}^{M} \omega_m^2 \begin{Bmatrix} \overline{u}_m \\ \overline{v}_m \end{Bmatrix} \mathrm{e}^{-\mathrm{i}\omega_m t} \\ &= -\sum_{m=1}^{M} \omega_m^2 \aleph \overline{\mathbf{u}} \mathrm{e}^{-\mathrm{i}\omega_m t} \end{aligned} \tag{23}$$

Subsequently, similar to the displacement field in equation (11), by employing FFT, the distributed load $\mathbf{q}$ and concentrated load $\mathbf{P}_k$ in the time domain are described as

$$\begin{aligned} \mathbf{q}(x, y, t) &= \sum_{m=1}^{M} \overline{\mathbf{q}}(x, y, \omega_m) \mathrm{e}^{-\mathrm{i}\omega_m t}, \\ \mathbf{P}_k(x_k, y_k, t) &= \sum_{m=1}^{M} \overline{\mathbf{P}}_k(x_k, y_k, \omega_m) \mathrm{e}^{-\mathrm{i}\omega_m t} \end{aligned} \tag{24}$$

For the convenience of description, the local elemental variables are transferred into the structural global ones as: $\overline{\mathbf{u}} = \mathrm{T}\overline{\mathbf{U}}$. Finally, equation (16) for an arbitrary element can be rewritten as

$$\Pi_P = \int_{t_1}^{t_2} \sum_{m=1}^{M} \left[\left(\frac{1}{2} \iint_\Omega \overline{\mathbf{U}}^T \mathrm{T}^T \boldsymbol{\Theta}^T \mathbf{D} \boldsymbol{\Theta} \mathrm{T} \overline{\mathbf{U}} \, \mathrm{d}x \, \mathrm{d}y - \int_S \overline{\mathbf{q}}^T \aleph \mathrm{T} \overline{\mathbf{U}} \, \mathrm{d}s - \sum_{k=1}^{K} \overline{\mathbf{P}}_k^T \aleph^k \mathrm{T} \overline{\mathbf{U}} \right. \right.$$

$$-\frac{1}{2}\omega_m^2\iint_\Omega \overline{\mathbf{U}}^T \mathrm{T}^T \aleph^T \boldsymbol{\vartheta} \aleph \mathrm{T} \overline{\mathbf{U}}\,\mathrm{d}x\,\mathrm{d}y\Big)(\mathrm{e}^{-\mathrm{i}\omega_m t})^2\Big]\mathrm{d}t$$
$$-\frac{1}{2}\int\int_\Omega \frac{\mathrm{d}\boldsymbol{\delta}^T}{\mathrm{d}t}\boldsymbol{\vartheta}\boldsymbol{\delta}\,\mathrm{d}x\,\mathrm{d}y\Big|_{t_1}^{t_2} \tag{25}$$

Using a variational principle, the FE equilibrium equation is obtained as

$$(\overline{\mathbf{K}} - \omega_m^2\overline{\mathbf{M}})\overline{\mathbf{U}} = \overline{\mathbf{P}} \tag{26}$$

where the complex matrices are expressed as follows:

$$\overline{\mathbf{K}} = \sum_1^{NE}\int\int_{\Omega_e} \mathrm{T}^T \boldsymbol{\Theta}^T \mathbf{D}\boldsymbol{\Theta}\mathrm{T}\,\mathrm{d}x\,\mathrm{d}y \tag{27a}$$

$$\overline{\mathbf{M}} = \sum_1^{NE}\int\int_{\Omega_e} \mathrm{T}^T \aleph^T \boldsymbol{\vartheta} \aleph \mathrm{T}\,\mathrm{d}x\,\mathrm{d}y \tag{27b}$$

$$\overline{\mathbf{P}} = \sum_1^{NE}\int_S \overline{\mathbf{q}}^T \aleph \mathrm{T}\,\mathrm{d}s - \sum_{k=1}^{K}\overline{\mathbf{P}}_k^T \aleph^k \mathrm{T} \tag{27c}$$

where NE is the number of elements. The main advantage of the above formulation is that a complex distribution in the y axis can be modeled easily by Lagangian FE interpolation, and a long but finite span in the x axis can be modeled accurately using a much smaller number of these new elements compared to the standard Lagrangian FE model. Moreover, the near-exact feature of wave propagation characteristics along the x axis is ensured, which leads to spectral convergence for interpolation parallel to the x axis. Subsequently, the h convergence can be expected for interpolation parallel to the y axis, since the wave modes are only functions of the x axis.

4 NUMERICAL IMPLEMENTATION

In the elemental matrices in equation (27a–c), the integrals encountered are of the form

$$I_{lm} = \int_{-1}^{1}\int_{-1}^{1} f(\xi,\eta)\mathrm{e}^{\mathrm{i}(k_l x)}\mathrm{e}^{\mathrm{i}(k_m x)}|\mathbf{J}|\mathrm{d}\xi\,\mathrm{d}\eta \tag{28}$$

where $\mathbf{J}$ is the Jacobian matrix for isoparametric mapping. The expression $f(\xi,\eta)$ involves the product of the "old shape function", their derivatives, etc. In this section, the evaluation of these integrals is carried out using higher-order Gauss–Legendre integration scheme. At the integration points within an element, x of $\mathrm{e}^{\mathrm{i}(k_l x)}$ and $\mathrm{e}^{\mathrm{i}(k_m x)}$ in equation (28) can be evaluated from the shape functions N_j of the current element. The number of integration points depends on the element nodal spacing with respect to the smallest wavelength ($\lambda_l = 2\pi/k_l$) at a given frequency ω_m. As shown later, only a few of the proposed elements in the spanwise direction of the beam, and hence, a few degrees of freedom can produce sufficient accuracy even for high-frequency excitation if the proper numerical integration scheme is used. Therefore, unlike the Lagrangian FEM, the computational time is mainly consumed at the step of numerical integration while calculating the dynamic stiffness matrix and the mass matrix, but not at the step of FE system solution. Numerical implementation of the proposed element requires efficient integration algorithms, such as frequency-dependent and elemental size-dependent numerical integration schemes. Consider a section with unit length, i.e., $x \in [0, 1]$, the number of cycles of sine and cosine functions within the domain is around $0.1k_1$. Therefore, to integrate one single cycle accurately, at least 30 G integration points are needed. For example, for more accuracy, if 60 G integration points are taken for one cycle of sine and cosine functions, the number of Gauss integration points (NG) for the element i in the x axis is roughly determined as $NG^i = 6L_e^i k_1^i(\omega_m)$, where $k_1^i(\omega_m)$ is the flexural wavenumber of the element i at frequency ω_m, and L_e^i is the length along the x axis of the element i. However, the minimum number of Gauss integration points is set to be 6. Such a consistent choice of frequency-dependent and elemental size-dependent integration scheme can efficiently reduce the computational cost. In the direction parallel to the y axis, the number of Gauss integration points is set to be two for an 8-noded element and three for a 12-noded element, respectively.

Having obtained $\overline{\mathbf{U}}$ containing A_j^l and B_j^l, the displacements in the frequency domain can be calculated using equation (9); therefore, the solution in the time domain is evaluated simply by applying the inverse FFT.

4.1 Assemblage of the interior and the exterior regions using global–local approach

As verified later from the numerical examples, the proposed PUFEM is very efficient for quasi-two-dimensional waves propagation at low, as well as high frequencies. However, at high frequencies, the accuracy is not so high when the forward and the backward propagation exist simultaneously and the propagation distance is long. The main reason is the dissimilar orders in the diagonal elements of the stiffness and the mass matrices, which are contributed by the exponential terms, i.e., the terms determined by wavenumbers k_3 and k_4. For high-frequency waves, the components of stiffness and mass matrices, which involve $\psi_3 = \mathrm{e}^{\mathrm{i}[k_3(x-x_L)]}$ in equation (9) for large x, and $\psi_4 = \mathrm{e}^{-\mathrm{i}[k_4(x_U-x)]}$ in equation (9) for large x_U and small x, are too small compared to the other elements in the matrices. These small elements, especially small diagonal elements of the stiffness and mass matrices, may cause the numerical instability. For instance, to deal with the boundary conditions for propagation in both directions, the forward and backward terms are coupled at the boundary. When x is large at the boundary, the forward terms involving $\psi_3 = \mathrm{e}^{\mathrm{i}[k_3(x-x_L)]}$ are very small. On the other hand, the backward terms involving $\psi_4 = \mathrm{e}^{-\mathrm{i}[k_4(x_U-x)]}$ are well conditioned. The numerical instability is thus inherent.

For the cases of unidirectional propagation of waves, e.g., only forward propagation alone, the elements of the stiffness matrix and the mass matrix involve only the term $\psi_3 = \mathrm{e}^{\mathrm{i}[k_3(x-x_L)]}$. As stated above, although this term has the similar exponential characteristics as x increases, by collocating the diagonal elements corresponding to the exponential decay in the matrix $(\overline{\mathbf{K}} - \omega_m^2 \overline{\mathbf{M}})$ in a decreasing sequence, the numerical instability can be effectively removed. However, this technique is not suited for the cases of the simultaneous propagation of forward and backward waves. For such double directional propagation of high-frequency waves, the PUFEM is only applicable for short traveling distance. In fact, from the authors' numerical experience, the existence of the exponential decay causes many numerical problems. To overcome this problem, the new element needs to be combined with the ordinary spectral element model or any other efficient discretized model of the exterior region. As shown in Figure 1, this new element is employed for the smaller interior region, and the ordinary spectral elements are used to model the exterior region. Another purpose of assembling the ordinary spectral element for the uniform exterior region is to reduce the computational cost to a greater extent.

In the global–local approach, the displacement continuity at the boundary of the two regions must be ensured. With the help of equation (9), and by setting $N_j = 1$, the condition of displacement continuity between the interior and the exterior regions (see Figure 1) at the node j in an arbitrary new element can be expressed as

$$\overline{u}_m(x, y, \omega_m) = \sum_{l=1}^{NW} \psi_l A_j^l = -y\overline{\phi}(x, \omega_m) \quad (29a)$$

$$\overline{v}_m(x, y, \omega_m) = \sum_{l=1}^{NW} \psi_l B_j^l = \overline{w}(x, \omega_m) \quad (29b)$$

where $\overline{\phi}(x, \omega_m)$ and $\overline{w}(x, \omega_m)$ are the rotation and the transverse displacement degrees of freedom in the spectral element on the side of the exterior region (see [27] for details).

There exist three different approaches for enforcing the interface displacement continuity in the context of global–local FE analysis. The first approach is the direct enforcement of the constraints at the interfaces as reported by Gopalakrishnan and Doyle [36]. The second approach is the weak enforcement using Lagrange multiplier as reported by Halliday and Grosh [37]. Finally, the third approach is the weak enforcement based on multipoint constraints as reported by Mahapatra and Gopalakrishnan [12]. While using two dissimilar models, e.g., standard Lagrangian FE model for the interior region and the ordinary spectral element model for the exterior region, direct enforcement of interface constraints [36] appears computationally intensive and requires cross-checking against numerical convergence. Again, from the authors' numerical experience, it is found that the penalty function method is not efficient while using dissimilar models for the exterior and the interior regions, since the choice of penalty parameters is very difficult and the introduction of large penalty parameters may result in numerical instability. In the present global–local approach,

the Lagrange multiplier method is employed to enforce the displacement continuity conditions given in equation (29a and b).

5 NUMERICAL EXAMPLES

5.1 Comparison with the traditional FEM

Consider a one-dimensional (1-D) beam shown in Figure 2, which is subjected to a transverse load $P(t)$ at the free end, i.e., $x = 0$, which is expressed as

$$P(t) = \begin{cases} 0.5\left[1 - \cos\left(\dfrac{2\pi f t}{N}\right)\sin(2\pi f t)\right], & \dfrac{t \le N}{f} \\ 0, & \dfrac{t > N}{f} \end{cases} \tag{30}$$

where f is the central frequency in hertz and N is the number of sinusoidal cycles within a pulse.

To compare with the traditional FEM, the authors consider the low-frequency excitation case, where $f = 50$ Hz and $N = 15$ cycles. The sample duration time T is 4.8 s. The Nyquist frequency is $N_q/2T$, where the number of sampling points is $N_q = 2^k$, $k = 12$, and is used consistently in the several examples that follow. The traditional 2-D eight-noded isoparametric element is employed for comparison. The traditional FEM mesh possesses 84 elements with 2 elements in the thickness direction and 42 elements in the spanwise direction. Only six eight-noded PUFEMs are used with two elements in the thickness direction and three elements in the spanwise direction. The same eight-noded elements are used in all the examples. The beam is made of aluminum with the following properties: $E = 73.0$ GPa, $G = 28.08$ GPa, $\nu = 0.3$, $\rho = 2770\,\mathrm{kg\,m^{-3}}$. The thickness of the beam (h) is equal to 10.0 mm. The span of the beam, for the present example, is taken as 1260.0 mm. The width of the beam is taken as 10.0 mm. The above constants are consistently used in all the examples. The responses at the far ends are assumed to be zero and the reflected wave modes are eliminated. To impose such absorbing boundary conditions, the nodal degrees of freedom corresponding to the backward propagating modes are set to be zero. It means that A_j^2, A_j^4, B_j^2, and B_j^4 in equation (9) are set to be zero at all the nodes. Furthermore, A_j^1, A_j^3, B_j^1, and B_j^3 in equation (9), which are the degrees of freedom corresponding to the forward propagation, are set to be zero at the nodes on the far end. Two measurement points are considered at $x = 0.0$ mm, and at $x = 210.0$ mm from the source of excitation. Comparison of the time histories of deflections at the measurement points is shown in Figure 3. This result reveals that the PUFEM can attain very high accuracy, although the mesh is very coarse. In fact, the present method is almost insensitive to the number of elements when a sufficiently higher-order Gauss integration scheme is employed in the x axis.

5.2 Comparison with the throw-off spectral element

Consider a similar problem as shown in Figure 2. The high-frequency case, where $f = 20$ kHz, and $N = 5$ cycles is investigated. The sample duration time T is 0.012 s. The authors compare the performance of the PUFEM with that of the throw-off spectral element [27], which only tackles the unidirectional wave propagation. It means that in throw-off elements, waves propagate in one direction toward infinity without any reflections. Unlike the example in Section 5.1, the performance of the PUFEM under a much higher excitation frequency is checked here. In this example, the beam is considered to have enough length, i.e., 1200.0 mm. The response at the far end is imposed to be zero and the reflected wave modes are excluded.

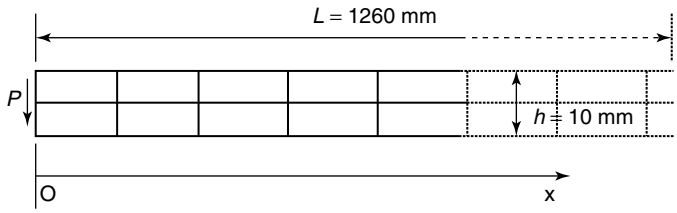

Figure 2. Schematic diagram of a 1-D problem.

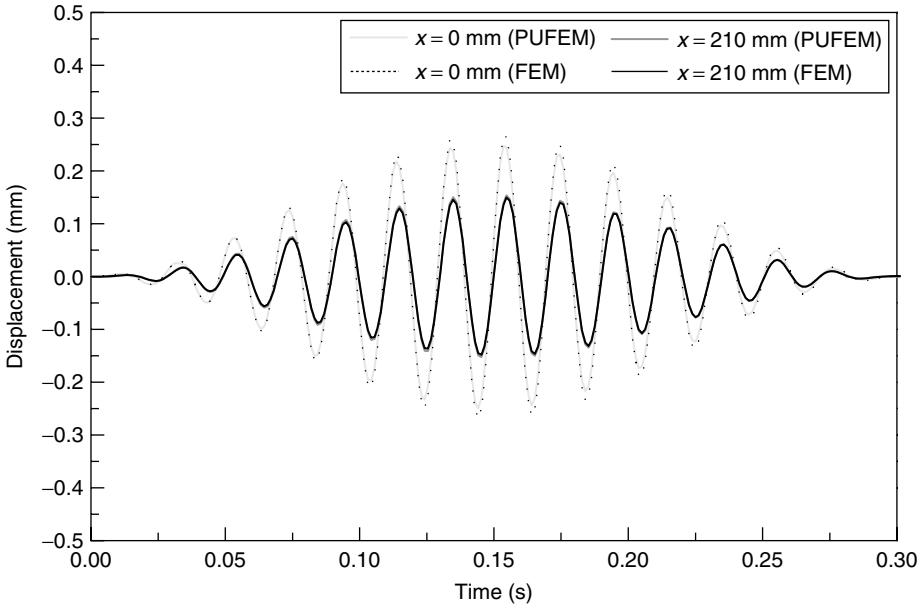

Figure 3. Deflections of the PUFEM and the traditional FEM at two measurement points.

Therefore, the unknown parameters, i.e., A_j^l and B_j^l are dealt in the same way as in the previous example. The present approach employs 16 elements with 2 elements in the thickness direction and 8 elements in the spanwise direction. For high-frequency cases, the amplitude of deflection becomes very small, and here the transverse velocity is selected for plotting. The transverse velocities at two measurement points, i.e., at $x = 0.0$ and 100.0 mm are obtained. Comparison of the time histories of transverse velocity at these measurement points is shown in Figure 4. It may be noted that the result obtained using the PUFEM is in good agreement with those obtained using the spectral throw-off element. The influence of the number of Gauss integration points on the results is investigated. It was found that the integration number determined by $NG^i = 6L_e^i k_1^i(\omega_m)$ can yield the sufficiently converged results.

5.3 Comparison with the ordinary spectral element

In this section, a cantilever beam as shown in Figure 5(a) is considered and two ordinary spectral elements [27] are employed, i.e., one finite and the other throw off. The material properties are the same as in the previous examples, and $f = 20$ kHz, and $N = 5$ cycles are chosen. The length of the beam from the fixed end to the point of application of transverse load is 2000.0 mm. As shown in Figure 5(b), the entire domain in Figure 5(a) is divided into three parts, i.e., two finite ordinary spectral elements with lengths of 990.0 mm, and one interior region with a length of 20 mm, discretized by the PUFEM. Two PUFEMs are employed for the interior region between two normal spectral elements in Figure 5(a), where in the span direction, only one element is used. The comparison of time histories of transverse velocity at the loading point is depicted in Figure 6. This figure shows both the incident and the reflected waves clearly. It can also be noted that both results, which are based on the meshes in Figure 5(a) and (b), are in good agreement. However, there are some small oscillations while using the global–local approach. This phenomenon may be caused by the mismatch between the present elemental dynamic stiffness and that of the ordinary spectral element due to the different assumptions for the displacement field interpolation. The fact is that there is no contraction in the thickness direction considered in the ordinary spectral element model. In fact, by

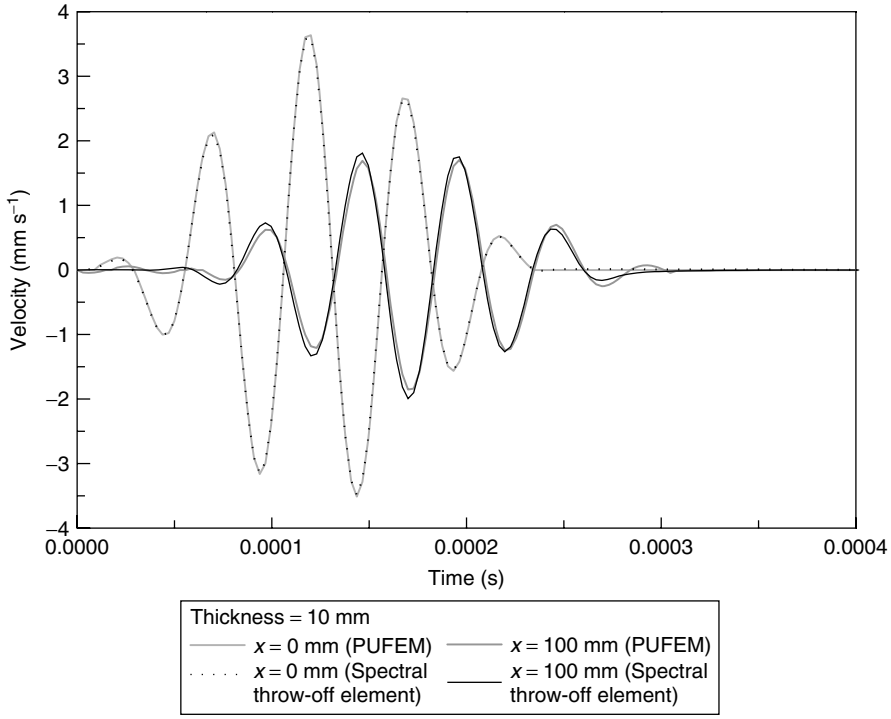

Figure 4. Transverse velocities of the PUFEM and the throw-off spectral element at two measurement points for a beam of thickness of 10 mm.

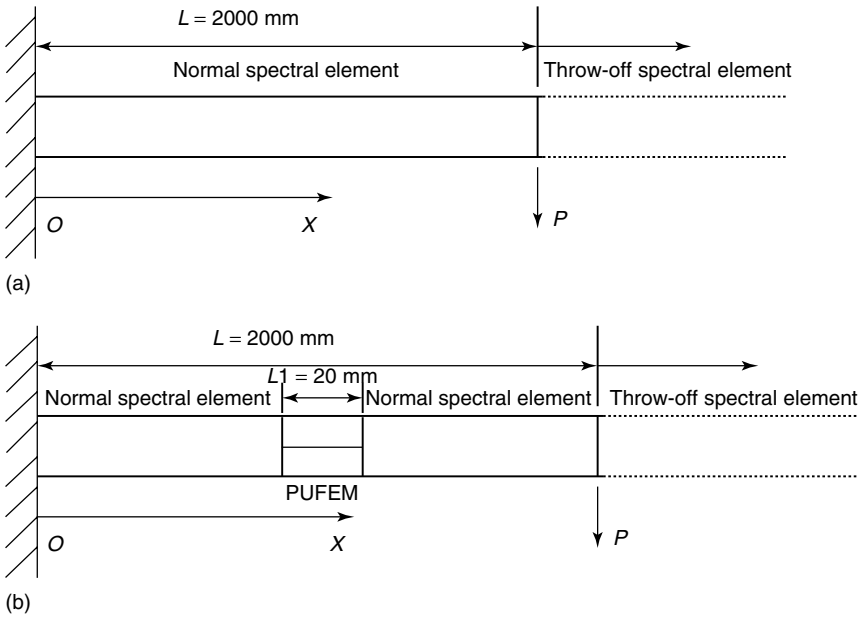

Figure 5. (a) Schematic diagram of a cantilever beam using the spectral element only. (b) Schematic diagram of a cantilever beam using the hybrid approach.

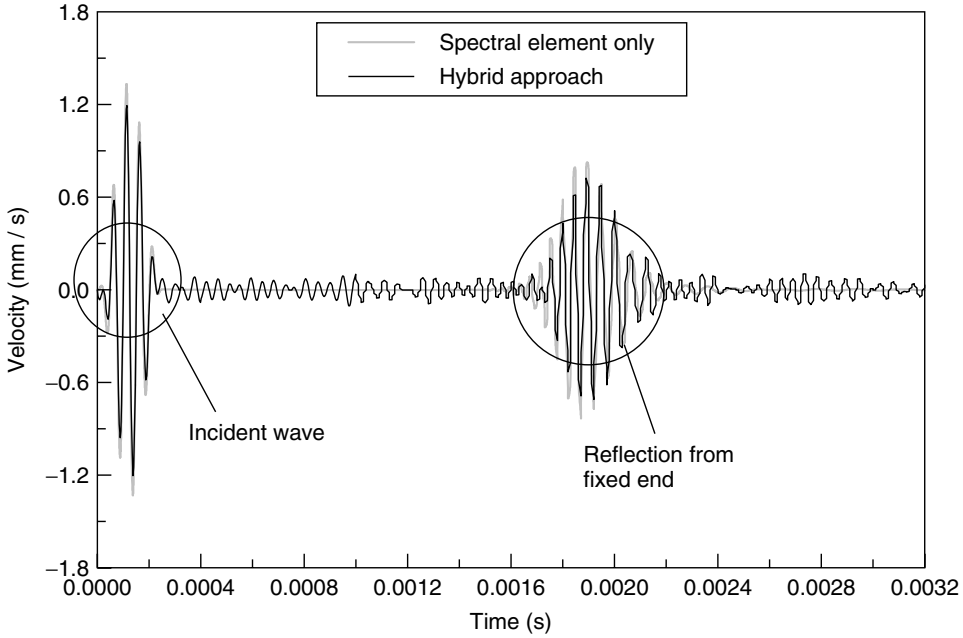

Figure 6. Transverse velocities of the spectral element only and the hybrid approach at the load point.

observing Figure 4, it can also be found that the results of the PUFEM do not completely match with those of the throw-off spectral element. Generally, this mismatch does not cause a serious problem in the low-frequency cases. However, with the increase in the excitation frequency, the effects of mismatch become more obvious. From the authors' numerical experience, increasing the number of the PUFEM along the span and thickness directions to alleviate the effects of this mismatch is not effective.

5.4 A cantilever beam with two symmetric transverse cracks

In this section, another example identical to the previous one is considered, except that there are two symmetric transverse cracks having depth $h1$ as shown in Figure 7. Six PUFEMs are employed to model the interior region. With the PUFEM, the crack geometry can be easily modeled. The placement of the element nodes at the interior region and the crack surfaces are shown in Figure 7. The crack surfaces essentially form the interelement discontinuity. The effect of contact between the two crack surfaces is neglected. The time histories of transverse velocity of the intact and cracked beams ($h1 = 3.0\,\text{mm}$) at the loading point are shown in Figure 8. The first reflection from the cracks can be accurately identified in Figure 8, which arrives at $t = 0.001\,\text{s}$. The first reflection from the fixed end can be identified for both the intact and cracked cases. However, the amplitude of the first reflection from the fixed end in the cracked beam is much lower than that of the intact beam. Furthermore, the second reflection from the fixed end can also be identified for the cracked beam. Here, the second reflection is the combination of (i) part of the first reflection from the fixed end, which is reflected by the cracks back to the fixed end and (ii) the second reflection stated in (i) by the fixed end, which finally arrives at the measurement point. This second reflection does not appear in the case of the intact beam. Moreover, as shown in Figure 9, four transverse cracks are considered. The interior region is 120-mm long, and the distance between the two sets of transverse cracks is 80 mm. Nine PUFEMs are employed for the interior region, and the crack depth $h1 = 3.0\,\text{mm}$. Other conditions are identical to the above example. The transverse velocity at the loading

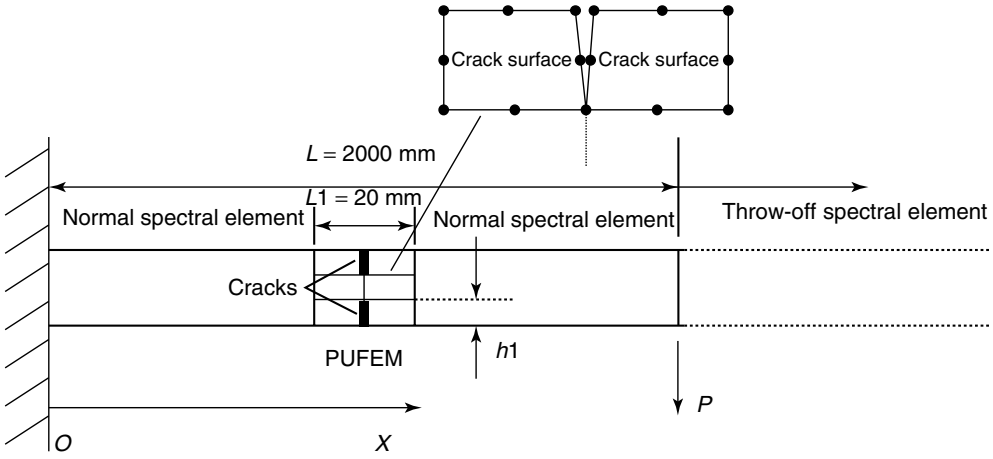

Figure 7. Schematic diagram of a cantilever beam with two symmetric transverse cracks.

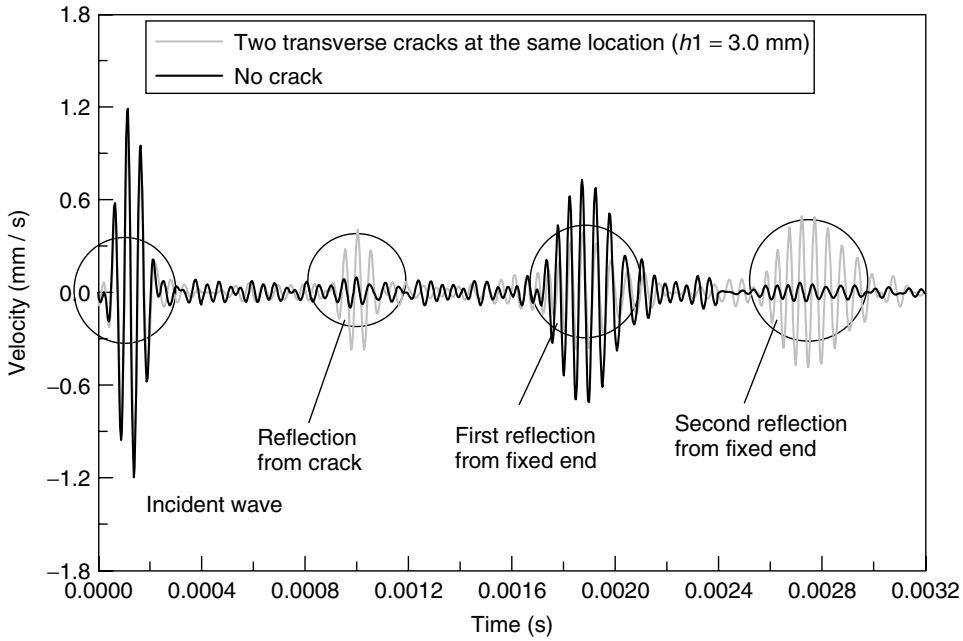

Figure 8. Transverse velocities of intact and cracked beams for $h1 = 3.0$ mm at the load point.

point is shown in Figure 10. It can be seen that the reflections from two sets of cracks overlap due to the short distance between the cracks. Compared with the result of the problem with two transverse cracks in Figure 8, the amplitude of reflection from the four cracks is higher. However, the reflection from the fixed end has decreased significantly.

5.5 A cross-ply cantilever beam with a delamination at midplane

Here, a cross-ply cantilever beam shown in Figure 11 is considered, where a delamination of length of 25 mm is located at the midplane of the beam. We consider six-ply laminates with $[0/90/0]_s$ in

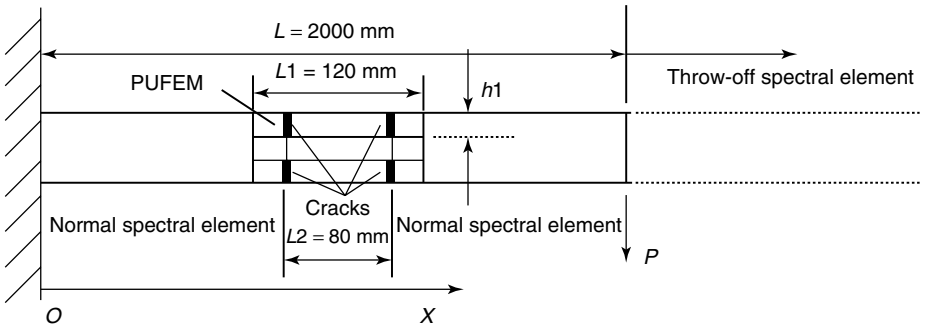

Figure 9. Schematic diagram of a cantilever beam with four transverse cracks.

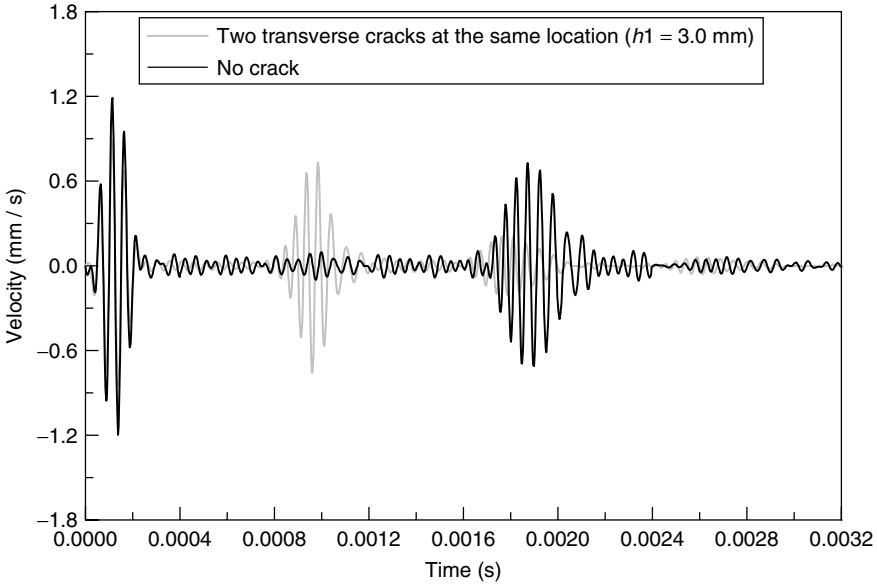

Figure 10. Transverse velocities of intact and cracked beams at the load point (transverse cracks).

stacking sequence with the following material properties of the lamina: $E_{11} = 145.5\,\text{GPa}$, $E_{22} = 9.69\,\text{GPa}$, $G_{12} = G_{13} = 5.97\,\text{GPa}$, $G_{23} = 2.91\,\text{GPa}$, $\nu_{12} = 0.32$, $\rho = 1550\,\text{kg m}^{-3}$. The lamina thickness is 0.5 mm. Six PUFEMs, with three elements in the spanwise direction and two elements in the through-thickness direction, are employed to model the interior region. Other conditions are identical to the above examples. Note that the dispersion relationship in the delamination area is different from that of the intact portion. The effect of contact between the two crack surfaces is neglected. Time histories of transverse velocity at the loading point for the two different crack lengths are shown in Figure 12 for $f = 20\,\text{kHz}$. This figure reveals that the reflection from the delamination can be clearly identified.

6 CONCLUSIONS

This article presents a new global–local approach to model wave propagation in beams with various types of damages. In this approach, the ordinary spectral element method is employed to simulate the behavior of wave propagation in the exterior regions, whereas newly proposed elements are used to model the interior region containing damages in the form of cracks. Formulation of the proposed

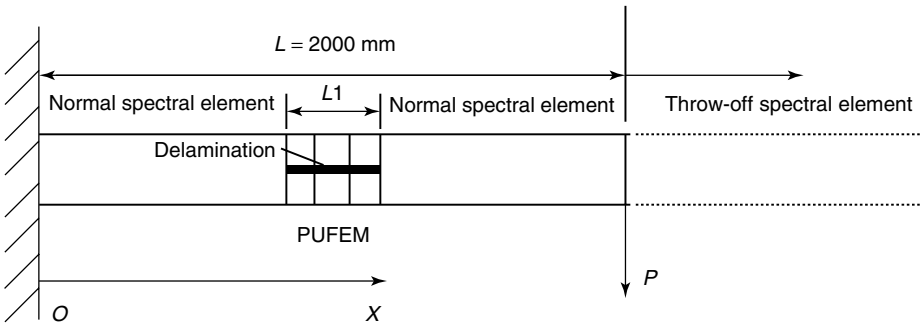

Figure 11. Schematic diagram of a cantilever beam with a delamination at midplane.

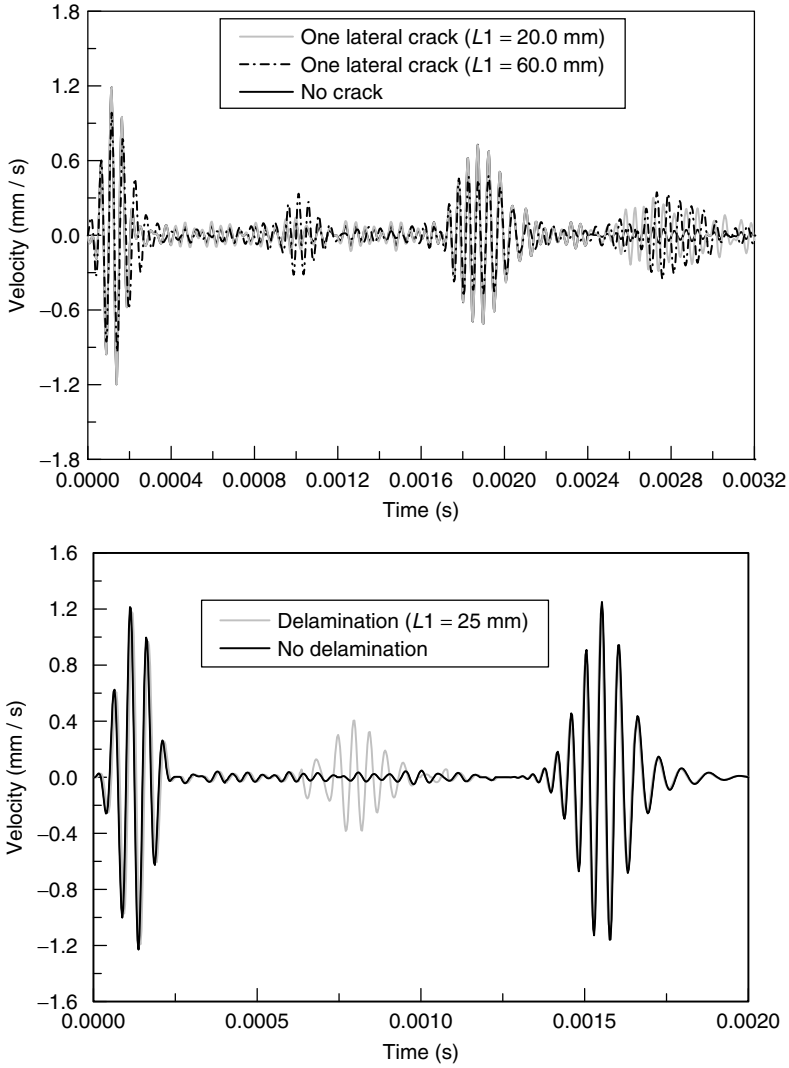

Figure 12. Transverse velocities of intact and delaminated beams at the load point (an in-plane delamination).

element is based on the hybrid interpolation scheme, where the Lagrangian family of interpolation bases is enriched by introducing four wave modes (two flexural wave modes and two shear wave modes) associated with the interpolation along one of the two mutually orthogonal coordinates for the 2-D plane elastodynamic problem. A frequency-domain FE model is then obtained by minimizing the Hamiltonian. The proposed approach essentially balances the advantages of (i) the ordinary spectral element model, which is the direct solution to the strong form, in which the solution is enforced in a pointwise sense, as well as (ii) the weakly formulated FE, where the solution is enforced in a piecewise discrete sense. The advantage of (i) is in the high numerical efficiency while solving transient elastodynamics. The advantage of (ii) is in the efficient handling of complex geometry.

With this balanced approach, accurate analyses can be realized with a very coarse FE mesh. The proposed element is highly efficient and flexible, and hence can be used to model more complex problems. Some numerical examples are shown to illustrate the effectiveness of the 8-noded PUFEM. Wave propagation in beams with various damages in the form of transverse cracks and delaminations in metallic and composite materials has been studied. It is shown from the numerical results that the reflection from the damages can be identified, and the pattern of wave propagation in beams with complex damage configurations can be efficiently studied. The identified reflection from the damage can be used to effectively locate the damage position in SHM.

Chapter 47

Damage Detection Using Piezoceramic and Magnetostrictive Sensors and Actuators

Srinivasan Gopalakrishnan

Department of Aerospace Engineering, Indian Institute of Science, Bangalore, India

1 INTRODUCTION

In recent years, considerable research has been focused on improving the structural integrity (or increasing the life) of the structure. The structural integrity and the evolution of lightweight structural design form the two most severe design constraints a structure has to satisfy throughout its service life. Structural integrity performance of a structure is affected owing to the presence of minor cracks in the structure that are not visible to the naked eye. Detecting these cracks early in their service life poses a major challenge. An early detection of these cracks and adopting a suitable patch repair scheme will result in prolonging the service life of a structure. The area of crack detection in metallic and composite structure is a well-researched topic world over and large amount of literature is available on various methods of detecting cracks (or delaminations). This article highlights one such method of detecting cracks using embedded/surface-mounted smart magnetostrictive or piezoelectric material patches.

The stringent lightweight design constraints have forced the manufacturers of next generation aerospace and automobile vehicles to look for composites as structural members. They provide numerous opportunities to tailor the strength in the required direction and enable the placement of embedded sensors and actuators at any critical location to monitor the performance of the structure. This facility is not available in conventional metallic structures. Damage tolerant design of such structures is an unexplored area of research. Unlike the design of metallic structures, for composites, this information has not been fully integrated into design extensively. Although matrix cracking, fiber breaking, debonding, etc. are often the initiating failure mechanisms for laminated composites during its manufacture and in service, interlaminar crack, or delamination, is the one that is commonly found vulnerable and can grow, thus reducing the life of a structure. Impact is also a major source of delamination in composites. Traditionally,

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

conventional nondestructive techniques (NDT) such as ultrasonics, fractography, thermography, or tomography have been extensively used to detect the presence of damage. However, these techniques require that the position of damage is known *a priori* and the region that is being inspected is readily accessible [1]. These limitations make them very expensive for damage detection in aircraft or spacecraft structures, which need frequent inspection. Therefore, in-service damage-detection (health monitoring) system is essential, which can constantly monitor the integrity of the structure and also determine the location and extent of damage with built-in sensors. Some of the examples of sensors/actuators embedded in composites for damage detection are reported in [2, 3]. The authors had embedded the piezoelectric material in composites in the form of wafer, fiber, and powder form. Also, the use of shape memory alloy for damage detection is reported in [4]. The use of fiber-optic sensors for damage detection is reported in [5]. This article demonstrates one such built-in system with both collocated and noncollocated magnetostrictive and piezoelectric sensor/actuator combination to detect the presence of damage.

We now review some of the damage-detection methods for structural health monitoring. The most popular approach in structural health monitoring is to use modal parameters such as natural frequencies, damping ratios, and mode shapes to determine the existence of damage in structures. It is based on the principle that the presence of damage will change the natural frequencies of the structure owing to reduction in its stiffness. Monitoring the natural frequencies before and after the damage can confirm its presence. References 6 and 7 show the use of modal test data for evaluating structural integrity of offshore structures. Crawley and Adams [8] used the same technique for composite laminates, wherein they showed that the presence of delamination not only decreases natural frequencies but also increases damping in structures. In all the above studies, variation of mass matrix, mode shapes, uncertainty in structural parameters, or instrumentation accuracy were not considered. West [9] presented what is possibly the first systematic use of mode shapes for damage detection. A finite element (FE) study conducted by Chen and Swamidas [10] on a cracked cantilever plate showed that the higher order modes are least affected by the presence of damage. Reference 11 shows the use of lower order modes for nondestructive damage detection and sizing of cracks in beams. A new method based on the singular value decomposition was proposed by them to detect the structural damage. One of the fundamental difficulties with modal methods is that a small delamination causes very negligible loss of stiffness in composites. As a result, the frequency changes are so small that they are very difficult to measure accurately.

Residual force method (damage force method) is another technique of determining damage in structures. This is done by taking the difference between the measured damaged model properties with the undamaged (baseline) model properties. The advantage of this method is that one need not solve the complete system to determine the damage. References 12, 13 have shown the use of this technique in the modal domain. Schulz *et al.* [14] used the undamaged stiffness and mass matrix, obtained by the FEs, to determine the location of damage. Nag *et al.* [15] modified this method for its use in frequency domain through a spectral element formulation. The main advantage of the spectral formulation is that the system sizes are very small owing to exact mass distribution. Requirement of too many sensor measurements is the main disadvantage of the damage force method.

The recent trend is to use wave-based techniques for health monitoring. Pines [16] showed that damage could be ascertained by looking at the changes in the local wavenumber of a Lamb wave. In [17], a narrow-band modulated pulse, impacted transversely on a laminated composite beam, was used to detect damage. The characteristic of this pulse is that it travels nondispersively even in a dispersive medium. When such a pulse interacts with a crack, it produces an additional reflection from the crack tip owing to impedance mismatch. This reflection is easily recognizable, as it does not change its shape. Knowing the length of travel and speed of the medium, the location of the damage can be assessed. References 15, 18 show the use of spectral element model in damage modeling and assessment. (*See* **Damage Measures** for more details on the methods described in the last few paragraphs.)

Next we consider multifunctional composites with embedded or surface-bonded piezoceramic patch made from lead zirconate titanate (PZT) material. If we strain the structure, the PZT material permittivity

changes, which generates an electric field across the sensor and hence introduces an electrical displacement, which produces a voltage across the sensor, which is called *open circuit voltage* (*OCV*). The structure can, in fact, be strained through another PZT embedded/surface-bonded patch, by passing a voltage in the required poled direction. In the presence of the damage, the OCV changes owing to a different stress state. The difference in the OCVs between the healthy and the damaged structure, which is called *damage-induced voltage* (*DIV*), confirms the presence of damage. This is the principle on which this work is based. The same principle is applied with the help of magnetostrictive material patch, wherein, one has to apply a magnetic field to strain the material, which causes the permeability of the medium to change, which introduces a magnetic field across the sensor. This changes the magnetic flux density, which produces a voltage across the senor, which is the OCV. As stated earlier, the difference in the OCVs of healthy and damaged state will confirm the presence of damage in the structure.

This article is organized as follows. In the next two sections, modeling aspects of the PZT and Terfenol-D embedded/surface-mounted composites are addressed. Modeling aspects in general and FE modeling in particular have already been addressed in **Modeling Aspects in Finite Elements**; **Finite Elements: Modeling of Piezoceramic and Magnetostrictive Sensors and Actuators**. Hence, only a brief summary is given here. This is followed by some aspects of experimental study undertaken for the analysis of magnetostrictive composites. Next, some numerical examples and results are provided, followed by a summary of the article.

2 DAMAGE DETECTION USING PIEZOELECTRIC SENSORS/ACTUATORS

Damage detection requires a robust mathematical model and a number of measured responses. Both baseline (response from the undamaged structure) and the response from the damaged structure are required for detection purposes. The detection will be based on the voltage generated across the sensor owing to a mechanical load. Voltage changes depending on the stress condition of the structure. Difference in the voltages between the undamaged and the damaged configuration indicates the presence of damages. Voltage signatures are different for different types of damages, which is helpful to characterize the damages. In this section, we use the mathematical model based on FEs, which was explained in detail in **Piezoceramic Materials—Phenomena and Modeling** on the modeling of piezoelectric sensors/actuators. Also, only the final equations are provided for the sake of completeness. The first step in the development of the mathematical model is to write the constitutive model. As explained in **Piezoceramic Materials—Phenomena and Modeling**, the piezoelectric material has two constitutive laws: one is called the *sensing law*, which is extensively used in this section, and the second is the *actuation law*. When the piezoelectric material is embedded in the composites, the stresses would get coupled, resulting in stiffness coupling such as the bending-axial coupling, etc. Assuming that the condition of plane stress exists in the composites, the constitutive law for piezoelectric composites can be written as

$$\begin{Bmatrix} \{\boldsymbol{\sigma}\} \\ \boldsymbol{D}_z \end{Bmatrix} = \begin{bmatrix} [\hat{\boldsymbol{C}}] & -[\hat{\boldsymbol{e}}] \\ [\hat{\boldsymbol{e}}]^T & \hat{\boldsymbol{\mu}} \end{bmatrix} \begin{Bmatrix} \{\boldsymbol{\varepsilon}\} \\ \boldsymbol{E}_z \end{Bmatrix} = \begin{Bmatrix} \sigma_{xx} \\ \sigma_{zz} \\ \sigma_{xz} \\ D_z \end{Bmatrix} = \begin{bmatrix} \hat{C}_{11} & \hat{C}_{12} & 0 & -\hat{e}_{31} \\ \hat{C}_{13} & \hat{C}_{33} & 0 & -\hat{e}_{32} \\ 0 & 0 & \hat{C}_{55} & 0 \\ \hat{e}_{31} & \hat{e}_{32} & 0 & \hat{\mu}_{33} \end{bmatrix} \begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{zz} \\ 2\varepsilon_{xz} \\ E_z \end{Bmatrix} \quad (1)$$

where $\{\boldsymbol{\sigma}\}^{\mathrm{T}} = \{\sigma_{xx} \quad \sigma_{zz} \quad \tau_{xz}\}$ is the stress vector, $\{\boldsymbol{\varepsilon}\}^{\mathrm{T}} = \{\varepsilon_{xx} \quad \varepsilon_{xx} \quad \gamma_{xz}\}$ is the strain vector, $\boldsymbol{D_i}$ is the electrical displacement, and E_z is the electrical field in the out-of-plane direction. $\hat{C}_{ij}$ are the stiffness coefficients and $\hat{\boldsymbol{e}}_{ij}$ are the piezoelectric coefficients. The explicit expression of the stiffness coefficients are provided in **Finite Elements: Modeling of Piezoceramic and Magnetostrictive Sensors and Actuators** on the modeling of piezoelectric sensors/actuators.

A four-noded smart composite FE with two mechanical degrees of freedom and one electrical degree of freedom was derived in **Finite Elements: Modeling of Piezoceramic and Magnetostrictive Sensors and**

Actuators. Here, we use this element as the mathematical model for damage detection. The FE equation is of the form

$$\begin{bmatrix} [\boldsymbol{M}_{uu}] & [\boldsymbol{0}] \\ [\boldsymbol{0}] & [\boldsymbol{0}] \end{bmatrix} \begin{Bmatrix} \{\ddot{\boldsymbol{u}}\}_e \\ \{\ddot{\boldsymbol{E}}_z\}_e \end{Bmatrix} + \begin{bmatrix} [\boldsymbol{K}_{uu}] & [\boldsymbol{K}_{uE}] \\ [\boldsymbol{K}_{uE}]^T & [\boldsymbol{K}_{EE}] \end{bmatrix} \begin{Bmatrix} \{\boldsymbol{u}\}_e \\ \{\boldsymbol{E}_z\}_e \end{Bmatrix} = \begin{Bmatrix} \{\boldsymbol{F}\}_e \\ \{\boldsymbol{q}\}_e \end{Bmatrix} \tag{2}$$

where, $[\boldsymbol{M}_{uu}]$ is the mass matrix, $[\boldsymbol{K}_{uu}]$ is the stiffness matrix corresponding to mechanical degrees of freedom, $[\boldsymbol{K}_{uE}]$ is the stiffness matrix due to electromechanical coupling, and $[\boldsymbol{K}_{EE}]$ is the stiffness matrix due to electrical degrees of freedom alone. Also, the nodal displacement vector at the four nodes is $\{\boldsymbol{u}\}_e = \{u_1\ w_1\ u_2\ w_2\ u_3\ w_3\ u_4\ w_4\}^T$ and the corresponding electric field vector is $\{\boldsymbol{E}_z\}_e = \{E_{z1}\ E_{z2}\ E_{z3}\ E_{z3}\}^T$. Here, $\{\boldsymbol{F}\}_e$ is the elemental nodal vector and $\{\boldsymbol{q}\}_e$ is the elemental charge vector. A detailed expression for these matrices is given in **Finite Elements: Modeling of Piezoceramic and Magnetostrictive Sensors and Actuators**.

The solution of equation (2) begins by expanding the equation:

$$\{\boldsymbol{E}_z\} = [\boldsymbol{K}_{EE}]^{-1}\{\boldsymbol{q}\} - [\boldsymbol{K}_{EE}]^{-1}[\boldsymbol{K}_{uE}]^T\{\boldsymbol{u}\} \tag{3}$$

Using the above equation in equation (2) and simplifying, we get

$$[\boldsymbol{M}_{uu}]\{\ddot{\boldsymbol{u}}\} + [\overline{\boldsymbol{K}}_{uu}] = \{\overline{\boldsymbol{F}}\} \tag{4}$$

where

$$[\overline{\boldsymbol{K}}_{uu}] = [\boldsymbol{K}_{uu}] - [\boldsymbol{K}_{uE}][\boldsymbol{K}_{EE}]^{-1}[\boldsymbol{K}_{uE}]^T \tag{5}$$

$$\{\overline{\boldsymbol{F}}\} = \{\boldsymbol{F}\} - [\boldsymbol{K}_{EE}]^{-1}\{\boldsymbol{q}\} \tag{6}$$

First, equation (4) is solved for the applied actuator loading $\{\overline{\boldsymbol{F}}\}$ to obtain the nodal displacement vector $\{\boldsymbol{u}\}$, which is substituted in equation (3), to get the induced electric field in the sensor patches, which is then postprocessed to get the voltage distribution. The approach to obtain the voltage distribution is quite different for the static and dynamic loading cases, which are explained below.

2.1 Postprocessing for sensor output signal

The embedded thin piezoelectric patches electroded on the surfaces are modeled using the above FEs. The present study is to investigate the feasibility and characteristic behavior of these embedded patches for sensing the presence of cracks under static and dynamic loading in metallic or composite structures. While embedding the sensors during the wet lay up process or by any other fabrication technique, residual stresses and residual charge may develop. However, during sensor calibration, such residual charge can be removed by grounding the circuit. The existing residual stresses can be expected to add a bias in the sensor output voltage level without any considerable change in the linear transduction characteristics under transients. Therefore, by assuming no residual stresses and no residual charge on the embedded piezoelectric patches, the sensor equation at the element level can be written as given in equation (3).

2.1.1 Static case

The voltage that develops across each sensor owing to the deformation-induced electric field E_z acting in the out-of-plane direction is given by

$$\overline{V} = \sum E_z \Delta_Z \tag{7}$$

where Δ_Z is the distance between the pair of element nodes across the depth. Corresponding charge Q stored on the surface of this sensor segment is

$$Q = \int D_Z t\, \mathrm{d}x = \int [\hat{e}_{31}\varepsilon_{xx} + \hat{e}_{32}\varepsilon_{zz} + \hat{\mu}_{33}E_z]t\, \mathrm{d}x\Big|_z \tag{8}$$

The above equation is obtained after substituting for electrical displacement from equation (1). The strains can be expressed in terms of nodal displacements using the strain–displacement relationship and the electrical field can be written in terms of nodal electrical field ($E_z = \sum N_i E_{zi}$), where the nodal electrical field is obtained from equation (3). In doing so,

equation (8) becomes

$$Q = \int [\hat{e}]^T [B_u] \{u\}_e t \, dx + \int \hat{\mu}_{33} [N]^T \{E_z\}_e t \, dx \Big|_z \tag{9}$$

In the above equation, $[B_u]$ is the strain–displacement matrix corresponding to normal stress, $\{u\}_e$ is the nodal displacement vector, and $\{E_z\}_e$ is the nodal electrical field vector. Equation (9) is evaluated at each of the piezoelectric sensor locations. Since this sensor segment behaves as a capacitive device with capacitance $C = Q/V$, the stored electric energy $(1/2CV^2)$ can be equated to obtain the equivalent open circuit voltage V_a measurable as the output of the distributed sensing. That is, the equivalent OCV accumulated on a single sensor surface $\Omega = \sum t \, \Delta x$ (having Δx as the length of individual sensor elements) can be computed as

$$V_a = \frac{\sum VQ}{\sum Q} \tag{10}$$

Although the mechanical deformation is under static loading, in actual experiment, the sensor output scaled by a charge amplifier is to be measured as the initial transient after closing a resistive capacitive circuit. This is because of the leakage of the electrostatic charge in the surrounding medium.

2.1.2 Dynamic case

In this case, the developed voltage V and charge Q are both time dependent. Equations (7–9) hold. The current from each sensor element is

$$\dot{Q} = \int [\hat{e}]^T [B_u] \{\dot{u}\}_e t \, dx + \int \hat{\mu}_{33} [N]^T \{\dot{E}_z\}_e t \, dx \Big|_z \tag{11}$$

Unlike the capacitive model in the static case, here the developed electric power $P = V\dot{Q}$ is to be equated to obtain the equivalent open circuit voltage V_a due to distributed sensing over the single sensor surface $\Omega = \sum t \, \Delta x$. That is,

$$V_a = \frac{\sum V\dot{Q}}{\sum \dot{Q}} \tag{12}$$

$$\sum \dot{Q} \neq 0 \tag{13}$$

The above equations for static and dynamic loading cases are used in the examples to follow in the next section to obtain the OCV distribution across the sensors due to the presence of cracks.

2.2 Numerical examples

To study the effectiveness of piezoelectric material patch in predicting the presence of cracks, we consider a double cantilever beam (DCB), wherein, three piezoelectric sensor patches are embedded, two of them above and below the crack and one in the line of the crack as shown in Figure 1. The dimensions of the beam along with the cross section are also shown in the figure. The structure is a unidirectional (0°) graphite/epoxy beam, whose material properties are shown in Table 1.

In the chosen configuration, as shown in Figure 1, the locations of the piezoelectric sensor patches are fixed and the length of the crack (delamination) varies from 25 to 50 mm. For the configuration with delamination length 50 mm, the DCB specimen was discretized with 540 elements (including the sensor patch as shown in the deformed mesh in Figure 2) producing a system size 928×928. The objective here is to see the variation of the OCV as a function of crack length. We now consider voltage distribution under static loading. Static load of 50 N is distributed

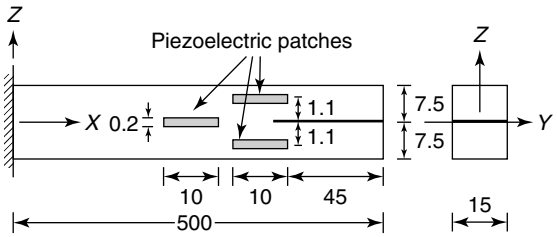

Figure 1. Configuration of a laminated composite double cantilever beam (DCB) with three embedded piezoelectric patches ahead of the advancing delamination tip. All dimensions are in millimeters.

Table 1. Material property of the double cantilever beam specimen used for numerical experiment

Material property	Graphite/epoxy beam	PZT
Young's modulus E_{11} (GPa)	150	63
Young's modulus $E_{22} = E_{33}$ (GPa)	9	63

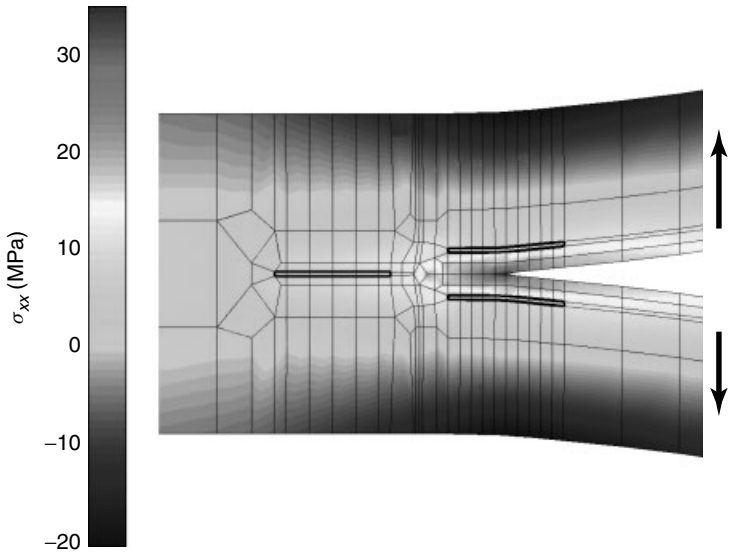

Figure 2. Distribution of stress σ_{xx} under vertical static 50-N loading. Delamination length is 50 mm. Delamination tip is midway between the top and bottom sensor patch.

vertically in the opposite direction at the tip cross section of each of the branches of the DCB specimen (Figure 1). Such a loading will cause what is termed in fracture mechanics as *mode* -1 or *opening mode loading*. Figure 2 shows the distribution of the stresses σ_{xx} for delamination length of 50 mm, where the crack tip is midway between the top and bottom sensor patches. One can clearly see the high stress in the region very close to the crack tip. Locations of the three sensor patches are shown by thick solid lines. Owing to these distributions of stress field, it is important to look into the nature of voltages developed between the parallel electroded surfaces of the front, top, and bottom sensor patches. These are shown in Figure 3(a) and (b), respectively. The locations of the points on the sensor surface at which the voltages are computed are indicated by their x coordinate measured from the fixed end of the DCB specimen. Equation (10) is used to perform the required post-processing. It can be seen from Figure 3(a), for the front sensor patch, that for a smaller delamination length (delamination tip away from the patch), the voltage distribution is almost constant. For higher length of delamination (delamination tip entering in the zone surrounding the sensor group), the voltage at the front portion of the front sensor patch is higher

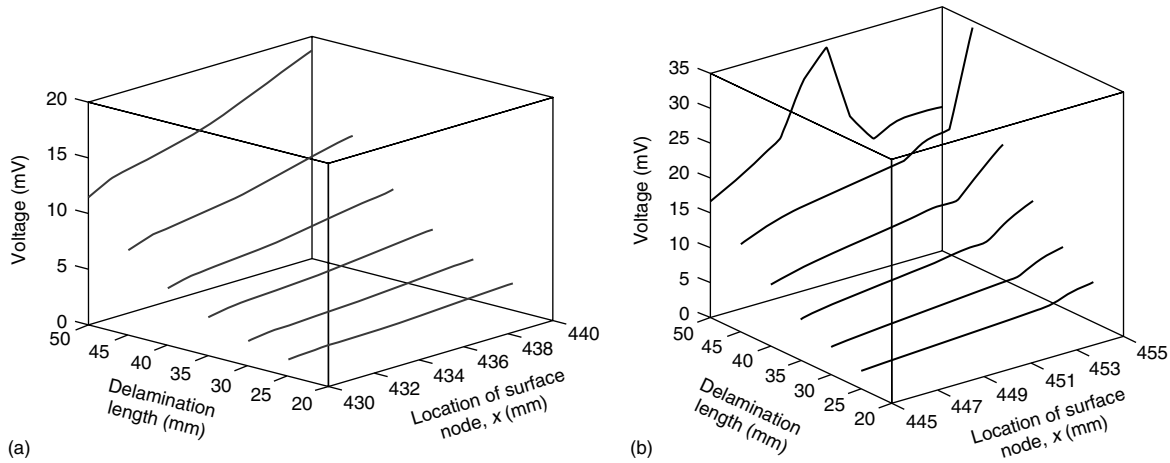

Figure 3. Voltage distribution along x under static 50-N loading for increasing the length of delamination: (a) in the front sensor patch and (b) bottom sensor patch.

than its rear portion. However, the effect of intense crack-tip field approaching toward this front sensor patch could not be captured. This is captured in the bottom and top sensor patches. Figure 3(b) shows the voltage distribution in the bottom sensor patch, where the effect of the crack-tip field entering the midway between the top and bottom sensor patches is clear from the sudden jump in the voltage, first for delamination length of 45 mm and then 50 mm. Owing to symmetry in the material configuration, geometry and loading, the similar feature (but with opposite sign in the voltage) was also captured for the top sensor patch, which is not shown. From these figures, we can clearly see that OCV across the sensor patches can be used as a damage measure to detect the presence of damage.

We now change the loading to a vertical load that is distributed uniformly across the entire cantilever tip. Such a loading, in fracture mechanics terminology, causes shear fracture mode or it is also called the *mode-II loading*. The loading magnitude is kept at 100 N. The OCV distribution in the three piezoelectric sensor patches is shown in Figure 4(a–c), respectively. From the voltage distribution in the front sensor patch in Figure 4(a), it is clear that the dominant stress field σ_{xx} is antisymmetric about the middle plane along x axis. Increase in the voltage due to increasing length of delamination is negligible. From the voltage distribution in the top sensor patch in Figure 4(b), it can be seen that for increasing the length of delamination, the portion of the patch toward the free end of the DCB specimen develops higher voltage compared to the portion nears the front sensor patch, and this variation is almost linear. Slight fluctuation compared to this feature is obtained in the case of the bottom sensor patch, which is shown in Figure 4(c). Interestingly, the antisymmetric stress field σ_{xx}, which is visible from the spanwise antisymmetric voltage distribution in the top as well as bottom sensor patches, gets perturbed as the delamination grows toward the sensor group. Also, the effect of delaminated surface is dominant here in generating the voltage, not the crack-tip field.

These examples have clearly shown the utility of piezoelectric material patches in detecting the presence of damage. Next, we study the voltage distribution under dynamic loading. Here, we study the effects only under shear loading considered previously. In this study, a triangular pulse of 50-μs duration and peak amplitude of 100 N is applied vertically at the cross section of the tip of the DCB specimen (Figure 1). Similar high-frequency transient pulse is typical to many composite structures under impact-type loading, where the damage and structural failure are the most important aspects of structural design and structural health monitoring [18, 19]. First, the time-dependent distribution of the voltage at the spanwise locations on the front, top, and bottom sensor patches are studied. Equations (12) and (13) are used for the required postprocessing. Figure 5(a) shows the

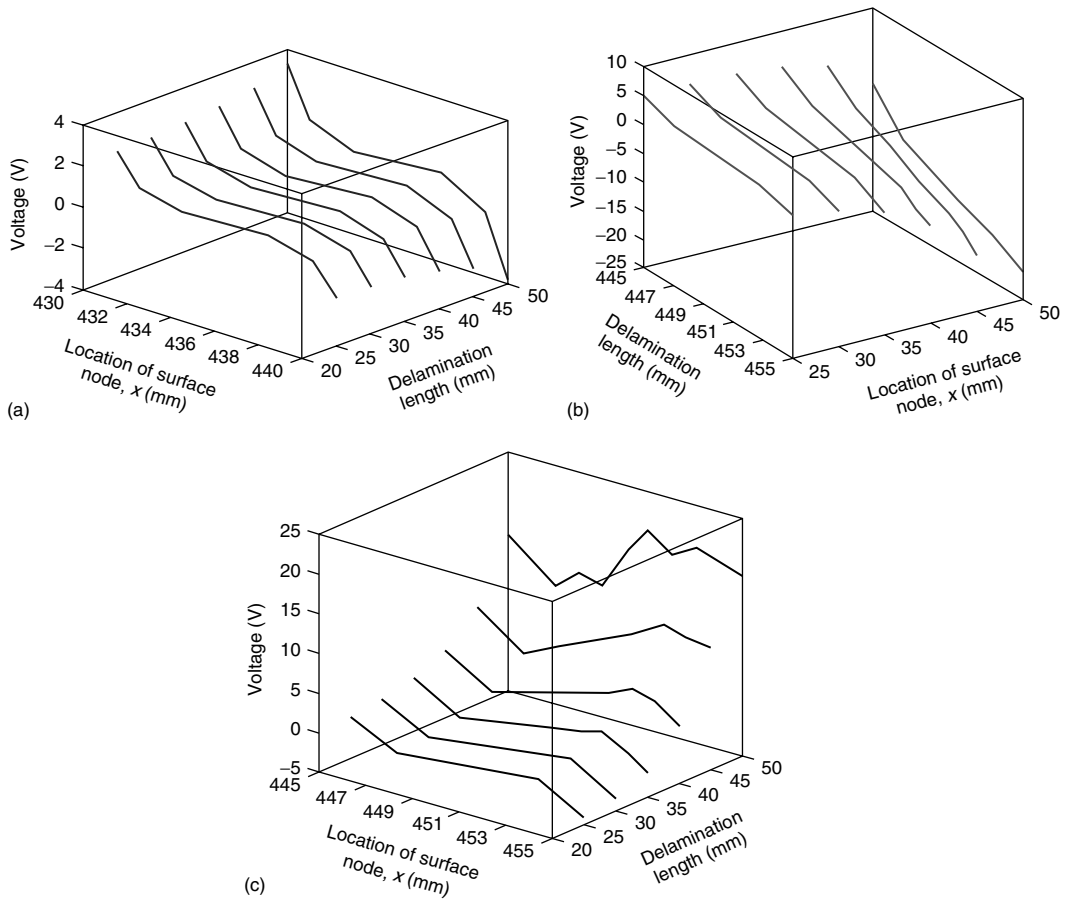

Figure 4. Voltage distribution along x under static 100-N shear loading for the increasing length of delamination: (a) in the front sensor patch, (b) top sensor patch, and (c) bottom sensor patch.

voltage history at the front sensor patch. The points along the x direction on the surface of sensor patches are indicated by the x coordinate measured from the fixed end of the DCB specimen. Since the loading is transient in nature, it produces stress waves traveling with corresponding flexural speed, shear speed, and phase dispersion. Note that the inertia effect is also included, which makes the dynamic behavior different from the quasi-static case. The first peak in each time history, as seen in Figure 4(a), corresponds to the stress waves reaching certain segments of the sensor patch. The second peak in each time history corresponds to the stress waves released from the crack tip. It can be observed that the voltage generated (second peak in the time history) at the front end of the front sensor patch is very high, which is actually the effect of the arrival of the wave at the 50-mm delamination tip (most severe case). In the voltage histories for the top as well as the bottom sensor patches (Figure 5b and c), maximum voltage is generated from the segment confining the delaminated faces behind the crack tip.

In summary, two aspects are very clear from these examples. First, it is shown that there is significant variation in the OCV distribution across the sensor owing to the presence of cracks. These voltage patterns cannot only tell about the presence of cracks (or delamination) but also give a qualitative nature of the damage. Hence, the OCV can indeed be used as a damage measure. The second aspect that is clear is that piezoelectric material can be effectively used as a sensor for damage-detection purposes.

3 DAMAGE DETECTION USING MAGNETOSTRICTIVE SENSORS/ACTUATORS

In this section, a simple FE based on uncoupled constitutive model of magnetostrictive material (Terfenol-D) is considered for modeling of the smart material patches. The results of the model are compared with the experiments. The details of the experiments can be found in [20]. Magnetostrictive material such as "Terfenol-D" was thought of as an actuator material until recently [21]. Compared to PZT material, they offer large block force and large free strain. In addition, they are available in powder form, which makes it possible to embed them in composites. Reference 22 was perhaps the first work reported on the properties of magnetostrictive particle layers that would make them useful for sensing purposes. Reference 23 showed the use of horseshoe coil arrangement for creating the magnetic circuit, which is necessary for damage-sensing application. The present study uses the above concept to demonstrate the effectiveness of magnetostrictive material for damage-sensing purposes. Here, the health monitoring is based on the concept that when an ac current is passed to the actuation coil, it generates mechanical stress (strain). This stress changes not only with the change in delamination location but also with its size. This change in stress produces a change in the magnetic flux, and hence in the voltages across the sensing coil. Measuring the change in the voltage (which is easily measurable quantity compared to strains/stresses) before and after the delamination has taken place determines the condition of the structure.

As mentioned earlier, we use the uncoupled constitutive model of Terfenol-D for the FE analysis purpose and hence assume the magnetic field as the product of coil current and the number of turns of the coil. From the FE point of view, the magnetic field can be converted as a block force and lumped on to the structure. The computation of the block force is first explained.

The magnetostrictive material has the following constitutive law. The first law is the actuation law, while the second is the sensing law.

$$\varepsilon = S^{(H)}\sigma + \mathrm{d}H \tag{14}$$

$$B = \mathrm{d}\sigma + \mu^{(\sigma)}H \tag{15}$$

where, ε is the induced strain, S is the material compliance measured at constant magnetic field H, σ is the induced stress, B is the magnetic flux density, and $\boldsymbol{\mu}$ is the permeability of the medium measured at constant H (*see* **Constitutive Modeling of Magnetostrictive Materials** for more details on the constitutive models for magnetostrictive materials). In the absence of mechanical forces, the strain and induced stress from the actuation law become

$$\varepsilon(t) = \mathrm{d}H(t) \tag{16}$$

$$\sigma(t) = E\varepsilon(t) = E\,\mathrm{d}H(t) \tag{17}$$

where E is the Young's modulus of the material. If A is the cross-sectional area of the smart match, the block force experienced by the smart patch owing to magnetic field intensity of H is given by

$$F(t) = E\,\mathrm{d}AH(t) \tag{18}$$

An actuation current is an alternating current (I) that generates a magnetic flux (B) while passing through one arm of the horseshoe coil and also creates a magnetic field in the layer of smart patch. This current varies sinusoidally with time as

$$I(t) = I_0 \sin \Omega t \tag{19}$$

where I_0 is the applied current amplitude and Ω is the applied current frequency. The magnetic field is related to the current by the expression

$$H(t) = n_{\mathrm{a}} I(t) \tag{20}$$

where n_{a} is the number of turns in the actuation coil. Using equations (19) and (20) in equation (18), the applied force can be written as

$$F(t) = E\,\mathrm{d}AI_0 n_{\mathrm{a}} \sin(\Omega t) \tag{21}$$

The obtained force is applied as concentrated force on the nodes of the patch in the longitudinal direction. This force causes the stress across the sensing coil. From this, the nodal FE stresses σ_{nodal} can be computed. The actual stress is then calculated as

$$\sigma_{\mathrm{total}} = \sigma_{\mathrm{nodal}} + \sigma_{\mathrm{induced}} = \sigma_{\mathrm{nodal}} + E\,\mathrm{d}H \tag{22}$$

The sensing constitutive law (equation 15), in the presence of pure mechanical load becomes

$$B = \mathrm{d}\sigma_{\text{total}} \tag{23}$$

Knowing the stresses from equation (22), and using this in equation (23), the OCV can be computed from the relation

$$V = -n_s A \frac{\mathrm{d}B}{\mathrm{d}t} \tag{24}$$

where, n_s is the number of turns in the sensing coil.

The FE of the beam of size 200 mm × 24 mm × 2.4 mm is discretized using 1920 3-D brick elements. In the longitudinal direction, it is divided into 20 segments, in the lateral direction 6 segments, and in the thickness direction it is divided into 16 segments. The total number nodes in the model is 2499. The magnetostrictive patch is modeled using one 3-D brick element. The complete FE model is shown in Figure 5. The beam is fixed at one end and the equivalent block force is applied in the longitudinal direction of the magnetostrictive patch as shown in Figure 6. Transient dynamic analysis using Newmark time-marching scheme is employed to compute the response histories. Stress histories are computed after postprocessing the displacement histories and subsequently using equation (22). From the stress histories, the OCV is calculated for different times using equation (24).

In order to study the effectiveness of the magnetostrictive patch as a sensor and its ability to sense damage, a cantilever beam structure with both embedded and surface-bonded smart patches is considered. The magnetostrictive patch is bonded (or embedded) in the specimen at a distance of 23 mm

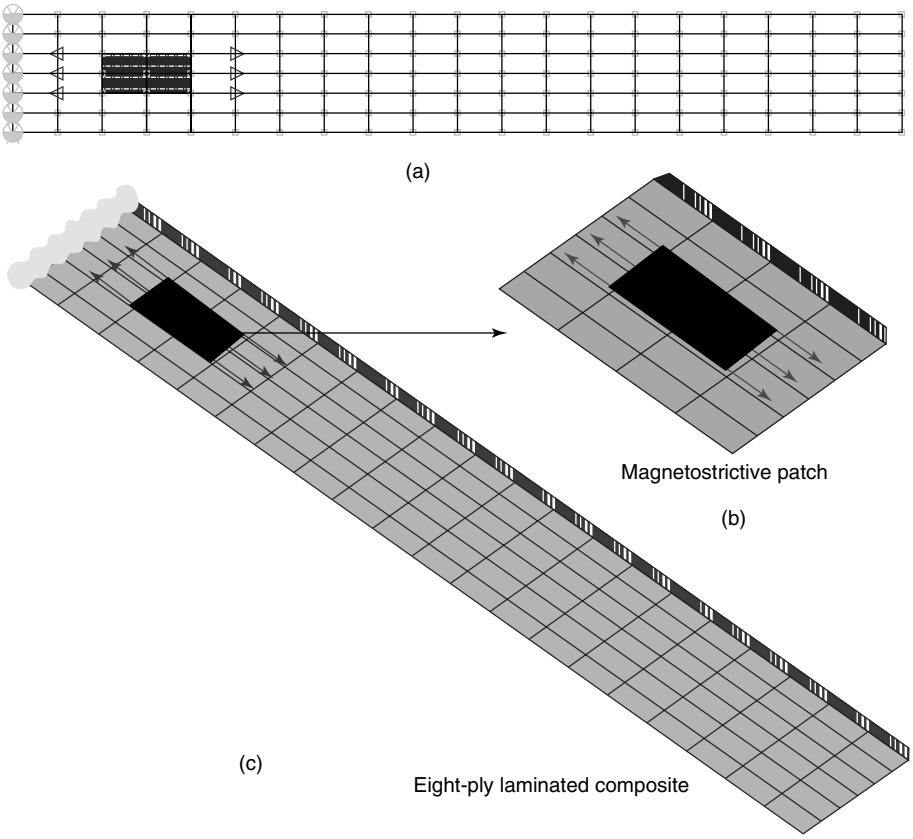

Figure 6. 3-D finite element model for laminated composite beam: (a) plan view of the mesh, (b) enlarged isometric view of the region near the smart patch, and (c) isometric view of the complete model.

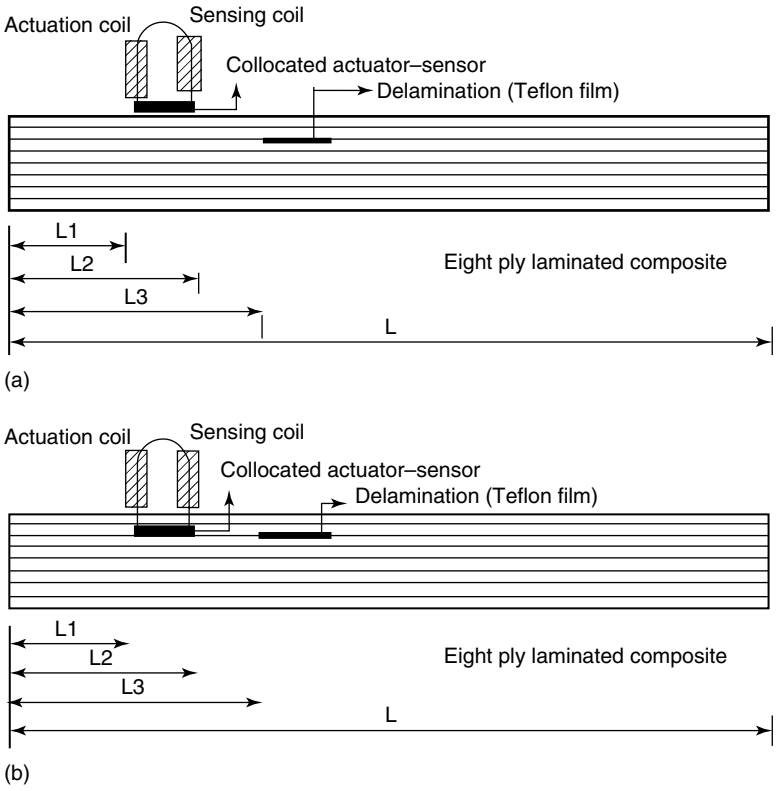

Figure 7. Laminated composite with (a) surface-bonded patch and (b) embedded single patch.

from the root in the longitudinal direction. The delamination length is varied from 24 to 14 mm. The delamination is placed between the second and third layer of an eight-layer unidirectional composite. Figure 7 shows the position of the magnetostrictive patch. The material properties of the laminate and patch are listed in Table 2. It also tells how to induce a magnetic circuit using horseshoe coil to create a magnetic field experimentally. The dynamic excitation is provided by the magnetic field generated by an ac current. This current varies sinusoidally with time and hence the magnetic field as well as the dynamic excitation also varies in a similar manner. The ac current is varied from a frequency range of 100–400 Hz. The current amplitude is varied between 1 and 4 mA. In each case, the OCV is measured and the DIV, which is given by

$$DIV = OCV_{\mathrm{d}} - OCV_{\mathrm{h}} \tag{25}$$

Table 2. Material properties for composite laminate and smart patch used in finite element simulation

Property	Laminated composite	Smart patch
E_{x} (GPa)	53.48	32.7
E_{y} (GPa)	17.92	32.7

ν_{yz}	0.25	0.3
ν_{xz}	0.34	0.3
ρ (kg m^{-3})	1500	2330

is computed. Here $\mathrm{OCV_d}$ is the OCV in a delaminated beam and $\mathrm{OCV_h}$ is the OCV in a healthy beam.

First, a beam with surface-mounted patch is analyzed. For this case, delamination of size 24 mm

is introduced between the second and third layer at a distance of 50 mm from the tip of the sensor patch. OCV histories are obtained for varying current amplitudes and frequencies. Figure 8 shows the peak voltage (OCV) as the function of current amplitude for a current frequency of 100 Hz. We see from the figure that OCV increases with the current amplitude and there is excellent agreement of the results with the FE prediction. Figure 9(a) and (b) shows the OCV and DIV time histories for the same delamination configuration at 200-Hz frequency. These figures show that the voltage history exhibits inverted cosine profile. This is due to the presence of time derivative for computing magnetic flux intensity (B)

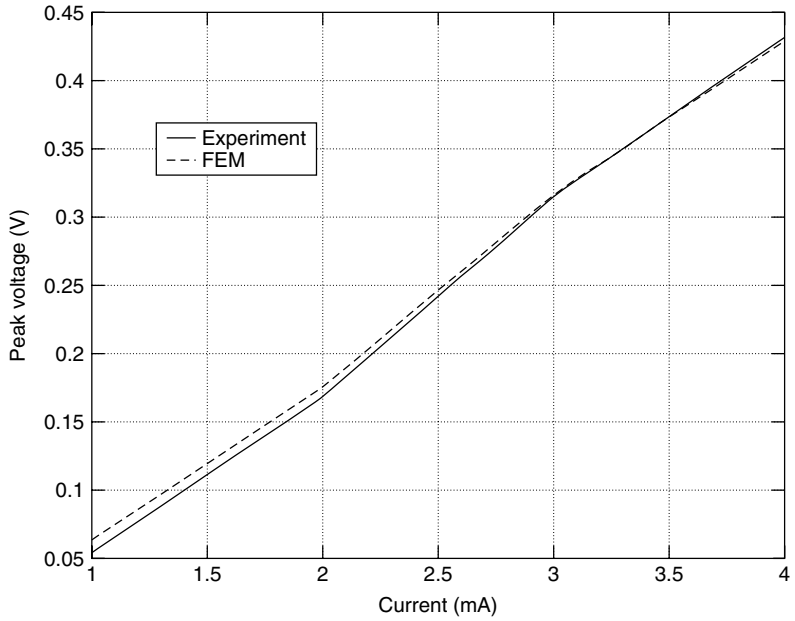

Figure 8. Comparison of experimental and FEM peak open circuit voltages for a beam with surface-bonded patch at 100-Hz frequency.

200	78	87	94	103	77	86	93	102
300	84	92	101	109	82	91	99	108
400	89	96	106	112	90	96	104	113

in equation (23). It is seen that the DIV is in the order of millivolts, which is easily measurable using normal instrumentation. Table 3 gives the comparison of DIV obtained from experiments and FE analysis for various frequencies. The table shows that the DIV increases with increase in current amplitudes and current frequencies. These results agree very well with the FE analysis predictions.

In the next example, the smart Terfenol-D patch is embedded in between plies of a composite beam and the OCV and the DIV or computed. In this case, three different sets of experiments are performed. In the first set, the delamination sizes are varied for a fixed location of 50 mm from the smart patch. Three different delamination sizes of 24, 18, and 14 mm, respectively, are considered for the study. These delaminations are again introduced between the second and third layer. OCV histories are obtained for these specimens. Tables 4–6 give the peak DIV values computed from the peak OCV values of

Table 4. Damage-induced voltage for embedded single patch with delamination size of 24 mm

300	50	64	78	95	48	61	76	95
400	62	76	90	108	59	73	91	110

delaminated and healthy beam specimens for different current frequencies and current amplitudes. From the tables, we see that, for the delamination of size 24 mm, the DIV slightly decreases compared to the surface-bonded case, especially for low current frequency. However, at higher current frequencies and current amplitudes, DIV is higher than for the surface-bonded case. Hence, parameters such as the position of the sensor (patch), the current frequencies, and the current amplitudes, all influence the magnitude of DIV. Here again, the experimental results agree well with the FE solutions. When the delamination size is changed to 18 and 14 mm, respectively, we see that the magnitude of DIV drops with the reduction in the delamination size. This is to be expected, since smaller the delamination size, smaller will be

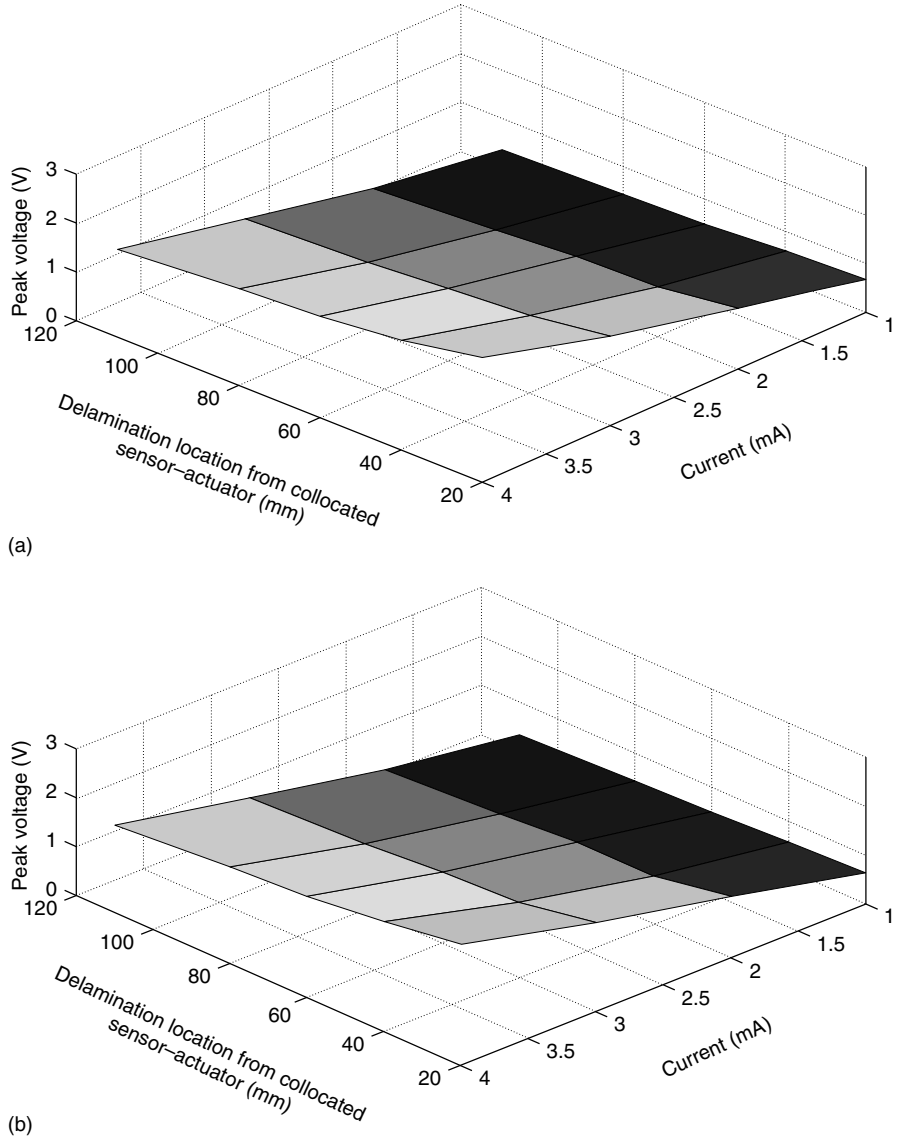

Figure 10. Peak OCV for different delamination locations along the length of a laminated composite with embedded single patch at 100-Hz frequency: (a) experiment and (b) FEM.

the change in the induced stress, and hence smaller will be the DIV. As before, DIV increases with the current frequency and amplitude. FE results, again, match very well with the experiments [20].

In the second set of experiments on a single-patch collocated sensor/actuator configuration, the location of delamination is varied lengthwise with respect to smart patch for a fixed delamination size of 18 mm. OCV histories are obtained for five different locations of 30, 50, 70, 90, and 120 mm from the smart patch. The peak value of OCV is plotted as a function of current amplitude and delamination location at 100-Hz frequency. This is shown in Figure 10. We see from the plots that the peak value of the OCV increases with the current amplitude and, as expected, the maximum value occurs near the sensor location. The parameters that govern the sensitivity of the response are the peak values of DIV very close and far away from the sensor location. From the figures, we see that the peak DIV decreases with the increase in distance between the smart patch and delamination location.

In the last set of experiments on single-patch collocated configuration, the location of delamination of size 18 mm is varied depthwise by introducing it at the successive ply levels starting from the

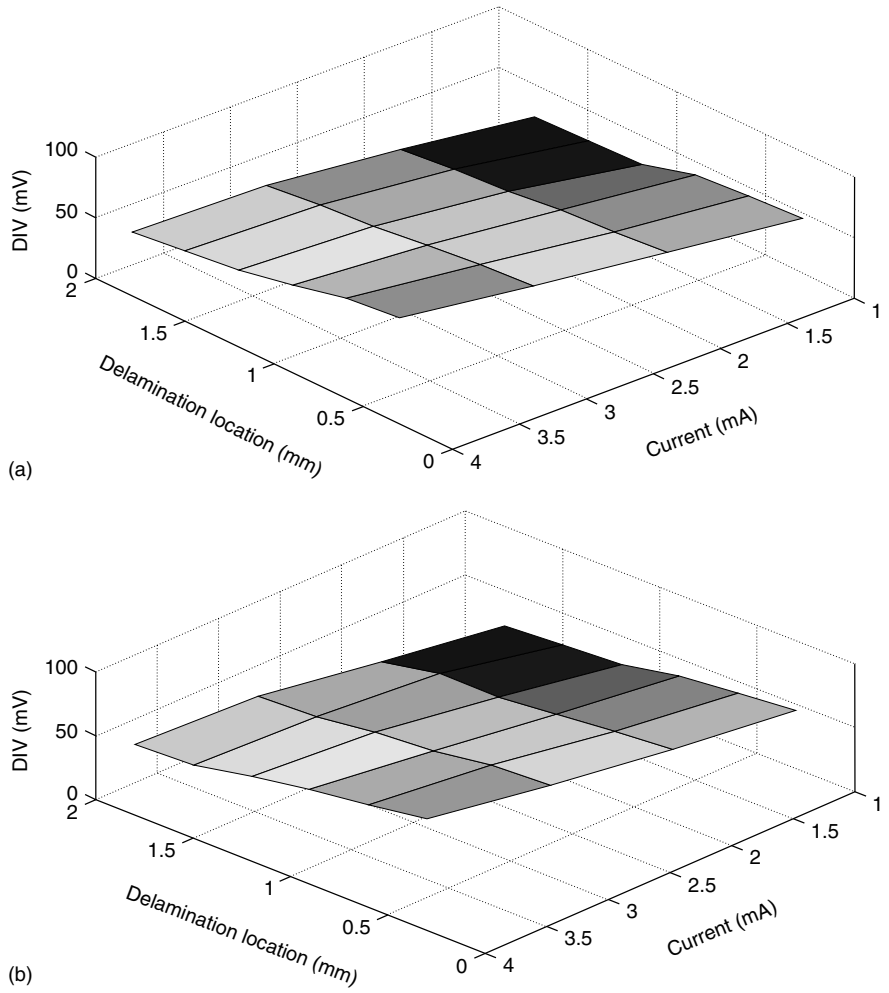

Figure 11. Peak damage-induced voltage for different delamination locations along depth of a laminated composite with embedded single patch at 100 Hz frequency: (a) experiment [20] and (b) FEM.

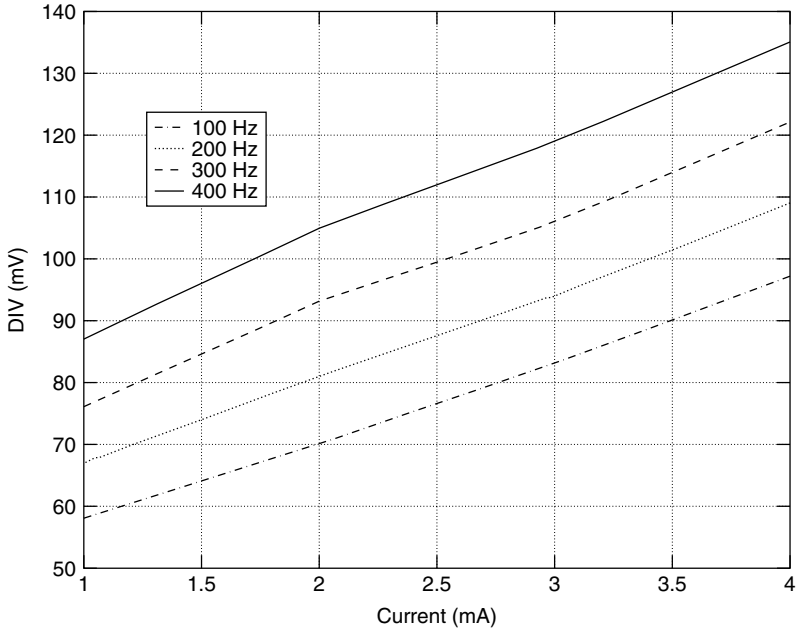

Figure 12. Peak values of damage-induced voltage for delamination of 18 mm located in between collocated sensor and actuator.

second–third layer interface. The lengthwise location of this is at 50 mm from the smart patch. OCV histories are obtained for these configurations. The peak DIV values are plotted as a function of current amplitudes for a current frequency of 100 Hz. This is shown in Figure 11. Higher voltages are predicted when the delamination is very close to the sensor patch (that is, when the delamination is between the second and third layer). When the delamination locations at ply levels are far from the sensor, the induced peak voltage is small and almost constant for all current amplitudes. The next logical step is to introduce the delamination exactly in between the collocated sensor and actuator in the second layer. This is done by making the delamination exactly 18 mm, which is the size of the smart patch in the longitudinal direction. Figure 12 gives the peak DIV values for various current frequencies. These plots indicate a linear behavior of current amplitudes with voltages for all the frequencies. The peak values of DIV change almost 1.5 times when the current amplitude changes from 1 to 4 mA. Hence, it can be concluded that the lengthwise variation of the delamination has more pronounced effect from the sensitivity of the response to the delamination.

4 SUMMARY

This article presents the utility of the smart material patches, which act as both sensors and actuators, to sense the presence of damage in a composite beam. Two different smart materials, namely, the PZT and Terfenol-D, are used in this study. Both these materials require baseline measurement in terms of the OCV across the sensor for predicting the presence of damage. This voltage gets perturbed in the presence of damage. Many numerical experiments are used in this study to demonstrate the concept of damage detection. FEs are used as the mathematical models and some results, especially those with magnetostrictive patches, are compared with the experiments.

Chapter 48
Damage Measures

Massimo Ruzzene
School of Aerospace Engineering, Georgia Institute of Technology, Atlanta, GA, USA

1 INTRODUCTION

The objective of a structural health monitoring (SHM) system is to identify anomalies or damages such as cracks, delaminations, and disbonds in structures. The term identification includes the determination of the existence of damages, their location, and their size as accurately as possible. In the literature, the amount of information that can be obtained regarding a damaged structure is typically classified into five levels: (i) identification of the presence of damage, (ii) determination of the location of the damage, (iii) classification of the type of damage, (iv) quantification of its extent, and (v) estimation of the remaining life of the component under investigation. The definition of an effective measure of damage responds to the requirements of the first four stages of the information, and ideally provides inputs to step number (v). Damage measures proposed in the literature from an SHM perspective are meant to identify and locate the damage, and, in some cases, provide an indication regarding the extent of the damage and its progression.

Many SHM techniques developed over the years are based on the detection of changes in the dynamic behavior of the monitored components. Valuable reviews of the state of the art in dynamics-based SHM can be found in [1–3]. The existing techniques vary on the basis of the type of dynamic response signals used for the analysis and on the features or parameters considered as damage indicators. Such features or parameters must obviously be sensitive to damage and must vary monotonically with the extent of the damage. Dynamics-based inspection techniques are typically classified as vibration-based methods and wave-propagation methods. Vibration-based damage detection techniques typically monitor changes in modal frequencies, changes in measured mode shapes (and their derivatives), and changes in measured flexibility coefficients, while wave-propagation inspections look for reflections and mode conversion phenomena caused by the presence of damage.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

Early studies in vibration-based techniques evaluated the influence on the natural frequencies of localized stiffness reductions caused by damage. These investigations have shown that natural frequencies are damage indicators, which generally show low sensitivity, and do not allow the determination of the location of damage. More recent studies have investigated the effects of localized and distributed damage on mode shapes, operational deflection shapes (ODSs), and corresponding curvatures. The detection of small changes in the deformed configuration of the structure can be used to localize damage and potentially estimate its severity. In particular, small variations from an undamaged state can be highlighted by successive spatial differentiations of the deflections, as typically required for estimating curvature modes and associated strain energy. These modal-based methods are very attractive, as they provide information regarding the general state of health of the structure. However, they tend to have limited sensitivity and generally they are not accurate enough to provide detailed information regarding damage type and extent.

The lack in sensitivity and capability of discriminating damage from changes in the operating conditions of modal-based methods can be overcome by applying inspection techniques based on guided ultrasonic waves (GUWs) propagation [3–5]. Guided waves, such as Lamb waves, show sensitivity to a variety of damage types and, as opposed to bulk waves used in traditional ultrasonic techniques, have the ability to travel relatively long distances within the structure under investigation. For this reason, GUWs are particularly suitable for SHM applications, which may employ a built-in sensor/actuator network to interrogate and assess the state of health of the structure. In most applications, GUWs are generated and received by piezoelectric transducers, which can both excite the structure and record its response. As an alternative, an array of transducers and actuators can be distributed over the surface of the structure according to convenient patterns [3, 4, 6, 7]. The fundamentals of this type of operation consist in evaluating the characteristics of the propagation along the wave path between each transducer/receiver pair and detecting reflections associated with damage. The interpretation of the characteristics of the signals and the detection of reflections is, however, complicated by the multimodal and dispersive nature of GUW signals. For this reason, significant efforts are being devoted to improvements in the defect characterization procedures. Advanced signal-processing techniques are being employed to highlight signal features, which are sensitive to the presence of damage and which can be used for its classification and for the estimation of its extent [5].

This article is organized in four sections including this introduction. Section 2 presents an overview of vibration-based damage measures, with specific focus on a few interesting techniques, while Section 3 illustrates research efforts in the area of GUWs-based inspection. Section 4 concludes the article with a short summary.

2 VIBRATION-BASED DAMAGE MEASURES

The analysis of the modal properties of the structure and their variation due to damage has received considerable attention from researchers over the last 30 years. An excellent and thorough review of the research in the area can be found in [1]. Most of the damage measures proposed assume the possibility of comparing current measurements with baseline information regarding the undamaged state of the structure. This is a significant drawback, as it assumes the availability of data on the component under test in its pristine state and also that any measured change is due to damage only, and not due to changing environmental or boundary conditions applied to the component. The techniques presented below are examples of solutions proposed over the years, whose practicality can be significantly improved if coupled with procedures aimed at generating data approximating the undamaged response of the structure. An example of such a procedure, proposed in [8], is presented at the end of this section (Section 2.5).

2.1 Frequency changes

Modal parameters are global properties of a vibrating structure, and their change can indicate the presence of a damage without performing direct measurements at or near the damage site. One of the typical effects of damage is a localized reduction of stiffness, which produces a corresponding change in modal

frequencies. Analytical quantification of the change in modal frequencies related to loss of stiffness in simple beam and plate structures can be found, for example, in [9–11], where perturbation methods are applied to estimate modal properties in the presence of notch-type defects. It is nowadays quite accepted that simple monitoring of frequency changes is not a reliable and sensitive-enough method for early damage detection, and cannot easily provide location information [1]. Noteworthy attempts include the work of Cawley and Adams [12], who investigated frequency shifts due to damage in composite materials. The ratio between shifts at various modes $\Delta\omega_i/\Delta\omega_j$ is used to construct an error term, which allows to estimate the damage location. This technique, which does not account for multiple damage sites, was revisited in [13, 14] using the sensitivity of modal frequency changes in terms of local stiffness and mass changes. The following error function for the ith mode and pth structural member was introduced:

$$e_{ip} = \frac{z_i}{\sum_j z_j} - \frac{F_{ip}}{\sum_j F_{jp}} \tag{1}$$

where z_i is ith term in the array of squared modal frequency changes, which is defined as

$$\{z\} = [F]\{\alpha\} - [G]\{\beta\} \tag{2}$$

with $[F]$ and $[G]$ denoting the changes in elemental stiffness and mass magnitudes, respectively. The member that minimizes the error in equation (1) is determined to be the damaged one, again under the assumption of single defect. The estimation of the frequency change sensitivity is obviously based on the finite element (FE) model of the structure under consideration, which may be problematic in the case of complex structures. Hearn and Testa [15] employed the FE formulation to introduce a damage severity parameter for structural member n representing the stiffness loss of the element, i.e.,

$$[\Delta k_n] = \alpha_n [k_n] \tag{3}$$

which, under the assumption of single damage location, can be directly related to a frequency shift according to the following expression:

$$\Delta\omega_i^2 = \alpha_n \frac{\{\varepsilon_n(\phi_i)\}^{\mathrm{T}}[k_n]\{\varepsilon_n(\phi_i)\}}{\{\phi_i\}^{\mathrm{T}}[M]\{\phi_i\}} \tag{4}$$

where $\{\varepsilon_n(\phi_i)\}$ are the nth member's deformations computed on the basis of the undamaged mode shapes ϕ_i, while $[M]$ and $[k_n]$ describe the mass of the structure and the stiffness of the nth member. This equation directly relates the effect of damage on a specific component n to the corresponding shift in frequency, under the assumption that the evaluation of this direct relation can be performed on the basis of predamage modal information. The hypothesis that damage only produces a change in stiffness $[\delta K]$ is exploited in Richardson and Mannan [16], where the orthogonality properties of the damaged and undamaged structure is used to obtain the following sensitivity equation:

$$\{\phi_i\}^{\mathrm{T}}[\delta K]\{\phi_i\} = (\omega_i^{(d)})^2 - (\omega_i^{(u)})^2 \tag{5}$$

where it is again assumed that damage causes a negligible change in the mode shapes.

2.2 Mode-shape changes

Mode-shape changes are found to be quite sensitive to damage, especially when higher modes are considered, and are able to directly provide damage location information. The problem associated with mode-shape monitoring is clearly related to the need of sufficient spatial measurement resolution, which complicates the experimental procedures. The required measurement resolution can be easily achieved through the use of a scanning laser Doppler vibrometer (SLDV), which has become an important tool for dynamic testing. Alternatively, the number of measurement locations can be reduced if the FE model of the structure under investigation is available for its use in increasing the information on the structure's behavior and for interpolation purposes. Most of the early work on mode-shape analysis consider the modal assurance criterion (MAC) to compare measured, or damaged, modes, with undamaged or numerical ones. For example, West [17] used the MAC to correlate the modes of an undamaged space shuttle orbiter body flap with those after the flap

has been exposed to acoustic loading. Another technique presented in [18] considered a damage measure based on changes in the mode shape and mode-shape slope. Changes were simulated for stiffness reductions in each structural member and compared with measured changes to determine the damage location. Other techniques of various nature exploit comparisons through different types of modal correlation criteria. For example, Fox [19] proposed the concept of an MAC based on measurement points close to a node point for a particular mode ("node line MAC"), Kim *et al.* [20] investigated the use of the partial modal assurance criterion (PMAC) to compare the MAC values of coordinate subsets of the modal vectors, and Ko *et al.* [21] presented a method that uses a combination of modal assurance criterion (COMAC) and sensitivity analysis to detect damage in steel-framed structures. Finally, a damage signature based on the mode shape normalized by the change in the modal frequency of another mode is proposed in [22], as a way to combine frequency shift and changes in mode shapes as damage indicators.

More recent investigations apply the wavelet transform (WT) as a signal-processing tool to highlight the presence of discontinuities in the modal deflections. The spatial information resulting from multipoint measurements are fed to wavelet algorithms to obtain information regarding anomalies related to damage in the deformed shapes. Plots obtained upon the wavelet analysis localize the damage and may be used, after proper calibration, to quantify the extent of damage [23–25]. Figure 1(b) shows, for example, the WT analysis of the fourth mode of the cracked beam shown in Figure 1(a), as presented in [23]. The considered WT of the spatial modal signal clearly locates the damage along the beam length and can be used to monitor its progression through the thickness. Results for plates using a similar approach are presented in [24].

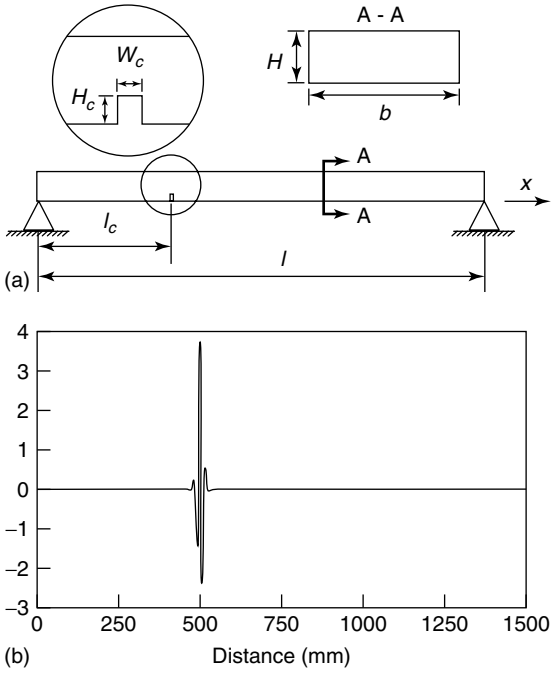

Figure 1. Configuration of cracked beam (a) and result of WT decomposition of fourth mode (b) (from [23]).

2.3 Mode-shape curvature changes

An alternative to using mode shapes to obtain spatial information about structural changes is using mode-shape derivatives, such as curvatures or strain energy distributions obtained from spatial integration of curvature modes. For example, in 1991 Pandey *et al.* [26] demonstrated the use of absolute changes in curvature as good indicators of damage for a beam-type structure. They used a central difference-based numerical differentiation technique to compute the curvature from numerically obtained mode shapes. Their results showed that the absolute changes in curvature were localized around the damaged region and that damage could be quantified by establishing a relationship between the changes in curvature and the extent of damage. The evaluation of changes in the curvature of dynamic deflection shapes as a tool for damage detection and localization were also investigated in [10] and subsequently in [11]. In these studies, the dynamic behavior of beams with notch defects and delaminations was studied analytically and experimentally. Analytical models described the dynamic behavior and the curvature modes of cracked beams through perturbation of the modal parameters of the undamaged beams, so that approximated analytical expressions for the damaged modes were obtained. The analytical studies were supported by experimental investigations performed on simple beam structures. Their results show the potentials of the technique when applied to the first mode of the beam. The limitation to a single mode was

mainly dictated by the limited spatial resolution available in the accelerometers-based experiments. Ho and Ewins [27] formulated a damage index defined as the quotient squared of the corresponding modal curvatures of the undamaged and damaged structure. The damage index was found to be highly susceptible to noise as measurement errors were amplified owing to second-derivative computations based on numerical techniques. They also demonstrated that spatially sparse measurements adversely affect the performance of the damage index. As an alternative, Ho and Ewins [28] investigated the changes in the square of the slope of mode shapes of beams. Oscillations in the slope computations were reduced through polynomial fit of the measured mode shape as compared to the use of finite difference approximation. They also reported that higher derivatives can be more sensitive to damage, but are more subject to numerical errors.

2.4 Damage measure based on energy functional distributions

Other authors have used curvatures for the evaluation of the strain energy distribution over the structure under consideration. This approach has been pursued, for example, by Kim and Stubbs [29] to formulate a damage index based on the comparison of strain energy distributions for damaged and undamaged structures. In [29], and in the subsequent papers by the same authors, the technique is applied to beam structures using mode shapes, ODSs, or time-domain data to obtain information on both damage location and extent. The same technique was extended to plate structures in [30], where accelerometers are used to measure the deflections to be interpolated for successive differentiation. The basis of the technique can be easily illustrated in the case of a beam in bending, for which the strain energy is given by

$$U_i = \frac{1}{2}\int_0^L EI(x)\phi_i^2(x)_{,xx}\,\mathrm{d}x \tag{6}$$

with L and EI denoting the beam's length and flexural stiffness, respectively, while $\phi_{i(x)}$ is the beam's ODS corresponding to its excitation at the ith natural frequency. The beam is subdivided into N regions so that its total strain energy can be expressed as [30] (Figure 2):

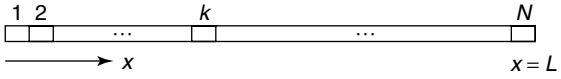

Figure 2. Schematic of beam divisions.

$$U_i = \frac{1}{2}\sum_{k=1}^{N} EI_k \int_{x_k}^{x_{k+1}} \phi_i^2(x)_{,xx}\,\mathrm{d}x$$

$$U_i = \sum_{k=1}^{N} U_{i_k} \tag{7}$$

where it is assumed that the flexural rigidity of the beam over each region is constant. In addition, it is assumed that damage is localized in a single region $k = p$, and that at the damage location,

$$\frac{U_{i_p}}{U_i} \approx \frac{U_{i_p}^*}{U_i^*} \tag{8}$$

so that an estimation of the reduction in stiffness rigidity can be obtained as

$$\frac{EI_p^*}{EI_p} \approx \frac{U_i^*}{U_i}\frac{\displaystyle\int_{x_p}^{x_{p+1}} \phi_i^2(x)_{,xx}\,\mathrm{d}x}{\displaystyle\int_{x_p}^{x_{p+1}} \phi_{i^*}^2(x)_{,xx}\,\mathrm{d}x} = f_{i_p} \tag{9}$$

where the ratio f_{i_p} is the considered damage measure. The damage measure is expected to be equal to 1 over the undamaged regions, and different than one over a damaged region. It is, in general, convenient to combine information obtained from the analysis of several modes (I) and therefore to consider a cumulative damage measure, defined as

$$f_k = \frac{1}{I}\sum_{i=1}^{I} f_{i_k} \tag{10}$$

This cumulative index provides a single piece of information, which combines the results from several ODSs and associated strain energy distributions. ODSs are not affected by damage because their particular location will not contribute, i.e., they will give unit contributions, whereas the index for modes altered by the defect will be combined to provide a robust indication of a defect.

2.5 Interpolation of the measured response and synthesis of undamaged baseline

The damage index as proposed in [30] is based on a comparison between damaged and undamaged strain energy over the considered region of the structure. In practice, however, it may be difficult to have or obtain baseline information from the structures to be analyzed. This, in fact, assumes that either an undamaged specimen or historical data of the same kind as those currently being collected are available. This limitation can be overcome in the presence of high spatial resolution of the measurements, as provided, for example, by SLDVs. The technique introduced in [8] synthesizes undamaged information through spatial decimation of the response. In the proposed approach, the ODSs are measured at several locations over the structure, so that spatial derivatives can be accurately estimated through spline interpolation of the measured data. The ODS $\phi(x, y)$ for a plate structure can, for example, be approximated as

$$\phi(x, y) \cong \sum_{p,q} h_p(x) h_q(y) \Phi_{p,q} \qquad (11)$$

where $\Phi_{p,q}$ defines the value of the ODS measured experimentally at the sensor location p, q, or at a point of an SLDV grid, while $h_p(x), h_q(y)$ are spline basis functions. The curvature estimations can be obtained by taking derivatives of the spline functions, while keeping the nodal or measured values as weighting parameters.

Baseline information can be generated by using a subset of the measurement points. The baseline interpolated deflection can be expressed as

$$\phi^*(x, y) \cong \sum_{r,s} h_r(x) h_s(y) \Phi_{r,s} \qquad (12)$$

where r, s are a subset of the measurement grid points p, q, such that $r < p, s < q$. The resulting undersampling of the data has the purpose of intentionally "missing" any discontinuity or anomaly corresponding to damage, which can generally be detected only through a refined measurement grid. The baseline information can be then differentiated and used for the estimation of the strain energy generically denoted as U^*.

This technique is demonstrated experimentally on a thin aluminum plate with artificially induced damage. The plate measures 35.6 cm × 35.6 cm × 0.10 cm (14″ × 14″ × 0.4″), and it is cantilevered at the base. A piezoceramic disc of 2.79 cm (1.1″) diameter and 0.076 cm (0.030″) thickness is used as an exciter. The plate, with actuator and damage location, is shown in Figure 3. The damage is a 3.6 cm (1.41″)-long, 1.3 mm (0.05″)-wide, and 0.4 mm (0.015″)-deep groove, which was cut in the plate at the location shown. The forced response at the plate's natural frequencies in the excitation range and the corresponding curvatures are evaluated. The modal damage measure shown in Figure 4(a) clearly highlights the location of damage in the plate. Some deviation from unity can be observed at other locations, one of them being located close to the exciter and the other most likely due to measurement and/or numerical noise. This spurious information can be effectively filtered out by considering a cumulative index obtained from the superposition of several modal information. The cumulative index obtained from the superposition of the first five modes of the plate is shown in Figure 4(b), which provides an unambiguous indication about damage presence and location.

The procedure is also demonstrated on the wing skin of an F15 aircraft. The part is a complex structure with rivet holes, thickness variations, and stiffeners manufactured integrally with the skin. The

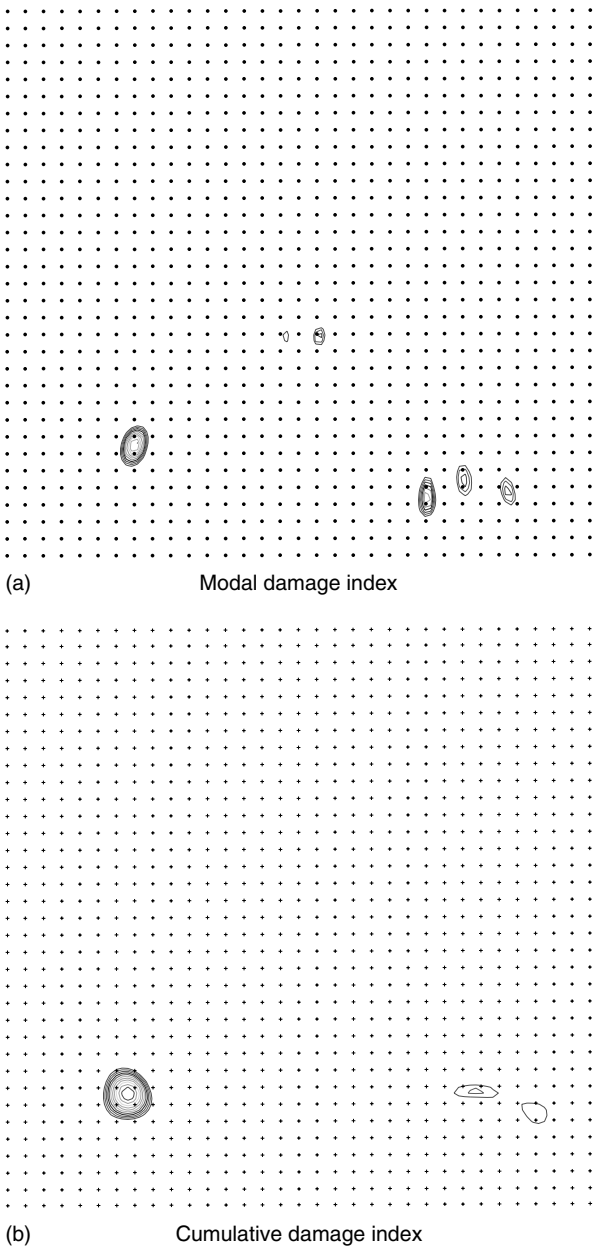

Figure 4. Modal (a) and cumulative (b) damage index.

material of the part is aluminum, and the base thickness is equal to 3.2 mm (1/8″). Figure 5 shows pictures of the front and back of the component to highlight its complexity. In the laboratory setup, the part is hung using elastic bands to fixed rails mounted on the ceiling. Damage is artificially created in a region between two stiffeners. The considered damage is a 3.8 cm (1.5″)-long slit, which causes approximately a 30% reduction in the skin thickness. Modal testing is performed by exciting the skin through a piezoelectric actuator placed at the location shown in Figure 6(a). The deformed configurations

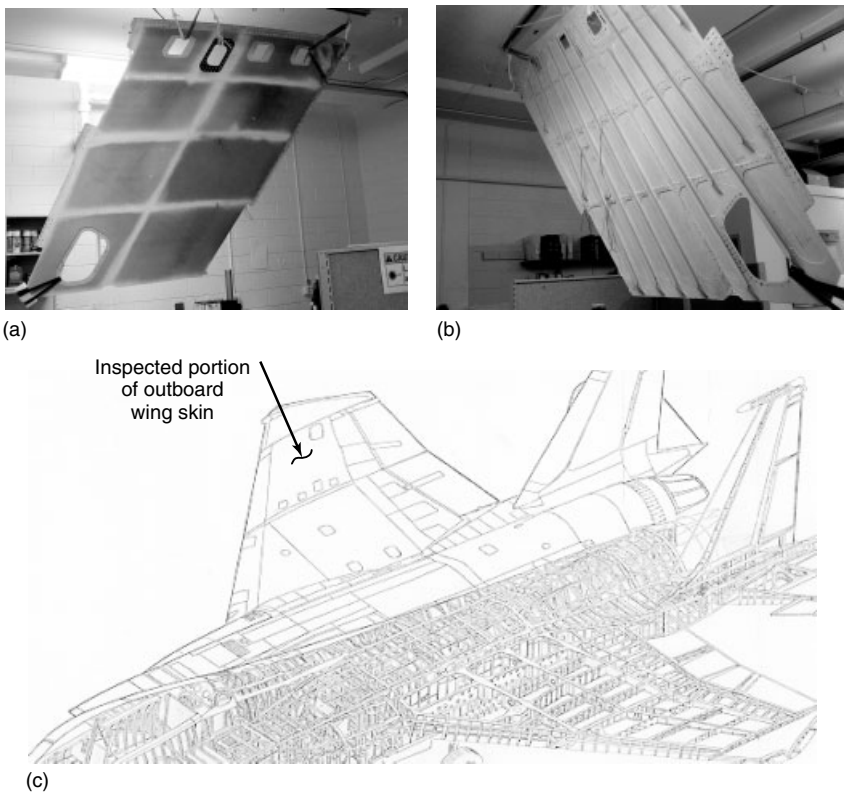

Figure 5. F15 wing skin: front (a) and back (b) views, and location of component on the aircraft (c).

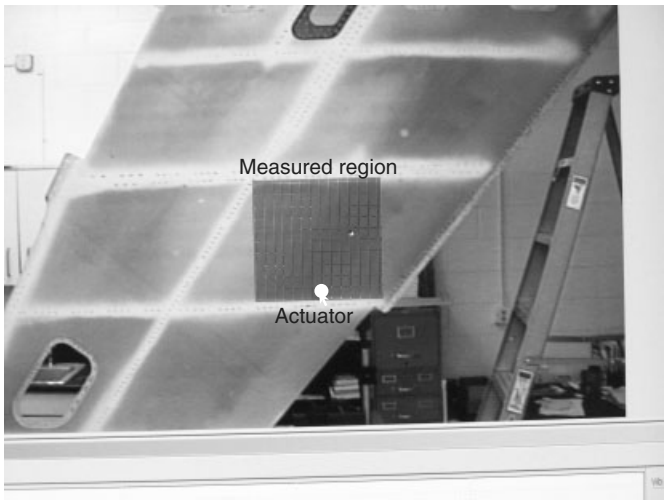
obtained are used to evaluate the energy distribution over the monitored region and the corresponding damage measure, whereby the decimation of the full data set is used to generate baseline information. The damage measure map resulting from the combination of the first 10 modes of the skin is shown in Figure 6(b). The map clearly shows the presence of damage, which is highlighted as a dark region on the white background corresponding to the unit value.

3 GUIDED ULTRASONIC WAVES-BASED DAMAGE MEASURES

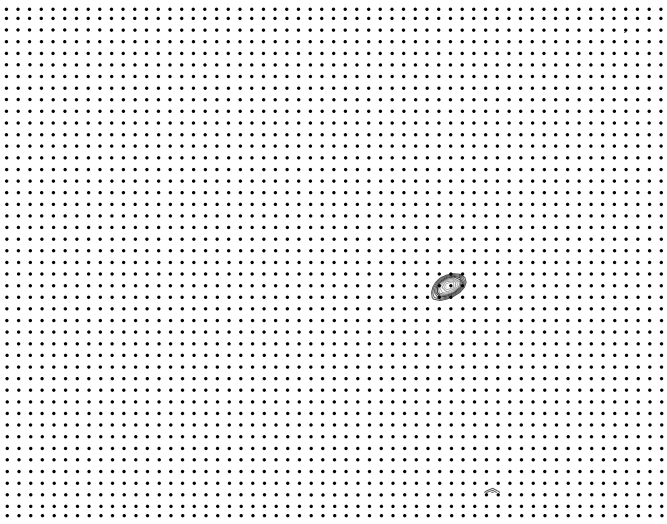
The application of GUWs as inspection tools for SHM is receiving attention by a large number of researchers. The most attractive feature is the ability of GUWs to travel long distances in plate and shell-like structures, which makes the inspection of large areas possible. The complicating factors are the multi-modal and dispersive natures of GUW signals, which require the development of proper interpretation tools. The objective is the extraction of relevant features from the recorded response, which may be related to damage.

3.1 Signal processing

In this regard, proper signal-processing algorithms are essential features of GUW-based SHM techniques. Overviews of signal-processing strategies used for GUW interpretation and damage measure formulation can be found in [3, 5]. Time frequency transforms (TFTs) are well-suited for the analysis, decomposition and denoising of GUW signals, which are typically nonstationary. Short time Fourier transforms (STFT) [31], Wigner–Ville distributions (WVD) [32, 33], and, more recently, the Hilbert–Huang transform (HHT) [34, 35] are examples of



(a)



(b)

Figure 6. Measurement grid considered for modal testing (a) and resulting damage index map (b).

various techniques used to observe the propagation of various modes, to separate reflections from incident waves, and to formulate associated damage measures. The WT in its various forms is a very important and versatile tool, used extensively for denoising, as well as for feature extraction and selection [3]. The discrete wavelet decomposition is applied, for example, in [36] as part of a feature extraction and automatic classification framework developed for GUW inspection of pipes. Reflection measurements are taken to construct a six-dimensional damage index, which is fed to a neural network (NN), tasked to evaluate size and location of a notch damage. The damage index compares features f_i $(i = 1, \ldots, n)$ associated with the reflected signal with the corresponding ones in the signal traveling from transmitter to receiver:

$$DI = \frac{f_i^{(\text{Reflec})}}{f_i^{(\text{Direct})}} \tag{13}$$

Results are presented to show the monotonic variation of the damage index in terms of the defect size, and the effectiveness of the considered features as inputs to the NN for classification purposes. The STFT is applied in [37] to select and isolate the first symmetric mode (S0), known for being particularly sensitive to crack-type damages, and to formulate the following damage index:

$$DI = \left[\frac{\int_{t_i}^{t_f} |S_{\mathrm{sc}}(\omega_0, t)|^2 \, \mathrm{d}t}{\int_{t_i}^{t_f} |S_{\mathrm{b}}(\omega_0, t)|^2 \, \mathrm{d}t} \right]^{\alpha} \tag{14}$$

where S_{sc} is the time varying spectral amplitude of the scattered signal, S_{b} is the corresponding amplitude for a baseline signal, ω_0 is the excitation frequency, t_i and t_f are time bounds, and α is a gain factor set to better match experimental fatigue crack growth trends. The damage measure obtained using built-in piezoceramics showed a good correlation with crack growth observed by visual inspection, and an alternative formulation based on the energy of the A0 mode is suggested for the detection of disbonds.

A network of sensors is used to construct GUW tomograms used to inspect anisotropic composite plates in [38]. The approach accounts for attenuation in the composite material by using the energy of the earliest wave signals as the reconstruction parameter, and by normalizing the wave energy of the defective sample with respect to that of the undamaged one. For quantitative comparisons between tomograms, a parameter β is introduced as the ratio of the considered values in the defect-free region to that of the defective region of a tomogram.

Higher dimensional Fourier transforms (FTs), transforming the signal in the wavenumber/frequency domain, are also used to identify wave modes and to investigate mode conversion phenomena caused by crack-like damages [39]. Examples of numerical investigations of mode conversion phenomena can be found in [40]. Recently, Ruzzene [41] has applied two-dimensional and three-dimensional FTs as tools to decouple incident and reflected waves, and to filter out the incident component from the recorded signal. The experimental application of this concept is enabled by the application of the SLDV, which easily provides the spatial measurement resolution needed to perform FTs in the spatial domain. A damage measure based on this concept is currently in the works. The SLDV was also used by Staszewski *et al.* [42] to investigate maximum amplitudes of low-frequency Lamb waves propagating in plate structures. Amplitude reductions and sudden increases across the defect were considered as indicators of damage.

3.2 Pattern recognition

As in [36], signal-processing tools are often combined with tools that are able to classify the identified signal features and relate them to damage type and extent. The most common technique for pattern recognition is certainly the use of NNs. Examples of their application for GUW SHM can be found in [43], where spectrographic features from Lamb wave signals in the time-frequency domain were used to construct a damage parameters database, through which an NN was then trained for its successive use for the identification of delaminations in quasi-isotropic composite laminates. A multilayer perceptron (MLP) NN is used in [44] as part of a novelty detection method. The technique is applied to a thin, isotropic plate, where GUWs are sequentially transmitted and captured by eight piezoelectric patches bonded on the plate to act both as sensors and actuators. Scattering waveform responses representing normal and damaged conditions are transformed into a set of novelty indices that are fed as inputs to the NN, incorporating the MLP architecture to compute and predict the damage location on the plate.

3.3 Strain energy distribution

The technique presented in Section 2.4, can be easily adapted to transient time signals corresponding to GUW propagation. The strain energy distribution of equation (9) can be rewritten in terms of displacements $w(x, t)$ and corresponding curvatures in the time domain:

$$U_i(t) = \frac{1}{2} \int_0^L EI(x) w_{,xx}(x, t)^2 \, \mathrm{d}x \tag{15}$$

Again, undamaged, or baseline, information can be synthesized through the decimation process described

in Section 2.5, assuming a sufficient number of measurement locations is available. This formulation leads to a time-dependent damage measure, which can be represented as maps that evolve over time as waves propagate within the structure. The advantages of a time-domain damage measure include the possibility of limiting the investigation to a particular time window. In fact, a recognized problem in wave-propagation-based inspections arises when the incoming wave hides the presence of damage and the resulting wave reflections. The analysis of the trailing part of the wave, after the main pulse has decayed, is often rich in information regarding damage location and extent, as damage generally behaves like a secondary wave source. The considered time-domain formulation allows to select the time interval, where structural response and associated energy distribution are most affected by damage. Examples of results obtained through this approach are presented in the following. Wave propagation tests are performed on the F15 wing skin previously considered. A 40 kHz, five-cycle sinusoidal burst excites the structure through a piezoelectric actuator. A snapshot of the recorded response is shown in Figure 7, which demonstrates the complexity of the wavefield as a result of the structural complexity. In particular, it is shown how the stiffeners tend to reflect the wave and cause it to propagate perpendicular to their length. Such a behavior makes the interpretation of the signals through standard time-of-flight estimation particularly difficult, as it would be almost impossible to differentiate multiple reflections from the one associated with the damage. The

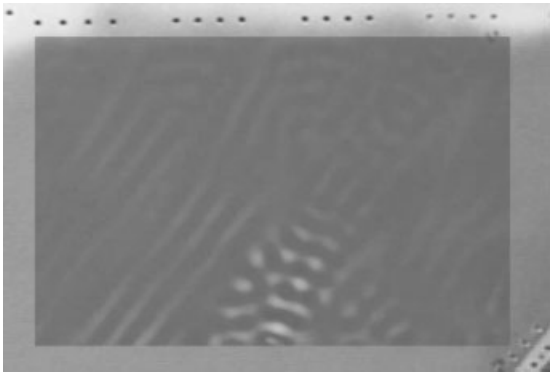


Figure 7. Snapshot of F15 wing skin response resulting from excitation at 40 kHz.

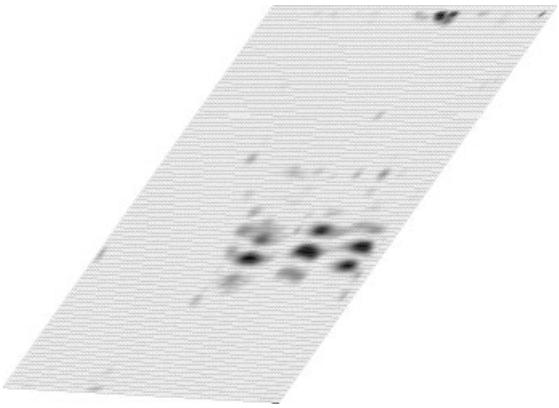

Figure 8. Damage measure evaluated on F15 wing through wave-propagation analysis.

application of the considered damage measure, on the contrary, does not require previous knowledge of the response of the structure, nor does it rely on the availability of a model. It thus represents an attractive solution for the analysis of complex or built-up structures. The damage measure maps obtained on the restricted region, defined by the results of the modal tests described in Section 2.4, are shown in Figure 8, which clearly outline the longitudinal extension and the location of the crack. Results from the experiments conducted on a 1.3 mm (0.050″)-thick metal rib from an F15 aircraft wing are also illustrated. The specimen was removed from service because of the hairline crack in the flange, which can be observed in Figure 9. A piezoceramic actuator was mounted at the location shown in the figure and used to excite elastic waves in the specimen. The excitation is a sinusoidal burst at 35 kHz, which is a frequency that provides the best compromise between short wavelength and wave attenuation through the specimen. The time history corresponding to the propagating elastic wave is recorded at the scan points represented by the dots in Figure 10. The measured displacements are then used as a basis for the interpolation of the response of the scanned region and for the successive formulation of the damage measure in the time domain, which is shown, upon summation over time, in Figure 10. The contours clearly highlight the hairline crack and vividly outline its shape, thus providing its initial characterization.

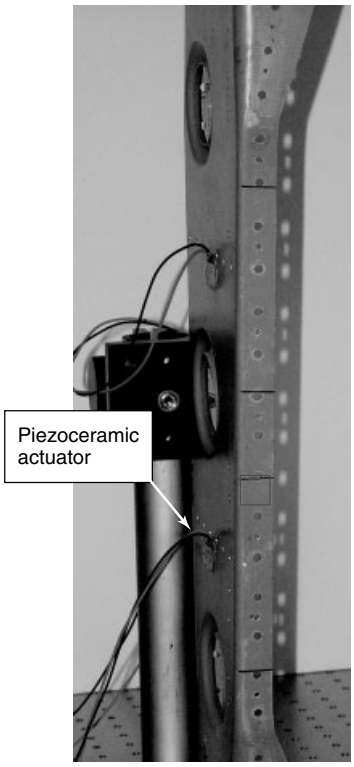

Figure 9. F15 rib.

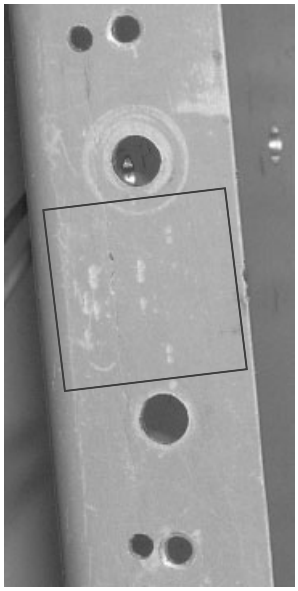
4 CONCLUSIONS

This article is devoted to vibration-based and wave-propagation-based inspection techniques and to the formulation of damage measures. The overview presents a limited range of solutions proposed in the last 15–20 years, and does not claim to be all-inclusive and exhaustive, due to the wealth of literature available in the field. The presented techniques and the list of references should, however, be sufficient to guide a researcher beginning investigations in this area. The article does not address nonlinear techniques, both in the modal and wave-propagation domains, which, however, are very promising and should be considered as natural extensions of most of the techniques presented earlier. Among the nonlinear techniques, nonlinear acoustics for the evaluation of nonlinear stress–strain parameters as damage precursors and indicators is an area that has received much attention, and that still holds great promises for future research contributions.



(a) Detail of the crack

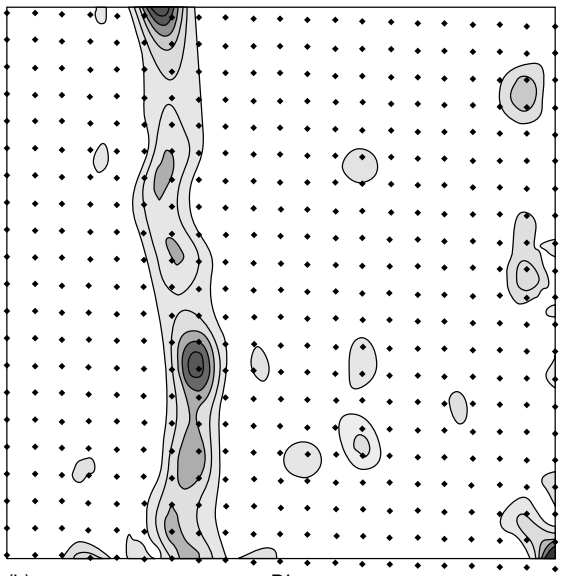


Figure 10. Detail of crack and time-domain damage measure evaluated at 35 kHz.

Future challenges consist in the development of novel and robust interpretation algorithms, as well as in the implementation of novel actuation and sensing strategies. The results presented, in fact, show that detailed spatial measurements provide an enormous

amount of information, which can be exploited in several ways to identify, locate, and quantify damage. Nowadays, such spatial refinement can only be achieved through complex, and often bulky, equipment, or lengthy inspections, and great advantages may be gained if similar detail could be achieved with portable, or *in situ*, devices. The development of such systems could lead to significant advancements in the general area of SHM.

Chapter 49

Modeling of Lamb Waves in Composite Structures

Abir Chakraborty

India Science Laboratory, General Motors R & D, Bangalore, India

1 INTRODUCTION

The methodology of assessing the integrity of structural composites, traditionally based on nondestructive techniques (NDT), has evolved into the generic field of structural health monitoring (*see* **Lamb Wave-based SHM for Laminated Composite Structures**). In NDT, propagation of elastic waves in structures is used to probe for the existence of damage, its location, and its severity. For composite structures, complexity increases owing to the anisotropic and inhomogeneous nature of the constituent materials and the architecture of the composite itself. Further, because of the layered structure of composites, generated waves get reflected and transmitted multiple times resulting in a complex wave pattern and making it difficult to interpret the signal. The boundaries are also responsible for the creation of new kinds of waves. For example, when elastic waves propagate in an isotropic platelike structure, they would experience repeated reflections at the top and bottom surfaces alternately and a new kind of wave—called the *Lamb wave*—is generated from the original primary and secondary waves. Thus, the Lamb wave is a guided wave [1] (*see* **Fundamentals of Guided Elastic Waves in Solids**) propagating in a domain bounded by two parallel traction-free surfaces. The importance of the Lamb wave in NDT applications lies in its ability to inspect large areas at a time by propagating a long distance without attenuation. Hence, the Lamb wave finds immense application in structural health monitoring for ultrasonic inspection of platelike aircraft components, missile cases, pressure vessels, oil tanks, pipelines, etc (*see* **Ultrasonic Methods**).

Classical wave analysis begins with the plane-wave assumption (harmonic dependence of the displacement field on the spatial and temporal variables), i.e.,

$$\mathbf{u}(x, y, z, t) = \mathbf{A}\exp(j(k_x x + k_y y + k_z z - \omega t) = \mathbf{A}\exp(j(\mathbf{k}\cdot\mathbf{x} - \omega t), \quad j^2 = -1 \quad (1)$$

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

where boldface letters denote vectors or matrices. The unknowns in this case, i.e., the wave amplitude vector **A** and the wavenumbers k_x, k_y, and k_z are related to the excitation frequency ω. Substitution of the assumed form of the displacement field in the governing equations

$$\sigma_{mn,\,n} = \rho \ddot{u}_m, \quad \sigma_{mn} = C_{mnpq}\varepsilon_{pq} \tag{2}$$

results in the algebraic form of the governing equation:

$$(\Gamma_{mn} - \rho\omega^2\delta_{mn})A_n = 0, \quad \Gamma_{mn} = C_{mnpq}k_p k_q \tag{3}$$

which is an eigenvalue problem for ω. The characteristic polynomial Γ provides the necessary relation between the wavenumbers and frequency, called *the dispersion relation*. The dispersion relation is also expressed in terms of the frequency and phase speed vector ($\mathbf{c}_\mathrm{p}$)

$$\mathbf{c}_\mathrm{p} = \frac{\omega(\mathbf{k})}{|\mathbf{k}|}\mathbf{k}, \quad \mathbf{k} = (k_x, k_y, k_z) \tag{4}$$

and the frequency and group speed vector ($\mathbf{c}_\mathrm{g}$)

$$\mathbf{c}_\mathrm{g} = \nabla_\mathbf{k}\omega(\mathbf{k}) \tag{5}$$

For isotropic materials, the group speed vector points toward the direction of energy propagation. The group speed is also of higher significance than phase speed as it is related to one of the important parameters of NDT methods, the time of flight. Thus, the first step toward wave analysis is finding out the dispersion relation and the second step is finding out the time-domain response using this relation.

It is to be noted that the governing equation provides only one condition to be satisfied by **k** and ω. However, for the three components of **k** to be completely determined by ω, it is necessary to have three conditions. In the absence of these extra conditions, a few of them are to be assumed, and the rest are expressed in terms of the assumed ones. Thus, for the analysis of three-dimensional (3-D) media of infinite extent, two components of **k** are to be provided, and the third component is solved from the dispersion relation. In this case, the phase and group speed are constant, and the waves are nondispersive in nature. For isotropic material, only two kinds of waves can propagate in a 3-D unbounded media. They are called *dilatational (primary or P-wave)* and *shear (secondary or S-wave) waves*. Further, depending upon the plane of propagation, shear waves are categorized as shear vertical (SV) and shear horizontal (SH) waves. However, for anisotropic material, clear distinction between the P and S waves cannot be made, and they are referred to as *quasi-P* and *quasi-shear* waves.

In the case of singly or doubly bounded media, where the boundary comes into play, the speeds become functions of ω and the waves become dispersive, i.e., they cannot retain their shape while propagating. Historically, the dispersion relation for an elastic isotropic plate with infinite extent in plane strain state was first derived by Lamb [2], thus marking the beginning of a new kind of wave. The presence of boundary imposes another condition to be satisfied by the components of **k** and ω. For the analysis of 2-D media, this extra condition is sufficient to calculate **k** for a given ω. However, for 3-D geometry, one of the wavenumber components should be assumed.

The Lamb wave propagates in doubly bounded media and traction-free boundary conditions are to be imposed at the edges. Imposition of this condition restricts the freedom of choosing wavenumber components and only few admissible wavenumbers exist at a particular frequency. These wavenumbers constitute the fundamental modes of propagation, similar to the fundamental modes of vibration (standing wave). As happens in the latter case, excitation frequency determines modal participation of the Lamb wave modes. Thus, it is necessary to have information about the modes in advance to analyze the wave generated by the actuators.

For isotropic materials, it is possible to distinguish between the symmetric and antisymmetric modes (Figure 1). However, for composite materials, as stated before, this kind of distinction is hard to make. In the case of symmetric laminates, it is possible

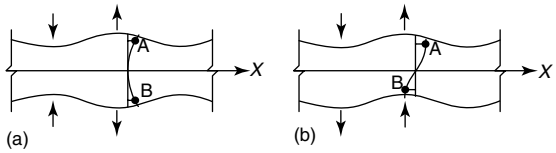

Figure 1. (a) Symmetric Lamb wave propagation and (b) antisymmetric Lamb wave propagation.

to separate the Lamb waves into symmetric and antisymmetric modes. For symmetric modes, one type is designated as quasi-extensional (qS_n), where the dominant component of the polarization vector is along the propagation direction, and the other type is quasi-horizontal shear (qSH_{2n}), where the polarization vector is mainly parallel to the plane of the plate. Similarly, for the antisymmetric types of wave modes, the quasi-flexural (qA_n) and quasi-horizontal shear (qSH_{2n-1}) waves are generated.

In general, there are two theoretical approaches to investigate Lamb waves in composites: one is the exact solution by 3-D elasticity theory, and the other involves approximate solutions by plate theories. For the approach using 3-D elasticity, Nayfeh and Chimenti [3] gave dispersion relations of Lamb waves in a composite lamina. Later, Nayfeh [4] developed the transfer matrix technique to obtain the dispersion curves for Lamb waves in laminates. In this method, the displacements and stresses of one interface are related to the other interface by a system matrix developed from the governing equation and stress displacement relation. This matrix is assembled for more than one layer, and the resulting system needs to be solved after imposing the boundary conditions. A comprehensive review of the theories and applications of Lamb waves is given by Chimenti [5]. Although the exact solutions provide accurate results, the computation for dispersion characteristics of multilayered composites is intensive because of the transcendental nature of the equations. To circumvent this problem, approximate solutions are obtained from higher order laminated plate theories. There are other analytical–numerical approaches for modeling Lamb waves, e.g., on the basis of discrete layer theory and multiple integral transform [6], coupled finite element (FE)–normal mode expansion method [7], or boundary element–normal mode expansion method [8]. The conventional FE method is suitable only for wave propagation simulation, and no information can be obtained for the dispersion relation.

The assumed form of the displacement field indicates an integral transform-based approach for wave-propagation analysis. The spectral finite element method (SFEM) is a confluence of the Fourier transform and conventional FE-based matrix approach, which is an inexpensive way of constructing the Lamb wave modes as well as predicting time-domain signals [9–15]. The SFEM in two dimensions (2-D) is based on simplified geometry like layered media and the method is not vastly different from the transfer-matrix-based method [16–18]. However, the stiffness matrix form, along with the exact representation of the layer, makes it more efficient for modeling multiple layers and for analyzing high-frequency impact loading. The complete solution in SFEM is formulated on the basis of the partial wave technique (PWT). In the PWT-based method of Lamb wave analysis, once the partial waves are found, the wave coefficients are made to satisfy the two nonzero tractions specified at the top and bottom of the layer. In the general case, the formulation is slightly different, as no specific problem-oriented boundary conditions are imposed. Thus a system matrix is established, which relates the tractions at the interface to the interfacial displacements. This generalization enables the use of the system matrix as a finite-element dynamic stiffness matrix, although formulated in the frequency–wavenumber domain. These matrices can be assembled to model different layers of different ply orientation or inhomogeneity, which obviates the necessity for the cumbersome computation associated with multilayer analysis [19]. The only shortcoming of the method is that each spectral layer element (SLE) can accommodate only one fiber angle; thus for different ply stacking sequences, the number of elements will be at least equal to the number of different ply angles in the stacking.

In the next section, the procedure for solving the 2-D elastodynamic equation is outlined for arbitrary load and boundary conditions. Then, the method of obtaining the Lamb wave modes from the 2-D solutions is discussed. Next, different beam theories are evaluated to predict Lamb modes, which are subsequently compared with the 2-D solutions. Finally, the propagation of the lower-order Lamb waves is simulated.

2 SOLUTION OF 2-D ELASTICITY EQUATION

It is assumed that there is no heat conduction in and out of the system, the displacements are small, the material is homogeneous and anisotropic, and the domain is 2-D Euclidean space. The general elastodynamic equation of motion for three dimensions is given by

$$\sigma_{ij,j} = \rho(x_1, x_2, x_3)\ddot{u}_i, \quad \sigma_{ij} = C_{ijkl}(x_1, x_2, x_3)\varepsilon_{kl}$$
$$\varepsilon_{ij} = \frac{(u_{i,j} + u_{j,i})}{2} \tag{6}$$

where comma (,) and dot ($\dot{}$) denote partial differentiation with respect to the spatial variables and time, respectively.

For 2-D model with orthotropic material construction, complexity of the above equation can be further reduced by the following assumptions: the nonzero displacements are $u_1 = u$ and $u_3 = w$ in the direction $x_1 = x$ and $x_3 = z$, respectively (Figure 2). Then the nonzero strains are related to these displacements by

$$\varepsilon_{xx} = u_x, \quad \varepsilon_{zz} = w_z, \quad \varepsilon_{xz} = u_z + w_x \tag{7}$$

The nonzero stresses are then related to the strains by the relation

$$\sigma_{xx} = Q_{11}\varepsilon_{xx} + Q_{13}\varepsilon_{zz}$$
$$\sigma_{zz} = Q_{13}\varepsilon_{xx} + Q_{33}\varepsilon_{zz}, \sigma_{xz} = Q_{55}\varepsilon_{xz} \tag{8}$$

where Q_{ij}'s are the stiffness coefficients, which depend on the ply lay up, its orientation, and the z coordinate of the layer. Substituting equation (8) in equation (6) and imposing the assumptions, the elastodynamic equation for 2-D homogeneous orthotropic media is given by

$$Q_{11}u_{xx} + (Q_{13} + Q_{55})w_{xz} + Q_{55}u_{zz} = \rho\ddot{u}$$
$$Q_{55}w_{xx} + (Q_{13} + Q_{55})u_{xz} + Q_{33}w_{zz} = \rho\ddot{w} \tag{9}$$

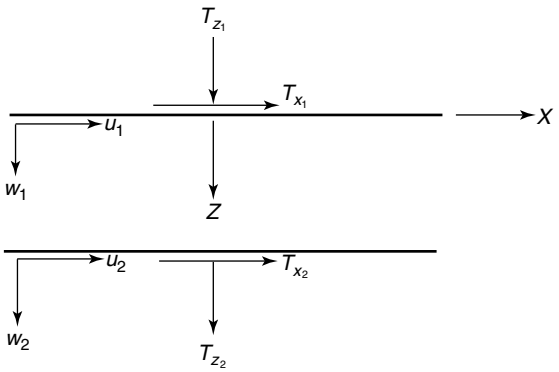

Figure 2. Spectral finite element and the associated degrees of freedom.

We attempt to reduce the governing partial differential equations (PDEs) to a set of ordinary differential equations (ODEs). For this, we need to remove two variables out of the system and introduce two new parameters instead. To achieve this, we take Fourier transform in time and Fourier series in space. With this assumption, the spectral form of the displacement field becomes

$$u(x, z, t) = \sum_{n=1}^{N-1}\sum_{m=1}^{M-1} \hat{u}(z, \eta_m, \omega_n) \begin{Bmatrix} \sin(\eta_m x) \\ \cos(\eta_m x) \end{Bmatrix} \mathrm{e}^{-j\omega_n t} \tag{10}$$

$$w(x, z, t) = \sum_{n=1}^{N-1}\sum_{m=1}^{M-1} \hat{w}(z, \eta_m, \omega_n) \begin{Bmatrix} \cos(\eta_m x) \\ \sin(\eta_m x) \end{Bmatrix} \mathrm{e}^{-j\omega_n t} \tag{11}$$

where ω_n is the discrete angular frequency and η_m is the discrete horizontal wavenumber. As the assumed field suggests, for $M \to \infty$, the model has infinite extent in the positive and negative X direction, although the domain is finite in the Z direction, i.e., it is a layered structure. In particular, the domain can be written as $\Omega = [-\infty, +\infty] \times [0, L]$, where L is the thickness of the layer. The boundaries of any layer are specified by a fixed value of z. The X dependency of the displacement field (sine or cosine) is determined on the basis of the loading pattern. In all subsequent formulation and computation, symmetric load pattern is considered, i.e., $\sin(\eta_m x)$ for u and $\cos(\eta_m x)$ for w. The real computational domain is $\Omega_c = [-X_L/2, +X_L/2] \times [0, L]$, where X_L is the X window length. Discrete values of η_m depend upon the X_L and the number of mode shapes (M) chosen.

This displacement field reduces the governing equations to a set of ODEs as

$$\mathbf{A}\hat{\mathbf{u}}'' + \mathbf{B}\hat{\mathbf{u}}' + \mathbf{C}\hat{\mathbf{u}} = \mathbf{0}, \quad \hat{\mathbf{u}} = \{\hat{u}\ \hat{w}\} \tag{12}$$

where prime denotes differentiation with respect to z. The matrices **A**, **B**, and **C** are

$$\mathbf{A} = \begin{bmatrix} Q_{55} & 0 \\ 0 & Q_{33} \end{bmatrix}$$
$$\mathbf{B} = \begin{bmatrix} 0 & -(Q_{13} + Q_{55})\eta_m \\ (Q_{13} + Q_{55})\eta_m & 0 \end{bmatrix} \tag{13}$$

$$\mathbf{C} = \begin{bmatrix} -\eta_m^2 Q_{11} + \rho\omega_n^2 & 0 \\ 0 & -\eta_m^2 Q_{55} + \rho\omega_n^2 \end{bmatrix} \quad (14)$$

The associated boundary conditions are the specifications of the stresses σ_{zz} and σ_{xz} at the layer interfaces. From equation (8), the stresses are related to the unknowns as

$$\hat{\mathbf{s}} = \mathbf{D}\hat{\mathbf{u}}' + \mathbf{E}\hat{\mathbf{u}},\ \hat{\mathbf{s}} = \{\sigma_{zz}\ \sigma_{xz}\}$$
$$\mathbf{D} = \begin{bmatrix} 0 & Q_{33} \\ Q_{55} & 0 \end{bmatrix}, \quad \mathbf{E} = \begin{bmatrix} \eta_m Q_{13} & 0 \\ 0 & -\eta_m Q_{55} \end{bmatrix} \quad (15)$$

The original boundary-value problem reduces to finding $\hat{\mathbf{u}}$, which satisfies equation (12) for all $z \in \Omega_c$ and specification of $\hat{\mathbf{u}}$ or $\hat{\mathbf{s}}$ at $z = 0$ or $z = L$. Once the solution is obtained for different values of z in the frequency–wavenumber domain ($Z - \eta - \omega$ domain, for given values of ω_n and η_m), summation over η_m brings the solution back to the $Z - X - \omega$ domain and inverse Fourier transform brings the solution back to time domain, i.e., $Z - X - t$ domain.

The solution to these ODEs are of the form $u_0 e^{-jkz}$ and $w_0 e^{-jkz}$, which yields the polynomial eigenvalue problem

$$\mathbf{W}\{\mathbf{u}_0\} = \mathbf{0},\ \mathbf{W} = -k^2\mathbf{A} - jk\mathbf{B} + \mathbf{C},\ \{\mathbf{u}_0\} = \{u_0 w_0\} \quad (16)$$

where $\mathbf{W}$ is the wave matrix given by

$$\mathbf{W} = \begin{bmatrix} -k^2 Q_{55} - \eta_m^2 Q_{11} + \rho\omega_n^2 & jk\eta_m(Q_{13} + Q_{55}) \\ -jk\eta_m(Q_{13} + Q_{55}) & -k^2 Q_{33} - \eta_m^2 Q_{55} + \rho\omega_n^2 \end{bmatrix} \quad (17)$$

The singularity condition of $\mathbf{W}$ yields the following equation for determining the spectrum relation:

$$Q_{33}Q_{55}k^4 + \{(Q_{11}Q_{33} - 2Q_{13}Q_{55} - Q_{13}^2)\eta_m^2 - \rho\omega_n^2(Q_{33} + Q_{55})\}k^2 + \{Q_{11}Q_{55}\eta_m^4 - \rho\omega_n^2\eta_m^2(Q_{11} + Q_{55}) + \rho^2\omega_n^4\} = 0 \quad (18)$$

It is to be noted that for each value of η_m and ω_n, there are four values of k, denoted by $k_{lmn}, l = 1, \ldots, 4$, which are obtained by solving equation 18. Explicit solution of the wavenumber k is $k_{lnm} = \pm\sqrt{-b \pm \sqrt{b^2 - 4ac}}/2a$, where a, b, and c are the coefficients of k^4, k^2, and k^0, respectively, in equation 18.

There are certain properties of the wavenumbers that will be explored now. As can be seen from equation 18, for $\eta_m = 0$, the equation is readily solvable to give the roots $\pm\omega\sqrt{\rho/Q_{33}}$ and $\pm\omega\sqrt{\rho/Q_{55}}$. Since none of the ρ, Q_{33}, or Q_{55} can be negative or zero, these roots are always real and linear with ω. When η_m is not zero, k becomes zero for ω satisfying

$$Q_{11}Q_{55}\eta_m^4 - \rho\omega_n^2\eta_m^2(Q_{11} + Q_{55}) + \rho^2\omega_n^4 = 0$$
$$\text{i.e.,}\quad (Q_{11}\eta_m^2 - \rho\omega^2)(Q_{55}\eta_m^2 - \rho\omega^2) = 0$$
$$\text{i.e.,}\quad \omega = \eta_m\sqrt{Q_{11}/\rho}\,,\quad \eta_m\sqrt{Q_{55}/\rho} \quad (19)$$

which are the cutoff frequencies. For frequencies lower than the cutoff frequencies, the roots are imaginary and nonpropagating, and above these frequencies, the roots are real and propagating. For isotropic materials, the cutoff frequencies are given by $c_p\eta$ and $c_s\eta$ [20]. The current expressions for the cutoff frequencies are also reducible to that of isotropic materials if we identify Q_{11} and Q_{55} with $\lambda + 2\mu$ and μ, respectively, where λ and μ are the Lame's parameters. If we identify the qP wave with Q_{33} (or Q_{11}) and the qSV wave with Q_{55}, then, as the cutoff frequencies suggest, for the same value of η_m, it is the qSV wave that becomes propagating first, since $Q_{11} > Q_{55}$. In Figure 3, the wavenumbers are plotted for three different ply angles, 0°, 45°, and 90°. For all the ply angles, Q_{33} and Q_{55} are assumed 9.69 and 4.13 GPa, respectively. For Q_{11} and Q_{13}, the following values are assumed. For 0°, $Q_{11} = 146.3$ GPa and $Q_{13} = 2.98$ GPa, for 45°, $Q_{11} = 44.62$ GPa and $Q_{13} = 1.62$ GPa, and for 90°, $Q_{11} = 9.69$ GPa and $Q_{13} = 2.54$ GPa. In Figure 3, the imaginary part of the wavenumbers is plotted in the horizontal plane and the real part in the vertical plane. Further, the imaginary part of the wavenumbers for 0° and 90° are plotted on the positive side, whereas for 45° it is plotted on the negative side, for distinction. Two different η_m values are considered. The linear variation of the real part of the wavenumbers are for $\eta_m = 0$ and the variation for the rest of

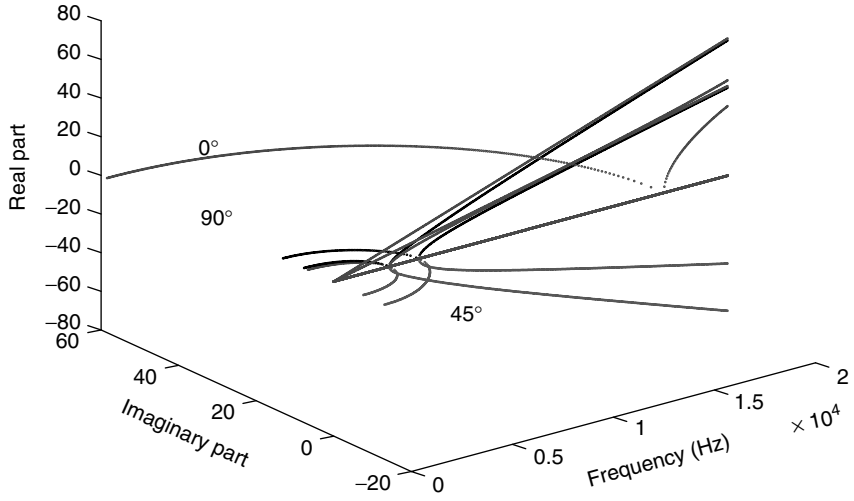

Figure 3. Variation of wavenumber with ω_n ($\eta_m = 10$).

the plots are for $\eta_m = 10$. As discussed previously, the slope of the linear portion depends upon Q_{33} and Q_{55}, and as they are equal for all the ply angles, this part is common for all the ply angles. The difference comes in the imaginary part and the cutoff frequencies. Two different cutoff frequencies are seen in the figure for each ply angle, where the largest value is for the 0° ply angle because of the large Q_{11} value. Further, the shear cutoff frequency is the same for all the ply angles as Q_{55} is the same for all the cases.

Once the required wavenumbers k for which the wave matrix $\mathbf{W}$ is singular are obtained, the solution $\mathbf{u}_0$ at frequency ω_n and wavenumber η_m is

$$u_{nm} = R_{11}C_1 e^{-jk_1 x} + R_{12}C_2 e^{-jk_2 x} + R_{13}C_3 e^{-jk_3 x} + R_{14}C_4 e^{-jk_4 x} \quad (20)$$

$$w_{nm} = R_{21}C_1 e^{-jk_1 x} + R_{22}C_2 e^{-jk_2 x} + R_{23}C_3 e^{-jk_3 x} + R_{24}C_4 e^{-jk_4 x} \quad (21)$$

where R_{ij} are the amplitude coefficients to be determined and they are called *wave amplitudes*. For any wavenumber k_p, the wave amplitudes R_{1p} and R_{2p} satisfy the relation

$$W_{11}R_{1p} + W_{12}R_{2p} = 0, \quad W_{21}R_{1p} + W_{22}R_{2p} = 0 \quad (22)$$

Any of these two relations can be used to express one in terms of the other. Once the four wavenumbers and wave amplitudes are known, the four partial waves can be constructed and the displacement field can be written as a linear combination of the partial waves. Each partial wave is given by

$$\mathbf{a}_i = \begin{Bmatrix} u_i \\ w_i \end{Bmatrix} = \begin{Bmatrix} R_{1i} \\ R_{2i} \end{Bmatrix} e^{-jk_i z} \begin{Bmatrix} \sin(\eta_m x) \\ \cos(\eta_m x) \end{Bmatrix} e^{-j\omega_n t} \quad i = 1 \ldots 4 \quad (23)$$

and the total solution is

$$\mathbf{u} = \sum_{i=1}^{4} C_i \mathbf{a}_i \quad (24)$$

Once the solutions of u and w are obtained in the form of equations (20) and (21) for each value of ω_n and η_m, the same procedure as outlined in the 1-D element formulation is employed to obtain the element dynamic stiffness matrix at ω_n and η_m. Thus, the nodal displacements are related to the unknown constants by

$$\{u_{1nm}\ v_{1nm}\ u_{2nm}\ v_{2nm}\}^{\mathrm{T}} = [\mathbf{T}_{1nm}]\{C_1\ C_2\ C_3\ C_4\}^{\mathrm{T}} \quad (25)$$

i.e.,

$$\{\hat{\mathbf{u}}\}_{nm} = [\mathbf{T}_1]_{nm}\{\mathbf{C}\}_{nm} \quad (26)$$

Using equation 15, nodal tractions are related to the constants by

$$\{\hat{\mathbf{t}}\}_{nm} = [\mathbf{T_2}]_{nm}\{\mathbf{C}\}_{nm}$$
$$\{\hat{\mathbf{t}}\}_{nm} = \{\sigma_{zz1},\ \sigma_{xz1},\ \sigma_{zz2},\ \sigma_{xz2}\} \tag{27}$$

where inhomogeneity of the material is used while evaluating the tractions at the nodes.

Explicit forms of $\mathbf{T}_{2nm}$ and $\mathbf{T}_{1nm}$ are

$$\mathbf{T_1} = \begin{bmatrix} R_{11} & R_{12} & R_{13} & R_{14} \\ R_{21} & R_{22} & R_{23} & R_{24} \\ R_{11}\mathrm{e}^{(-jk_1L)} & R_{12}\mathrm{e}^{(-jk_2L)} & R_{13}\mathrm{e}^{(+jk_1L)} & R_{14}\mathrm{e}^{(+jk_2L)} \\ R_{21}\mathrm{e}^{(-jk_1L)} & R_{22}\mathrm{e}^{(-jk_2L)} & R_{23}\mathrm{e}^{(+jk_1L)} & R_{24}\mathrm{e}^{(+jk_2L)} \end{bmatrix} \tag{28}$$

$$\begin{aligned} T_2(1, p) &= -Q_{55}(-jR_{1p}k_p - \eta R_{2p}) \\ T_2(2, p) &= jQ_{33}R_{2p}k_p - Q_{13}\eta R_{1p} \\ T_2(3, p) &= Q_{55}(-jR_{1p}k_p - \eta R_{2p})\mathrm{e}^{(-jk_pL)} \\ T_2(4, p) &= \{-jQ_{33}R_{2p}k_p + Q_{13}\eta R_{1p}\}\mathrm{e}^{(-jk_pL)} \end{aligned} \tag{29}$$

where p ranges from 1 to 4.

Thus, the dynamic stiffness matrix becomes

$$[\hat{\mathbf{K}}]_{nm} = [\mathbf{T}_2]_{nm}[\mathbf{T}_1]^{-1}_{nm} \tag{30}$$

which is of size 4×4 and has the parameters ω_n and η_m. This matrix represents the dynamics of an entire layer of any length L at frequency ω_n and horizontal wavenumber η_m. Consequently, this small matrix acts as a substitute for the global stiffness matrix of FE modeling, whose size, depending upon the thickness of the layer, is many orders larger than the size of the layer element stiffness matrix.

2.1 Prescription of boundary conditions

Essential boundary conditions are prescribed in the usual way as is done in FE methods, where the nodal displacements are simply arrested or released, depending upon the nature of the boundary conditions. The applied tractions are to be prescribed at the nodes. It is assumed that the loading function (for symmetric loading) can be written as

$$F(x, z, t) = \delta(z - z_j) \times \left(\sum_{m=1}^{M} a_m \cos(\eta_m x)\right)\left(\sum_{n=0}^{N-1} \hat{f}_n \mathrm{e}^{(-j\omega_n t)}\right) \tag{31}$$

where δ denotes the Dirac delta function, z_j is the Z coordinate of the point where the load is applied, and the z dependency is fixed by suitably choosing the node where the load is prescribed. No variation of load along the Z direction is allowed in this analysis. $\hat{f}_n$ are the Fourier transform coefficients of the time-dependent part of the load, which are computed by fast Fourier transform (FFT), and a_m are the Fourier series coefficients of the x-dependent part of the load.

There are two summations involved in the solution and the two associated windows, one in time T and the other in space X_L. The discrete frequencies ω_n and the discrete horizontal wavenumber η_m are related to these windows by the number of data N and M chosen in each summation, i.e.,

$$\begin{aligned} \omega_n &= 2n\pi/T = 2n\pi/(N\Delta t) \\ \eta_m &= 2(m-1)\pi/X_L = 2(m-1)\pi/(M\Delta x) \end{aligned} \tag{32}$$

where Δt and Δx are the temporal and spatial sample rates, respectively.

2.2 Determination of Lamb wave modes

As defined earlier, the Lamb waves are guided waves (Figure 1), propagating in a free plate, and the two lateral guiding surfaces are traction free. There are two main approaches to the analysis of the Lamb waves. The first one is the method of potentials. In this method, Helmhöltz decomposition of the displacement field is obtained and the governing equations are uncoupled and written in terms of the potentials. Solutions are sought for these potentials,

which contain four arbitrary constants. The displacement field and the stresses are expressed in terms of the potentials, and the imposition of the traction-free upper and lower surfaces generates the necessary condition for finding the unknown constants and the dispersion equation (see [19]). The advantage of this method is that the symmetric and antisymmetric modes can be isolated during formulation (Figure 1a and b). However, the method is applicable only to the isotropic waveguides.

The second approach is based on the PWT, which is discussed below in detail. In the SLE formulation, there are two summations in the solutions. The outer one is over the discrete frequencies and the inner one is over the discrete horizontal wavenumbers. Each partial wave of equation 24 satisfies the governing PDEs (equation 9), and the coefficients C_i, as a whole, satisfy any prescribed boundary conditions. As long as the prescribed natural boundary conditions are nonhomogeneous, no restriction is imposed upon the horizontal wavenumber η and this leads to a double summation solution of the displacement field. However, this is not the case for traction-free boundary conditions on the two surfaces, which are the necessary conditions for generating Lamb waves. The governing discrete equation for finite layer (equation 30), in this case, becomes

$$[\hat{\mathbf{K}}(\eta_m, \omega_n)]_{nm}\{\hat{\mathbf{u}}\}_{nm} = 0 \tag{33}$$

and we are interested in a nontrivial $\mathbf{u}$. Hence, the stiffness matrix $\hat{\mathbf{K}}$ must be singular, i.e., $\det(\hat{\mathbf{K}}(\eta_m, \omega_n)) = 0$, which gives the required relation between η_m and ω_n. Since, ω_n is made to vary independently, the above relation must be solved for η_m to render the stiffness matrix singular, i.e., η_m cannot vary independently. More precisely, for each value of ω_n, there is a set of values of horizontal wavenumber η_m (one for each mode), and for each value of ω_n and η_m, there are four vertical wavenumbers k_{nm}. The difference in this case is in the value of η_m, which is to be solved for, as opposed to its expression in equation 32, and M is the number of Lamb modes considered rather than Fourier modes. Now, for each set of $(\omega_n, \eta_m, k_{nml}), l = 1, \ldots, 4, \hat{\mathbf{K}}$ is singular and $C_l, l = 1, \ldots, 4$ is in the null space of $\hat{\mathbf{K}}$. Now, using equation 24, the total solution can be constructed. Following the normal practice, the traction-free boundary conditions (i.e., $\sigma_{zz}, \sigma_{xz} = 0$) are prescribed at $z = \mp h/2$. Using equation 16, the governing equation for C_i and η_m becomes

$$[\mathbf{W}_2(\eta_m, \omega_n)]\{\mathbf{C}\}_{nm} = \mathbf{0}, \ \ \mathbf{C} = \{C_1, C_2, C_3, C_4\} \tag{34}$$

where $\mathbf{W}_2$ is another form of the stiffness matrix $\hat{\mathbf{K}}$ and given by

$$\begin{aligned}
W_2(1, p) &= (Q_{110}R(1, p)\eta \\
&\quad - jQ_{130}R(2, p)k_p)\mathrm{e}^{jk_p h/2} \\
W_2(2, p) &= (Q_{110}R(1, p)\eta \\
&\quad - jQ_{130}R(2, p)k_p)\mathrm{e}^{-jk_p h/2} \\
W_2(3, p) &= Q_{550}(-R(1, p)k_p + jR(2, p)\eta)\mathrm{e}^{jk_p h/2} \\
W_2(4, p) &= Q_{550}(-R(1, p)k_p + jR(2, p)\eta)\mathrm{e}^{-jk_p h/2}
\end{aligned} \tag{35}$$

The dispersion relation is $\det\{\mathbf{W}_2\} = 0$, which yields $\eta_m(\omega_n)$ and the phase speed for Lamb waves c_{nm} are given by ω_n/η_m. Once the values of η_m are known for the desired number of modes, the elements of $\mathbf{C}_{nm}$ are obtained by the technique of singular-value decomposition as described in [17, 18]. Summing over all the Lamb modes, the solution for each frequency is obtained.

3 LAMB WAVE ANALYSIS BY BEAM/PLATE THEORIES

As stated before, to avoid the complexity of solving the classical elasticity equation, Lamb waves are also constructed from the beam and plate theories. Depending upon the order of the polynomial involved in the assumed displacement field, Lamb wave modes are captured. Generally, the modes are represented well in the low-frequency regime. However, at high frequencies, appearance of the new modes and deviation from the existing modes become too apparent and indicate the boundary of the applicability of beam/plate theories.

In this section, two basic beam theories are considered, namely, the classical or Euler–Bernoulli theory (EBT) and first-order shear deformation or the Timoshenko beam theory (TBT). It is assumed that the boundaries are given by $z = z_1$ and $z = z_2$ and

the wave is propagating in the X direction. Also the Y dimension is considerably low compared to the X dimension. The displacement field in terms of X displacement, U, and Z displacement, W, for each of the beam theories is as follows:

$$\text{EBT:} \quad U(x,z,t) = u(x,t) - z\partial W(x,t)/\partial x$$
$$W(x,z,t) = w(x,t) \tag{36}$$
$$\text{TBT:} \quad U(x,z,t) = u(x,t) - z\phi(x,t)$$
$$W(x,z,t) = w(x,t) \tag{37}$$

Assuming plane-wave solution for all the unknowns, i.e.,

$$\{u, w, \phi\}(x,t) = \{\hat{u}, \hat{w}, \hat{\phi}\}\exp(j(kx - \omega t)) \tag{38}$$

the algebraic form of the governing equation takes the familiar form

$$\mathbf{W}\{\mathbf{u}_0\} = \{\mathbf{0}\} \tag{39}$$

Imposing the condition of nontrivial solutions, i.e., $\det(\mathbf{W}) = 0$, generates the dispersion relation, i.e., the $k - \omega$ relation. Appealing to the definition of phase (ω/k) and group speeds $(\mathrm{d}\omega/\mathrm{d}k)$ the Lamb wave modes can be obtained. This method is relatively simple, as only polynomial equations are involved (owing to the assumed polynomial form of the displacement field). The number of Lamb wave modes captured depends upon the number of unknowns in each theory. For example, in EBT, the first symmetric (u) and antisymmetric (w) modes participate, whereas, in the TBT, the second antisymmetric mode is present along with the previously mentioned modes.

It is worth realizing that the governing equations considered in each case are devoid of any distributed load. Thus the top and bottom surfaces of the beam are stress free, which is exactly the condition of Lamb wave propagation. This is why the dispersion relation of the beam/plate generates the dispersion relation of the Lamb wave. To extend this idea further, if we are interested in finding the Lamb wave modes for a pipeline system, the method worth trying would be to compute the dispersion relation for shell structure, rather than directly working with the axi-symmetric 3-D elasticity solution.

4 PROPAGATION OF LAMB WAVE

First, the Lamb wave modes are computed by directly solving the 2-D elasticity equation following the procedure outlined in Section 2.2. For this purpose, AS4/3502 composite lamina with the following material properties are considered: $E_1 = 144.5\,\text{GPa}$, $E_{2,3} = 9.63\,\text{GPa}$, $\nu_{13,12} = 0.3$, $\nu_{23} = 0.02$, $G_{23,13,12} = 4.12\,\text{GPa}$, and $\rho = 1389\,\text{kg}\,\text{m}^{-3}$. An angle-ply lamina of 2-*mm* thickness is considered for the Lamb wave propagation study. Analysis is performed for three different fiber directions, 0°, 45°, and 90°.

The dispersion relation (relation between $c_\text{p} = \omega/\eta$ and ω) is usually left in the form of a determinant equal to zero because of its complexity. Hence, solution for this kind of implicit equation requires special treatment. The solution, in particular, is multivalued, unbounded, and complex (although the real part is of interest). One way to solve these equations is to appeal to the strategies of nonlinear optimization, which are based on nonlinear least-square methods. There are several choices of algorithms, like the trust-region dogleg method, the Gauss–Newton method with a line search, or a Levenberg-Marquardt method with line search. Here, the MATLAB function *f solve* is used, and the default option for medium-scale optimization—the trust-region dogleg method—is adopted, which is a variant of the Powell's dogleg method [21].

Apart from the choice of algorithm, there are other subtle issues in root capturing for the solution of wavenumbers, as the solutions are complicated in nature. Moreover, except for the first one or two modes, all the other roots escape to infinity at low frequency. For isotropic materials, these cutoff frequencies are known *a priori*. However, no expressions can be found for anisotropic materials and in most cases the modes (solutions) should be tracked backward, i.e., from the high-frequency to the low-frequency region. In general, two strategies are essential to capture all the modes within a given frequency band. Initially, the whole region should be scanned for different values of the initial guess, where the initial guess should remain constant for the whole range of frequency. This sweeping opens up all the modes in that region, although they are not completely traced. Subsequently, each individual mode should be followed to the end of the domain

or to a preset high value of the solution. For this case, the initial guess should be changed for each frequency to the solution of the previous frequency step. Also, sometimes it is necessary to reduce the frequency step in the vicinity of high gradient of the modes. Once the Lamb modes are generated, they are fed back into the frequency loop to produce the frequency-domain solution of the Lamb wave propagation, which through inverse Fourier transform produces the time-domain signal. As the Lamb modes are generated first, they need to be stored separately. To this end, data are collected from the generated modes at several discrete points in the whole range of frequency. Next, a cubic spline interpolation is performed for a very fine frequency step within the same range. While generating the time-domain data, the interpolation is performed from these finely graded data to get the phase speed (hence, η).

To get the time history of the propagating Lamb waves, a modulated pulse of 200-kHz center frequency is applied at one end of an infinite plate, and the X and Z velocities are measured for a propagating distance of $320h$, where h is the thickness of the plate. While studying the time-domain representation, the thickness of the plate is taken as 10 mm, which amounts to a frequency-thickness value of 2. This increased thickness is taken because, for this value, at least three modes are excited in all the cases, as shown by their respective dispersion curves (Figures 4, 8, and 11).

In all the dispersion plots of the Lamb modes, the abscissa is given in terms of frequency times the thickness. Figure 4 shows the first 10 Lamb modes for fiber angle 0°. As is seen in the figure, the first antisymmetric mode (mode 1) converges to a value of $1719\,\mathrm{m\,s^{-1}}$ in a range of 1 MHz-mm, where all the other modes converge. In analogy to the isotropic case, this is the velocity of the Rayleigh surface waves in 0° fiber laminae. The first symmetric mode (mode 2) starts above $10\,000\,\mathrm{m\,s^{-1}}$ and drops suddenly at around 1.3 MHz-mm to converge to $1719\,\mathrm{m\,s^{-1}}$, before which it has a fairly constant value. All the other higher order modes escape to infinity at various points in the frequency range. Also, the symmetric and the antisymmetric pair of each mode escape at almost the same frequency.

For the 0° ply stacking, Lamb modes are computed by the beam theories and compared with the previous solutions in Figure 5. As the figure suggests, EBT fails to predict mode 1, although it predicts mode 2

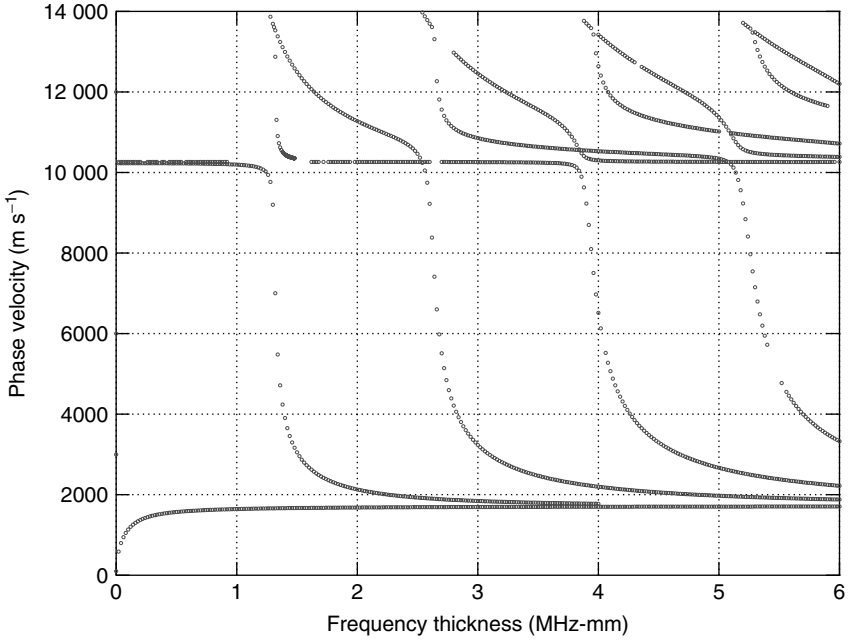

Figure 4. Lamb wave modes for 0° ply angle.

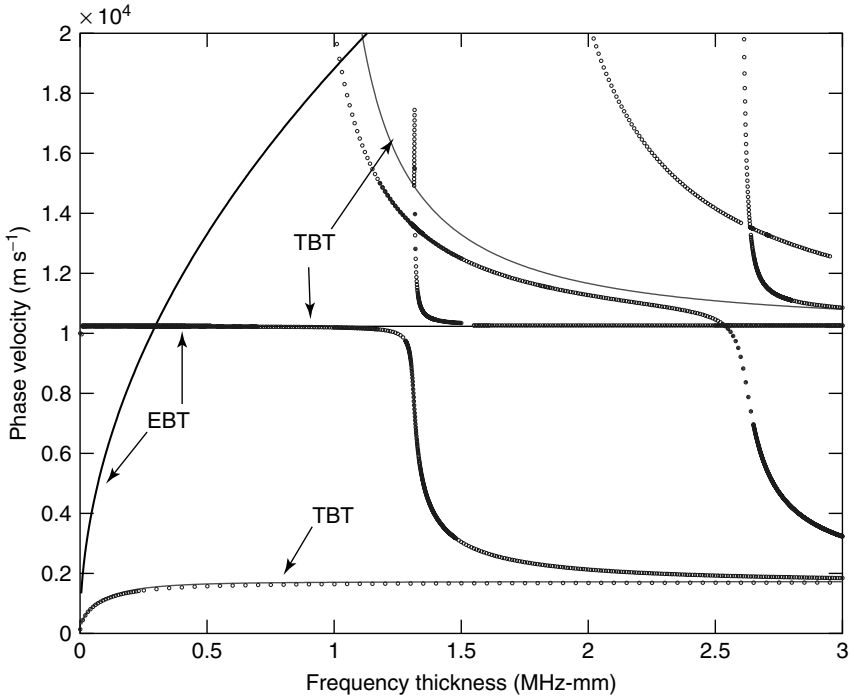

Figure 5. Lamb wave modes for 0° ply angle: comparison with beam theories.

accurately. On the other hand, TBT predicts mode 1 and 2 accurately but approximates the second antisymmetric mode. This prediction can be improved if a correction factor is introduced in the shear modulus. Thus, depending upon the order of the beam theory, different Lamb wave modes are captured.

Propagation of these modes are plotted in Figure 6 and 7 for the first three modes (a_0, s_0, and a_1), here referred to as modes 1, 2, and 3 respectively. The Z velocity history is plotted in Figure 6, whereas the X velocity history is plotted in Figure 7. The figures readily show the different propagating modes, each corresponding to one blob. It is to be noted that the wave propagation velocity is given by the group speed (and not the phase speed). Hence, Figure 4 cannot help us to predict the appearances of different modes. However, as Figure 6 and 7 suggest, mode 2 has a lower group speed than mode 1, and mode 3 has a group speed much higher than both modes 1 and 2. One difference in the $\dot{u}$ and $\dot{w}$ history can be observed. For $\dot{u}$, the higher mode generates velocity of comparatively lesser magnitude, whereas, for $\dot{w}$, the magnitude is the highest.

Next the fiber angle is changed to 45°, and the Lamb modes are plotted in Figure 8. Here, the phase velocity of mode 1 (a_0) is lower than the previous values for 0° (1690 m s^{-1}). Also, the initial phase velocity of mode 2 (s_0) has come down to less than 6000 m s^{-1} in comparison to its 0° counterpart (10 000 m s^{-1}). Further, the cutoff frequencies of all the higher modes are smaller compared to the previous case. Also, there are considerable differences in these cutoff frequencies for each pair of symmetric and antisymmetric modes, which is absent in the 0° case. Further, the number of modes is increased to 11 from 10 in the previous case. The time-domain representations of the propagating waves are shown in Figures 9 and 10. In this case, however, the second mode has higher group velocity than the first mode, and the third mode has the highest group speed.

Finally, the fiber angle is changed to 90°, and the resulting dispersion relation is plotted in Figure 11. The shifting of the modes to the left of the figure continues as the number of modes is increased to 12. Further, the first symmetric mode has come down to 2600 m s^{-1} and the first antisymmetric mode is

reduced to a converged speed of $1510\,\mathrm{m\,s^{-1}}$. For these modes, the propagating Lamb wave is plotted in Figures 12 and 13 for $\dot{u}$ and $\dot{w}$, respectively. As the figures suggest, mode 2 again has lower group speed compared to mode 1, and mode 3 has higher speed than both modes 1 and 2. However, the difference between the mode 3 group speed and mode 2 group speed is not very high as opposed to the previous cases.

5 CONCLUSION

A general procedure is presented to solve the 2-D elastodynamic equation for anisotropic media and the method of obtaining the Lamb wave modes as a special case. The solution is compared with the beam solutions and approximations involved in various theories are demonstrated. The complexities involved in obtaining the Lamb wave modes from 2-D equations and various strategies to overcome them are discussed in detail. The study of Lamb wave propagation reveals some important effects of ply angle. It is observed that the increase in the ply angle increases the number of active modes within a defined frequency range and reduces the cutoff frequencies and the phase speeds of a particular mode. Moreover, the difference in the cutoff frequencies increases with an increase in the ply angle.

Probabilistic Approaches to Sensor Layout Design, Data Processing, and Damage Detection

Sankaran Mahadevan, Xiaomo Jiang and Robert F. Guratzsch
Vanderbilt University, Nashville, TN, USA

1 INTRODUCTION

This article focuses on uncertainties in sensor performance and data and on methods to address these uncertainties and to improve the reliability of structural diagnosis. Although substantial research has been conducted in the past decade [1–17], accurate real-time structural health monitoring (SHM) is still a particularly challenging problem because of several important issues related to sensors: (i) sensitivity of damage detection to sensor configuration, (ii) presence of noise in the sensor data, (iii) incomplete (missing) nature of the sensor data, and (iv) variability in sensor data. This article presents probabilistic methodologies to address these issues.

The development of an effective SHM system for condition assessment depends on two important factors: sensing technology and the associated signal analysis and interpretation algorithm. Many sensor technologies (e.g., strain gauges, thermocouples, and accelerometers) are available for use of health monitoring and damage diagnosis [2, 18–20]. These traditional sensors are embedded in or attached to a structure at selected locations and are used to measure the dynamic response of the structure with the purpose of monitoring the structural integrity and performance. Recently, several new sensor technologies, such as fiber-optic sensors [21], remote wireless or noncontact sensing technologies [22], and active and passive ultrasonic sensing methods [23], have been developed for SHM. More recently, Blackshire and coworkers [24–26] developed and applied

surface-bonded piezoelectric transducers in experimental settings for aerospace materials.

Upon instrumentation of a structural system with sensors, an enormous amount of response data can be quickly collected. Information reliability is a critical issue in using the sensor data for damage detection. The data collected by sensors contain *imperfections*, in the form of imprecision (errors, fuzziness, etc.), incoherence (conflicting information), and uncertainty (partial knowledge, randomness, etc.), and could also be affected by sensor performance degradation. Yet, such data do contain a wealth of useful information that needs to be mined and interpreted to identify the structural condition. A critical challenge in SHM is how to deal with the data imperfection and extract useful information in support of decision making. The focus of this article is to develop probabilistic methodologies for sensor layout design and sensor data analysis that explicitly address imperfectly sensed vibration data and information uncertainty and maximize the probability of successfully identifying the structural damage.

Instrumentation of sensors in structures is expensive, and it is infeasible to instrument the entire structure. Therefore, it is desirable to develop an optimal sensor configuration that can minimize the cost, while maximizing the reliability of the SHM system. However, sensed data from real structures is nondeterministic owing to natural variability (described through stochastic or random processes) and uncertainties (due to lack of knowledge) in the inspection setup, measurement conditions, and different measured quantities of interest. Sensor configuration is optimal if, in addition to minimizing cost, it accounts for both sensor reliability and uncertainties in measurement conditions. Ignoring uncertainty and reliability issues may result in an expensive and ineffective SHM system design that adversely impacts the real-time condition assessment or damage detection after the data is collected. Therefore, one of the contributions of this article is to present a probabilistic analysis method to optimize sensor placement.

After instrumentation of a structural system using sensors, SHM requires analysis of the sensed data to detect changes in the global or local conditions of the structure. This is still a challenging problem owing to (i) the complicated nonlinear behavior of structural systems under natural hazards or even ambient effects (e.g., wind), (ii) the incomplete (missing outputs and/or immeasurable inputs) and noise-contaminated nature of the sensed data, and (iii) the uncertainty and variability in the sensed data. While significant advances are being made in innovative hardware technologies such as sensors and communication and measurement tools, equally important is the development of advanced data processing and damage assessment techniques to take advantage of the improvements in hardware. This article pursues a probabilistic data processing methodology (wavelets, dynamical neural network (NN), fuzzy clustering, and Bayesian statistics) to achieve this objective.

In general, damage detection is realized by comparing the sensor data collected from the real structural system with measurements from the healthy or undamaged structure, or against predictions by a trained model of the healthy structure. The existing damage detection techniques can be divided into two categories: vibration-based and wave-propagation-based methods. The vibration-based technique detects the damage-induced changes in the dynamic response of the entire structure under external excitations, in either time or frequency domains. Features are usually extracted from the time-series measurement or modal analysis of the structure for the detection purpose. Time-series analysis-based pattern recognition techniques, such as autoregressive and autoregressive with exogenous inputs prediction models, have been widely applied for health monitoring and damage detection of various structural systems [7, 27, 28]. Recently, modal analysis-based techniques have also been developed for detecting loose bolts in space operation vehicles [8, 29].

In the wave propagation approach, an impact or excitation is applied to a continuum structure, the structure generates dispersive waves, and changes in the wave propagation parameters (i.e., reflection and transmission coefficients, and wave travel times) are used to detect damage [30–35]. The wave propagation parameters are more sensitive to structural damage than mode shapes and frequencies in the classical vibration-based methods, and therefore have good potential for damage detection in a continuum structure.

Sensor data, however, always contain noise. A dilemma is that it is not possible to know with any measure of certainty whether and how much the measured data are corrupted by noise. If denoising

techniques are indiscriminately applied to data with very little noise, then useful information may be removed from the data, leading to erroneous results [36]. Therefore, it becomes an especially challenging problem to effectively denoise the sensor data and improve the accuracy of structural damage detection. Recently, Jiang and Mahadevan [17, 37] developed a Bayesian discrete wavelet packet transform (DWPT) denoising technique to investigate the effect of noise on the accuracy of structural system identification and damage detection. A comparative study has demonstrated that the proposed approach outperforms the existing denoising methods [37].

There are two different modeling approaches for structural damage detection: parametric and nonparametric methods. Unlike the parametric or physically based method, the system model in the nonparametric or nonphysically based approach does not represent any physical quantity directly, but it is trained to approximate a physical structure and predict its response. As such, the approach does not require complete measurements of the structural response. In addition, a nonlinear autoregressive moving-average approach is commonly used in the nonparametric methods for mapping the input–output relationship. Thus, the nonparametric approach can effectively represent a nonlinear structural system to address its nonlinear behavior. Nonparametric methods, however, usually do not perform damage isolation or quantification. Parametric methods may be further utilized to isolate the damage for health monitoring of a structural system.

Both parametric and nonparametric damage detection approaches need to account for the nondeterministic nature of sensor data and the modeling error of the analytical model. In addition to the uncertainty in the analytical or predictive model, sensor data always contain uncertainty resulting from the inspection setup, measurement conditions, and different measured quantities of interest. Ignoring the uncertainties may result in an erroneous decision making in the structural condition assessment after the data is collected. Recently, several researchers have pursued Bayesian probabilistic methods for structural damage detection and health monitoring, and addressed data uncertainty and modeling errors [38–41].

In the following sections, probabilistic methodologies are presented to address the aforementioned challenges. The proposed methodologies have been grouped into two categories and presented. In the first part, a probabilistic analysis approach is presented to address the issue of optimum layout design of sensor arrays of SHM systems under uncertainty. The sensor layout optimization combines probabilistic FEA, damage detection algorithms, and reliability-based optimization techniques. It is illustrated for the optimum sensor layout design for a thermal protection system (TPS) panel of a space operations vehicle (SOV), using FEA under transient mechanical and thermal loads, and uncertainty quantification techniques. The finite element model is validated with sensor data, accounting for uncertainties in experimental measurements and model predictions.

In the second part, a Bayesian wavelet probabilistic methodology is presented to address the noisy, incomplete, and uncertain characteristics of the sensor data. A Bayesian DWPT-based denoising approach is employed to perform data cleansing prior to damage detection. A nonparametric system identification method is applied to predict dynamic responses of the structure subjected to external excitations. Bayesian hypothesis testing is developed to assess the difference between the sensor data and the model prediction. The Bayesian assessment metric is treated as a random variable, and its probability density function (pdf) is constructed using Monte Carlo simulation to incorporate possible uncertainties. The method is validated using the sensor data collected from a five-story test steel frame.

2 SENSOR LAYOUT DESIGN

This section presents a probabilistic methodology for maximizing the reliability of damage detection by designing the locations of SHM system sensors. This includes the following steps: (i) probabilistic FEA, (ii) damage detection, and (iii) sensor placement optimization (SPO). The methodology is illustrated for layout design of sensor arrays for a TPS panel [42].

Several studies have investigated SPO during recent years. Hiramoto *et al.* [43] and Abdullah *et al.* [44] have addressed the need to place actuators in an optimal way to control the behavior of dynamic structures. Hiramoto *et al.* use the explicit solution of the algebraic Riccati equation to determine the optimal actuator placement, whereas Abdullah *et al.*

utilize genetic algorithms (GAs) to solve the optimization. GAs have also been employed to search for optimal locations of actuators in active vibration control [45–48].

Related more closely to SPO of SHM systems of next generation flight vehicles, Li *et al.* [49] proposed an algorithm that aims to identify modal frequencies and mode shapes best, as well as increase the signal-to-noise ratio. However, it is not shown that a sensor array that best identifies modal frequencies and mode shapes optimizes more traditional SHM performance measures such as the probability of correct classification. Gao and Rose [50, 51] define a probabilistic SPO approach, where a probabilistic damage detection model that describes detection probabilities over a confident monitoring region with radius R is defined for each sensor of a given sensor set. The entire effectiveness of the sensor network is then assumed to be the joint effect of all sensors as estimated at a point by the union probability of all sensors. A covariance matrix adaptation evolution strategy is used to search the decision variable domain. Difficulties arise in defining the probabilistic damage detection models and sources for uncertainty are not identified specifically. A similar SPO framework that addresses imprecise detection probabilities, as well as uncertain terrain properties, is proposed by Dhillon *et al.* [52]; Parker and Frazier [53] address SPO for SHM based on the concept of observability from the fields of dynamic systems theory and engineering design optimization. The technique uses a dynamic model of the structure in question to obtain performance measures with respect to damage detection and localization; however, it does not include uncertainty.

To the authors' best knowledge, the issues associated with SPO under uncertainty for SHM systems due to the spatial and temporal stochastic variability of material, geometric, and loading parameters have not been sufficiently addressed. The methodology presented in this article includes the stochastic nature of the model input parameters to perform a probabilistic FEA to derive the stochastic characteristics of the model outputs, which are used with appropriate damage detection algorithms to estimate probabilistic performance measures of a given sensor layout. Single-objective and multiobjective functions that use the probabilistic performance measures individually and in combination are considered.

2.1 Sensor placement optimization method

2.1.1 Probabilistic analysis

Structural model parameters such as distributed loads, and material and geometric properties, have temporal and spatial variability and cannot be expressed as single random variables, but must be represented as random processes and random fields [54]. Thus random process/field modeling is a key step in probabilistic FEA. Several methods, such as Karhunen–Loeve expansion [55], the Pierson–Moskowitz wave spectra [56], Sakamoto's polynomial chaos decomposition [57], and Shinozuka's Gaussian stochastic process formulation [58], have been used to simulate Gaussian random processes. Random field realizations can be used to simulate component thickness, material moduli, and spatially distributed loads such as thermal and pressure loading. Representing spatially or temporally distributed model inputs through discretized random process/field realizations allows the inclusion of their uncertainty in >FEAs.

Once the model input parameters are randomly generated via the discretization of random processes/fields and applied as inputs to FEA models, repeated simulations of the FEA at each realization are used to generate statistical and/or sensitivity information on model outputs at each possible sensor location. For practical purposes, each node of the FEA model may represent a possible sensor location.

2.1.2 Damage detection algorithms

Damage detection and location identification algorithms of a continuum structure include wavelet-based approaches [59], two-stage modal frequency analysis [60], and methods for eddy-current-based damage detection [61]. Property matrix updating, nonlinear response analysis, and damage detection using NNs are all methods used to manipulate the information gathered by SHM systems for decision making. However, most structural damage detection methods and algorithms found in the literature examine the changes in the measured structural vibration response and analyze the modal frequencies, mode shapes, and flexibility/stiffness coefficients of the structure [62]. This can be achieved either

actively or passively, where active damage detection algorithms use the system response to an auxiliary excitation and passive methodologies use only the responses to operational vibrations. A comprehensive review of the state-of-the-art damage detection and location identification algorithms is provided in Doebling *et al.* [62].

The probabilistic FEA in the previous section quantifies the statistics of the model outputs at all possible sensor locations. Additional analysis is needed to estimate the probability of correctly identifying the structural state of a component for a given sensor layout, x (i.e., $P(CD) = P(\text{correct structural classification}|\text{sensor layout } x)$). This can be accomplished via any appropriate diagnostics signal analysis procedure (i.e., damage detection algorithm). The signal analysis procedure employed in this study follows the general concepts of Duda *et al.* [63] and utilizes the feature extraction and state classification methodologies defined by DeSimio *et al.* [64]. Repeated analyses using different realizations of the random inputs to healthy and damaged structural FEA models and their respective state classification construct a classification matrix from which several performance measures of the given sensor layout can be estimated. Further details of such a procedure are given in Section 2.2.3.

2.1.3 Sensor placement optimization

The SPO problem can be generalized as "given a set of n candidate locations, find a locations, where $a \ll n$, which provide the best possible performance" [65] in damage detection. Studies by Padula [65–67] and Raich and Liszkai [68] have examined the problems and issues involved with SPO. Integer and combinatorial optimization methods have been used to optimize the placement of actuators for vibration control and noise attenuation. In addition, GAs for the optimization of sensor layouts [68] have been proposed. Multivariate stochastic approximation using simultaneous perturbation gradient approximation allows for the inclusion of noise in function evaluations or experimental measurements and has been shown to be efficient for large-dimensional problems [69].

An approach to SPO that includes uncertainty is to employ Snobfit (stable noisy optimization by branch and fit) [70], an optimization scheme that is designed for bound-constrained optimization of noisy objective functions, which are costly to evaluate because of their computational or experimental complexity. The major advantage of using Snobfit is that the algorithm does not require a previously determined set of candidate sensor locations, but rather considers the following optimization problem.

$$\begin{aligned} &\min \ f(x) \\ &s.t. \ x \in [u, v] \end{aligned} \tag{1}$$

where x is continuous and $[u, v]$ is a bounded box in $\Re^n$ with a nonempty interior [70].

The underlying idea of the optimization formulation is to identify a sensor layout, x, that will maximize some performance measure, such as the probability of correctly classifying the structure as either healthy or damaged (i.e., classifying the structure as healthy when it is indeed healthy and as damaged when it is damaged). Here x represents a vector containing the coordinates of the SHM sensors for a given layout. From the reliability analysis described above and a diagnostics signal analysis procedure, a performance measure such as $P(CD)$ is known. This allows the optimization formulation given in equation (1) to be utilized, where $f(x) = -P(CD)$ and $[u, v]$ are the geometric constraints on x given by the physical dimensions of the structure.

2.2 Illustrative example

The proposed methodology is implemented using the following example problem for illustrative purposes. The structure under consideration is a simplified TPS component that is described in detail in [71], and shown in Figure 1. The test article consists of a heat-resistant, 6.35 mm-thick aluminum plate, held in place via four 6.35 mm-diameter bolts located 12.7 mm. from the edges of the plate.

2.2.1 Structural simulation and model validation

The structure under consideration is modeled using the commercial finite element software ANSYS [72]. A portion of the finite element model is shown in Figure 2. Four-noded shell elements (Shell63) and two-noded spring elements (Combin14) are utilized to model the aluminum plate and bolted boundary

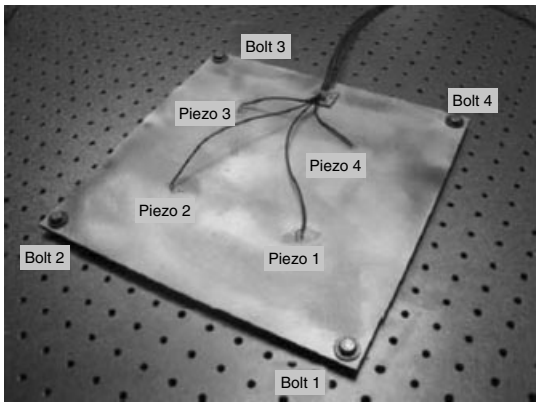

Figure 1. Experimental setup of TPS test article showing bolts and piezoelectric transducer placement [71].

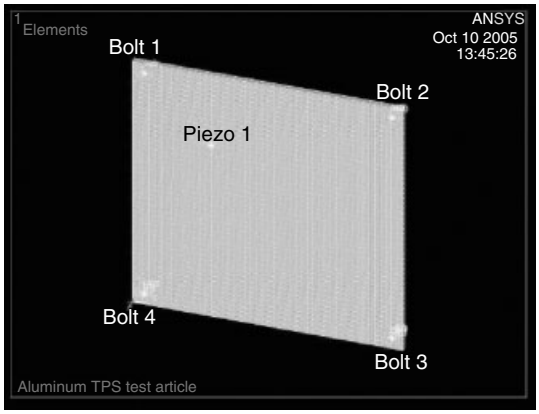

Figure 2. Finite element model of TPS component.

conditions. Approximately 3300 nodes and 2800 elements comprise the 19 836 degree of freedom (DOF) models. In Figure 2, the four points located near the corners of the plate simulate the bolted boundary conditions via 48 spring elements per bolt with varying stiffness coefficients (depending on which structural state the model simulates), while the point near the center of the upper left quadrant of the plate simulates the piezoelectric actuator. The analysis is transient and includes a dynamic mechanical load consisting of a sinusoidal frequency sweep, exciting the structure from 0 to 1500 Hz in approximately 2.0 s. This excitation represents the auxiliary input used with active damage detection algorithms. Owing to the high frequency of the excitation function, a mode superposition (MSP) transient analysis was used to evaluate the FEA model simulations. MSP analysis sums factored mode shapes obtained from a modal analysis to calculate the dynamic response [72].

2.2.2 Probabilistic FEA

In the current example, plate thickness, Young's modulus, Poison's ratio, and density are modeled as Gaussian random fields with independent but equal correlation structures along orthogonal axes. A two-dimensional stochastic process was generated for these model inputs using the spectral representation as defined in equation (1) via Shinozuka's formulation [73] and the Wiener–Khinchine relations [74]. The Gaussian random field $g_o(x_1, x_2, \phi)$ can be simulated by the following series as N_1 and N_2 approach infinity:

$$g_o(x_1, x_2, \phi) = 2 \sum_{k_1=1}^{N_1-1} \sum_{k_2=1}^{N_2-1} \left[\sqrt{S(\omega_{k_1}) S(\omega_{k_2}) \Delta\omega_1 \Delta\omega_2} \times \cos(\omega_{k_1} x_1 + \omega_{k_2} x_2 + \phi_{k_1,k_2}) \right] \quad (2)$$

where $\Delta\omega_i = \omega_{u_i}/N_i$ and $\omega_{k_i} = k_i \Delta\omega_i$, for $i = 1, 2$. Here ω_{u_i} is the upper cutoff frequency beyond which $S(\omega_{k_i})$ is considered to be zero. $S(\omega_{k_i})$ is the two-sided power spectral density (PSD) function of the random field in the i direction and ϕ_{k_1,k_2} an array containing the independent random phase angles uniformly distributed between 0 and 2π. N_i defines the number of terms to be included in the dual summation in the i direction. The random fields in this article use the following PSD functions: $S(\omega_{k_i}) = 1/4\sigma_i^2 b_i^3 \omega_{k_i}^2 \cdot \exp(-b_i \omega_{k_i})$ for $i = 1, 2$. Here σ_i is the standard deviation of the stochastic process in the i direction and b_i its corresponding "correlation distance".

For the random fields considered as FEA inputs to models of the test article, $b_1 = b_2 = 3$ and $\sigma_1 = \sigma_2 = 1$, where the magnitude of $g_o(x_1, x_2, \phi)$ is scaled after the test to match the mean and coefficient of variation (COV) of the random field to be simulated. $\omega_{u_1} = \omega_{u_2} = 5\pi$, while $N_1 = N_2 = 35$. Table 1 lists the mean and COV used for each of the random fields simulated with equation (2).

Temperature uncertainty was included as a random variable uniformly distributed between 65 and 75 °F.

Table 1. Mean and COV values used for random field simulation

	Panel thickness	Young's modulus	Poison's ratio	Density
Mean	6.24 mm	6.72E04 MPa	0.3	7.169 kg m^{-3}
COV	0.02	0.02	0.02	0.02

The following temperature effect model was constructed via a quadratic regression analysis of data by Kohavi and Provost [75]:

$$F(t) = (-1.151525 \times 10^{-6})t^2 + (2.75775 \times 10^{-5})t + 1.00067 \quad (3)$$

where $F(t)$ is a scale factor for Young's modulus and t is the plate temperature in degrees Fahrenheit.

Repeatedly executing deterministic FEAs using realizations of the model inputs provides data for statistical analysis of the model responses. For the example at hand, 500 simulations using 500 realizations of the random inputs were executed; 100 simulations of the healthy model, 100 simulations of the model damaged at bolt 1, 100 simulations of the model damaged at bold 2, and so on, where a damaged bolt refers to a bolt at 25% nominal torque (damage was simulated analytically by altering the stiffness constants of the spring elements surrounding each bolt location). These five sets of simulations and their corresponding response statistics are used for damage detection.

2.2.3 Damage detection and state classification

Figure 3 shows a typical sensor layout, where sensor location 1 is the point of input excitation and is stationary, while sensor locations 2, 3, and 4 are the points of sensing and are variable. Also shown in Figure 3 are the locations of the four bolts that hold the test structure in place and are the locations of fastener damage. The hatched areas in Figure 3 are regions where it is infeasible to place SHM sensors.

From the pool of simulation output of the probabilistic FEA consisting of temporal displacement data, an equivalenced von Mises stress for each possible sensor location is calculated by ANSYS 2004 [72].

$$\sigma_{vM} = \sqrt{\sigma_x^2 - \sigma_x\sigma_y + \sigma_y^2 + 3\tau_{xy}^2} \quad (4)$$

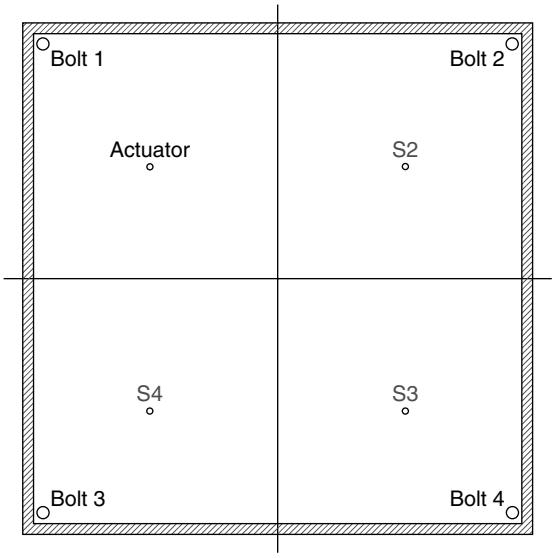

Figure 3. TPS test plate with typical sensor layout, actuator, and fastener damage locations.

where σ_x, σ_y, and τ_{xy} are the in-plane stress components, which are estimated from the displacement records of the four nearest neighboring nodes. Plane stress conditions are assumed.

From the estimated von Mises stress records at sensor locations S2, S3, and S4, a set of features is extracted. Features are characteristics unique to a signal generated under a given set of parameters. The set of features utilized for this example problem is based in the frequency domain and is extracted via the well-known Welch method [76, 77] from the PSDs of the signals. This damage detection algorithm is then applied to testing data, which consists of the second 50 simulations of each structural state. This yields a classification matrix corresponding to a given sensor layout, from which several performance measures may be estimated. Refer to Guratzsch and Mahadevan [42] for details about the feature extraction. A sample classification matrix is shown in Table 2.

Using the information contained in the classification matrix one can estimate several probabilistic performance measures of a given sensor layout, such as the probability of false alarm (type I error), the probability of missed detection (type II error), the probability of correct detection (accuracy), and the probability of misdetection (1-accuracy) [75]. P(false alarm) is defined as the likelihood that the

Table 2. Sample classification matrix for a given sensor layout

		Classified states				
		Damaged 1	Damaged 2	Damaged 3	Damaged 4	Healthy
True states	Damaged 1	1	21	0	0	1
	Damaged 2	78	98	0	2	0
	Damaged 3	0	1	91	7	1
	Damaged 4	0	10	0	89	1
	Healthy	0	11	0	1	88

damage detection algorithm classifies a healthy structure as damaged. P(missed detection) is the probability that the damage detection method classifies a damaged structure as healthy. Accuracy is measured via P(correct detection), which is defined as the probability that the damage detection method will classify a given structure correctly into its proper structural state (i.e., P(classify structure as $\omega_i \mid$ structural state is ω_i)). The compliment of P(correct detection) is P(misdetection). These probabilities can be used to evaluate a given sensor array [42]. The performance measures are expressed as follows:

$$P(\text{false alarm}) = \frac{\text{Sum of first four elements in row 5 of CM}}{\text{Sum of all elements in row 5 of CM}} = P(\text{type I}) \quad (5)$$

$$P(\text{missed detection}) = \frac{\text{Sum of first four elements column 5 of CM}}{\text{Sum of all elements in column 5 of CM}} = P(\text{type II}) \quad (6)$$

$$P(\text{correct detection}) = \frac{\text{Sum of diagonal elements of CM}}{\text{Sum of all elements of CM}} = P(CD) \quad (7)$$

$$P(\text{misdetection}) = 1 - P(\text{correct detection}) \quad (8)$$

Evaluating equations (5)–(8) for the classification matrix shown in Table 2 yields the following results: P(false alarm) = 0.12; P(missed detection) = 0.033; P(correct detection) = 0.89; and P(misdetection) = 0.11. As an example, the performance measures for the five randomly selected sensor layouts shown in Figure 4 are shown in Table 3.

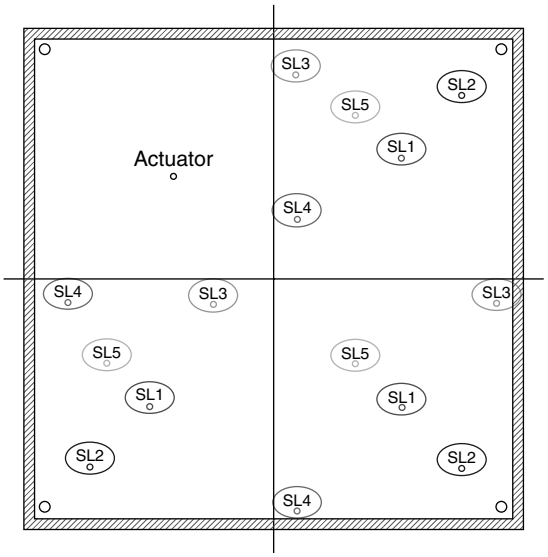

Figure 4. Five randomly selected sensor layouts.

$0.5(1 - P(CD)) + 0.25P$(type I) $+ 5.0P$(type II)	44	196	7.0, 8.5	11.73, 0.27	5.75, 1.25	0.0375	0.916	0.01	0

Units conversion for coordinates of sensors S2, S3 and S4: 1 in. = 25.4 mm

summarizes the optimization results, where N_{ite} is the number of Snobfit iterations, N_{obj} is the number of objective function evaluations, and E is the measure of accuracy of the quadratic model at the optimal solution as estimated by Snobfit. The coordinates given are with respect to the bottom left corner of the plate (Figure 3).

From Table 4, it can be concluded that although the solution varies for different objective functions, the optimal sensor arrays corresponding to objective functions 2 through 5 are nearly identical. Additionally, it was observed during Snobfit's iterations that the optimal solutions to objective functions 2 through 5 were robust and insensitive to small changes in the independent variables (i.e., shifting sensors S2, S3, and/or S4 by less than 0.25 in. in any direction, did not significantly alter the performance measures). However, the solution to the first objective function was very sensitive with respect to small changes in the independent variables (i.e., shifting sensors S2, S3, and/or S4 by less than 0.25 in. in any direction, significantly degraded the performance measures).

3 DENOISING SENSOR DATA

Suppose that the sensor data is contaminated by an additive white Gaussian noise, $\varepsilon(t_i)$, as follows:

$$f(t_i) = g(t_i) + \varepsilon(t_i) \quad i = 1, 2, \ldots, N \qquad (9)$$

where $f(t_i)$ and $g(t_i)$ represent the noisy and denoised sensor data, respectively. The noise term $\varepsilon(t_i) \sim N(0, \sigma^2)$ is a vector of independent, identically distributed (i.i.d.) errors with mean zero and variance σ^2. In the DWPT decomposition of the time series, the noise item $\varepsilon(t_i)$ in equation (9) is also resolved into a series of corresponding noise ε_{jk}. Then Bayesian hypothesis testing is applied to the DWPT coefficients. The goodness of fit of the denoised time series is measured by its signal-to-noise ratio (SNR). It is defined as the ratio of the sum of square of the signals to that of the noise. The thresholded coefficients are then used to reconstruct the denoised time series.

Figure 5 shows the Bayesian DWPT denoising approach done in five steps (identified by numbers 1–5 in Figure 5):

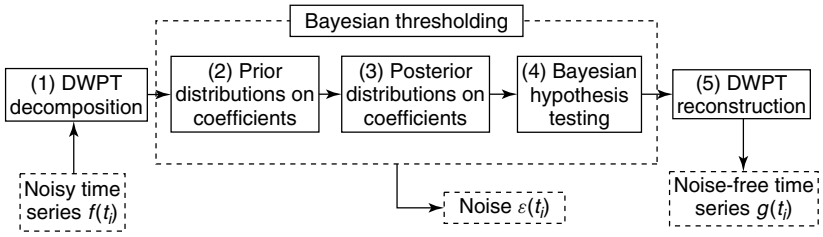

Figure 5. Bayesian discrete wavelet packet transform (DWPT) denoising procedure for time series.

1. The measured data is resolved into a series of wavelet coefficients by a DWPT decomposition.
2. Noninformative prior distributions are imposed on the decomposed coefficients.
3. Posterior distributions of the coefficients are derived based on Bayes theorem.
4. The noise is removed from the coefficients through a Bayesian hypothesis testing.
5. The denoised data is reconstructed through an inverse wavelet transform.

Refer to Jiang *et al.* [37] for the details of the Bayesian DWPT denoising method.

This denoising approach has been demonstrated to outperform the conventional wavelet-based and translation-invariant soft thresholding methods [37]. It has the following three features that are advantageous in structural damage detection. First, it avoids the subjective selection of the threshold required in conventional wavelet-based denoising methods. Second, it can address the uncertainty of noise effectively through Bayesian hypothesis testing. Third, it provides more accurate data denoising, particularly for the sensor data even with low noise, due to the adroit integration of the discrete wavelet packets decomposition and Bayesian hypothesis testing.

4 DAMAGE DETECTION USING INCOMPLETE DATA

Nonparametric system identification is used in this section for damage detection using incomplete data. The nonparametric dynamic fuzzy wavelet neural network (WNN) model developed by Adeli and Jiang [79] is used in this research for nonparametric system identification of structures to generate model predictions. The general dynamic input–output mapping in the model is

$$\hat{y}_i = \sum_{k=1}^{M} w_k \sum_{j=1}^{D} \varphi\left(\frac{X_{ij} - c_{kj}}{a_{kj}}\right) + \sum_{j}^{D} b_j X_{ij} + d$$
$$i = 1, \ldots, N, a \in \Re, \varphi(.) \in L^2(\Re) \quad (10)$$

where $\varphi(.)$ is the nonorthogonal Mexican hat wavelet function; X_{ij} is the jth value in the ith input vector, X_i, and c_{kj} is the jth value in the kth cluster of the multidimensional input vector obtained using the fuzzy C-means clustering approach [80]. The parameter D is the input dimension or the size of the input vector in nonlinear autoregressive moving average with exogenous inputs (NARMAX) approach [81]. The parameter M is the number of wavelets, which is also equal to the number of the fuzzy clusters as well as the number of wavelet nodes used in the WNN model. The parameters $a_{kj} \neq 0$ denote the frequency (or scale) corresponding to the multidimensional input vector; w_k represents the kth wavelet coefficient linking the hidden node to the output; b_j is the weight of the link of the jth input to the output; d is a bias term, and $\Re$ is the set of real numbers. The parameter N is the number of input vectors.

Unlike conventional NN models such as backpropagation NN, the fuzzy WNN model is a dynamic NN that preserves the time sequence of the input vectors and memorizes the past of the time-series data. The model is based on the integration of multiple paradigms including chaos theory (based on nonlinear dynamics theory), wavelets (a signal processing method), and two complementary soft computing methods, i.e., fuzzy logic and NNs. It has been demonstrated to provide more accurate nonlinear approximation than the conventional NN [79].

Note that the fuzzy WNN model is trained using the data collected from a healthy structure subjected to a low-level excitation, using the adaptive Levenberg–Marquardt least squares (LM-LS) algorithm [16, 17, 37, 82]. Therefore, the trained model represents a structural system without any damage such that the predicted outputs should represent the structural responses without any damage as well. The trained model is then used to predict dynamic responses of the structure with unknown conditions under a high-level excitation. Both sensor data and model predictions under the same excitation are used to assess the health status of the structure based on the Bayes metric described in Section 5.

5 DAMAGE DETECTION UNDER UNCERTAINTY

5.1 Bayes metric

Structural damage evaluation involves comparing the model prediction (based on original healthy condition

of a structure) with the experimental result (representing current condition of the structure). When the outputs predicted from the model are compared with the sensor data (under some input excitation), the difference between them will be used to detect the structural damage. The relative root mean square (rrms) error has been widely used to measure structural damage [5, 83, 84]. It is customary to assume that structural damage has occurred when the rrms error exceeds a predefined threshold level obtained by trial and error (for example, 0.6). However, the rrms error method is not always accurate because two other sources also contribute to this error: (i) training of the model to approximate the structural properties and (ii) sensor data, which are imperfect and contain measurement noise. As such, the rrms error method may be ineffective for structural damage detection when imperfection and uncertainty in the data are considered.

In this article, Bayesian hypothesis testing is pursued as a quantitative measure to detect the structural damage based on the denoised sensor data. Let y_{true} be the (usually unknown) true response of the original healthy structure under the input excitation being considered at present, y_{exp} the sensed structural response under the current (may be unknown) condition, and y_{pred} the prediction output representing structural responses under healthy condition. (All three quantities—y_{true}, y_{exp}, and y_{pred}—are under the same input excitation being used for damage detection). Within the context of binary hypothesis testing, consider two hypotheses H_0 and H_1. The point null hypothesis (H_0: $y_{\text{exp}} = y_{\text{pred}}$) indicates that the structure is healthy. The alternative hypothesis (H_1: $y_{\text{exp}} \neq y_{\text{pred}}$) indicates that the structure is damaged. Their prior probabilities of acceptance are denoted by $\pi_0 = Pr(H_0)$ and $\pi_1 = Pr(H_1)$. On the basis of Bayes theorem, the relative posterior probabilities of the two hypotheses are obtained as

$$\frac{Pr(H_0|\text{data})}{Pr(H_1|\text{data})} = \left[\frac{Pr(\text{data}|H_0)}{Pr(\text{data}|H_1)}\right]\left[\frac{Pr(H_0)}{Pr(H_1)}\right] \quad (11)$$

The term in the first set of square brackets on the right hand side of equation (11) is referred to as the "Bayes factor" [85]. Thus, the Bayes factor is the ratio of probability of observing the data given the null hypothesis (i.e., structure is healthy) to the probability of observing the data given the alternate hypothesis (i.e., structure is damaged), obtained as follows [86]:

$$B(y_{\text{pred}}) = \frac{P(\text{data}|H_0: y_{\text{exp}} = y_{\text{pred}})}{P(\text{data}|H_1: y_{\text{exp}} \neq y_{\text{pred}})} \quad (12)$$

Mahadevan and Rebba [87] showed that, under practical conditions, the Bayes factor simply becomes the ratio of posterior to prior pdfs of the structural response at $y_{\text{exp}} = y_{\text{pred}}$ (Figure 6):

$$B(y_{\text{pred}}) = \frac{h_2}{h_1} = \left.\frac{f(y_{\text{pred}}|\text{data})}{f(y_{\text{pred}})}\right|_{y_{\text{exp}}=y_{\text{pred}}} \quad (13)$$

When $B(y_{\text{pred}})$ is greater than unity, the sensor data is said to favor the null hypothesis. However, if $B(y_{\text{pred}}) < 1$, it may be inferred that the data supports the alternative hypothesis that the structure is damaged. Since $B(y_{\text{pred}})$ is nonnegative, the value of $B(y_{\text{pred}})$ is often converted into the logarithm scale for the convenience of comparison among a large range of values (i.e., $b_{01} = \ln[B(y_{\text{pred}})]$, where ln[.] is a natural logarithm operator with a basis of e). As such, a positive value of b_{01} indicates that the structure is healthy (i.e., accepting H_0) while a negative value indicates that the structure is damaged (i.e., rejecting H_0). Kass and Raftery [86] suggest interpreting b_{01} between 0 and 1 as weak evidence in favor of H_0, between 3 and 5 as strong evidence, and $b_{01} > 5$ as very strong evidence. Negative b_{01} of the same magnitude is said to favor H_1 by the same amount. A key difference from the rrms metric is that the Bayes-factor metric explicitly accounts for the uncertainty in sensor data during the computation of the posterior pdf [87].

Assume $\mathbf{y}_{\text{exp}} = \{y_{1,\text{exp}}, y_{2,\text{exp}}, \ldots, y_{n,\text{exp}}\}$ and $\mathbf{y}_{\text{pred}} = \{y_{1,\text{pred}}, y_{2,\text{pred}}, \ldots, y_{n,\text{pred}}\}$ to be n samples of

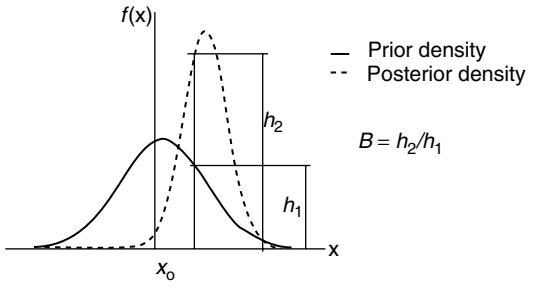

Figure 6. Bayes-factor metric B for damage detection.

sensor data and model predictions, respectively. Let $e_i = y_{i\,\mathrm{exp}} - y_{i\mathrm{pred}}$ represent the difference between the ith experimental data and the ith model prediction, and $\varepsilon_{\mathrm{obs}} = \{e_1, e_2, \ldots, e_n\}$ represent n values of the error, which is usually assumed to follow a normal distribution $N(\mu, \sigma^2)$ with σ known in this study (estimated using the data set $\boldsymbol{\varepsilon}_{\mathrm{obs}}$). Here we do not know the distribution of the difference *a priori*, so we assume Gaussian as an initial guess, and then do a Bayesian update. The damage detection problem becomes testing $H_0: \mu = 0$ versus $H_1: \mu \neq 0$ with $\mu|H_1 \sim N(\rho, \tau^2)$, in which ρ and τ are two parameters of the prior density of μ under the alternative hypothesis (denoted by $f(\mu|H_1)$). If no information on $f(\mu|H_1)$ is available, the parameters $\rho = 0$ and $\tau^2 = \sigma^2$ are suggested by Migon and Gamerman [88]. This selection assumes that the amount of information in the prior is equal to that in the observation, which is consistent with the Fisher information-based method [86].

Note that H_0 becomes a simple hypothesis with $f(\mathrm{data}|H_0) = f(\boldsymbol{\varepsilon}_{\mathrm{obs}})$, which is referred to as the marginal likelihood of H_0 given data $\boldsymbol{\varepsilon}_{\mathrm{obs}}$. Using Bayes theorem, Jiang and Mahadevan [17] explicitly derived an expression to calculate the Bayes factor in the logarithm scale as follows:

$$b_{01} = \ln[B(\mathbf{y}_{\mathrm{pred}})] = \frac{1}{2}\ln\left(\frac{n\tau^2 + \sigma^2}{\sigma^2}\right) + \frac{n}{2}\left[\frac{(\overline{\varepsilon}_{\mathrm{obs}} - \rho)^2}{n\tau^2 + \sigma^2} - \frac{\overline{\varepsilon}_{\mathrm{obs}}^2}{\sigma^2}\right] \quad (14)$$

Thus, a value of b larger than 0 indicates that the error data $\boldsymbol{\varepsilon}_{\mathrm{obs}}$ are judged to support H_0 (i.e., the structure is healthy). Otherwise, the error data $\boldsymbol{\varepsilon}_{\mathrm{obs}}$ are judged to reject H_0 (i.e., the structure is damaged).

5.2 Confidence assessment

On the basis of the Bayes factor calculated using equation (14), quantitative assessment of confidence in the structural damage detection result may be done in two ways: deterministic and stochastic. In the deterministic context, given a set of sensed data $\mathbf{y}_{\mathrm{exp}}$ and model prediction $\mathbf{y}_{\mathrm{pred}}$, the likelihood ratio in the logarithmic scale is calculated using equation (14). The uncertainties in data and prediction are not considered. Thus, the Bayesian measure of evidence that the structure is healthy may be quantified by the posterior probability of the null hypothesis $Pr(H_0|\mathrm{data})$, denoted by λ. Using the Bayes theorem, the value of λ can be derived:

$$\lambda = P(H_0|\mathbf{y}_{\mathrm{exp}}) = \frac{B(\mathbf{y}_{\mathrm{pred}})P(H_0)}{P(H_1) + B(\mathbf{y}_{\mathrm{pred}})P(H_0)} \quad (15)$$

Equation (15) is used to quantify the confidence in accepting the null hypothesis (i.e., the structure is healthy) based on the specific experimental data and prediction output. Before conducting experiments, it is usually assumed that $P(H_0) = P(H_1) = 0.5$ owing to the absence of any prior knowledge about the two hypotheses. In that case, equation (15) is simplified as $\lambda = B(\mathbf{y}_{\mathrm{pred}})/[1 + B(\mathbf{y}_{\mathrm{pred}})]$, and $B(\mathbf{y}_{\mathrm{pred}}) \to 0$ indicates 0% confidence in accepting the null hypothesis, and $B(\mathbf{y}_{\mathrm{pred}}) \to \infty$ indicates 100% confidence.

In the stochastic context, the Bayes factor, $B(y_{\mathrm{pred}})$, is treated as a random variable to consider the uncertainties in both experimental data and model prediction. Given the pdf of $\boldsymbol{\varepsilon}_{\mathrm{obs}}$, the M sets of mean ($\overline{\varepsilon}$) and sum of squared error (SSE) (s) values are created by sampling m error data using Monte Carlo simulation technique ($m = 5000$ and $M = 10\,000$ are taken in the example presented in this section). The resulting M b_{01} values by equation (14) are used to construct its density distribution function. As such, the probability of the event that the structure is healthy (i.e., accepting the null hypothesis) can be obtained by using the pdf or estimated by finding the proportion of $b_{01} > 0$, i.e., $\gamma = Pr(b_{01} > 0)$. Thus, the stochastic approach directly provides a quantitative probability of damage.

6 ILLUSTRATIVE EXAMPLE

As an illustrative example, the sensor data used in the numerical implementation are collected from a test five-story steel frame. The proposed probabilistic methodology has also been illustrated by Jiang and Mahadevan [17] using the sensor data collected from a 38-story concrete building test model. All sensor data in this example are denoised using the Bayesian DWPT denoising method. A three-level DWPT decomposition is found adequate for signal denoising using the proposed denoising approach

[37]. Structural damage evaluation is conducted on the test structure using both original and denoised data, using the proposed probabilistic evaluation method.

6.1 Problem description

This structure was tested at the National Center for Research on Earthquake Engineering in Taiwan [5]. It is a 3-m long, 2-m wide, and 6.5-m high steel frame (Figure 7a). This test frame was subjected to five different levels of excitations, all derived from an original Kobe earthquake acceleration time history, that is, the acceleration amplitudes at 20, 32, 40, 52, and 60% of the original Kobe time history amplitude. These excitations are denoted as Kobe1, Kobe2, Kobe3, Kobe4, and Kobe5, respectively. Acceleration responses were measured using acceleration sensors at the four corners of each floor in two horizontal directions (x and y directions in Figure 7a) over a period of 25 s at increments of 0.001 s. Thus, around 25 000 output data points are recorded in a single test. All acceleration response data are normalized to the gravity acceleration (g) to improve computational efficiency in the structural system identification. As an example, Figure 7(b) shows the acceleration responses at the first, second, and third floors of the test frame under Kobe1 earthquake.

In this example, only the acceleration response data at the first, second, and third floors in the x direction (Figure 7a) are used as both training and testing data sets. The dynamic fuzzy WNN model is constructed using the measured input–output data under the lower Kobe1 earthquake and then trained using the adaptive LM-LS algorithm, as described by Adeli and Jiang [79]. The trained model is then used to represent the structural system and predict the acceleration responses at the second floor of the test frame under the other four stronger earthquakes, i.e., Kobe2, Kobe3, Kobe4, and Kobe5.

6.2 Damage detection

All measured data are denoised using the proposed Bayesian DWPT approach. The first 10 000 points of the pairs of original and denoised experimental data obtained at Kobe1 earthquake are used to train the model, one set at a time, resulting in two trained models. Each trained model is tested using the remaining 15 000 points of the denoised data and the original experimental data. Furthermore, each trained model is used to predict the original and the denoised acceleration responses under four different levels of excitations (Kobe2 to Kobe5). As such, 10 different sets of system identification results are produced, including the two testing cases. The rrms errors and b_{01} values between the measured and predicted output are computed for all 10 test cases and shown in Table 5. The 10 corresponding probabilities in accepting the null hypothesis are calculated using equation (15) and also shown in Table 5.

Table 5. Detection results at the second floor of a five-story frame in terms of rrms, b_{01}, and γ metrics

Excitation		Kobe1	Kobe2	Kobe3	Kobe4	Kobe5
rrms	Original	0.12	0.233	0.250	0.207	0.199
	Denoised	0.06	0.150	0.162	0.157	0.181
b_{01}	Original	2.757	2.438	−0.765	−5.469	−5.073
	Denoised	3.167	1.196	−3.917	−11.076	−9.944
λ (%)	Original	94.0	92.0	31.8	0.4	0.6
	Denoised	96.0	76.8	2.0	0.0	0.0
γ (%)	Original	91.8	82.6	40.9	8.6	9.7
	Denoised	94.5	65.8	14.7	0.6	1.4

6.2.1 *Deterministic case*

A difference between the prediction output and the sensor data is used as an indication of the structural damage. Assuming a damage threshold $\varepsilon = 0.15$, two observations are made from the results. First, all rrms values obtained using four sets of noisy data (Kobe2 to Kobe5 in Table 5) are larger than ε, implying that the frame structure is damaged under all four scenarios. However, when the original data is denoised and then used for structural system identification and damage evaluation, the rrms values of only the last three scenarios (Kobe3 to Kobe5) are larger than ε, implying that the structure is damaged under only the three scenarios. The experimental observations described by Hung *et al.* [5] demonstrate that there exists distinguishable damage or inelastic structural behavior under only the strong earthquake Kobe3 to Kobe5. Therefore, it is reasonably concluded that the noise in the sensed data adversely affects the detection results. Second, the damage detection results obtained using the Bayesian metric have further indicated that the Bayesian data denoising approach followed in this study improves the accuracy of detection results significantly.

As an example, Figure 8 shows the comparison of detection results using the original and denoised acceleration response data of the second floor subjected to Kobe4 earthquake. Figure 8(a) shows the comparison result in the time domain, while Figure 8(b) shows the comparison in the frequency domain. The PSDs are used in Figure 8(b) because the difference between noisy and denoised response data cannot be identified visually in the time-series plots (Figure 8a). The PSD of every time series is calculated through fast Fourier transform with the length 1024. Refer to Stoica and Moses [89] for details of spectral analysis. It is observed that the difference of PSDs between the original data and the denoised data is significant in the frequency domain.

6.2.2 *Stochastic case*

Using the statistics of the error data (i.e., its mean and variance) for various scenarios, the value of $\overline{\varepsilon}_{\text{obs}}$

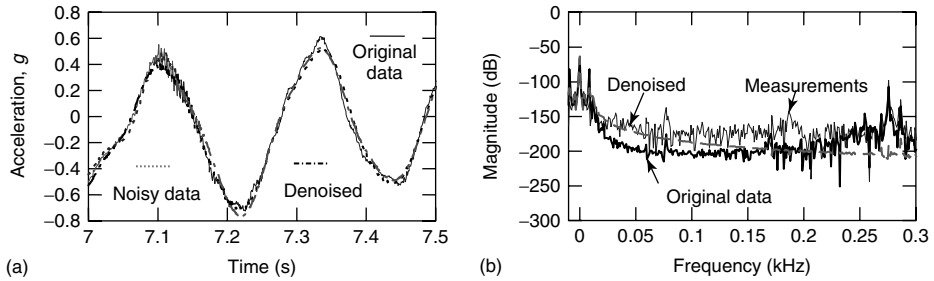

Figure 8. Comparison of detection results using original and denoised acceleration response data under Kobe4. (a) Time domain and (b) power spectral densities.

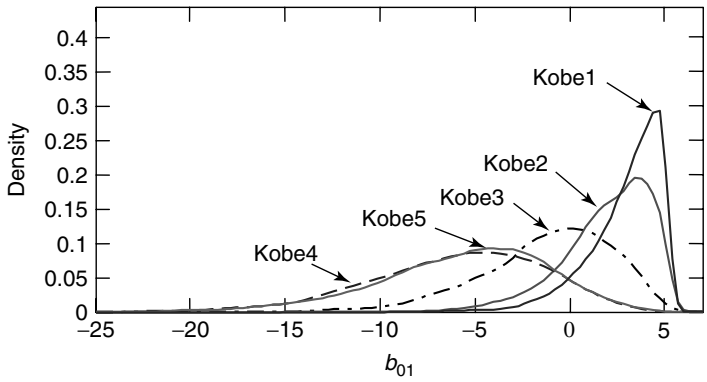

Figure 9. Simulated results of $\gamma = \Pr(b_{01} > 0)$ for various excitation levels in five-story frame: the densities are kernel density estimates based on samples of size 10 000 from the respective densities in the denoised case.

and σ^2 are simulated by sampling 5000 data points using Monte Carlo technique. In each scenario, a b_{01} value is obtained using equation (14) for the simulated data, and 10 000 simulations are run to yield a pdf of b_{01}. The overall probabilities of accepting the event that the structure is healthy (γ), i.e., accepting the null hypothesis, for all 10 scenarios are approximated by finding the proportion of $b_{01} > 0$ from the simulated results and summarized in Table 5. It is observed that the probabilistic assessment results lead to the same conclusion as obtained from the deterministic evaluation. As an example, Figure 9 shows the pdfs of b_{01} for five denoised cases (Kobe1 to Kobe5).

7 CONCLUDING REMARKS

In this article, probabilistic methodologies are presented to address several important and challenging issues in SHM that are related to sensors. The methodologies include a probabilistic FEA approach to optimize sensor placement, a wavelet-based Bayesian approach to cleanse sensor data, a nonparametric model based on NN and fuzzy clustering to perform structural system identification using incompletely sensed data, and a Bayesian hypothesis testing approach to assess the structural status, considering uncertainties in both model prediction and experimental observations. The proposed methodologies are investigated for application in two different disciplines, namely, aerospace (TPS panel) and civil (five-story frame structure) engineering.

Further work is required in regard to validating the proposed probabilistic methodologies for more complicated applications. For example, in sensor layout optimization, additional investigation is necessary to determine the optimum number of sensors. Instead of the fixed number of sensors considered in this article, it is more reasonable to assume a variable number of sensors to maximize the reliability of damage detection. As the number of sensors distributed across the structure increases, the estimated SHM performance measures might be expected to improve. However, owing to weight penalties associated with additional sensors, as well as complexity constraints with respect to the amount of data acquired by the sensing system that requires processing (and therefore processing power), the number of sensors applied to the structure must be minimum.

Future work needs to account for sensor damage and reliability under various environmental and operating conditions, both in sensor layout design and damage detection. A bond graph-based parametric approach appears to be a promising approach to distinguish between structural and sensor damage [90, 91]. Using the bond graph, a temporal causal graph can be derived to represent the causal relations among the structural variables and parameters. The possible causes (either structural damage or sensor fault) leading to the system damage can be isolated by a damage signature matrix. After isolation, the quantification of the amount of damage (parameter estimation) can be done using analysis of only the isolated substructure containing the

damage, leading to computational efficiency. Preliminary results with structural frames are promising; further work is needed for continuum structures in combination with FEA.

ACKNOWLEDGMENTS

The research described in this article is partly sponsored by the United States Air Force Research Laboratory (project monitor: Mark Derriso) through subcontracts to Anteon Corporation and General Dynamics Information Technology. The authors gratefully acknowledge this support. The authors also gratefully acknowledge valuable discussions and help from Dr Steven Olson at University of Dayton Research Institute and Dr Martin DeSimio at Alliant Techsystems, Inc., with respect to the TPS panel example.

Chapter 51

Development of Fuzzy Rules for Damage Detection and Location

Ranjan Ganguli

Department of Aerospace Engineering, Indian Institute of Science, Bangalore, India

1 INTRODUCTION

Structural damage leads to changes in some measurable system properties. In structural health monitoring (SHM), we try to detect the damage from such measurable system behavior. The problem of damage detection becomes complicated because of the presence of noise in the measured data and errors in modeling. We can visualize that structural damage causes patterns in the measurement space, and our objective is to device algorithms that can predict the location and size of damage from these patterns (*see* **Statistical Pattern Recognition**). In recent years, methods such as those based on neural networks (*see* **Artificial Neural Networks**), genetic algorithms (GAs), and system identification have been used to solve damage detection problems. An alternative method for structural damage detection, which has several advantages over the neural network and GA approaches, is based on fuzzy logic and is discussed in this article.

As mentioned by Boller in a recent article [1], there is no need for a health monitoring system to locate damage to within a few millimeters. The cost and effort involved in predicting damage to a high level of accuracy can be prohibitive. In addition, because of measurement, model, and signal-processing inaccuracies, a health monitoring system that claims to predict damage with great accuracy is likely to give false alarms and lose the faith of maintenance personnel using it. A better idea is to roughly locate the damage to within about 1 m using a health monitoring system and then to use standard non-destructive evaluation (NDE) methods for a closer analysis of the damage area [1]. Such an approach is well suited to the use of fuzzy logic, which gives linguistic outputs such as "large damage at root of beam" instead of numerical values.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

For successful SHM, we need to solve the inverse problem relating the change in measurements between the damaged and undamaged structure to the presence, location, and size of the structural damage (*see* **Damage Presence/Growth Monitoring Sensors**). The inverse problem is complicated by incomplete information (not all states of the system are available) and uncertainty in modeling, measurement, and signal processing. As mentioned before, the inverse problem for structural damage detection is typically solved by computational intelligence methods like neural network [2–7] and GA [8–10]. GAs used directly for damage detection problems can have some limitations. For example, GA has to run each time the structure is evaluated to obtain the measured dynamic characteristics. This can be very time consuming and may not be suitable for on-line applications. In contrast, neural networks are computationally fast once they have been trained. However, neural networks have the reputation of being black boxes that are difficult to understand.

Fuzzy systems allow for easier understanding because they are expressed in terms of linguistic variables [11], which are expressed in terms of a set of rules. In many ways, a set of rules obtained from observation and experience is what human experts also use for monitoring the health of many structures and for making decisions. Fuzzy systems have a built-in fuzzification process at the front end that accounts for uncertainty and does not need to be trained on several cycles of noisy data like neural networks to account for uncertainty [12]. It is well known that feedforward neural networks are universal function approximators [13]. Recently, it has been proved that classical feedforward neural networks can be approximated to an arbitrary degree of accuracy by a fuzzy logic system (FLS), without having to go through the laborious training process needed by a neural network [14]. Therefore, fuzzy systems share the universal approximation characteristics with neural networks and can perform any function approximation or pattern-recognition task that a neural network can perform.

Fuzzy logic is a useful and efficient method for modeling complex systems where uncertainty and imprecision can be important, and can be used to solve the damage detection problem. Fuzzy systems address uncertainty directly by using linguistic reasoning, which is more robust to uncertainty than pure numerical reasoning. Very few researchers have used fuzzy logic for structural damage detection, primarily because of the lack of familiarity with fuzzy logic among most structural engineers. Some researchers have used fuzzy logic to improve neural network approaches for damage detection. For example, Ramu and Johnson [15] and Nyongesa *et al.* [16] used fuzzy logic for improving the performance of neural networks for damage detection of composite structures. Ramu and Johnson created a fuzzy neural network to detect, classify, and estimate the extent of damage in a composite structure from its vibration response. They mention that fuzzy representation was found to be the most efficient means of treating uncertainties. Nyongesa *et al.* [16] developed an automated system for feature recognition from shearograms of composites impacted by damage. The use of shearograms for impact damage detection in composites is difficult because the fringe patterns for damage such as a delamination is not clear. The pattern-recognition problem is noisy and has significant uncertainty. The use of a neural network pattern classifier along with a fuzzy logic inference was found to improve damage detection accuracy.

A generalized methodology for structural damage detection using fuzzy logic is presented by Sawyer and Rao [17]. They point out that the development of smart structures with built-in damage detection systems are well suited to automated reasoning tools such as fuzzy logic. Fuzzy associations between structural damage and observable system response were generated using finite element simulations. They considered static and dynamic response of structures to determine their health state. Damage was modeled using the principles of continuum damage mechanics by appropriately reducing the stiffness at the damage location. They found that the fuzzy approach is better suited to tolerate noise and uncertainty than system-identification-type methods. Ganguli [18] demonstrated the use of fuzzy logic for damage detection and isolation in presence of noise for a BO-105 hingeless helicopter rotor. Fuzzy rules were generated from numerical data obtained from finite element simulations. Frequencies were used for damage detection, and it was found that a gross estimate of damage location and size could be obtained from the first four frequencies. He showed that the fuzzy system performed very well even in the presence of noisy data. He also pointed out that with the advent of

embedded and surface-mounted piezoelectric sensors and actuators in structures, operational health monitoring of structures from structural response data using FLSs has become possible.

Sazonov *et al.* [19] developed a fuzzy logic expert system to automate the process of damage detection from strain energy mode shapes. They pointed out that strain energy mode shapes require curvature information and are therefore sensitive to measurement noise, which gets amplified by the double differentiation of displacement needed to get curvature. The peaks in the strain energy mode shapes are the damage indicators, and false peaks can result with noisy data. They developed a set of fuzzy rules from a finite element model of a simple beam. The fuzzy system was then developed to mimic a human expert and very accurate damage detection results were obtained, using mode shapes acquired by impact testing and/or noncontact laser vibrometer methods.

The traditional fuzzy system is an effective tool for damage detection. However, their rules need to be developed and fine-tuned by the user on the basis of the available data. For example, the rules need to be regenerated for different structures and for each time that the set of measurements or the fault changes. The process of rule development is therefore time consuming, not very accurate, and certainly not optimal. Therefore, to make the rule generation and tuning process automatic, GA is used in advanced soft computing techniques, known as the *genetic fuzzy system* [20, 21]. These systems combine the approximate reasoning capability of fuzzy systems with the learning capabilities of GAs. Recently Pawar and Ganguli [12] used a GA for automating the process of rule generation for a fuzzy system for application to structural damage detection. They demonstrated the algorithm for a beam-type structure and a helicopter rotor blade modeled using the finite element method. Such a system represents an alternative to the neural network and GA-based methods for structural damage detection problem.

We see that the use of fuzzy logic in SHM has been rather limited, compared to other soft computing methods. In this article, an introduction is given for developing a fuzzy system using some simple problems. The article is organized as follows. First, a brief description of fuzzy logic is given. Then an FLS is formulated for structural damage detection. The example problem used here is damage detection in a cantilever beam, using frequencies. Next, a method of using GA to automate the development of fuzzy rules is presented. This genetic fuzzy system is illustrated using a composite thin-walled beam with matrix cracking as the damage and frequencies as measurements. Finally, some concluding remarks are made.

2 FUZZY LOGIC SYSTEM

Before using fuzzy logic for damage detection, we introduce the FLS as a function approximation and decision making tool. An FLS is a nonlinear mapping of an input feature vector into a scalar output [22, 23]. Fuzzy set theory and fuzzy logic provide the framework for the nonlinear mapping. FLSs have been widely used in engineering applications because of the flexibility they offer designers and their ability to handle uncertainty. Only a brief introduction to FLSs is given here. Several books provide a detailed introduction to fuzzy logic [22, 24–26].

A typical multi-input single-output (MISO) FLS performs a mapping from $V \in R^m$ to $W \in R$ using four basic components: rules, fuzzifier, inference engine, and defuzzifier. Here, $f : V \in R^m \rightarrow W \in R$ where $V = V_1 \times V_2 \times \cdots \times V_n \in R^m$ is the input space and $W \in R$ is the output space. A typical FLS is shown schematically in Figure 1. Once the rules driving the FLS have been fixed, the FLS can be expressed as a mapping of inputs to outputs.

Rules can come from experts or can be obtained from numerical data. Expert knowledge is typically transformed into fuzzy rules by interviewing

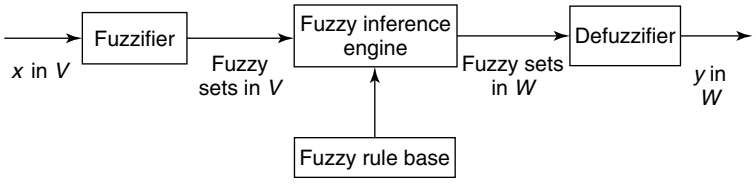

Figure 1. Schematic representation of a fuzzy logic system.

knowledge workers about the problem. Rules from numerical data can be obtained by qualitative analysis of the data obtained by parametric study, or by more formal methods such as GAs as discussed later in this article. It is also possible to combine rules obtained from numerical data with those obtained from experts. Whatever be the approach used to create the rules, they are expressed as a collection of IF-THEN statements such as "IF u_1 is HIGH, and u_2 is LOW, THEN v is LOW". To formulate such a rule we need an understanding of the following:

1. Linguistic variables versus numerical values of a variable. For example, a height of 190 cm is a numerical value that can be labeled with the linguistic variable "Tall". Similarly, a frequency change of 5% due to damage can be labeled as "High".
2. Quantifying linguistic variables. For example, u_1 may have a finite number of linguistic terms associated with it, such as NEGLIGIBLE, SMALL, MEDIUM, HIGH, and VERY HIGH, which is done using fuzzy membership functions.
3. Logical connections between linguistic variables (for example, AND, OR, etc.).
4. Implications such as "IF A THEN B". We also need to understand how to combine more than one rule.

The fuzzifier operates on numerical data and maps crisp input numbers into fuzzy sets. It is needed to activate rules that are expressed in terms of linguistic variables. The process of transferring numerical data into linguistic variables through the fuzzifier is a direct approach to handling uncertainty built-in at the front end of the fuzzy system. An inference engine of the FLS maps fuzzy sets to fuzzy sets and determines the way in which the fuzzy sets are combined. In several applications, crisp numbers are needed as an output of the FLS. In those cases, a defuzzifier is used to calculate crisp values from fuzzy values. The key terms and elements of an FLS are defined next.

Fuzzy sets

A fuzzy set F is defined on a universe of discourse U and is characterized by a degree of membership $\mu(x)$, which can take on values between 0 and 1. Here U represents the set of all possible values that can be taken by the number x. A fuzzy set generalizes the concept of an ordinary set whose membership function only takes two values, zero and unity.

Linguistic variables

A linguistic variable u is used to represent the numerical value x, where x is an element of U. A linguistic variable is usually decomposed into a set of terms $T(u)$, which cover its universe of discourse.

Membership functions

The most commonly used shapes for membership functions $\mu(x)$ are triangular, trapezoidal, piecewise linear, or Gaussian. The designer of the FLS selects the type of membership function used. The Gaussian functions overlap to some degree across all fuzzy sets, and therefore allow all fuzzy rules to fire simultaneously. Therefore, they smooth out the output signal [27]. There is no theoretical requirement that membership functions overlap. However, one of the major strengths of fuzzy logic is that membership functions can overlap. FLS systems are robust because decisions are distributed over more than one input class. For convenience, membership functions are normalized to one, so they take values between 0 and 1, and thus define the fuzzy set.

Inference engine

Rules for the fuzzy system can be expressed as:

$$R_i : \textbf{IF } x_1 \text{ is } F_1 \textbf{ AND } x_2 \text{ is } F_2 \text{ AND } \ldots \ x_m \text{ is } F_m$$
$$\textbf{THEN } y = C_i, \quad i = 1, 2, 3, \ldots, M$$

where m and M are the number of input variables and rules, x_i and y are the input and output variables, and $F_i \in V_i$ and $C_i \in W$ are fuzzy sets characterized by membership functions $\mu_{F_i}(x)$ and $\mu_{C_i}(x)$, respectively. Each rule can be viewed as a fuzzy implication $F_{12\cdots m} = F_1 \times F_2 \times \cdots F_m \rightarrow C_i$, which is a fuzzy set in $V \times W = V_1 \times V_2 \times \cdots V_m \times W$ with membership function given by

$$\mu_{R_i}(x, y) = \mu_{F_1}(x_1) * \mu_{F_2}(x) * \cdots * \mu_{F_m}(x_m) \times \mu_{C_i}(y) \qquad (1)$$

where $*$ is the T-norm with $x = [x_1 x_2 \cdots x_m] \in V$ and $y \in W$. This sort of rule covers many applications. The algebraic product is one of the most widely used T-norms in applications, and leads to a product inference engine.

Defuzzification

Popular defuzzification methods include maximum matching and centroid defuzzification [28]. While centroid defuzzification is widely used for fuzzy control problems where a crisp output value is needed, maximum matching is often used for pattern matching problems where we need to know the output class only. In structural damage detection, it is often better to leave the damage location, size, and other information in linguistic terms. For example, "large damage at root" is more useful and credible than numerical values. In fact, a linguistic output is useful for creating maintenance alerts and suggests prognostic action.

Suppose there are K fuzzy rules and, among them, K_j rules ($j = 1, 2, \ldots, L$ and L is the number of classes) produce class C_j. Let D_p^i be the measurements of how the pth pattern matched the antecedent conditions (**IF** part) of the ith rule, which is given by the product of membership grades of the pattern in the regions that the ith rule occupies.

$$D_p^i = \prod_{i=1}^{m} \mu_{li} \tag{2}$$

where m is the number of inputs and μ_{li} is the degree of membership of measurement l in the fuzzy regions that the ith rule occupies. Let $D_p^{\max}(C_j)$ be the maximum matching degree of the rules (rules $j_l, l = 1, 2 \ldots, K_j$) generating class C_j.

$$D_p^{\max}(C_j) = \max_{l=1}^{K_j} D_p^{j_l} \tag{3}$$

then the system will output class C_{j^*}, provided that

$$D_p^{\max}(C_{j^*}) = \max_j D_p^{\max}(C_j) \tag{4}$$

If there are two or more classes that achieve the maximum matching degree, we select the class that has the largest number of fired fuzzy rules (a fired rule has a matching degree greater than zero) [29].

3 FUZZY LOGIC SYSTEM FOR DAMAGE DETECTION

The description of the FLS given above may appear abstract and mathematical. We illustrate the FLS with a simple problem of damage detection in a cantilever beam using natural frequencies (*see* **Modal–Vibration-based Damage Identification**). A schematic representation of the problem requirement is shown in Figure 2. Damage is modeled using a reduction in element stiffness and a percentage damage parameter D is defined such that

$$D = 100\frac{E^{\text{undamaged}} - E^{\text{damaged}}}{E^{\text{undamaged}}} \tag{5}$$

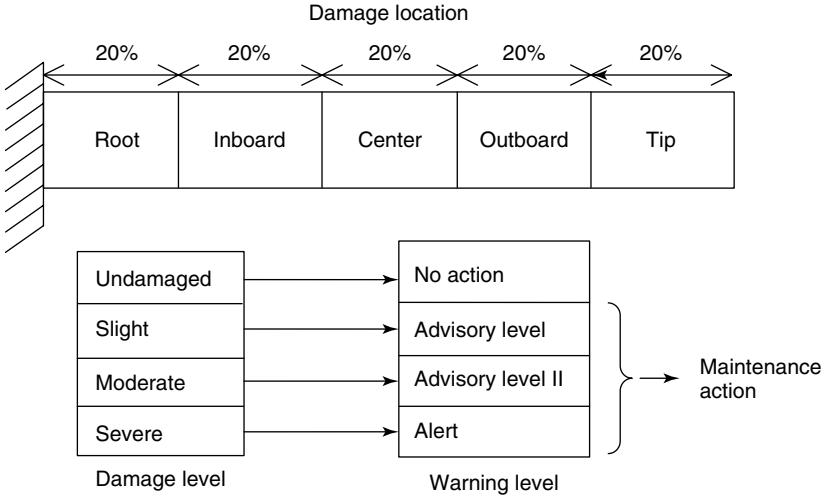

Figure 2. Schematic representation of structural damage detection in a cantilever beam.

where E is the Young's modulus of the material. The beam is 4.94-m long and has a mass per unit length of $6.46\,\mathrm{kg\,m^{-1}}$ and a flexural modulus of $103\,955.3\,\mathrm{N\,m^2}$ [18].

The beam is divided into five uniform segments of equal lengths. These segments are labeled as "root", "inboard", "center", "outboard", and "tip", as shown in Figure 2. The structural damage in each segment is modeled by stiffness reductions (D) of 5, 15, and 25% and these three damage sizes are classified as "slight damage", "moderate damage", and "severe damage", respectively. Damage sizes below "slight damage" are classified as undamaged. A damage size larger than "severe damage" is classified as "catastrophic damage".

From a practical implementation viewpoint, given a slight damage, the warning issued by the diagnostic system is classified as a "level I advisory". For a moderate damage, the warning issued is a "level II advisory" and for severe damage, the maintenance action is an "alert". No warning is issued for an undamaged beam. This form of classification of the structural damage allows for development of a user-friendly decision system that can be deployed in a handheld electronic device or field computer. With the requirements of the damage detection system defined, we proceed to formulate the fuzzy logic behind it.

3.1 Input and output

Let the beam be divided into five damage locations as shown in Figure 2. We want to detect damage in this beam using the first four frequencies. Define measurement deviations from the undamaged beam frequencies as measurement "deltas" given as

$$\Delta\omega = 100\frac{\omega^{(\mathrm{u})} - \omega^{(\mathrm{d})}}{\omega^{(\mathrm{u})}} \tag{6}$$

Here $\omega^{(\mathrm{u})}$ and $\omega^{(\mathrm{d})}$ correspond to the undamaged and damaged frequency. Inputs to the FLS developed for damage detection are then measurement deltas and outputs are structural damage. We have four measurements represented by z and five fault locations represented by x. The objective is to find a functional mapping between z and x, which can be represented as

$$\mathrm{x} = F(\mathrm{z}) \tag{7}$$

where

$$\mathrm{x} = \{\text{Root, Inboard, Center, Outboard, Tip}\}^{\mathrm{T}} \tag{8}$$

$$\mathrm{z} = \{\Delta\omega_1, \Delta\omega_2, \Delta\omega_3, \Delta\omega_4\}^{\mathrm{T}} \tag{9}$$

Each frequency measurement delta has uncertainty.

3.2 Fuzzification

The structural damage locations are crisp numbers. For example, "root" ranges from 0 to 20% of the blade, "inboard" from 20 to 40%, "center" from 40 to 60%, "outboard" from 60 to 80%, and "tip" from 80 to 100%, as shown in Figure 2. To get a degree of resolution of the extent of damage, each of these damage locations is allowed several levels of damage and split into linguistic variables. For example, consider "root" as a linguistic variable. Then it can be decomposed into a set of terms

$$\begin{aligned} T(\text{root}) = \{&\text{Undamaged, slight damage,}\\ &\text{moderate damage, severe damage,}\\ &\text{catastrophic damage}\} \end{aligned} \tag{10}$$

where each term in $T(\text{root})$ is characterized by a fuzzy set in the universe of discourse $U(\text{root}) = \{0, 30\}$, in terms of damage variable D. The other structural damage variables are fuzzified in a similar manner.

The measurement deltas $\Delta\omega_1$, $\Delta\omega_2$, $\Delta\omega_3$, and $\Delta\omega_4$ are also treated as fuzzy variables. To get a high degree of resolution, they are further split into linguistic variables. For example, consider $\Delta\omega_1$ as a linguistic variable. It can be decomposed into a set of terms

$$\begin{aligned} T(\Delta\omega_1) = \{&\text{Negligible, very low, low,}\\ &\text{low medium, medium, medium high,}\\ &\text{high, very high, very very high}\} \end{aligned} \tag{11}$$

where each term in $T(\Delta\omega_1)$ is characterized by a fuzzy set in the universe of discourse $U(\Delta\omega_1) = \{0, 9\}$. The other three measurement deltas are defined using the same set of terms as $\Delta\omega_1$. Measurement deltas larger than those covered by the universe of discourse will represent an extensive structural damage indicative of a catastrophic failure.

Fuzzy sets with Gaussian membership functions are used for the input variables. These fuzzy sets can be defined as follows:

$$\mu(x) = \mathrm{e}^{-0.5((x-m)/\sigma)^2} \tag{12}$$

where m is the midpoint of the fuzzy set and σ is the uncertainty (standard deviation) associated with the variable. Table 1 gives the linguistic measure associated with each fuzzy set and midpoint of the set for each measurement delta. The midpoints are selected to span the region ranging from an undamaged beam (all measurement deltas are zero) to one with significant damage. The standard deviations for $\Delta\omega$ are 0.35%, and are selected to provide for enough intersection between the fuzzy sets so as to optimize accuracy of detection. Note that we have developed the fuzzy sets manually using a simple uniform discretization in the measurement variables.

3.3 Rules and fault isolation

Rules for the fuzzy system are obtained by fuzzification of the numerical values obtained from the finite element analysis using the following procedure [23, 30]:

A set of four measurement deltas corresponding to a given structural fault is input to the FLS and the degree of membership of the elements of $\Delta\omega_1$, $\Delta\omega_2$, $\Delta\omega_3$, and $\Delta\omega_4$ are obtained. Therefore, each measurement has nine degrees of membership based on the linguistic measures in Table 1.

Table 1. Gaussian fuzzy sets for frequencies of a cantilever beam

Linguistic measure	Symbol	Midpoints of $\Delta\omega$
Negligible	N	0
Very low	VL	1
Low	L	2
Low medium	LM	3
Medium	M	4
Medium high	MH	5
High	H	6
Very high	VH	7
Very very high	VVH	8

1. Each measurement delta is then assigned to the fuzzy set with the maximum degree of membership.
2. One rule is obtained for each fault by relating the measurement deltas with maximum degree of membership to a fault.

These rules are tabulated in Table 2 for the frequencies. The linguistic symbols used in this table are defined in Table 1. These rules can be read as follows for the "moderate damage at root" fault:

IF $\Delta\omega_1$ is medium high **AND** $\Delta\omega_2$ is low **AND** $\Delta\omega_3$ is very low **AND** $\Delta\omega_4$ is low **THEN** moderate damage at root.

The rules for the other faults can be similarly interpreted. These rules provide a knowledge base and represent how a human engineer would interpret data to isolate structural damage using frequency shifts. For any given input set of measurement deltas, the fuzzy rules are applied for a given measurement, we have degrees of membership for each fault. For fault isolation, we are interested in the most likely fault. The fault with the highest degree of membership is selected as the most likely fault.

A close inspection of Table 2 shows that each of the rules is independent of the other. This is useful for preventing confusion between the rules. The level of discretization in the measurement deltas in terms of the selection of midpoints and standard deviations must be sufficiently high to make the rules independent, for best performance of the FLS. Also note that the set of rules have a built-in damage detection function, since if the first rule fires, the beam is undamaged. Firing of any of the other 15 rules indicates a damaged beam. The problem of location and identification of the damage size is handled through the 15 rules shown in Table 2 after Rule 1. Thus, the three critical functions of damage detection, location, and identification can be handled by a set of simple fuzzy rules. As shown in Figure 2, these rules can also be used to give maintenance alarms.

3.4 Accessing the performance of a fuzzy logic system

If an FLS has been developed properly, it will give excellent results for noise-free numerical data.

Table 2. Rules for fuzzy system for damage detection in a cantilever beam

Rule no.	Damage	Frequency measurement deltas			
		$\Delta\omega_1$	$\Delta\omega_2$	$\Delta\omega_3$	$\Delta\omega_4$
1	Undamaged	N	N	N	N
2	Slight damage at root	VL	VL	N	N
3	Slight damage at inboard	VL	N	VL	N
4	Slight damage at center	N	VL	N	VL
5	Slight damage at outboard	N	VL	VL	N
6	Slight damage at tip	N	N	N	VL
7	Moderate damage at root	MH	L	VL	L
8	Moderate damage at inboard	LM	VL	L	VL
9	Moderate damage at center	VL	LM	VL	L
10	Moderate damage at outboard	N	L	LM	L
11	Moderate damage at tip	N	N	VL	L
12	Severe damage at root	VVH	M	LM	LM
13	Severe damage at inboard	MH	VL	M	LM
14	Severe damage at center	L	H	VL	M
15	Severe damage at outboard	N	M	MH	LM
16	Severe damage at tip	N	N	VL	LM

In such cases of ideal data, the fuzzy rules are similar to a classical expert system. However, the strength of the fuzzy system comes out when numerical data is contaminated with noise, which is the case for most damage indicators used in structural damage detection. The FLS is tested using noise contaminated simulated data. Given a computed frequency measurement delta $\Delta\omega$, a random number $u = [-1, 1]$ and a noise level α, the noisy simulated measurement delta is given as $\Delta\omega_{\text{noisy}} = \Delta\omega(1 + u\alpha)$. We observe that noise addition to $\Delta\omega$ accounts for both model and measurement uncertainty. Five thousand noisy data points are generated for each seeded fault, and the percentage success rate for the fuzzy system in isolating a fault is calculated. Table 3 shows the average success rate of damage detection for increasing levels of noise. It is clear that the damage detection accuracy is 100% for a noise level of up to 15% in the data, and shows a gradual reduction after that.

The example problem discussed above clearly shows the ability of the FLS to detect damage accurately from noisy data. For most structural damage detection problems, such a fuzzy system can be developed manually by engineers. However, as the complexity of the problem increases in terms of number of measurements, damage levels, and damage locations, it becomes difficult to develop the fuzzy rules manually. Each time a fuzzy discretization is selected and rules obtained, the performance of the FLS needs to be evaluated. If the performance is not good, one has to adjust the fuzzy sets until a good performance is achieved. The process of adjusting the fuzzy sets involves changing the midpoints and standard deviations of Gaussian sets, if they are being used, calculating the new rules for the fuzzy sets selected, and then evaluating them for ideal and noisy data. This process involves trial and error, and becomes very cumbersome with increasing number of fuzzy sets and rules. In the next section, we

Table 3. Average percent success rate in fault detection using frequencies at different noise levels

Damage level	$\alpha = 0$	$\alpha = 0.05$	$\alpha = 0.1$	$\alpha = 0.15$	$\alpha = 0.2$	$\alpha = 0.25$	$\alpha = 0.3$
Undamaged	100	100	100	100	100	100	100
Slight	100	100	100	100	99	97.24	93.94
Moderate	100	100	100	100	99.33	97.84	96.51
Severe	100	100	100	100	99.7	98.24	96.32

discuss an approach for automating the rule development process for fuzzy systems by using optimization methods such as the GA.

4 GENETIC FUZZY SYSTEM

In this section, we formulate the genetic fuzzy system for detection of crack density and location of matrix cracks in a thin-walled hollow circular composite beam, shown in Figure 3. Inputs to the genetic fuzzy system are measurement deltas and outputs are crack density and locations of cracks (*see* **Lamb Wave-based SHM for Laminated Composite Structures**). The objective is to find the mapping between eight frequency measurement deltas and 10 locations of matrix cracking.

Composite cross sections used in many applications are thin-walled and are produced with various cross-sectional dimensions and ply orientations. Here, a hollow circular cross section with uniform diameter and thickness along the length is considered. The wall consists of $[\pm\theta_m/90_n]_s$ family of composite laminates. The ply orientation angle is with respect to the longitudinal direction (along the length of the beam). The dynamic analysis is done by a one dimensional (1-D) finite element analysis. For this

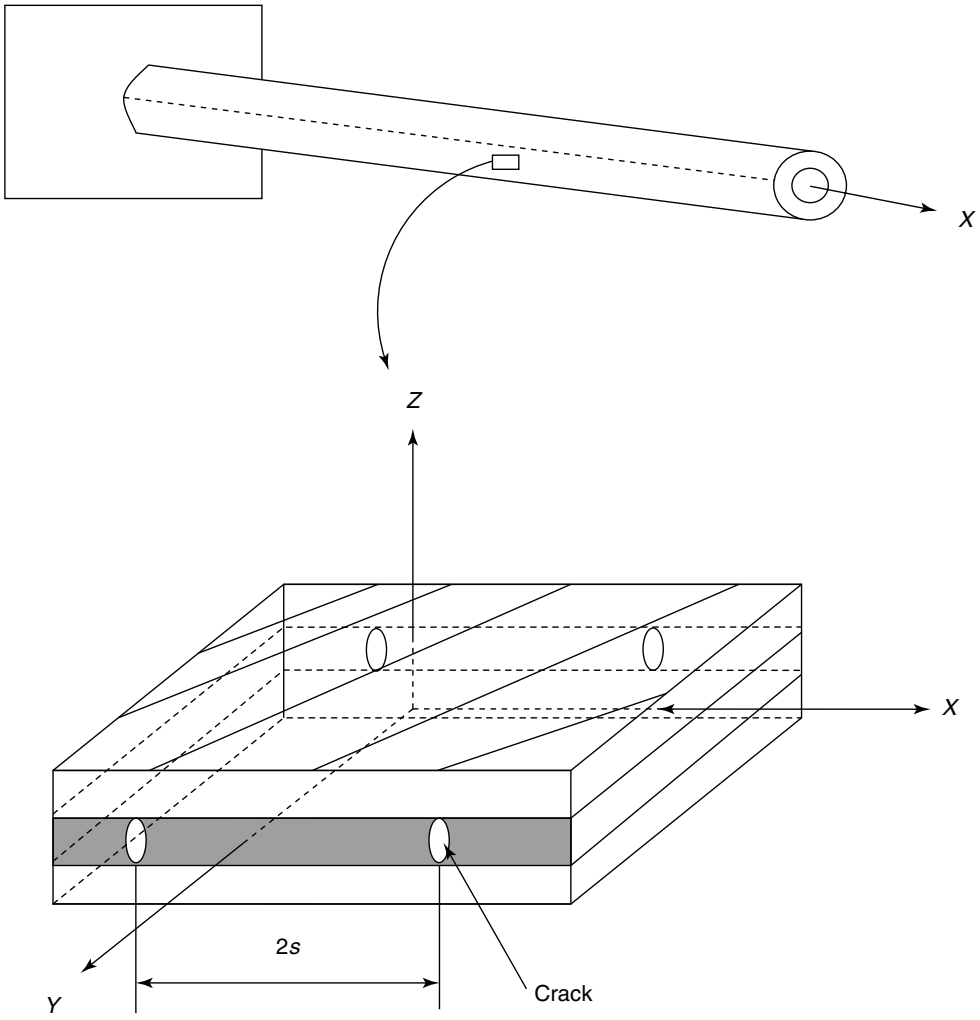

Figure 3. A hollow circular cantilever beam showing a small cross section of the wall with matrix cracks.

1-D model the effective elastic modulus is required, which accounts for all composite properties including the effect of matrix cracking. The effective elastic modulus is formulated considering the small cross section of the beam as a 2-D composite plate.

The beam length is 18 m and the outer diameter of the circular cross section is 600 mm. These properties are taken from Polyzois *et al.* [31] Material properties corresponding to glass epoxy are $E_1 = 48\,\text{GPa}$, $E_2 = 13.30\,\text{GPa}$, $\nu_{12} = 0.235$, and $G_{12} = 5.17\,\text{GPa}$ where the subscript 1 denotes the fiber direction and the subscript 2 denotes the transverse direction. The other properties are material density $\rho = 1.94\,\text{g cm}^{-3}$ and the wall contains 50 plies each 0.22-mm thick. The total thickness of the beam wall cross section is 11 mm. The natural frequencies of the beam are compared with Polyzois *et al.* [31]. Detailed calculations of measurement deltas (change in frequencies) for a thin-walled hollow circular composite beam structure are explained in [32].

In this fuzzy system, location of matrix cracking L_{10} ranges from 0 to 10% of the beam from fixed end, L_{20} from 10 to 20%, and so on, up to L_{100} from 90 to 100%. To get a degree of resolution of the extent of matrix cracking, each of these matrix cracking locations is allowed several levels of damage level and split into linguistic variables. These classifications are based on the numerical results obtained for matrix cracking. The matrix crack density can broadly be classified as "undamaged" for zero crack density, as "slight damage" for 1–5 crack density, as "moderate damage" for 5–10, as "severe damage" for 10–20 and as "very severe damage" for more than 20. Crack density, in this study, refers to the number of cracks per 10 cm.

The measurement deltas $\Delta\omega_1, \Delta\omega_2, \ldots, \Delta\omega_8$ are also treated as fuzzy variables. Fuzzy sets with Gaussian membership functions are used to define these input variables. Change in frequency (measurement delta) is calculated by using finite element simulations for a combination of 10 different locations and four different levels of damages (undamaged, slight damage, moderate damage, and severe damage). Crack densities greater than 20 represent very severe damage and are excluded when formulating the fuzzy system.

Rules for the fuzzy system are obtained by fuzzification of the numerical values obtained from finite element analysis. The fuzzy sets corresponding to $\Delta\omega_1, \Delta\omega_2, \ldots, \Delta\omega_8$ are generated by taking the $\Delta\omega$ values obtained by the finite element method (FEM) solution as midpoints of the membership function corresponding to a location of matrix cracking and damage level. This strategy for selecting the midpoint ensures that the maximum degree of membership ($\mu = 1$) for each fuzzy set occurs at the values of $\Delta\omega$ since the Gaussian function is highest at the midpoint. The standard deviation of the Gaussian membership functions are calculated using GA for optimization of the success rate as discussed next.

Typical resolution for the natural frequencies of a lightly damped mechanical structure is 0.1% [33]. Therefore, we consider a noise level of 0.1 to simulate data used for developing the genetic fuzzy system. Noise is added to the finite element simulations. Here the noise level $\alpha = 0.1$ corresponds to normal-quality data, $\alpha = 0.05$ to good-quality data, and $\alpha = 0.15$ to low-quality data.

By generating noisy frequency deltas and testing the fuzzy system for a known damage, we can define a success rate as

$$S_R = \frac{N_c}{N} \times 100 \tag{13}$$

Here N_c is the number of correct classifications among N number of noisy training samples. Since the midpoints of the fuzzy sets are tuned using FEM, the success rate is a function of the standard deviations of the Gaussian functions for the fuzzy system, i.e.,

$$S_R = S_R(\sigma_{ij}) \tag{14}$$

The design of the fuzzy system can be posed as an optimization problem and can be written in standard form [12] as

Maximize

$$S_R(\sigma_{ij})$$

subject to the move limits

$$\sigma^{\min} \le \sigma_{ij} \le \sigma^{\max}, \qquad i = 1, 2, \ldots, M \quad j = 1, 2, \ldots, P \tag{15}$$

The use of formal optimization to design the fuzzy system leads to an optimal diagnostic system, which provides the best results for the given structure, measurement set, and noise level in the data. GAs provide useful optimization tools since they can find

global optima and do not need gradient information that is required by most traditional optimization algorithms. Details of GAs can be found in [33].

The schematic representation of the FLS and the genetic fuzzy system are shown in Figures 1 and 4, respectively. Figure 1 shows the components of a classical FLS where data is fuzzified, the rules are evaluated, and the defuzzification is used to determine the final output of the system. For the current problem, inputs are measurement deltas ($\Delta\omega$) and the outputs are the damage presence, location, and size. Figure 4 shows how the FLS in Figure 1 is trained. Data from the finite element simulation is used to obtain the midpoints of the fuzzy system to maximize the success rate (S_R) by using the standard deviations as design variables. The outputs of the genetic fuzzy system are damage presence, location, and size, which are the same as those for the fuzzy system in Figure 1. However, the addition of learning using GA allows the genetic fuzzy system to optimize its rule base.

In this way, the "undamaged" level of damage is represented by one rule and the three damage levels "slight", "moderate", and "severe" at 10 locations are represented by a total of 10 rules each. Therefore, the complete matrix crack detection system can be represented by 31 rules. For example "slight" damage at 0–10% part of the beam can be written as "slight L_{10}". The rules are detailed and complex due to the large number of measurements and locations, and are given in Table 4 in terms of the midpoints and standard deviations of the fuzzy sets.

For the GA, the population size, crossover probability, mutation probability, and maximum number of generations are 20, 0.8, 0.05, and 30, respectively. These parameters are obtained by numerical experiments. Midpoints and standard deviations are two data sets required for the formulation of the genetic fuzzy system for damage detection of structures. These midpoints change for different structures and damage combinations since they are dependent on geometrical and material properties of the structure and on the damage model. Since this method is based on model-based diagnostics, an FEM of the structure needs to be developed. Once such an FEM is developed, GA is used with this model to design the fuzzy system. Once the genetic fuzzy system is developed, it can detect and isolate faults from measured frequencies. Table 5 shows the average success rate of the fuzzy system for different levels of noise in the data for $[\pm\theta_8/90_9]$ types of composites. Here, a training noise level of 0.1 was used. It can be seen that the fuzzy system is robust to quite high levels of noise in the data.

An interesting feature of the genetic fuzzy system is that though damage location accuracy can decline

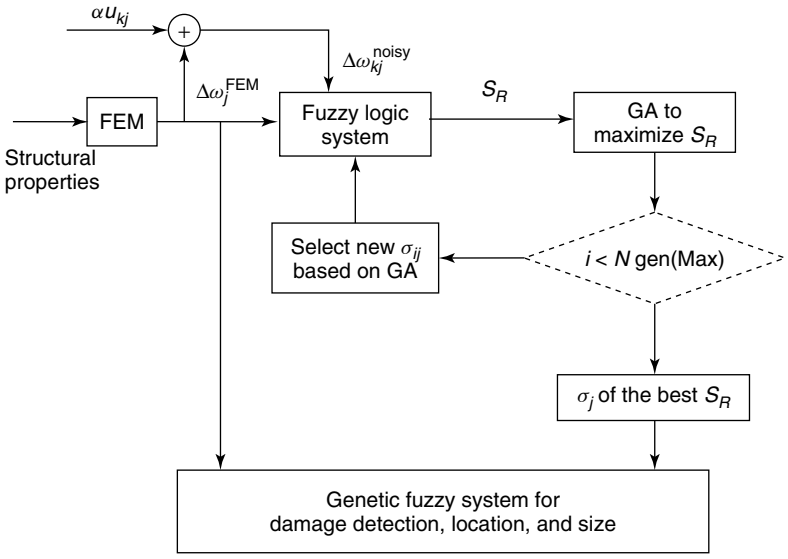

Figure 4. Schematic representation of a genetic fuzzy logic system.

27	Severe L_{60}	2.74 (0.30)	3.21 (0.33)	2.67 (0.32)	3.14 (0.34)	2.73 (0.31)	3.10 (0.34)	2.83 (0.31)	3.06 (0.31)
28	Severe L_{70}	2.68 (0.30)	3.11 (0.30)	3.06 (0.33)	2.68 (0.33)	3.16 (0.32)	2.84 (0.32)	2.88 (0.34)	3.17 (0.34)
29	Severe L_{80}	2.65 (0.33)	2.89 (0.34)	3.26 (0.34)	3.01 (0.30)	2.68 (0.30)	2.96 (0.30)	3.17 (0.34)	2.89 (0.33)
30	Severe L_{90}	2.64 (0.31)	2.70 (0.31)	2.94 (0.30)	3.20 (0.32)	3.24 (0.30)	3.02 (0.34)	2.79 (0.33)	2.79 (0.30)
31	Severe L_{100}	2.63 (0.32)	2.64 (0.32)	2.66 (0.33)	2.72 (0.33)	2.82 (0.31)	2.94 (0.32)	3.07 (0.33)	3.18 (0.31)

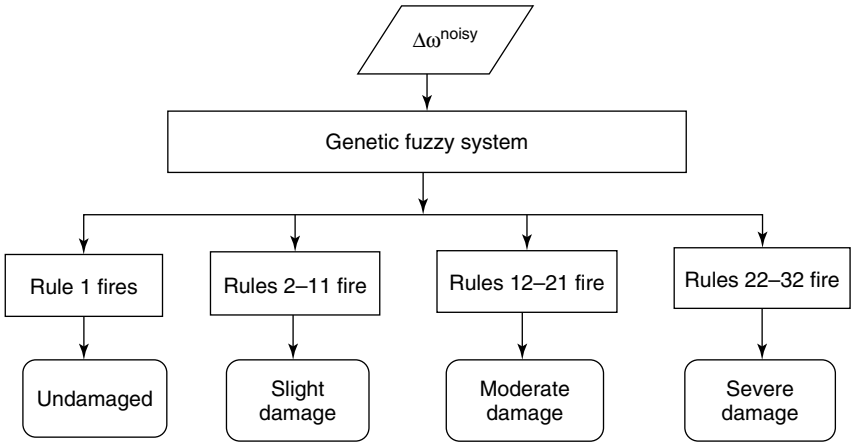

Figure 5. Damage detection and identification using genetic fuzzy system.

Table 5. Average success rate of genetic fuzzy system at different noise levels

Ply angle	$\alpha = 0.05$	$\alpha = 0.1$	$\alpha = 0.15$
0	100	97.31	89.40
30	100	99.80	96.27
60	100	100	100

at higher noise levels, the estimate of damage detection remains good for high levels of damage [32]. Figure 5 shows how the rules in Table 4 can be used to detect whether damage is present and also to identify the size of damage.

5 CONCLUDING REMARKS

Fuzzy logic provides a powerful approach for solving the inverse problem of structural damage detection from noisy data. The use of linguistic rules and a built-in fuzzifier at the front end of the fuzzy system provides an elegant approach to handling uncertainty in decision making. Simple fuzzy systems can be easily developed for most damage detection problems, using a method to relate the most likely situations to rules. As the number of measurements, damage locations, and number of damage types increases, the genetic fuzzy system can be considered. We also note that it is also possible to combine fuzzy rules generated from data to those generated from expert knowledge, a feature that is not possible with the neural network approach.

Fuzzy systems have enormous potential in SHM as they can handle uncertainty in measurements and models. They can be used for addressing uncertainty in finite element models due to variations in material and geometric properties. However, fuzzy systems suffer from the "curse of dimensionality" as the number of measurements and damage levels increase since the number of fuzzy rules can become very large. In general, it is advantageous to use fuzzy systems for SHM where the number of measurements and damage levels is relatively small.

Chapter 53
Operational Loads Sensors

William F. Ranson and Reginald I. Vachon
Direct Measurements, Inc., Atlanta, GA, USA

1 INTRODUCTION

Load sensors for structural health monitoring (SHM) measure force, torque, pressure, and strain. The data are translated into information to determine the effect of loads and/or vibration on operating dynamic systems and static infrastructures. Sensors used to make these measurements are accelerometers, frequency devices, or strain gauges. The theory of operation of each is fundamental. Nonetheless, there are a number of manifestations of theory for each by commercial companies and research laboratories providing accelerometer, frequency, and strain gauge devices. Some of these devices are described and the general theory for the major types of accelerometers and strain gauges are presented.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

The transition from usage monitoring to individual component damage tracking is the challenge for these types of sensors. The areas of regime recognition, loads, strain prediction, and component serialization need to improve for enhanced structural health assessment. Of these three requirements, loads and strain prediction along with serialization represent the direct application for SHM.

The current developments of sensors of this type are to overcome the limitations of complex instrumentation, long wiring lengths, and in rotating components of the elimination of slip rings. Strain sensor development is focused on wireless technology, serialization, and energy harvesting for power. The accelerometers used in health usage monitoring systems (HUMS) such as the Navy V-22 and the Army Apache and Blackhawk helicopters are incorporating regime recognition in the onboard data acquisition systems.

2 ACCELEROMETERS

2.1 Overview

Accelerometers are one of the basically three vibration measuring instruments, which measure displacements, vibrations, and accelerations as a result of harmonic motion of a base relative to a mass system. The most common types are the displacement and acceleration measurement instruments. They consist

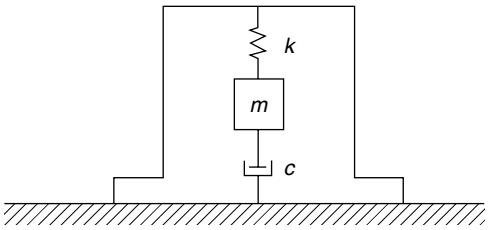

Figure 1. Schematic of an accelerometer.

of a case containing a spring mass damper system of the type shown in Figure 1 and a device measuring the displacement of the mass relative to the case. The mass is usually constrained to move along a given axis. Measurement of the mass relative to the case is measured electrically. When the frequency of the base is low relative to the spring mass damper of the system, the instrument is proportional to the acceleration of the case.

2.2 Theory

A single-degree-of-freedom mechanical model with viscous damping as shown in Figure 1 can be used to describe the mechanical behavior of instruments to measure force, pressure, and motion. Accelerometers are a special case of this type of instrument where a component with frequencies far below the natural frequency of the transducer, the relative motion between the base and the transducer, is proportional to the base acceleration. Figure 1 is a schematic that represents the vibration of a base by $y(t) = Y \sin \omega t$. From Newton's second law of motion [1], the equation of motion for the seismic mass is obtained. Thus

$$m\frac{\mathrm{d}^2 z}{\mathrm{d}t^2} + c\frac{\mathrm{d}z}{\mathrm{d}t} + kz = m\omega^2 Y \sin \omega t \qquad (1)$$

where m is the mass of the seismic body, k is the linear spring constant, and c is the viscous damping constant, $z = x - y$ is the relative displacement between seismic mass and the base, and $z, \mathrm{d}z/\mathrm{d}t, \mathrm{d}^2 z/\mathrm{d}t^2$ are the relative displacement, velocity, and acceleration.

A steady-state solution is assumed in the form $z = Z \sin(\omega t - \phi)$ and $Z = m\omega^2 Y$.

The solution yields

$$Z = \frac{Y\left(\omega/\omega_n\right)^2}{\sqrt{\left(1 - \left(\omega/\omega_n\right)^2\right)^2 - \left(2\zeta\left(\omega/\omega_n\right)\right)^2}} \qquad (2)$$

$$\tan\phi = \frac{2\zeta\left(\omega/\omega_n\right)}{1 - \left(\omega/\omega_n\right)} \qquad (3)$$

where $\zeta = c/c_c$ is the viscous damping ratio and ω_n is the seismic mass natural frequency.

Accelerometers have a small frequency ratio $\omega/\omega_n \ll 1$ and $\zeta \ll 1$ (small damping); then

$$Z = \frac{\omega^2 Y}{\omega_m^2} = \frac{\text{Base acceleration}}{\omega_n^2} \qquad (4)$$

The crystal accelerometer behaves like an underdamped, spring mass system with a single degree of freedom. Equation (1), a classical second-order differential equation, can be used to describe the behavior of the electromechanical crystal accelerometer system.

Piezoelectric crystals subjected to a force exhibit an electrical charge. Slicing a quartz crystal, for example, relative to an xyz axis results in a sensor producing a charge based on the direction of the applied force. This fact is used to design accelerometers used in dynamic systems as well as for quasi-static measuring systems using a quartz crystal with special signal conditioning. Examples can be given for quasi-static measurements over periods of minutes and even hours.

Piezoelectric crystal sensors are of high impedance or low impedance. Low-impedance sensors have a built-in charge-to-voltage converter and require an external power source to power the device and to separate the output voltage from the bias dc voltage. These low-impedance systems are tailored to a particular application. High-impedance units require a charge amplifier or external impedance converter for charge-to-voltage conversion. The high-impedance sensors are more versatile than the low-impedance devices.

Time constant and drift are two terms associated with the use of charge amplifiers with piezoelectric devices. The time constant is the discharge time of an ac-coupled circuit. One time constant is the period of time the input decays by 63–37% of its original value.

The product of the time constant resistor R_t and range capacitor C_t yields the time constant. Figure 2 depicts a high-gain inverting voltage amplifier typically used with crystal sensors.

The amplifier yields an output voltage that can be expressed by

$$V = -\frac{Q}{C_\mathrm{r}}\left[\frac{1}{\left[1+\frac{1}{A}C_\mathrm{r}(C_t+C_\mathrm{r}+C_\mathrm{c})\right]}\right] \quad (5)$$

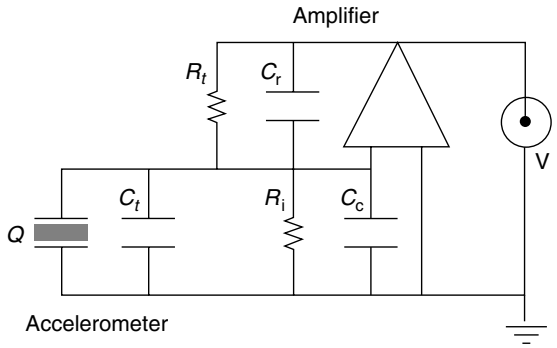

Figure 2. Typical accelerometer circuit.

where C_t is the sensor capacitance, R_i is the cable and sensor resistance, C_c is the cable capacitance, C_r is the range capacitor, R_t is the time constant, A is the open-loop gain, and Q is the charge generated.

When the open-loop gain is high, the output voltage is a function of the input charge and range capacitance.

$$V = -\frac{Q}{C_\mathrm{r}} \quad (6)$$

High-impedance crystals coupled with an amplifier with a high open-loop gain produce a usable output voltage. Quartz-based piezoelectric sensors are widely used because they operate up to temperatures of 498.9 °C, and stresses of up to approximately 137 895 Pa, ultrahigh insulation resistance of 1014 Ω, which permits low frequency (1 Hz), negligible hysteresis, high rigidity, and high linearity.

There are a variety of accelerometers. Listing includes capacitive spring mass based; electromechanical servo; null balance; resonance; magnetic induction; optical; surface acoustic wave; laser; bulk micromachined piezoresistive; bulk micromachined capacitive; capacitive spring mass based; piezofilm; piezoelectric; shear mode accelerometer; thermal

(submicrometer CMOS process); and modally tuned impact hammers.

2.3 Example of operational load sensors for SHM

An excellent example of operational load sensors is the University of South Carolina (USC) drivetrain test stand laboratory. The test stands (see Figures 3 and 4) in this facility are capable of testing drivetrain components (bearings, gearboxes, swashplates, oil coolers, and shafts) of AH-64, UH-60, and ARH-70 aircraft. Additionally, they are able to provide up to 150% of aircraft power at full speed for the components under testing. These stands are also capable of handling shaft misalignment requirements while remaining safe. Other stands at USC include AH-64, ARH-70, CH-47, and UH-60 hydraulic pump stands, as well as AH-64, ARH-70, CH-47, and UH-60 main rotor swashplate bearing assembly stands. All test stands utilize several data acquisition systems, including current in-flight monitoring systems such as the HUMS (Multi Signal Processing Unit (MSPU) and/or Integrated Mechanical Diagnostics (IMD)-HUMS), as well as a specialized laboratory data acquisition system capable of recording torque, speed, temperature, vibration, and acoustic emissions. All test stands are controlled on the basis of monitored data measures of torque, speed, and temperature, which are collected every 2 s. All vibration and acoustic emissions data are collected every 2 min. Operational load sensors of this type have been developed for rotary wing aircraft. References 2–5 describe applications in maneuver regime recognition and SHM using drivetrain, gearbox, engine, rotor track, and balance accelerometers as part of the HUMS onboard system.

3 STRAIN GAUGES AND STRAIN MEASUREMENT

3.1 Overview

Strain gauges measure the relative displacements of a small straight line segment between usually undeformed and deformed configurations of a body subjected to loads. The electrical resistance strain gauge is based on this principle and was first established by Lord Kelvin in 1856 and accounted for more than 80% of the stress analysis applications in the 1980s. Also, electrical resistance strain gauges are widely used as sensors in transducers that have been developed to measure load, torque, and pressure. Historically, strain measurement for operational SHM has relied on electrical resistance strain gauge applications. In recent years, optical-based

techniques have been developed to measure strains. Some of these very useful laboratory technologies [6, 7] include digital image correlation, interferometry, photoelasticity, holographic interferometry, and fiber-optic strain gauges.

The concentration here is the electrical resistance strain gauge and one optical technique suitable for in-the-field measurement and verification of engineered residual strains intended to enhance fatigue life for operating systems such as fastener holes in aircraft structures. The theory of each is discussed and examples are given.

3.2 Electrical resistance strain gauge

The characteristics for electrical resistance gauges are listed in [6, 8] based on the premise that they are usually the most economical. Some of the gauge characteristics are as follows:

1. The gauge constant should be stable with respect to both temperature and time.
2. Strain measurement accuracy of $\pm 1\,\mu\mathrm{m\,m^{-1}}$ (μin./in.) over a range of $\pm 5\%$ strain.
3. The gauge length and width should be small.
4. The inertia of the gauge should be minimal for the measurement of dynamic strains.
5. The response or output of the gauge should be linear over the entire strain range of the gauge.

These characteristics are not only criteria but also constraints predicated on the limitations of the electrical resistance gauge. They also provide a basis for comparison and contrasting of other strain gauges such as inductance, capacitance, and optical gauges.

3.3 Theory of electrical resistance strain gauge

The electrical resistance strain gauge uses the analog of the change in resistance to resistance ratio to translate the change in resistance of the wire gauge as it undergoes strain into strain readings. The strain sensitivity (S_A) is termed the *gauge factor*. This is expressed by

$$S_A = \frac{dR/R}{dl/l} \tag{7}$$

where dR is the change in resistance, R is the initial resistance, dl is the length change of a small line segment, and l is the initial length of a small line segment.

Equation (7) can be now expressed in terms of the strain:

$$\varepsilon_g = S_A \frac{dR}{R} \tag{8}$$

where $\varepsilon_g = dl/l$ is the gauge strain from the measured resistance change.

Theoretically, the change in the resistance of the gauge is a function of surface deformations. Real considerations that affect the change in resistance include the adhesive used to affix the gauge to the surface, stability of the surface, temperature, and the material. Also, axial strain measurement is not sufficient to achieve complete analysis. A combination of gauges is required to yield orthogonal strains and associated shear strains. The electrical resistance strain gauge has wide use and utility. There are a variety of gauge configurations and wire filaments used to achieve stability, temperature sensitivity, and strain characteristics of the sensor. Many strain gauge filament materials degrade over time and are temperature sensitive. Thus, long-term continuous applications require attention to drift and temperature compensation. Selecting a gauge is based on the gauge characteristics that include gauge factor, thermal coefficient of resistively, resistance, and temperature coefficient of gauge factor. There are several manufacturers of gauges and the wide variety of gauges can be appreciated by reviewing available products.

3.4 Example of operational strain gauge application

The need exists to improve the accuracy of load/strain prediction by directly measuring data in flight. Microstrain has demonstrated a sensor that relies on piezoelectric energy harvesters capable of measuring strain, acceleration, and temperature. This type of sensor is a powerful combination of real-time sampling rates up to 4 KHz and onboard data storage. Microstrain sensors are configured to be efficient when using energy to sample, record, and communicate over a bidirectional radio link. Microstrain has

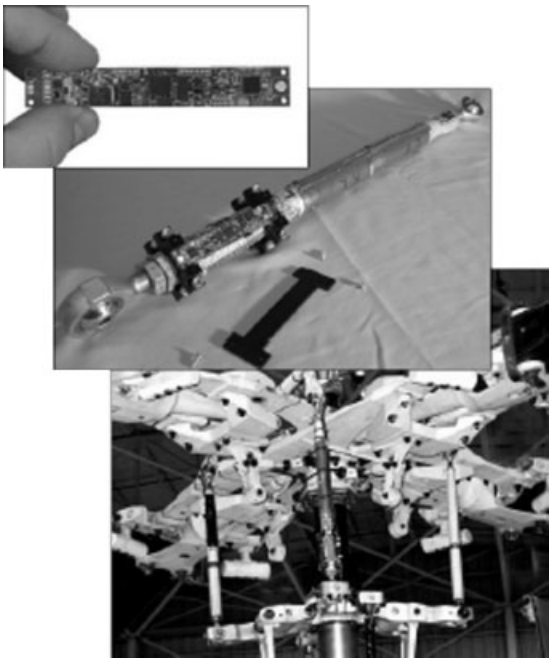

Figure 5. Wireless strain gauge on a Bell pitch link.

successfully demonstrated this technology to measure operational loads/strains on a Bell 412 helicopter pitch link as shown in Figure 5 [9].

3.5 Theory of optical strain gauge

The theoretical basis for the optical strain gauge is shown in Figure 6. Straight line segments are recorded in the undeformed and deformed configurations with the end points *MNOP* mapped to the endpoints $M^*N^*O^*P^*$ [10]. The strains along these orthogonal directions are calculated from the following formulas:

$$E_{MN} = \frac{M^*N^* - MN}{MN} \tag{9}$$

$$E_{NO} = \frac{N^*O^* - NO}{NO} \tag{10}$$

$$E_{OP} = \frac{O^*P^* - OP}{OP} \tag{11}$$

$$E_{PM} = \frac{P^*M^* - PM}{PM} \tag{12}$$

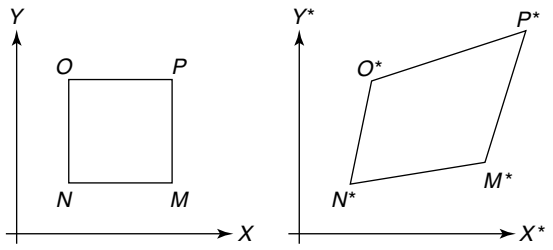

Figure 6. Optical strain gauge in undeformed and deformed configurations.

This type of strain gauge [11] has further properties of serialization as shown in Figure 7. The encoded serialization is shown in the boundaries of the gauge similar to a bar code. The target gauge can be in the form of a thin polymer with the gauge design laser machined into the multilayer polymer to achieve the light and dark patterns or the gauge can be laser bonded onto the surface. The polymer gauge can be affixed to the surface with M-Bond 200, which is the same process used for thin-film electrical resistance gauges. The other alternative application is to laser bond the pattern onto the surface.

This is accomplished by spraying the surface with fine metallic particles suspended in a vehicle of water or alcohol in a normal hand-held aerosol spray can. When the surface has dried, a low-power laser is used to fuse the particles to the surface to create the pattern. The surface is then cleaned with a cloth and water. A third application is to paint the surface with a specialized paint that discolors in response to exposure to a low-power laser. The result is that the gauge is integral to the paint layer. Examples of the

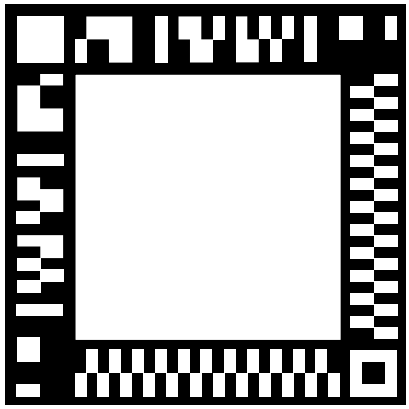

Figure 7. Gauge serialization.

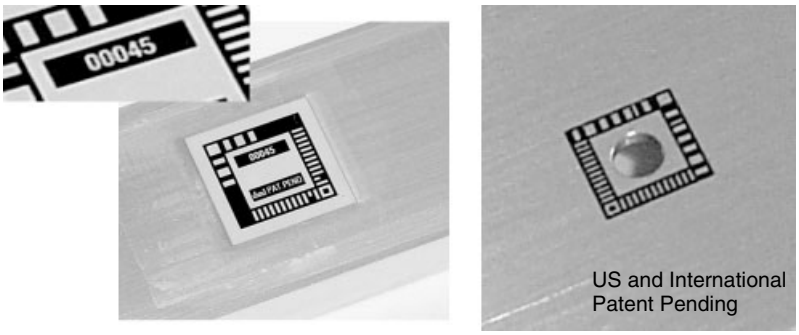

Figure 8. (a) Polymer gauge with serialization and (b) laser-bonded gauge.

polymer gauge and the gauge laser bonded around a hole are shown in Figure 8(a) and (b).

3.6 Features of the technology

(i) Self-contained strain/fatigue monitoring system; (ii) minimal skilled labor required; (iii) nonlinear, multicomponent strain sensor: two orthogonal extensional strains and shear strain from a single gauge; (iv) resting system error $<5\,\mu\varepsilon$; (v) measurement repeatability: $<30\,\mu\varepsilon$; (vi) accuracy increases as strain increases; (vii) temperature compensation enabled; (viii) no fragile electrical components, connection free; (ix) line-of-sight target acquisition; (x) material independent (works on plastics, metals, composites, etc.); (xi) gauge application process does not denigrate material/mechanical properties of host material; and (xii) gauge contains binary encoded information (for gauge location, serial number, or asset management) up to 4 billion unique numbers for each gauge.

3.7 Cold-working validation using optical strain gauge

A 7075-T6 specimen with five fastener holes was used to demonstrate the application of the technology to validate cold working [11]. Wire-free Direct Measurements, Inc. (DMI) gauges were applied around each hole as shown in Figure 9 (front) and baseline readings made and recorded. The specimen

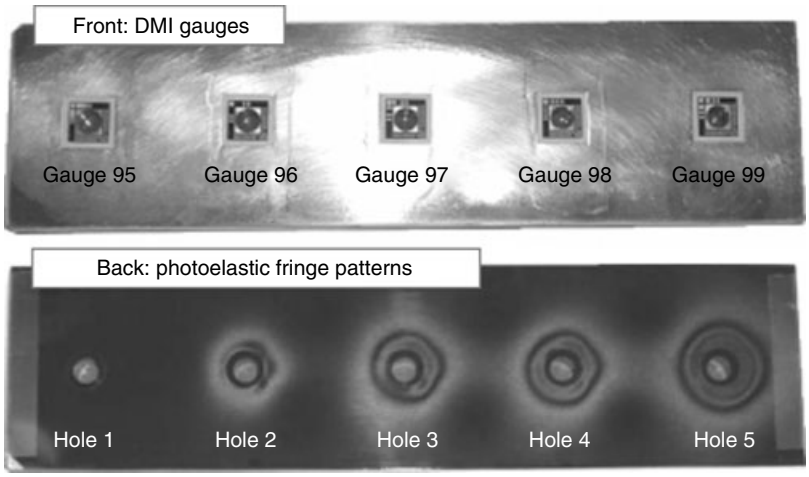

Figure 9. 7075-T6 test specimen front and back.

Table 1. Cold work by hole and gauge

Hole #	CX type	DMI gauge #
1	None	95
2	2%CX (under expanded)	96
3	CB minimum (minimum standard)	97
4	CB maximum (maximum standard)	98
5	CA nominal (over expanded)	99

CX, Cold Work Expansion

was cold worked by Fatigue Technology Inc. (FTI). Prescribed expansions were achieved according to Table 1. After FTI completed cold-work expansion, each gauge was read and the residual strain was measured and recoded. This summary presents the results of the strain measurements and shows the applicability of DMI technology to cold-work expansion.

Residual strain measurements were made on both the inner and outer boundary of each gauge and measured strain components E1, E2, E3, and E4 were recorded according to Figure 9. The holes and corresponding gauge codes are shown in Table 1 and Figure 10.

The DMI gauge outer and inner boundary measurements are shown in Figures 11 and 12. This demonstrates that the residual strain magnitudes follow the trend in photoelastic patterns in Figure 9. Note that the right-hand side fringe order is slightly higher in holes 3, 4, and 5. Accordingly, the strain component E2 measured on the right-hand side of gauges 97, 98, and 99 is also slightly higher. In this figure, gauge 98 fails to indicate higher E2 components due to inner

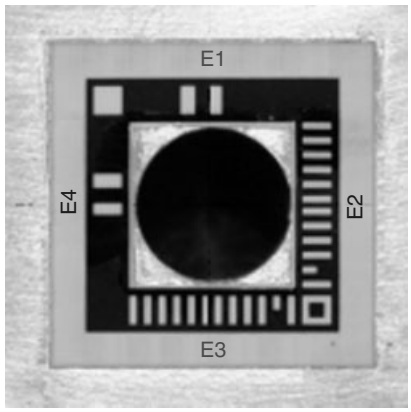

Figure 10. Gauge 96 surrounding hole 2.

boundary gauge damage during cold-work expansion. Nonetheless, the remaining components give sufficient indication of the degree of cold working. In addition, DMI gauges can be produced with dimensions that better match holes sizes, thereby avoiding damage.

4 CONCLUDING REMARKS

Operational load sensors that measure force, torque, pressure, and strain have been successively employed in operating mechanical systems for many years. Specific applications of accelerometers that are used in HUMS systems for rotary wing aircraft measure data associated with exceedance monitoring, rotor track and balance, operational usage, regime recognition, and drivetrain diagnostics. Strain gauges are ideal for dynamic load measurements such as the

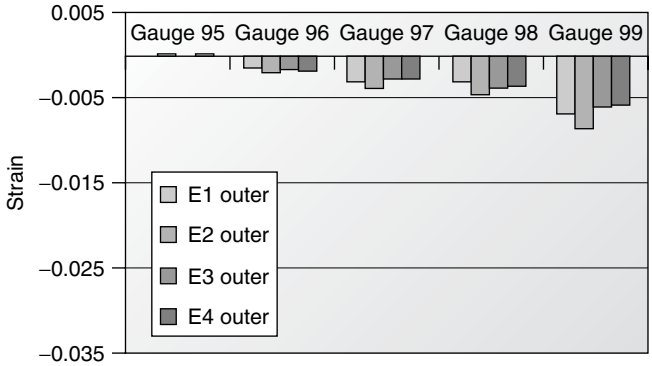

Figure 11. Outer boundary gauge residual strains.

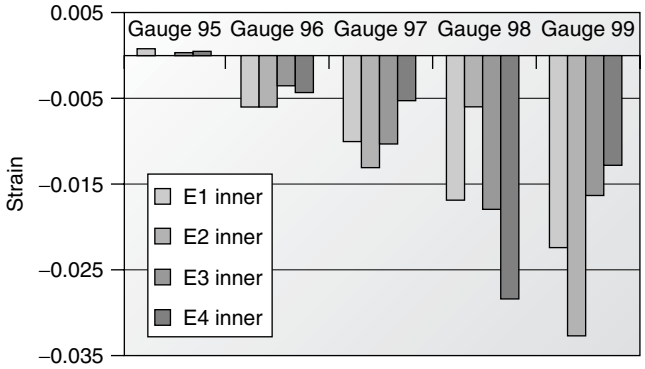

Figure 12. Inner boundary gauge residual strains.

axial load application for the pitch link illustrated in this article. The electrical resistance strain gauge has been an important sensor for measurements in full-scale fatigue tests in both fixed and rotary wing aircraft. The need to develop small scale gauges of this type for operational aircraft has led to the development of energy harvesting wireless strain gauges such as the one by Microstrain. Strain gauge applications of this type measure strains that can be calibrated to axial, bending, pressure, and torque loading. The application of the optical strain gauge while used to measure strains due to cold working are not a measure of loads directly. Cold working of fastener holes increases aircraft fatigue life; however, due to overloads, these compressive residual strains can be relaxed, thus reducing the expected fatigue life. The optical strain gauge measures the compressive strain relaxation and is thus an indirect measure of the effects of overload conditions.

1 INTRODUCTION

Most damage detection methods are based on the fact that damage will change the stiffness, mass, or energy dissipation properties of a system. As a result, the measured dynamic response will change as well. Most global damage detection methodologies suffer from lack of sensitivity. Since damage is a local phenomenon, it may not tremendously influence the global response of a structure, which usually deals with lower frequencies measured during vibration tests. Other environmental and operational variations, such as varying temperature, moisture, loading conditions, and the complexity of the structure itself, make damage detection more challenging [1].

The employment of Lamb waves in nondestructive testing has attracted more and more attention in structural health monitoring research community. Lamb waves are able to propagate over a long distance with very little amplitude loss. If a receiving transducer is positioned at a remote location on the structure, the received signal contains information about the integrity of the line between the transmitting and receiving transducers. The test thereby monitors a line rather than a point and so considerable testing time may potentially be saved [2, 3].

Perhaps the most important work in Lamb wave inspection is conducted by three groups of researchers—Peter Cawley's group from the Imperial College, London, Joseph Rose's group from the Pennsylvania State University, and Victor Giurgiutiu's group from the University of South Carolina. Work from these researchers can be found in numerous literatures [2–34].

The excitation and reception of Lamb waves in structures can be carried out by using interdigitated transducers (IDTs). These transducers have a comb structure composed of sets of periodically distributed fingers with a spatial period equal to the excited

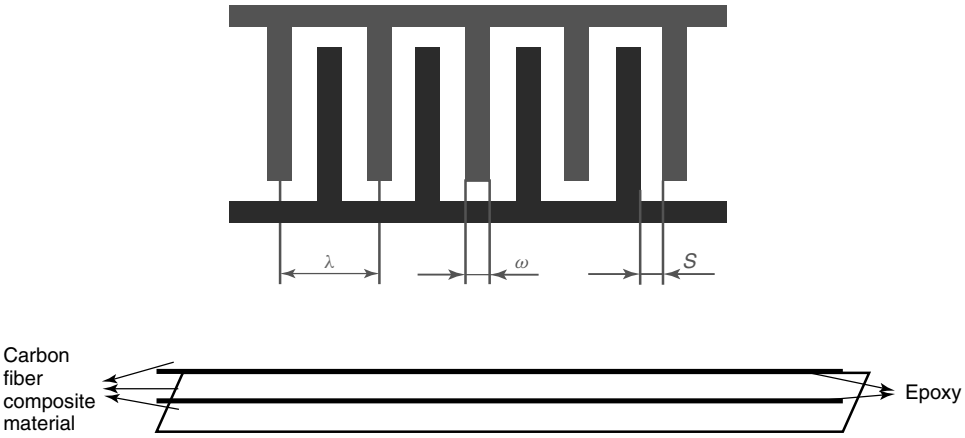

Figure 1. Schematic of a PVDF IDT.

Lamb wavelength [12, 35]. It is a common application to have an interdigital electrode on the surface of a piezoelectric material form an IDT. Owing to its broad bandwidth and low unit price, polyvinyldine fluoride (PVDF) film has envisioned itself to be a suitable substrate for surface and guided-wave transducers that are required to couple electrical energy with the piezoelectric material to detect the wave. The advantages of using PVDF IDTs are as follows. Firstly, PVDF IDTs are low profile and unobtrusive compared with other types of Lamb wave devices. Secondly, PVDF-based IDTs are flexible, so that they can be used on convex or concave surfaces such as pipes and pressure vessels [7].

Lamb wave signals are usually complex and nonstationary. At least two Lamb wave modes can propagate at a given frequency. Conventional fast Fourier transform (FFT) is unable to reveal the nature of Lamb wave signals containing frequency information that varies with time. To solve this problem, time–frequency representations (TFRs) (*see* **Time–frequency Analysis**) are commonly employed for signal analysis in Lamb wave applications. The continuous wavelet transform (CWT) is used as a TFR in this work.

2 DESIGN AND FABRICATION OF A PVDF IDT

A successfully designed PVDF IDT will have a finger pattern sitting on top of a PVDF film as indicated in Figure 1. λ, w, and s represent wavelength, finger width, and finger spacing, respectively. These parameters along with the length of the transducer are the criteria that need to be considered during a design process.

It has been proved that as long as $50\% \leq \frac{w}{w+s} \leq 90\%$ holds true, there is little difference among different finger widths [19]. As for the length of the transducer, a single pair of electrodes/fingers cannot excite surface acoustic waves very efficiently. Therefore, several pairs of electrodes/fingers are commonly seen in an interdigital transducer. A long transducer with many pairs of electrodes/fingers tends to be efficient for exciting and receiving signals only over a narrow frequency range. Consequently, it is also easier to generate a certain wave mode. However, it is practically not possible to build a sensor with infinite length. Besides, the more finger pairs the sensor has, the narrower the bandwidth of the sensor becomes. It is undesirable to design a sensor with very narrow bandwidth that limits its applications. Therefore, it is common to have IDTs with five or six pairs of electrodes/fingers.

The wave length λ is determined depending on the dispersion curves of the materials to be tested. Figure 2 displays the phase velocity dispersion curves of the tested structure used in this study. It is a laminated structure composed of 3 layers of carbon fiber reinforced polymer (CFRP) material. As the dispersion curves have explained themselves, the wave propagation in this structure, composed of anisotropic material, is much less dispersive than that

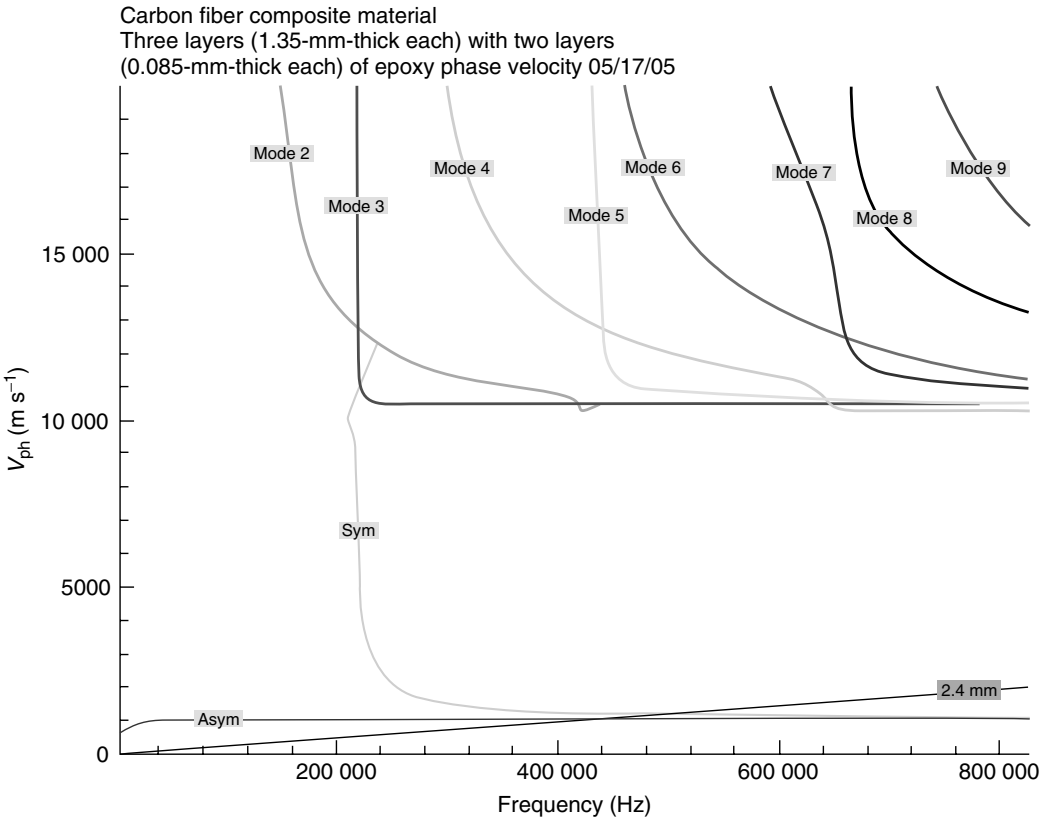

Figure 2. Phase velocity of laminated CFRP plate.

in an isotropic material, such as steel. Since the wave length of IDT is determined by $\lambda = \frac{c_{ph}}{f}$, a straight design line starting from the origin of phase velocity diagram is drawn to help the design process. The slope of the line represents a certain wavelength that if intersects with a dispersion mode will excite that mode at the corresponding frequency. To simplify the wave signal that is to be received, a sensor with a wavelength of 2.4 mm is designed, which ideally only generates symmetric and antisymmetric wave modes in a large frequency band.

The fabrication of PVDF IDTs is realized by using the etch-back photolithography technology adopted from semiconductor industry, which is carried out in a photolithography bay inside a clean room. PVDF films with gold coating on one of the surfaces are acquired from manufacturer. The reason for choosing gold is twofold. Firstly, backing with a high-density material such as gold enhances the performance of PVDF film at low frequencies. Secondly, gold has superb conductivity. After the surface is cleaned, a thin layer of photoresist is evenly spun on top of the gold coating. The finger pattern design is carefully printed out on transparencies and transferred to the photoresist layer through exposing. After being developed, the pattern then stays on the film. The finger pattern is revealed by etching out gold not covered by the resist and the transducer is finalized by removing the photoresist.

3 EXPERIMENTAL SETUP

The test sample structure is 915 mm long, 51 mm wide, and 4.22 mm thick. Through voids of different sizes have been introduced to the middle layer of the laminated structures. They are 0, 1, and 5 mm wide. Figure 3 shows the schematic of the experimental setup. A tone burst sinusoidal signal with a Hanning

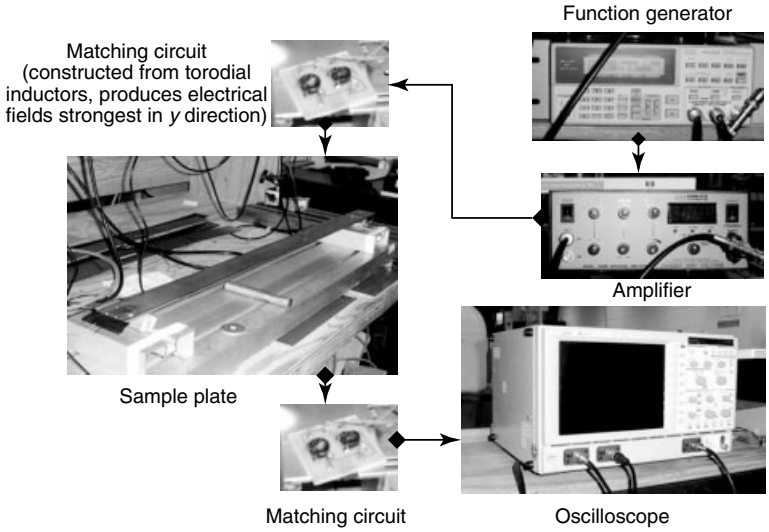

Figure 3. Schematic of the experimental setup.

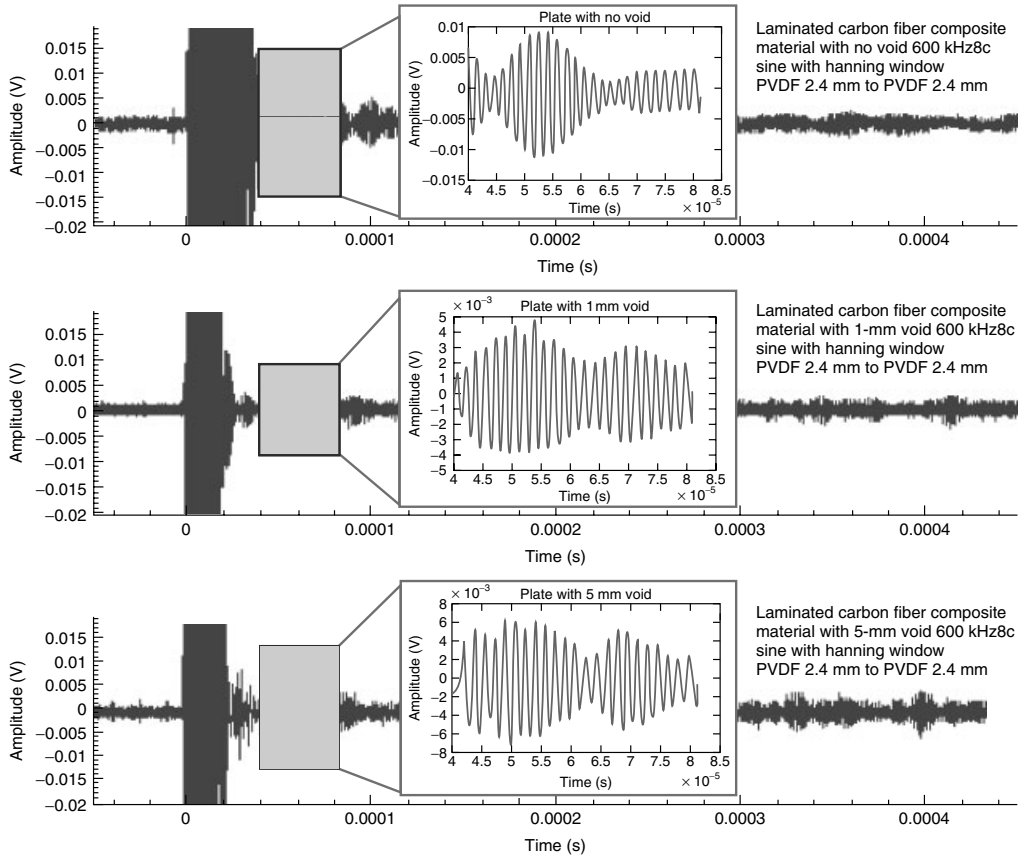

Figure 4. Response from PVDF IDTs on CFRP plates with different void sizes.

window is sent to the function generator as the excitation signal. The signal is then amplified by a high-voltage amplifier before passing through a custom-designed circuit. This circuit applies antiphase voltage on these two groups of fingers of PVDF IDT. As a result, these fingers move in opposite directions, and Lamb waves are generated. After propagating on the plate, wave signals are acquired by another piece of PVDF IDT functioning as a receiver. Another customized matching circuit similar as before is used and converts antiphase voltage into a single-phase voltage before the wave signals are eventually sent to the oscilloscope.

4 RESULTS AND DISCUSSION

Signals received from PVDF IDTs on CFRP plates with no void, 1-mm void, and 5-mm void are plotted in Figure 4. Part of each signal has been extracted and downsampled to reduce the amount of data the computer has to deal with as well as de-noise the signals. Conventional FFT is unable to reveal the nature of signals containing frequency information that varies with time, such as Lamb wave signals. TFRs are usually used for Lamb wave signal processing, among which the CWT is one of the most widely used TFRs for Lamb wave signals. CWT uses a window function called *mother wavelet* to chop the original signal into small sections (*see* **Wavelet Analysis**). Wavelet transform is then applied on each section. The CWT has been performed on the downsampled signals as illustrated in Figure 5.

The results in Figure 5 reveal the fact that if no voids exist in a plate, all the wave modes are integrated in a single pack; once voids appear, wave modes tend to separate from each other; and they get more separated as the size of the void increases.

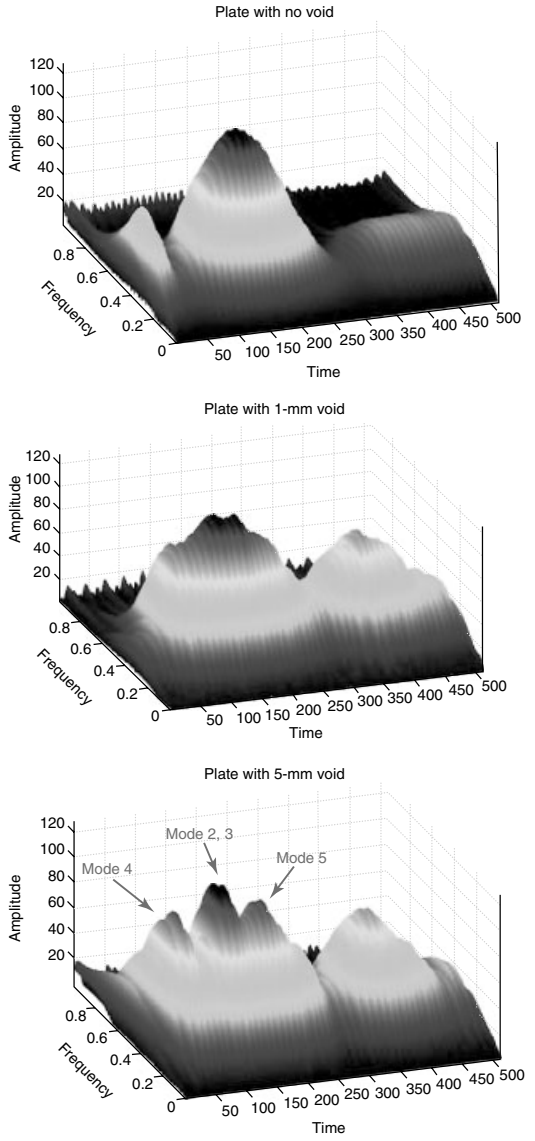

Figure 5. CWT of signals from plates with different void sizes.

5 CONCLUSIONS

A PVDF IDT has been built and used for damage detection in structural health monitoring by generating and receiving Lamb waves. The fabrication of the sensor is achieved on the basis of the etch-back photolithography technology, which gives the sensor a monolithic structure. Results have shown the ability of this PVDF IDT to detect the existence and the severity of damage with the assistance from advanced digital signal-processing methods such as CWT.

Nondestructive Evaluation/Nondestructive Testing/Nondestructive Inspection (NDE/NDT/NDI) Sensors—Eddy Current, Ultrasonic, and Acoustic Emission Sensors

Mark Blodgett, Eric Lindgren, Shamachary Sathish and Kumar V. Jata

Air Force Research Laboratory, Wright Patterson Air Force Base, Dayton, OH, USA

1 INTRODUCTION

Nondestructive evaluation (NDE) exploits the measurement of changes in physical properties of materials using methods that leave the material in undisturbed state after measurements. The basic NDE methods most often exploit electromagnetic, elastic, and thermal properties of materials. Elastic properties are often measured using acoustic/ultrasonic wave propagation methods, while the electrical and magnetic properties can be measured using eddy current and microwave propagation. The thermal property measurements are often performed using infrared detection.

The eddy-current method utilizes a coil energized by a sinusoidal electromagnetic signal. When the coil is brought near an electrically conductive material, the changing magnetic field induces eddy currents. The eddy currents oppose the changing magnetic field causing changes in the impedance of the coil. The magnitude of the impedance change is directly related to the electrical conductivity of the material. Presence of defects in a material will significantly affect eddy-current generation that is detected as impedance changes in the coil. The frequency of the electromagnetic signal and the electrical conductivity of the material determine the penetration depth of the eddy currents. The resolution and size of the defect that can be detected depends on the diameter of the eddy-current probe. Since eddy current can be generated only in electrically conductive materials, the technique is excellent for crack and defect

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

detection in metallic materials and structures. This article describes in detail the basic principles, coil design, application to defect detection, and advanced developments in material characterization using eddy current.

In general, ultrasonic waves propagated into a material or structure measure the elastic properties (velocity/modulus, attenuation/damping). Whenever the propagating ultrasonic waves are obstructed by defects, the energy is reflected, transmitted, and scattered. Examination of the reflected/transmitted/scattered signals is used to locate and identify the defects in the material. The frequency and wavelength of the ultrasonic wave determine the size of the defect that can be detected and the attenuation in the material determines the penetration depth into the material. In systems that use scanning mode of operation, the physical dimensions of the transducer limits the resolution. One of the major advantages of ultrasonic NDE is the ability of ultrasonic waves to propagate through any type of material. The section on ultrasonic sensors describes in detail the generation, detection, and the interaction of ultrasonic waves with defects in varieties of materials for NDE application.

Some NDE sensors are also used to detect signals emitted by a material when a component is under external load. Strain energy is released when excessive deformation, crack initiation, and certain types of crack propagation occur, and this energy is then converted to acoustic energy. The sudden bursts of acoustic energy can be listened to by an acoustic emission sensor. The acoustic emission monitoring is a passive listening method and the sensors can be attached to the structure permanently and can be used for periodic or continuous interrogation of the material. This method is gaining popularity in structural health monitoring applications.

2 EDDY-CURRENT SENSING

2.1 Background

Eddy currents are closed loops of induced current circulating in planes perpendicular to the magnetic flux, making them useful for nondestructive inspection (NDI), thickness gauging, and position sensing. Typically, eddy currents travel parallel to the exciting coil's windings and their spread is limited by the size of the inducing magnetic field. Eddy currents concentrate in the near-surface layers adjacent to the excitation coil and their strength decreases with distance from the coil according to Maxwell's equations, which show that eddy-current density decreases exponentially with depth, known as the *skin effect*. The depth that eddy currents penetrate into a material is affected by the frequency of the excitation current, the electrical conductivity, and the magnetic permeability of the specimen (Figure 1). The depth of penetration decreases with increasing frequency and increasing conductivity and magnetic permeability. The depth at which eddy-current density has decreased to 1/e, or approximately 37% of the surface density, is called the *standard depth of penetration,* δ. "Standard" penetration denotes the use of a plane-wave approximation to the electromagnetic field interaction with the test sample and is unaffected by the size of the coil. The eddy-current inspection methodology is widely regarded as the most common electromagnetic NDE tool and is used in many applications for detection and quantification of defects in strength critical structures like pipelines and aircraft, thickness measurements, coating measurements, and various applications involving measurement of conductivity.

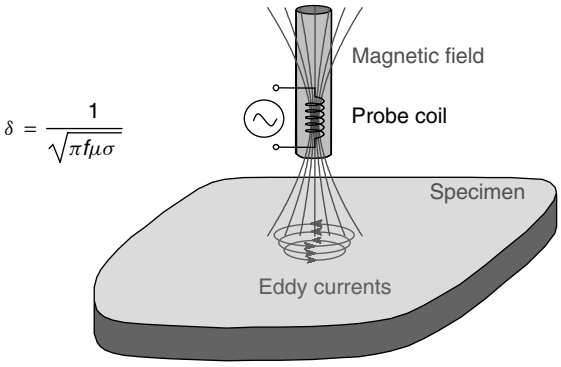

Figure 1. An illustration describing the interaction of the alternating current excited eddy-current probe coil with a conducting specimen to generate eddy currents. The standard penetration is shown as, δ (mm), where $\pi = 3.14$, $f =$ frequency (Hz), $\mu =$ magnetic permeability (H mm^{-1}), and $\sigma =$ electrical conductivity (%IACS) International Annealed Copper Standard.

2.2 Early discoveries

Contemporary eddy-current sensors and instrumentation are the result of decades of development and have an even longer history in terms of the fundamental principles on which the technology is founded. Electromagnetism was discovered in 1820 by Hans Christian Oersted when he demonstrated the effect of electricity in a wire on a compass needle. He discovered that the wire conducting electric current generated invisible magnetic lines of force, which when placed above the compass needle caused it to swing perpendicular to the direction of the current flow and to swing in the opposite direction upon reversal of the current flow. Of course, magnets also have invisible lines of force and several years later, Michael Faraday and Joseph Henry made nearly simultaneous independent discoveries of electromagnetic induction, in 1831. Both men used iron bars bent into a circle and wrapped in copper wire to create an electromagnet, and then in different arrangements demonstrated the principle of electromagnetic induction, namely that the induced current is proportional to the rate of change of magnetic flux through a coil. Some time later, Lèon Foucault discovered in 1851 that a changing magnetic field produces a circulating current upon intersection with a conductor. These swirls or eddies of current produce magnetic fields that oppose the applied magnetic field, which created them in the first place and are only present when the applied magnetic field is either physically moving or changing in strength. Capping off the early discovery era is the influential work of D. E. Hughes [1], who demonstrated in 1879 that eddy currents can be used as a basis to compare and sort materials by virtue of differences in electrical parameters, such as conductivity and permeability. Hughes showed that the principle of electromagnetic induction can be used to measure properties of coinage and the relative conductivities of metals and also demonstrated techniques for enhancing sensitivity. By combining these seminal early discoveries, it is possible to begin to see the foundation of modern eddy-current testing take shape, given (i) an alternating current (ac) used to excite a probe coil that gives rise to a changing magnetic field; (ii) when placed near a conductor the energized probe produces eddy currents in the solid, which have their own magnetic fields; and (iii) the magnetic fields of the induced eddy currents oppose the applied magnetic field thereby affecting the impedance of the probe coil, which is the basis of most modern eddy-current testing.

2.3 Measurement and testing applications

Modern eddy-current testing has evolved over the course of more than a century of research and development and finds its origins in metal sorting and comparing. During this long development period tremendous advances have been made in sensors, electronics, integrated circuitry, microprocessors, and computers leading us to today's handheld, portable eddy-current NDE instrumentation geared for field applications. In the latter part of the 1930s, Friedrich Förster, the person widely regarded as the forefather of modern eddy-current testing, began to make significant advances to the field by developing theory for complex impedance analysis, experimental equipment, calibration procedures, and nondestructive techniques to quantitatively test the properties of metals [2]. These early developments led to the production of commercially available electromagnetic induction testing equipment in the United States in the 1950s. Today's eddy-current test devices and instrumentation are available for a wide range of industrial applications such as aerospace (*see* **Military Aircraft**; **History of SHM for Commercial Transport Aircraft**; **Fatigue Monitoring in Military Fixed-wing Aircraft**; **Monitoring of Aircraft Engines**), energy (*see* **Fiber-optic Sensor Principles**; **Wind Turbines**; **Large Rotating Machines**), marine (*see* **Monitoring Marine Structures**; **Ship and Offshore Structures**), and automobile (*see* **Sensor Technologies for Direct Health Monitoring of Tires**) industries. An extensive accounting of contributions by early researchers in this field is documented in the NDT Handbook on Electromagnetic Testing [3].

Eddy-current testing techniques are primarily used to measure material properties such as conductivity and permeability, discriminating components based on the presence of flaws or discontinuities, and precise measurement of displacement, thickness, positioning, and proximity. Many critical applications require automated computer-controlled handling of eddy-current sensors and test objects due to the large scale of the inspection area, which allows the

inspection area to be mapped to the component requiring inspection. For example, turbine engine components are designed to optimize aircraft performance, while accommodating the adverse effects of high temperatures and dynamic loading conditions. In critical components such as turbine disks, the hardware is closely monitored throughout its service life using eddy current and other NDIs. Some United States Air Force ((USAF)) turbine engines are entirely disassembled and components are subjected to intensive NDIs to ensure that dimensional tolerances are met and surfaces are free from life-limiting flaws. Many individual components are cleaned and prepared for eddy-current inspections in an effort to detect surface-breaking fatigue cracks, fretting damage, and foreign object damage along with other detrimental features such as dents and gouges. Moreover, with appropriate calibration standards and tracking methods based on the initial fabrication conditions, microstructure, and alloy composition, quantitative eddy-current conductivity measurements could be potentially made to complement eddy-current flaw inspections, which are based on probability-of-detection standards, for the same critical engine components.

Eddy-current NDE techniques have been practiced for several decades, primarily as a means of flaw detection in the near-surface of metallic parts. For turbine engine applications, eddy-current testing is the primary method used to inspect the surface for life-limiting surface flaws, and a great array of probes have been manufactured to allow comprehensive inspections of these complex components. The optimal frequency range of a given probe, and therefore its sensitivity and effective penetration depth, may be selected by manipulating the probe's diameter, the number of wire turns in the coil, and the impedance matching circuitry. Eddy-current inspection is based on the electromagnetic induction principle, i.e., that a changing magnetic field will induce electrical currents in a nearby conductor, which in turn will load the coil and affect the phase and magnitude of its impedance. Accurate measurement of these eddy-current loading effects on the probe's impedance is the basis of most eddy-current measurements and provides the means to evaluate materials for near-surface cracking and inclusions, heat treatment verification, and thickness gauging. It is well known that eddy-current conductivity is affected by a number of things including residual stress, chemical composition, microstructure, hardness, surface roughness, and temperature. Therefore, it is essential to use stable quantitative test equipment and reliable procedures to assure integrity of the acquired experimental data and repeatability of the measurements. Calibration and reference standards are also essential for accurate eddy-current measurements and typically consist of materials with either known conductivities (or permeabilities for magnetic materials) for materials property characterization or with known flaw sizes for defect detection and characterization.

Eddy-current inspection is often used to detect corrosion, erosion, cracking, and other changes in tubing. Heat exchangers and steam generators, which are used in power plants, have thousands of tubes that must be prevented from leaking. This is especially important in nuclear power plants where reused, contaminated water must be prevented from mixing with freshwater that will be returned to the environment. The contaminated water flows on one side of the tube and the freshwater flows on the other side. The heat is transferred from the contaminated water to the freshwater and the freshwater is then returned back to its source, which is usually a lake or river. It is very important to keep the two water sources from mixing, so power plants are periodically shut down so that the tubes and other equipment can be inspected and repaired. The eddy-current test method provides high-speed inspections for these types of applications.

2.4 Basic measurement instrumentation

Most modern eddy-current testing equipment consist of a probe coil, an ac source, a voltmeter (or ammeter), and a display for analysis of the data. Most instruments used to measure eddy-current NDI data are based on the electromagnetic principle of mutual induction, which can be illustrated as an electrical circuit between the energized eddy-current probe and the conductive object undergoing testing. Since eddy currents generate their own magnetic fields that affect the primary field of the coil, it is essential that the instrument is capable of measuring the changes in resistance and inductive reactance of the probe coil at a given frequency. The mutual inductance between the probe and the test object is affected by electrical conductivity, magnetic permeability, and liftoff,

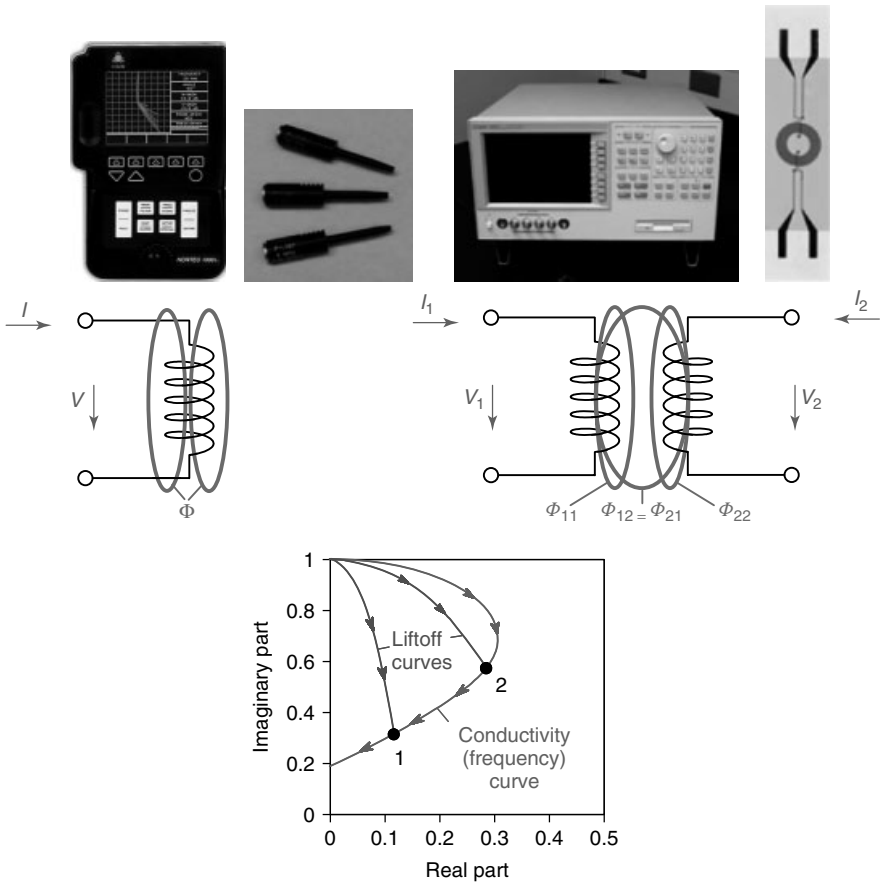

Figure 2. Some commonly available eddy-current probes, flexible coil and associated instrumentation; resonance eddy-current probe circuits and an impedance plane diagram showing the result of an eddy-current scan of a conducting material including the effects of lifting the probe from the surface of the material.

which is the distance between the inspection object and the probe. Most commercially available eddy-current instruments have a broad range of excitation frequencies from, for example, 100 Hz to 6 MHz. The basis for the eddy-current measurement is the (Maxwell) ac bridge, which is used to measure unknown inductances in terms of calibrated resistance and capacitance. Since the phase shift between inductors and capacitors is 90° out of phase, capacitive impedance can be used to balance out an inductive impedance if they are in opposite legs of the ac bridge. The eddy-current instrument display is essentially an impedance plane with resistance along the abscissa and inductive reactance along the ordinate and the measured impedance is the vector addition of the two components.

Eddy-current probes typically consist of a primary coil, which is capable of being brought into close proximity with the test object, and an identical reference coil housed in the body of the probe to accommodate temperature changes and minimize thermal drift (Figure 2). Probes are essentially resonant circuits, but operated well below the resonance to avoid stray capacitance and other parasitic affects. A wide variety of eddy-current probes exist today for different types of inspection applications including absolute probes for conductivity measurement or thickness gauging, differential probes for crack detection complex geometry, and reflection probes for materials characterization. Hybrid probes exist for applications such as detection of tiny surface cracks in aerospace components, where a split-D

type of transducer might be used, which consists of a drive coil encompassing two D-shaped sensing coils. Other types of eddy-current probes also exist, which might use giant magnetoresistive elements, Hall-effect sensors, or flexible thin-film sensors for specialized applications (*see* **Eddy-current *in situ* Sensors for SHM**; **Electric and Electromagnetic Properties Sensing**). Similarly, a wide variety of probe configurations exist for surfaces, bolt-holes, and inner- and outer-diameter inspections of pipes and tubing. Often, probes will have a ferrite core to intensify the magnetic lines of force near the core or take advantage of shielding to limit the spread of the probes magnetic field and therefore that of the eddy currents. In most applications, sensing the eddy currents involves assessing the impedance changes of a detector coil using an ac bridge where the impedance of the probe is compared to known impedances, forming a balancing arm in the bridge circuit. High sensitivity is achieved by matching the impedance of the probe to the impedance of the measuring instrument, otherwise known as *nulling the instrument*. The fundamental science of electromagnetic nondestructive test methods and applications for engineers and students can be found in [4].

3 ULTRASONIC SENSORS

Ultrasound is the commonly used technique in NDE to detect the presence of defects or determine the elastic properties of materials. Ultrasound is a linear elastic mechanical wave that propagates at frequencies greater than 20 kHz. Typically, frequencies between 1 and 10 MHz are used in production NDE, but frequencies in the range of hundreds of megahertz have been used in specialized inspections. The most common method to generate and detect ultrasonic waves is to place a sensor in contact with the material being evaluated. These sensors are called *transducers* and use a variety of material properties to generate and detect the mechanical wave. The most common class of transducers is based on piezoelectricity. However, other types of transducers can be based on magnetostrictive, electromagnetic, or capacitive behavior of the element in the transducer, where the element refers to the component of the transducer that physically moves to generate and detect the ultrasonic mechanical waves and converts this energy into electrical signals that can be viewed and/or recorded on oscilloscopes or similar displays. This article will provide an overview of piezoelectricity and a review of the key components that are typically required in a contact piezoelectric transducer. It will also provide a brief description of other methods to generate and detect ultrasound, plus a summary of noncontact methods, including the use of lasers. It is important to note that this article is a short summary of these items. There is a substantial volume of literature, including books, monographs, and conferences, dedicated to the design, development, and evaluation of ultrasonic transducers [5–8] and the reader is encouraged to explore these for additional information.

Piezoelectricity is described as a material property that converts electrical signals to mechanical deformation and *vice versa*. This behavior was first observed by Jacques and Pierre Curie in 1880 by detecting the presence of an electric charge when certain materials were compressed. Later work indicated that inverse behavior can occur. This behavior is caused by the crystallographic structure of the piezoelectric crystal. The most commonly cited natural piezoelectric material is quartz, which has a hexagonal crystal structure [9]. To obtain the piezoelectric behavior, single crystals of this material are needed and they have to be cut along specific axes to obtain the desired deformation. Figure 3 illustrates the application of an electric field to a single hexagonal crystal to generate a longitudinal ultrasonic wave and Figure 4 shows how a transverse, or shear, wave is generated from a single crystal cut along a different plane.

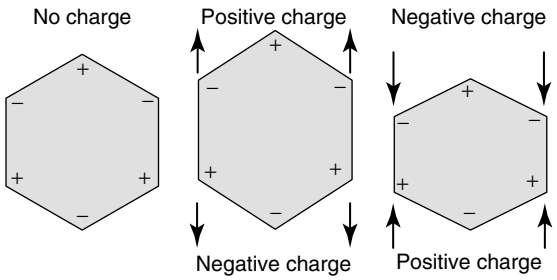

Figure 3. A schematic demonstrating the generation of longitudinal ultrasonic waves by applying an electrical pulse to a hexagonal quartz crystal.

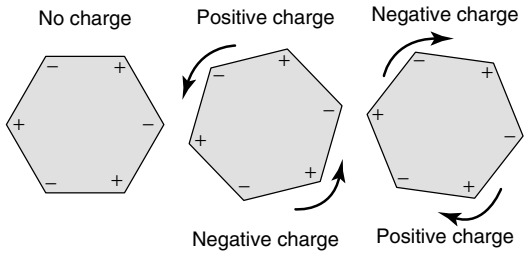

Figure 4. A schematic demonstrating the generation of shear, or transverse, ultrasonic waves by applying an electrical pulse to a hexagonal quartz crystal.

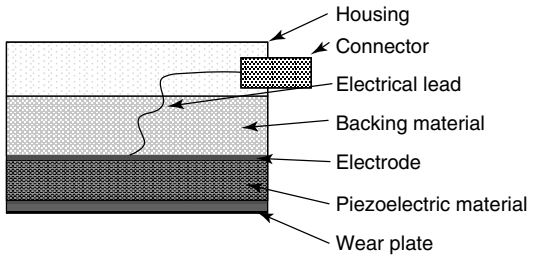

Figure 5. A cross section of a typical commercial transducer showing the typical components of such a transducer.

When an electrical spike is applied to the crystal, it will deform to either attract or repel the electrical charge in response to the asymmetric balance of charges in the signal crystal. The linear deflection of the single crystal generates a longitudinal wave, whereas the rotational deformation will generate a shear, or transverse, wave. Note that a much thicker couplant capable of supporting shear motion must be used when generating or detecting shear waves using a piezoelectric element. Alternative methods, such as those using angle-beam techniques, generate shear waves using refraction, which can occur with less viscous couplants, such as water or inert gels.

Subsequent developments in piezoelectric materials resulted in the discovery and development of ceramic materials, such as lead zirconate titanate (PZT) and lead metaniobate. An advantage of these materials is that they do not need to be single crystals to demonstrate piezoelectric behavior. These materials are poled at elevated temperatures to align their piezoelectric properties, which yield a deformation in these materials when they are exposed to an electrical field. Using this approach, the physical motion of these materials enables the preparation of transducers that can generate and detect both longitudinal and shear waves. This eliminates the need for careful sectioning of a ceramic crystal, as required for quartz, but has the disadvantage that these materials can only be used at temperatures below the depolarization temperature, which can range between 130 and 575 $^{\circ}$C. These materials are very sensitive to surface displacements, which make them ideal transmitters and receiver of ultrasonic energy that remains in the linear elastic regime [10].

Commercially available transducers typically use these materials as their active element. Common features of commercial transducers are shown in a representative cross section of a transducer in Figure 5. The transducer is typically a metallic case. The active element is protected from the inspection surfaces by a wear plate, which is made of a material that minimizes wear and matches the acoustic impedance of the active element as much as possible. Electrical leads are coupled to either surface of the piezoelectric material to apply the voltage spike or tone burst to excite the element. A significant amount of the volume of a transducer is dedicated to the dampening material that minimizes the resonance of the piezoelectric element. The dampening material decreases the number of cycles the piezoelectric material will resonate, which assists in resolving multiple reflections from the material being inspected. For example, this minimizes the interference of these signals when trying to detect damage close to the location of the transducer. Note that electrical wire failure and disbanding of the dampening material are the most common causes of failure in a transducer, which would lead to a diminished response or a perturbation in the received signal from damage.

A more recent development in transducer design is the emergence of composite elements. These transducers, which have been commercially available for approximately 10 years, combine a polymer material together with the piezoelectric material, usually to assist in the dampening process. The polymer-based material is commonly introduced into the transducer by cutting thin channels in the ceramic element and filling the channels with the polymer material. The polymer can dampen the vibration of the ceramic while minimizing the effect on the sensitivity of the ceramic when compared to a traditional dampening backing layer. Thus, composite transducers are frequently used when high sensitivity and resolution are needed.

A multitude of other materials and methods have been explored to generate and detect ultrasonic waves. Several polymer materials, most notably poly(vinylidene fluoride) (PVDF), have been shown to have piezoelectric properties. This material can be configured into relatively thin films and retains its piezoelectric behavior when flexed, making it a desired sensor when trying to conform to a complex geometry. These materials are typically very effective detectors of ultrasonic signals, but are not very efficient transmitters. In addition, their response can be very dependent on temperature, requiring these sensors to be used in a stable environment.

The transducers described above are used in most bulk material ultrasonic NDE applications. However, for acoustic emission (AE), the performance requirements of transducers change as these sensors are tailored to detect ultrasonic signals emitted from crack propagation, delaminations, and similar types of damage. To maximize the detection of these signals, AE transducers typically have a response that is very flat as a function of frequency. With conventional piezoelectric transducers, this performance characteristic is typically obtained by increasing the dampening of the piezoelectric element. Therefore, these sensors are commonly larger than conventional transducers and frequently have broadband preamplifiers to amplify the dampened signal. An alternative approach is to make the contact area of the sensing element very small, which can be exemplified by conical transducers and pinducers. With these small contact areas, extra dampening material is not required as the sensor functions as a point detector. Owing to the requirement that these sensors be very broadband, they are also very inefficient and are not commonly used as transmitters. Note that other broadband sensors, such as PVDF, can also be very effective AE sensors.

Alternative materials have been used for generation and detection of ultrasonic signals. Magnetostrictive materials convert magnetic fields into mechanical deformation by the alignment of their magnetic moments [11]. These materials are commonly used for sound navigation and ranging (SONAR) applications as they are very effective and efficient at low frequencies. Capacitive transducers use changes in capacitance between the sensor and the material in which the ultrasonic wave is propagating to sense ultrasonic signals [12]. As this behavior can occur through air, these transducers do not require couplant, but typically must be in close proximity of the surface of the specimen in which the ultrasonic wave is propagating. Electromagnetic acoustic transducers (EMATs) are used with electrically conductive materials. These sensors use an radio frequency (RF) coil to generate eddy currents in the specimen. When the coil is placed inside a permanent magnetic field, the eddy currents interact with the magnetic field to generate mechanical waves in the material. Note that these three effects occur in reverse order when the ultrasonic signal is detected. Several efforts have used piezoelectric materials for air-coupled transducers. They are most effective in a through transmission mode for composite materials, which have a lower acoustic impedance when compared to metallic structures.

Another noncontact method that has been researched extensively is the use of lasers to generate and detect ultrasound. For generation, it is common to use a short pulse laser that causes very rapid and localized heating to thermoelastically generate a mechanical wave. If too much energy is deposited on the surface, the generation method becomes ablative, which will cause material to be removed from the surface. Detection is typically performed using an optical interferometer, such as Michelson or Fabry–Perot. Extensive literature exists that explores multiple laser-based variations to generate and detect ultrasonic signals [9].

A final type of transducer to consider is array transducers. These transducers include multiple piezoelectric elements sufficiently small to be considered as point sources of ultrasonic signals. These elements are excited in a controlled manner to use the principle of superposition to direct the effective wavefront in different directions. There are limits to the amount an ultrasonic wave can be directed and controlled, which is determined by the material, the number and size of the individual elements, and the physics of ultrasound. However, the use of arrays is growing in popularity, especially in structures that do not contain an excessive number of scattering features that can interfere with the superposition of the ultrasonic waves generated from the point sources of ultrasound.

4 SUMMARY

This article described some introductory ideas of eddy-current coils used for material characterization

and detecting damage in materials and structures. Similarly, ultrasonic transducers were described for the generation and detection of ultrasonic waves. There are extensive volumes of literature that describe the material properties and physics that enable these NDE transducers to work as designed and the reader is strongly encouraged to explore this literature before embarking on research and development efforts in this field.

1 A BRIEF INTRODUCTION TO THE GLOBAL POSITIONING SYSTEM

1.1 GPS constellation

The full term of the well-known acronym GPS is NAVSTAR global positioning system, where NAVSTAR stands for NAVigation System with Time And Ranging [1]. GPS is a satellite-based navigation and positioning system that was designed in the early 1970s by the US military to allow soldiers to autonomously and continuously determine their position within 10–20 m of accuracy, at any point on the earth's surface and under any weather conditions. Providing precise timing information is another important function of GPS. GPS was originally utilized even for the military operations of US military forces; the last two decades have seen a rapid expansion of civilian GPS user groups. The current GPS configuration consists of three segments: the space segment—a constellation of 24 (nominal) satellites distributed in six orbital planes of 55° inclination to the equator with an altitude of 20 200 km above the earth's surface as shown in Figure 1; the control segment—comprises a master control station, worldwide distributed monitor stations, and ground control stations; and the user segment—anyone who receives and uses GPS signal with any type of GPS-enabled devices. More detailed information about GPS segments can be found in [1, 2].

1.2 GPS measurements

Each GPS satellite transmits at least two carrier signals in an L-band, such as L1 and L2 carriers, and more signals are available for the modernized

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

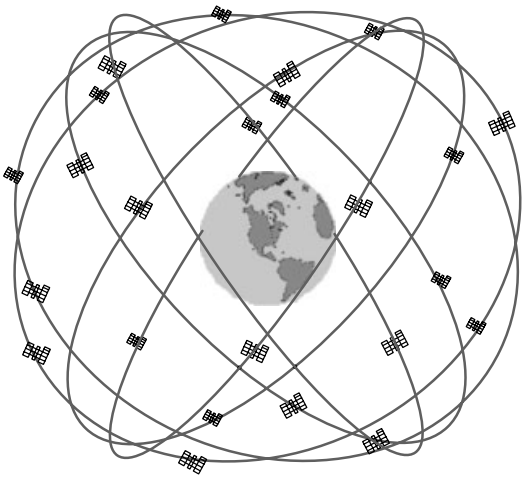

Figure 1. Current GPS constellation (http://www.faa.gov/about/office_org/headquarters_offices/ato/service_units/techops/navservices/gnss/).

GPS satellites. The L1 and L2 carriers are modulated by ranging codes and navigation information such as orbital parameters. The carriers together with ranging codes are used mainly to determine the distance from the antenna of a user's receiver to the GPS satellites in view [3]. These uncorrected distances are called *code* or *carrier pseudoranges* since they include the true geometric distance between the receiver antenna and the tracked satellites plus small range corrections to account for the orbital and clock errors, signal delays caused by the atmosphere, and multipath due to the signal reflection by the surroundings in the vicinity of the GPS antenna [1]. For determining a three-dimensional (3D) location of a GPS antenna, simultaneous tracking to three GPS satellites is adequate. However, since a GPS receiver is normally equipped with a much cheaper clock, compared with the atomic ones used by the GPS satellites, tracking to at least one more satellite is required to solve the clock bias of the GPS receiver for achieving a higher positioning accuracy.

1.3 GPS relative positioning

A prerequisite for achieving GPS positioning accuracy of a few meters (code pseudorange) to centimeters or even subcentimeters (carrier phase) is the effective cancelation of various ranging errors. The number of satellites tracked by a GPS receiver and their spatial distribution are also major affecting factors to the achievable positioning accuracy. Generally, the GPS relative positioning technique involves a pair of GPS receivers simultaneously tracking at least four well-distributed identical satellites for solving the position of an unknown stationary GPS antenna and at least five satellites for a moving antenna. For canceling out spatially correlated GPS ranging errors, one GPS receiver must be installed on a precisely measured benchmark called a *reference station* to help solve the unknown coordinates of another receiver called a *rover*, either in a stationary mode or a continuous motion mode. When relative positioning is utilized in surveying, differencing the GPS ranging measurements made to two satellites simultaneously by a reference receiver and a rover receiver could eliminate both the satellite clock and the receiver clock biases. Carrier and/or code pseudorange measurements can be used in GPS relative positioning and the positioning solutions in the form of 3D coordinate time series can be obtained either in real time or through postprocessing of collected GPS measurements.

1.4 Achievable positioning accuracy and major inhibitors to GPS positioning accuracy

Both code and carrier phase pseudorange measurements are "polluted" by errors that originate from GPS receivers, GPS satellites, signal propagation medium, and observation environment [1, 3]. In the data processing stage, incorrect processing models adopted and/or bugs in the software packages also cause positioning errors. There are many studies in this area on how to effectively reduce, mitigate, and eventually eliminate GPS error sources through mathematical modeling, software development, and digital signal-processing approaches, and hardware design and configuration. Some error sources, which are observation environment oriented and change from place to place, prove very difficult to be modeled or mitigated. For instance, pervasive multipath effect, which is a major error source for both the carrier

phase and the code-pseudorange-based GPS positioning, makes the effort for achieving highly accurate GPS positioning elusive. Most GPS antenna will not be able to detect which signals are directly transmitted by the satellites and which are reflected from the objects surrounding a GPS antenna. As a result of the complexity of objects surrounding an antenna, there is virtually no versatile model or physical antenna design to effectively reduce multipath, which introduces a maximum error of up to about 5 cm for carrier-phase-based positioning, a quarter of its L1 wavelength, and several meters for code-pseudorange-based GPS positioning.

1.5 Integer ambiguity resolution for high accuracy positioning

Centimeter or even subcentimeter positioning accuracy can be achieved through using carrier-phase-based GPS relative positioning under the condition of successful resolution of the initial integer ambiguities. When carrier phase measurements are employed in positioning, only a fraction of the wavelength of the carrier phase is recorded by a GPS receiver, but the whole number of carrier wavelengths or cycles between a GPS antenna and the tracked satellites remains unknown. Reliable and quick resolution of the unknown number of cycles from a tracked satellite to a GPS antenna is vital in using carrier phase measurements for subcentimeter positioning. Until the early 1990s, GPS was only used to monitor static deformation of structures with low dynamics, for example, dams and low buildings. The least squares adjustment, Kalman filtering, statistical process, and other search techniques can resolve this ambiguity and determine the most probable solution [4, 5]. Furthermore, the invention of integer ambiguity on-the-fly (OTF) algorithms by different researchers around the world in the beginning of 1990s made the real-time kinematic global positioning system (RTK GPS) a viable tool for monitoring more flexible structures such as long suspension bridges, high-rise buildings, and slender TV or communications towers [6, 7], or for tracking high-speed moving objects such as low earth orbit (LEO) satellites, because of its high accuracy, productivity, flexibility, and simplicity in data processing (conducted by the embedded receiver firmware). The positioning solutions produced by the internal processor of a GPS receiver can be streamed to a control center via cable connection or through wireless communications for further analysis and visualization of resulting solutions. However, the collected raw carrier phase measurements, which are recorded with memory cards inside the GPS receivers, can be decoded as American Standard Code for Information Interchange (ASCII) data files in a receiver independent exchange (RINEX) format. These data files can be postprocessed in a kinematic mode by using the OTF approach with any commercial or household GPS postprocessing software to output each epoch positioning solution. More accurate positioning results can be obtained because of the possibility to edit and clean GPS measurements.

1.6 Communication links

Radio modems provide wireless communications between GPS reference receivers and rover receivers for carrying out real-time relative positioning. When a reference GPS receiver broadcasts the corrections via its radio modem transmitter, an unlimited number of rover GPS receivers can pick up these data via their own radio modems. The transmission range depends on the power of the radio modem transmitter and also on the terrain and the radio antenna setup. There are many different radio modems in the market and ultrahigh frequency (UHF), very high frequency (VHF), and spread spectrum are the most commonly used in RTK GPS positioning. Government authorization may be required for using certain types of radio modems. In some countries, there are bands that are allocated for public use without the need for any special authorization. For instance, the 900-MHz band in the United States and 2.4 GHz in most European countries are allowed for spread spectrum communications without any special authorization (but there are limitations on the amount of power that one can use to transmit signals, for instance, in the United Kingdom, only 0.5-W carrier power is allowed). More recently, some GPS manufacturers adopted cellular communication technology or the third-generation (3G) wideband digital networks, such as global system for mobile communications (GSM) and general packet radio service (GPRS), as an alternative GPS communication link. Since subscribers only pay for the data amount that they

have actually transmitted or received, the use of GPRS technology is more flexible and much cheaper compared with a GSM communication link. Dedicated local area network (LAN) can also be utilized to transmit GPS corrections from reference stations to the rovers over the Internet. Satellite-based wireless communication approach is becoming popular and has already been employed to transmit corrections to the rovers in the area where there is no GSM/GPRS coverage and the use of radio modems is constrained by the local terrain and transmission power limitation.

2 GPS FOR STRUCTURAL HEALTH MONITORING (SHM)

2.1 Brief history of GPS for SHM

According to [8], the process of implementing a damage detection strategy for aerospace, civil, and mechanical engineering infrastructures is referred to as *structural health monitoring* (SHM) and a damage is defined as changes to the material and/or geometric properties of these systems, including changes to the boundary conditions and system connectivity, which adversely affect the performance of the systems. The SHM process involves the observation of a system over time, using periodically sampled dynamic response measurements from an array of sensors, the extraction of damage-sensitive features from these measurements, and the statistical analysis of these features to determine the current state of system health. The output of this process is periodically updated information regarding the ability of the structure to perform its intended function in light of the inevitable aging and degradation resulting from operational environments. An SHM system should have the capacity to provide, in near real time, reliable information regarding the integrity of the structure after earthquakes or blast loading.

Recent advances in GPS positioning, computer science, telecommunications technologies, and advanced digital signal processing have made GPS a much more robust, reliable, convenient, accurate, and cost-effective tool for the deformation monitoring of natural and artificial structures. To date, GPS is widely used to monitor volcano eruptions [9, 10], crustal movements [11, 12], vertical land movements [13], landslides [14], earth structures [15], dams [11], buildings [16–21], and bridges [22–29]. In general, these applications can be roughly categorized into three levels, i.e. large, medium, and local scales, according to the separations of the GPS stations. A variety of regional continuous global positioning system (CGPS) networks, such as EUREF Permanent Network (as of March 04, 2007, it has 199 permanent GNSS tracking stations, which cover the European continent); the OS Net of the Ordnance Survey in the United Kingdom, which consists of more than 100 permanent stations; and the Geographical Survey Institute's GPS Network, which comprises 1224 GPS real-time stations in Japan (www.euref.eu; www.ordnancesurvey.co.uk; www.gsi.go.jp), are typical examples of the first category applications. These networks play a vital role in monitoring crustal movement, which is crucial for the evaluation process of seismic and volcanic activity as well as the extraction of geodynamic information. On a medium scale, GPS-based volcano eruption monitoring presents a good example. The last level of GPS-based monitoring applications takes place on a variety of natural or artificial structural deformation and deflection monitoring in the local scale, which is the main scope discussed in this article (*see* **Ambient Vibration Monitoring**).

2.2 Case studies of GPS for SHM of long suspension bridges

Under different loading conditions, a suspension bridge generally experiences two distinct types of deformations, i.e., the long-term movement caused by the foundation settlement, bridge-deck creep, and stress relaxation; and the short-term motion of the bridge, or bridge deflection, such as those activated by wind, tidal current, earthquake, or traffic [27, 30]. The latter deformation is recoverable in most cases and the bridge will resume to its original status from the deformation with the release of external forces.

When GPS is utilized to monitor bridges, it has the capacity to detect two different kinds of deformations simultaneously [25, 31]. Analyzing the response of a long bridge to the short-term irregular loading is much more important in terms of risk level of major damage and its significance for the improvement of design code. However, it is more difficult to be measured compared with the identification of

long-term foundation settlement, concrete creep, loss of prestress, and thermal expansion or contraction. In monitoring foundation displacement, averaging GPS time series of a few hours or more can be used, producing positioning accuracy of a few millimeters, since error sources such as multipath (an unwanted indirect signal reflected by the surroundings before reaching a GPS antenna), which characterizes as a low period of movement, could be effectively removed. To measure the deformations occurring over a time interval of a few seconds, there is a much shorter or even no averaging time available for mitigating errors; the time interval may not even be long enough for resolving the critical initial integer ambiguities. This significantly restricts the usage of GPS positioning in monitoring short-term movements of more flexible structures. Also, to measure short-term effects, sampling rates of GPS sensors must be significantly increased, which will incur heavier onboard data processing and communication overloads if RTK GPS positioning is required.

In the last decade or so, with rapid advances in GPS technology, digital signal processing (DSP), telecommunications, and computing science, as well as with the continuous efforts conducted by the researchers around the world, GPS positioning is gradually being accepted by the civil engineering community as a viable monitoring tool and has started to play an important role in SHM. This is mainly due to the advent of OTF integer ambiguity resolution technology. As discussed in the previous section of this article, solving the unknown number of cycles from a tracked satellite to the GPS antenna is vital in using carrier phase measurements for subcentimeter positioning, which is a prerequisite for GNSS-based SHM. The significant increase in the GPS sampling rate from 1 Hz to rates higher than 50 Hz currently is another reason for the acceptance of GPS-based SHM of long suspension bridges.

Structural aging and degradation resulting from changes in the materials and operational environments such as significantly increased traffic volume and weight, as well as the boundary conditions and system connectivity, and flaws in design are the main reasons for many recent bridge closures and failures around the world. Transport agencies and researchers have strong interests in finding appropriate sensor systems and computational models to implement on-line monitoring and diagnosing systems to detect and locate the changes to the materials and/or geometric properties of bridges. Of various monitoring tasks, measuring short-term dynamic behavior of such structures is of particular interest.

The Tsing Ma Bridge in Hong Kong, China, is the sixth longest suspension bridge in the world and it is the longest single-span suspension bridge that carries both road and rail traffic [32]. The Tsing Ma Bridge and other two cable-stayed linking bridges are perhaps the only bridges around the world that are equipped with the most comprehensive and sophisticated sensor systems, forming a part of six whole SHM components. The six integrated modules include the sensory system, the data acquisition and transmission system, the data processing and control system, the structural health evaluation system, the structural health data management system, and the inspection and maintenance system.

The main objective of the Tsing Ma SHM system is to monitor the loading and structural parameters so that the performance of the bridge under current and future loading conditions can be evaluated and predicted. Such evaluated results will facilitate the planning of bridge inspection activities, and help the determination of not only the causes of damages, but also the extent of remedial works, once the damage is identified [33, 34].

There are nine different types of sensors to form the sensory systems, which include anemometers, thermometers, servo-type accelerometers, dynamic weigh-in-motion sensors, GPS receivers, leveling sensing stations, displacement transducers, weldable strain gauges and monitoring CCTV cameras, making a total of 848 sensors on the Tsing Ma and two other adjacent cable-stayed bridges [33]. GPS technology was introduced because of its improved measurement efficiency and accuracy [29]. Of a total of 29 high-grade geodetic-type dual-frequency GPS receivers (using both L-band carries), two GPS receivers were set up as the reference stations. On the Tsing Ma Bridge, 14 GPS receivers were permanently installed as the monitoring stations at the critical locations of the bridge deck where maximum displacements are expected: four pairs on the bridge deck itself, one pair on the each side of the supporting towers, and one pair on the cable at midspan. The remaining 13 GPS receivers were installed onto two cable-stayed bridges near the Tsing Ma Bridge to form a large monitoring system in the region. Both chokering

and lightweight antennas were used for the reference stations and monitoring stations, respectively. Most GPS stations were installed close to the leveling and sensing stations or to the accelerometers for validating and comparing the data sets from different monitoring sensor systems. GPS data were collected at a sampling rate of 10 Hz continuously, and optical fibers were used to transmit the positioning results from each monitoring station to a processing center for further analysis and visualization purposes.

The Akashi Kaikyo Bridge in Japan is the world's longest road suspension bridge. It was constructed using a newly developed wind- and seismic-resistant design and it is necessary to verify the design assumptions and constants during strong winds and severe earthquake loadings [25]. Navigation is extremely difficult and there have been many shipping accidents in the Akashi Strait because of the hostile environmental conditions. To keep the world's longest suspension bridge in a safe operating condition and also to study the dynamic response to various loadings, an experimental trial was carried out by using dual-frequency GPS receivers in 1999 to monitor bridge deformation in a real-time mode. The first results from the monitoring of the Akashi Kaikyo Bridge were presented in [25]. GPS receivers were set up at three locations, constituting a reference station at the anchorage on the Kobe side of the bridge and two monitoring stations on the top of a supporting tower and at midspan, to monitor three-dimensional displacements. Wind loading and temperature data were also collected simultaneously. The displacement time series of six months were analyzed together with recorded time series of wind and temperature loadings. The instantaneous gradients of displacement and temperature were calculated. The regression functions established could be used to identify future abnormal deflections after attacks of strong wind loading or earthquakes. Data from other sensors are also available for this bridge, but for a bridge of this size, three GPS receivers seem inadequate for even picking up global displacements.

China has many of the world's longest suspension bridges, which were constructed in recent years as a result of the high demand for land transport infrastructure. Structural safety has already caused great concern and many SHM systems have been installed in many new bridges. The most commonly used sensors are anemometers, accelerometers, temperature sensors, and strain gauges. Only a very few long suspension bridges in the mainland China such as the Jiangying Bridge (main span of 1385 m) and the Runyang Bridge (main span of 1490 m), both over the Yangtze River were installed with permanent GPS monitoring systems. Like the Akashi Kaikyo Bridge, only a limited number of monitoring GPS stations have been installed at the critical locations on the bridge deck and supporting towers. For instance, there are nine permanently installed dual-frequency GPS receivers forming an important part of the monitoring system for the Jiangyin Bridge. One GPS receiver is used as the reference station and other eight receivers are placed atop the two bridge towers, and at the 1/4, 1/2, and 3/4 points of the bridge span [35]. The sampling rate of the GPS receivers is set to 20 Hz.

In other countries, GPS has been used in a number of bridge monitoring studies, mostly carried out by GPS receivers temporarily installed on the bridge decks or supporting towers to collect sample data sets. For example, GPS receivers were employed to monitor the displacement of France's Normandy Suspension Bridge under controlled traffic loading to verify whether the performance of the bridge was consistent with the design specifications [36]; the Danish Road Directorate used GPS to determine the as-built geometry and assess temporal deformations of Denmark's Storebaelt Bridge and other bridges [37]; and the Applied Research Laboratory (ARL) of the University of Texas at Austin in the United States has conducted a series of research on GPS-based structural deformation monitoring since the beginning of 1990s and published many valuable articles on relevant topics [26, 38–43]. The research conducted by the ARL is perhaps the earliest practice in GPS-based bridge deformation monitoring.

The results of a three-day experiment, in which GPS technology was used to measure the motion of a cable-stayed suspension bridge over the Mississippi River near New Orleans, were presented in [26]. The goals of this experiment were to verify the feasibility of using GPS to achieve centimeter-level accuracy in bridge deflection monitoring, and to evaluate the practicability and limitations of the whole monitoring system. Twelve Trimble 4000 SST GPS receivers were used in the test. Two receivers were located on the shore at known reference sites about 10 m apart, approximately 1.6 km away from the bridge. This approach made it possible

to distinguish real bridge motion from GPS-induced biases or errors through a thorough data processing. The remaining 10 GPS receivers were situated at the critical bridge sites where minimum and maximum bridge displacements were expected. A 10-s sampling rate was chosen because the expected bridge motion during a 10-s period was considered to be negligible, and this allowed all the data to be stored on receivers for the whole monitoring period. The result showed a maximum relative vertical displacement of about 7 cm caused by a change in ambient temperature during the experiment. The results revealed a strong relationship between the vertical position of the bridge roadbed and the change in ambient temperature. Multipath also made significant error contribution to the positioning solution and caused problems in the displacement analysis. It was clear that the cables and metal surroundings, the bridge sites, coupled by the passing vehicles, had created a severe multipath environment and additional multipath analysis and mitigation techniques are apparently essential for achieving high accuracy positioning. Other GPS-based bridge deformation trials were also carried out by the ARL team with the attempt to monitor more dynamic bridge performance induced by traffic and wind loadings with 10-Hz GPS receivers, identify the multipath signature and quantify the measurement quality, compare GPS-measured displacements with those of servo accelerometers, and assess the reliability and performance of system components [42].

Preliminary results from ARL and other research teams around the world proved that GPS is a viable tool for detecting both transient deformations of flexible bridge structures and long-period movements. It was also recognized that the big challenge with GPS-based bridge deformation monitoring was how to effectively eliminate or reduce the impact of multipath. Other factors restraining large-scale GPS applications to structural deformation monitoring are the high price of dual-frequency GPS receivers, the large amount of data generated during data collection when a high sampling rate is used, and the existing gaps between the demanded high precision with what can be offered by current GPS positioning technology of centimeter accuracy.

Researchers at the IESSG in the University of Nottingham have conducted a series of trials using state-of-the-art dual-frequency GPS receivers to monitor the movements of a number of long suspension bridges and other structures in the United Kingdom [22, 28, 44]. In particular, several trials were conducted on the Humber Bridge under both a controlled loading environment and using ambient vibration to monitor the bridge deflection [22, 45]. The viability of GPS technology to monitor the displacements of the Humber Bridge subjected to known loading conditions was verified. The initial research of the IESSG was focused on the viability of GPS technology to monitor both long-term bridge settlements and dynamic response to external loading, and the latest work is on the development of a systematic approach for the sensor integration, field test arrangement, data collection, algorithm, and software development, quality control, advanced signal processing, and multipath mitigation techniques, data analysis and dynamic response identification, and result visualization [46–53] (*see* **Modular Architecture of SHM System for Cable-supported Bridges**; **Monitoring of Bridges in Korea**; **Bridge Monitoring in Japan**; **Continuous Vibration Monitoring and Progressive Damage Testing on the Z24 Bridge** and **SHM of a Tall Building**).

2.3 Advantages and limitations of GPS for bridge deformation monitoring

Very few conventional bridge monitoring sensor systems have versatile capacities like GPS. In summary, the advantages in using GPS for SHM of long bridges are as follows [27, 38–41, 54, 55]:

- monitoring both static and dynamic movements;
- fully automatic, real-time, all-weather, and long-life data acquisition;
- 3D absolute displacements linked to a global datum WGS84 (World Geodetic System of 1984 —very important for foundation monitoring);
- accurate velocity and acceleration extractions from 3D displacements, which can be validated by the measurements of other sensors such as an accelerometer;
- precisely synchronized positioning solutions for all GPS monitoring sites;

- a precise time source for time stamping/synchronizing other measurements/sensors (accelerometers, weather station, strain gauge, etc.);
- continuously increasing sampling rate (50 Hz for dual-frequency GPS receivers and up to 100 Hz or higher for single frequency GPS receivers);
- no long-term positioning accuracy degradation like accelerometers;
- a data fusion platform for integrating GPS with other sensors for a more robust monitoring system;
- continuous improvement in space segments, regional augmentation systems, ground tracking facilities/algorithms, and end-user hardware (futuristic GGG—GPS, GLONASS, GALILEO—receivers will be able to track more than 80 satellites);
- in the near future, a single GGG receiver based real-time solution of millimeter positioning accuracy at a sampling rate for at least 100 Hz will be possible.

GPS also has some inherent disadvantages, which are the potential inhibitors to a wide acceptance of GPS for SHM. The main disadvantages are as follows [27, 38–41, 54, 55]:

- The high price of GPS hardware and software is the major inhibitor for a wide application of GPS for SHM; a much cheaper single frequency GPS receiver cannot fix its initial integer ambiguity, which prohibits centimeter positioning accuracy.
- Line of sight to at least five well-distributed satellites poses a current challenge for GPS owing to signal obstruction by surroundings.
- The positioning accuracy of the vertical component is worse than the horizontal one and the ratio of the positioning accuracies of two horizontal components changes with geographical locations.
- Unmodeled residual tropospheric delays, such as those induced by the height differences, might cause a few centimeter errors.
- At the moment, high level of multipath caused by surrounding reflection cannot be effectively mitigated.
- The relatively slow sampling rate is not adequate for monitoring short span bridges or the higher frequency band of a long span bridge.
- Data processing and interrogation can be complicated.
- There has not been a thorough research into the integration of GPS measurements with a computational model, nor has there been a successful demonstrator to justify the high investment in the establishment of the sensor system.

3 IMPLEMENTATION OF GNSS CENTERED SENSOR SYSTEMS FOR SHM

3.1 Reference and monitoring GPS stations

For the establishment of a permanent GPS-based bridge monitoring system, monuments need to be installed for mounting both the reference and monitoring antennas as shown in Figure 2(b, c). Different GPS antennas have different weights, physical dimensions and multipath mitigation capacity, and can

(a) (b) (c)

Figure 2. (a) A chokering antenna; (b) a reference station set up on the Jingyin Bridge in China; (c) a monitoring station atop the Akaishi Kaikyo Bridge in Japan [photos courtesy of Leica Geosystems].

be used for different GPS sites. For instance, a chokering antenna covered with a dome could be used for the reference station since its location is usually lower than the bridge deck. High multipath signature caused by the supporting towers, dense cables, passing vehicles, and buildings is evident and can be mitigated by a chokering antenna. A chokering antenna consists of a series of cylinders that stop reflected signals from the ground and from nearby reflective surfaces as shown in Figure 2(a). To significantly reduce multipath induced by the reference stations and for designing a more secure and robust monitoring system, a reference configuration comprising multiple GPS receivers is highly recommended [27]. An inexpensive and lightweight patch antenna as shown in Figure 2(c) can be used for the monitoring sites on the bridge sites. This antenna has a metallic ground plate, which can effectively stop the reflected signals coming underneath the antenna but will not be able to reject multipath from surrounding objects such as cables, towers, and passing vehicles. This is why the high monuments for monitoring sites are preferred as shown in Figure 2(c).

For temporary bridge deformation monitoring practices, antennas of the reference stations can be mounted on tripods, which are centered to the precisely measured ground marks as shown Figure 3(a) (the Forth Road Bridge). In this monitoring, two adjacent reference stations about 6 m apart were used to reduce multipath caused by the reference stations through a data processing procedure. The other reason for this reference station setup is to reduce the risk of potential hardware failure caused by either of the reference stations. The antennas of the bridge monitoring sites can be locked to the bridge handrail using specially designed clamps. A direct access to power was made available by the bridge authority. Figure 3(b) shows a typical example of a monitoring station setup on the Forth Road Bridge [51].

At the moment, the sampling rate of the operational or experimental bridge monitoring systems is set to 10 Hz or a maximum of 20 Hz. At such a sampling rate, it is estimated that the average data volume in a binary format is $7\,\mathrm{Mb\,h^{-1}}$. For a permanent monitoring system, the GPS receivers at the monitoring sites will conduct real-time coordinate computation and then stream these continuous time series to the control center for a further analysis. These receivers might also be able to log the raw measurements into onboard flash memory cards and send the data sets to the center on a regular basis in case of some important event analysis, for instance, an earthquake. For the experimental tests, raw data is recorded into the flash memory cards and up to 4-GB cards are currently available, which means that raw data sets of more than 574 h (equivalent to an observation of 23 days) can be continuously recorded. However, it might cause computation problem with a postprocessing GPS processing software package due to the huge file size after uncompressing the binary data. It is recommended that a data set of 12 h should be used since this data size can be handled by any commercial GPS software and a standard desktop PC. The use of two flash cards at one site could assure nearly continuous measurements at each site.

(a) (b)

Figure 3. Reference stations setup and a monitoring station on the Forth Road Bridge [51].

3.2 GPS sensor locations on the bridge

As previously discussed in this article, a widely adopted sensor configuration for most bridge monitoring systems is to install the GPS sensors onto both sides of the supporting towers, at the 1/4, 1/2, and 3/4 points of the bridge span, with the attempt to extract structural dynamics [29, 51, 56]. With a sensor configuration as described in Figure 4, special events or structural response can be easily identified. Figure 5 shows the vertical deflection of a 100-t lorry that passed each of the monitoring sites from south to north on the Forth Road Bridge. Whether this configuration is optimal and adequate for detecting global bridge deformation and deflection is still an unanswered question. Some preliminary research was conducted using a short span suspension bridge as a case study for the optimal determination of the number and locations of GPS sensor [56].

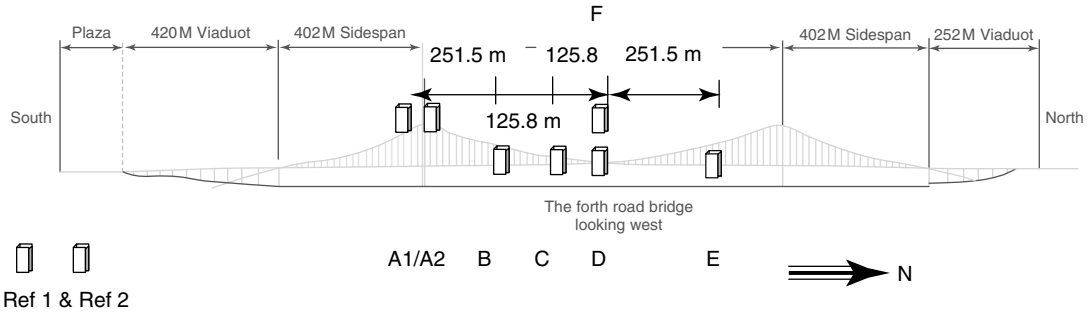

Figure 4. GPS antenna layout for monitoring the Forth Road Bridge [51].

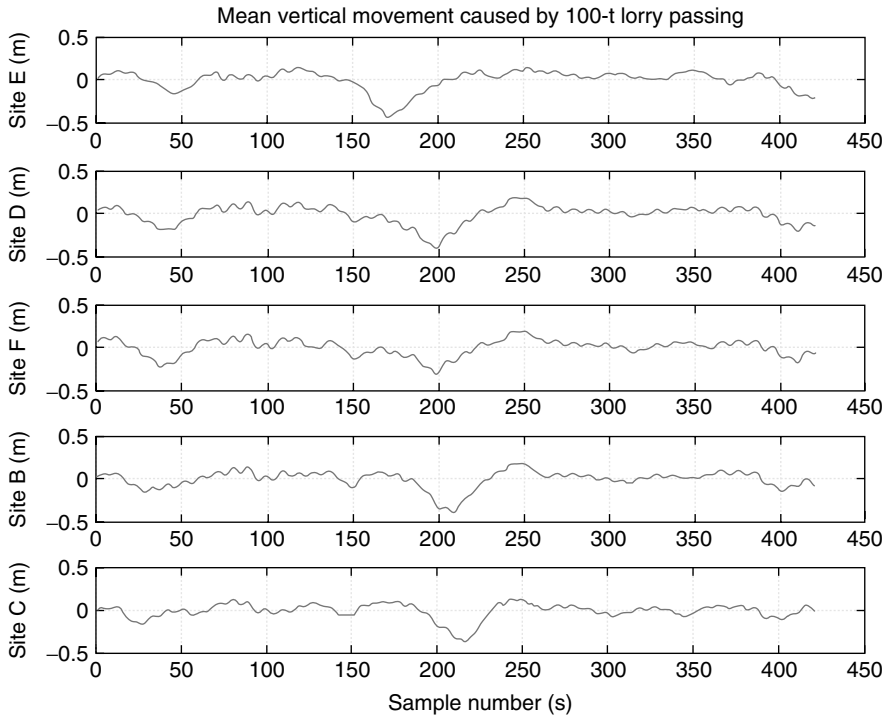

Figure 5. Vertical deflection of five GPS sites caused by a 100-t lorry passing.

3.3 Coordinates and coordinate transformation

The reference datum adopted by GPS positioning is called *the World Geodetic System of 1984*, or *WGS84*, which is a 3D, earth-centered earth-fixed (ECEF) system. Under this reference system, the coordinates determined by a GPS receiver are expressed as either geodetic coordinates (latitude, longitude, and ellipsoidal height) or Cartesian coordinates (x, y, and z). These coordinates do not make sense for many engineering applications such as analyzing 3D bridge deformation, since they are not aligned with the bridge axes. So, these geodetic coordinates within WGS84 must be transformed into rectangular grid coordinates (easting and northing). With the information about the local mean sea level, which defines a local height datum, geoid, the difference between WGS84 (ellipsoid) and the geoid can be estimated, which is called as *geoidal height*. By using this geoidal height the measured ellipsoid height of a point on the earth surface can transformed as the orthometric height, a height referred to as the local geoid. For GPS-based SHM application, using either orthometric height or ellipsoidal height does not make any difference if only one height datum is chosen for whole data analysis. However, the engineering coordinate system of a bridge, or a bridge coordinate system (BCS), is normally defined as a right-handed Cartesian coordinate system using the longitudinal axis of the bridge as x axis, the lateral direction as the y axis, and the vertical direction as z axis [27]. Hence, a second coordinate transformation for transforming the coordinates in a local coordinate system to those in a BCS involving translation and rotation is further conducted through the determination of a rotation angle of the bridge main axis from the north direction and the coordinates of BCS origin in the local grid coordinate system.

3.4 Identification of wind and thermal induced bridge deformation through GPS positioning

GPS is a very useful tool in detecting deformations induced by wind and thermal loadings. The bridge response to wind loading characterizes a short-term vibration but the deformation induced by the diurnal change of temperature is a very slow process. Figure 6(a) shows wind speed measured in a period of 48 h and Figure 6(b) shows the lateral responding deformation at a midspan point of the Forth Road Bridge. The cross-correlation coefficient between wind speed and lateral deformation is 77%, demonstrating a very high level force and response effect [49]. Figure 7 describes the relationship between the thermal loading and the vertical bridge deformation. Delay in the deformation is evident. The calculated correction coefficient is -39%. In considering the deformations caused by other affecting factors, such as traffic and wind loading, this correlation is still very high. From these two figures, the capacity of GPS for monitoring both dynamic and semistatic deformations is further confirmed.

3.5 Deformation analysis and interface with computational models

A simple bridge deformation analysis is to draw 3D deformation time series and compare these deformation curves with safety thresholds. Fast Fourier transform (FFT) algorithm can be used to identify dominant vibration frequencies and maybe the changes of these frequencies could provide some information about the change of the bridge's properties. A more complicated time-frequency analysis approach has attracted the interest of many researchers around the world and can also be employed to analyze the change of these frequencies against time [18, 27, 57]. When all the deformation time series collected from each monitoring site are gathered, it is expected that GPS can be used for the global monitoring of a bridge dynamics with the possibility to connect to localized sensors for detecting potential damage, as proposed in [34]. Hence, correct interpretation of GPS data for structural dynamics forms an important and unique part of an SHM system. From field data collection point of view, any procedures that could assure the measurement quality in a cost-effective manner should be taken. However, more study should be initiated in the near future for the interpretation and analysis of field measurements (*see* **Time–frequency Analysis**).

Some preliminary research has been carried out to extract dynamics from GPS-measured coordinate time series [58]. How the GPS measurements could

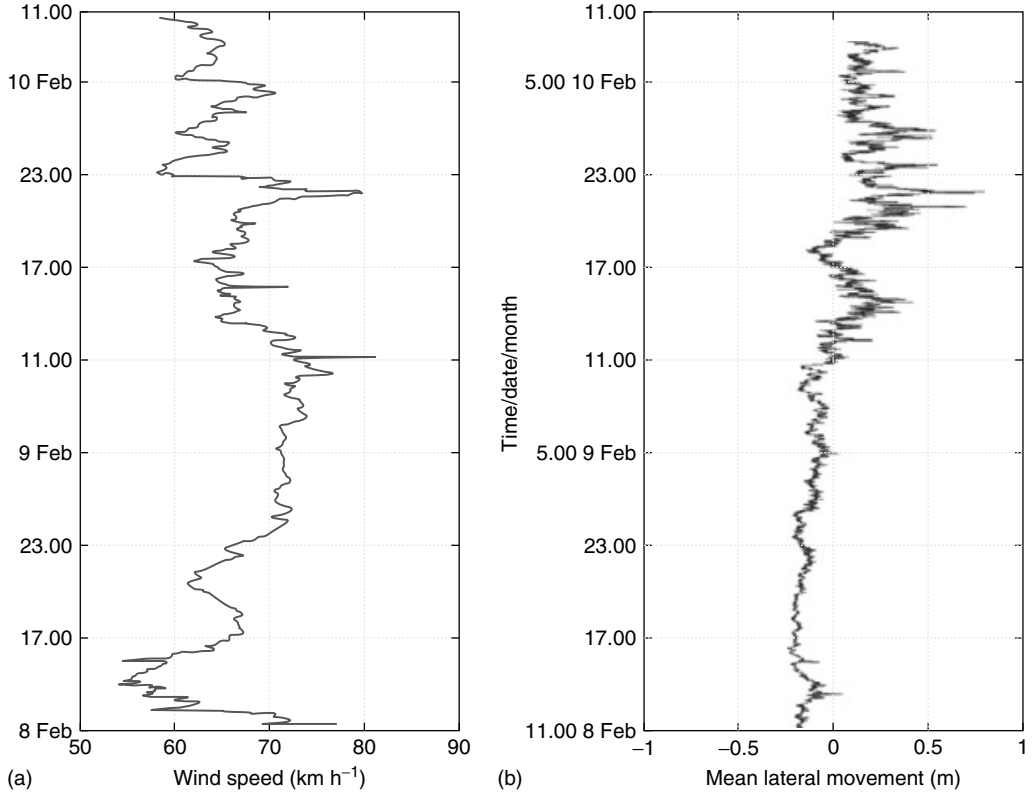

Figure 6. Wind loading and the lateral deflection of the Forth Road Bridge (a 48-h period).

be synergized with a computational model such as a finite element (FE) model is recommended in [58] and the whole loop of a practical SHM comprises the following steps:

Step 1—initial FE model creation;
Step 2—optimal sensor placement;
Step 3—bridge monitoring data collection;
Step 4—model updating (correlation of the FE model to the test data);
Step 5—further bridge monitoring data collection;
Step 6—FE model/real data comparison (comparison between the predictions of an FE model with real bridge deformations during its operational life).

3.6 Integrated sensor systems

Owing to the severe environmental conditions encountered in the bridge deflection monitoring, the instruments used must be lightweight, portable, reliable, and easy to install and the results must be easy to interpret. These are of great importance under extreme loading scenarios such as strong wind, volcanic eruption, and earthquake. At the same time, for correctly interpreting the dynamics of monitored bridges, the measurements should meet accuracy specification requirements. This means the deflections of the bridge should be measurable with available surveying instruments. For instance, to measure centimeter-level deflections the internal accuracy of a GPS receiver should be better than a few millimeters level, and multipath and other error sources should be appropriately mitigated or modeled.

Conventional surveying methods such as leveling have been used in the past to monitor static displacements of engineered structures with millimeter level or higher accuracy, and will certainly continue to be used in the future.

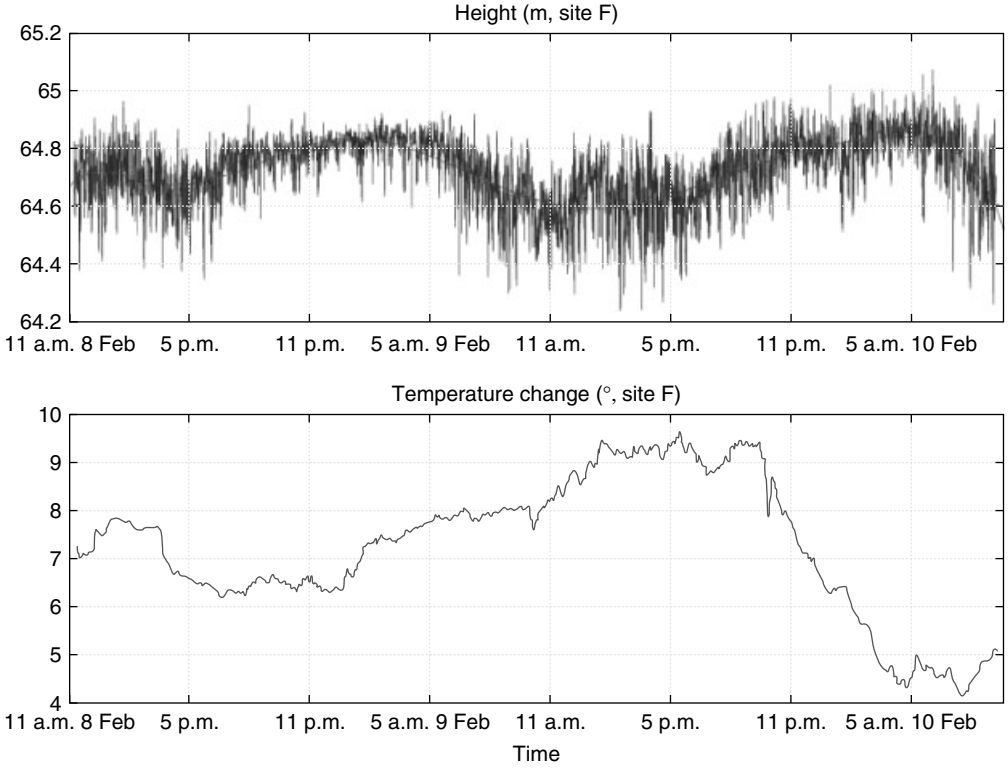

Figure 7. Diurnal temperature change versus the height variation at the midspan of the Forth Road Bridge (a 48-h period).

Modern leveling sensing stations could provide one-dimensional accuracy of about 2 mm at a sampling rate of 2.56 Hz [29]. Surveying robots, electronic distance meter (EDM), theodolites, surveying total stations, photogrammetry, and other surveying instruments could be employed to monitor structural deformation. However, the inherent disadvantages of these terrestrial surveying systems have greatly limited their applications. Previous research reveals that the main disadvantages of these surveying approaches can be summarized as follows:

- long-term intervals between measurements (days or even months);
- averaging of data over a relatively long time span (often some hours are smoothed, which leads to smoothing effects that could hide real movements of the stations);
- relatively low data sampling rate and a poor level of automation;
- batch mode analysis (data is collected, transmitted to a computer, and evaluated a few hours later).

Because of the above limitations of these terrestrial surveying methods, they cannot be employed to monitor structures with dynamic structural deflection and semistatic movements at the same time.

Accelerometer is used as an indispensable sensor in SHM of bridges for the identification of its dynamic characteristics. A triaxial accelerometer could measure three orthogonal accelerations simultaneously. Compared with other surveying systems, a triaxial accelerometer has some special advantages when it is used for bridge monitoring. For instance, the sampling rate can reach several hundreds of hertz depending upon application requirements. Triaxial accelerometers are superior to other sensors since they are not dependent on propagation of electromagnetic waves, and therefore avoid the problems of signal reflection or refraction and line-of-sight connections to the terrestrial or space objects. An

accelerometer could form a completely self-contained monitoring system, utilizing only measurements of accelerations to infer the positions of the system, through integration based on the laws of motion. However, the positional drift of an accelerometer grows extremely rapid with time and can reach hundreds of meters after an interval of several hours [59]. The main error sources come from the instrumental biases and scale factor offsets and the unknown gravity of the earth. Continuous updating such as zero velocity update (ZUPT) or coordinates update (CUPT) is used to avoid error accumulation. It is the need to update that has severely restricted the wide applications of accelerometer technology as a standalone positioning method in surveying. In bridge deflection monitoring, it is impossible to conduct ZUPT; CUPT aided with GPS fixes could be a realistic option to overcome drift problem of accelerometer.

An integrated monitoring system consisting of GPS receivers with triaxial accelerometers could overcome the shortcomings of each individual sensor system and provide a much improved overall monitoring system in terms of productivity and reliability. To eliminate any potential sensor misalignment errors, the researchers in the University of Nottingham designed a cage that hosts both GPS antenna and a triaxial accelerometer as shown in Figure 8 [27]. Detailed GPS and accelerometer data fusion technique was also introduced by the same author and other researchers [30, 60].

As discussed by [47, 50, 61], current GPS constellation causes an uneven distribution of satellites in view: in the equatorial area a more scattered satellite distribution is possible, which means a nearly identical easting and northing positioning accuracies; but in the polar areas, no satellites above 45° elevation angle are visible, which causes degraded 3D positioning accuracies. The worst factor prohibiting wide GPS application for SHM of bridge is that the vertical positioning accuracy is always the worst component in the three coordinates and this might lead to wrong interpretation of actual bridge deformation [50]. In addition to the introduction of high-level multipath, dense cables, supporting towers, and other surroundings also cause satellite visibility problem, making the visible satellites less than adequate for starting a positioning fix. If several ground-based pseudolites could be installed with very low elevation angles,

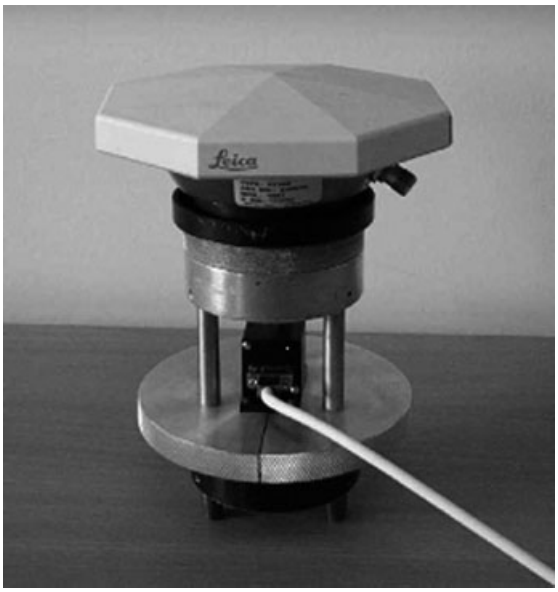

Figure 8. Device for integrated GPS antenna and a triaxial accelerometer.

it will significantly enhance the satellite geometry and positioning accuracy, especially in the vertical direction [47]. Pseudolites were used for the proof of GPS concept in the 1970s, before the launch of real GPS satellites. In the 1990s, due to the high demand in highly precise positioning solutions and the deficiency of current GPS constellation, the pseudolite concept was reinvented for augmenting GPS satellites.

A joint research has been conducted by the University of New South Wales and the University of Nottingham to verify the effect of introducing extra ground-based pseudolite transmitters for bridge deformation monitoring [48, 62–64]. Data processing of both GPS and pseudolite measurements reveals that if they are used correctly pseudolites can augment GNSS satellite geometries and improve 3D positioning accuracies to several millimeters. For the Wilford Bridge monitoring trials in Nottingham, three pseudolites were set up on the northern side of the bridge to fill the hole as shown in Figure 9 for obtaining more complete transmitter geometry. Compared with GPS-only solutions, the actual accuracy improvements in the north, east, and vertical directions are 14, 36, and 46%, respectively. The simulated accuracy improvement in the north, east,

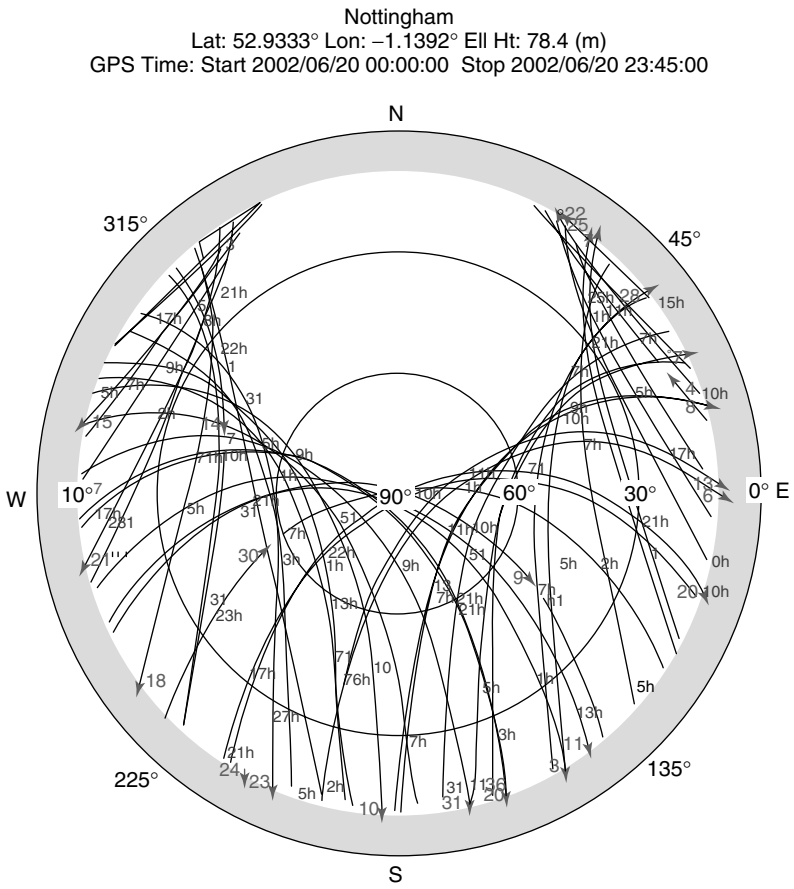

Figure 9. Skyplot of GPS satellites in Nottingham, showing the deficiency of GPS constellation.

and vertical directions are 19, 34, and 59%, which confirms the feasibility of an integrated GPS and pseudolite monitoring system for achieving more robust, accurate, and reliable results, especially in the vertical coordinate. However, since the early pseudolites transmitted on L1 frequency band, which could potentially interfere with GPS signals, the use of pseudolites was banned in many countries and its use was restrained in the United Kingdom. Collaborative research has lead to further cooperation in using a new generation pseudolite, Locatalite, which was pioneered by the Locata; it transmits at the 2.4-GHz frequency band to avoid the interference with the GPS signals [62].

Other integration approaches can also be employed in the SHM of long bridges, such as an integrated monitoring system consisting of an inertial navigation system (INS) and GPS. But the cost of this system could dramatically increase because of the high cost of an INS device.

4 FUTURE VISION

For improving positioning accuracy and availability, system integrity, and reliability, GPS is currently under its modernization through updating its space segment, improving signal quality and computation algorithms. Of course, the revival of Russia's GLONASS, and the development of European Galileo system will significantly increase signal availability and improve space geometry. China is expanding its regional navigation system, Beidou or COMPASS system, to a global coverage. Within a five-year period, the total number of

navigation satellites could reach more than 110 and this will make high and pervasive real-time positioning less of a challenge. For solving the problem of signal obstruction by surroundings and making positioning in severely obstructed areas possible, R&D of regional space-, ground-, and aircraft-based SatNav augmentation systems such as Australia's Ground-Based Regional Augmentation System (GRAS), India's GPS and GEO Augmented Navigation (GAGAN), Japan's Quasi-Zenith Satellite System (QZSS) system and MTSAT Satellite-based Augmentation System (MSAS), the European Geostationary Navigation Service (EGNOS), the United State's Wide Area Augmentation Systems (WAAS), etc., is the main activity of the national space programs of these countries. Establishment of network-based RTK GNSS reference station infrastructure at a national or regional level to support improved positioning accuracy and mobility is also a recent focus in GNSS development. For instance, the Ordnance Survey of the United Kingdom has established a network GNSS facility, which consists of more than 100 permanent stations, covering the whole country. High-quality real-time RTK corrections can be received wirelessly with a GPRS-embedded GPS receiver for achieving 3D positioning accuracy of a few centimeters OTF. For monitoring the deformation of the Humber Bridge, the bridge authority only need to subscribe to the service providers for the precise (The Radio Technical Commission for Maritime Services) RTCM corrections for carrying out continuous monitoring in a more cost-effective and reliable manner. The progress in GNSS receiver and antenna technology will also make future GNSS receivers and antenna more sensible to weak signals and more robust to reject external inference and multipath. However, the following questions need to be further addressed. For instance, is 3D positioning to an accuracy in millimeters high enough for extracting the parameters of bridge deformation at sampling rate of up to 100 Hz or higher? Will network RTK GNSS with more than 110 satellites and other regional augmentation systems be able to provide more reliable, continuous, and robust positioning for monitoring bridges from several meters to several thousand meters of bridge spans? Will future wireless communications fully replace current optic-fiber or cable-based communications for both streaming RTCM corrections from the reference stations to the rover receivers and also sending the positioning solutions to the control center for further analysis? Will GNSS positioning also be able to help predict the existing life span of a bridge effectively? More effort is required to address these questions through individual or collaborative research around world and this will eventually make GNSS positioning a feasible technology for SHM of not only bridges but any civil engineering structures as well.

Chapter 58
Eddy-current *in situ* Sensors for SHM

Neil Goldfine, Vladimir Zilberstein, Darrell Schlicker and Dave Grundy
JENTEK Sensors, Inc., Waltham, MA, USA

1 INTRODUCTION

This article complements **Eddy-current Methods**. The focus is on surface-mounted and embedded eddy-current sensors, arrays, and sensor networks for structural health monitoring (SHM). The reader is expected to have some knowledge of eddy-current methods.

Generally, eddy-current sensors include both scanning sensor arrays and sensors mounted at selected critical locations. This article describes primarily capabilities of surface-mounted and embedded eddy-current sensors for detection and monitoring of damage states as well as for monitoring of usage state variables such as stresses and temperatures.

Eddy-current SHM sensors described here are either permanently or temporarily placed in close proximity of, directly on, or within a structure at selected locations to provide enhanced observability of damage and usage state variables—*specifically to support life management decisions*. Arrays, as defined here, are local sensor constructs with a common drive (primary winding) and multiple one-dimensional or two-dimensional sensing elements that form an array in a plane positioned parallel to the surface of a component. One such sensor is the JENTEK MWM®-Array (MWM stands for meandering winding magnetometer) [1–10]. Networks of sensors and sensor arrays can be distributed throughout a structure to provide coverage of critical locations. Either (i) portable data-acquisition and analysis units, (ii) central onboard electronics, or (iii) distributed electronics modules can be used

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

to acquire data from eddy-current SHM sensor networks.

When used for damage detection and monitoring, embedded or surface-mounted eddy-current sensors perform a function similar to the function of eddy-current sensors for nondestructive testing (NDT) applications described in **Eddy-current Methods**. The advantage of permanently mounting these eddy-current sensors and arrays is that they can be used to inspect difficult-to-access locations without requiring disassembly or surface preparation. The principal disadvantages of such permanently mounted sensors for damage detection and monitoring are that (i) once in place, they cannot be scanned to sample areas that have no damage for relative comparisons with defect indications; (ii) they are limited in surface imaging resolution by the size of the individual sensing elements in an array (note that imaging resolution should not be confused with the crack detection capability since detectable cracks may be either bigger or smaller than the size of the sensing element depending on the signal-to-noise ratio); (iii) they cannot be removed for calibration in air or on standards at the time of the inspection; and (iv) in general, they can only detect damage directly under the sensor (or sensing elements of an array)[a].

Historically, SHM successes have been limited to usage and diagnostic state monitoring. There has been wide use of temperature, pressure, strain, and vibration sensing onboard aircraft and on other high value assets. This includes SHM implementations in aviation, automotive, energy, and many other market sectors. For example, vibration sensing, using inductive sensors, is common. These more traditional SHM uses are not addressed in this article. However, some of these more traditional uses can gain from the sensor technology described here. One example is weight and balance monitoring for aircraft that is limited by the ability of strain gauges or other load monitoring methods to provide reliable measurement of loads over long service periods. Attempts to implement reliable systems have generally not been successful. This article describes the approaches that can address the need for improved stress/load monitoring of both static and dynamic stresses.

To enable *individual component life management* beyond the push over the last few decades for individual aircraft tracking, two new, or at least recently reinvigorated, thrusts in SHM development have emerged. These include the need (i) to replace, or at least supplement NDT, which is typically performed with off-board sensors/probes, by direct onboard damage and condition monitoring, both continuous and intermittent, in difficult-to-access critical locations and (ii) to provide direct monitoring of local stress/strain, temperature, and environmental conditions at the critical locations that are most likely to accumulate damage or experience changes associated with relevant events, e.g., overloads and foreign object damage (FOD) for metals and composites.

To enable life extension and predictable performance for subsystems and components of high-value assets, such as aircraft, rotorcraft, ships, pipelines, bridges, etc., the often-stated goal of replacing or at least reducing the use of conventional NDT by introducing onboard SHM for *direct damage and material condition monitoring* comes from (i) the need to mitigate life cycle cost escalation while improving readiness for aging aircraft and (ii) the need, on new platforms and in platform upgrades, to improve mission readiness/capability rates, reduce field and depot logistics footprints, to enable more aggressive component/platform designs using less conservative safety margins and using advanced materials (composites, functional coatings, multi-material systems), to reduce overall aircraft weight by enabling application of damage tolerance methods by making difficult-to-access areas inspectable, to avoid collateral damage associated with disassembly for inspection, better manage mission loads, to alert to events such as excessive FOD and consequences of inadequate maintenance actions, and to remove the human from the field maintenance loop.

Thus, *the expanded use of onboard sensors for SHM is inevitable*, particularly when advanced surface-mounted and embedded sensors have proven, for some applications, to be far less invasive, with lower total implementation costs, than conventional off-board NDT methods in both logistics support requirements and practical impact on asset readiness/availability.

This article addresses the need for enhanced monitoring of (i) damage states, (ii) usage states, (iii) diagnostic states, including (iv) detection of upset events.

Damage states are scalar, vector, or multidimensional quantities that (i) can be used in models to

predict damage behavior progression, e.g., degree of relaxation of compressive residual stresses intentionally introduced to mitigate damage such as fatigue or stress corrosion cracking or (ii) provide a measure of one or more damage features (e.g., crack size, material loss from corrosion, or composite disbond/delamination area).

Usage state variables of interest include stresses and temperatures that directly affect cumulative exposure to mechanical and/or thermal conditions at critical locations on individual components, for which damage evolution needs to be monitored. Enhanced stress, temperature, and environmental monitoring are continually identified as necessary to achieve the promise of SHM for aircraft and rotorcraft.

Diagnostic states of interest include geometric misalignment, vibration levels, thermal effects, and overload events. The focus of new developments in this area of SHM development is to enable onboard or temporarily installed monitoring capability for such diagnosis at reduced cost and with limited logistics support requirements.

Upset *event detection* through monitoring of *event-dependent states* of a material (e.g., impact or overheating in metallic or composite components) is often identified as a separate requirement that must be addressed. Event detection is particularly important to components managed on a safe-life basis (as practiced by the US Navy).

Of course, there is an inevitable overlap and interdependence in the above definitions, for example, between some diagnostic states and upset events. Upset event identification is certainly a part of diagnostics. Also, detected upset events should be accounted for in the assessment of usage.

This article specifically discusses eddy-current sensor capabilities demonstrated over the last decade to provide material damage monitoring, including fatigue, corrosion, and overloads, as well as stress and temperature monitoring. The focus of this article is on the MWM and MWM-Array eddy-current sensors [11–15, 18–22], since these sensors address the above categories of interest (damage, diagnostics, and usage).

For detection and monitoring of damage or parameters of interest with the available mountable eddy-current sensors, such as MWM sensors or MWM-Arrays, portable units plug into onboard sensors for inspection or short duration monitoring at difficult-to-access locations. These portable units can support onboard NDT, diagnostic, or usage survey function.

Onboard instrumentation, when available, would provide continuous monitoring capabilities for damage, diagnostics, and usage recording. Such onboard resources could be queried in parallel, through prescribed multiplexing. Alternatively, they can be allocated using a concept named *neural plasticity* by analogy to a phenomenon related to human neurological development. Neural plasticity is a concept that enables the use of limited onboard resources that learn and grow in capability with experience by reallocating limited resources.

Onboard SHM applications of eddy-current sensors are beginning to transition to operational fleet use, having been proven extensively in the laboratory and more recently in full-scale component and full-scale aircraft tests. Extensive flight testing of eddy-current sensors for fatigue monitoring and stress monitoring with portable data-acquisition systems is expected to occur within the next few years, followed by transition to fully integrated onboard systems using eddy-current sensors. One example of a potential application would be fatigue-critical locations on landing gear components (*see* **Landing Gear**).

In **Eddy-current Methods**, the concept of mapping and tracking of fatigue damage using time-sequenced scanning with advanced eddy current methods is introduced. For example, in some critical areas in aircraft components, such as engine disk slots, where early damage detection using onboard SHM sensors is not feasible, the only means for early detection is mapping and tracking with improved scanning NDT. On the other hand, integration of onboard SHM sensor data with such mapping and tracking, when practical, would significantly enhance health monitoring capabilities.

In general, (i) onboard SHM sensors for damage detection and monitoring, (ii) traditional scanning NDT methods, (iii) advanced NDT using new mapping and tracking methods for damage evolution, and (iv) enhanced direct load monitoring capability, using onboard SHM sensors, are all needed to implement next-generation adaptive life management programs.

One advantage of using MWM-Array eddy-current sensors in support of adaptive life management is that eddy-current measurements in scanning mode

and with onboard SHM sensors are complementary (providing self-consistent data formats). For fatigue damage, for example, each of these methods provides a measure of the effective electrical conductivity or magnetic permeability variation, with the damage level of interest, for the material under test.

One proposed adaptive life management approach, described by Goldfine *et al.* [13] and modified here to include mounted "onboard" sensors, is outlined in the flow chart in Figure 1.

This approach relies on the availability, reliability, and reproducibility of the NDT scanning/imaging capability and surface-mounted or embedded capability for both coupons and in-service components. Until recently, there were no depot/field inspection tools that could meet this requirement. Now, not only the MWM-Array sensors can meet this need and enable the adaptive life management approach, but other advanced methods, including Ultrasonic Testing (UT), laser UT, thermography, and digital radiography, offer the potential to deliver the previously unattainable level of reproducibility needed to support mapping and tracking of relatively early damage behavior. Also, onboard MWM-Array, UT, and alternative SHM sensors are becoming available. We anticipate that many such technologies will be proven and reach commercial maturity during the next decade.

In the near term, the approach described above is envisioned as an integration of advanced scanning NDT (mapping and tracking) with periodic or scheduled data from onboard SHM sensors recorded using portable (not onboard) data-acquisition units. In a more broadly integrated approach, onboard SHM sensors might provide continuous monitoring, with onboard electronics, along with periodic NDT scanning of selected locations. The goal is to provide the required observability of damage, diagnostics, usage state variables, and significant events.

For aluminum and titanium structural components in aircraft and rotorcraft, there are practical onboard SHM sensing alternatives to scanning NDT inspection methods. This article focuses on these applications for onboard SHM damage monitoring. Also, this article describes the value of surface-mounted and embedded sensors for laboratory fatigue and corrosion testing. Furthermore, new magnetic (eddy current) stress gauge capabilities are described for direct load monitoring.

2 EXAMPLES OF ADVANCED EDDY-CURRENT SHM IMPLEMENTATIONS

In the following five main sections, examples of detection/monitoring of damage and measurements related to diagnostics as well as to usage state variables are described within the following categories: (i) fatigue, (ii) corrosion, (iii) stress, (iv) temperature, (v) mechanical damage, and (vi) composite disbonds/delaminations. These sections rely on MWM-Array implementations to frame the discussion of *in situ* eddy current sensor applications, since the authors are most informed on this advanced sensor implementation. Some of these sections include a discussion of performance evaluation needs and methods for surface-mounted and embedded SHM sensors.

The focus here is on the use of permanently surface-mounted or embedded sensors. However,

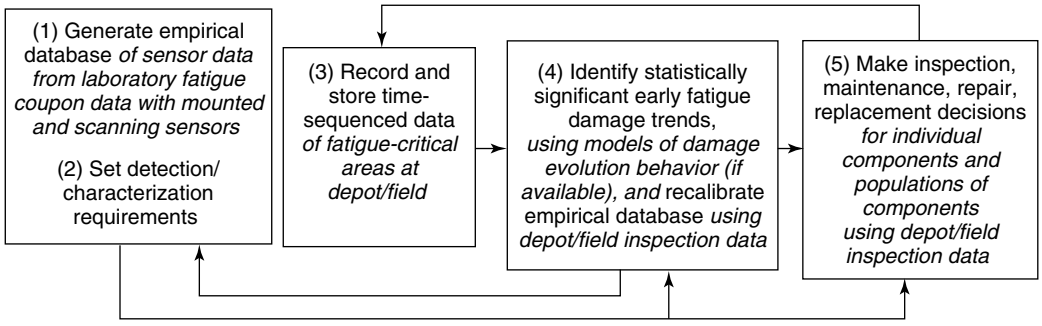

Figure 1. Flow chart of proposed adaptive life management framework.

some discussion is included on integrated methods that combine such SHM data with more conventional NDT data, including mapping and tracking using repeated NDT type imaging.

3 FATIGUE MONITORING

3.1 Fatigue case study 1: linear MWM-Arrays inside bolt holes

In **Eddy-current Methods**, an example of a mapping and tracking application for crack detection and monitoring using scanning MWM-Array bolt-hole inspection, with C-scan imaging, is provided. In Figure 8 of **Eddy-current Methods**, permanently mounted MWM-Array data is also provided for the same coupon test.

As shown in Figures 7 and 8 of the same article (*see* **Eddy-current Methods**), the combination of MWM-Array scanning and permanently mounted sensor data provides valuable insight into the crack growth behavior. This format of coupon testing, using both sensing modes, is useful for generating and calibrating damage behavior databases, as well as for generating real-crack specimens that can be used for sensor performance verification and for building probability of detection curves for both scanning and permanently mounted sensors.

3.2 Fatigue case study 2: detection of small fatigue cracks at a dimple

Also, in **Eddy-current Methods** and in [15], a method of detecting cracks at mechanical damage sites was described (*see* Figure 9, **Eddy-current Methods**). Figure 2 shows the customized titanium coupon designed for that test. In Figure 3(a) and (b), a special scanner is shown for periodically scanning the fatigue-critical area on the coupon to simulate in-service time-sequenced NDT imaging. Figure 3(c) shows a 7-channel MWM-Array designed for this purpose. Figure 2 of **Eddy-current Methods** illustrates the measurement grid approach developed by Goldfine *et al.* [5] for this purpose. This method enables real-time conversion of thousands of digital eddy-current measurements into two images: (i) conductivity image—used to detect cracks and

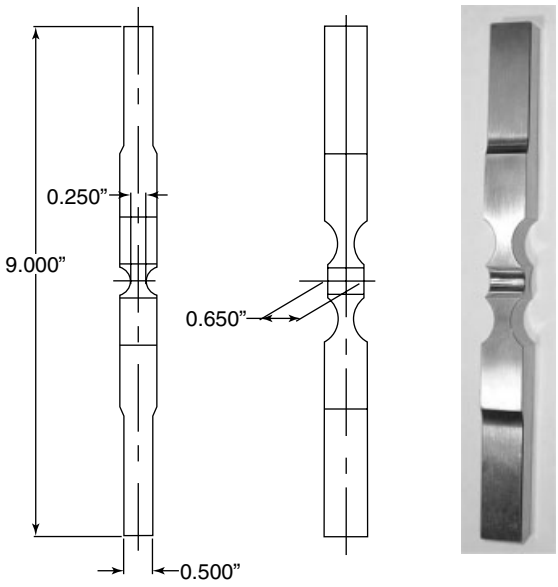

Figure 2. Schematic and photograph of a customized Ti-6Al-4V coupon with exposed fatigue-critical surfaces [8].

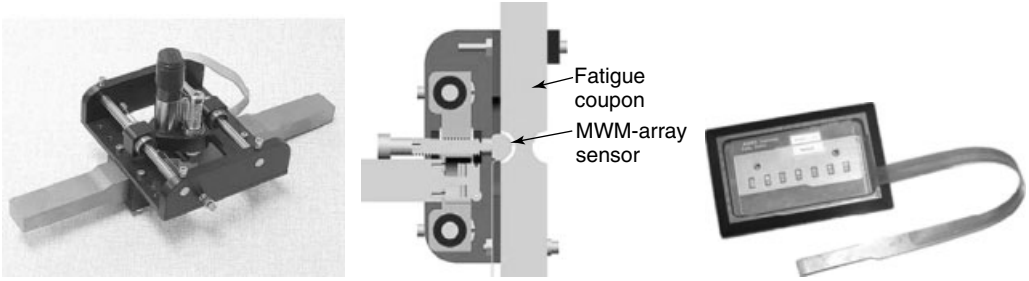

Figure 3. (a) Photograph of the coupon scanner used in support of the fatigue testing, (b) solid model representation of the coupon scanner showing the sensor position, and (c) MWM-Array FA43 sensor.

(ii) liftoff (sensor proximity to the material surface) image—used for self-diagnostics to ensure that liftoff is within an acceptable range at each of the thousands of points within an image.

Furthermore, this approach uses "air calibration," as described in ASTM Standard Practice E2338-04 [16], to improve robustness compared to conventional eddy-current testing (ET) methods that use crack (or simulated crack, e.g., EDM (electrical discharge machining) notch) standards to calibrate. This proven method is now a standard practice at US Navy and US Air Force bases, and is in use by foreign military services (FMS) as well.

This test and the data provided in Figure 9 of **Eddy-current Methods** illustrate the value of a combined approach that integrates NDT and permanently mounted sensor data. This combination could be implemented in fatigue tests and on actual structural members. For example, when localized mechanical damage or a small crack is detected using a scanning array, the damage can be either repaired or left in place, and then a permanently mounted sensor could be applied at this location to monitor initiation and/or growth of cracks at the location. One goal is to estimate the probability of failure before the next inspection for the purpose of scheduling inspection intervals and enabling life extension. The coupon fatigue test data and in-service data obtained from such combined monitoring can also be used to calibrate databases of damage evolution behavior.

Eventually, this should also enable reliable life extension through restoration of parts with localized damage using laser shock processing, low plasticity burnishing, laser additive manufacturing, or other repair methods. It is anticipated that substantial (possibly over additional 100% of design life) life extension for many components is possible if such "health control" actions are implemented.

One key attribute is the portability of experience from one component to the next. If the entire process must be repeated for each new component, then this is not a practical approach. Thus, coupon tests and NDT databases must be sufficiently generic to adapt (i.e., recalibrate) with limited effort for the next application.

Reliable mapping and tracking with MWM-Arrays has been demonstrated for titanium alloy components, in coupon fatigue tests and on engine components. With the use of titanium alloys on both commercial and military aircraft and rotorcraft, the need to detect early fatigue damage and deliver on-condition maintenance is critical. For example, titanium alloys are typically notch sensitive. Thus, small nicks, dings, and scratches introduced during handling, assembly or in service can initiate cracks at fatigue-critical surfaces earlier than predicted by design life estimates. Blending of such surface defects is sometimes allowed followed by, for example, re-shot peening to enhance remaining life. However, many parts are not re-shot peened because of quality control issues; thus, their fatigue resistance is not fully restored. In other cases, components are simply replaced, if surface defect depths exceed a prescribed limit (often just a few thousandths of an inch). This is extremely costly. Thus, methods are needed to provide early detection of damage for critical titanium alloy components, as well as to image and size surface defects to support on-condition maintenance decisions. The combination of surface-mounted sensor monitoring and mapping and tracking has proven to be very effective for such applications. Moreover, surface-mounted sensor monitoring followed by a one-time MWM-Array scanning of the suspect areas can be sufficiently effective, as well.

3.3 Fatigue case study 3: embedded MWM-Arrays for crack initiation and growth monitoring

In a series of fatigue tests, MWM-Arrays embedded between two aluminum alloy layers (Figure 4) monitored crack growth in both 4-hole and 10-hole lap joint tests. These MWM-Arrays retained their integrity as they were removed and reused for a number of successive tests to failure of the lap joints. The four-hole tests were performed under NAVAIR (The Naval Air Systems Command) funding, and the ten-hole tests were performed under US Air Force funding for Lockheed Martin to address a specific need for the F-16 aircraft as described previously [17]. A variety of precrack configurations were tested with larger ("primary") precracks at the center hole and smaller ("secondary") precracks at the other holes. The crack tip progression data are shown in Figure 5. The lines indicate the progression of crack tips from one hole towards another as a function

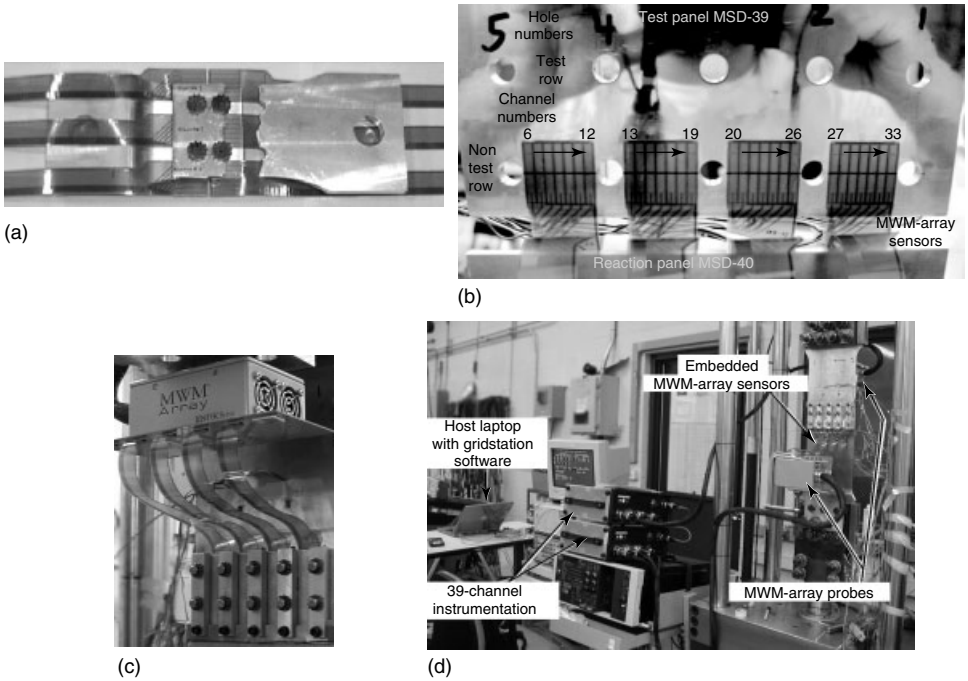

Figure 4. (a) Four-hole lap joint test specimen with embedded MWM-Arrays, (b) the 10-hole specimen with embedded MWM-Arrays shown prior to bolting up, (c) the 10-hole specimen mounted in the load frame, and (d) laboratory fatigue test setup for the 10-hole test.

of number of cycles. The MWM-Arrays successfully monitored crack growth throughout the test with the sensors embedded at the buried interface between the metal plates.

3.4 Fatigue case study 4: buried cracks at bolt holes with MWM-Rosettes

Also, under a separate program funded by NAVAIR, subsurface cracks were detected and monitored by MWM-Rosettes, which were configured as smart washers and operated in a continuously monitoring mode at low frequencies (see Figure 6). This test is part of a NAVAIR funded program that is to follow by installation on two high-time aircraft for flight testing of this method.

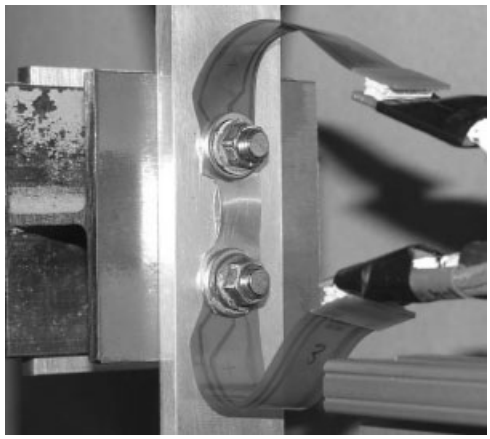

Figure 6. Photograph of the MWM-Rosette fatigue test setup.

For the test described in Figure 7, two MWM-Rosettes were fastened to an approximately 0.2-in.-thick aluminum coupon using bolts and nuts supplied by the Navy. The coupon was manually notched on the far side to promote the initiation of a fatigue crack on the side of the coupon opposite to that of

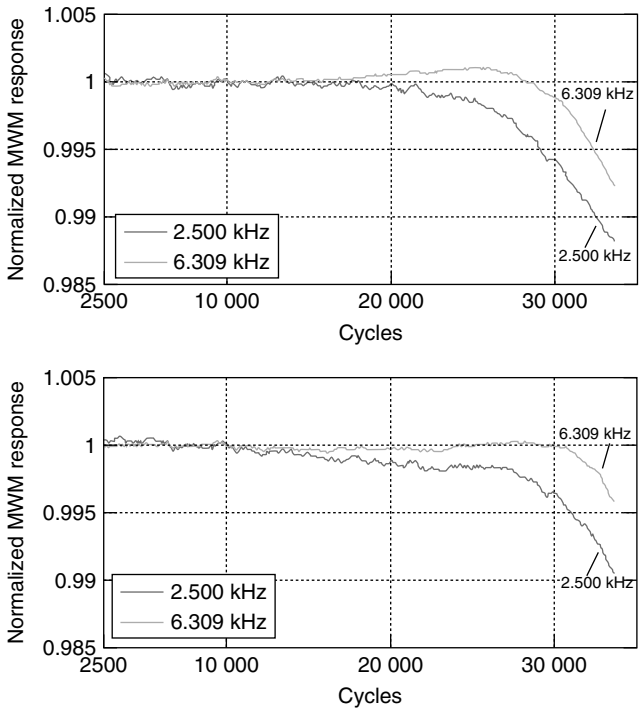

Figure 7. Normalized response of MWM-Rosette in the top hole (top plot) and bottom hole (bottom plot) acquired during a coupon fatigue test. The test data displayed is from approximately cycle 2500 to cycle 33 600. Both sensors were still functional after two fatigue tests and the accumulation of 90 000 total fatigue cycles. The "radial by axial" size of the cracks was 0.10 in. × 0.15 in. (top) and 0.11 in. × 0.14 in. (bottom).

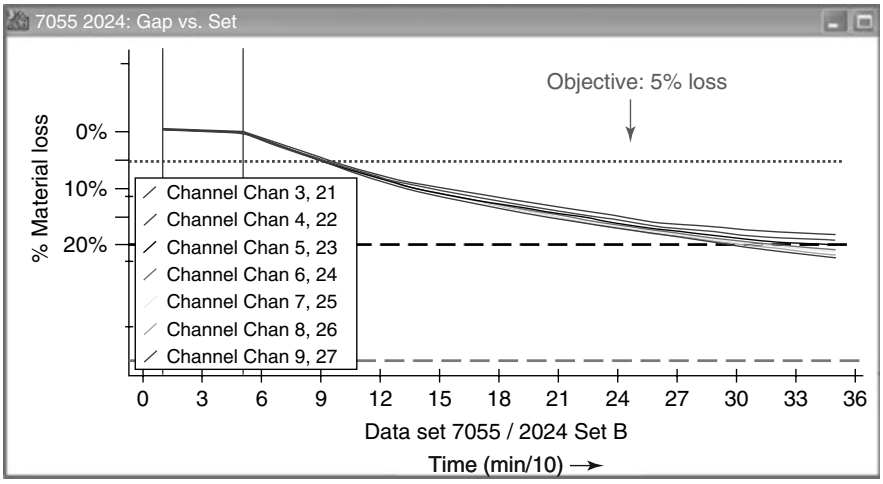

Figure 8. MWM-Array detection and monitoring of hidden corrosion during an accelerated corrosion test.

the MWM-Rosettes. Results of the fatigue test are shown in Figure 7. Cracks initiated at the notches at both holes. The crack extension was then monitored by the MWM-Rosettes. The test was stopped at 33 600 cycles, and acetate replicas of the cracked surfaces were taken. Measurements on the acetate replicas taken after the test showed that at the top hole, the crack extended radially 0.10 in. along the surface and axially 0.15 in. into the hole. At the bottom hole, the crack extended radially 0.11 in. along the surface and axially 0.14 in. into the hole. The cracks produced a reduction of 0.95 to 1.1% in the MWM signal. The MWM-Rosette was able to both detect the buried cracks and monitor their growth.

To illustrate the durability of the MWM-Rosettes operating in the smart washer configuration, a second fatigue test was performed using the same sensors. The sensors accumulated over 90 000 fatigue cycles and were still operable at the end of the test. The results of these tests provide an excellent example of the fatigue monitoring capability of MWM-Array networks.

4 CORROSION MONITORING

Hidden corrosion detection and monitoring has also been demonstrated in various tests using both mounted and scanning MWM-Array sensors [18–20]. The goal is to provide onboard detection and monitoring of hidden corrosion in difficult-to-access locations with mounted, large footprint MWM-Array sensors as well as hidden corrosion detection and monitoring in large accessible areas using wide-area scanning sensor arrays. Figure 8 shows the results of an accelerated corrosion testing program in which hidden corrosion was detected rather early and monitored with a one-dimensional MWM-Array mounted on the opposite side of the wall [19].

Figure 9 shows a surface-mountable two-dimensional MWM-Array for hidden corrosion detection and monitoring. This array is designed to monitor remaining wall thickness under its 6 in. × 6 in. footprint as metal is lost on the far side due to corrosion. Figure 10(a) shows data on a measurement grid for

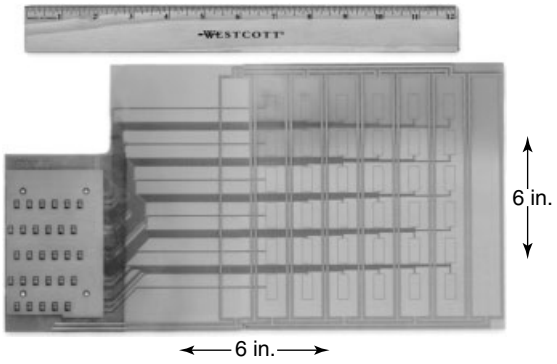

Figure 9. A two-dimensional MWM-Array for onboard monitoring of hidden corrosion.

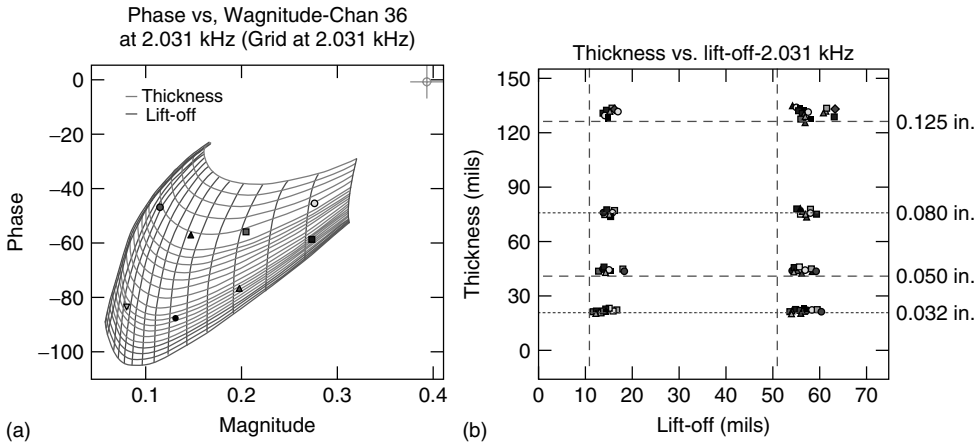

Figure 10. (a) Hidden corrosion monitoring results displayed on a metal (aluminum alloy) layer thickness—lift-off measurement grid and (b) comparison of metal layer thickness measured by MWM-Array with nominal values.

remaining metal layer thickness and liftoff, demonstrating independent measurement of these two variables. The comparison of estimated layer thicknesses with "nominal" values is shown in Figure 10(b). Only a calibration in air was performed prior to making this absolute measurement, using the air calibration methods described in an ASTM standard [16]. This capability to provide onboard monitoring of hidden corrosion loss in fuel tanks, joints (metal–metal and metal–composite), and other difficult-to-access areas can offer substantial maintenance cost reductions by avoiding costly visual corrosion inspections.

5 STRESS MONITORING

Demonstrated capability of MWM sensors and MWM-Arrays to monitor stresses in steel components [8, 21, 22] permits monitoring of dynamic stresses in rotorcraft components using a network of these sensors called *magnetic stress gauges*. This capability is illustrated here for a vibrating steel strip, as shown in Figure 11. The magnetic stress gauges mounted on opposite sides of the strip detect the alternating tensile and compressive stresses and correctly indicate their phase relationship as well as gradual reduction of stresses due to damping. The third magnetic stress gauge was mounted orthogonal to the other two gauges and, consequently, was insensitive to the motion, since it responds to transverse stress that is zero in the case of plane stress, i.e., sufficiently close to the edges of the strip.

In separate overload tests on an actual steel component loaded well outside the elastic range, we have found, however, that a magnetic stress gauge mounted

orthogonal to the principal stress *can* provide an indication of an overload event, which affects permeability in both directions as a result of the changes in residual stresses caused by stress redistribution due to plastic deformation that resulted from such an overload event. Stresses can also be monitored in components fabricated from nonferrous alloys as long as selected regions are coated with a ferromagnetic coating. Dynamic stress monitoring can be performed in a noncontact mode, as has been demonstrated in laboratory tests.

6 TEMPERATURE MONITORING

As shown in Figure 12, a deep penetration MWM-Array has been used to demonstrate the capability to monitor temperature of an aluminum plate separated from the sensor by air gap and an intermediate aluminum plate [14]. This capability of either single- or multiple-frequency MWM-Arrays eddy-current sensors to monitor temperature noncontact and/or through metal layers offers a unique value for the SHM of propulsion systems, energy systems, and other systems with high internal temperatures. Because these sensors require only a conducting path with remote instrumentation, they can also be used to operate in harsh environments or within processing facilities. Figure 13 illustrates that, if the temperature of the intermediate plate is not properly accounted for, the measurement of the buried plate temperature is incorrect. Thus, as illustrated in Figure 13, the use of a three-dimensional lattice (database) for the estimation of three unknowns (the conductivity of the two aluminum plates, and the gap between them) is essential. The relationship between temperature and conductivity is stable up to several hundred degrees. Thus, this is a practical tool for many applications.

7 COMPOSITE DISBOND/ DELAMINATION MONITORING

MWM-Arrays have also demonstrated the capability to provide monitoring of buried disbonds/ delaminations in graphite fiber composites. As shown in Figure 14, the MWM-Array was used to monitor the initiation and growth of damage in a composite–composite joint test performed at Lockheed Martin. This test performed under NAVAIR funding demonstrated the capability of the MWM-Array to monitor disbond growth through over 0.2-in.-thick composite material, during the test, using a surface-mounted MWM-Array.

Unfortunately, eddy-current sensors only detected changes to the fibers (positions, directions, fiber cracking, and bulk conductivity changes associated with density and contacts). Thus, matrix damage is not detectable with this method. Other methods such as ultrasonics and thermography offer the

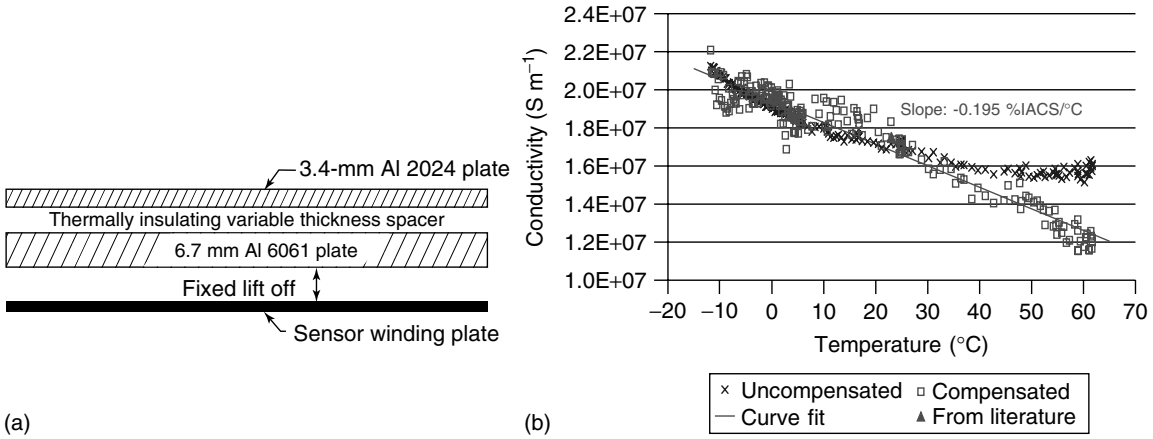

Figure 12. (a) Schematic of the demonstration setup and (b) response of MWM-Array with and without correction for the temperature variation of the intermediate aluminum plate. Note that the temperature of the two plates is measured independently using the MWM-Array at one frequency with two different-shaped magnetic field excitations [14].

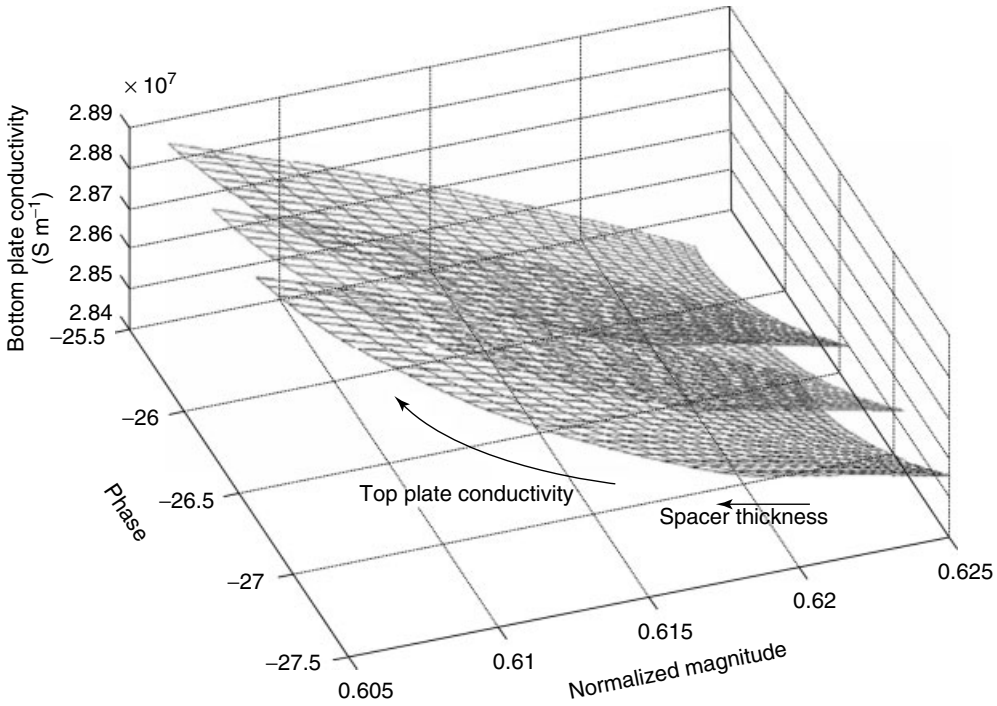

Figure 13. Lattice (precomputed database) for independent estimation of two plate temperatures (via conductivities) and the gap between them.

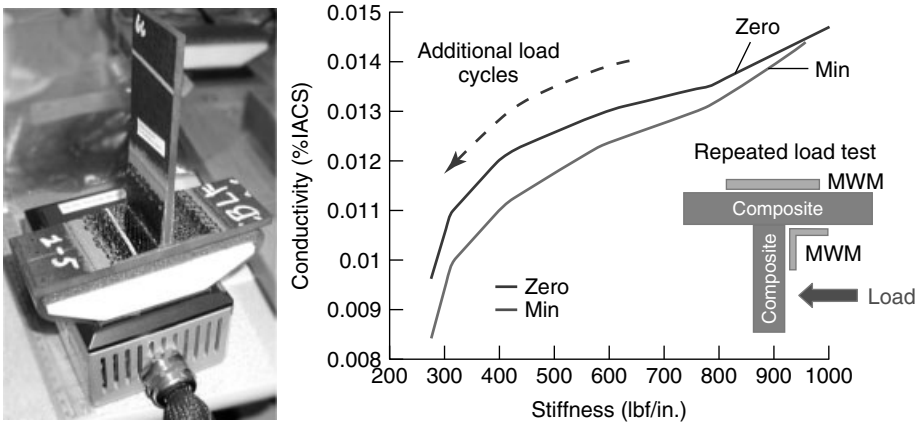

Figure 14. Composite–composite joint test performed at Lockheed Martin. MWM-Array measurements of conductivity are strongly correlated with the decreasing stiffness of the specimen as it undergoes load cycling.

capability to monitor matrix and fiber damage. One interesting method being demonstrated under ongoing NASA funding is Magneto-Thermography™. This promising method, developed by JENTEK Sensors, Inc., takes advantage of the demonstrated capability of MWM-Arrays to monitor buried fiber temperatures, to produce thermography images. This magneto-thermographic method, still in the research stage, can be implemented in a scanning or permanently mounted mode.

8 CONCLUSIONS

Eddy-current *in situ* health monitoring methods are now advancing and transitioning into use. These methods are now used in laboratory fatigue and corrosion test monitoring. In the next couple of years, the broader use of these methods are expected to accelerate owing to planned on-aircraft testing of fatigue sensor networks, using smart washer configurations of the MWM-Rosettes for buried cracks and linear MWM-Arrays for surface-breaking cracks.

Magnetic stress gauges also offer promise for near-term implementation. Full-scale testing and laboratory testing have proven the capability of this method to deliver reliable stress monitoring. This method is also expected to transition into use within the next few years.

Finally, adaptive life management, combining both installed fatigue monitoring and scanning NDT data, is expected to deliver the promise of cost savings and reduced logistics footprints for a variety of future and legacy platforms.

This is an exciting time for both offboard NDT and onboard SHM.

END NOTES

[a.] Note that for materials that exhibit significant variation of effective electrical properties, e.g., electrical conductivity or magnetic permeability with applied or residual stress measured by MWM, the potential to monitor remote damage is possible—by relating such damage occurrence to measured stress changes.

Chapter 68

Miniaturized Sensors Employing Micro- and Nanotechnologies

Kenneth J. Loh and Jerome P. Lynch

Department of Civil and Environmental Engineering, University of Michigan, Ann Arbor, MI, USA

1 INTRODUCTION

As structural health monitoring (SHM) systems continue to be deployed to monitor and assess engineered structures, there has been growing interest in the miniaturization of sensing transducers used to record structural behavior. The advantages of miniaturization are multiple; for example, reduction in sensor size and weight is critically important when considering the use of SHM systems in lightweight structures such as aerospace structural systems (e.g., rockets and satellites). Smaller sensors are also easier to install, particularly if the sensor is embedded within structural elements; an example might be thin-film sensors installed within a layered composite material (e.g., carbon fiber-reinforced polymer (CFRP) composites). In addition, miniaturization can lead to potential improvements in sensing accuracy, simultaneous to significant reductions in fabrication costs. Finally, microelectromechanical system (MEMS) sensors are more power efficient than their macroscale counterparts.

Macroscale sensor design concepts can be miniaturized by adopting emerging technologies associated with the MEMSs and nanotechnology fields. Already, MEMS has had a major impact with SHM systems widely using MEMS sensors [1]. MEMS is defined by the use of fabrication methods associated with integrated circuits (ICs) to construct mechanical structures within semiconductor substrates such as silicon (Si), germanium (Ge), and gallium arsenide (GaAs) [2]. By miniaturizing macroscale sensor transduction concepts to the micron-dimensional scale, the approach is commonly termed a *top-down* methodology. Since the initial introduction of MEMS pressure sensors in the 1960s [3], the field of MEMS has rapidly evolved over the past four decades. Today, a plethora of other miniaturized sensing transducers have been proposed by the MEMS community including accelerometers, gyroscopes, gas sensors, and ultrasonic transducers among many others [4]. These examples of MEMS sensors have been shown to offer measurement accuracies on par

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

with macroscale counterparts. MEMS adoption of IC technologies for device fabrication allows computing and wireless communication circuits to be collocated with the MEMS sensor, thereby offering complete system-on-a-chip (SoC) solutions [2]. Furthermore, IC-based manufacturing offers fabrication of MEMS sensors by a batch process, with hundreds of devices fabricated on a single semiconducting wafer [4]. While MEMS sensors have shown tremendous promise, their market adoption has been greatest in automotive (e.g., pressure and acceleration sensing) and inertial sensing markets where high sales volume is able to amortize high fabrication costs [2, 5].

In light of the limitations of MEMS, the interdisciplinary nanotechnology field has emerged to offer chemical tools and processes that permit further miniaturization of sensors designed for SHM applications [6]. Specifically, it is now possible to design materials with specific macroscopic mechanical, electrical, and chemical properties by controlling structure and assembly at the atomistic length-scale, which is nanometers in dimension [7]. This "bottom-up" approach is in stark contrast to the "top-down" design methodology currently adopted by MEMS. Currently, molecular structures such as nanotubes [8], nanoparticles [9], and self-assembled materials [10] are finding their way into the design of sensors [11]. Clearly, future advances in miniaturized sensors will be derived from the technological developments within the nanotechnology domain.

The balance of this review is delineated into two major sections. In the first section, an overview of MEMS is provided. The general methods of MEMS fabrication are described, including bulk and surface micromachining methods. In addition, a plethora of MEMS sensors that have found use in SHM applications are presented. To illustrate the impact MEMS has had on the SHM field, applications of MEMS sensors to SHM problems investigated in the laboratory and field settings are also described (*see* **Microelectromechanical Systems (MEMS)**). In the second section, the tools and processes of the nanotechnology field relevant to the miniaturization of sensors are presented (*see* **Nanoengineering of Sensory Materials**). In essence, nanotechnology allows engineers to address many of the technological limitations currently encountered in MEMS design. A novel suite of sensors assembled at the nanoscale is highlighted to reinforce the future promise of the "bottom-up" sensor design approach for SHM.

2 MICROELECTROMECHANICAL SYSTEM SENSORS

2.1 Fabrication of MEMS structures

There are two major fabrication methods employed in MEMS design to construct three-dimensional structures, namely, bulk and surface micromachining. In the first method, bulk micromachining, the structure is built into the substrate through the removal of substrate material. In contrast, surface micromachining builds the MEMS structure on top of a substrate by depositing materials to the substrate surface. How a MEMS sensor is fabricated is very important to consider at the outset of the design process since each fabrication method uniquely constrains the final geometric shape of the MEMS device. In this section, the general steps of both fabrication approaches are delineated; methods presented are primarily for silicon, which is the preferred substrate material of most MEMS foundries. The interested reader is referred to Kovacs [2] for a more complete presentation of each fabrication approach and for information on how nonsilicon substrates such as Ge and GaAs can be integrated with the MEMS fabrication process.

2.1.1 Bulk micromachining

In bulk micromachining, three-dimensional MEMS structures are fabricated within the substrate by etching. Etching is the process by which substrate material is selectively removed to create structures within the substrate. All etching methods can be classified as part of two major etching categories: wet and dry etching.

In wet etching, liquid chemical compounds react with the silicon substrate so as to remove substrate material. In general, wet etchants are either isotropic or anisotropic depending upon their relationship with the silicon crystalline structure. For example, isotropic etchants remove silicon in all crystal directions at the same rate; the result is structures with rounded features. A common isotropic etchant is HNA, which is a solution of hydrofluoric, nitric, and

acetic acids (HF, HNO_3, and CH_3COOH, respectively). In contrast, anisotropic etchants possess different reaction times depending upon the silicon crystal orientation. Using Miller index notation to denote the various planes of crystalline silicon, it is the (111) plane of silicon that is the slowest to react with anisotropic etchants. Owing to the slow etch time of the (111) plane, it is preferentially exposed during etching. In other words, the (111) plane that is exactly 54.7° relative to the (100) plane is exposed in the final structure after anisotropic etching. Alkali hydroxides (e.g., potassium hydroxide (KOH)) are typically used for anisotropic wet etching of silicon.

In dry etching, noble gas fluorides (e.g., xenon fluoride (XeF_2)) are introduced in a chamber containing a silicon substrate to induce isotropic substrate etching. Dry etching using noble gas fluorides can be tightly controlled through the temperature and pressure of the chamber. An additional benefit of dry etching is that traditional masking can be used to selectively etch the substrate. However, one drawback is the final etched structure is defined by high surface roughness. Another approach to dry etching is reactive ion etching (RIE). An RIE chamber consists of parallel-plate electrodes to which an alternating current (AC) is applied, resulting in an oscillatory electromagnetic (EM) field. As fluorinated gases enter the sealed chamber, the EM field strips electrons and produces highly energized ions. When a silicon wafer is placed upon one of the electrodes, the accelerating ions bombard the substrate surface with high energy, resulting in the removal of substrate material. The ion flux is generally perpendicular to the substrate, resulting in bulk micromachined structures defined by vertical side walls. For silicon, the etch gas used in RIE is generally sulfur hexafluoride (SF_6). An extension of RIE in which polymer is deposited along the sidewalls of the etched structure is termed *deep reactive ion etching* (DRIE). DRIE has gained considerable popularity in recent years owing to the high-aspect ratio structures attainable; smooth, polymer-coated vertical wall structures with aspect ratios as high as 30 : 1 have been achieved [2].

Both wet and dry etchings are assisted using masking and sacrificial layers. For example, silicon dioxide (SiO_2) can be thermally grown upon the surface of a silicon wafer to serve as a masking layer during wet etching. Also, photosensitive resist layers (photoresists) can be deposited upon the surface of a silicon wafer as a masking layer. Using optical lithography, portions of the resist can be exposed to ultraviolet (UV) light; after exposure, the exposed resist is dissolvable in a solvent such as acetone.

2.1.2 Surface micromachining

When employing surface micromachining for fabrication of a MEMS structure, the structure is built upon the substrate using structural thin films, including polycrystalline silicon, aluminum, and silicon nitride (Si_3N_4). Integral to surface micromachining is the incorporation of sacrificial layers of silicon dioxide and photoresists. In the fabrication of MEMS structures, both structural and sacrificial layers can be etched to selectively remove portions of each layer. Typically, wet etching of silicon dioxide is done using HF, while polycrystalline silicon is wet-etched using traditional silicon etchants. Dry etching can also be used in a surface micromachining process. In surface micromachining, MEMS structures are generally defined by large in-plane areas and small out-of-plane thicknesses; in essence, two-and-a-half dimensional (2.5D) structures are formed.

2.1.3 Fabrication of a cantilever

To illustrate the fabrication methods presented above, a simple MEMS structure widely used in the design of MEMS accelerometers is adopted. The steps included in the fabrication of a cantilever beam are detailed for both bulk and surface micromachining processes [12]. The bulk micromachining fabrication process begins with a silicon wafer upon which a layer of silicon dioxide is thermally grown. In addition, a thin layer of photoresist is deposited over the silicon dioxide. Using a photomask containing a pattern of the cantilever, lithography is used to selectively expose the resist layer (Figure 1a). Placement of the wafer in a developer solvent removes the exposed resist (Figure 1b) (in this case, a positive photoresist is employed, where areas exposed to UV light are removed by the solvent). The exposed layer of silicon dioxide can be selectively removed where there is no resist using hydrofluoric acid (Figure 1c). In the last step, the wafer is placed in a wet etchant bath (e.g., KOH) to perform anisotropic etching (Figure 1d). If a [100] wafer is used, a deep trench beneath the cantilever will result with the (111) plane revealed.

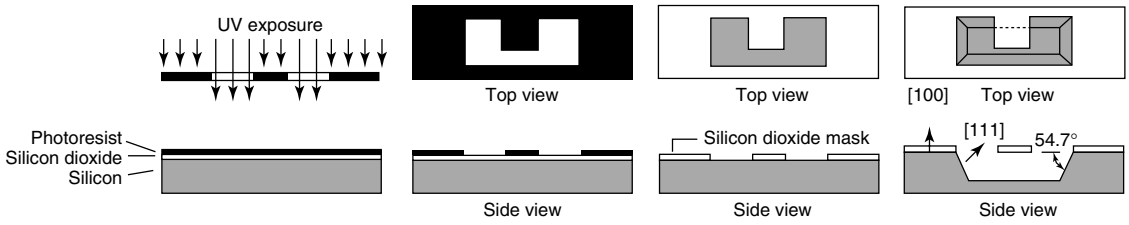

Figure 1. Fabrication of a cantilever by bulk micromachining: (a) silicon wafer with a silicon dioxide layer buried under photoresist is exposed to UV light; (b) resist is dissolved to reveal the underlying silicon dioxide layer; (c) silicon dioxide is etched to reveal the underlying silicon; (d) anisotropic wet etching of silicon results in undercutting of a cantilever element.

The surface micromachining process begins with a silicon wafer upon which silicon dioxide is thermally grown; in this process, silicon dioxide will serve as a sacrificial layer. Positive photoresist is again deposited upon the silicon dioxide and exposed to UV light so as to expose the underlying layer of silicon dioxide (Figure 2a). The silicon dioxide is etched using a wet etchant (such as HF) to reveal the underlying silicon substrate. The remaining silicon dioxide will serve as a sacrificial layer that will be removed during subsequent steps (Figure 2b). A structural layer of polycrystalline silicon is patterned and deposited upon both the silicon and silicon dioxide layers (Figure 2c). To release the cantilever, the remaining silicon dioxide beneath the cantilever is etched (Figure 2d).

2.2 Accelerometers

Accelerometers represent one of the most successful examples of a MEMS sensor in the commercial market. MEMS accelerometers have been used to measure acceleration in automotive (e.g., airbag deployment) [13], aerospace (e.g., inertial sensing) [14], and medical (e.g., pacemaker regulation) [15] applications. The design of all MEMS accelerometers consists of four major functional components within a single sensor package: proof mass, spring, damper, and readout mechanism (Figure 3a). The proof mass is a passive element that undergoes displacement due to inertial forces. The spring restrains the mass motion through a restoring force. Damping is necessary to ensure that the ratio of mass displacement to acceleration amplitude is constant up to the resonant frequency (f_R) of the accelerometer's mass–spring system. Since the displacement of the proof mass will be linearly proportional to the acceleration of the sensor package, an electromechanical transducer is needed to convert the proof mass displacement to an electrical signal. MEMS accelerometers use either capacitive, piezoresistive, or piezoelectric electromechanical transducers as readout mechanisms.

The very first MEMS accelerometer fabricated is the one proposed by Roylance and Angell [16]. The accelerometer is bulk micromachined in silicon using anisotropic wet etching. The device consists of a square proof mass connected to its silicon housing through a thin cantilever element acting as a spring. A scanning electron microscope image of the accelerometer is shown in Figure 3(b); note that the

Figure 2. side walls are at a 54.7° angle with the top surface of the substrate. Air within the sealed device (the silicon structure is sandwiched between two glass plates) provides viscous damping. A piezoresistor is implanted upon the top face of the cantilever to serve as the primary readout mechanism of the sensor; as the proof mass deflects, the cantilever beam experiences strain, which in turn results in a proportional change in resistance of the implanted piezoresistor. The accelerometer is reported to have a low noise floor ($0.001g$), large range ($\pm 200g$), and high bandwidth (2 kHz).

Since the seminal work by Roylance and Angell [16], a number of researchers have proposed piezoresistive MEMS accelerometers. Most recently, Partridge *et al.* [17] have prototyped a high-performance planar accelerometer for shock applications. Their accelerometer uses DRIE to define a pie-slice-shaped proof mass connected to the silicon substrate through a thin cantilever element (Figure 3c). Boron implantation in the cantilever results in a piezoresistive element for the readout of the sensor acceleration measurements. An attractive feature of the accelerometer is that the proof mass displacement is in the plane of the substrate. This restrains undesirable displacements of the proof mass during high-acceleration (shock) motions, thereby protecting the accelerometer from failure. The full dynamic range of the accelerometer is well above $10g$ with a resolution of $20\,\mu g$ at an acceleration bandwidth of 650 Hz.

While piezoresistive accelerometers are easy to fabricate and offer simple electrical interfaces, they exhibit extreme sensitivity to temperature that hampers their use in applications where environmental temperatures vary [20]. As a result, piezoresistive accelerometers have given way to MEMS accelerometers using capacitive readout mechanisms. Capacitive accelerometers have been successfully implemented in the commercial sector by Analog Devices (Norwood, MA). The Analog Devices *i*MEMS accelerometer family adopts a surface micromachining process to fabricate one- and two-axis accelerometers in polycrystalline silicon [18]. The accelerometer's square proof mass is

fabricated in a polycrystalline silicon layer that is attached to the silicon substrate through folded springs (Figure 3d). The proof mass is released after a sacrificial layer of silicon dioxide is removed; "through holes" are drilled in the proof mass to ensure that capillary forces during wet release do not destroy the device. The electromechanical transduction mechanism consists of differential capacitors integrated along the sides of the square proof mass. Various version of the *i*MEMS accelerometer exist with different dynamic ranges (e.g., from ± 1.2 to $250g$). Depending upon the user's application, the bandwidth and noise floor of the sensor can be varied using discrete circuit elements installed along with the sensor. An attractive feature of the *i*MEMS accelerometer is its low cost (approximately \$10 per sensor). Other commercial capacitive accelerometers include those from Silicon Designs (SD Series), Endevco (7290 Series), and Crossbow (CXL-LF Series). A force-balanced MEMS accelerometer based on a capacitive design has also been proposed by Lemkin *et al.* [19] (Figure 3e).

MEMS accelerometers have been applied to SHM applications over the past decade. In the civil engineering sector, MEMS accelerometers are low-cost alternatives to traditional seismic accelerometers (e.g., piezoelectric and force-balanced accelerometers). For example, a dense array of Crossbow CXL-LF accelerometers has been instrumented on the Geumdang Bridge (Icheon, Korea) to measure the bridge response to traffic [21]. The Analog Devices ADXL202 and Silicon Design SD2210 MEMS accelerometers have also been deployed on a pedestrian bridge on the University of California, Irvine campus [22]. The high-performance planar accelerometer proposed by Partridge *et al.* [17] has been validated to measure the acceleration of the Alamosa Canyon Bridge (southern New Mexico) [23]. It is interesting to note that in all of these cases, the MEMS accelerometers have been interfaced to battery-powered wireless sensors. This is due in part to the low-power requirements of MEMS. These applications serve as powerful examples of the success MEMS accelerometers have had in SHM.

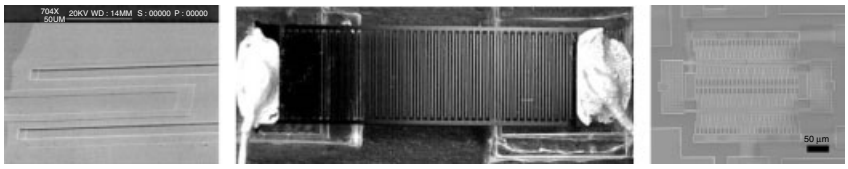
2.3 Strain sensors

Damage (e.g., cracking) is typically localized to a specific location in a structure; as a result, measurement of global structural responses (e.g., acceleration) is generally inadequate for accurate damage detection. Damage detection can be improved if local responses like strain are utilized. Toward this end, a number of researchers have proposed MEMS strain sensors defined by high-accuracy and small-form factors.

MEMS strain sensors have found early use in biological and medical applications. For example, one of the earliest MEMS strain sensors includes a sensor proposed in 1980 for measuring strain in animal tissue [2]. The strain sensor is fabricated from silicon using bulk micromachining techniques to define the sensor geometry and to implant a piezoresistive element. Strain sensors have also been included in the design of MEMS-based neural probes to measure the forces used to penetrate tissue [24]. Recently, MEMS strain sensors proposed for measuring strain in thin films [25–27] have matured with devices now suitable for measuring strain in structural systems.

A novel MEMS strain sensor is proposed by Hautamaki *et al.* [28] for embedment in CFRP composite plates. Their sensor employs a doped polycrystalline silicon element acting as a piezoresistor placed upon a silicon nitride cantilever element (Figure 4a). Upon embedment in the epoxy matrix during construction, strain in the composite panel would be transferred to the cantilever, thereby allowing strain to be accurately measured. Their sensor exhibits a 1–2% change in resistance at $1000\,\mu\varepsilon$.

While piezoresistive MEMS strain sensors are easy to install, they exhibit sensitivity to temperature, thus requiring compensatory circuitry. In contrast, capacitive strain sensors are more stable in varying thermal environments. Aebersold *et al.* [29] propose a bulk micromachined capacitive strain sensor for measuring strain in bending structural elements. On the basis of an interdigitated finger design, the capacitive sensor is fabricated in a 150-μm-thick silicon wafer using DRIE (Figure 4b). The sensor is tested on a structural element loaded in four-point bending, resulting in a repeatable nonlinear change in capacitance as a function of strain. A high-performance MEMS strain sensor based on capacitive sensing is also proposed by Ko *et al.* [31]. Designed for measuring strain in rotating machinery, the device features a resolution of $0.09\,\mu\varepsilon$ and is able to accurately measure static and dynamic strains up to 10 kHz. While silicon is



(a) (b) (c)

Figure 4. MEMS strain sensors: (a) piezoresistive strain sensor fabricated on a silicon nitride cantilever for impregnation in fiber-reinforced composite panels [Reproduced with permission from Ref. 28. © IEEE, 1999]; (b) capacitive strain sensor for measurement of bending strain [Reproduced with permission from Ref. 29. © IOP Publishing Ltd., 2006]; (c) SiC MEMS resonant strain sensor for harsh environments. [Reproduced with permission from Ref. 30. © IEEE, 2007.]

a robust structural material, it can experience wear and corrosion in harsh environments. As a result, a MEMS strain sensor fabricated from polycrystalline silicon carbide (SiC) has been proposed for SHM of high-temperature components (e.g., turbine blades) [30]. This MEMS strain sensor is designed as a comb-driven tuning fork resonator whose resonant frequency varies in linear proportion to strain (Figure 4c); a resolution of 0.11-$\mu\varepsilon$ and 10-kHz bandwidth is achieved in the laboratory.

In the commercial sector, a low-cost MEMS strain sensor has been marketed by Sarcos [32]. Their uniaxial strain transducer (UAST) is a MEMS device in which strain is correlated to signals generated between electrostatic field emitters and measured by on-chip field detectors. This device has been successfully applied to monitor the health of railroad tracks as train cars traverse the track; peak strain is measured and stored for further fatigue analysis [32].

2.4 Acoustic transducers

Acoustic emission (AE) sensing is an important technology in the SHM field. AE sensing strategies seek to capture transient stress waves generated by damage initiation in a structure in order to identify and quantify the damage. Traditionally, AE requires piezoelectric ceramic transducers that are mounted to the surface of the structure to capture stress waves; however, transducers can be both costly and bulky [33]. MEMS represents an enabling technology for the reduction of both the size and cost of AE sensors. Toward that end, a variety of ultrasonic transducers fabricated as MEMS devices have been proposed in the SHM literature. The majority of MEMS sensors proposed for AE has been surface micromachined based on capacitive mechanisms. Jones *et al.* [34] propose the design of a silicon nitride membrane deposited on a silicon wafer to produce a resonant cavity. Deposition of electrodes on the bottom of the cavity and upon the top surface of the membrane creates a capacitor whose capacitance varies with membrane deflection. Square cavity geometries are used ($1\,mm^2$), while the membrane thickness is adjustable from 1 to $2\,\mu m$ with thinner membranes exhibiting greater sensor sensitivity. The authors have conducted various laboratory tests of the AE MEMS sensor using CFRP composite panels. The tests revealed excellent AE detection to ball drops and pencil lead-breaks on the CFRP panel.

Ozevin *et al.* [33] extend on the AE MEMS sensor design proposed by Jones *et al.* [34] by fabricating seven AE detectors on a single die; each detector is tuned to a different resonant frequency spanning from 100 kHz to 1 MHz. The readout mechanism utilized in the AE sensor is a two-plate capacitor with one plate moving in response to the AE stress wave; changes in plate location result in a measurable change in device capacitance. The AE sensor is fabricated using surface micromachining of polycrystalline silicon in the commercial multiuser MEMS processes (MUMPs) foundry. The performance of the fabricated AE MEMS sensor is compared to a commercial piezoelectric transducer during laboratory testing. Both sensors are surface-mounted to a steel beam in which a weld is included in the beam center. Cyclic three-point bending of the beam results in fatigue cracks in the weld; the performance of the MEMS sensor is shown to be comparable to the commercial piezoelectric AE sensor.

2.5 Corrosion sensors

Corrosion is a serious structural deterioration confronting many engineered structures including aircrafts, bridges, and machineries among others. Over the past few years, a number of novel corrosion sensors based on MEMS technology have been proposed in the literature. Niblock *et al.* [35] describe a MEMS fabricated corrosion sensor based on the measurement of linear polarization resistance (LPR); since LPR is correlated to the rate of corrosion, the sensor provides insight into the speed of the corrosion process. The sensor proposed is fabricated from the host metal, which is to be monitored by the MEMS corrosion sensor. The metal is machined into small 25 mm squares and ground to thicknesses as small as 50 μm. The square stock is then chemically etched to form interdigitated fingers separated by a small gap (150 μm). After formation of the fingers, a thermosetting polymer is used to fill the gaps between the electrodes. When a small potential (ΔE) is externally applied across the electrodes, a current flow at the metal surface can be measured (ΔI). The slope of the $\Delta E - \Delta I$ represents the LPR; the LPR can be used to determine the corrosion current directly. Laboratory tests of the LPR sensor reveal its ability to accurately measure the corrosion current in steel specimens.

The Southwest Research Institute (SwRI) has proposed a MEMS sensor for monitoring stress corrosion cracking [36]. Their device consists of a cantilevered beam that is fabricated from the same material for monitoring corrosion. The cantilever is notched along its center so as to allow it to crack under stress and corrosion. Measurement of the beam resistance is directly related to the splitting of the beam (which is assumed to be correlated to stress corrosion cracks developing in the host structure). For additional discussion regarding application of corrosion monitoring for aircraft applications, (*see* **Aircraft Structural Diagnostic and Prognostic Health Monitoring for Corrosion Prevention and Control**).

2.6 Wireless interdigital transducers

Another class of MEMS sensors more recently adopted by the SHM community is known as *surface acoustic wave* (*SAW*) *sensors*. SAW sensors are physically small and can be easily designed for wireless interrogation, thereby making them suitable for embedment within structural components. In order to generate SAWs within a piezoelectric substrate material (*see* **Piezoelectricity Principles and Materials** for a discussion on piezoelectricity principles and materials), interdigitated transducers (IDTs) are patterned on the substrate surface using traditional lithography and metallization. Basically, IDTs consist of thin-film comb-shaped electrodes (typically patterned using aluminum) mounted on top of a piezoelectric element (Figure 5). When a voltage is applied to the IDT electrodes, dynamic strain is induced in the piezoelectric substrate, which in turn generates a SAW [5]. The electrode finger spacing (d) is controlled to be half of the SAW wavelength, λ. This spacing ensures that stress waves traveling in both directions from an IDT constructively interfere. The simplest IDT–SAW sensor, known as the *nondispersive delay line*, consists of a pair of IDTs. One IDT connected to an AC source acts as the SAW generator, while the other serves as the sensing element. Depending on the crystallographic cut of the piezoelectric element and the orientation of the IDT electrodes, various types of acoustic waves (e.g., Rayleigh, Love, and shear horizontal) can be generated [37].

In general, SAW sensors correlate a physical phenomenon (e.g., strain) with a change in the

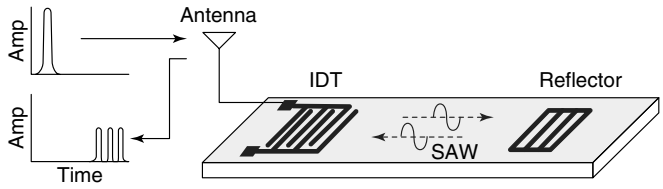


Figure 5. Surface acoustic wave (SAW) sensor with an interdigitated transducer (IDT) patterned upon the piezoelectric substrate along with a reflector element. A wireless interface receives a pulse signal. Reception of the pulse results in multiple reflections that are emitted wirelessly after a short delay.

properties of the SAW elastic wave such as velocity, v, and attenuation. Such changes can be measured by observing changes in the SAW resonant frequency, $f = v/\lambda$, as well as the phase and amplitude differences between the sensor input and output signals [37]. For example, in SAW strain sensors, strain induces a change in the separation distance between reflectors. This results in a measurable phase lag between the sensor's input–output signals, such that the measured phase lag is linearly proportional to strain [5, 38]. Many variations of SAW sensors have been proposed for gas [39], chemical [40], and acceleration [5] measurements, among others [41]. For many of the sensors proposed, antennas are integrated with the SAW sensor to accommodate input excitation and output measurements by a wireless interface [5].

3 NANOSCALE ASSEMBLY OF SENSING MATERIALS

While MEMS processing has offered a plethora of high-performance sensors for SHM, the fundamental design principle is derived from miniaturization of macroscale devices. Despite advances in lithographic patterning, etching methods, and deposition techniques, there exist technological limitations to MEMS and IC manufacturing. For example, lithographic patterning is difficult at nanometer length-scales, thereby retarding continued miniaturization of MEMS structures. Alternatively, nanotechnology offers tools and techniques that allow for the intentional assembly of novel materials at molecular length-scales (*see* **Nanoengineering of Sensory Materials**). Today, the IC and MEMS industries are investing heavily in nanotechnology so that transistors and MEMS structures can continue to be miniaturized [42].

The SHM community will also be a beneficiary of the nanotechnology field. In particular, nanotechnology offers a "bottom-up" assembly approach to the design of multifunctional materials. A multifunctional material is a material system that achieves multiple functional objectives, such as the ability to take load and the capability to sense its response to loading. Integral to the development of multifunctional materials is the use of nanometer-scaled structures (e.g., carbon nanotubes (CNTs) [43], carbon black [44], and nanoparticles [45], among others) included in composite material assemblies. While many of these molecular building blocks have been employed in the design of sensors for SHM, the use of CNTs (Figure 6a) has been very popular due to their impressive physical, mechanical, and electrical properties [43, 46–53].

3.1 Multifunctional carbon nanotube materials

Since the discovery of CNTs by Iijima in 1991 [8], researchers have sought to take advantage of their impressive electrical and mechanical properties for developing novel sensors for SHM [48]. Early realization of CNTs as ideal candidates for strain sensing stems from experimentally measuring the electromechanical response of individually suspended CNTs subjected to localized atomic force microscope probe deformations [49]. Both *in situ* resistance measurements and molecular dynamics simulation results indicate that single-walled carbon nanotube (SWNT) conductance can decrease more than two orders of magnitude while remaining completely reversible over multiple deformation cycles. Although individual CNTs have demonstrated piezoresistive response to applied strain, SHM applications require macroscale sensors that can be installed and queried in engineered structures. In an effort to preserve the inherent piezoresistive properties of individual CNTs while scaling up from a nano- to a macroscale sensing material, researchers have proposed inclusion of CNTs within polymeric matrices. The result is multifunctional materials that can take considerable load [45], yet are capable of self-sensing their strain response to loading [47].

A number of researchers have embedded CNTs within polymeric matrices for strain-sensing applications. Wood *et al.* [50] embedded CNTs within a UV-curable urethane acrylate polymeric thin film. After correcting for temperature-induced strains, they showed that Raman spectra peaks decrease with applied tensile strain. Since Raman spectroscopy requires bulky equipment and is difficult to use in the field, many other researchers have proposed CNT-based "buckypaper" specimens for strain sensing [51–53]. Upon vacuum filtration of a dispersed CNT solution, buckypaper specimens can be peeled off the filter to form the final thin-film strain sensor.

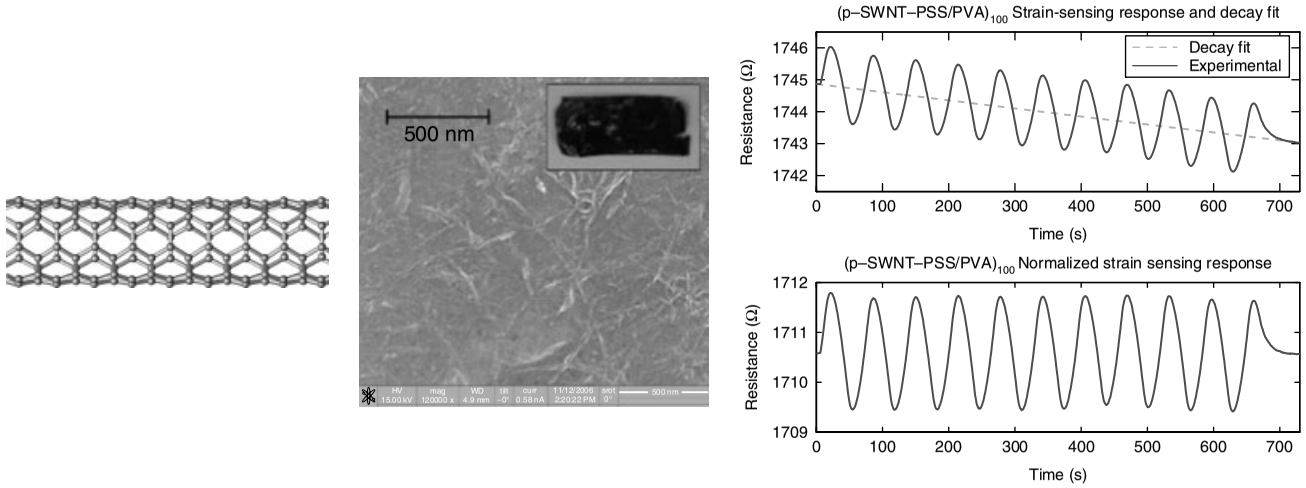

Figure 6. (a) Single-walled carbon nanotube (SWNT) [Courtesy Prof. Vincent Crespi, Penn State]; (b) microscopic view of SWNT-polymeric multifunctional material (insert: final free-standing thin film) [Reproduced with permission from Ref. 46. © IOP Publishing Ltd., 2007]; (c) variation of SWNT-based multifunctional material resistance as a function of mechanical strain. [Reproduced with permission from Ref. 47. © IOP Publishing Ltd., 2007.]

Initial studies conducted by Dharap *et al.* [51] have shown that, using a movable four-point probe technique, SWNT buckypapers exhibit multidirectional linear piezoresistive response up to $\pm 350\,\mu\varepsilon$ strains. Continued work by Li *et al.* [52] measures the Raman wave number shift of the G-band of CNT films and confirms that nanotubes within the buckypaper matrix are strained during applied tensile strains (up to $1000\,\mu\varepsilon$). Using buckypapers fabricated with SWNTs dispersed in dimethyl formamide and then mixed with poly(methyl methacrylate) (PMMA), Kang *et al.* [53] have derived an equivalent electrical circuit model using electrical impedance spectroscopy (EIS) to characterize the SWNT–PMMA thin films. Although SWNT–PMMA thin films exhibit a decrease in gauge factor (strain sensitivity) with increasing CNT weight concentration, pure SWNT buckypapers exhibit a gauge factor of 7 while behaving linearly within $\pm 500\,\mu\varepsilon$ strains. However, strain sensors for structural health monitoring must be robust and reliable over long periods of time. In particular, strain sensors require high sensitivity, linearity, and a wide measurable range (e.g., more than $5000\,\mu\varepsilon$).

Although a variety of carbon nanotube-based thin-film strain sensors have been presented for structural monitoring applications, each aforementioned sensor suffers from some drawbacks. Typically, buckypaper strain sensors exhibit high gauge factors but are very brittle materials; this limits their measurable strain range to within $1500\,\mu\varepsilon$. In response to these limitations, a more homogenous thin-film composite with CNTs within a polymeric matrix can be achieved by layer-by-layer (LbL) self-assembly [45–47]. LbL thin films are assembled by sequential dipping of a charged substrate in polyanionic and polycationic solutions to achieve excellent phase integration and homogenous morphology. Loh *et al.* [47] propose the design of multilayered thin films assembled from solutions containing SWNTs stabilized in poly(sodium 4-styrene sulfonate) (PSS) and poly(vinyl alcohol) (PVA). Free-standing thin films are deposited on a glass substrate with 50–200 layers typically deposited. Subsequent scanning electron microscopy (Figure 6b) reveals good dispersion of SWNTs within the PSS/PVA matrix. Upon application of uniaxial tensile loading, the SWNT-PSS/PVA thin film is shown to be piezoresistive with excellent linearity and high sensitivity (gauge factors span from 1 to 2) (Figure 6c).

4 CONCLUSION

MEMS is a revolutionary technology that positively impacts the field of SHM. MEMSs offer the community microscale sensors that are as accurate as macroscale counterparts at a fraction of the cost and size. Other benefits include the collocation of signal-processing circuitry on the sensor and low-power consumption. As battery-powered technologies such as wireless sensors grow in popularity, low-power MEMS sensors will serve to preserve scarce battery resources. A variety of MEMS sensors have been proposed for use in SHM applications including accelerometers, strain gauges, corrosion sensors, and acoustic transducers. Many novel design and fabrication techniques are constantly being proposed and implemented in the MEMS community to design high-performance sensing devices. On the other hand, the field of nanotechnology also promises to further improve SHM sensing technologies. Unlike the MEMS' "top-down" design methodology, nanotechnology enables molecular manipulation to achieve high-sensitivity and -selectivity, multifunctional sensors. To date, CNT-based multifunctional materials have been developed, which self-sense their response to loading and self-heal in response to damage. In future years, nanotechnology will play an increasingly greater role in the development of next-generation miniaturized sensing technologies. The combination of MEMS low-cost high-throughput fabrication techniques with the versatility of sensor designs originating from the nanotechnology domain can yield novel sensors that outperform those of the current generation.

1 INTRODUCTION

Nanoengineering is important because advanced sensors with high sensitivity, small size, and low cost may be developed on the basis of nanoscale materials. This article gives an overview of the development of nanoscale material sensors for use in structural health monitoring (SHM). The field of nanoengineering of sensors is in the beginning stages and research in this area is exciting and progressing quickly. Nanotechnology has introduced new materials such as carbon nanotubes (CNTs), zinc oxide nanobelts, nanowires (NWs), and metal or semiconductor nanoparticles that are expected to revolutionize the fields of biochemical, electrical, and mechanical sensing. Having 1–100 nm nanoscale size and a high surface to volume ratio, nanomaterials can be combined in host materials to produce changes in the electronic, photonic, catalytic, or other properties of the bulk material for use in virtually all types of sensing applications [1, 2]. Among the nanomaterials available, CNTs are promising for developing unique and revolutionary sensors owing to their structural and electrical characteristics. CNTs have high

strength and high thermal and electrical conductivities and therefore can provide structural and functional capabilities simultaneously, including actuation [3] and sensing [4–6]. CNTs can be synthesized from a few microns to 1.5-cm long with nanometer diameters [7]. For applications at the macroscale, CNT smart materials are usually based on composite materials [8]. The small size of CNTs allows them to have high sensitivity in mechanical environments. Thanks to their smart material properties and many fabrication possibilities, CNTs are producing various kinds of sensors from the nano to the macroscale in size, which are described next.

In nanoscale experimentation, Tombler *et al.* [9] investigated the change of electrical conductivity of a single-wall carbon nanotube (SWCNT) under mechanical deformation using the tip of an atomic force microscope (AFM). Watkins *et al.* [10] used lithography and aligned SWCNT to fabricate an SHM sensor based on strain measurement. This microelectromechanical systems (MEMS) technique can measure small strain and it can also detect very small cracks. For macroscale sensing, Kang *et al.* [11] reported a CNT polymer-based piezoresistive strain sensor for SHM applications. To develop a sensor and actuator embedded in a structure, Jalili *et al.* [12] have been investigating next-generation functional fabrics utilizing SWCNT composites. Functional fabrics and yarns are being developed with distributed actuation/sensing capabilities using CNT-based mono- and multifilament yarns. Having high energy density storage, and the ability to be activated using low power, a nanomaterial-based sensor can be light and flexible and easily embedded into a structure. These characteristics are suitable for developing new sensors required for health monitoring of lightweight structures. *In situ* sensors can monitor the behavior of structures assessing damage or deterioration. Flexible and easily embedded CNT sensors are envisioned to be useful for *in situ* SHM for ageless vehicles that are capable of remaining in "as new" operating condition indefinitely, regardless of use. This concept has been proposed by NASA. The ageless vehicle requires structural self-assessment and repair capabilities to be carried out by distributed sensors [13].

Extraordinary recent nanoscale materials work by Baughman *et al.* [14–18] has been to develop artificial muscles that are powered electrically or by fuel cells, nanotube yarn and sheets that are a reinforcing material that is also used for strain sensing, and biological sensors. Using longer nanotubes to improve the properties of the spun fibers is one of the objectives of the continuing research by Baughman, Zhang, *et al.* Lynch *et al.* [19] have developed an electrical impedance tomography method for damage detection in CNT composite materials. NASA has developed nanotube sensors for mechanical, chemical, and biological applications. A good reference is the book by Meyyappan [20]. Varadan *et al.* have developed a strain sensor using nanotubes with a semiconductor matrix [21]. Yuan and Jin have modeled the elastic properties of CNTs [22], which may be used for modeling nanotubes in composites for strain sensing applications. A strain sensor using nanotube materials is described by Ramaratnam *et al.* in [23]. Getty has formed a magnetic compass using a ferromagnetic needle mechanically coupled to SWCNTs [24]. The needle is deflected in a magnetic field and bends the SWCNTs, which can cause orders of magnitude change in their resistance thus forming a tiny highly sensitive magnetic field sensor.

In the area of civil engineering, significant investigation is underway to determine if nanotubes added to cement can act as bridges across cracks and voids to transfer load and create a material more impervious to bending tensile loading [25, 26]. Nanotubes have a high strain to failure, which helps in the load transfer across cracks. Multiwall carbon nanotubes (MWCNTs), after being functionalized (chemically modified) using H_2SO_4 and HNO_3 solutions, were added to cement matrix composites. The treated nanotubes improved the flexural strength, compressive strength, and failure strain of the cement matrix composite. The porosity and pore size distribution of the composites were also reduced. The phase composition was characterized with Fourier transform infrared spectroscopy. Interfacial interactions were found between the CNTs and the hydrations in the cement (such as C−S−H and calcium hydroxide), which should produce a high bonding strength between the reinforcement and cement matrix.

There is the exciting potential to develop nanoscale hybrid materials that have designed-in properties to meet specific applications. As an example of a novel hybrid material, researchers at Argonne National Laboratory have combined the world's hardest

material—diamond—with the world's strongest material—CNTs [27]. The process for "growing" diamond and CNTs together is the first successful synthesis of a diamond–nanotube hybrid material and opens the way for its use in energy-related applications and SHM owing to anticipated piezoresistive behavior.

In the general context of developing new sensory materials, there are many types of starting nanomaterials available. These 1D nanostructures include nanobelts, NWs, nanorods, nanotubes, nanonails, nanoflowers, etc. There are four commonly available nanoparticle materials that are particularly important for use in SHM and the related areas of engineering asset evaluation and condition monitoring. These nanoparticles can also be used to develop sensor systems that perform data mining at the sensor level [28, 29] and that can harvest power from ionic flow [30]. These four materials [31–36] are NWs, carbon nanofibers (CNF), carbon nanosphere chains (CNSCs), and CNT arrays, as shown in Figure 1. NWs (Figure 1a) have semiconducting, conducting, magnetic, and other properties, and have high density compared to other nanoparticles. CNF (Figure 1b) are nested MWCNTs that have a 20° conical shape, larger diameter than nanotubes, good properties, and very low cost. CNSC (Figure 1c) are carbon onions linked together, catalyst-free, highly electrically conductive when post treated, and low cost. With a specific post treatment, CNSC also have weak magnetic properties. Thus, carbon is now a member of the magnetic club. CNT arrays (Figure 1d) are parallel forests of aligned MWCNT up to 1.5-cm long with good electrical and mechanical properties.

Other upcoming nanomaterials not as commonly available are shown in Figure 2. These include telescoping MWCNTs, coiled MWCNT, alloy NWs, piezoelectric NWs, and zinc oxide NWs and nanobelts that are piezoelectric.

Properties of SWCNT are discussed briefly. Other types of nanotubes have properties that are similar but not as good as SWCNT. SWCNT is the strongest and most flexible molecular material known because of the C−C covalent bonding and seamless hexagonal network architecture. SWCNT have a Young's modulus of 1 TPa, which is above the modulus of 70 GPa for aluminum, and 700 GPA for carbon fiber. The strength-to-weight ratio of an SWCNT nanocomposite could be 4 times the same ratio for graphite/epoxy as predicted in Chapter 15 of [37]. The maximum strain of SWCNT can be ∼10%, and the thermal conductivity is $\sim 3000\,\mathrm{W\,mK^{-1}}$ in the axial direction. SWCNT have semiconducting or conducting electrical properties depending on the chirality (angle of twist) of the nanotube. Electrically conductive nanotubes are called *metallic tubes* and armchair nanotubes have electrical conductivity like metal while semiconducting tubes have transistor properties. Nanotubes have a high current carrying capacity and have a high aspect ratio and small tip radius of curvature ideal for field emission. SWCNT have magnetoresistive and piezoresistive properties, but negligible piezoelectric property. They also have electrochemical properties and a supercapacitance property in an electrolyte and can form an electrochemical actuator. Properties of MWCNT are similar to SWCNT but MWCNT are electrical conductors. Electrochemical actuation, a nanobearing, structural reinforcement, a telescoping actuator, and co-ax cable are some of the envisioned applications of MWCNT.

Processing materials with nanoscale features require extra care in most steps of the procedure. In the area of synthesis, researchers are continuously improving control over CNT length, diameter, and array density by careful control over substrate preparation and nanotube synthesis conditions (Chapter 5 of [37]). Dispersion of nanoparticles in polymers is another critical step that is continually being

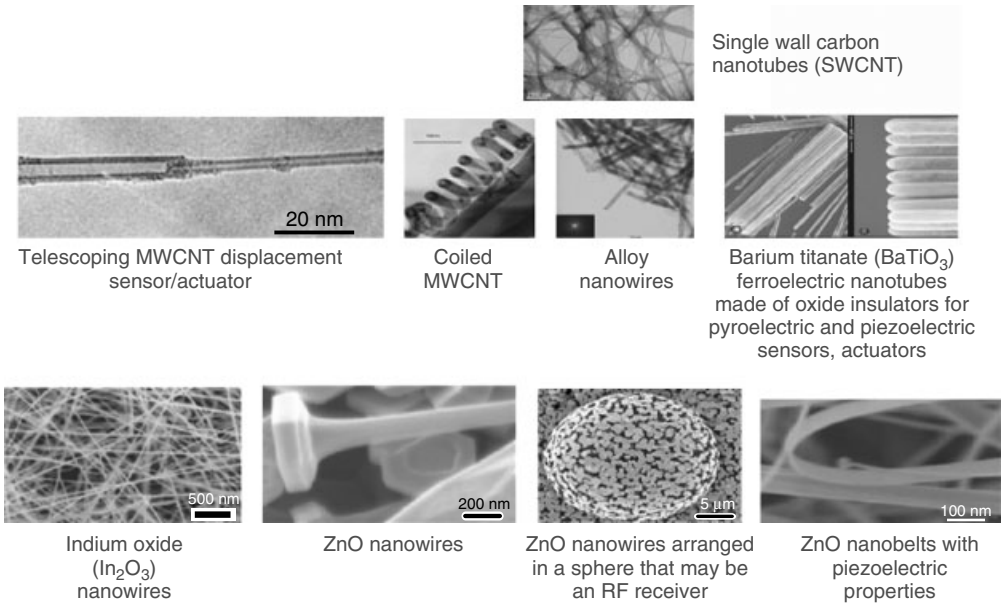

Figure 2. Less common types of nanoscale materials that may form SHM sensors.

improved [38]. High-resolution transmission electron microscopy, X-ray photoelectron spectroscopy, and environmental scanning electron microscopy are the primary tools used to characterize the nanoparticles and their smart materials. Our philosophy in developing nanoparticles and products follows from a Sherlock Holmes quote: "The world is full of obvious things which nobody by any chance ever observes." Careful observation at every step of material processing is needed in the field of nanoengineering.

Some general guidelines are discussed next to aid in the design of nanomaterials for sensors. As the size of the particle goes down, the surface area to volume ratio goes up and the properties of materials often improve. Characteristics of nanoscale materials and devices that may be helpful in sensor design are (i) viscosity increases at the nanoscale; (ii) electrostatic attraction is large at the nanoscale, particles stick together, and surface tension is large; (iii) friction depends on nanoscale surfaces, MWCNT nested nanotubes that are straight are almost friction-free translational and rotational bearings, van der Waals forces cause retraction of tubes or bundling of tubes; (iv) increased heat transfer may change the efficiency of tiny machines; (v) the melting point of nanomaterials may decrease as the thickness decreases; (vi) as size goes down, the frequency of electric circuits built using nanoparticles goes up; (vii) nanotube contact resistance is high and may be reduced by coating the nanotube ends such as with titanium and gold; and (viii) there are other electronic and optical effects described in the literature that may be useful for SHM sensing and power harvesting. In the next sections, several types of nanoparticle-based sensors are described to give an overview of the field. Since this field is rapidly changing, readers are encouraged to survey the literature for new developments.

2 NANOPARTICLE SPRAY-ON SENSORS

Many types of nanoparticles can be dispersed in a solvent or polymer and sprayed onto a structure to form a sensor. Here, we consider fabrication of a long spray-on sensor using CNTs, which can be considered to be a continuous sensor like a dendrite of a sensory or afferent neuron that conveys information from tissue and organs to the central nervous system in the human body. A structural neuron is formed using a CNT continuous sensor (a dendrite) and an analog electronic processor (the

cell body) that collects inputs and generates an electrical output (fire). The output flows through a wire conductor (an axon in the biological system) to a computer (the brain) for analysis. A network of structural neurons can cover large areas and monitor a structure for damage (pain) in real time using parallel processing (as in the biological neural system) and a small number of channels of data acquisition. The CNT-based neuron can be used as an alternative to the piezoelectric ceramic-based neurons used in [39]. Piezoelectric-based neurons are described in **Wind Turbines**. A structural neural system (SNS) can be built with a dispersed MWCNT solution that can be sprayed with an airbrush on a patterned surface of a structure as shown in Figure 3. The CNT neuron is a thin and narrow polymer film sensor that is sprayed, bonded, or taped onto a structure [40]. The electrochemical impedance (resistance and capacitance) of the neuron changes due to deterioration of the structure where the neuron is located.

The neuron has bulk piezoresistivity due to the CNTs in a polymer matrix, which is useful as a strain sensor for engineering applications. The polymer improves interfacial bonding between the nanotubes and enhances the strain transfer, repeatability, and linearity of the sensor. The largest contribution of piezoresistivity of the sensor may come from slippage of overlaying or bundled nanotubes in the matrix, from a macroscopic point of view. Nano interfaces of CNTs in a polymer matrix also contribute to the linear strain response compared to other microsize carbon fillers. Low weight percentages of nanotubes in a polymer not only have a percolation behavior with high sensitivity but also may have a nonlinear response. Buckypaper is formed by dispersing nanotubes and forming a film by solution evaporation. SWCNT are the best nanoparticles to form buckypaper because the van der Waals forces are large for small diameter nanoparticles. However, buckypaper is still relatively weak. Although buckypaper has a large gauge factor for strain sensing, the response is more nonlinear and the strain range is smaller as compared to using a polymer host for the nanotubes. A typical response of a nanotube-polymer sensor on a cantilever beam is shown in [11, 40] and can be modeled as $V = 0.0016 \times S$, where $V =$ voltage, $S =$ microstrain.

2.1 Strain sensing

The CNT-based neuron is modeled as a parallel R−C circuit as shown in Figure 4(a). The neuron can monitor static and dynamic strain as shown in Figure 4(a, b). This testing showed that the neuron has a bandwidth of about 20 Hz and measures the average strain over the length of the sensor. The strain sensitivity is similar to that of a strain gauge. The CNT-based neuron is a practical sensor because the monitoring signals are low voltage and form a simple circuit.

2.2 Crack detection testing

CNT-based neurons can monitor damage by two methods. The first is by the change in impedance of the sensor if a crack propagates through the sensor. In this case, a fine network of micron thin neurons could cover a structure. The second approach is to monitor the change in dynamic response of the structure. The dynamic response will change when damage occurs in the structure. A CNT neuron was tested to measure cracking on a composite beam. Deterioration due to cross-sectional damage or a crack was detected using the dynamic strain response of the neuron. The local stiffness of the structure changes due to damage, which, in turn, influences the dynamic response of the system. The CNT-based neuron can also monitor crack growth because the

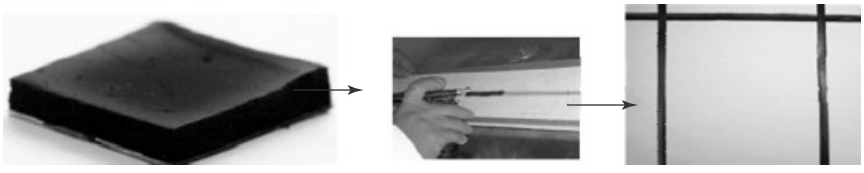

Figure 3. CNTs array dispersed in a solvent or polymer and sprayed onto a structure to form long thin continuous sensors that are analogous to a dendrite of the biological sensory neuron.

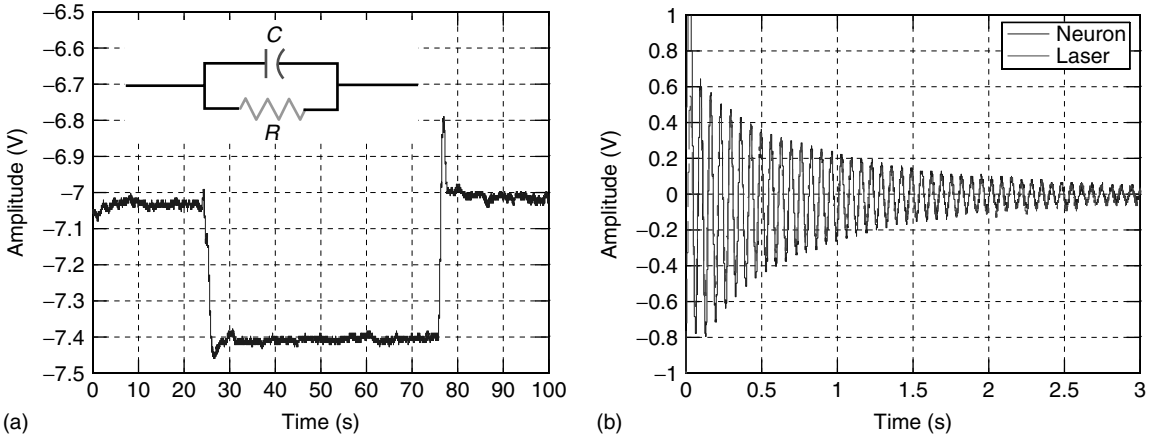

Figure 4. Modeling and strain responses of the CNT-based neuron on a glass fiber cantilever beam: (a) Electrical model and response of the CNT-based neuron under a static load; (b) dynamic strain response of the neuron during free vibration due to an initial displacement, the displacement response of the beam was measured by a laser displacement sensor (Keyence, LC-2400 Series) and almost overlays the strain response of the neuron.

nanotube film will change resistance when a crack propagates through it. Under crack propagation, the resistance of the neuron increases and the capacitance decreases, which changes the voltage response of the neuron, which can be measured using a bridge electrical circuit. The response of the neuron as a crack propagates through it is shown in Figure 5(a). The normalized crack size is defined as the ratio of crack size divided by neuron width when the crack progresses through the neuron normal to its length direction. A crack size of 100% means complete separation of the neuron by the crack. The increased resistance due to damage causes a higher amplitude voltage and the reduced capacitance induces a phase shift of the dynamic response. With this crack sensor approach, damage must change the strain at the neuron. A high density of micron size neurons can be used to detect small damage.

2.3 Corrosion detection testing

The same CNT neuron used for strain measurement can effectively measure corrosion because of the high electrochemical sensitivity of the nanotubes. Corrosion occurring on a metallic structure produces

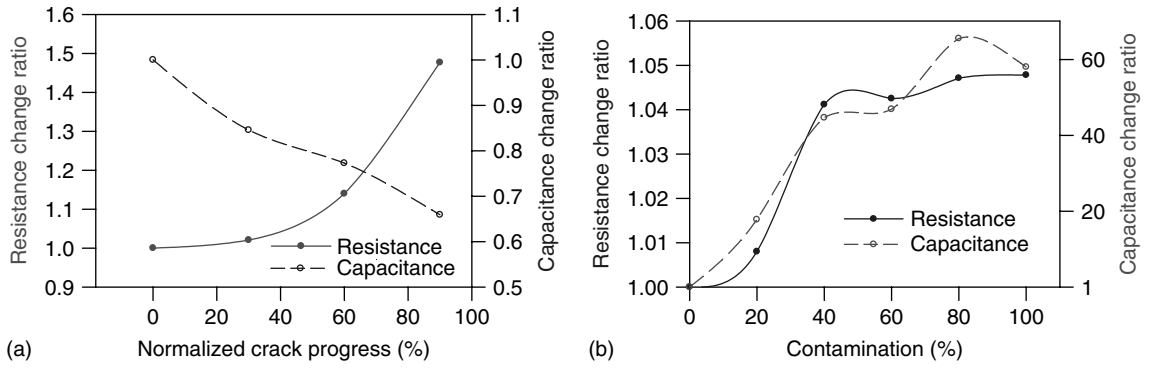

Figure 5. Response of the neuron due to cracking on a vibrating beam: (a) The variation of resistance and capacitance of the neuron as the crack propagates through the CNT neuron for the static beam; (b) The CNT neuron used as a corrosion sensor.

a diffusion layer at the interface between the structure and the CNT neuron. The corrosion ions penetrate into the CNT polymer sensor and form a double layer charge (Chapter 15 [37]) on the nanotube surface. The diffused ions also change the electrical parameters of the CNT sensor much like a doping effect. Having a large surface area, the capacitance of the CNT can be changed by orders of magnitude by the ions produced by corrosion, and the resistance will also change a small amount. A preliminary test of the corrosion sensitivity of the sensor was performed. A chemical buffer solution was used to simulate corrosion. The contamination percent is defined as the percent contaminated area on the neuron. After applying the solution, the variation in resistance and capacitance of the sensor is shown in Figure 5(b). The capacitance of the neuron sensor dramatically increased by a factor of 50 while the resistance decreased by only 5%. For composites, moisture absorption, corrosion at interfaces, and chemical degradation of the polymer may be monitored using the electrochemical response of the neuron.

As shown in the above experiments, the CNT sensor is versatile and can measure multiple physical properties of a structure. The electrical parameters of the CNT consist of a parallel resistor and capacitor and show distinct changes and trends related to physical measurements that are useful for SHM. Strain mostly causes a change of resistance. The capacitance is not affected much by strain. The sensor is moderately sensitive to changes in both resistance and capacitance when monitoring cracking. However, the sensor is dramatically sensitive to the change of capacitance when monitoring corrosion. On the basis of these sensitivities, the multifunctional capability of the neuron is a new approach for SHM. Since corrosion, infiltration of water, cracking, delamination, temperature, and change of pH can all possibly change the impedance of the nanotubes, the neuron is a sensitive barometer of the overall health of the structure. The multifunctionality is expected to effectively detect multiple symptoms of damage occurring at the same time and at the same location in complex structures. CNT neurons can be applied in the field by spraying the material onto the structure. Different types of nanoparticles (SWCNT, MWCNT, CNF, and CNSC), polymers (polymethylmethacrylate (PMMA), epoxy, polyvinyl alcohol (PVA)) and processing methods (dispersion, functionalization, vacuum, pressure, and temperature) were investigated to develop the neuron [8].

3 PIEZORESPONSIVE POLYMERS USING NANOPARTICLES

Piezoresponsive materials change properties due to strain of the material. Three types of piezoresponsive materials are generally being considered to form sensors. The materials are piezoresistive (change electrical resistance with strain), piezomagnetic (change magnetic properties with strain), and piezoelectric (produce a charge with strain). The piezoresponsive materials are usually formed by loading a polymer host material with one or more nanoparticles that have specific sensing properties. This section gives examples of different piezoresistive sensors being developed at the University of Cincinnati and by collaborators based on integrating sensor nanoparticles into polymers. Since the polymer is often used as the matrix of a composite material, the piezoresponsive polymer can be used to form self-sensing nanocomposite materials. CNSC-epoxy nanoskin and CNSC-polyurethane nanoskin are two new materials being developed to provide a means to tailor the surface properties of structures.

A general procedure to fabricate nanocomposite and sensor materials follows four steps: (i) selecting the nanoscale constituent material, synthesis, and properties characterization of nanoparticles including tubes, wires, spheres, and plates, with desired electrical, magnetic, and other properties; (ii) performing intermediate processing to prepare the material for incorporation into a host material, involves purification, thermal treatment, functionalization, spinning thread, and partial self-repair by welding or recrystallization; (iii) forming the bulk material and nanostructured smart materials including nanocomposites, sensors, films, actuators, wires, or casting into polyacrylonitrile/pitch resin (PAN/PITCH) carbon fibers; and (iv) material design for specific applications including mechanical, thermal, electrical, and environmental.

Processing of nanocomposite materials (step ii) is challenging because nanofillers have several, not all good, effects on the bulk material. Nanotubes are so small that they may affect the crystallization of the polymer and the heat transfer of the polymer

affects the curing cycle. Bonding the nanoparticle to the polymer usually requires attaching interface molecules to the surface of the nanoparticle. Modification of the surface of nanoparticles is called *functionalization*, and a good overview is given in [38, 41]. Noncovalent attachment of molecules relies on van der Waals forces or polymer chain wrapping. The noncovalent bonding alters the nanoparticle surface to be compatible with the bulk polymer with the advantage that the mechanical properties of the nanoparticle are not changed. A disadvantage is that the forces between the wrapping molecule and nanoparticle are often weak, which reduces the efficiency of the load transfer between the matrix and nanoparticle.

On the other hand, covalent bonding of functional groups to the nanoparticle produces a strong connection that may improve the efficiency of load transfer between the particle and matrix. Covalent bonding is usually specific to a given system with crosslinking possibilities. On the down side, covalent bonding is done using strong acids or plasma, which will likely introduce defects in the nanoparticles, such as holes in the walls of CNTs. Defects will lower the strength of the nanoparticle and may affect the electrical and other properties of nanotubes. Ultrasonication using a tip sonicator is used to disperse nanotubes, but the sonicator may put defects into the nanotubes. A good practice is to observe the walls of the nanotubes using a high-resolution transmission electron microscope after sonication to check that the damage is small.

Using the processing methods described and different nanoparticles, a number of recipes are being developed and improved for fabricating nanocomposite multifunctional materials (Table 1). We envision that future nanocomposite materials will be custom blended for specific applications. Several nanocomposite materials in development are discussed next.

3.1 Piezoresistive epoxy

Piezoresistive epoxy is formed by adding CNF or CNSC to epoxy. CNF material is commercially available at low cost [33] and probably is the nanomaterial most commonly used to reinforce polymers. The material comes in different grades including prefunctionalized material that is chemically modified using acid treatment to improve bonding to polymers. Results of putting CNF in polymers are described in [37, 41]. The CNSC is a newer material that has

Table 1. Recipes for fabricating nanocomposite self-sensing materials

Nanoscale material	Intermediate processing	Bulk material properties
Nanotube array	Spin into thread	Strong nanocomposite self-sensing and repair
Nanotube array	Cast polymer into array (epoxy, rubber, other)	Polymer nanocomposite (piezoresistive)
Nickel NW	Disperse in polymer	Polymer nanocomposite (piezomagnetic, NDE of composites)
CNSC/CNF	Disperse in polymer	Polymer nanocomposite (piezresistive)
CNSC/CNF	Disperse in cement mix	Nanocement (piezoresistive)
ZnO nanobelt	Align in polymer	Nanocomposite (piezoelectric)
A + B + C	Disperse in D	Nano A,B,C,D (piezo)

an onion-like morphology and is highly electrically conductive and catalyst-free. The CNSC material is commercially available from Clean Technologies International [32]. Modeling nanocomposites using the simple rule of mixtures, dispersion of CNSC in the polymer, and testing CNSC/Epoxy nanocomposites are described in [42]. The basic procedure for manufacturing nanocomposites involves dispersing CNSC in epoxy resin using a shear mixer and ultrasonicator simultaneously, as shown in Figure 6(a). A compression test setup and the compression stress–strain curve are shown in Figure 6(b, c). The mechanical properties of the polymer improve a small amount by addition of 3 wt% of CNSC. The elastic modulus increased from 2.9 to 3.3 GPa, a 13% improvement, and the strength increased from 106 to 113 MPa, a 6% improvement. Dispersion of up to 5 wt% of CNSC in epoxy has been done. Plasma functionalization is also being done to improve dispersion and bonding to the polymer. Studies of the mechanical, electrical, and thermal properties of this material are under way.

3.1.1 Electrical testing of carbon nanosphere chain/epoxy nanocomposites

Nanocomposite button samples were fabricated for electrical testing. Argon plasma treated CNSC were dispersed in epoxy resin and cast in Teflon button shape molds. Epoxy Epon 862 resin with W curing agent was used. Figure 7(a) shows the resistivity of a 2-wt% CNSC-epoxy nanocomposite sample versus stress. It can be seen that the resistivity decreases initially with increasing stress and then approaches a constant value. The beginning part of the graph indicates that one can use the composite for a pressure or strain sensor. Figure 7(b) shows the resistivity of a 10-wt% CNSC-epoxy nanocomposite sample versus stress. The electrical conduction of CNSC-epoxy for

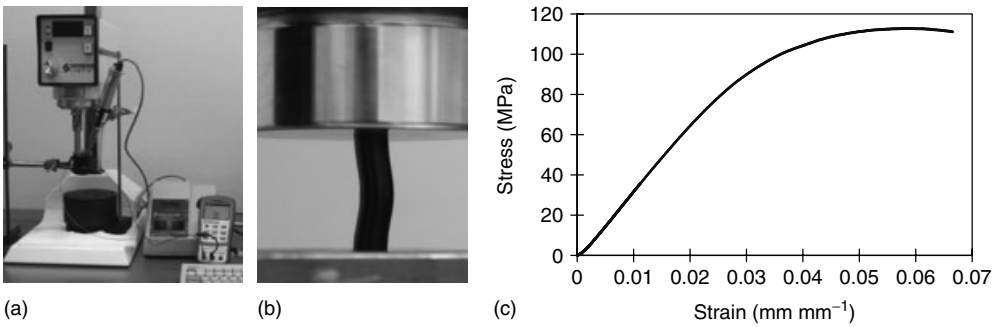

Figure 6. CNSC material processing: (a) mixer, ultrasonicator, and impedance measurement for dispersing nanoparticles; (b) nanocomposite testing; (c) stress–stain CNSC/epoxy 3 wt%.

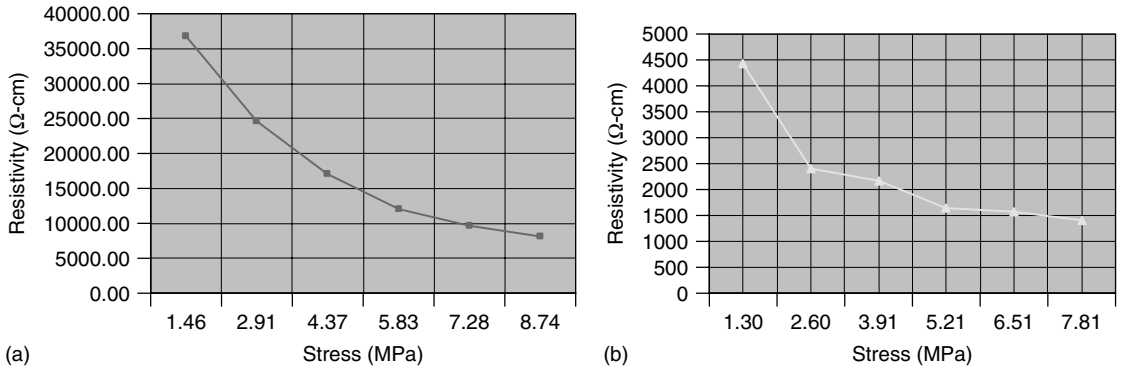

Figure 7. Resistivity versus compressive stress for CNSC/epoxy nanocomposites: (a) 2 wt% CNSC; (b) 10 wt% CNSC.

10 wt% loading is greater than for 2 wt% loading. The mechanical properties of this material have not been evaluated yet. A goal for some applications is to increase the electrical conductivity as much as possible without degrading the mechanical properties. In this case, the resistance between electrodes on the structure can be monitored to detect damage. At higher weight percentages, the viscosity of the polymer becomes very high and may prevent wetting of microfibers in a composite. To sense strain, a low weight percentage of CNSC could be used to provide a high gauge constant. High sensitivity is obtained when the loading is near the percolation level for the material, about 1 wt% or less of CNSC. Functionalization of the CNSC is under investigation to improve dispersion and to prevent reagglomeration when curing.

In general, nanoparticle-enhanced polymer design can provide electrical conductivity to the polymer and can reinforce epoxy and other matrix materials. The CNSC when compacted are highly electrically conductive, and presently about 5% by weight of CNSC can be added to the epoxy to provide electrical conductivity. A limiting factor is to not make the viscosity too high for wetting microfibers when making a laminated composite. The next step in the nanocomposite development is to investigate in detail functionalization (chemically modifying their surface) of CSNC by plasma etching to provide better dispersion and adhesion to the matrix. The plasma treatment will be controlled so that the electrical properties of the CNSC are not significantly affected. In general, a goal is to provide multifunctionality to the material, which means, for example, (i) having the greatest electrical conductivity possible, (ii) self-sensing to detect cracks, corrosion, and delamination in composites, and (iii) to do this without reducing the other properties of the matrix material. It would also be interesting to use a combination of different scales of nanoparticles (smallest to largest, SWCNT, MWCNT, CNSC, and CNF), which might stay dispersed better and might transfer load more gradually to the matrix.

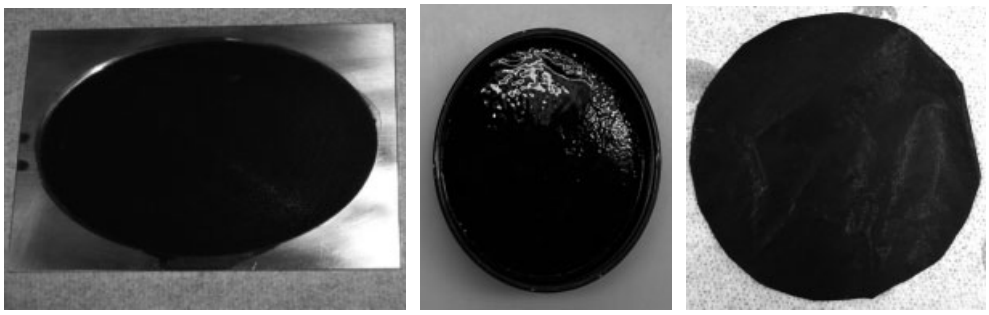
3.2 Carbon nanosphere chain-polymer nanoskin materials

Carbon nanosphere chain epoxy, polyurethane (PU), and PVA nanoskin materials are discussed in this section. It has been shown that the electrical conductivity of nanoparticles depends on mechanical contact pressure. Higher pressure increases conductivity. When forming nanocomposites by dispersing nanoparticles in a polymer, it is difficult to apply contact pressure because of the shape of the mold and because the phase diagram changes (e.g., the material may not cure). Therefore, a skin material is considered because it can be held together by pressure during curing, which improves the electrical properties. CNSC are used to form the nanoskin in these examples, but other materials can be used. CNSC have high electrical conductivity after post treatment. Oxidization in air starts at about 500 °C. The CNSC are thus useful for developing moderate temperature range sensors. Advantages of CNSC are low cost, large quantities of the material can be produced, and it is catalyst-free, which is useful in obtaining a large signal and to avoid toxicity. CNSC magnetic properties are under investigation.

3.2.1 Carbon nanosphere chain epoxy nanoskin

Nanoskin is formed by (i) a solution casting a CNSC film or other nanoparticles in a mold; (ii) coating the film with epoxy or other polymers; and (iii) pressure casting in a mold. The nanoskin material formed has good electrical and thermal conduction, piezoresistive and possibly piezomagnetic properties, and possibly power harvesting properties when a plasma gas or electrolyte is passed over the skin. An interesting property of nanoskin formed in this way is that it is electrically conductive on one side of the skin and electrically insulating on the other side of the skin. The film is shown in Figure 8(a). It is expected the skin could be made electrically conductive through the thickness by increasing the pressure and percentage of CNSC in the mold. Areas for improvement of CNSC-epoxy are to increase the wt% in dispersion with polymers and using higher compression casting to push the electrical conductivity closer to that of the compressed powder material. The electrical conductivity of nanoskin is quite below the conductivity of aluminum, but is being improved by postprocessing and by improved casting procedures.

The electrical resistance of a section of the epoxy nanoskin was measured by polishing the surfaces



(a) (b) (c)

Figure 8. CNSC polymer multifunctional nanoskin: (a) bottom of mold to form CNSC-Epoxy nanoskin; (b) CNSC-Polyurethane nanoskin; (c) CNSC-Polyvinyl Alcohol nanoskin.

of the nanoskin to expose the nanoparticles and applying copper foil electrodes to the two sides of the skin. The skin was compressed and the force and resistance values were recorded and range from 64 N and 2000 Ω to 383 N and 877 Ω. This data shows that the resistance decreases with increasing load because the contact resistance of the copper and nanotube interface is reduced with pressure, and possibly because the nanoparticles are coming into closer contact in the epoxy. There is potential to greatly reduce the resistivity of the nanoskin by using a larger volume of CNSC and higher pressure during casting. The powder form of the CNSC under compaction has a resistivity of 0.5 Ω cm for the as-grown material. Post-treated material has orders of magnitude lower resistivity. The lowest resistivity possible for the nanoskin is the resistivity of the power material.

3.2.2 Carbon nanosphere chain-polyurethane nanoskin

A PU elastomer film was prepared using CNSC. The procedure was to disperse CNSC in N,N-Dimethylformamide (DMF) solvent, and evaporate the solvent in a mold leaving a thin film of CNSC on the mold. Then PU was poured over the CNSC and cured. The resulting film shown in Figure 8(b) was elastic, electrically conductive on the CSNC side, and electrically insulating on the topside. CNSC-PU material may be used for damage detection by sputtering thin film electrodes on the surface and monitoring the electrochemical impedance between the electrodes to detect cracks or corrosion. Applications of the electrically conductive PU elastomer might be an anti-icing heater film, erosion resistant coatings, and a low impedance piezoresistive sensor, and there may be medical applications such as to repair the body and build artificial organs. Electrical and mechanical characterizations are being carried out.

3.2.3 Carbon nanosphere chain-polyvinyl alcohol nanoskin

PVA nanoskin was formed by dispersing CNSC in water using a magnetic stirrer and a long mix cycle. The film was cured at room temperature in air for 48 h. The resulting film is shown in Figure 8(c). The electrical resistance of the PVA nanoskin was 150 Ω for 10% concentration of CNSC by weight. The electrical measurement was made using a two-point probe and multimeter. Resistivity will be determined using a four-point probe.

3.3 Piezoresistive and piezomagnetic nickel nanowire polymers

Nickel NWs and the general physics of NWs are discussed briefly to provide ideas for future sensor applications. NWs differ from their corresponding bulk (3D) materials because of an increased surface area to volume of the material and because of quantum confinement effects. NWs also exhibit different optical and electrical properties from the bulk material, e.g., transistor and magnetic properties, but here only the magnetic attraction and electrical conduction properties are considered for developing sensors. First, there are two basic approaches to

synthesize NWs: nontemplate-assisted growth and template-assisted growth. A simple way to make NWs is to use a mold or template [43]. In this experiment, nickel NWs are grown inside the pores of an alumina filter and then the filter is removed by etching to yield magnetic NWs. The nanoporous membranes used were designed for healthcare applications including virus filtration, sample preparation, and liposome manufacture (http://www.whatman.com). These alumina membranes are manufactured by applying a large electrical potential to a piece of aluminum metal submerged in an acid. Aluminum is oxidized to alumina (Al_2O_3) and pores are created. The size of the pores depends on the applied potential. In this experiment, membranes with a pore size of $0.02\,\mu m$ are used as templates.

Template-assisted growth used here requires the following steps: template preparation; filling the template with NW material; and etching away the template. Ni NWs are formed by electrochemical deposition of Ni on a cathode electrode in the electrolyte solution. One possible application for magnetic NWs filled in a polymer is for SHM of composites. The electrical or magnetic properties of the composite can be monitored and changes can be related to damage. It may be possible to adapt the eddy-current method from aircraft nondestructive evaluation (NDE) to Ni NW composites. The integration of Ni NWs in composites is in the beginning stages. Some characteristics of NWs are that they are much denser than nanotubes and initially seem more difficult to disperse. Also, the NWs affect the thermal conduction when processing the composite. Functionalization of the NWs to bond to epoxy must be explored. NWs should be much easier to align in a polymer because of their large magnetic attraction. Electrical and magnetic characterization will be performed for Ni NW nanoskin and nanocomposites.

4 ELECTRICALLY CONDUCTIVE CEMENT USING CARBON NANOFIBERS

Developing smart materials for civil infrastructure applications is an important area of research because of the huge volume of material that might be used. CNF are considered for this application because CNF are produced in large volumes in a continuous chemical vapour deposition (CVD) process using an iron catalyst. The nested carbon cones (Figure 9a) or spiral cones are electrically conductive, 70–150-nm diameter, micrometer long, have good strength, are low cost \$45/kg, and are available already functionalized (PR–24–XT oxidized and debulked). Applied Sciences Inc. (Cedarville Ohio) observed very good machinability at 1–3 wt% of nanofiber in cement as evidenced by the image in Figure 9(b) of a thread on a machined cement bolt. The University of Cincinnati has pressure cast CNF into mortar mix to provide electrical conductivity and piezoresistive sensing, but brittleness of the material is a challenge.

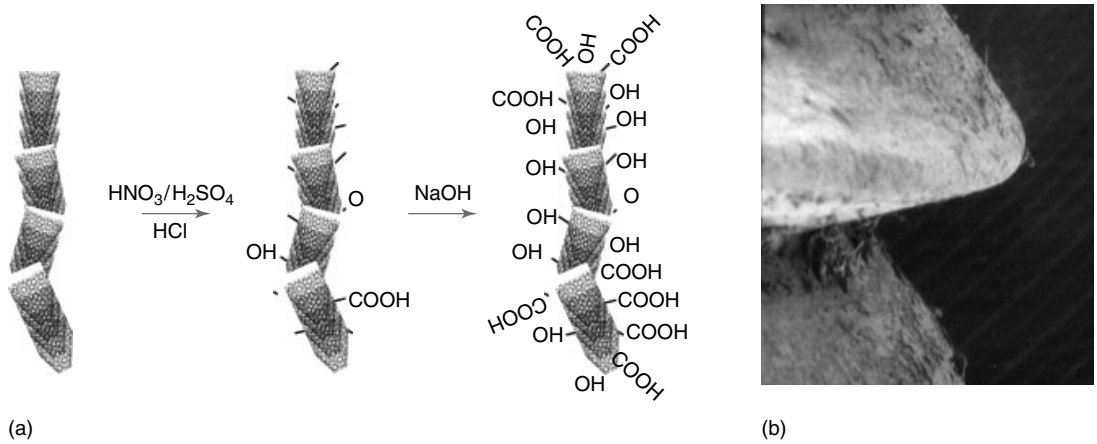


Figure 9. CNF-nanocement: (a) CNF functionalized; (b) screw threads in a nanocement bolt (image from Applied Sciences, Inc.).

The recipe to fabricate nanocement is (i) mortar mix, (ii) CNF (5% wt), (iii) ball mill 3 h, (iv) add water and mix, (v) pressure cast, (vi) heat treat, (vii) apply electrodes, and test. The CNF must be mixed with the cement as a powder because the small amount of water used would not allow a high enough percent of CNF to disperse. The cement/CNF powder is mixed by ball milling. Then water is added in slight excess and mixed to form a paste. The paste is put into a cylindrical mold and pistons are used to compress the nanocement mixture to remove air voids and excess water. Final curing is done in an oven. Electrodes are placed on the cement to compute the electrical resistance. An increase in resistance between any two electrodes indicates damage, corrosion or cracking. A specimen of the nanocement is shown in Figure 10. The resistivity decreases with increasing load until a resistivity of about 10 Ω cm is reached. This is an initial result and the dispersion and mechanical properties must be evaluated. Improvement in the properties of this initial sample is possible.

CNSC are the other material that seems ideal for integration into cement due to the high volume of material that can be produced at low cost and CNSC have high electrical conductivity and no catalyst. Nanotubes may be too expensive to use for reinforcing cement. Presently, high-grade cement uses chopped fiberglass with microscale fibers. It may be possible to develop hybrid cement using different types of fibers. The cement may be used to heat and melt ice, as an antenna material, and as a supercapacitor material. When wet, the cement may tend to increase corrosion of steel reinforcement bars (rebar) by providing an electrical path for corrosion to occur. This aspect has to be considered further.

5 ELECTROCHEMICAL IMPEDANCE SPECTROSCOPY FOR SHM

The analysis method to detect cracking and corrosion in nanocomposites including polymer, elastomer, and cement is electrochemical impedance spectroscopy (EIS) as shown in Figure 11.

A sine wave with a zero or nonzero dc voltage is applied to the sensor. The current is measured and the complex impedance is calculated. A redox chemical is sometimes used to reduce the impedance at a particular dc potential at which the redox reaction occurs. As an example of the use of EIS, a gold electrode was functionalized and used in an electrolyte with a redox couple. The EIS of the electrode was computed over a frequency range of 0.1 Hz–300 KHz. EIS was performed using a three-electrode cell, consisting of a gold electrode as the working electrode, an Ag|AgCl reference electrode, and a platinum wire counter electrode. EIS measurements were performed using a Gamry Potentiostat (model: PCI4/750) coupled with a Gamry EIS300

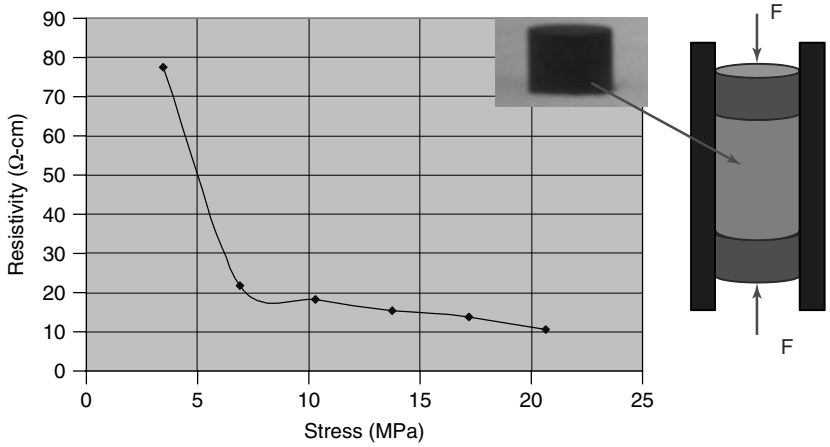

Figure 10. CNF and nanocement sample showing resistivity versus stress, the sample (inset) and schematic of pressure casting CNF in cement to improve the strength/electrical conductivity.

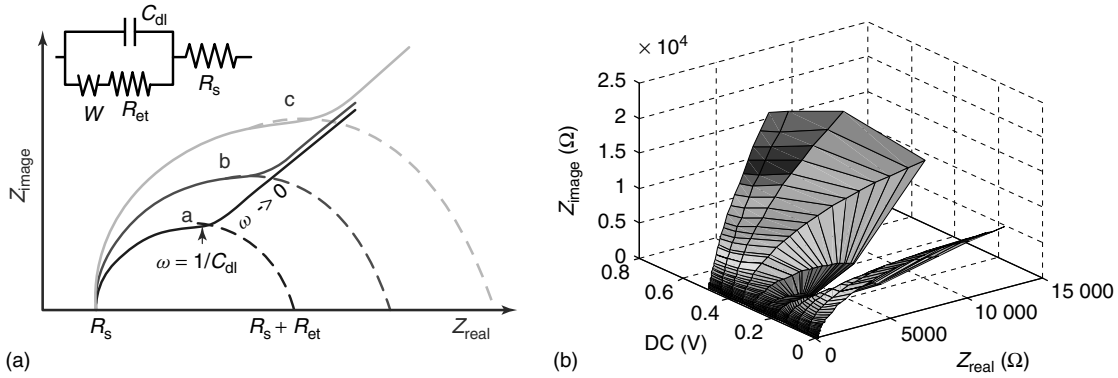

Figure 11. Electrochemical impedance spectroscopy to detect corrosion and cracking: (a) EIS model of an electrode and the response; (b) 3D EIS of a gold electrode in phosphate buffer saline with 5.0 mM K3Fe(CN)6 and 5 mM of K4Fe(CN)6. The effect of dc potential is shown.

software. Figure 11 shows the EIS response. Note that at the dc potential of 0.2 V the redox reaction greatly lowers the impedance. The EIS response can be modeled using the Randal Warburg equation $Z(\omega) = R_s + [R_{et}/(1 + \omega^2 R_{et}^2 C_{dl}^2)] - [j\omega R_{et}^2 C_{dl}/(1 + \omega^2 R_{et}^2 C_{dl}^2)]$, where $R_{et}, C_{dl}, R_s, \omega$ are the electron transfer resistance, double layer capacitance, solution resistance, and frequency, respectively. The EIS method can be adjusted to detect chemical degradation such as from corrosion, UV deterioration, hygrothermal degradation, and resistive degradation because of cracking and delamination of electrically conductive composites. A solid polymer electrolyte can also be used to further tailor the EIS signature of a composite. EIS monitoring is possibly a simpler approach than propagating waves to detect damage in large complex structures. Electrically conductive polymer, elastomer, or cement nanocomposites are multifunctional materials whose electrochemical properties change with damage or corrosion. The use of EIS is a new approach that takes advantage of the electrical conductivity properties of composites to simplify SHM.

6 NANOTUBE THREAD WITH BUILT-IN MULTIFUNCTIONALITY

Another approach for developing a multifunctional sensor material is to develop an intermediate product that can be used as a sensor material and as a fiber reinforcing material in composites. The proposed material is CNT thread. The thread is made from spinning long CNT. Long CNT are produced on wafers as shown in Figure 12. Properties of various fibers for comparison to CNT are given in [37] and show that SWCNT have higher strength, and stiffness, and are lighter than any other fiber. If a thread could be made that has similar properties to SWCNT, many new structural and electronic applications would open up. The mechanical properties of fiber nanocomposites [37] show that a polymer nanocomposite may have significantly better properties than conventional composite materials. Spinning long nanotubes into threads for reinforcement, self-sensing, and self-repair may produce a variety of versatile new smart materials.

SHM, data mining, and structural materials development have traditionally been separate enterprises, but this is changing. These disciplines are coming together to meet the needs of developing advanced integrated vehicle health monitoring systems for aerospace vehicles and other applications from nanomedicine to mars exploration. The logical way to attack this need is through the bottom-up design of a structural material that has multifunctional properties. Properties that are important for this material include high strength, high stiffness, light weight, electrical conductivity, self-sensing for damage, limited self-repair of damage, and a sensor architecture that enables data mining and other special properties depending on the application. These properties can be achieved by building a nanocomposite material based

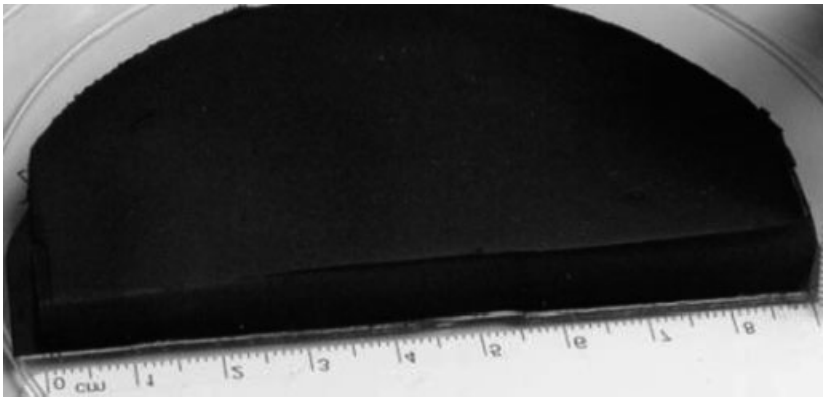

Figure 12. Carbon nanotubes grown up to 1-cm long on a silicon wafer. The CNT are used for spinning thread. (CNT grown by First Nano Inc. using UC substrate.)

on nanotube thread. Long nanotubes and different types of nanoparticles can be blended to spin a thread. In this article, we have discussed blending short nanoparticles in a polymer. The polymer and thread may also be combined to form a nanocomposite with unique properties, such as high electrical conductivity and high strength. The blended materials approach makes all the capabilities of nanotechnology virtually available for developing enabling new materials for advanced applications. In particular, nanotube thread can bring multifunctionality to composite materials.

Designing smart materials from the bottom up can provide multifunctional material properties and practical application for SHM. However, the sensing capability should be designed into the material. In other words, all the properties of the material must be designed together. Threads are necessary to provide bulk reinforcement because CNT cannot be grown beyond approximate centimeter length, currently. Thus, centimeter-long nanotubes must be spun into thread to provide a strong bulk material. The thread can be made completely of nanotubes or it can be blended using two or more materials. For example, to provide intermediate properties and reasonable cost, long nanotubes could be blended with polyester to form the thread. In another approach, the CNT might be blended with small percentages of CNSC, or a variety of other nanoparticles, to give the desired properties of the thread. It is also possible that the CNT could be functionalized to modify their adhesion or other properties before spinning thread. The goal is to provide a strong thread with smart material properties that cannot be achieved by any other material system on earth. Multiple threads will be woven together to form a fiber. The fibers can be used to form unidirectional prepreg plies or woven into a fabric to provide two-directional properties. EIS can be used to monitor the electrical properties of the thread for damage. A smart fabric design is also possible using the thread. Smart fabric can be made by weaving the nanotube thread into cloth. Smart fabric should have several interesting applications including reinforcing fabric in composites, as tough materials for garments for soldiers, firefighters, and first-responders, as electromagnetic radiation shielding materials, and other applications. Mixing the different types of nanotube or nanoparticles and in some cases conventional thread provides a large design space to build in properties so that the material will do what we want it to.

Spinning nanoscale thread is a new area of research that is expected to become very important in the future. In general, fibers with small diameter generally have better mechanical properties. Most commercial fibers are in the micron diameter range due to economic considerations. This suggests that small diameter nanotube thread could have good mechanical properties and might replace microfibers. This idea has produced considerable interest in spinning nanotubes into thread and multistrand fibers using different approaches. Electrospinning is a method to produce continuous nanofibers from polymer solutions in high electric fields [44]. A thin polymer jet is ejected when the electric force on induced charges on the polymer liquid overcomes the surface

tension. The charged jet is elongated and accelerated by the electric field, dries, and is deposited on a substrate as a random nanofiber mat. Over a hundred synthetic and natural polymers were electrospun into fibers with diameters ranging from a few nanometers to micrometers. The resulting nanofiber samples are often uniform and do not require expensive purification, and the electrospun nanofibers are continuous. Electrospinning has the potential for low-cost electromechanical control of fiber placement and integrated manufacturing of two- and three-dimensional nanofiber assemblies.

The assembly of CNT into continuous fibers has been achieved mostly through postprocessing methods. Fibers of nanotubes or nanotube-polymer blends have been drawn or spun from solutions or gels. A thread of nanotubes can be dry-drawn from an aligned assembly on a silicon substrate as a result of van der Waals interactions [17]. However, direct spinning of CNT is also being done. Nanotube thread has been formed after the pyrolysis of hexane, ferrocene, and thiophene directly in a furnace [45]. By mechanically drawing CNT directly from the gaseous reaction zone, continuous fibers were wound without an apparent limit to the length. Continuous spinning requires rapid production of high-purity nanotubes to form an aerogel in the furnace hot zone and forcible removal of the product from the reaction by continuous wind-up. Ferrocene and thiophene are used in the process. The overall question of spinning is discussed next.

6.1 To spin or not to spin

Rarely do we find noncompromising solutions to materials problems. The impasse with nanotechnology is bringing the properties of nanoscale materials to the macroscale. A key question is, how can we use CNT in the real world of airplanes and other structures for sensing and reinforcement? Spinning nanotubes into thread is one way to bring the properties of short fibers or nanotubes to the macroscale, but spinning is a compromise solution because the properties of thread are generally below the properties of the fiber or nanotube. However, thread also has advantages of energy absorption, tailorable stiffness, multicomponent material, and others as compared to nanotubes alone. When spinning, the longer the nanotube is, the smaller the thread angle becomes and possibly the greater the properties of the thread. Another compromise solution is linking nanotubes by using a binder material or by welding nanotubes to each other. There is no binder material that has mechanical properties in the order of the properties of nanotubes and unless the load path is continuous through nanotubes, the thread properties will be low. Welding nanotubes to tungsten has been done but welding nanotubes to nanotubes is difficult, based on initial investigations. There appears to be some potential to weld nanotubes to each other using a welding filler material and this technique is under investigation.

Not spinning would be the ideal solution because the full properties of nanotubes would be available at the macroscale. The problem with not spinning becomes one of synthesizing nanotubes to meter lengths. In theory, we believe that synthesis of continuous nanotubes is possible, but in practice the catalyst turns off after the nanotubes are in the centimeter-length range. Also, the quality of the nanotubes decreases with length. Considerable effort is being expended to grow the longest nanotubes possible [46, 47]. Lengths beyond the centimeter range and high quality are expected. Recently, forming nanotubes into threads or films is being done by several industries including Industrial Nano, CNT Technologies, Nanocomp, General Nano, and universities including Cambridge University, UT Dallas, and the University of Cincinnati for composites applications and possibly for use in a space elevator [48]. Spinning for simultaneous reinforcement, self-sensing, and limited self-repair may produce a versatile new smart material. Initial blend thread produced at the University of Cincinnati is shown in Figure 13. Properties of the initial thread are being evaluated. Without post processing, electrical resistivity is about $0.02\,\Omega\,\text{cm}$. This thread has promise for applications in hundreds of commercial products.

7 A STRUCTURAL NEURAL SYSTEM USING CARBON NANOTUBES

In the case of SHM of aerospace systems, many sensors are typically needed to provide sensitivity to small damage on large structures, and different

Figure 13. Long CNT called *Black Cotton* spun into thread may provide reinforcement, sensing, and partial self-repair simultaneously. Figures show spinning of thread from long CNT arrays. Two or three threads can be rolled into one yarn ~0.2-mm diameter. A spinning machine is used to spin the thread based on the approach developed by Zhang *et al.* [17].

types of sensors are needed to monitor different types of components. Also, aerospace and other systems are becoming more and more complex. This means that onboard sensors and signal processing instrumentation are needed to simultaneously monitor the integrity of their multiple subsystems that contain structural, mechanical, and electrical components. Besides integrity monitoring, large sensor networks are also being used in qualification testing, monitoring unmanned vehicles, and for feedback control and damage mitigation of systems. In all these applications, the integration and mining of increasing amounts of data from many sensors and systems is becoming impractical based on size, weight, reliability, and cost of the monitoring and support systems. A new approach to sensing is presented next wherein only anomalous responses are obtained from sensors as opposed to longtime histories of sensor raw data.

7.1 The structural neural system

An SNS was developed for anomalous event detection and to significantly reduce the complexity and cost of SHM and data mining by selectively processing signals at the sensor level. The SNS is formed using continuous sensors and a biomimetic signal processing architecture. A continuous sensor is a one-circuit connection of multiple sensor nodes that has one output signal that is a combination of signals from the individual sensor nodes. An anomalous response from any sensor node is detected within the combined output signal from all the sensors by filtering and thresholding. Thus, a continuous sensor has only one output signal and can replace many individual sensor nodes and still detect abnormal events. A trade-off of the continuous sensor is that the exact time response of each sensor node is not available. Only hallmark events are captured by the SNS based on the analog electronics that are used to define an anomalous event. The SNS can be customized by combining many continuous sensors into a network that is designed on the basis of the particular configuration (geometry and materials) of the component. The SNS has a biomimetic architecture that processes signals like the biological neural system—in a highly distributed massively parallel fashion. This means that many continuous sensors (which are akin to biological neurons) can operate all the time, but the neural system processes only signals that contain unusual events. This effectively reduces the burden of data mining because only anomalous events are passed to the data logging system by the SNS. In a concept future digital version of the SNS, tens of continuous sensors each with potentially 10 or more nodes (hundreds of sensors in total) can be monitored using a grid pattern and only four channels of analog to digital signal conversion. An SNS using nanotube spray-on film neurons would detect cracking and corrosion by changes in the electrochemical impedance of the neurons, thus locating and quantifying the size of the damage. More details of the SNS and testing using piezoelectric ceramic sensors are given in **Wind Turbines**, and also in [49].

7.2 Multistate continuous sensors

The problem of monitoring different types of components and damage may require that several types of sensors be used in the SNS. Therefore, a recent

advance in the capability of the SNS is the development of multistate continuous sensors with different types of sensor nodes. Continuous sensors can use almost any type of sensor node, but within each continuous sensor the sensor nodes must be the same type, because the analog electronics that control the output are matched to the specific sensor type. This means that the output of the sensor network will provide the same information on the location of damage and characteristics of the aberrant waveform, no matter which sensor types are used. By knowing which neuron is "firing", the waveform can be decoded into the appropriate sensor information in the computer. This allows one generic sensor network to be used for SHM, regardless of the type of sensor and system being monitored. Almost any type of sensor node such as accelerometers and strain gauges can be used to form a continuous sensor, but the interface electronics are usually specific for each sensor type. Several types of nanotube type materials can be integrated within a composite material and used as continuous sensors.

7.3 Applications of CNT thread

In many applications, the sensor material can be integrated into composite materials and provide multifunctional properties such as reinforcement, thermal conduction, and damage monitoring. In the aerospace and defense sectors, there are hundreds of likely components that could benefit from simultaneous structural improvement and monitoring using CNT thread. Use of the SNS with CNT neurons has potential for damage detection on large structures such as aircraft, building, bridges, and health monitoring of a cable for the space elevator. Leaving the Planet by Space Elevator [50] is a grand challenge problem for space exploration systems, SHM, and data mining systems. Organizations supporting the space elevator concept include NASA, Black Line Ascension, and the Spaceward Foundation. CNT thread may form a ribbon for the space elevator and EIS might be used to evaluate the condition of the ribbon. A video camera on the elevator will also monitor the ribbon. Data mining from impedance spectra and video will be needed. Long CNTs called *Black Cotton*™ are being spun into thread, which may provide reinforcement, sensing, and partial self-repair simultaneously. Potential applications of CNT are quite open. In complex composite materials, CNT thread can be put where we want it inside composite materials in sections of changing thickness and curvature, joints, around holes, in bond lines, and anywhere health monitoring is required. The thread is mostly inert and will be nanometer or micron thick and will not affect structural integrity or weight. Sensor thread can be put inside all types of structures where other sensors are impractical, such as in flexbeams and rotor blades of helicopters, in composite pressure vessels, in cement, on the surface of bridges, aircraft, space vehicles, and in elastomers.

8 FUTURE EMBEDDED WIRELESS NANOSENSORS

There are many compelling reasons for wanting to embed small sensors or devices inside composite materials. Thus far, technologically, industry has been able to develop radio frequency identification (RFID) tags that can identify a product or object, or micromotes that are battery powdered and report some physical variable. However, these devices are just the beginning. Nanoscale materials are opening up the possibility to build revolutionary devices and tiny sensors that can go inside materials (and the human body) and do what we want them to. This section presents initial analyses toward building an active microsensor that can go inside structural materials and detect damage early. Active microsensors perform electrochemical measurements and produce an electronic signal that is used to detect cracking, delamination, or electrolytes due to corrosion or water ingestion in structural materials. The active microsensor also has a feedback mechanism to increase its sensitivity or to activate a control function. The active microsensor will be built using larger electronic components first, and finally pushed down in size using nanoscale materials. Building small sensors and developing a way to communicate with them is an extraordinary difficult technological problem. To attack this problem, nanoscale electronic components (nanotubes, NWs, capacitors, inductors, solenoids, antennas, transistors, and actuators) and a four-arm nanomanipulator operating under an environmental scanning electron microscope can be used to assemble the components into prototype devices.

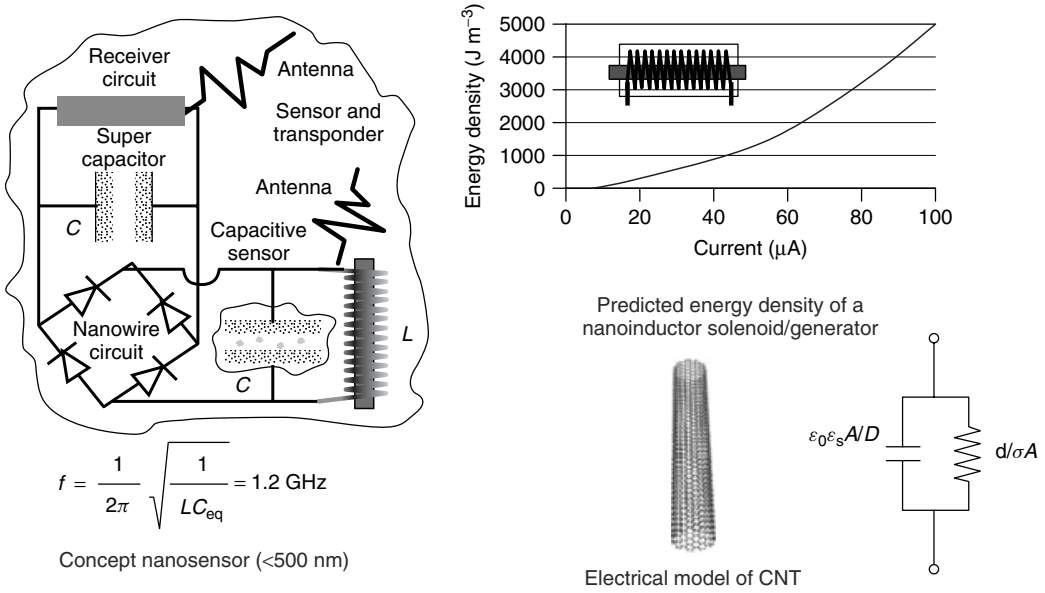

Figure 14. Initial design of a sensor transponder for asset evaluation and condition monitoring of composite structures and later for in-body detection of disease. The sensor works by receiving an RF signal, storing charge, and discharging into a transmitter circuit whose resonant frequency depends on the supercapacitance of nanotube sensors in an electrolyte.

As an example of a novel device, a transponder sensor is proposed (Figure 14) to detect damage in composites.

Developing *in situ* sensors holds great promise for making revolutionary advances in self-sensing nanocomposite materials. The circuit was analyzed using standard electronics circuit and component equations with nanoscale components. Refinement of the model is needed and details of the antenna and transistor circuit are under consideration. Once the sensor design is verified, a method to mass produce the sensors by chemical vapor deposition synthesis will be investigated.

9 SUMMARY AND CONCLUSIONS

This article introduced nanoengineering of sensor materials and discussed their potential for applications in the near future. A major advantage of sensors based on nanomaterials is that several nanomaterials can be blended to fabricate a sensor material that can do what we want it to. The blending can be in a polymer to form a polymer-based sensor material or nanoparticles can be blended in the intermediate form of a thread. The polymer and thread can be used together in composite materials to form self-sensing materials. Prospects for developing new sensors that have high sensitivity are wide open, making nanoengineering of sensors from the bottom up an exciting new field. Engineering asset evaluation and condition monitoring using nanomaterials may have hundreds of applications in components where smart nanocomposites can be used for multifunctional properties improvement, self-sensing of damage, and limited self-repair. In particular, long CNT arrays with further optimization are expected to be an enabling material for structural, electrical, sensing, and thermal applications. "Nanoizing" materials and structures is a new technological science that SHM and NDE engineers should pay attention to.

ACKNOWLEDGMENTS

This work was sponsored by Clean Technologies International Corp., North Carolina A&T SU through the ONR, the Institute for Nanoscale Science and Technology at UC, NSF grant CMS-0510823, and the Korea Institute of Industrial Technology.

Development of the SNS was supported by the National Renewable Energy Laboratory under subcontract number XCX-2-31214-01. Alan Laxson is the technical monitor of the project. Henry Westheider and Douglas Hurd built the fixtures for the smart materials casting and testing. Tom Baca, John Hurtado, and Todd Simmermacher of Sandia National Laboratories sponsored early work on health monitoring. Bradley Edwards of Industrial Nano provided suggestions about SHM of the space elevator ribbon. All this support is gratefully acknowledged.

Chapter 52
Piezoelectricity Principles and Materials

Victor Giurgiutiu
Department of Mechanical Engineering, University of South Carolina, Columbia, SC, USA

1 INTRODUCTION

Piezoelectricity (discovered in 1880 by Jacques and Pierre Curie) describes the phenomenon of generating an electric field when the material is subjected to a mechanical stress (direct effect), or, conversely, generating a mechanical strain in response to an applied electric field. The *direct piezoelectric effect* predicts how much electric field is generated by a given mechanical stress. This *sensing effect* is utilized in receiving piezoelectric sensors. The *converse piezoelectric effect* predicts how much mechanical strain is generated by a given electric field. This *actuation effect* is utilized in transmitting piezoelectric sensors. Piezoelectric active sensors act as both transmitters and receivers of elastic waves.

Piezoelectric properties occur naturally in some crystalline materials, e.g., quartz crystals (SiO_2) and Rochelle salt. The latter is a natural ferroelectric material, possessing an orientable domain structure that aligns under an external electric field and thus enhances its piezoelectric response. Piezoelectric response can also be induced by electrical poling in certain polycrystalline materials, such as piezoceramics. In recent years, affordable high-performance piezoceramics have become commercially available at affordable prices.

Piezoelectric materials are some of the major building blocks of the structural health monitoring (SHM) sensors. The intrinsic active behavior of these materials, which change dimensions in response to electric fields, and produce electricity in response to mechanical strain and stress, makes them ideal for actuation and sensing as required in SHM applications.

2 BASIC EQUATIONS

2.1 Piezoelectric equations

Electroactive materials can be distinguished into piezoelectric and electrostrictive. *Linear piezoelectric materials* obey the constitutive relations between the mechanical and electrical variables, which can be

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

written in tensor notations as

$$S_{ij} = s^E_{ijkl} T_{kl} + d_{ijk} E_k + \delta_{ij} \alpha^E_i \theta \quad (1)$$

$$D_j = d_{jkl} T_{kl} + \varepsilon^T_{jk} E_k + \tilde{D}_j \theta \quad (2)$$

where S_{ij} is the mechanical strain, T_{kl}, mechanical stress, E_k, electrical field, and D_j, electrical displacement. The variable s^E_{ijkl} is the mechanical compliance of the material measured at zero electric field ($E = 0$), ε^T_{jk} is the dielectric permittivity measured at zero mechanical stress ($T = 0$), and d_{kij} is the piezoelectric coupling between the electrical and mechanical variables. The variable θ is the temperature, and α^E_i is the coefficient of thermal expansion under constant electric field. The coefficient $\tilde{D}_j$ is the coefficient that connects electric displacement with temperature. The stress and strain variables are second-order tensors, while the electric field and the electric displacement are first-order tensors. Since thermal effects only influence the diagonal terms, the respective coefficients, α_i and $\tilde{D}_j$, have single subscripts. The term δ_{ij} is the Kroneker delta ($\delta_{ij} = 1$ if $i = j$; zero otherwise).

Compressed matrix notations (Voigt notations) are often used in engineering practice in lieu of the tensorial equations (1) and (2). The stress and strain tensors are arranged as six-component vectors, with the first three components representing *direct* stress and strain, and the last three representing *shear* stress and strain. When written in compact form, equations (1) and (2) become

$$S_p = s^E_{pq} T_q + d_{kp} E_k + \delta_{pq} \alpha^E_q \theta, \quad p, q = 1, \ldots, 6 \quad k = 1, 2, 3 \quad (3)$$

$$D_i = d_{iq} T_q + \varepsilon^T_{ik} E_k + \tilde{D}_i \theta, \quad q = 1, \ldots, 6 \quad i, k = 1, 2, 3 \quad (4)$$

Please note that the piezoelectric matrix in equation (3) is the transpose of the piezoelectric matrix in equation (4). Equations (3) and (4) can also be written in matrix format, i.e.,

$$\{\mathbf{S}\} = [\mathbf{s}]\{\mathbf{T}\} + [\mathbf{d}]^t\{\mathbf{E}\} + \{\boldsymbol{\alpha}\}\theta \quad (5)$$

$$\{\mathbf{D}\} = [\mathbf{d}]\{\mathbf{T}\} + [\boldsymbol{\varepsilon}]\{\mathbf{E}\} + \{\tilde{\mathbf{D}}\}\theta \quad (6)$$

Electromechanical coupling coefficient is the square root of the ratio between the mechanical energy stored and the electrical energy applied to a piezoelectric material, i.e.,

$$k^2 = \frac{\text{Mechanical energy stored}}{\text{Electrical energy applied}} \quad (7)$$

For direct actuation, $k^2_{33} = d^2_{33}/s_{33}\varepsilon_{33}$, where Voigt matrix notations are used. For transverse actuation, $k^2_{31} = d^2_{31}/s_{11}\varepsilon_{33}$; and for shear actuation, $k^2_{15} = d^2_{15}/s_{55}\varepsilon_{11}$. For uniform in-plane actuation, one uses the planar coupling coefficient, $\kappa_p = \kappa_{13}\sqrt{2/(1-\nu)}$, where ν is the Poisson ratio. The piezoelectric response in axial and shear directions is depicted in Figure 1.

2.2 Electrostrictive equations

In contrast to linear piezoelectricity, the *electrostrictive response* is quadratic in electric field. Hence, the direction of electrostriction does not change as the polarity of the electric field is reversed. The general constitutive equations incorporate both piezoelectric and electrostrictive terms as follows:

$$S_{ij} = s^E_{klij} T_{kl} + d_{kij} E_k + M_{klij} E_k E_l \quad (8)$$

$$D_m = d_{mkl} T_{kl} + \varepsilon^T_{mn} E_n + 2M_{mnij} E_n T_{ij} \quad (9)$$

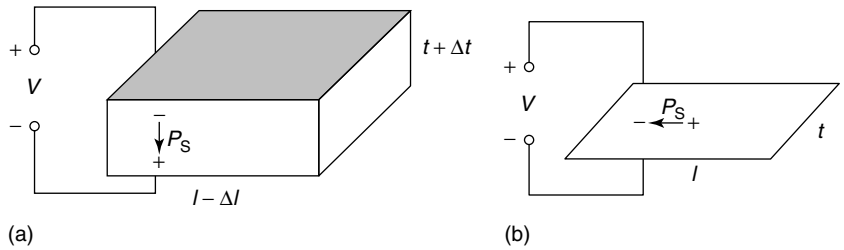

Figure 1. Induced-strain responses of piezoelectric materials: (a) axial strain and (b) shear strain.

Note that the first two terms in each equation are similar to the linear piezoelectric behavior. However, in electrostrictive materials, the linear piezoelectric response is much weaker than in piezoelectric materials. The third term represents the strong nonlinear electrostrictive behavior. The coefficients M_{klij} are the electrostrictive coefficients.

2.3 Magnetostrictive equations

Most magnetoactive materials are based on the magnetostrictive effect. The *magnetostrictive constitutive equations* contain both linear and quadratic terms as follows:

$$S_{ij} = s^{E}_{ijkl} T_{kl} + d_{kij} H_k + M_{klij} H_k H_l \qquad (10)$$

$$B_m = d_{mkl} T_{kl} + \mu^{T}_{mk} H_k + 2 M_{mnij} E_n T_{ij} \qquad (11)$$

where, in addition to the already defined variables, H_k is the magnetic field intensity, B_j is the magnetic flux density, and μ^{T}_{jk} is the magnetic permeability under constant stress. The coefficients d_{kij} and M_{klij} are defined in terms of magnetic units. The magnetic field intensity in a rod surrounded by a coil with n turns per unit length depends on the coil current, I, i.e.,

$$H = nI \qquad (12)$$

Magnetostrictive material response is quadratic in the magnetic field, i.e., the magnetostrictive response does not change sign when the magnetic field is reversed. However, the nonlinear magnetostrictive behavior can be linearized about an operating point through the application of a bias magnetic field. In this case, *pseudo-piezomagnetic* behavior, in which response reversal accompanies field reversal, can be obtained. In Voigt matrix notations, the equations of linear piezomagnetism are as follows:

$$S_i = s^{H}_{ij} T_j + d_{ki} H_k, \quad i, j = 1, \ldots, 6; \quad k = 1, 2, 3 \qquad (13)$$

$$B_m = d_{mj} T_j + \mu^{T}_{mk} H_k, \quad j = 1, \ldots, 6; \quad k, m = 1, 2, 3 \qquad (14)$$

where, S_i is the mechanical strain, T_j is the mechanical stress, H_k is the magnetic field intensity, B_m is the magnetic flux density, and μ^{T}_{mk} is the magnetic permeability under constant stress. The coefficient s^{H}_{ij} is the mechanical compliance measured at zero magnetic field ($M = 0$). The coefficient μ^{T}_{mk} is the magnetic permeability measured at zero mechanical stress ($T = 0$). The coefficient d_{ki} is the *piezomagnetic constant*, which couples the magnetic and mechanical variables and expresses how much strain is obtained per unit applied magnetic field.

3 FERROELECTRIC PEROVSKITES

The popular piezoceramic materials owe their piezoelectric behavior to the ferroelectric phenomenon observed in a class of crystalline materials called *ferroelectric perovskites*.

3.1 Ferroelectricity

Ferroelectricity is the property of having permanent electric polarization, and of being able to alter it by the application of an external electric field. The term *ferroelectricity* was derived by analogy with the term *ferromagnetism*, which describes how permanent magnetization is altered by the application of an external magnetic field. As the electric field applied to a ferroelectric material is increased beyond a critical value called *coercive field*, E_c, the polarization suddenly increases to a high value. This value is more or less maintained when the electric field is decreased, such that at zero electric field the ferroelectric material retains a permanent spontaneous polarization P_S. When a negative electric field is applied beyond the negative value $-E_c$, the polarization suddenly switches to a large negative value, which is roughly maintained as the electric field is decreased. At zero electric field, the permanent spontaneous polarization is $-P_S$. As the electric field is again increased into the positive range, the polarization is again switched to a positive value, as the field increases beyond E_c. Characteristic of this behavior is the high hysteresis loop traveled during a cycle. The ferroelectric behavior can be explained through the existence of aligned internal dipoles that have their direction switched when the electric field is sufficiently strong.

3.2 Perovskite structure

Perovskites are a large family of crystalline oxides with the metal-to-oxygen ratio 2 : 3. Perovskites derive their name from a specific mineral, perovskite, first described in 1839 by the geologist Gustav Rose, who named it after the famous Russian mineralogist Count Lev Aleksevich von Perovski (1792–1856). The simplest perovskite lattice has the expression, $X_m Y_n$, in which the X atoms are rectangular close-packed and the Y atoms occupy the octahedral interstices. The rectangular close-packed X atoms may be a combination of various species, X^1, X^2, X^3, etc. For example, in the barium titanate perovskite, $BaTiO_3$, we have $X^1 = Ba^{2+}$ and $X^2 = Ti^{4+}$, while $Y = O^{2-}$ (Figure 2). In the lattice structure, the Ba^{2+} divalent cations are at the corners, the Ti^{4+} tetravalent cation is in the center, while the O^{2-} anions are on the faces. The Ba^{2+} cations are larger, while the Ti^{4+} cations are smaller. The size of the Ba^{2+} cation affects the overall size of the lattice structure. Perovskite arrangements like in $BaTiO_3$ are generically designated ABO_3. Their commonality is that they have a small, tetravalent metal ion, e.g., titanium or zirconium, in a lattice of larger, divalent metal ions, e.g., lead or barium and oxygen ions (Figure 2). Under conditions that confer tetragonal or rhombohedral symmetry, each crystal has a dipole moment.

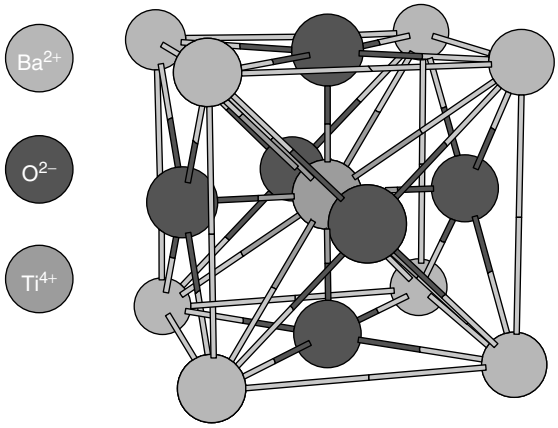

Figure 2. Crystal structure of a typical perovskite, $BaTiO_3$: the Ba^{2+} cations are at the cube corners, the Ti^{4+} cation is in the cube center, and the O^{2-} anions on the cube faces.

3.3 Spontaneous strain and spontaneous polarization of ferroelectric perovskites

At elevated temperatures, the primitive perovskite arrangement is symmetric face-centered cubic (fcc) and does not display electric polarity (Figure 3a). This symmetric lattice arrangement forms the *paraelectric phase* of the perovskite, which exists at

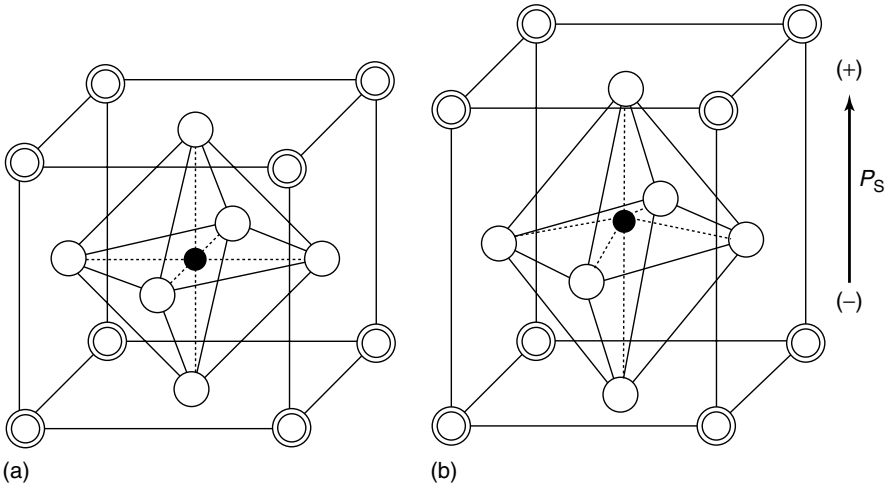

Figure 3. Spontaneous strain and polarization in a perovskite structure: (a) above the Curie point, the crystal has a cubic lattice, displaying a symmetric arrangement of positive and negative charges and no polarization (paraelectric phase) and (b) below the Curie point, the crystal has a tetragonal lattice, with an asymmetrically placed central atom, thus displaying polarization (ferroelectric phase).

elevated temperatures. As the temperature decreases, the lattice shrinks and the symmetric arrangement is no longer stable. For example, in barium titanate, the Ti^{4+} cation snaps from the cube center to other minimum-energy locations situated off center. This is accompanied by the corresponding motion of the O^{2-} anions. Shifting of the Ti^{4+} and O^{2-} ions causes the structure to be altered, creating strain and electric dipoles. The crystal lattice becomes distorted and slightly elongated in one direction, i.e., tetragonal (Figure 3b). In barium titanate, the distortion ratio is $c/a = 1.01$, corresponding to 1% strain in the c direction with respect to the a direction. This change in dimensions along the c axis is called *spontaneous strain*, S_S. The orthorhombic tetragonal structure has polarity because the centers of the positive and negative charges no longer coincide, yielding a net electric dipole, i.e., spontaneous polarization P_S. This polar lattice arrangement forms the *ferroelectric phase* of the perovskite, which exists at lower temperatures. The transition from one phase into the other takes place at the phase transition temperature, commonly called the *Curie temperature*, T_C. In barium titanate, $BaTiO_3$, the phase transition temperature is around 130 °C. As the perovskite is cooled below the transition temperature, T_C, the paraelectric phase changes into the ferroelectric phase and the material displays spontaneous strain, S_S, and spontaneous polarization, P_S; vice versa, when the perovskite is heated above the transition temperature, the ferroelectric phase changes into the paraelectric phase, and the spontaneous strain and spontaneous polarization are no longer present.

4 TYPICAL ELECTROACTIVE CERAMICS

Ceramics are hard, brittle, heat resistant, and corrosion-resistant materials made by shaping and then firing a nonmetallic mineral, such as clay, at a high temperature. Ceramics are polycrystalline materials. Commonly, ceramics are electrical and thermal insulators.

Electroactive ceramics are a class of ceramics that display very strong piezoelectric and/or electrostrictive response. Electroactive ceramics consist of polycrystalline structures of ferroelectric perovskites with strong piezoelectric and/or electrostrictive properties. The electroactive ceramics are synthetic compounds that can be fabricated with engineered properties tailored to meet specific operational requirements. On a macroscale, ferroelectric ceramics are given single-crystal symmetry by poling. Poled ferroelectric ceramics are commonly called *piezoelectric ceramics* (ANSI/IEEE 176). Most piezoelectrics are crystalline solids. Some piezoelectric materials are single crystals, either natural or synthetic. Others are polycrystalline materials that are given macroscale single-crystal-like symmetry through poling.

Electroactive ceramics display significant mechanical response under applied electric field, and electrical response under applied mechanical action. Typical strain response of commercially available electroactive ceramics is around 0.1% in the quasi-linear range. Higher strain response can be obtained by taking the electroactive ceramics in the strongly nonlinear range at high electric fields. Nonlinear strains of up to 0.2% have been reported in certain electroactive ceramics. The operation in the high nonlinear range is usually associated with a marked increase in hysteresis. This results in significant internal heating under high-frequency operation. Operation in the high nonlinear domain also results in a marked decrease in fatigue life.

The ceramic perovskites display both piezoelectric and electrostrictive behavior. One or the other of these two properties is usually enhanced through chemical formulation and processing. Some of these electroactive ceramics can display, according to detailed formulation and processing, either a predominantly piezoelectric or a predominantly electrostrictive behavior.

4.1 Fabrication and poling of electroactive ceramics

Conventional fabrication of ferroelectric ceramics is done in several stages as follows:

1. synthesis of the ferroelectric perovskite powders;
2. sintering and compaction of the perovskite powders into ferroelectric ceramics;
3. electric poling of the ferroelectric ceramics.

More novel methods for fabrication of ferroelectric ceramics include the following:

1. coprecipitation
2. sol–gel (alkoxide hydrolysis)
3. thin-film fabrication
4. single-crystal growth.

During cooling, the lead zirconate titanate (PZT) ceramic undergoes phase transformation from paraelectric state to ferroelectric state. This transformation takes place as the material cools below the Curie temperature, T_C. The resulting ferroelectric ceramic has a polycrystalline structure (grains) with randomly oriented ferroelectric domains (Figure 4a). If the grains are large, ferroelectric domains can exist even inside each grain. Owing to the random orientation of the electric domains, individual polarizations cancel each other, and the net polarization of the virgin ferroelectric ceramic is zero.

This random orientation can be transformed into a preferred orientation through *poling*. Poling aligns the dipole domains and gives a net polarization to the piezoceramic material. A poled ferroelectric ceramics behaves more or less like a single crystal. Poling of piezoceramics is attained at elevated temperatures in the presence of a high electric field. The application of a high electric field at elevated temperatures results in the alignment of the crystalline domains. This alignment is locked in place when the piezoceramic is cooled with the poling electric field still applied, thus resulting in permanent polarization. During poling, the orientation of the piezoelectric domains also produces a mechanical deformation. When the piezoceramic is cooled, this deformation is locked in place (permanent strain). Poling is performed in silicon oil bath at elevated temperature under a dc electric field of $1-3\,\mathrm{kV\,mm^{-1}}$.

4.2 PZT piezoceramics

PZT is a ferroelectric perovskite consisting of a solid solution of $Pb(Zr_{1-x}Ti_x)O_3$. In the PZT perovskite unit cell, lead, Pb^{2+}, occupies the corners, oxygen, O^{2-}, the faces, and titanium/zirconium, Zr^{4+}/Ti^{4+}, the octahedral voids. To date, many PZT formulations exist, the main differentiation being between "soft" (e.g., PZT 5-H) and "hard" (e.g., PZT 8). PZT attains the highest piezoelectric coupling and the maximum electric permittivity near the morphotropic phase boundary. This corresponds to the change in the crystal structure from the tetragonal phase to the rhombohedral phase, which happens when the Zr/Ti ratio is approximately 53/47. The explanation for this phenomenon is as follows: above the Curie temperature, PZT has a cubic lattice and is paraelectric. The Curie temperature varies with the alloying proportion, from $\sim 250\,^{\circ}\mathrm{C}$ for pure $PbZrO_3$ to $\sim 500\,^{\circ}\mathrm{C}$ for pure $PbTiO_3$. Below the Curie temperature, PZT is ferroelectric; but its lattice can be either tetragonal or rhombohedral, according to the alloying proportion.

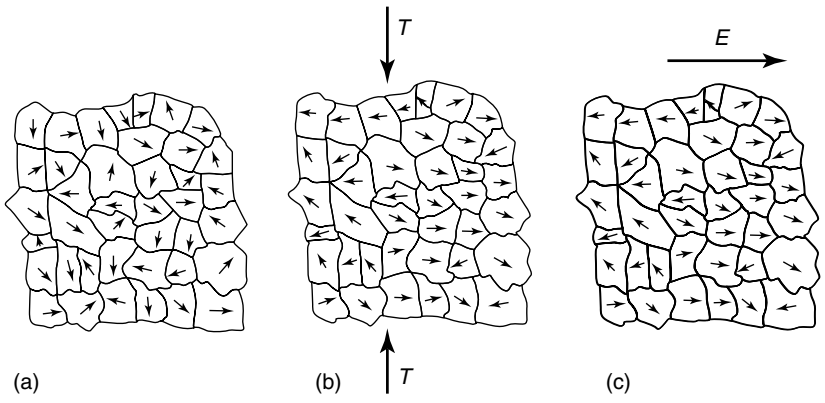

Figure 4. Piezoelectric effect in polycrystalline perovskite ceramics: (a) in the absence of stress and electric field, the electric domains are randomly oriented; (b) application of stress produces orientation of the electric domains perpendicular to the loading direction. The oriented electric domains yield a net polarization; and (c) application of an electric field orients the electric domains along the field lines and produces induced strain.

On the phase diagram, the line separating the two phases is called the *morphotropic phase boundary*. At room temperature, this boundary is placed around the 47/53 alloying ration.

Within the linear range, PZT-like piezoelectric ceramics produce strains that are more or less proportional to the applied electric field or voltage. Induced strains in excess of 1000 $\mu\varepsilon$ (0.1%) are encountered (Figure 5).

4.3 Electrostrictive ceramics—relaxor ferroelectrics

Electrostrictive ceramics are perovskite materials in which the electrostrictive response is dominant. Perovskites that display a large electrostrictive response are the disordered complex perovskites, which have high electrostrictive coefficient, M, with respect to the electric field and a diffuse transition temperature. Such ferroelectric ceramics are also called *relaxor ferroelectrics*, because they display large dielectric relaxation, i.e., frequency dependence of the dielectric permittivity. In a relaxor ferroelectric, the permittivity decreases as the test frequency increases. In addition, the value of temperature at which the permittivity peaks shifts upward. This behavior is in contrast to that of conventional ferroelectrics, for which the temperature at which the permittivity peaks hardly changes with frequency. The dielectric relaxation phenomenon can be attributed to the presence of microdomains in the crystal structure.

In relaxor materials, the transition between piezoelectric behavior and loss of piezoelectric capability

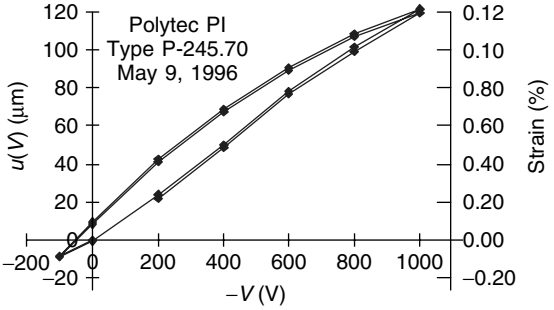

Figure 5. Induced-strain displacement versus applied voltage for Polytec PI model P-245.70 PZT actuator of 100-mm nominal length; induced strain of around 0.12% is observed.

does not occur at a specific temperature (Curie point), but instead occurs over a temperature range (Curie range). Thus, electrostrictive ceramics have a rather diffused phase transition that spans a temperature range around the transition temperature. Hence, the temperature dependence of electrostrictive ceramics around the transition temperature is markedly less than that of normal perovskite solid solutions. Sometimes, their transition temperature range is lower than the room temperature, which is beneficial for stable operation at elevated temperatures.

Lead magnesium niobate/lanthanum formulations, and lead nickel niobate currently are among the most studied relaxor electrostrictive ferroelectrics. They have very high dielectric permittivity and polarization. The coercive field of electrostrictive ceramics is much smaller than that of piezoelectric ceramics.

A common electrostrictive ceramics is lead magnesium niobate, $Pb(Mg_{1/3}Nb_{2/3})O_3$, also known as *PMN*. Another commonly used electrostrictive ceramic is lead titanate, $PbTiO_3$, also known as *PT*. Combination of these two formulations are also common, under the designation PMN–PT. Another electrostrictive ceramic is (Pb, La)(Zr, Ti)O_3, also known as *PLZT*. Other ferroelectric ceramic systems that have been found to display strong electrostrictive behavior include lead barium zirconate titanate, (Pb, Ba)(Zr, Ti)O_3, and barium stannate titanate, Ba(Sn, Ti)O_3. To obtain large electrostriction, it is essential that ferroelectric microdomains in the ceramic structure are generated. Various methods are used in this property, such as the doping with ions of a different valence or ionic radius, or the creation of vacancies, which introduce microscopic spatial inhomogeneity.

The strain versus electric field curves of electrostrictive ceramics display the typical quadratic behavior (Figure 6a). On such curves, a positive mechanical strain is obtained for both positive and negative electric fields. However, the strain field curve is strongly nonlinear, as appropriate to quadratic behavior. What is remarkable about electrostrictive ceramics is their very low hysteresis. Figure 6(a) shows that the increasing and decreasing curves superpose almost everywhere, with only a small exception in a limited region at relatively low fields.

Commercially available PMN formulations are internally biased and optimized to give quasi-linear behavior. In this situation, they display much less

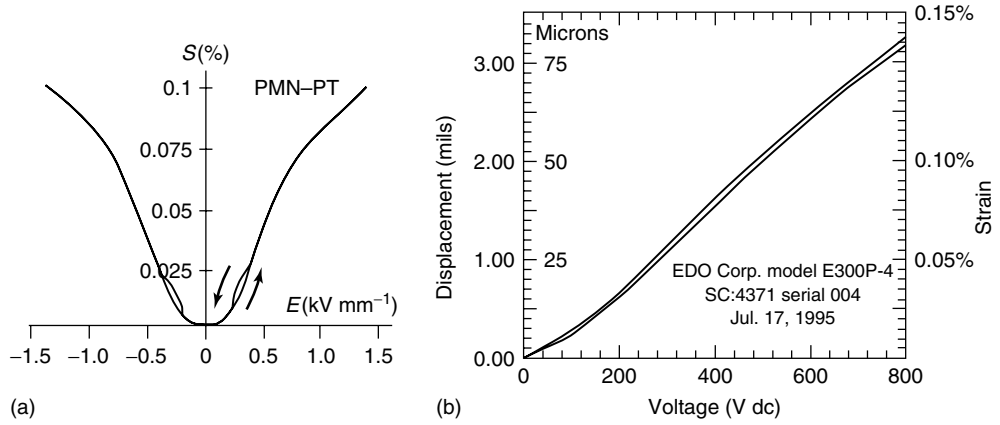

Figure 6. Electrostrictive ceramic: (a) field induced strain in 90–10 PMN–PT and (b) induced strain and displacement versus applied voltage for a 57-mm-long stack of EDO Corporation EC-98 electrostrictive PMN ceramic.

nonlinearity than the conventional quadratic electrostriction, and resemble more the conventional linear piezoelectricity (Figure 6b). Linearized electrostrictive ceramics retain the very low hysteresis of quadratic electrostrictive ceramics. Thus, from this standpoint, they are superior to conventional piezoelectric ceramics. However, linearized electrostrictive ceramics do not accept field reversal. After linearization, the constitutive equations of electrostrictive ceramics resemble those of conventional piezoceramics, i.e.,

$$S_{ij} = s^E_{ijkl} T_{kl} + \tilde{d}_{ijk} E_k \tag{15}$$

$$D_m = \tilde{d}_{mkl} T_{kl} + \varepsilon^T_{mn} E_n \tag{16}$$

The symbol $\sim$ indicates that the piezoelectric constants, $\tilde{d}_{ijk}$, of equations (15) and (16) are different from the corresponding constants d_{ijk} in the original equations (8) and (9). This is due to the linearization process. In equations (8) and (9), the d_{ijk} constants were quite small, since the main effect was due to the quadratic effects represented by the m_{klij} constants. In equations (15) and (16), the $\tilde{d}_{ijk}$ constants are quite significant, since they represent the effect of the linearization of equations (8) and (9).

4.4 Piezopolymers

Piezoelectric polymers are polymers that display piezoelectric properties similar to those of quartz and piezoceramics. Piezoelectric polymers are supplied in the form of thin films. They are flexible and show large compliance. Piezoelectric polymers are cheaper and easier to fabricate than piezoceramics. The flexibility of the polyvinylidene fluoride (PVDF) overcomes some of the drawbacks associated with the brittle nature of piezoelectric ceramics. Its applicability has been proven in keyboards, headphones, speakers, and high-frequency ultrasonic transducers. A typical piezoelectric polymer is the PVDF or PVF_2. This polymer has strong piezoelectric and pyroelectric properties. Its chemical formulation is $(–CH_2–CF_2–)_n$. This polymer displays a crystallinity of 40–50%. The PVDF crystal is dimorphic, the two types being designated I (or β) and II (or α). In the β phase (i.e., type I), PVDF is polar and piezoelectric. In the α phase, PVDF is not polar and is commonly used as electrical insulator. To impart piezoelectric properties, the α phase is converted into β phase and then polarized. Stretching α-phase material produces the β phase. The symmetry of PVDF is $mm2$. Remarkable progress has recently been made in developing piezoelectric polymeric materials through the use of copolymers. The copolymer VDF/TrFE consists mostly of piezoelectric β phase with high crystallinity ($\sim$90%). The film is then cut into various sizes to form piezopolymer sensors.

The piezopolymer surface is metallized to produce the surface electrodes. Silver ink can be screen-printed in patterns onto clear PVDF film. Leads are attached according to customers' specifications. Crimp or eyelet lead attachments are used. After surface metallization, polarization is obtained through

the application of a strong electric field. Improved polarization is obtained through *field cooling*, i.e., cooling with the electric field applied to the sample. To achieve this, the PVDF specimen is to be held at 90–130 °C for 15–120 min under a field of 500–1000 kV cm^{-1}. It is then cooled to room temperature while maintaining the same electric field level.

One important advantage of piezopolymer films is their low acoustic impedance ($Z = \rho c$). The acoustic impedance values of piezopolymers are closer to those of water, biotissue, and other organic materials than the acoustic impedance of piezoceramics. For example, the acoustic impedance of PVDF film is only 2.6 times larger than that of water, whereas the acoustic impedance of piezoceramics is typically 11 times that of water. When the acoustic impedance of two media has similar values, the transmission between the two media is enhanced, and reflection at the interface is reduced.

4.5 Magnetostrictive materials

In simple terms, *magnetostriction* is the material property that causes certain ferromagnetic materials to change shape when an external magnetic field is applied. Magnetostrictive materials expand in the presence of a magnetic field, as their magnetic domains align with the field lines. Magnetostriction was initially observed in nickel, cobalt, iron, and their alloys but the values were small ($<50\,\mu\varepsilon$). Large strains ($\sim 10\,000\,\mu\varepsilon$) were observed in the rare-earth elements terbium (Tb) and dysprosium (Dy) at cryogenic temperatures (i.e., below 180 K). Large room-temperature magnetostriction exists in terbium–iron alloy $TbFe_2$. The binary alloy Terfenol-D ($Tb_{0.3}Dy_{0.7}Fe_{1.9}$), developed at Ames Laboratory and the Naval Ordnance Laboratory (now Naval Surface Weapons Center), displays magnetostriction of up to $2000\,\mu\varepsilon$ at room temperature and up to 80 °C and higher. Current Terfenol-D binary alloy formulations are of the form $Tb_{1-x}Dy_xFe_{1.9-2}$ where x is the relative proportion of dysprosium, while the proportion of iron can vary between 1.9 and 2.

5 SUMMARY AND CONCLUSIONS

This article has reviewed the equations of piezoelectricity and piezomagnetism, given a brief physical explanation of the phenomenon origin, and briefly discussed basic types of electroactive and magnetoactive materials.

Electroactive and magnetoactive materials are materials that modify their shape in response to electric or magnetic stimuli. Such behavior is essential in SHM sensors applications. On the one hand, elastic wave sensing with electroactive and magnetoactive materials creates direct conversion of mechanical energy into electric and magnetic energy. Under dynamic conditions, strong and clear voltage signals are obtained directly from the piezosensor without the need for intermediate gauge bridges, signal conditioners, and signal amplifiers. This direct sensing effect is especially significant at high frequencies when the rapid alternation of polarity prevents significant charge leaking. On the other hand, elastic wave actuation is achieved with active materials that display dimensional changes when energized by electric or magnetic fields.

Piezoelectric, electrostrictive, and magnetostrictive materials have been presented and analyzed. Of these, piezoelectric (PZT), electrostrictive (PMN), and magnetostrictive (Terfenol-D) materials have been shown to have excellent frequency response and good induced-strain capabilities (~0.1%). Figure 7 compares induced-strain response of some commercially available piezoelectric, electrostrictive, and magnetostrictive materials. It can be seen that the electrostrictive materials have less hysteresis, but more nonlinearity. The little hysteresis of electrostrictive ceramics can be an important addition in certain applications, especially at high frequencies. However, one should be aware that this low hysteresis is strongly temperature dependent. As the temperature decreases, the hysteresis of electrostrictive ceramics increases, such that, below a certain temperature, the hysteresis of electrostrictive ceramics may exceed that of piezoelectric ceramics. In general, since the beneficial behavior of the electrostrictive ceramics is related to the diffuse phase transition in the relaxor range, their properties degrade as the operation temperature gets outside the relaxor phase transition range.

In summary, one can conclude that the potential of active materials for sensing and actuation SHM applications has been demonstrated in several successful applications. However, this field is still in its infancy and further research and development is

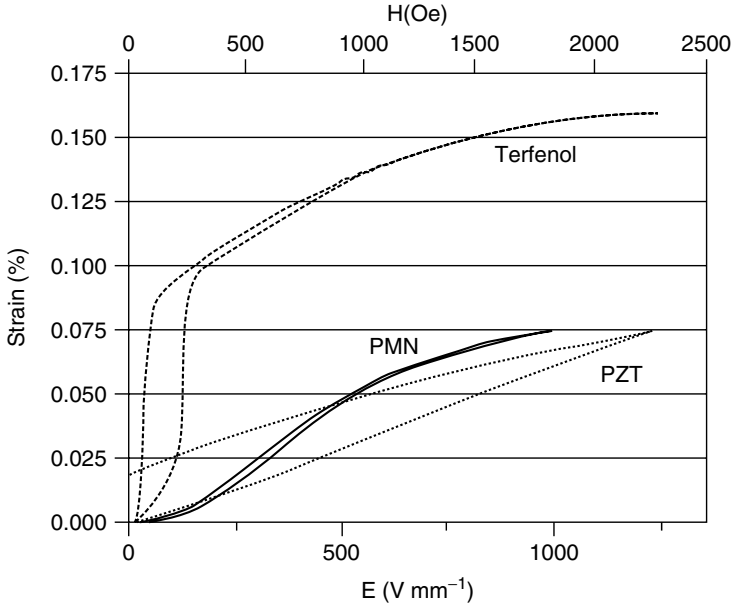

Figure 7. Strain versus electric-field behavior of currently available induced-strain materials.

being undertaken to establish these active materials as reliable, durable, and cost-effective options for large-scale engineering applications.

Chapter 57

Piezoelectric Paint Sensors for Ultrasonics-based Damage Detection

Yunfeng Zhang

Department of Civil and Environmental Engineering, University of Maryland, College Park, MD, USA

1 INTRODUCTION

Structural defect inspection and corresponding retrofit actions lead to a prolonged life and enhanced reliability of structural systems. However, in practice, manual inspection is still the most commonly used approach; this can be quite costly and time consuming, and therefore unsuitable for rapid assessment of structural conditions. It is thus desirable to replace manual inspection with on-line structural defect detection techniques. For example, existing nondestructive evaluation (NDE) techniques for fatigue crack detection include dye penetrants, eddy current, radiography, acoustic emission (AE), magnetic particle inspection, ultrasonic testing, etc. All these NDE techniques have limited use for on-line fatigue crack monitoring due to either one or a combination of the following problems: accessibility, automation, bulky size, power supply, environmental noise, and long-term durability. In particular, most NDE instruments give results that need to be interpreted by a skilled operator, with a potential for subjective mistakes.

In the past decade or so, sensors made of piezoelectric materials have gained increasing popularity in the field of structural health monitoring (e.g. [1, 2]; *see* **Integrated Sensor Durability and Reliability**). For example, recent research works by Ayres *et al.* [3], Park *et al.* [4], Giurgiutiu [5], and Yu [6] (*see* **Piezoelectric Wafer Active Sensors**) on piezoelectric active wafer sensor have made it quite a promising technique for NDE applications. Piezoelectric materials can be broadly classified into three major categories [7]: ferroelectric ceramics, piezoelectric polymers (e.g., polyvinylidene fluoride, PVDF), and piezoelectric composites. Because of their electromechanical coupling property, piezoelectric materials have been widely used for sensing and actuation applications [8–11]. Piezoelectric ceramics

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

are perhaps the most popular piezoelectric materials for sensing purpose. As of today, most piezoelectric sensors are made of piezoelectric ceramics like lead zirconate titanate (PZT). However, limitations of the mechanical properties of PZT such as brittleness and cracking at large deformations could impede its use in certain applications. Additionally, prefabricated PZT wafers do not fit well on surfaces with complex geometry such as welded joints.

To overcome these problems associated with conventional piezoelectric materials such as PZT, polymer-based piezoelectric paints have been investigated by a few researchers as a potential substitute for piezoelectric ceramics in certain sensing applications [12–22]. Piezoelectric paint typically consists of tiny piezoelectric particles randomly dispersed within a polymer matrix and therefore belongs to the 0–3 piezoelectric composite family. Table 1 summarizes the composition and piezoelectric activity of the piezoelectric paint formulations developed by different researchers. Like piezoelectric ceramics, piezoelectric paint can be used for ultrasonic NDE. Piezoelectric paint that can be directly deposited onto the surface of host structures has several advantages over conventional piezoelectric ceramics. This article reviews the past and current research work in the area of piezoelectric paint as well as its potential use as sensing material for ultrasonic NDE, particularly distributed AE sensor or ultrasonic guided wave–based embedded sensor in metal or fiber reinforced polymer (FRP) structures. Although a comprehensive experimental program still needs to be carried out to fully investigate the potential of piezoelectric paint sensor technology, it can be concluded on the basis of preliminary experimental results that piezoelectric paint sensor appears to provide a promising inexpensive NDE technique for ultrasonic-based monitoring of structural defects such as fatigue cracks in structures.

2 COMPOSITION AND FABRICATION OF PIEZOELECTRIC PAINT

Piezoelectric composite materials consisting of ferroelectric ceramics and polymer [26–31] have received considerable interest as sensing elements because of their favorable material properties that often cannot be obtained in single-phase materials. Through judicious selection of the polymer matrix, the composite properties of the piezoelectric paint can be tailored to meet the specific requirements of application conditions. For example, piezoelectric paint might be more suitable for use in fiber reinforced polymer composite structures because of its improved acoustic impedance matching property compared to piezoelectric ceramics.

The arrangement of the component phases within a composite is critical for the electromechanical properties of composites [22]. Newnham *et al.* [32] have developed the concept of connectivity to describe the manner in which the individual phases are self-connected. In a diphasic system, there are 10 types of connectivities in which each phase is continuous in zero, one, two, or three dimensions. The 10 connectivities are denoted as the following: 0–0, 0–1, 0–2, 0–3, 1–1, 1–2, 2–2, 1–3, 2–3, and 3–3. It is conventional for the first digit to refer to the piezoelectrically-active phase. Piezoelectric paint typically consists of tiny piezoelectric particles mixed within polymer matrix and therefore belongs to the "0–3" piezoelectric composite. The "0–3" means that the piezoelectrically active ceramic particles are randomly dispersed in a three dimensionally connected polymer matrix. Conceivably, the advantages of "0–3" piezoelectric composites over other connectivity types are their ease of fabrication into complex shapes including large flexible thin sheets, extruded bars and fibers, and molded shapes; they may conform to any curved surface. In general, the 0–3 composite family has been found to exhibit high hydrostatic piezoelectric voltage coefficients and "figure of merit" when compared to the properties of conventional single-phase materials [12].

Piezoelectric paint is comprised of three major components: piezoelectric ceramics powder with average particle size in the range of 3–20 μm, a polymer binder to carry the powder in suspension during application and bind it together on curing, and additives including defoamer, dispersants, and surfactants to enhance the paint mixing, deposition, and curing properties. The properties of 0–3 composites are strongly dependent on both the piezoelectric and polymer phases utilized, as well as the fabrication method employed [26]. Among all piezoelectric materials, PZT, $BaTiO_3$, $PbTiO_3$, $LiTaO_3$ ceramics,

Table 1. Summary of piezoelectric paint properties in prior research (number in bracket indicates volume fraction of the respective constituent phases)

Researchers	Ingredients		Fabrication method		Piezoelectric activity d_{33} (pC N^{-1})
	Ceramics	Polymer	Application/cuing	Poling	
Hanner *et al.* [12]	PZT/$PbTiO_3$ (60–70%)	Acrylic copolymer in suspension form or polyurethane	Spreading/24-h drying in air +24-h drying in vacuum oven at 110 °C	Oil bath poling at 100 °C with 10–15 MV m^{-1} or corona poling	26–39
Egusa and Iwasawa [13]	PZT (53%)	Epoxy	Screen printing/3-day drying in air	Conventional poling at 20 MV m^{-1} for 30 min	Unknown
Wenger *et al.* [14]	PTCa (65 or 60%)	P(VDF-TrFE) or epoxy	Hot-rolling/unknown curing method	Conventional poling at 10–25 MV m^{-1} for 30 min at 100 °C	33 or 30
Badcock and Birt [17]	PZT-5H (60%)	Epoxy	Spreading/unknown curing method	Oil bath poling at 19 MV m^{-1} for 5 min at 60 °C	16.5
Sakamoto *et al.* [18]	PZT (59%)	Polyurethane	Pressed at 20 MPa into thick film	Conventional poling at 3 MV m^{-1} for 1 h at 100 °C	12
Li *et al.* [19]	PZT (35–70%)	Cement	Spread into 3-mm-thick film/cured in concrete curing room (23 °C, 100% humidity) for 26 days	Oil bath poling at 20 MV m^{-1} for 1 h at 150 °C	7–33
Hale *et al.* [23]	PZT (40%)	Acrylic paint	Spray painting/unknown curing method	Conventional poling at 60 °C up to 1 h	20
Zhang and Li [24]	PZT (30%)	Epoxy	Spreading/cured at elevated temperature 50 °C for 3 days	Conventional poling (5 MV m^{-1}) at 70 °C for 30 min	5
Kobayashi *et al.* [25]	PZT	Unknown sol–gel solution	Spray/drying and firing by heat gun	Corona poling at 120 °C for 10 min	30
Lahtinen *et al.* [22]	PZT (60%)	Unknown sol–gel solution	Spreading with paint applicator/unknown curing method	Conventional poling (12.5 MV m^{-1}) at room temperature for 15 min	Unknown

and the mentioned ceramics with different dopings have been used for 0–3 composites, while PZT is by far the most popular active ingredient for piezoelectric paints. Marin-Franch *et al.* [33] used calcium modified lead titanate/poly(ether ketone ketone) (PTCa/PEKK) composites to detect AE when mounted on carbon fiber reinforced composite panels. PTCa ceramic is selected because it has the appropriate piezoelectric properties together with a low Curie temperature 260 °C, so it can be readily poled at temperatures appropriate to the polymer.

Han *et al.* [34] developed a colloid processing method to improve the microstructural homogeneity and decrease the chance of void formation in 0–3 composites. With this technique, piezoceramic powder was dispersed in a dilute polymer solution, allowing a polymer coating to be absorbed onto the powder surface. Colloidally processed composites composed of coprecipitated PT-BF powder and Eccogel polymer were measured to have the largest d_{33} ($65\,\mathrm{pC\,N^{-1}}$) and highest figure of merit ($dg = 6000 \times 10^{-15}\,\mathrm{m^2\,N^{-1}}$) of all "true" 0–3 composites [26]. Han *et al.* also studied the effect of the particle size on dielectric and piezoelectric properties of 0–3 composites. Lau *et al.* [35] studied incorporation of nanosized PT powder into a poly(vinylidene fluoride - trifluoroethylene) [P(VDF-TrFE) 70/30 mol%] matrix to form a 0–3 nanocomposite with a 0.2 volume fraction of PT. A thin film of 5-μm thickness was prepared by spin coating the composite on a glass substrate. The transducer was 1.2 mm in diameter with a center frequency of 40 MHz.

The polymer matrix material is critical to the ease of fabrication and performance characteristics of piezoelectric paint sensor. For example, to investigate the effect of the polymer on resistivity and dielectric properties of 0–3 composites, Han *et al.* [34] prepared PT composites with Eccogel polymer, PVDF copolymer, and ethylene-propylenediene monomer (EPDM) polymer. It was found that although higher poling conditions could be applied to the PVDF copolymer and EPDM composites, the highest d_{33} value was obtained from the epoxy composites. The higher electrical conductivity of the polymer matrix may have created more electric flux paths between the ceramic particles. This in turn increased the electric field acting on the ceramic filler and made poling of the ceramic easier [26]. The epoxy gave the highest figure of merit ($d_h g_h = 5600 \times 10^{-15}\,\mathrm{m^2\,N^{-1}}$) and the EPDM gave the lowest figure of merit ($600 \times 10^{-15}\,\mathrm{m^2\,N^{-1}}$).

The poling of ferroelectric materials to induce piezoelectricity is an important stage in the fabrication of piezoelectric paint. Poling can be carried out by two rather different techniques—the conventional dc poling method and the Corona discharge method. Poling of composites having a polymer matrix with 0–3 connectivity is especially difficult because the electric field within the high-dielectric-constant grains is far smaller than in the low-dielectric-constant polymer matrix [36]. Since most polymers have a lower dielectric constant compared with piezoelectric ceramic materials, most of the applied electric field will pass through the lower dielectric constant phase. Moreover, local breakdown at weak spots short-circuits the electrodes and prevents further poling since very large electric fields are required to pole these types of composites. One way to resolve this difficulty with poling is to introduce a third conductive phase between the piezoelectric particles. Sa-Gong *et al.* [37] prepared such composites by adding carbon, germanium, or silicon to PZT. Sakamoto *et al.* [18] doped 0–3 piezoelectric composites of PZT powder and vegetable-based polyurethane (PU) with small amounts of carbon powder (vol% in the range of 0.5–2.0%) to ease the poling by creating a continuous electric flux path between PZT grains.

The corona poling technique has been proposed by Waller and Safari [36] to pole flexible piezoelectric composites such as piezoelectric paints. This technique has been successful in poling PVDF films. In the Corona poling method, electric charge from a corona point is sprayed onto the unelectroded surface of the sample, creating an electric field between the sample faces. Because of the absence of electrodes, there is no short-circuiting of the sample at weak spots. This is particularly beneficial for poling of piezoelectric paint sensors because short-circuited piezoelectric paint sensors have to be manually removed from the host structure after poling. Generally speaking, heating lowers the coercive field and makes poling easier. The piezoelectric properties of ceramics and composites poled by the Corona method are comparable or better than those poled by the conventional poling technique.

3 REVIEW OF PIEZOELECTRIC PAINT SENSOR DEVELOPMENT

In their early studies of thin-film 0–3 polymer/piezoelectric ceramic composites, Hanner *et al.* [12] prepared two formulations of piezoelectric paints—one based on an acrylic copolymer and the other based on a PU and the electrical properties of these piezoelectric paints were characterized. Both formulations were loaded with 60–70% volume fraction of PZT and a coprecipitated $PbTiO_3$. The paint samples, with a film thickness ranging between 200 and 500 μm, were placed in a vacuum oven at 110 °C for 24 h to remove residual water or solvent. Poling of the paints was accomplished by both the conventional oil bath and the corona discharge techniques. The values of the piezoelectric charge constant d_{33} for the PZT-filled composites were found to be 25–28 pC N^{-1}, while those for the coprecipitated $PbTiO_3$/acrylic copolymer composites were 35–38 pC N^{-1}.

Egusa and Iwasawa [13] prepared an epoxy resin-based piezoelectric paint with 53 vol% PZT powder as filler. The paints were spread onto one side of a 30-mm-wide aluminum beam. The 152-μm-thick paint film was then cured in air at room temperature for at least three days or at 150 °C for 45 min. The effects of poling field, film thickness, and cure temperature on the paint's piezoelectric activity were investigated [38]. The piezoelectric sensitivity of the paint film as an AE sensor was also evaluated in their study [39]. A nearly flat frequency response of the paint film to AE waves was observed in the frequency range above 0.3 MHz.

Hale and Tuck [15], White *et al.* [20], and Hale *et al.* [23] fabricated and tested a piezoelectric paint-based strain sensor for use in structural vibration monitoring. The paint formulation comprised of milled PZT ceramic powder mixed in a water-based acrylic paint, based with PZT powder concentrations of up to 80% by weight (approximately 40% by volume). The cured paint was poled at 600 V for 1 h. For trouble-free spraying and high-quality paint films, it was found necessary to perform high-shear mixing for half an hour prior to coating application. It was found from the tests by White *et al.* [20] that the most successful spray system was a miniature DeVilbiss 0.8-mm air-atomizing spray gun operating at approximately 1.7 bar using a gravity feed paint cup. The piezoelectric charge coefficient d_{33} was found to vary between 10 and 30 pC N^{-1} with a predominance around 20 pC N^{-1} [23].

Paints belonging to the class of 0–3 piezoelectric composites, consisting of a ferroelectric ceramic powder of calcium modified PTCa dispersed in a polymer matrix, have been fabricated and their ferroelectric properties have been investigated by Wenger *et al.* [14]. Two formulations of 0–3 composites, one with a copolymer of P(VDF-TrFE) and the other with a thermosetting epoxy resin, were studied. The composite of the ceramic with the epoxy, 60/40 vol% PTCa/epoxy, was prepared by gradually adding the ceramic powder to the resin while stirring continuously to ensure an even mixture [40]. The ceramic/copolymer composite PTCa-P(VDF-TrFE) with a 65/35 volume fraction was prepared by a hot-rolling technique. The composite films were subsequently poled in a dc field of $1–2.5 \times 10^7$ V m^{-1} for 30 min at 100 °C in an insulating silicone oil bath. The d_{33} coefficients for the composites of PTCa/P(VDF-TrFE) and PTCa/epoxy are 33 and 26 pC N^{-1} respectively. Surface-mounted AE sensors were fabricated using the composite films thus obtained and their frequency response was evaluated using a face-to-face technique over the frequency range of 300 kHz to 50 MHz. Embedded transducers, constructed from the piezoelectric composite films were used to detect plate waves within a laminate glass/epoxy plate measuring 304.8 mm × 304.8 mm × 1.9 mm. It was found in their study [14] that, in the case of the embedded transducers, the PTCa/epoxy films seem to be the better choice of transducer material, producing signals comparable in amplitude to those of an embedded PTCa/P(VDF-TrFE) film but more clearly defined.

Sakamoto *et al.* [18] studied a flexible piezoelectric composite with 0–3 connectivity, made from PZT power and castor oil-based PU, which was doped with a small amount of fine-grained carbon powder to facilitate poling at relatively low electric field in a short time span. The carbon particles located between the PZT particles help create a continuous electric flux path. The PZT powder was mixed with carbon by a vibrator for 30 min prior to introducing this mixture in the PU matrix. The composite was placed between two paraffin papers and pressed at room temperature. The applied pressure was about 20 MPa and it was possible to obtain samples in the thickness range

of 250–350 μm. All the samples were poled with a 3 MV m^{-1} electric field at 100 °C for 1 h. After poling, the d_{33} coefficient was measured and it was observed that the highest value of the d_{33} coefficient (around 12 pC N^{-1}) was achieved with PZT/C/PU samples with 59/1/40 vol% composition. On adding 1.0 vol% of carbon, the d_{33} coefficient increased by 25% in comparison with the composite without the semiconductor phase. The disadvantage associated with carbon doping appears to be the relatively low electrical breakdown voltage of about 6 MV m^{-1}. The PZT/C/PU composite has shown the ability to detect both extensional and flexural modes of simulated AE at a distance of up to 8.0 m from the source [41].

Badcock and Birt [17] have examined the use of piezoelectric 0–3 composite as embedded Lamb wave sensors for damage detection in carbon fiber reinforced composite plates (E-glass/913 and T800/924 aerospace composites). The 0–3 composite consists of PZT-5H powder dispersed in an epoxy matrix. Cured PZT/epoxy materials with a PZT volume fraction of 60% was immersed in an oil bath for poling at a predefined temperature in the range of 50–120 °C. It was found that the greatest poling efficiency is achieved at 60 °C (most samples were poled at a field of 19 kV mm^{-1} for 5 min), with sensitivities of around 17 pC N^{-1} for the piezoelectric charge constant d_{33}. Comparative study of three different transducers—a conventional PZT ultrasonic transducer, a 500-μm-thick PVDF element, and a 600-μm-thick piezoelectric 0–3 composite film—were carried out to receive the Lamb wave signal at a fixed distance from the transmitting transducer. It was found the piezoelectric 0–3 composites were twice as sensitive when compared with PVDF films.

Li *et al.* [19] developed cement-based 0–3 piezoelectric composites containing up to 70 vol% of PZT particles by normal mixing and spreading method. Cement and PZT particles were first thoroughly mixed together without adding water, and then water and superplasticizer were added to the mixture. The mixture was then spread on a glass plate to form a disk with a diameter of ∼10 mm and thickness of ∼3 mm. The samples were put in the curing room at a temperature of 23 °C and relative humidity of 100% for 28 days before measurement. Poling was conducted in a silicon oil bath at a temperature of ∼150–160 °C for 1 h. The d values were found to vary from 7.2 pC N^{-1} for the 35 vol% of PZT formulation to 33.4 pC N^{-1} for the 70 vol% of PZT formulations. The cement-based 0–3 piezoelectric composites were shown to have a slightly higher piezoelectric factor and electromechanical coefficient than those of 0–3 PZT/polymer composites with a similar content of PZT particles.

A sol–gel spray technique was used by Kobayashi *et al.* [25, 42] to produce thick-film broadband ultrasonic transducers that are based on piezoelectric 0–3 composites. The piezoelectric particles of PZT and $LiTaO_3$ were dispersed in a sol–gel solution with a viscosity suitable for spray painting [42]. The fabrication process involved spray coating, firing at 420 °C using a heat gun or gas torch, and annealing at 650 °C to optimize the PZT sol–gel. Multiple layers were made to reach the desired transducer thickness. After sputtering the platinum top electrodes, the piezoelectric films of a 50–60-μm thickness were poled at 380 °C with a 7–9 MV m^{-1} electric field. The films were observed to be able to withstand more than 10 thermal cycles between the room temperature and 250 °C without being detached from the steel rod substrate. The d_{33} values of the films were measured to be 0.1 pC N^{-1}. Ultrasonic pulse–echo signals with a signal-to-noise ratio of more than 25 dB have also been received by the PZT/$LiTaO_3$ composite films at elevated temperatures up to 250 °C. More recently, Kobayashi *et al.* [25] used the sol–gel spray technique to deposit PZT/PZT sol–gel composite directly onto selected substrates including graphite/epoxy, aluminum, and steel. The Corona poling technique was used to pole the cured film for 10 min at 120 °C. The piezoelectric constants d_{33} and d_{31} of the films were 30×10^{-12} and -26×10^{-12} m V^{-1}, measured by an optical interferometer and optical coherence tomography, respectively.

Zhang and Li [24] developed an epoxy-based flexible piezoelectric paint that cures at room temperature. The paint film from this recent formulation is very compliant after curing, as can be seen from the bent shape of the paint sample in Figure 1. PZT-5A powder was chosen as the active piezoelectric material in this paint formulation. The epoxy resin used in this study is a liquid resin comprised mainly of diglycidyl ether of bisphenol A (DGEBPA). Additives such as dispersing agents and defoamers were also added to the paint mixture during the paint grinding and mixing process. Curing of the paint was

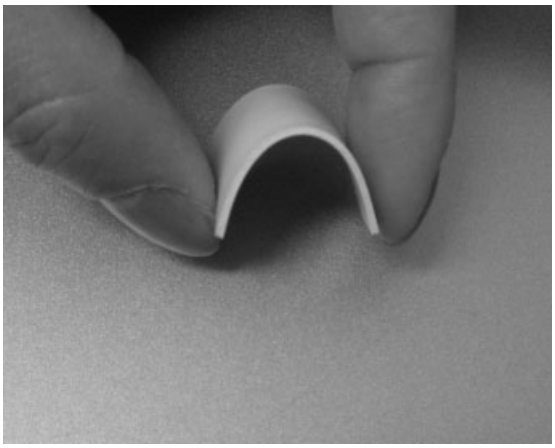

Figure 1. Sample of flexible piezoelectric paint.

done at elevated temperature (50 °C) for three days before applying conductive paint-based electrode to the top side of the paint. The volume fraction of PZT power in cured paint was about 30%. After the curing and electroding process had been completed, poling of the piezoelectric paint was carried out to activate its piezoelectric effect. In this study, poling was performed using a conventional electrode poling device at a temperature of 70 °C for 30 min at an electrical field of 5 MV m^{-1}. The average value of d_{33} was measured to be 5 pC N^{-1}. The ultrasonic sensing characteristic of the piezoelectric paints from this study is described in the next section.

Lahtinen *et al.* [22] developed a piezopaint-based vibration sensor by mixing piezoceramic powder with epoxy resin, which has been shown to be a very sensitive vibration monitoring device. The paint was mixed with 60 vol% PZT pigment concentration. The PZT powder was PZ27 produced by Ferroperm Electroceramics A/S, Denmark. The size range of the powder particles was 0–25 μm, with average particle size of 5 μm. The paint was applied with a laboratory applicator and the dry film thickness was 80 μm. Poling of the piezopaint layer was carried out by applying a 1-kV potential over the piezo layer for a period of 15 min at room temperature. Dynamic loading test of the piezopaint vibration sensors was conducted both in the laboratory and in field conditions. The thermal stability of the piezopaint sensor is excellent compared with piezoelectric polymers because of the fact that the piezoelectricity is a property of a ceramic material in the composite. The thermal stability is limited to the properties of the polymer matrix and the electrode materials. The thermal stability could possibly be further enhanced by applying more stable polymer matrix materials such as Polyetheretherketone (PEEK).

Hale and Lahtinen [43] conducted a program of testing to evaluate the susceptibility of piezoelectric paint to environmental degradation and so to evaluate its suitability for use in shock and vibrations sensors on large outdoor structures. Controlled weathering trials show that the sensors drop in sensitivity over the first few months from manufacture, but thereafter maintain a constant sensitivity irrespective of exposure to sunlight, rain, or frost, etc. Field trials on river crossing bridges in United Kingdom and Finland have shown that the sensors can survive harsh outdoor conditions and remain functional for six years, with no sign of an end to their lives at that time.

4 ULTRASONIC SENSING CHARACTERISTICS OF PIEZOELECTRIC PAINT

Like all other piezoelectric materials, piezoelectric paint can produce electric voltage signals proportional to the applied mechanical deformation in its film plane. Without loss of generality, we assume that piezoelectric paint sensor is only subjected to unidirectional strain in its film plane. The dielectric displacement D_3 is related to the generated electric charge by the following relationship,

$$q = \iint D_3 \, \mathrm{d}A_3 \tag{1}$$

where $\mathrm{d}A_3$ is the differential electrode area in the 1–2 plane of the piezoelectric paint. The electric charge generated by the sensor is

$$q = \mathrm{d}_{31} Y_C b_C \int_{lc} \varepsilon_1 \, \mathrm{d}l \tag{2}$$

where Y_C is the Young's modulus of the piezoelectric paint, and l_c and b_c are the length and width of the piezoelectric paint sensor, respectively.

Sirohi and Chopra [44] studied the behavior of PZT and PVDF strain sensor over a frequency range of 5–500 Hz. In their work, a typical piezoelectric

patch sensor is considered as a parallel plate capacitor, which stores the electric charge generated by the piezoelectric sensor when mechanical deformation is applied. It is shown that if only one-dimensional in-plane deformation is considered, the voltage generated across the electrodes of the capacitor can be related to the average in-plane strain by a sensor sensitivity parameter and the sensor capacitance. If a charge amplifier is connected to the sensor electrode, then the output voltage is

$$V_{\text{out}}(t) = -\frac{q}{C_f} = -\frac{d_{31} Y_C b_C}{C_f} \int_{lc} \varepsilon_1 \, dl \qquad (3)$$

Therefore, the sensor output voltage is proportional to the integral of the in-plane strain in the 1-direction.

AE consists of a propagating elastic wave generated by a sudden release of energy within a material (see, e.g. [45–47]; *see* **Acoustic Emission**; **Applications of Acoustic Emission for SHM: A Review**). In recent years, AE has been shown to provide real-time information on the progression of damage within metallic structures. The elastic wave generated by structural damage propagates through the solid to the surface where it can be detected by surface-mounted sensors. The sensor captured AE waveforms contain information about the damage source, like location, size and type, etc.; it is possible to extract such information by analysis of those waveforms. In a manner different from ultrasonic active sensing, which intentionally excite elastic waves in a solid, AE sensors passively listen for acoustic signals generated by crack initiation and progression. AE has been proved to be a useful NDE method for the investigation of local damage in structural members.

The AE sensing capability of piezoelectric paints has been verified by a number of researchers including Egusa and Iwasawa [39], Wenger *et al.* [14, 40], Sakamoto *et al.* [41], Kobayashi *et al.* [25, 42], Marin-Franch *et al.* [33], and Li and Zhang [48]. Egusa and Iwasawa [39] evaluated the sensitivity of piezoelectric paint film with a PZT volume fraction of 53% to film thickness and poling field as an AE sensor in the frequency range of 0–1.2 MHz. Wenger *et al.* [14] examined the suitability of piezoelectric 0–3 composites embedded into glass-reinforced laminate plates as AE sensors. Piezoelectric bimorph sensors for embedded AE sensing in glass–epoxy laminate platelike structures have been fabricated and investigated by Wenger *et al.* [40]. The bimorphs can differentiate between two types of plate wave propagation—flexural and extensional modes of Lamb waves, although the differentiation is attributed to the wavelength of the acoustic wave relative to the sensor dimensions. Sakamoto *et al.* [41] have shown that the piezoelectric 0–3 composite film with a PZT volume fraction of 49% can successfully detect both extensional and flexural modes of simulated AE at a distance up to 8 m from the source on a fiberglass reinforced plate. Marin-Franch *et al.* [33] developed a PTCa/PEKK composite to detect AE from delamination in carbon fiber reinforced composite panels. It is demonstrated that in a square array they can be used to locate AE sources with good accuracy.

We recently conducted a series of ultrasonic tests including pitch–catch ultrasonic test and pencil break test to examine the sensing capability of piezoelectric paint sensor over ultrasonic frequency range. The piezopaint sensor loaded with 30% by volume of PZT powder was deposited to a 609.6 mm × 609.6 mm × 1.59 mm aluminum plate. A layer of conductive silver paint was applied on top of the piezopaint having a size of 7 mm × 7 mm. The paint film thickness was 1 mm. After curing and electroding, poling of the piezoelectric paint was carried out to activate its piezoelectric effect. A 7 mm × 7 mm × 0.2 mm piezoelectric ceramic patch was also bonded along the centerline of the piezoelectric paint sensors as the actuator to excite Lamb waves in the aluminum plate. A five-cycle windowed toneburst excitation signal was generated by a function generator at various frequencies. Generally, guided waves propagating through metal structure surface are highly dispersive and tend to decay very fast with the increase of the propagation distance. Piezoelectric paint sensors were used to measure the guided-wave propagation at corresponding sensor locations. An AD745 high-speed operational amplifier circuit with a voltage gain of 100 was connected to the piezoelectric paint sensor as a preamplifier and then the amplified signal was recorded with a Tektronix TDS 2024 oscilloscope connected to a computer via a general purpose interface bus (IEEE488) (GPIB) adapter.

In our test, the PZT wafer was excited by 10 V peak-to-peak voltage signal, and ultrasonic lamb waves were received by a piezoelectric paint sensor

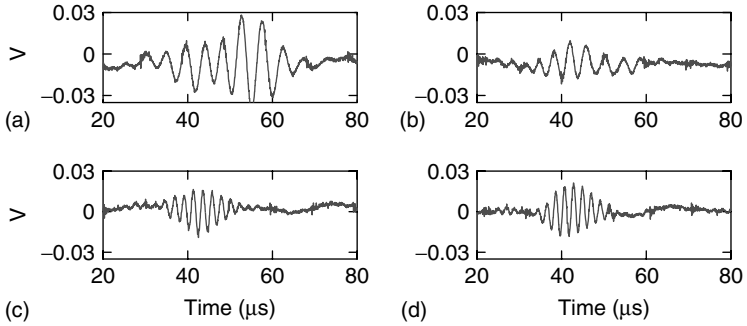

Figure 2. Raw data received by piezoelectric paint sensor: (a) 40-kHz excitation, (b) 60-kHz excitation, (c) 80-kHz excitation, and (d) 100-kHz excitation.

which was 25 mm away from excitation. The received raw time traces at excitation frequencies of 40, 60, 80, and 100 kHz are shown in Figure 2. The amplitude of the received signals at piezoelectric paint sensors was in the range of 20 mV peak-to-peak. Before raw sensor data can be interpreted to determine structural health condition, signal processing is necessary to ease the interpretation process. This is especially true for piezoelectric paint sensor because of its low sensitivity and hence low signal-to-noise ratio compared with a PZT sensor. In the present research, discrete wavelet transform (DWT) technique was used to filter the signal captured by piezoelectric paint sensor. Figure 3 shows the DWT-filtered signals (using a db (Daubechies) 6 level 5 wavelet) at piezoelectric paint sensors using wavelet transform. The filtered signals clearly show the propagation of Lamb waves over time. This experimental study conforms that piezoelectric paint sensor can be used to detect ultrasonic wave motion in platelike structures.

To verify the capability of piezoelectric paint sensor as an AE sensor, we performed pencil break tests on the same aluminum plate. Pencil break source (also called *Hsu-Neilsen source*) is a common approach to simulate AE due to its simplicity and reproducibility. In our study, a pencil lead with a 0.5-mm diameter was broken by pressing against the aluminum plate to simulate AE signal from a microcrack. The same data-acquisition equipment as in the ultrasonic test was used here. For comparison purpose, a 7 mm × 7 mm × 0.2 mm PZT sensor has been placed right next to the piezoelectric paint sensor on the aluminum plate to capture the AE signal. The same amplifier used in the ultrasonic test was applied to the piezoelectric paint sensor. The pencil lead was fractured at the same distance of 127 mm (∼5 in.) away from both the PZT and piezoelectric paint sensor. Figure 4(a) plots the captured AE signals collected at a sampling rate of 2.5 MHz. After filtering with the db 6 level 5 wavelet, the filtered

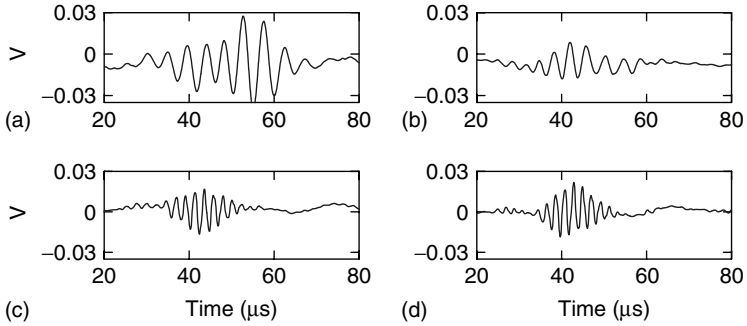

Figure 3. Filtered signal received by piezoelectric paint sensor: (a) 40-kHz excitation, (b) 60-kHz excitation, (c) 80-kHz excitation, and (d) 100-kHz excitation.

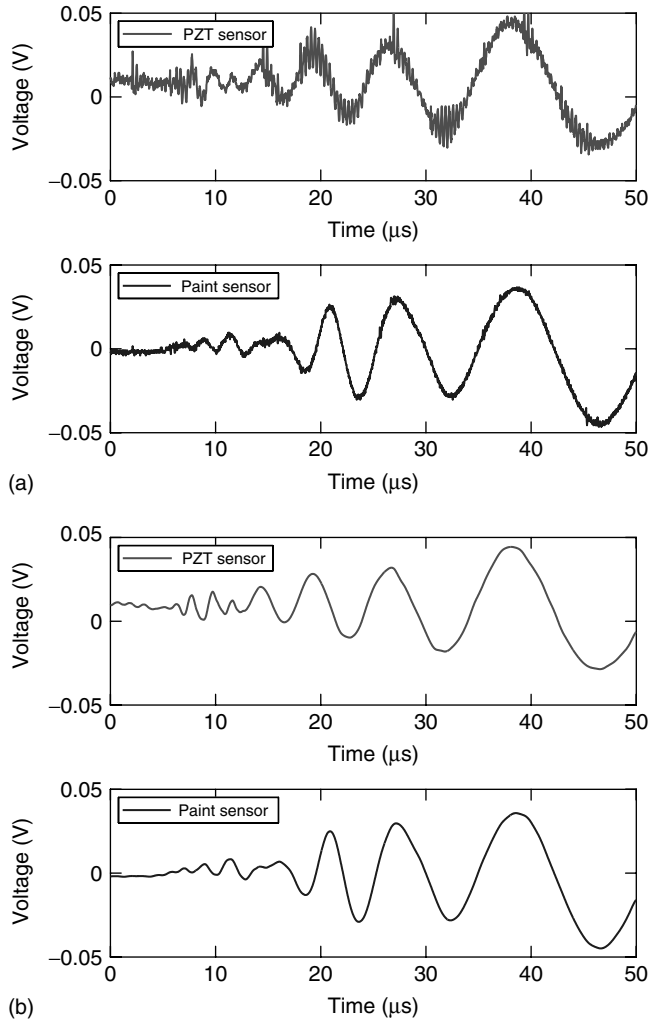

Figure 4. Acoustic emission signal received by piezoelectric sensors in pencil break test: (a) raw data and (b) DWT-filtered data.

AE signals are shown in Figure 4(b). The piezoelectric paint sensor (with amplifier) gave a peak-to-peak response close to that of the PZT sensor (without amplifier) both at the amplitude of 70 mV peak-to-peak. The two signals agree with each other very well.

5 CONCLUSIONS

The state of the art in piezoelectric paint sensor technology and its potential application to ultrasonic-based damage detection are reviewed in this paper. Piezoelectric paint is a composite piezoelectric material with adjustable material properties that are not easily attainable in a single-phase material. Through judicious selection of the polymer matrix, the composite properties of the piezoelectric paint can be tailored to meet the specific requirements of an application condition. Various formulations for piezoelectric paints have been developed over the last 20 years, and its ability to sense ultrasonic signals has been experimentally verified. Compared with conventional piezoelectric ceramics and piezoelectric polymers, piezoelectric paint has several advantages

for ultrasonic sensing application: (i) it enables true distributed sensing since piezoelectric paint can be applied to the surface of the structure in potential hot spots; (ii) painting represents an inexpensive way to apply this novel sensor technology over large surface areas of a host structure, especially for those with curved surfaces or complex geometries; and (iii) piezoelectric paint is more thermally stable than piezoelectric polymer such as PVDF. Additionally, a thickness range varying between 60 μm and 2 mm for piezoelectric paint film can be obtained, while the thickness of PVDF film is limited because of its high poling voltage.

Preliminary results from ultrasonic tests including pitch–catch tests and simulated AE tests that were carried out to verify the ultrasonic sensing capability of piezoelectric paint are reported in this paper and based on these preliminary results, piezoelectric paint sensor appears to offer a promising embedded sensor technology for ultrasonic-based NDE of structural defects or damages in either metallic or composite structure. However, extensive work still needs to be done to fully investigate the performance of piezoelectric paint sensor technology before this technique can be satisfactorily used in practical applications.

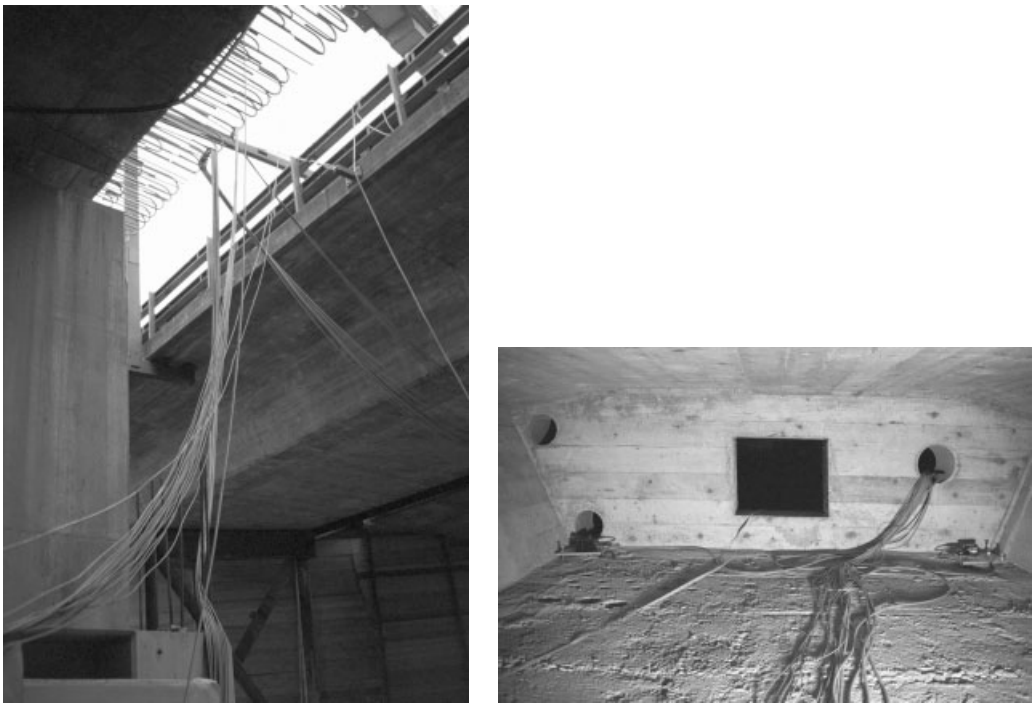
1 INTRODUCTION

Basically, every structural health monitoring (SHM) system is made up of various sensors measuring specific physical parameters, a data acquisition unit, and a storage device to save the acquired data. Traditional SHM systems show a starlike topology where each deployed sensor is connected via long cable runs to a central computer acting as data acquisition and storage device. The installation of such systems tends to be time consuming and therefore expensive (Figure 1). Especially in the field of civil engineering where the structures are typically large, the sensors can be located long way away from the data acquisition unit, resulting in high installation costs. These costs have proved to be a major issue, preventing a broad application of monitoring techniques to large-scale infrastructure. Furthermore, long cable runs are prone to pick up noise, reducing the effective accuracy of the acquired data, and hence require expensive high-quality cables. Moreover, these cables are susceptible to mechanical damage involving considerable maintenance efforts. Cabled systems also tend to offer a limited flexibility in terms of rearrangement of sensors and scalability. The adoption of wireless sensor network (WSN) techniques to SHM applications promises to overcome these drawbacks.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

1.1 Wireless sensor network

A WSN is essentially a computer network consisting of many small, intercommunicating computers equipped with one or several sensors. Each small computer represents a node of the network. These nodes are called sensor nodes or motes. The communication within the network is established using radio frequency transmission techniques. The sensor nodes typically form a multihop mesh network by establishing communication links to neighbor nodes. Multihop networks offer different advantages when monitoring data has to be transmitted over long distances. Mainly, the network robustness to sensor node failure and the high power efficiency [1] make multihop networks attractive for monitoring applications. Figure 2 illustrates a schematic multihop



(a) (b)

Figure 1. Traditional, wired SHM installation.

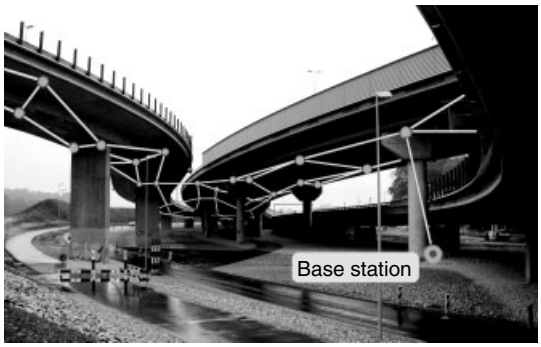


Figure 2. Wireless sensor network deployed on a road bridge. The spots illustrate the sensor nodes, the straight lines the communication links.

network deployed on a road bridge. The network consists of several dozens of sensor nodes. Theoretically, the number of sensor nodes is unlimited. All sensor nodes are equipped with specific sensors tailored to their measurement tasks. On the one hand, these nodes act as data sources, and on the other hand, they act as relaying stations, receiving and forwarding data from adjacent nodes. One or more particular sensor nodes act as base station and represent the data sink in the network. It aggregates all the data generated within the network. In addition, the base station establishes a communication link to a data logging unit or a remote site (e.g., control center), using standard wired or wireless communication technologies like universal mobile telecommunications system (UMTS) or wireless local area network (WLAN).

The initial research into WSNs was mainly driven by military applications like battlefield reconnaissance and surveillance, nuclear, biological, and chemical attack detection, etc. These projects focused on *ad hoc*, multihop WSNs that consisted of thousands of immobile nodes randomly distributed over a large geographical area (e.g., Smart Dust). The nodes were tiny (hardly noticeable), severely resource constrained, and homogeneous (identical hard- and software). Subsequently, the emergence of civilian applications of WSNs in different fields (environmental monitoring, home automation, health applications, production, inventory, delivery control,

etc.) produced a significant diversification of requirements with respect to deployment, mobility, size, cost, network topology, lifetime, etc., and therefore a flourishing of academic and commercial WSN platforms. To cope with these requirements, the platforms increased in size, computational resources, and hardware, as well as in software complexity.

The first commercial platforms appeared in the late 1990s. The most important platform was Crossbow's Rene mote, which emerged from the weC mote developed at the University of California, Berkeley, and which evolved later to the popular Mica platform. These platforms were the precursors of the recent Mica2 and MicaZ platforms (Table 1). A major reason for the popularity of Crossbow's early mote platforms was their open source policy with both hard- and software design open to the public. This policy built the base for the widespread diffusion of TinyOS as operating system for WSNs. Today, various commercial platforms with different characteristics in terms of computing resources, sensor interfaces, software architecture, etc., are available, which allow to cope with a wide spectrum of civilian applications.

2 HARDWARE ARCHITECTURES

The sensor nodes are the fundamental components of a WSN. To enable WSN-based SHM applications, the sensor nodes have to provide the following basic functionality (Figure 3):

- signal conditioning and data acquisition for different sensors;
- temporary storage of the acquired data;
- processing of the data;
- analysis of the processed data for diagnosis and, potentially, alert generation;
- self monitoring (e.g., supply voltage);
- scheduling and execution of the measurement tasks;
- management of the sensor node configuration (e.g., changing the sampling rate and reprogramming of data processing algorithms);
- reception, transmission, and forwarding of data packets;
- coordination and management of communication and networking.

2.1 General architecture

To provide the functionality described above, a sensor node is composed of one or more sensors, a signal conditioning unit, an analog-to-digital conversion module (ADC), a processing unit with memory, a radio transceiver, and a power supply (Figure 4).

If the sensor nodes are actually deployed in the field, especially in harsh environments like construction sites, they have to be protected against chemical and mechanical impacts. Therefore, an adequate packaging of the hardware is required (*see* **Microelectromechanical Systems (MEMS)**).

2.2 Hardware platform categories

Sensor node hardware platforms can be divided into three categories [2]. Each category shows a different hardware setup matched to diverse monitoring applications.

- **Adapted general-purpose computers**

These platforms are low-power personal computers (PCs), embedded PCs, and personal digital assistants (PDAs). These platforms mainly run on Windows CE, Linux, or other operating systems developed for mobile devices. These platforms are predominantly equipped with standard wireless communication devices like Wireless LAN (IEEE 802.11) and/or Bluetooth (IEEE 802.15.1). Because of the high processing ability and the high bandwidth communication, these platforms offer the opportunity to use higher level programming languages, which makes it easier to develop and implement software components. But in turn, they consume a considerable amount of energy and this can be prohibitive in some application scenarios. Additionally, they support networking protocols like Internet Protocol (IP). This simplifies the integration into a monitoring system.

- **Embedded sensor modules**

These platforms are assembled from commercial off-the-shelf (COTS) Chips. Using COTS offers several benefits. These components are widely used, making them cheap because of big production quantities, and are well supported by the manufacturers and communities. The microcontroller unit (MCU) of these platforms is mostly programmed in C. This

enables the development of a tight code that fits the limited memory size. Application developers have full access to hardware, but at the same time need to take care of all the resources. Examples from this category are Tmote from Moteiv, Mica2, MicaZ (Mica family), and Imote2 from Crossbow.

- **System on chip (SoC)**

These platforms integrate micro electromechanical systems (MEMS) sensors, microcontroller, and wireless transceiver technologies on one chip, an application-specific integrated circuit (ASIC). Because of this integration, platforms of this category are extreme low-power devices and have a small footprint/size. The smart dust node [3] is such an example.

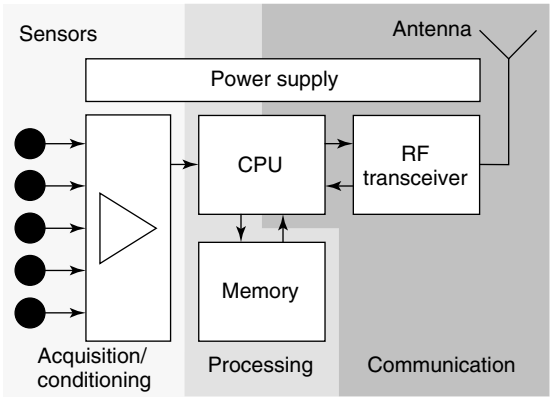

Figure 4. Sensor node (mote): hardware structure of a sensor node.

2.3 Energy-related aspects

The advantages of WSNs over wired sensing systems only have an effect if an unattended operation of the motes for a reasonably long period of time can be achieved. In terms of energy resources, this calls for a self-contained power source and has shown to be the most restrictive requirement in WSN applications. One approach to provide sufficient energy to operate the device over the desired period is to estimate the

total amount of energy that will be consumed and to equip the mote with adequately dimensioned energy storage upon deployment. Although this approach is a viable solution for some lowest-duty cycle applications, the required energy storage tends to become too big for long-term SHM systems. For monitoring applications that target overall system lifetime of several years, the dissipated energy has to be regenerated from mote-extern sources. This process is referred to as energy harvesting or scavenging. These sources absorb energy from the mote's environment and convert it to electrical energy.

Numerous different types of energy storage and harvesting concepts exist, but only the most important ones for SHM systems are presented here. An overview of other, partly inconvenient concepts is given in [4].

2.3.1 Communication versus computation

In terms of power consumption, wireless data transmission is much more expensive than data processing. To extend system lifetime, it is preferable to preprocess the raw sensor readings to reduce the data items needed to be transmitted to the base station. Many recent WSN-based SHM systems transmit the raw data streams to the base station and analyze them in the traditional centralized way. Without introducing huge batteries, this is not a viable solution if a system lifetime of several months to years is targeted. For long-term monitoring applications, distributed analysis algorithms have to be introduced, which allow for decentralized data reduction or even condition assessment.

2.3.2 Energy storage devices

- **Batteries**

The most popular energy storage is batteries. Many battery types with different characteristics have been developed. Every battery has its own advantages and drawbacks and the suitable battery technology has to be selected according to the application requirements. Rechargeable batteries are utilized if energy is harvested from the mote's environment.

- **Ultracapacitors**

The features of supercapacitors lie between those of capacitors and rechargeable batteries. Supercapacitors exhibit virtually unlimited charge–discharge cycles like capacitors, but offer a much higher capacity. These components are adequate as energy storage if it is emptied and replenished in short intervals.

- **Fuel cells**

This is a more recent but promising technology. Fuel cells oxidize hydrogen or hydrocarbon fuels and convert the heat into electrical energy. Currently, the commercially available fuel cells are too big in terms of size and converted energy to be applied to motes. However, much effort is being put into the development of small fuel cells for laptops and mobile phones. These devices will suit WSN applications well.

2.3.3 Energy harvesting and scavenging devices

Because of their nature, environmental energy scavenging devices do not provide a constant energy flow. Therefore, these devices are predominantly operated in conjunction with a storage device like a supercapacitor or a rechargeable battery. It stores excess energy and provides it later, when not enough can be harvested from the environment.

- **Solar cells**

The most popular energy scavenging sources are solar cells. A reasonably small panel delivers enough energy to power a sensor node. Solar cells are predominately operated in conjunction with a supercapacitor or a rechargeable battery. This energy storage is needed to provide energy, when the panel does not. Obviously, solar cells are only an option for outdoor applications.

- **Wind mills**

More unusual energy scavenging devices are small-scale wind mills or turbines. Like solar cells, this concept is only suitable for outdoor applications.

- **Vibration**

An energy harvesting method that is considered for civil engineering applications is to convert vibration energy. Civil engineering structures contain a lot of vibration energy, but it is extremely hard to extract it. The energy levels that current prototypes provide are far to low for monitoring applications. But it could evolve to an interesting source in the future.

2.4 Overview of recent architectures

Various hardware platforms for WSNs are available today and new ones emerge regularly. This diversity offers the possibility to choose a platform that best fits the needs of a specific application. An overview of recently used platforms is given in Table 1. This table only shows a selection. Further platforms are presented in [5] and regularly updated lists in the Internet can be found at [6–9].

2.5 Tmote Sky from Moteiv Corporation

Tmote [10] from Moteiv Corporation is presented as an example of a popular WSN platform (Figure 5). Many comparable platforms with similar hardware setups exist today. All these platforms are based on the Texas Instruments microcontroller family MSP430 and the Chipcon radio CC2420.

The main components of Tmote sensor node platform are the TI MSP430F1611 microcontroller, the FTDI FT232BM USB interface, which allows for programming the microcontroller over USB, and the Chipcon CC2420 low-power radio chip for the wireless communication.

The ultra-low-power microcontroller features 10 kB of RAM and 48 kB of program memory (flash). This 16-bit processor features several power-down modes with extremely low sleep-current consumption that permits the sensor node to run for a long period of time from a limited energy resource. The MSP430 has an internal, digitally controlled oscillator (DCO) that may operate up to 8 MHz. The microcontroller may be turned on from sleep mode in 6 µs, which allows for short reaction time upon the occurrence of an event. When the DCO is off, the MSP430 is clocked from an external 32 768-Hz watch crystal.

The MSP430 has eight external 12-bit ADC ports of which six are accessible on a pin header on the Tmote. The ADC input ranges from 0 to 3.0 V. The maximum total sampling rate for all ports is 200 kHz at 12-bit resolution. The internal ADC ports may be used to monitor the internal processor temperature and the supply voltage. A variety of peripherals are available, including serial peripheral interface (SPI) and universal asynchronous receiver/transmitter (UART), enabling the communication to digital output sensors, digital I/O ports, a watchdog timer, and timers with capture and compare functionality. The I^2C port, which is also integrated into the microcontroller, is mainly used to communicate to additional sensors and signal conditioning boards. The MSP430 also includes a 2-port 12-bit digital-to-analog converter (DAC) module, a supply-voltage supervisor, and a 3-port direct memory access (DMA) controller. Detailed features of the MSP430F1611 are presented in the Texas Instruments MSP430x1xx Family User's Guide [11].

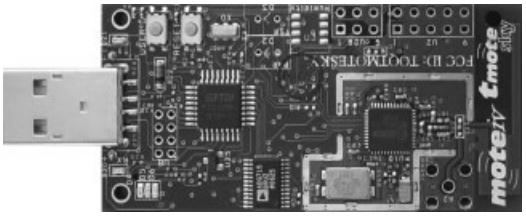

Figure 5. Picture of a Tmote Sky form Moteiv (top view).

The Tmote platform is equipped with the Chipcon CC2420 radio, enabling IEEE802.15.4 standard compliant wireless communication. It offers reliable wireless communication and power management capabilities to ensure low-power consumption. The CC2420 is controlled by the TI MSP430 microcontroller through the SPI port and a series of digital I/O. The radio may be shut off by the microcontroller for reducing the power consumption. The CC2420 provides a digital receive signal strength indicator (RSSI) that may be read at any time. The programmable transmitter output power enables to optimize the power consumption. The theoretically achievable maximum data throughput rate of the system is 250 kbps, without framing and packet headers.

3 SOFTWARE PLATFORMS

Unlike general-purpose operating systems for standard PCs such as Windows or Linux, the WSN software platforms are highly tailored to the limited node hardware. These WSN software frameworks are not full-blown operating systems, since they lack a powerful scheduler, memory management, and file system support. However, these frameworks are widely referred to as *WSN operating systems*. Therefore, this term is retained in the following section.

TinyOS [12], one of the most widespread operating systems, is presented in more detail in the following section. Other operating systems developed for WSNs are Contiki [13], Mantis [14], and SOS [15].

3.1 TinyOS

TinyOS is written in nesC [16], an extension to the C language, which supports event-driven component-based programming. The basic concept of component-based programming is to decompose the program into functionally self-contained components. These components interact by exchanging messages through interfaces. The components are event-driven. Events can originate from the environment (a certain sensor reading exceeds a threshold) or from other components, triggering a specific action. The main advantage of this component-based approach is the reusability of components.

The nesC language extension introduces several additional keywords to describe a TinyOS component and its interfaces. nesC and TinyOS are both Open Source projects supported by a fast growing community.

TinyOS has been ported to over a dozen WSN platforms (Table 1) and is also the native operating system of the presented Tmote platform. It provides a concurrency model and mechanisms for structuring, naming, and linking software components into a robust network embedded system. Today, TinyOS is a sort of *de facto* standard in WSN programming and widely used in the WSN community. As a result, a huge amount of software components for various sensors, network protocols, algorithms, and other WSN related topics is freely available on the Internet.

Chapter 70
Sensor Placement Optimization

Robert J. Barthorpe and Keith Worden
Department of Mechanical Engineering, University of Sheffield, Sheffield, UK

1 INTRODUCTION

The basic problem of fault detection is to deduce the existence of a defect in a structure from measurements taken at sensors distributed upon it. The quality of these measurements and thus the quality of structural health monitoring (SHM) achieved is, to a large extent, dependent upon where sensors are placed on the structure. Cost and practicality issues preclude the instrumentation of every point of interest on the structure and lead to the selection of a smaller set of measurement locations. The purpose of this article is to state the problem of sensor placement optimization (SPO) and describe the approaches that have been investigated for its solution. The following discussion focuses on sensor placement techniques for the category of SHM methods based upon the analysis of structural dynamics, although many of the issues raised are of wider relevance.

Traditionally, successful sensor placement has been heavily reliant upon the knowledge and experience of those performing the testing. Practical methods, for example, choosing locations near the antinodes of low-frequency vibration modes, are combined to create *ad hoc* sensor distributions. Where resources allow, several combinations of possible sensor configurations may be experimentally tested with the one that performs best chosen as the final design. While this is certainly a significant improvement on arbitrary placement, recent research has attempted to formalize the location process by casting it as a problem of optimization.

This research effort has led to the development of a variety of approaches to SPO, which are suited to different applications. An overview of the problem is given in Section 2, a review of the technical literature in Section 3, and an outline theory for a selection of the most influential techniques is given in Section 4.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

A case study to illustrate an application of SPO is presented in Section 5.

2 OVERVIEW OF THE SENSOR PLACEMENT OPTIMIZATION (SPO) PROBLEM

The aim of the sensor placement exercise can be stated as the need to select a subset of measurement locations from a large finite set of candidate locations, in order to represent the system as accurately as possible using the limited number of degrees of freedom (DoFs) available. This can be viewed as a three-step decision process:

1. Sensor quantity—How many sensors need to be installed on the structure to allow successful dynamic testing?
2. Sensor placement optimization—Where should these sensors be located to most accurately capture the required data?
3. Evaluation—How can the performance of different sensor configurations be measured?

In general, the first aspect would have been resolved during pretest planning. The minimum requirement for the system to be observable is that the number of sensors required cannot be less than the number of mode shapes to be identified, with an upper limit usually imposed either by the cost or availability of equipment. In practice, a greater number of sensors are likely to be required to allow the mode shapes to be visualized, and in cases where there are surplus sensors available, a decision must be made as to whether they are best used for improving visualization or as backup against sensor failure.

The second aspect is the area that has attracted the majority of research interest, and is the primary focus of this article. For the limited number of sensors available, the problem is the development of a suitable sensor placement performance measure to be optimized and the selection of an appropriate method with which it can be optimized. Some approaches require a single calculation to be performed, some are iterative, and many others take the form of an objective function to which an optimization technique must be applied. The majority of this article deals with presenting the available alternatives.

The third and final aspect includes several possibilities for assessing the performance of chosen sensor sets. While there is an ever-present temptation to leap into data collection at the earliest opportunity, time spent assessing the effectiveness of the chosen network is invariably well spent.

Throughout this article, the *candidate set* refers to the set of all DoFs that are available as sensor locations. The *measurement set* refers to the DoFs employed as sensor locations. The *full model* includes the measurements at all available points and the *reduced model* includes only the measurements available at the DoFs specified in the measurement set.

3 LITERATURE REVIEW

The problem of determining the optimum locations for sensor placement has been addressed from a variety of perspectives. It appears to have been first addressed by control engineers before finding broad application in the field of structural dynamics. In the recent years, there has been increasing interest in developing placement methods specific to the needs of SHM, typically the optimal identification of structural characteristics sensitive to damage. This development is reflected in the literature.

An influential class of techniques has emerged from the concept of assessing all the locations of the candidate sensor set against some objective function, and then iteratively deleting those sensors that perform least well until the required number of measurement locations remain. For the effective independence (EI) method introduced in [1], based upon earlier work in [2], the sensors are ranked according to their contribution in maintaining the determinant of the Fisher information matrix (FIM, described in Section 4). The location that contributes least at each iteration step is selected for deletion. The kinetic energy (KE) method, see for example [3], assumes that the sensors will have maximum observability of the modes of interest if the sensors are placed at points of maximum KE for that mode. It has often been noted that EI and KE methods can produce similar results, especially in structures with homogeneous mass distributions, and the inherent mathematical connection between the two methods is revealed in [4].

Further examples of the iterative approach include the eigenvalue vector product (EVP) [5], average

driving-point residue (ADPR) [6], effective independence driving-point residue (EI-DPR) [7], strain energy distribution [8], and modal assurance criterion (MAC)-based [9] methods. The comparative performance of several of the iterative techniques is investigated in [10, 11].

It should be noted that the iterative process does not necessarily need to be a reduction from the candidate set. In [12], an alternative EI approach is presented whereby the sensor set is iteratively expanded to include those sensor locations that offer the greatest increase in the determinant of the FIM. The expansion approach reduces the computational expense incurred when the candidate set is large and allows for any desired sensor locations to be specified at the outset, with the remaining sensors placed optimally.

In [13], optimal sensor placement is formulated as a mixed variable programming (MVP) problem. The emphasis is on the development of a general framework using MVP optimization that could be applied to any number of objective functions. The MVP formulation allows variables to be categorical, taking their values from a predefined set or list. For the sensor placement problem, a categorical position variable is defined for each sensor.

A further class of methods takes advantage of developments in the field of combinatorial optimization. Perhaps the first use of genetic algorithms (GAs) for the sensor placement problem is presented in [14]. The authors propose the GA as an alternative to the EI method, with the determinant of the FIM chosen as the objective function (the *fitness* function in GA terminology). In [15], the fitness function is taken as a product of two terms: the first term measures the fitness from the point of view of observability; the second component is geometric and penalizes the clustering of sensors.

In one of the first sensor placement approaches specific to SHM [16], a structural damage localization approach based on eigenvector sensitivity is adopted and an SPO approach using the same method is developed. The EI approach is applied to the sensitivity matrix that is to be used for damage localization, with the DoFs providing the greatest amount of information for localization retained. In [17], the difficulties that can occur in solving the sensitivity matrix are highlighted. The problem is reformulated and solved using an improved GA.

In [18], the selection of optimal sensor locations for impact detection in composite plates is approached using a GA to optimize a fitness function based upon the concept of mutual information. The concept is used to eliminate redundancies in information between selected sensors and rank them based on their remaining information content. In [19], an equally spaced configuration of measurement points is assumed, and the sensor spacing is varied to minimize the average mutual information between measurement locations. In [20], a statistical method for optimally placing sensors for the purposes of updating structural models for subsequent damage detection and localization is presented. The optimization is performed by minimizing information entropy, a unique measure of the uncertainty in the model parameters. The uncertainties are calculated using Bayesian techniques, and the minimization is realized using a GA.

In one of the first studies of sensor placement for an SHM problem, a neural network (NN) for the location and classification of faults and a GA for the determination of an optimal (or near optimal) sensor configuration were used [21]. The NN is trained using mode-shape curvatures provided by an FE model of a cantilever plate. The probabilities of misclassification for the different damage conditions are obtained from the NN, and the inverse of this measure is employed as a fitness function for the GA. The use of simulated annealing (SA) for the optimization has also been investigated [22].

In [23], an NN/GA approach was used to place sensors for the location and quantification of impacts on a composite plate. An artificial NN is trained to locate the point of impact, and a second NN employed to estimate the impact force. A GA was used to select an optimal set of measurement locations from the candidate set, using the estimation of the impact force provided by the NN as the parameter to be maximized. The work is extended to cover fail-safe sensor placements [24]. In [25], a new damage location method is presented that combines classical triangulation procedures with experimental wave velocity analysis and GA optimization.

The NN problem studied in [23] was investigated using a different optimization technique reported in [26]. Here, an ant colony metaphor was used to place sensors based upon the fitness functions generated by the NN, and the results were compared with those

from the GA and exhaustive search. This work is demonstrated in Section 5 (*see* **Artificial Neural Networks**).

4 THEORY

A large variety of performance indices have been developed for the problem of sensor placement, but it is only comparatively recently that the problem has been considered from an SHM perspective. Rather than attempting to cover this multiplicity of approaches in full, the intention of this section is to highlight some of the key considerations made in the selection and development of objective functions appropriate to the SHM practitioner. Several influential general approaches (notably the EI and KE methods) are covered, as are more recent techniques developed for the specific purpose of damage detection. The descriptions have been kept mathematically light intentionally; full descriptions of the algorithms may be found in the references.

4.1 Effective independence (EI)

The EI method makes use of the FIM, which offers a measure of the information that a sampled random variable contains about an unknown parameter; formally, Fisher information is the variance of the score with respect to the unknown parameter. Where there are multiple unknown parameters, it may be stated in matrix form with elements

$$(I(\boldsymbol{\theta}))_{ij} = E\left[\frac{\partial}{\partial\theta_i}\ln f(X;\boldsymbol{\theta})\frac{\partial}{\partial\theta_j}\ln f(X;\boldsymbol{\theta})\right] \quad (1)$$

where

- $\boldsymbol{\theta} = [\theta_1, \theta_2, \ldots, \theta_N]$ is the vector of unknown parameters
- $(I(\theta))_{ij}$ is the Fisher information with respect to the unknown parameters θ_i and θ_j
- X is the sampled random variable
- $f(X;\boldsymbol{\theta}) = L(\boldsymbol{\theta})$ is the likelihood function of $\boldsymbol{\theta}$
- E denotes the expectation.

For the SPO problem, the target mode shapes may be regarded as the unknown, sought parameters, with the sampled data being that available from the given sensor distribution. Every DoF in the candidate set is ranked according to its contribution to the determinant of the FIM, and the lowest ranked DoF is eliminated. The new, reduced set is then re-ranked, and the process repeated in an iterative manner until the desired number of sensors remains. This is adopted as the optimal measurement set. Maintaining the determinant of the FIM leads to the selection of a set of sensor locations for which the mode shapes of interest are as linearly independent as possible, while retaining sufficient information about the target modal responses. The approach is based on the EI distribution vector $\mathbf{E}_{\mathrm{D}}$, defined as the *diagonal of the prediction matrix*, $\mathbf{E}$:

$$\mathbf{E} = [\boldsymbol{\Phi}]\{[\boldsymbol{\Phi}]^{\mathrm{T}}[\boldsymbol{\Phi}]\}^{-1}[\boldsymbol{\Phi}]^{\mathrm{T}} \quad (2)$$

where $\boldsymbol{\Phi}$ is the matrix of FE target modes, in this case partitioned according to a given sensor distribution. Each diagonal element is the fractional contribution of each sensor location to the rank of E, which can only be full rank if the target mode partitions are linearly independent. The algorithm is iterative; at each step, terms in $\mathbf{E}_{\mathrm{D}}$ are sorted to give the least important sensor, which is then deleted. The corresponding elements in $\boldsymbol{\Phi}$ are also deleted. The iteration concludes when the required number of sensors is obtained.

4.2 Average driving-point residue (ADPR)

A drawback of the EI approach is that the algorithm can select sensor locations that display low signal strength, making the system vulnerable to noisy conditions. The ADPR offers a measure of the contribution of any point to the overall modal response. If $j = 1 \ldots N$ modes of interest are to be measured and ω_j is the eigenvalue of jth mode, the ADPR at the ith DoF can be calculated from FE data as

$$ADPR_i = \sum_{i=j}^{N} \frac{\Phi_{ij}^2}{\omega_j} \quad (3)$$

4.3 Effective independence driving-point residue (EI-DPR)

The values given by the EI algorithm are weighted by the ADPR values to give the EI-DPR vector. For

the ith DoF

$$E_{D_i}^{\text{EI-DPR}} = E_{D_i}^{\text{EI}} ADPR_i \tag{4}$$

This adaptation leads to a greater likelihood of sensors being placed in areas of high signal strength. In addition to improving signal-to-noise ratios, this tends to result in the selection of relatively uniformly spaced sensor locations.

4.4 Kinetic energy method (KE)

The KE method assumes that the sensors will have maximum observability of the modes of interest if the sensors are placed at points of maximum KE for that mode, and accordingly ranks sensor locations based on their dynamic contribution to the target mode shapes. It follows a similar procedure to that used in the EI method, the key difference being that a KE measure, rather than the determinant of the FIM, is maximized. It is alternatively known as the *modal kinetic energy* (*MKE*) *method* or the *kinetic energy method* (*KEM*) in the literature.

KE indices are calculated for all candidate sensor locations as follows:

$$KE_{ij} = \Phi_{ij} \sum_s M_{is} \Phi_{sj} \omega_j^2 \tag{5}$$

where **M** is the mass matrix. The sensor locations that offer the highest KE indices are selected as the measurement locations. As the method selects those sensor locations with the largest available signal amplitudes, the signal-to-noise ratios tend to be high, making the method attractive for use in noisy conditions. However, in contrast to EI, the KE method does not consider the linear independence of the target modes, an important consideration for both modal identification and test–analysis correlation.

4.5 Eigenvalue vector product (EVP)

The EVP method computes the product of the eigenvector components for candidate sensor location for the range of modes to be measured N: a maximum for this product is a candidate measurement point. Some modification may be required if a point is a node of one of the modes. The EVP of the ith DoF is calculated as

$$EVP_i = \prod_{j=1}^{N} |\Phi_{ij}| \tag{6}$$

4.6 Mutual information

Mutual information gives a measure of how much information one sensor location "learns" from another. If there are two sets of measurement locations, A and B, the amount of information learned by a_i about b_j is represented by the mutual information $I(a_i, b_j)$,

$$I(a_i, b_j) = \log_2 \left[\frac{P_{\text{AB}}(a_i, b_j)}{P_{\text{A}}(a_i) P_{\text{B}}(b_j)} \right] \tag{7}$$

where

- a_i and b_j are the measurements from locations A and B, respectively
- $P_{\text{A}}(a_i)$ and $P_{\text{B}}(b_j)$ are the individual probability densities for A and B
- $P_{\text{AB}}(a_i, b_j)$ is the joint probability density for measurements A and B.

If the measurement of a_i is completely independent of the measurement of b_j, $I(a_i, b_j)$ becomes zero. The average mutual information between A and B is calculated by averaging over all the sensor locations, and the optimal sensor location determined by minimizing the mutual information between sensors.

4.7 Information entropy method

Optimal sensor placement is achieved by minimizing the change in the information entropy $H(D)$, given by

$$\begin{aligned} H(D) &= E_\theta[-\ln p(\theta|D)] \\ &= -\int p(\theta|D) \ln p(\theta|D) \, \mathrm{d}\theta \end{aligned} \tag{8}$$

where

- θ is the uncertain parameter set (e.g., stiffness parameters, modal parameters, etc.)

- D is the dynamic test data
- E_θ is the mathematical expectation with respect to θ.

A rigorous mathematical description is given in [27].

4.8 Sensitivity-based methods

In the SHM-specific method proposed in [16], the prediction matrix **E** used in the EI method is adapted to use the sensitivity matrix developed for damage location. The modified matrix is given by

$$E = \boldsymbol{F}(\boldsymbol{K})[\boldsymbol{F}(\boldsymbol{K})^T \boldsymbol{F}(\boldsymbol{K})]^{-1} \boldsymbol{F}(\boldsymbol{K})^{\mathrm{T}} \qquad (9)$$

where

- $\boldsymbol{F}(\boldsymbol{K})$ is the vector of sensitivity coefficients of the mode shape changes with respect to a damage vector.

As for the EI approach, the diagonal terms of E provide the fractional contribution of the corresponding measurement location to the rank of E. The location that contributes the least is removed, and the process is repeated iteratively until the required quantity of sensors remains.

5 CASE STUDY—SENSOR PLACEMENT OPTIMIZATION USING AN ANT COLONY METAPHOR

A comparatively recent addition to the canon of combinatorial optimization algorithms are those based on "ant colony metaphors". These are founded on the cooperative interaction of simple computational agents termed *ants*. The basic forms of the algorithms—"ant-density", "ant-quantity", and "ant-cycle"—were introduced in [28]. Of these basic forms, ant-cycle proved to be the most effective and this was renamed *ant-system* and discussed in more detail in [29]. The ant algorithms have proved to be a useful addition to the set of methods, combining aspects of greedy search with population-based cooperative search. The work put forward in [26] is presented here to illustrate an interesting approach to the problem of sensor placement.

5.1 The ant algorithm

Real ants are well known to be capable of finding the shortest path to a food source from their nest without using visual cues [30]. This is done by exploiting pheromone information. Ants deposit pheromone as they move and follow pheromone trails deposited by previous ants. If a trail has higher pheromone information, an ant will follow it in preference to other trails with less pheromone. In other words, an ant will follow a trail with higher pheromone, with higher probability. Consider Figure 1. Initially, the ants leave the nest and have no preference as to which path they will follow and they will choose a path with equal probability. Assuming that all ants travel with equal speed, the ants taking the lower path will reach the food before those taking the upper one. When returning to the nest, they will choose the lower path with higher probability because the upper path ants have not arrived yet to lay trail. This reinforces the pheromone path on the lower trail. When the lower path ants arrive back at the nest, new ants will initially see twice as much trail on the lower path and choose it with higher probability. It is not difficult to see that a positive feedback mechanism emerges, which reinforces the desirability of the lower trail. Eventually, all ants will follow the shorter path. This simple example illustrates the idea behind ant algorithms, which is that simple agents can communicate, using distributed memory about the problem, to cooperate and solve an optimization problem. Because the aim here and elsewhere in the engineering literature is to solve an engineering problem and not to model real ant colonies, various simplifications are assumed. Artificial ants differ from real ants in the following ways:

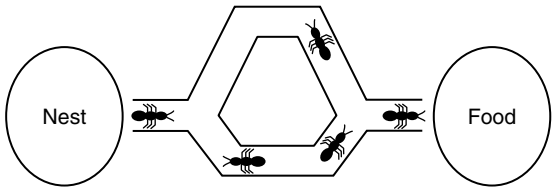

Figure 1. Ant foraging activity.

1. They are completely blind.
2. They have some memory.
3. They live in a discrete-time environment.

In order to explain the original ant-system algorithm, it is convenient to do so in the context of the classic traveling salesperson problem (TSP), which provided the original motivation for the algorithms. The basic TSP is formulated as follows: given N cities distributed randomly within the plane, find the shortest tour that visits each city only once and returns to the original city. The distance $d(i, j)$ between cities i and j with coordinates (x_i, y_i) and (x_j, y_j) is computed using the standard Euclidean norm. One can think of the problem in terms of a graph, where each pair of cities is potentially joined by an edge (i, j). The ants move around in this graph laying a pheromone trail with intensity $\tau(i, j)$ for each edge (i, j) they traverse. This trail can be updated locally as the ants move or can be updated globally at the end of an iteration when all ants have completed a tour. The global updating rule, which forms the basis of the ant-system algorithm, was shown to be superior to local rules in [29]. The ants are forced to complete a tour by maintaining a *tabu list* for each ant, which simply contains a list of the cities that the ant has already visited, and the ant is forbidden to revisit any city in the tabu list.

Given a state of the system at time t in a specific iteration, each ant k is at one of the cities. The probability that an ant will make the journey from city i to city j is assumed to be

$$P_k(i, j) = \frac{[\tau(i, j)]^\alpha [\eta(i, j)]^\beta}{\sum_{j \in J_k(t)} [\tau(i, j)]^\alpha [\eta(i, j)]^\beta} \tag{10}$$

where $J_k(t)$ are the allowed cities for ant k at time t, i.e., the complement of the tabu list. If j is not in $J_k(t)$, the transition is forbidden by setting $P_k(i, j) = 0$. In equation (10), $\tau(i, j)$ is the trail intensity associated with the edge (i, j). The *visibility* $\eta(i, j)$ is the inverse of the distance between cities i and j. This is included in order to allow a degree of greediness in the algorithm; the ants are more likely to move to a nearer city at a given step. This is not guaranteed to lead to a tour with overall minimum length as at step N; the ant may be very far from its starting city. The parameters α and β control the relative importance of trail and visibility. Note that the inclusion of visibility means that the ants are not totally blind in this variant of the algorithm. After N steps and the ants have completed a tour, the pheromone levels for each edge are updated using the rule

$$\tau(i, j) \longrightarrow \rho\tau(i, j) + \sum_{k=1}^{m} \tau_k(i, j) \tag{11}$$

where

$$\tau_k(i, j) = \frac{Q}{L_k} \tag{12}$$

if edge (i, j) is in the tour of the kth ant and $\tau_k(i, j) = 0$ otherwise. Q is a user-defined constant and L_k is the total tour length for ant k in that iteration. The total number of ants is m. The parameter ρ is also user defined. A number between 0 and 1 represents the trail persistence between iterations; $1 - \rho$ is a measure of trail *evaporation*.

This is how the ant-system algorithm is used to solve the TSP. In order to benchmark the code constructed to solve the sensor optimization problem here, the algorithm was applied to a known TSP problem—the Oliver30 problem. This was chosen as it was the problem used in the original ant-system paper [29]. Overall, 25 runs of the ant-system algorithm were carried out. The agreement between the runs was impressive. By 500 iterations, 16 of the runs had arrived at the best previously known solution, with a tour length of 423.74 (Figure 2).

Having established that the algorithm worked properly on the TSP problem, some modification was required before it could be applied to the SPO problem. The first important difference is that one is looking for an optimum subset of the candidate sensor locations and this means that a tour does not visit all locations. The second major difference is that the ants are truly blind. The sensor distributions can only be evaluated when all the members of the tour are known; there is no analog of visibility. The ant algorithm for SPO proceeds as follows. The ants are distributed randomly on the sensors with each edge initialized with the same trail intensity. At each step,

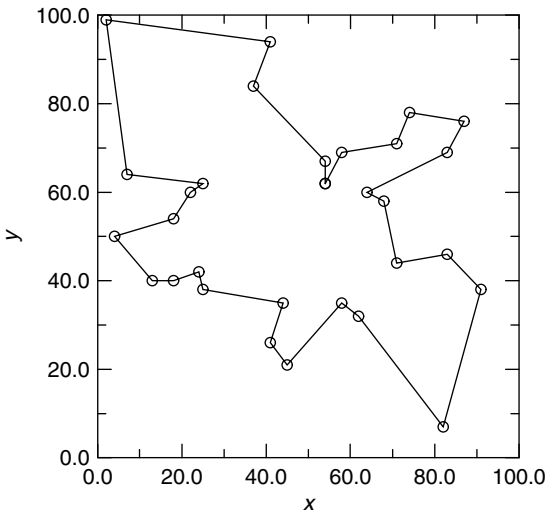

Figure 2. Best solution found to Oliver30 TSP problem.

each ant chooses a sensor to visit by means of a transition probability,

$$P_k(i, j) = \frac{\tau(i, j)}{\sum_{j \in J_k(t)} \tau(i, j)} \tag{13}$$

i.e., α is set arbitrarily to unity (and β is irrelevant). If the sensor has already been visited, transition is forbidden as before. The iteration ends when the required number of candidate locations has been visited. The (global) updating rule is very similar to the TSP variant,

$$\tau(i, j) \longrightarrow \rho\tau(i, j) + (1 - \rho) \sum_{k=1}^{m} \tau_k(i, j) \tag{14}$$

where $\tau_k(i, j) = F_k$, if (i, j) is in the tour for the kth ant and zero otherwise. F_k is the fitness of the kth tour, i.e., the value of the objective function to be maximized for the sensor distribution.

A little trial and error yielded 0.2 as a good initial trail level and the number of ants was taken as 10 simply because that led to optimum solutions in the Oliver30 TSP problem. The rationale behind the value of *persistence* ρ used is given later.

5.2 Impact test of the composite panel

A simple impact experiment was performed to study the effectiveness of NNs for the impact identification problem and also to experimentally investigate the optimal sensor location problem.

The structure under examination consisted of a rectangular 530 mm × 300 mm composite plate made from laminated carbon fibre reinforced plastic (CFRP) and four aluminum channels. The structure is shown in Figure 3. The top flanges of the channels were attached to the plate by a line of rivets; the bottom flanges were fixed rigidly with screws to a pneumatic measuring table. This box structure was intended to simulate the skin panel of an aircraft. The composite plate was instrumented with 17 piezoceramics (*PZT Sonox P5,* 15 mm × 15 mm) (*see* **Integrated Sensor Durability and Reliability**) fixed on the lower surface of the plate, the impacts being performed on the upper surface. The piezoceramics were used as strain sensors. Figure 4 shows the total distribution of the sensors used.

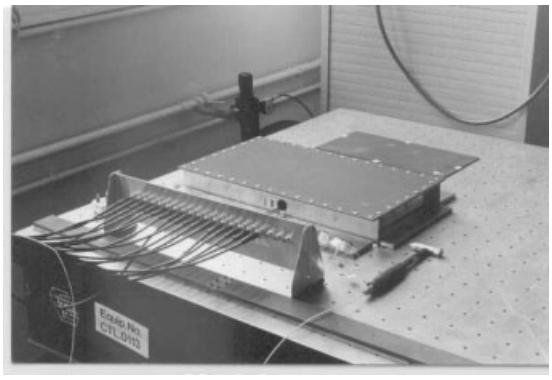

Figure 3. Composite box structure.

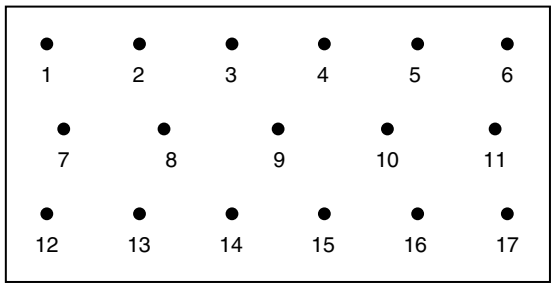

Figure 4. The candidate sensor locations.

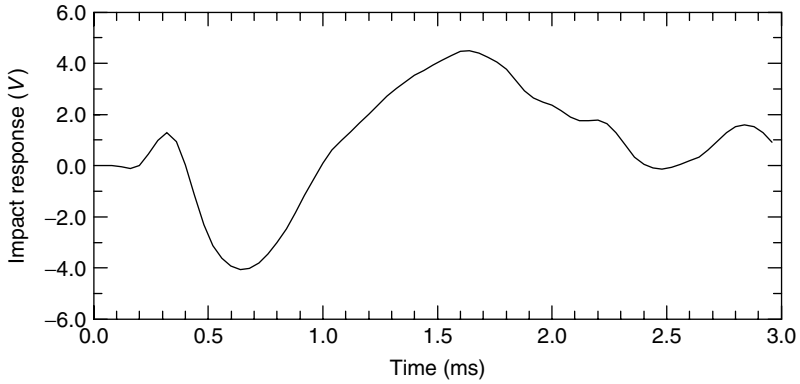

Figure 5. Example of a strain time-history.

The impacts were applied using a modally-tuned impact hammer. The levels of force applied were kept below 0.1 N in order not to damage the plate. As discussed below, two sets of measurements were made. The first comprised 80 impacts at random positions on the plate and was intended for use as network training data. The second set of measurements contained 95 impacts placed on a regular grid, and these were divided between the network validation and test sets: 48 in the former and 47 in the latter. In the validation and testing sets, each location was subjected to impacts of varying magnitudes.

The strain data were recorded using a DIFA SCADAS II 24 channel measuring system running the LMS 3.4.04 data-acquisition software. For each impact, 8192 samples were recorded at a frequency of 25 kHz. Figure 5 shows an example of the strain data recorded.

5.3 Impact identification strategy using neural networks

Before carrying out the subset optimization, a network training exercise was carried out using all 17 candidate sensors. This was in order to establish a lower bound for the error of the impact locator.

The NN paradigm used for this study was the standard multilayer perceptron (MLP) trained with the back-propagation learning rule. The particular implementation is described in more detail in [23].

The first problem in establishing the network analysis was to determine the appropriate features for the diagnosis, i.e., which data should be used to train the network. As described in [23], a preliminary study considered several different time and frequency domain features, namely, (i) time after impact of maximum response, (ii) magnitude of maximum response, (iii) peak-to-trough range of the response, and (iv) real and imaginary parts of the response *spectrum*, integrated over frequency. The features were investigated alone and in combination, and it was found that the best results were obtained using features A and B in tandem. This meant that each sensor contributed two features and the dimension of the pattern vectors for training was thus 34.

The next problem was to design the training strategy. A principled approach demanded the availability of three data sets. The first, the *training* set, is used to determine the network weights. The second, the *validation* set, is used to investigate the optimum structure for the network and the final *testing* set is used to assess the effectiveness of the optimized network. Part of the network training problem is to determine the best structure for the network, i.e., the number of layers and number of neurons per layer. The following approach was adopted as described in [31] and numerous structures were assessed. The number of neurons in the input and output layers of the network was fixed by the number of measurement features and diagnostic outputs, respectively. In this case, the network must have 34 inputs. As the network considered here was required to signal the location of damage, two outputs were required, namely, the x and y coordinates of the impact site. A single hidden layer was assumed, and the number of neurons in the layer was established by optimizing the network performance over the validation set; the

objective function used was the product of the mean x and y errors, i.e., the mean "area error". This was normalized to give a percentage of the plate area. Because the data sets are comparatively small, noise was added during training as a form of regularization. The root-mean-square (RMS) level of this noise was also established by minimizing the validation error.

For the location problem, the optimization procedure produced a minimum error over the validation set when there were eight neurons in the hidden layer and the RMS noise level was 0.1. When the corresponding network was evaluated on the testing set, the mean (modulus) of the x error was 23.1 mm and the mean y error was 25.7 mm. This gives an area corresponding to 1.5% of the plate area.

In order to have a tractable optimization problem, it was assumed that eight hidden units would also be the best choice when only a subset of the candidate sensor data was used for training. A similar assumption was made for the noise level. Following trial and error experiments, a training run of 100 000 iterations was applied.

5.4 Results

The algorithm summarized by equations (13) and (14) was used for the SPO problem here. The fitness F_k was evaluated as follows. If an ant k produced a certain tour at a given iteration, i.e., (1, 3, 7) in the search for an optimum three-sensor distribution, the NN was trained only with data from the sensors 1, 3, and 7. If this yielded an area error δA, the fitness was returned as $F_k = 1/\delta A$. Because the network structure was fixed, δA was taken from the validation set.

The main parameter controlling the efficiency of the algorithm was found to be the persistence ρ. Several values were experimented with, using a three-sensor search and the corresponding results from exhaustive search from [23] for comparison. Values of 0.95, 0.9, 0.8, and 0.5 were considered. As it was found that only $\rho = 0.9$ leads to the optimum under 59 iterations, this was chosen as the value for the runs. As observed above, 10 ants were used in each run and these were distributed randomly among the cities at initiation. A maximum of 50 iterations were allowed; this bounded the number of function evaluations at 500.

The method was demonstrated for finding a three-sensor distribution. The reason for this is that the number of candidate three-sensor distributions is 684 and it was feasible to compare the results of the optimization algorithms with those from exhaustive search. Also, three sensors are the minimum number that would be needed to locate the impact event from time-of-flight data using triangulation.

As the NN returns a value for the fitness that depends on the starting conditions for training, six separate exhaustive searches were carried out with different initial conditions. The best distribution found over the six runs was found to be 3 : 10 : 12 with an error of 1.99% (Table 1). As observed in [23], this solution agreed with engineering intuition in spacing the sensors in such a way as to effectively triangulate over a large area of the plate (Figure 6). When the GA was applied using the six sets of network starting conditions used for the exhaustive searches, it returned the same distribution (3 : 10 : 12) as the exhaustive search in every instance. In most of the cases, the GA found the optimal result faster than the exhaustive search would have.

For comparison, in 10 runs, the ant algorithm found the above solution once out of 10 runs, but

Table 1. Best three-sensor distributions from six exhaustive searches [23]

Search no.	Distribution	Area error (%)
1	3 : 12 : 17	2.16
2	8 : 11 : 12	2.15
3	1 : 3 : 17	2.15
4	3 : 12 : 14	2.19
5	3 : 7 : 11	2.13
6	3 : 10 : 12	1.99

Reproduced from Ref. 23. © Blackwell, 2000.

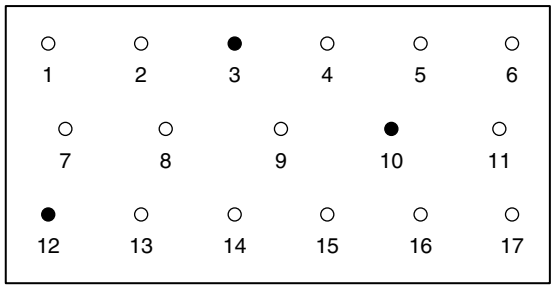

Figure 6. The optimal three-sensor distribution found by exhaustive search and by the genetic algorithm.

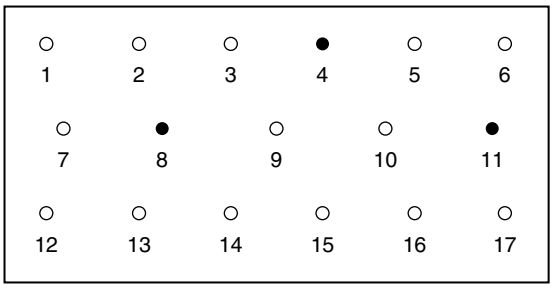

Figure 7. The optimal three-sensor distribution found by the ant colony algorithm.

also found a better solution with an error of 1.89% (distribution $4:8:11$ as shown in Figure 7). The average area error over the 10 runs was 2.11%. The ant algorithm found the optimal distributions faster than the exhaustive search would have.

5.5 Conclusions

The main conclusion of this article is that ant colony metaphors provide an effective solution to the SPO problem. The algorithm is shown to find the optimum in a problem with three sensors, which is amenable to an exhaustive search. Further, the optimal solution is discovered faster than when a GA is used. This result was not entirely expected, as the effect of the parameters α and β was investigated in [29] and it was found that searches based on pheromone alone ($\beta = 0$) were suboptimal.

6 REMARKS

The need for SPO techniques specific to SHM has been recognized, and promising approaches are emerging. Future methods are likely to be specific to the SHM methodology employed (as in the case investigated in [16] and the various NN approaches) and should be developed alongside them. A great number of techniques developed for other structural dynamics applications are also of use to the SHM practitioner. Techniques based upon maximizing the FIM determinant are widely used and represent a significant improvement on the *ad hoc* approaches of the past, with approaches based upon combinatorial optimization appearing to offer further significant advantages. This said, engineering judgment will always play a vital part in successful sensor placement and is pervasive in the application of SPO techniques.

In terms of the development of new algorithms, it is desirable that they should, wherever feasible, be compared with the results of an exhaustive search. This is admittedly limited to cases with low numbers of sensors in the candidate and measurement sets. Where the computational demands of exhaustive search prove prohibitive, "optimal" solutions should be validated both against randomly generated configurations, and against the configurations suggested by the symmetry of the analyzed structure. The robustness of the placement algorithm should be investigated to assess performance when factors such as sensor quantity and analytical model fidelity are altered. There remains a shortage of work concentrating on comparative studies of different approaches and validation of results. The former will give some guidance in engineering applications; the latter will increase confidence in the SPO methodology.

Wherever possible, successful numerical simulation should be followed by experimental study. Where sensor placement is being optimized for the purpose of SHM, extending the experimental study to cover the results of an SHM study would be informative, especially where comparison can be made between placement algorithms and exhaustive search results.

Chapter 71
Sensor Network Paradigms

Charles R. Farrar, Gyuhae Park and Kevin M. Farinholt
Engineering Institute, Los Alamos National Laboratory, Los Alamos, NM, USA

1 INTRODUCTION

Structural health monitoring (SHM) is the process of detecting damage in structures. The goal of SHM is to improve the safety and reliability of aerospace, civil, and mechanical infrastructure by detecting damage before it reaches a critical state. To achieve this goal, technology is being developed to replace qualitative visual inspection and time-based maintenance procedures with more quantifiable and automated damage assessment processes. These processes are implemented using both hardware and software with the intent of achieving more cost-effective, condition-based maintenance. A more detailed general discussion of SHM can be found in [1, 2].

The authors believe that all approaches to SHM, as well as all traditional nondestructive evaluation procedures (e.g., ultrasonic inspection, acoustic emissions, and active thermography) can be cast in the context of a statistical pattern-recognition problem [2, 3]. Solutions to this problem require four steps: (i) operational evaluation, (ii) data acquisition, (iii) feature extraction, and (iv) statistical modeling for feature classification; these form the statistical pattern-recognition paradigm for SHM. A specific topic that has not been extensively addressed in the SHM literature [4, 5] is the development of mathematically and physically rigorous approaches to designing the SHM sensing system that is used to address the data-acquisition portion of the problem. To date, most SHM system designs are done in a somewhat *ad hoc* manner where the engineer picks a sensing system that is readily available and that he or she is familiar with, and then attempts to demonstrate that a specific type of damage can be detected with that system. If an appropriate level of damage-detection fidelity cannot be obtained, then the system is modified in some empirical manner with the hope that the fidelity improves. Alternatively, as new sensing systems are developed by engineers outside the SHM field, researchers in this

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

field apply these systems to their respective SHM studies in an effort to see if these systems provide an enhanced damage-detection capability. Through these approaches, several sensor network paradigms for SHM have emerged, and this article summarizes and compares these paradigms. When making such a comparison, it should be noted that the authors do not believe there is one sensor network paradigm that is optimal for all SHM problems. All these paradigms have relative advantages and disadvantages. Also, the paradigms described are not at the same level of maturity and, hence, some may require more development to obtain a field-deployable system while others are readily available with commercial off-the-shelf solutions.

This article first addresses the data-acquisition portion of the paradigm, where the various parameters of the system that must be considered in its design and subsequent field deployment are summarized. Several sensor systems that have been developed specifically for SHM are then discussed in terms of these parameters. These sensor systems suggest the definition of three general SHM sensor network paradigms that are then described along with a summary of their relative attributes and deficiencies. A fourth sensor network that is currently under development is proposed that provides an alternative approach to sensing for SHM. This article also summarizes the practical implementation issues for SHM sensor systems in an effort to suggest a more mathematically and physically rigorous approach to future SHM sensing system design. The article concludes by referring the reader to fundamental axioms of SHM that have been proposed [6] and more specifically the subset of these axioms that address sensing issues for SHM.

2 DATA ACQUISITION FOR SHM

The *data-acquisition* portion of the SHM process involves selecting the excitation methods, the sensor types, number and locations, and the data-acquisition/storage/processing/transmittal hardware. The actual implementation of this portion of the SHM process is application specific. A fundamental premise regarding data acquisition and sensing is that these systems do not measure damage. Rather, they measure the response of a system to its operational and environmental loading or the response to inputs from actuators embedded with the sensing system. Depending on the sensing technology deployed and the type of damage to be identified, the sensor readings may be more or less directly correlated to the presence and location of damage. Data interrogation procedures (feature extraction and statistical modeling for feature classification) are the necessary components of an SHM system that convert the sensor data into information about the structural condition. Furthermore, to achieve successful SHM, the data-acquisition system has to be developed in conjunction with these data interrogation procedures.

Inherent in the data acquisition, the feature extraction and statistical modeling portions of the SHM process are data normalization, cleansing, fusion, and compression. As it applies to SHM, data normalization is the process of separating changes in sensor reading caused by damage from those caused by varying operational and environmental conditions [7]. Data cleansing is the process of selectively choosing data to pass on to, or reject from, the feature selection process. Data fusion is the process of combining information from multiple sensors in an effort to enhance the fidelity of the damage-detection process. Data compression is the process of reducing the dimensionality of the data, or the feature extracted from the data, in an effort to facilitate efficient information storage and to enhance the statistical quantification of these parameters. These four activities can be implemented in either hardware or software and usually a combination of these two approaches is used.

3 SHM SENSOR SYSTEM DESIGN CONSIDERATIONS

All sensor systems are deployed for one of the following applications:

1. detection and tracking problems;
2. model development, validation, and uncertainty quantification;
3. control systems.

SHM is a detection and tracking problem. The goal of any SHM sensor system development is to make

the sensor reading as directly correlated with, and as sensitive to, damage as possible (detection) and then have the sensor readings and associated damage-sensitive features extracted from these data change in a monotonic fashion with increasing damage levels (tracking). At the same time, one also strives to make the sensors as independent as possible from all other sources of environmental and operational variability. To best meet these goals for the SHM sensor and data-acquisition system, the following sensing system properties must be defined:

1. types of data to be acquired;
2. sensor types, number, and locations;
3. bandwidth, sensitivity, and dynamic range;
4. data acquisition/telemetry/storage system;
5. power requirements;
6. sampling intervals (continuous monitoring versus monitoring only after extreme events or at periodic intervals);
7. processor/memory requirements;
8. excitation source (active sensing).

Note that some sensor system properties are not independent. For example, increasing sensitivity usually is associated with decreasing dynamic range and increasing bandwidth is typically associated with decreasing frequency resolution. There can be even more issues that must be addressed when developing the sensing portion of the SHM process. Fundamentally, there are four issues related to a specific SHM application that control the selection of hardware to address these sensor system design parameters:

1. the length scales on which damage is to be detected;
2. the time scale on which damage evolves;
3. how varying and/or adverse operational and environmental conditions affect the sensing system;
4. cost.

In addition, the feature extraction, data normalization, and statistical modeling portions of the process can greatly influence the definition of the sensing system properties. Before such decisions can be made, two important questions must be addressed.

First, one must answer the question, "What is the damage to be detected?" The answer to this question must be provided in as quantifiable a manner as possible and address issues such as (i) type of damage (e.g., crack, loose connection, and corrosion), (ii) threshold damage size that must be detected, (iii) probable damage locations, and (iv) anticipated damage growth rates. The more specific and quantifiable this definition, the more likely it is that one will optimize one's sensor budget to produce a system that has the greatest possible fidelity for damage detection. Second, an answer must be provided to the question, "What are the environmental and operational variability that must be accounted for?" To answer this question, one will not only have to have some ideas about the sources of such variability, but one will also have to have thought about how to accomplish data normalization. Typically, data normalization is accomplished through some combination of sensing system hardware and data interrogation software. However, these hardware and software approaches are not optimal if they are not done in a coupled manner.

In summary, from the discussion in this section, it becomes clear that the ability to convert sensor data into structural health information is directly related to the coupling of the sensor system hardware development with the data interrogation procedures.

4 CURRENT SHM SENSING SYSTEMS

Sensing systems for SHM consist of some or all of the following components:

1. transducers that convert changes in the field variable of interest (e.g., acceleration, strain, and temperature) to changes in an electrical signal (e.g., voltage, impedance, and resistance);
2. actuators that can be used to apply a prescribed input to the system (e.g., a piezoelectric transducer bonded to the surface of a structure);
3. analog-to-digital (A/D) converters that transform the analog electrical signal into a digital signal that can subsequently be processed on digital hardware; for the case where actuators are used, a digital-to-analog (D/A) converter is also needed to change the prescribed digital signal to an analog voltage that can be used to control the actuator;
4. signal conditioning;
5. power;

6. telemetry;
7. processing;
8. memory for data storage.

The number of sensing systems available for SHM is enormous and these systems vary quite a bit depending upon the specific SHM activity. Two general types of SHM sensing systems are described below.

4.1 Wired systems

Here, wired SHM systems are defined as ones that telemeter data and transfer power to the sensor over a direct wired connection from the transducer to the central data analysis facility, as shown schematically in Figure 1. In some cases, the central data analysis facility is then connected to the internet such that the processed information can be monitored at a subsequent remote location. There are a wide variety of such systems. At one extreme is peak-strain or peak-acceleration sensing devices that notify the user when a certain threshold in the measured quantity has been exceeded. A more sophisticated system often used for condition monitoring of rotating machinery is a piezoelectric accelerometer with built-in charge amplifier connected directly to a hand-held, single-channel fast Fourier transform (FFT) analyzer. Here, the central data storage and analysis facility is the hand-held FFT analyzer. At the other extreme is custom-designed systems with hundreds of data channels containing numerous types of sensors that cost on the order of multiple millions of dollars such as the sensing system deployed on the Tsing Ma bridge in China [8].

There are a wide range of commercially available wired systems, some of which have been developed for general-purpose data acquisition and the others for SHM applications. Those designed for general-purpose data acquisition can typically interface with a wide variety of transducers and also have the capability to drive actuators. Most of these systems have integrated signal conditioning, data processing, and data storage capabilities and run off of AC power. Those designed to run off batteries typically have a limited number of channels and they are limited in their ability to operate for long periods of time.

One wired system that has been specifically designed for SHM applications consists of an array of piezoelectric lead zirconate titanate (PZT) patches embedded in a Mylar sheet that is bonded to a structure [9]. The PZT patches can be used as either an actuator or a sensor. Damage is detected, located, and, in some cases, quantified by examining the

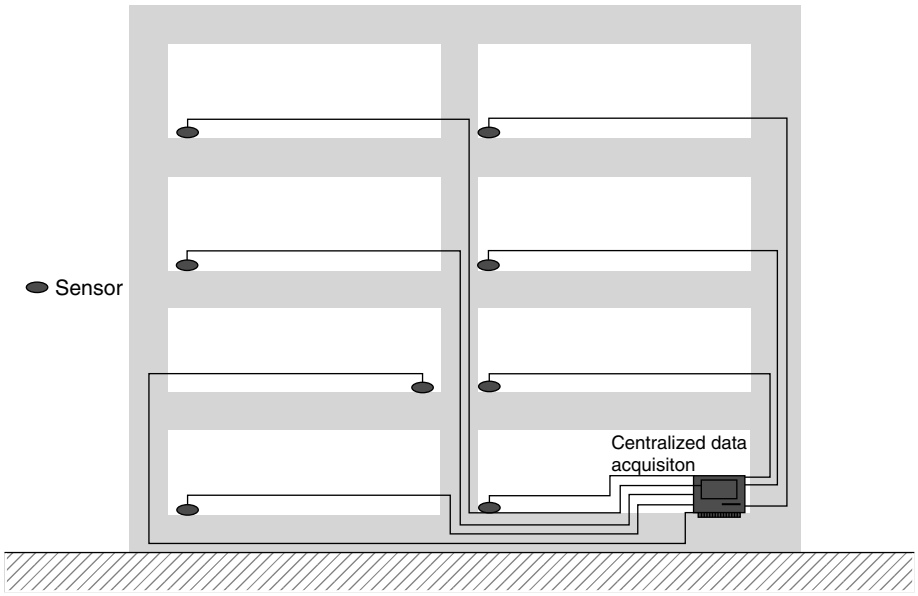

Figure 1. Paradigm I: a wired sensor network connected to a central data-acquisition system running off ac power.

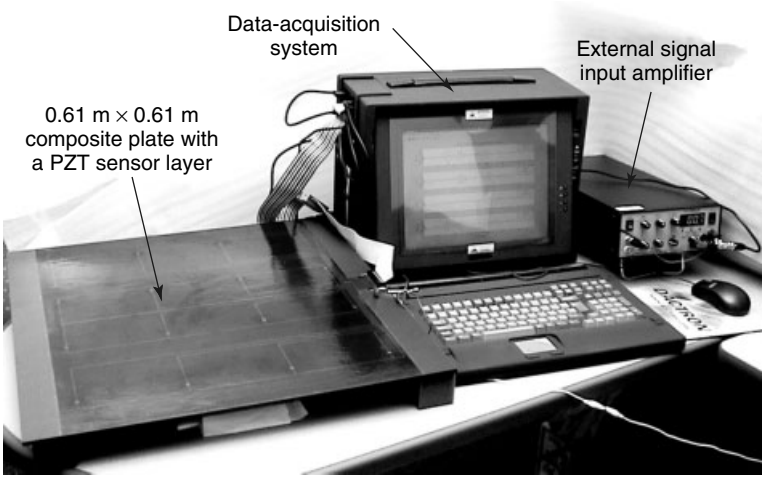

Figure 2. An example of a wired data-acquisition system designed specifically for SHM applications. This system consists of 16 piezoelectric patches in a Mylar sheet. The sensors are connected to a data-acquisition system through the ribbon wire.

attenuation of signals between different sensor–actuator pairs or by examining the characteristics of waves reflected from the damage. An accompanying computer is used for signal conditioning, A/D and D/A conversion, data analysis, and display of final results. The system, which runs on ac power, is shown in Figure 2. This system is described in more detail in **Stanford Multiactuator–Receiver Transduction (SMART) Layer Technology and Its Applications**.

4.2 Wireless transmission systems

More recently, researchers have been adapting general-purpose wireless embedded sensor nodes for SHM applications. Tanner *et al.* [10] modified an SHM algorithm to the limitations of commercial off-the-shelf wireless sensing and data processing hardware. A wireless sensing system of *motes* running TinyOS operating systems developed at the University of California, Berkeley, was chosen because of their commercial availability and their built-in wireless communication capabilities. A mote consists of modular circuit boards integrating a sensor, microprocessor, A/D converter, and wireless transmitter, all of which run off two AA batteries. A significant reduction in power consumption can be achieved by processing the data locally and only transmitting the results. The system was demonstrated using a small portal structure with damage induced by loss of preload in a bolted joint. The tested mote system is shown in Figure 3. However, the processor proved to be very limited, allowing only the most rudimentary data interrogation algorithms to be implemented. Another application of these sensor nodes to civil-engineering infrastructure can be found in **Wireless Sensor Network Platforms**.

Lynch *et al.* [11] presented hardware for a wireless peer-to-peer SHM system. Using off-the-shelf components, the authors couple sensing circuits and

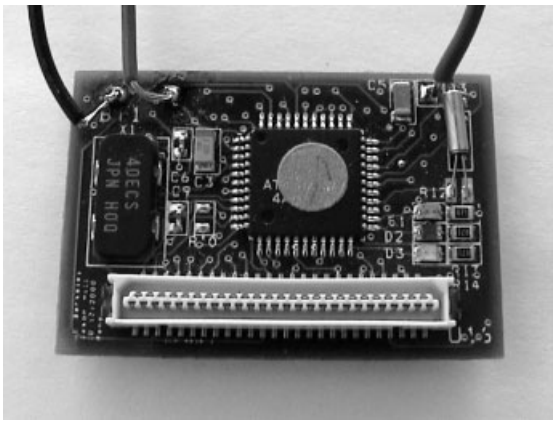

Figure 3. A mote sensor node that includes a microprocessor, sensor, A/D converter, and radio. A penny has been placed on the node for scale.

wireless transmission with a computational core allowing a decentralized collection, analysis, and broadcast of a structure's health. The final hardware platform includes two microcontrollers for data collection and computation connected to a spread spectrum wireless modem. The software is tightly integrated with the hardware and includes the wireless transmission module, the sensing module, and application module. The application module implements the time-series-based SHM algorithm. This integrated data interrogation process requires communication with a centralized server to retrieve model coefficients. The close integration of hardware and software with the dual microcontrollers strives for a power efficient design.

Spencer [12] provides the state-of-the-art review of current "smart sensing" technologies that includes the compiled summaries of wireless work in the SHM field using small, integrated sensor, and processor systems. A smart sensor is defined as a sensing system with an embedded microprocessor and wireless communication. Many smart sensors covered in this article are still in the stage where they simply sense and transmit data. The mote platform is discussed as an impetus for development of the next generation of SHM systems and a new generation of mote is also outlined. The authors also raised the issues that current smart sensing approaches scale poorly to systems with densely instrumented arrays of sensors that will be required for future SHM systems.

To develop a truly integrated SHM system, the data interrogation processes must be transferred to embedded software and hardware that incorporate sensing, processing, and the ability to return a result either locally or remotely. Most off-the-shelf solutions currently available, or in development, have a deficit in processing power that limits the complexity of the software and SHM process that can be implemented. Also, many integrated systems are inflexible because of tight integration between the embedded software, the hardware, and sensing. More recently, researchers have implemented distributed data interrogation algorithms where processing is done across the sensor network to enhance the computational capabilities of these sensor systems [13, 14].

To implement computationally intensive SHM processes, Farrar *et al.* selected a single board computer as a compact form for increased processing power [15]. Also included in the integrated system is a digital signal-processing board with six A/D converters providing the interface to a variety of sensing modalities. Finally, a wireless network board is integrated to provide the ability for the system to relay structural information to a central host, across a network, or through local hardware. Figure 4 shows the prototype of this sensing system. Each of these hardware parts are built in a modular fashion and loosely coupled through the transmission control protocol or Internet protocols. By implementing a common interface, changing or replacing a single component does not require a redesign of the entire system. By allowing processes developed in the Graphical Linking and Assembly of Syntax Structure (GLASS) client to be downloaded and run directly in the GLASS node software, this system became the first SHM hardware solution where new processes can be created and loaded dynamically. This modular nature does not lead to the most power optimized design, but instead achieves a flexible development platform that is used to find the most effective combination of algorithms and hardware for a specific SHM problem. Optimization for power is of secondary concern and will be the focus of follow-on efforts [15].

5 SENSOR NETWORK PARADIGMS

The sensor systems discussed in the previous section have led to three types of sensor network paradigms that are either currently being used for SHM or are the focus of current research efforts in this field. These paradigms are described below. Note that the illustrations of these systems show them applied to a building structure. However, these paradigms can be applied to a wide variety of aerospace, civil, and mechanical systems, and the building structure is simply used for comparison purposes.

5.1 Sensor arrays directly connected to central processing hardware

Figure 1 shows a sensor network directly connected to the central processing hardware. Such a system is the most common one used for SHM studies. The advantage of this system is the wide variety of commercially available off-the-shelf systems that can

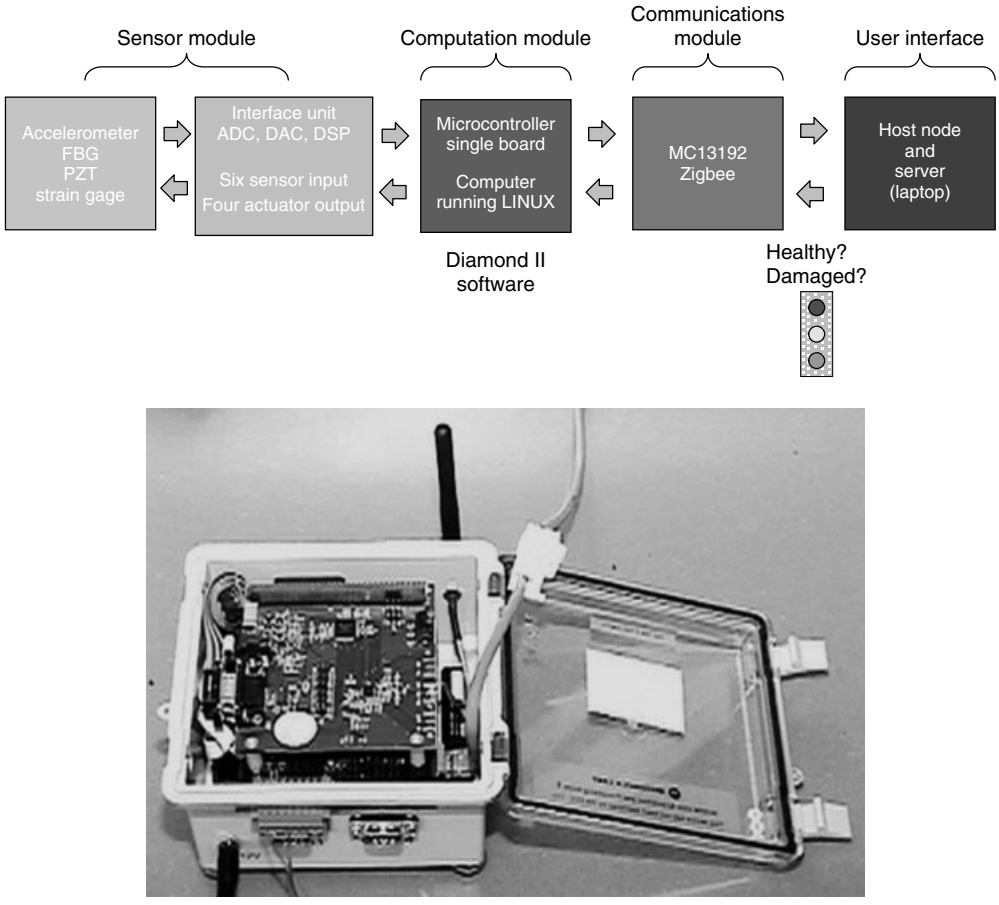

Figure 4. A sensor node incorporating a single board computer to increase processing power. Also included in the system is a digital signal-processing board with six A/D converters that interface to a variety of sensing modalities and a wireless network board that provides the ability to relay information to a central host, across a network, or through local hardware.

be used for this type of monitoring and the wide variety of transducers that can typically be interfaced with such a system. For SHM applications, these systems have been used in both a passive and active-sensing manner. Limitations of such systems are that they are difficult to deploy in a retrofit mode because they usually require ac power, which is not always available. Also, these systems are one-point failure sensitive as one wire can be as long as a few hundred meters. In addition, the deployment of such a system can be challenging with potentially over 75% of the installation time attributed to the installation of system wires and cables for large-scale structures such as those used for long-span bridges [16]. Furthermore, experience with field-deployed systems has shown that the wires can be costly to maintain because of general environmental degradation and damage caused by things such as rodents and vandals.

5.2 Decentralized processing with hopping connection

The integration of wireless communication technologies into SHM methods has been widely investigated to overcome the limitations of wired sensing networks. Wireless communication can remedy the cabling problem of the traditional monitoring system and significantly reduce the maintenance cost. The schematic of the decentralized wireless monitoring

system, which is summarized in detail by Spencer *et al.* [12], is shown in Figure 5.

From the large-scale SHM practice, however, several very serious issues arise with the current design and deployment scheme of the decentralized wireless sensing networks [12, 17]. First, the current wireless sensing design usually adopts *ad hoc* networking and hopping that result in a problem referred to as *data collision*. Data collision is a phenomenon that results from a network device receiving several simultaneous requests to store or retrieve data from other devices on the network. With increasing numbers of sensors, a sensor node located close to the base station will experience tremendous data transmission, possibly resulting in a significant bottleneck. Because the workload of each sensor node cannot be evenly distributed, the chances of data collision increase with expansion of the sensing networks. In addition, this decentralized wireless sensing network scales very poorly in active-sensing system deployment. Because active sensors can serve as actuators as well as sensors, the time synchronization between multiple sensor/actuator units is a challenging task. Because of the processor scheduling or sharing, the use of multiple channels on one sensor node would reduce the sampling rate, which provides neither a practical nor equitable solution for active-sensing techniques that typically interrogate higher frequency ranges. Therefore, for *in situ* applications, the current design scheme can potentially be a very expensive operation.

5.3 Decentralized processing with hybrid connection

The hybrid connection network advantageously combines the previous two networks, as illustrated in Figure 6. At the first level, several sensors are connected to a relay-based piece of hardware, which can serve as both a multiplexer and general-purpose signal router, shown in Figure 6 as a black box. This device will manage the distributed sensing network, control the modes of sensing and actuation, and multiplex the measured signals. The device can also be expanded by means of daisy-chaining. At the next level, multiple pieces of this hardware are linked to a decentralized data control and processing station. This control station is equipped with data-acquisition boards, on-board computer processors, and wireless telemetry, which is similar to the architecture of current decentralized wireless sensors. This device will perform duties of a relay-based hardware control, data acquisition, local computing, and transmission of the necessary results of the computation to the central system. At the highest

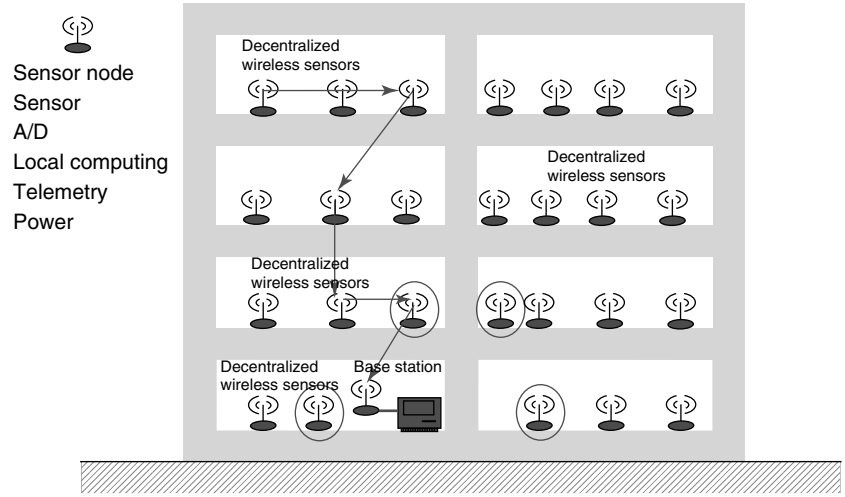

Figure 5. Paradigm II: decentralized processing with each sensor node running off battery power and utilizing a "hoping" telemetry protocol. The "mote" shown in Figure 3 is one such sensor node that can be deployed to form this type of sensor network.

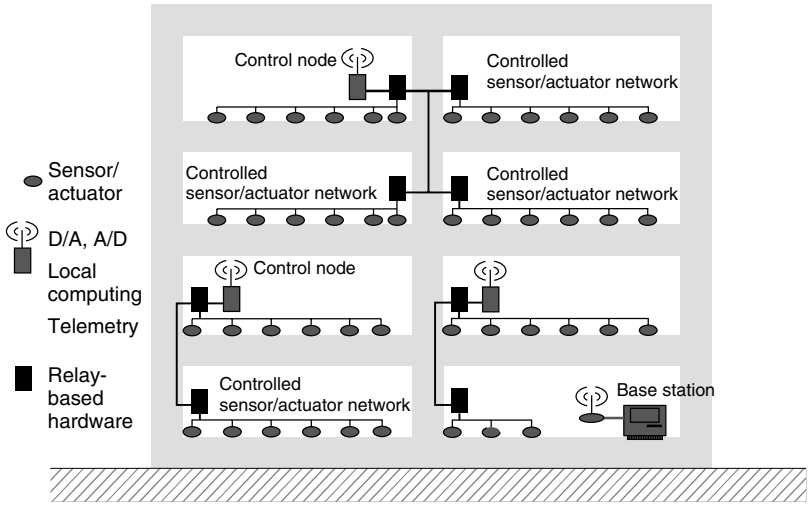

Figure 6. Paradigm III: a hybrid decentralized sensor system with local multiplexing and a hopping telemetry protocol.

level, multiple data processing stations are linked to a central monitoring station that delivers a damage report back to the user. Hierarchal in nature, this sensing network can efficiently interrogate large numbers of distributed sensors and active sensors while maintaining an excellent sensor–cost ratio because only a small number of data acquisition and telemetry units is necessary. This hierarchal sensing network is especially suitable for active-sensing SHM techniques, and is being investigated by Dove *et al.* [17]. In their study, the expandability or the sensing network was of most importance for significantly larger numbers of active sensors, as the number of channels on a decentralized wireless sensor is limited because of processor sharing and scheduling. The prototype of the relay-based hardware ("black box" shown in Figure 6) is illustrated in Figure 7.

6 FUTURE SENSING NETWORK PARADIGMS

The sensing network paradigms described in the previous section have one characteristic in common. The sensing system and associated power sources are installed at fixed locations of the structural system. As previously stated, the deployment of such sensing systems can be costly and the power source may not be always available. A new, energy-efficient future sensing network is currently being investigated collaboratively by Los Alamos National Laboratory and the University of California, San Diego, and is shown in Figure 8. This system couples energy-efficient embedded sensing technology and remote interrogation platforms based on either robots or unmanned aerial vehicles (UAV) to assess damage in structural systems [18]. This approach involves using an unmanned mobile host node (delivered via UAV or robot) to generate radio frequency (RF) signal near the receiving antennas connected to sensor nodes that have been embedded on the structure. Once a capacitor on the sensor node is charged by the RF energy emitted from the node on the UAV, the sensors measure the desired response (impedance, strain, etc.) at critical areas on the structure and transmit the signal back to a processor on the mobile host.

Figure 9 shows a sensor node that has been developed for this mode of remote powering and telemetry. This sensor node uses a low-power integrated circuit that can measure, control, and record an impedance measurement across a piezoelectric transducer. The sensor node integrates several components, including a microcontroller for local computing and sensor node control, a radio for wireless data transmission, multiplexers for managing up to seven piezoelectric transducers per node, energy storage mediums, and several triggering options including a wireless triggering into one package to realize a comprehensive, self-contained wireless active-sensor node for SHM applications. It was estimated that this sensor

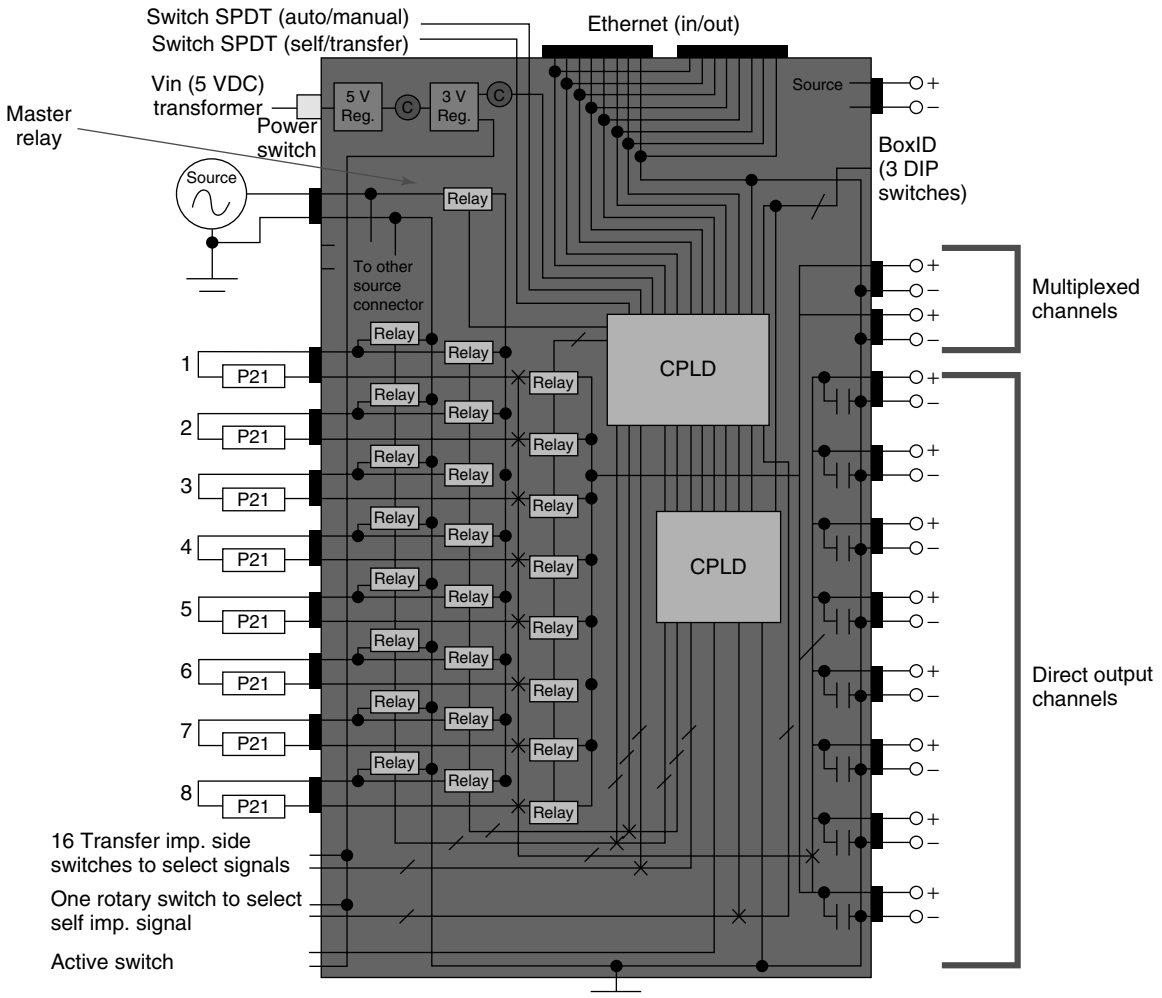

Figure 7. The relay-based hardware shown as a black box in Figure 6. This device manages the distributed sensing network, controls the modes of sensing and actuation, and multiplexes the measured signals.

node requires less than 60 mW of total power to operate, measure, compute, and transmit. Considering this amount of power consumption, the sensor node is within the range of the wireless energy transmission capabilities provided by the host node on the UAV as well as for energy harvesting devices such as small solar arrays.

One UAV with its power source, telemetry, and computing can be used to interrogate an entire sensor array placed on the structure and then can be used for other structures that have similar embedded sensor arrays. A recent field demonstration of this sensor network strategy is shown in Figure 10 where a remotely controlled helicopter was used to deliver power to sensor nodes mounted on a bridge structure. The next generation of this system will take traditional sensing networks to the next level of autonomy, as the mobile hosts (such as UAV), will fly to known critical infrastructure based upon a global positioning system (GPS) locator, deliver the required power, and then perform the SHM assessment without human intervention. This technology will be directly applicable to rapid structural condition assessment of buildings and bridges after an earthquake, where the sensor nodes may need to be deployed for decades during which conventional battery power will be

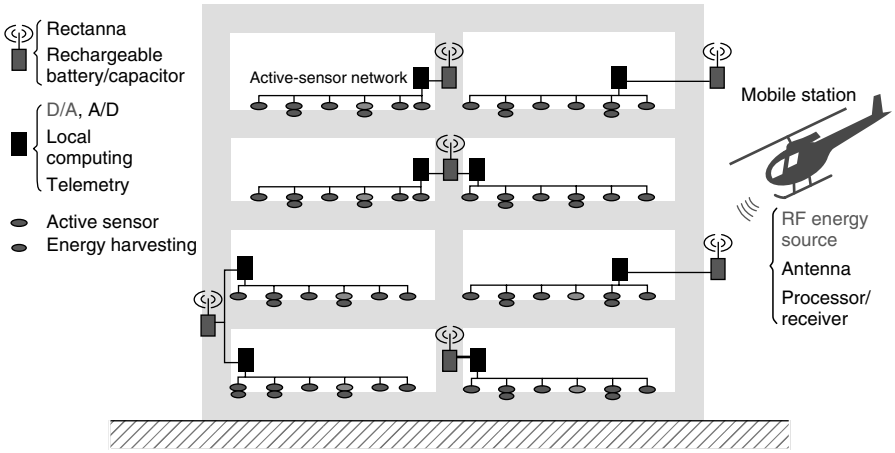

Figure 8. A new sensor network strategy where power and processing are brought to the sensor nodes on a robotic device. The sensor nodes are powered on demand by means of wireless energy transmission.

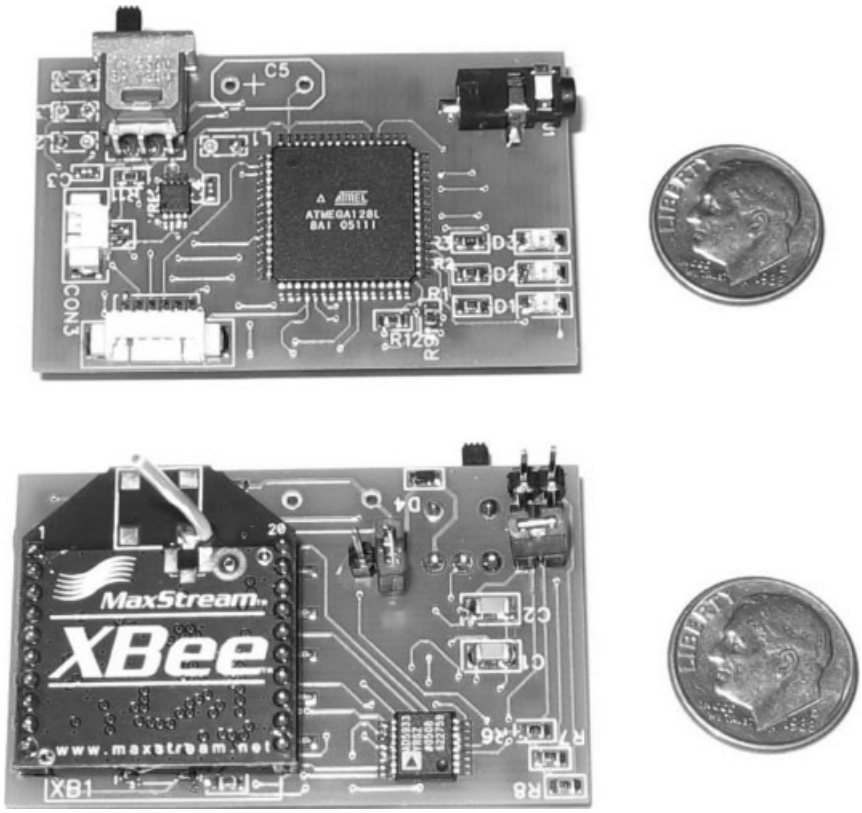

Figure 9. The sensor node that has been designed to receive power wirelessly from a remote host as depicted in Figure 8. This sensor node can measure impedance across up to seven piezoelectric sensors.

depleted. Also, this technology may be adapted and applied to damage detection in a variety of other civilian and defense-related structures such as nuclear power plants where it is advantageous to minimize human exposure to hazardous environments during the inspection process. A review of other applications of robotic devices for SHM sensing can be found in [19].

7 PRACTICAL IMPLEMENTATION ISSUES FOR SHM SENSING NETWORKS

A major concern in the current sensing network development is the long-term reliability of the network and how to power the network. Other concerns are the abilities of the sensing systems to capture local and system level response, that is, the need to capture response on widely varying length and time scales, and to archive data in a consistent, retrievable manner for long-term analysis. These challenges are nontrivial because of the tendency for each technical discipline to work more or less in isolation. Therefore, an integrated systems engineering approach to the damage-detection process and regular, well-defined routes of information dissemination are essential. The subsequent portions of this article address specific sensing system issues associated with SHM.

7.1 Sensor properties

One of the major challenges with defining sensor properties is that these properties need to be defined *a priori* and typically cannot be changed easily once a sensor system is in place. These sensor properties include bandwidth, sensitivity (dynamic range), number, location, stability, reliability, cost, telemetry, etc. To address this challenge, a coupled analytical and experimental approach to the sensor system deployment should be used in contrast with the *ad hoc* procedures used for most current damage-detection studies. First, critical system failure modes should be well-defined in as quantifiable a manner as possible, using high-fidelity numerical simulations or from previous experiences, before the sensing system is designed. The high-fidelity numerical simulations/experiences can be used to define the required bandwidth, sensitivity, sensor location, and sensor

number. Additional sensing requirements can also be ascertained if changing operational and environmental conditions are included in the models so as to determine how these conditions affect the damage-detection process. The outcome of such analyses may indicate that additional sensors are needed to quantify the effects of varying operational and environmental conditions on the damage-detection process. As an example, it has been shown that the dynamic properties of a bridge structure vary significantly with temperature [20]; however, a measure of ambient air temperature does not correlate with the change in dynamic properties. Instead, it was found that the change in dynamic properties was correlated with the temperature differential across the bridge, which implies the need for multiple temperature sensors in the sensing system.

Another potential level of integration between modeling and sensing resides in the integration of software and hardware components. Once the actuation and sensing capability has been selected, their location has been optimized for damage observability, and the specifications of the data-acquisition system have been met, it may be advantageous to integrate model output and sensing information as much as possible. For example, surrogate models can be programmed on local digital signal-processing chips and their predictions can be compared to sensor output in real time. One obvious benefit would be to minimize the amount of communication by integrating the analysis capability with real-time sensing. In an integrated approach, features can be extracted from sensing data and numerical simulation. Test-analysis comparison and parameter estimation can then be performed locally, which would greatly increase the efficiency of the damage-detection process.

7.2 Power consideration

A major consideration in using a dense sensor array is the problem of providing power to the sensors. This demand leads to the concept of "information as a form of energy". Deriving information costs energy. If the only way to provide power is by direct connections, then the need for wireless communications protocols is eliminated, as the cabled power link can also be used for the data transmission. However, if a wireless communication protocol is used, the development of micropower generators will provide significant advantages over battery power sources as the concept of autonomous embedded sensing cannot be realized if one has to periodically replace batteries. A possible solution to the problem of localized power generation is technologies that enable harvesting ambient energy to power the sensor nodes [21, 22] (*see* **Energy Harvesting and Wireless Energy Transmission for SHM Sensor Nodes**, **On the Way to Autonomy: the Wireless-interrogated and Self-powered "Smart Patch" System**; and **Energy Harvesting using Thermoelectric Materials**). Forms of energy that may be harvested include thermal, vibration, acoustic, and solar. Because such energy harvesting is somewhat new technology, the overriding consideration of reliability still exists, as it does with other components of the monitoring system. With two-way communication capability, the local sensing and processing units can also turn themselves off or go into a "sleep" mode for energy conservation and they can be resuscitated when a "wake-up" signal is broadcast. This approach to power management is discussed in detail in [22].

7.3 Sensor calibration, stability, and ruggedness

When discussing calibration, stability, and ruggedness, it must be clear that these concepts are applied to the entire sensor system and not just the sensor itself. Calibration is the process of determining the relationship between the field variable to be measured and the electrical signal generated by the sensor. Stability refers to how the calibration varies with time. Because SHM involves a comparison of measured response before and after a damaging event, stability is the more critical property for SHM sensor systems. Well-defined sensor calibration procedures exist, but approaches for establishing sensor stability are less well-defined. Most sensors are calibrated at a specialized calibration facility with well-established protocols and standards. This type of calibration is expected to endure, but for embedded sensor systems it needs to be supplemented by incorporating a self-diagnosing and self-calibrating capability into the sensors. In some cases, measurements are acceptable

with 20% error, as long as this error remains constant from one measurement to another one made at some future time. In other scenarios, absolute accuracies are necessary to ensure that the sensor has the fidelity to measure the changes in system response associated with the onset of damage.

Ruggedness of the sensors is a prime consideration for SHM. If part of the system is compromised, then the overall confidence in the system performance is undermined. For sensors implemented for SHM, several ruggedness considerations emerge:

1. The nontrivial problem of sensor selection for extreme environments (e.g. in-service turbine blades exposed to extreme temperatures, high-temperature components of an oil refinery and fluid systems of nuclear power plant that are exposed to radiation fields).
2. Sensors may be less reliable than the component they are monitoring—for example, reliable parts may have failure rates of 1 in 100 000 over several years time. Sensors are often small, complex assemblies with built-in microelectronics, so sensors subjected to the same operational and environmental loading conditions may fail more often than the component being monitored. Loss of sensor signal may then be falsely interpreted as component failure, not sensor failure.
3. Sensors may fail through outright sensor destruction while the component being monitored endures.

False indications of damage or damage precursors are extremely undesirable. If this occurs often, the sensor is either overtly or covertly ignored. Recently, several studies have focused on issues of sensor validation [23, 24]. However, in general, there is little data on the long-term stability and ruggedness of SHM sensor systems.

7.4 Multiscale sensing

Depending on the size and location of the structural damage and the loads applied to the system, the adverse effects of the damage can be either immediate or may take some time before it alters the system's performance. In terms of length scales, all damage begins at the material level and then under appropriate loading conditions progresses to component and system level damage at various rates. In terms of time scales, damage can accumulate incrementally over long periods of time such as that associated with fatigue or corrosion. Damage can also occur on much shorter time scales because of scheduled discrete events such as aircraft landings and from unscheduled discrete events such as enemy fire on a military vehicle. Therefore, the most fundamental issue that must be addressed when developing a sensing system for SHM is the need to capture the structural response on widely varying length and time scales.

The sensing systems that are able to capture the responses over varying length and time scales have not been substantially investigated by researchers, although it is quite possible to use the same piezoelectric patches in both an active, high-frequency mode and in a passive mode to capture the lower-frequency global response of the system. As an example, in the active mode, the piezoelectric sensors can be used to detect and locate damage on a local level using relatively higher frequency excitation and response measurements. This type of active sensing can be used to detect delamination in the composite skin on the wing of an unmanned aerial vehicle. In addition, the same sensors can be used in a passive mode to monitor the low-frequency global modal response of the wing when it is subjected to aerodynamic loading. This global response data can be used to assess the effect of the delamination on the flutter characteristics of that aircraft as determined by analysis of the coupling between the first bending and torsion mode of the wing.

7.5 Sensor–actuator optimization

Few researchers have addressed the issue of developing a systematic approach to the design of a sensor system for SHM. In very general terms, one approach is to consider the sensor system design as a constrained optimization problem. An example, of one such study that employed machine learning to optimize sensor number and location is given in [25]. In terms of a constrained optimization problem, the designer would like to maximize the "damage observability" subjected to a wide variety of possible constraints such as cost, weight, power (when active

sensing is used), and allowable locations. A challenge to actually implementing this approach is coming up with accurate mathematical definitions for damage observability and its relation to the various sensor system properties. This challenge is confounded by the fact that quite a few sensor system parameters may influence observability and the interactions between these various parameters may not be well understood.

One approach to solve the optimization problem is to determine (or assume) that a particular sensor to be employed has a certain damage-detection resolution (i.e., can detect a 1-mm crack through the thickness of a plate within 15-cm radius of the sensor). Then assume that you have an infinite number of sensors, which in turn maximizes observability. Next, optimization procedures such as genetic algorithms or gradient descent methods are used to maximize the observability while retaining some fraction of the infinite sensor array. This process produces a sensor layout with a minimum number of sensors placed at locations that maximize damage observability. Note that this optimization problem will become much more complicated when "real-world" issues such as operational and environmental variability have to be addressed. Also, one must consider the trade-offs between an optimal sensing system and a redundant sensing system. If one sensor or sensor node fails in an optimal system, it is most likely no longer optimal.

With the advent of active-sensing approaches, there can be SHM applications where the excitation is selectable, and, this excitation should be chosen to maximize damage observability. As a simple example, consider a beam or column with a crack that is nominally closed because of a preload. If the provided excitation is not sufficient to open and close the crack, the detectability of the crack in the measured output will be severely limited. Thus, if possible, it is important to answer the question: "Given ever-present physical limits on the level of excitation, and limited outputs that can be measured, what excitation should be provided to a system to make damage most detectable?" When one considers that an excitation may be viewed as a time series with hundreds or thousands of free parameters, optimization in this high-dimensional space might be a daunting task. However, as is demonstrated in [26, 27], a gradient-based technique may be used in which the gradient can be calculated very efficiently. This method does require a model of the system and the accuracy of that model will influence the results.

8 SUMMARY

In this article, the current sensor system design research that is being done to address the data-acquisition portion of the SHM problem is summarized. Several sensor systems that have been developed specifically for SHM are discussed. These sensor systems lead to the definition of several general SHM sensor network paradigms. All of these paradigms have relative advantages and disadvantages. Also, the paradigms described are not at the same level of maturity and, hence, some may require more development to obtain a field-deployable system, while others are readily available with commercial off-the-shelf solutions. At this time, no formal and accepted design methodology exists for the development of an SHM sensing system. As such, this article has also summarized practical implementation issues associated with the SHM sensor system in an effort to suggest the need for a more mathematically and physically rigorous approach to future SHM sensing system design. Finally, it should be noted that recently fundament axioms for SHM have been proposed [6] on the basis of the information published in the extensive amount of literature on SHM over the last 20 years. Of the eight axioms proposed in this article, seven are closely related to sensing aspects of the SHM problem and, therefore, should be considered when designing any SHM sensor network.

1 INTRODUCTION

Structural health monitoring (SHM) is increasingly being considered as a means of not only obtaining data related to the response of components and structural systems but also as a means of providing an assessment of the "health" of the system. While there are still substantial differences of opinion regarding the scope and applicability of SHM (i.e., does the system merely relate to the collection of data and provision of a rudimentary knowledge of response, or does it actually serve as an autonomous or semiautonomous means of interpreting structural state in terms of characteristics such as capacity, remaining life, and necessity of repair), there is no doubt that the appropriate implementation of such a system can provide significant information of value to the owner, hitherto not available either in the same timescale or in quantity/depth, or both. In fact, recent developments in this field have led to the introduction of the term *civionics* to describe the "hardware and physical installation of the sensors, wires, conduits, termination, and control boxes" [1], which complements SHM in terms of a system that enables the acquisition and interpretation of data beyond that represented by traditional nondestructive evaluation (NDE).

Currently, civil infrastructure systems such as bridges, pipelines, waterways, and buildings are inspected at routine intervals till significant distress is noted, after which the period between inspections is decreased and the level of inspection is increased till such time that the distress has been corrected by replacement or repair. This time-based monitoring is inefficient not just in terms of resources but also since it does not minimize "downtime" of the structure. Since civil infrastructure forms a critical part of a nation's well-being, its deterioration has immense effect on the economies of the region, as it serves as the basis for the transfer of goods and services. The decrease in "downtime" due to maintenance, rehabilitation, or even rapid replacement is

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

a critical aspect that needs to be addressed, and hence a move to a condition-based assessment of structures is advantageous. The implementation of condition-based assessment, however, requires that changes in structural response be monitored as a result of both normal operation and extreme events. This can be done through the implementation of a true SHM system, which could enable autonomous and continuous recording and assessment of predetermined response parameters associated with materials, components, and/or the entire system.

The development of an SHM system is essentially based on the ability to acquire data, transmit it, interrogate it, and then make decisions based on the cumulative sets of data stored in the database. Thus, in effect, the SHM system is essentially a decision system that is fronted by sensors and backed by a knowledge base, the critical elements of which are represented in Figure 1.

Tremendous advances in technologies related to sensor technologies, data compression and transmission, and interrogation make the deployment of an SHM system substantially easier today than in the past. For example, advances in image capture and analysis have made it possible to track vehicles in traffic for purposes of transportation planning such that vehicles can be tracked and classified over long periods of time to accumulate large volumes of tracking data, which can then be used to build models consisting of the traffic flow parameters such as density, flow, and speed [2]. In addition, tracking data can be used for event detection and definition of normal motion paths for detection of abnormal events, as shown schematically in Figure 2.

In addition, systems have already been developed and implemented for the rapid assessment of pavement condition in terms of the presence and extent of pavement cracks, potholes, and other damage, which can disrupt the smooth and efficient flow of traffic and overall safety. For example, the Hanshin Expressway Public Corporation (HEPC) in Japan has implemented an intelligent inspection system based on the use of Charge Coupled Device (CCD) cameras, laser emitters, and image-processing techniques—all on board vehicles that continuously traverse the road network to obtain data, which is then transmitted and used from a central location [3]. In this, as in other SHM systems, the main components are those of (i) data acquisition, (ii) data transmission, (iii) data processing and interrogation, (iv) data storage, (v) data retrieval, and (vi) diagnostics of long-term response. While a number of these aspects can be performed through direct assessment systems without need for comparison of historical data or excessive diagnostics, this hinders the full development of an SHM system that would enable true diagnosis and prognosis of a structure and the system that it is a part of (for example, a single bridge within a network

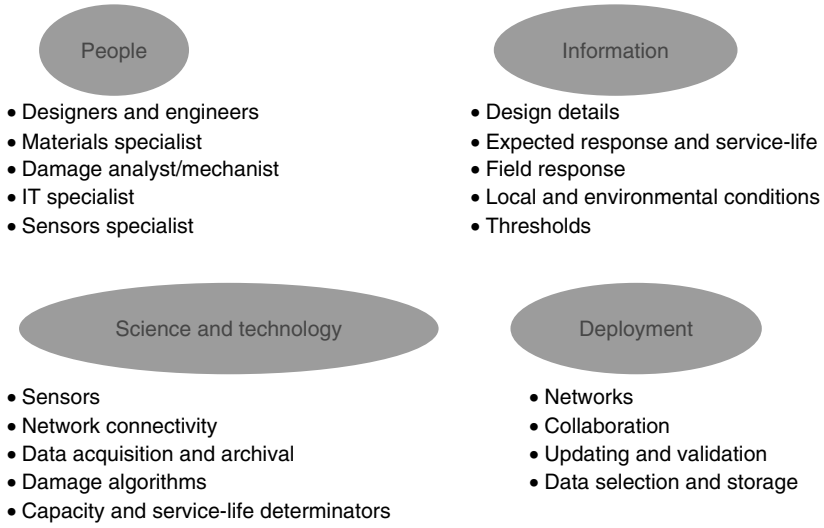

Figure 1. Critical elements of an SHM system.

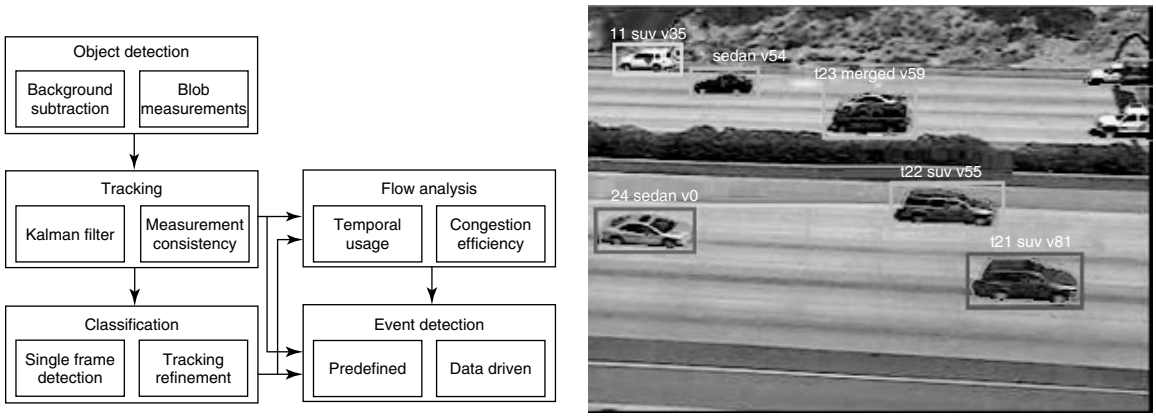

Figure 2. Schematic and basis for tracking of vehicles. [Courtesy of Mohan Trivedi, UCSD.]

of highways that have multiple bridges on them). For efficient use of such a system, it is incumbent that the SHM system be able to semiautonomously compare response at any point in time, not just with preset thresholds of performance but also with prior data to assess trends and develop self-learning models that can be used to predict future response. In addition, it is critical that the user be able to assess information rapidly about not just single structures but also about networks, so as to enable the assessment of the effect of deterioration in one element on the entire system and to thereby enable dynamic resource allocation. For example, in the case of earthquakes, it would be useful to be able to pull up, using regional maps, the location of critical structures, interrogate their health from a remote location, and reach decisions on which ones need immediate attention in terms of resources. All these aspects are best suited to be addressed through a web-based monitoring system.

2 COMPONENTS OF A WEB-BASED SHM SYSTEM

The essential components of a web-based SHM system are shown in Figure 3.

Data is collected from suites of sensors on individual structural components or systems and is brought back to a central location. While wireless systems are becoming ubiquitous, it must be remembered that vast amounts of data transmission, while possible, need large bandwidths. Depending on the location of the structures being monitored, it may be better to have packets of data sent at predetermined intervals, rather than on a continuous basis. Further, it may, in fact, be better to have the SHM itself be triggered to collect data only when specific thresholds are reached or exceeded (weight, deflection, acceleration, etc.). Once this data is brought into the system, it can be directly stored keeping in mind that storage can itself be a major issue. It is thus necessary to have a methodology in place by which data is assessed for storage through selection of "typical" sets for storage, events and novelties, and comparison with previously collected sets, and to store only the required values (such as maxima, minima, averages, etc.). The development and implementation of an appropriate selection and archival plan is essential, especially if the web-based SHM system is used for a large number of structures. A powerful backend database to manage raw data and analysis is essential in these cases. Data itself can be processed using both model-free and model-based approaches, which when compared to structural response models and thresholds can provide important characteristics for decision making. For a true level IV SHM system, it is important that the analysis tools be linked to predictive and "what-if" capabilities to provide the results that are of use to the owner/engineer in making decisions. A prototype system for web-based monitoring is used to demonstrate the requirements in the next section.

The value of the web-based system is threefold. First, it allows for direct assessment of data sets, both streaming and stored, by the user, using a forum

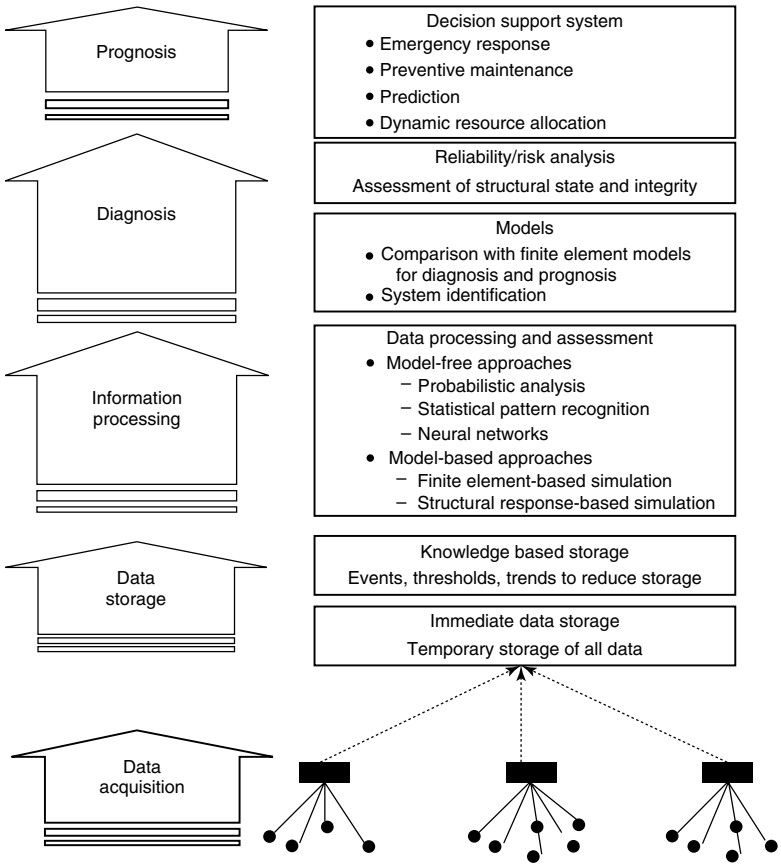

Figure 3. Components of a web-based SHM system.

that is now ubiquitous for rapid access of information. Secondly, it can be programmed to not only provide views of the data in sets chosen by the user (i.e., different users could simultaneously, from different sites, access different sets of sensors based on choices made from preset suites, or from the entire set) but to also interrogate the data, based on predetermined thresholds so as to enable rapid assessment of structural response. Thirdly, the use of a web-based schema allows for autonomous delivery of messages to personnel as needed. In addition, information from a set of bridges can be combined on a single system such that an entire network can be monitored remotely. It is essential, however, to recognize that the number of clients that can access the system at one time and the amount of data that can be accessed individually will depend intrinsically on bandwidth. In addition, the system has to be designed to both send and receive data, rather than the more commonly used schema of just receiving data, which is then accessed with a time delay. The use of a web-based interface also ensures that access is not restricted by location and that 24/7 communication and monitoring is available.

3 AN EXAMPLE FOR WEB-BASED SHM OF BRIDGES

3.1 Theoretical basis

Various health monitoring/NDE techniques have been proposed for continuous or time-based assessment of structural response, among which vibration-based damage detection (VDD) techniques have been widely accepted as a flexible choice for potential use

in long-term, real-time, remote monitoring systems. VDD can be described as a class of techniques that are capable of detecting the stiffness/mass change of the structure based on its dynamic response due to forced or ambient excitation. The change of stiffness/mass of the structure is often related to the damage of structural components and the consequent loss of performance. The general procedure of VDD can be roughly divided into four steps: (i) measurement of structural dynamic response in terms of accelerations or displacements; (ii) extraction of modal parameters, such as natural frequencies and mode shapes from the measurements obtained; (iii) calculation of stiffness/mass change based on modal parameters, used in conjunction with the same set of parameters from the as-built or "baseline" structure; and (iv) damage localization and severity estimation based on the results of the third step. In the present example, the time domain decomposition (TDD) method is used, which allows the extraction of mode shapes as the first step, followed by the determination of the corresponding natural frequencies as the second step. Although the TDD needs frequency information, it does not require use of discrete Fourier transforms, which result in substantial computational effort in most other modal parameter extraction algorithms. Once the modal parameters have been identified through this procedure, the next step in the modal-based damage detection procedure is localization of damage and severity estimation. This is done following the damage index method initially proposed by Stubbs and Osegueda [4]. The use of this methodology not only enables the monitoring of structural health but also assessment of damage and its progression as a function of time. In the present setup for a linear, undamaged structure, the ith modal stiffness of a linear, undamaged structure can be described as

$$K_i = \vec{\phi}_i^T \mathbf{C} \vec{\phi}_i \tag{1}$$

where $\vec{\phi}_i$ is the ith modal vector and $\mathbf{C}$ is the system stiffness matrix. The contribution of the jth member to the ith modal stiffness can then be given by

$$K_{ij} = \vec{\phi}_i^T C_j \vec{\phi}_i \tag{2}$$

The fraction of modal energy of the ith mode contributed by the jth member, also called *modal sensitivity*, is defined as

$$F_{ij} = K_{ij}/K_i \tag{3}$$

and correspondingly, using * to represent the damaged structure, the fraction of modal energy of a damaged structure can be defined as

$$F_{ij}^* = K_{ij}^*/K_i^* \tag{4}$$

in which

$$K_{ij}^* = \vec{\phi}_i^{*T} C_j^* \vec{\phi}_i^* \quad K^*{}_i = \vec{\phi}_i^{*T} C^* \vec{\phi}_i^* \tag{5}$$

and

$$C_j = E_j C_{jo} \quad C_j^* = E_j^* C_{jo} \tag{6}$$

A fundamental aspect in this method is that the modal sensitivity for the ith mode and jth member remain unchanged for both the undamaged and damaged structures, i.e.,

$$F_{ij}/F_{ij}^* = (K_{ij}^* K_i)/(K_i^* K_{ij}) = 1 \tag{7}$$

Therefore, a damage index β_j for the jth member, can be obtained as

$$\beta_j = \frac{E_j}{E_j^*} \quad \text{damage indicated when} \quad \beta_j > 1 \tag{8}$$

$$\beta_j = \frac{\gamma_{ij}^* K_i}{\gamma_{ij} K_i^*} = \frac{\phi_i^{*T} C_{jo} \phi_i^* K_i}{\phi_i^T C_{jo} \phi_i K_i^*} \tag{9}$$

and the severity of damage can be estimated by

$$E_j^* = E_j \left(1 + \frac{\mathrm{d}E_j}{E_j}\right) = E_j(1 + \alpha_j) \tag{10}$$

where

$$\alpha_j = \frac{\gamma_{ij} K_i^*}{\gamma_{ij}^* K_i} - 1 \tag{11}$$

in which

$$\gamma_{ij} = \vec{\phi}_i^T C_{jo} \vec{\phi}_i \quad \gamma_{ij}^* = \vec{\phi}_i^{*T} C_{jo} \vec{\phi}_i^* \tag{12}$$

3.2 Description of sensors and protocol

The bridge discussed in this article is a two-span highway bridge with a total length of approximately 20.1 m and a width of approximately 13.0 m. It carries two north-bound lanes on State Highway 86 in Riverside County, California. The superstructure is of slab-on-girder type, with two equal

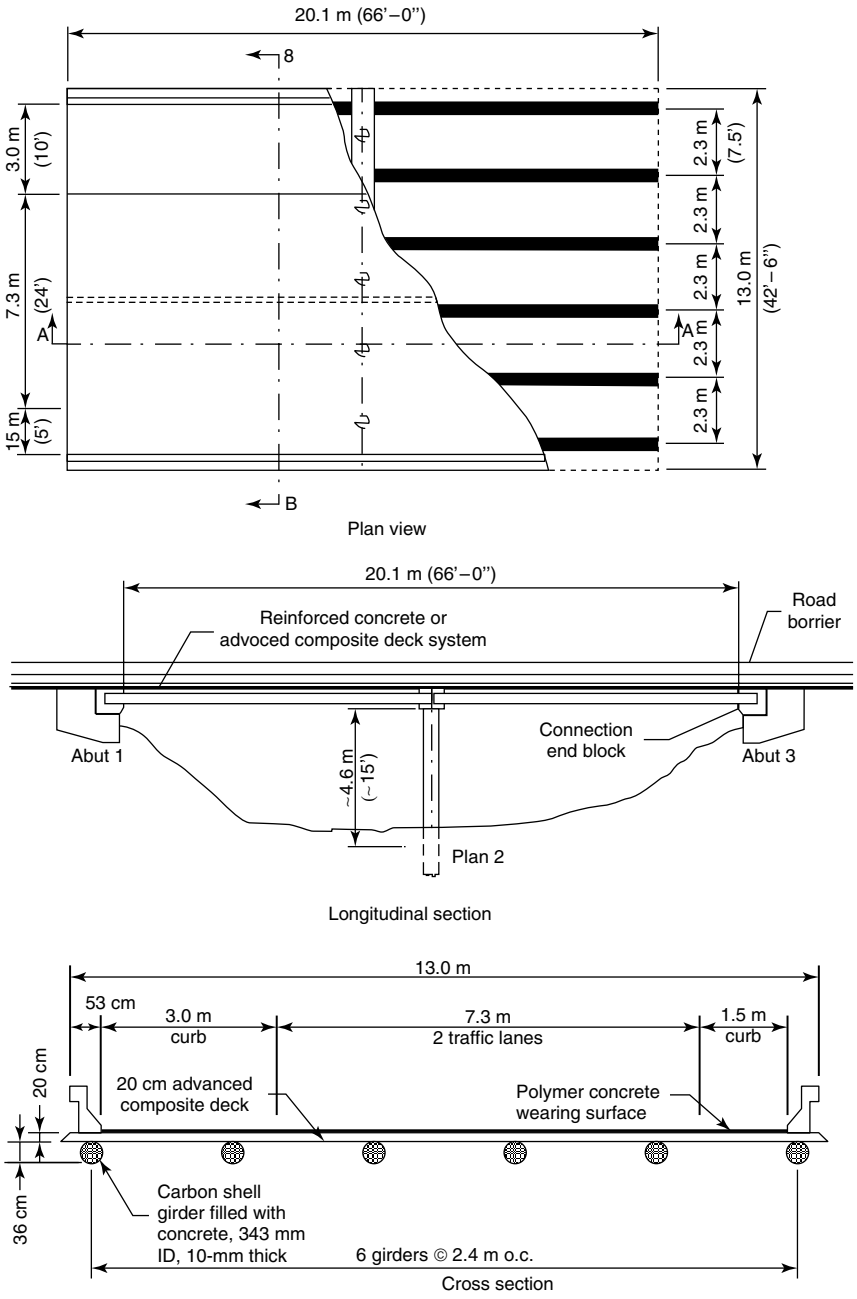

Figure 4. Schematic of the bridge.

spans of 10 m, and a cap beam connecting the two adjoining spans. The six main girders are composed of 10-mm-thick prefabricated filament-wound carbon/epoxy shells filled on-site with light-weight concrete, which support six modular E-glass fiber-reinforced polymer (GFRP) deck panels that serve as road surface, transfer vehicular loads to the girders, and also act as the transverse connections between girders. Schematics of the bridge are shown in Figure 4.

Details related to connections, proof testing at the component and systems levels, and design are reported in [5] and are hence not repeated herein. The bridge is open to heavy truck traffic and serves as a test bed for the implementation of SHM strategies, in addition to being one of the first fiber-reinforced polymer (FRP) vehicular bridges on a major route.

The response of the bridge is characterized through the placement of 63 accelerometers, 20 strain gauges, 4 linear potentiometers, 1 temperature sensor, and a pan-tilt-zoom (PTZ) camera. A total of 63 Model 3140 single axis accelerometers from IC Sensors, Inc. with a dynamic range of ± 2g, a sensitivity of $1\,\mathrm{V\,g^{-1}}$, and a frequency response of 0–200 Hz have been used. These provide an accurate measurement of the ambient-excitation-induced response of interest for this particular application. Forty-two accelerometers were placed at locations on the bottom of the composite deck, referred to as *nodes*, each protected by a sealed equipment housing. The nodes formed a 7×6 grid, with seven locations in the bridge longitudinal direction and six in the transverse direction (as shown in Figure 5), enabling the identification of several mode shapes required for damage detection, and for comparison with theoretical mode shapes already identified by finite-element analysis (FEA).

In addition to the 42 accelerometers measuring vertical acceleration, an additional horizontal accelerometer was installed in the same equipment housing at some of the nodes, to measure the horizontal accelerations that might be caused by an earthquake. A total of 20 bonded resistance gauges were also attached to critical locations on the bottom of the girder, the deck, and the middle section of the girder. Four linear potentiometers were used to measure the deflection of the composite girders at the midspan of two central girders, which experience the maximum deflection (as identified by previously conducted load tests).

A Campbell Scientific CR9000 modular high-speed data logger serves as the core of the data-acquisition system. The CR9000 is capable of making measurements at an aggregate sampling rate of 100 kHz for up to 200 channels. A Transmission Control Protocol/Internet Protocol (TCP/IP) interface enables communication and data collection via standard wired or wireless networks. The raw voltage data collected by the sensors are conditioned and digitized, and then stored into the cache memory of the CR9000 to be retrieved later. The High Performance Wireless Research and Education Network (HPWREN), funded by the National Science Foundation (NSF), which is operational in Southern California, is utilized as the wireless link for data transmission using a 900-MHz wireless antenna and a transmission rate of 45 Mbps. Figure 6 shows the bridge with the antenna used for data transmission.

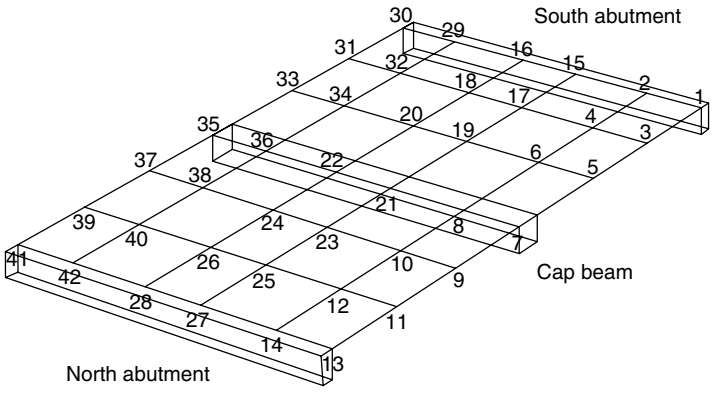

Figure 5. Location of accelerometers.

Figure 6. Bridge with antenna for data transmission.

The automated collection, digitization, and transmission of data are controlled by two collaborating programs. The first program, written in CRBASIC and running on a CR9000 DAQ system, serves the collection and digitization function. It enables data from all channels to be collected at preset intervals and when triggered either by an extreme event, such as an earthquake, or when a preset response threshold is exceeded, such as deflection or acceleration from extremely heavy traffic or permit loads. It also allows for data from a select number of channels, denoted as *streaming channels* to be collected and transmitted continuously in real time. The second program set is housed in the central server at the home node, and serves both data transmission and analysis functions. A schematic of flow is shown in Figure 7.

Continuous analyses performed on streaming data and results, such as peak displacement and strain, are then stored for retrieval on demand. Simultaneously, analyses are also performed on event-based data, as they become available, and the detailed results, such as estimates of damage localization and severity are also stored in the database. Event-based data are archived in an event data database. The server program also serves as a relay for streaming data to multiple end users.

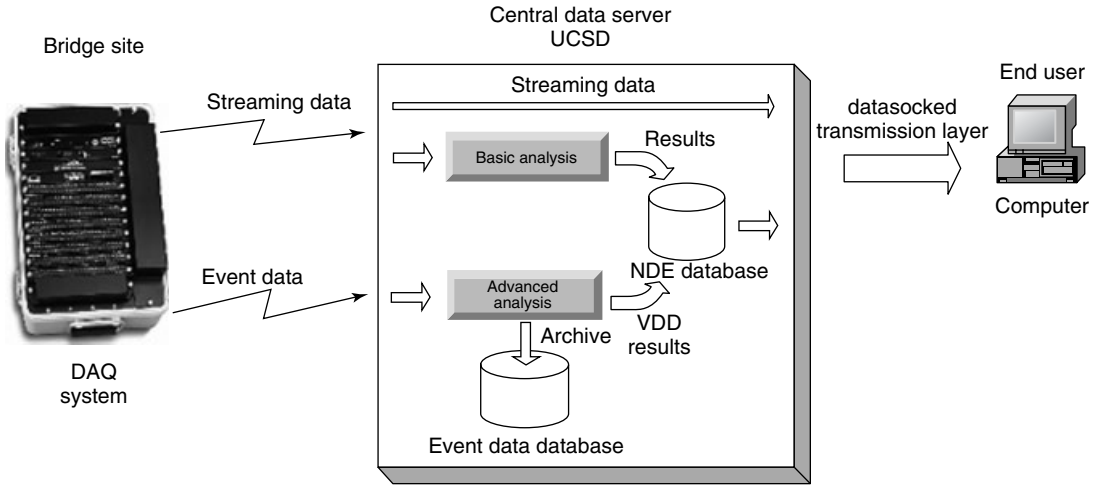

Figure 7. Schematic for information flow.

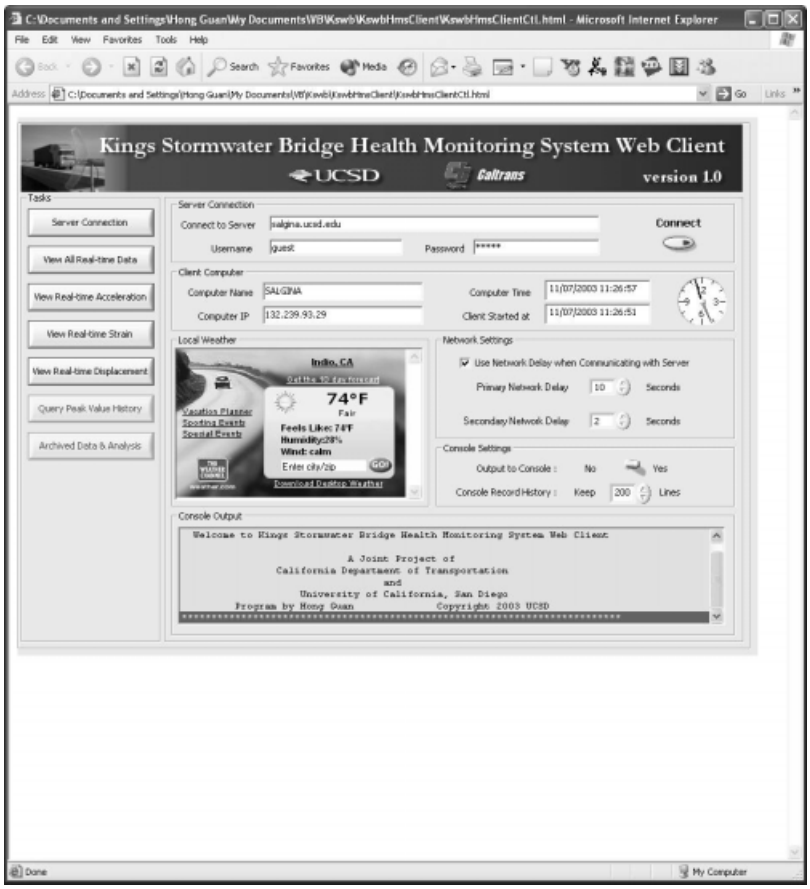

Figure 8. The web client page.

3.3 Web-based implementation

After the data is collected at the bridge site, controlled by a program running on the data logger, raw data is sent over the wireless network to a server located at the University of California, San Diego in La Jolla. A Matlab-based program then autonomously analyzes the raw data, generates results, and sends these to a web server. End users can then access these results using a standalone program or a specific web client, as shown in Figure 8.

The user can then select sensors for which data is desired using maps with sensor locations as in Figure 9.

The web-based user interface enables users with an appropriate connection to monitor the bridge's behavior and assess pertinent serviceability, reliability, and durability aspects related to the structure. By making use of the data stored on the central server, users can access historical data to make comparisons and/or to determine effects of specific events. For the purposes of the current investigation, an event is defined as a *significant excitation to the bridge*, usually caused by single or multiple vehicles crossing the bridge. In terms of measurement, an event is usually a time period over which the bridge is subject to excitation and measurements are taken. Both raw data and processed data are analyzed and stored with reference to the specific event through a date–time stamp. Users can either choose to plot sensor records pertaining to a single event, multiple events, or even records of

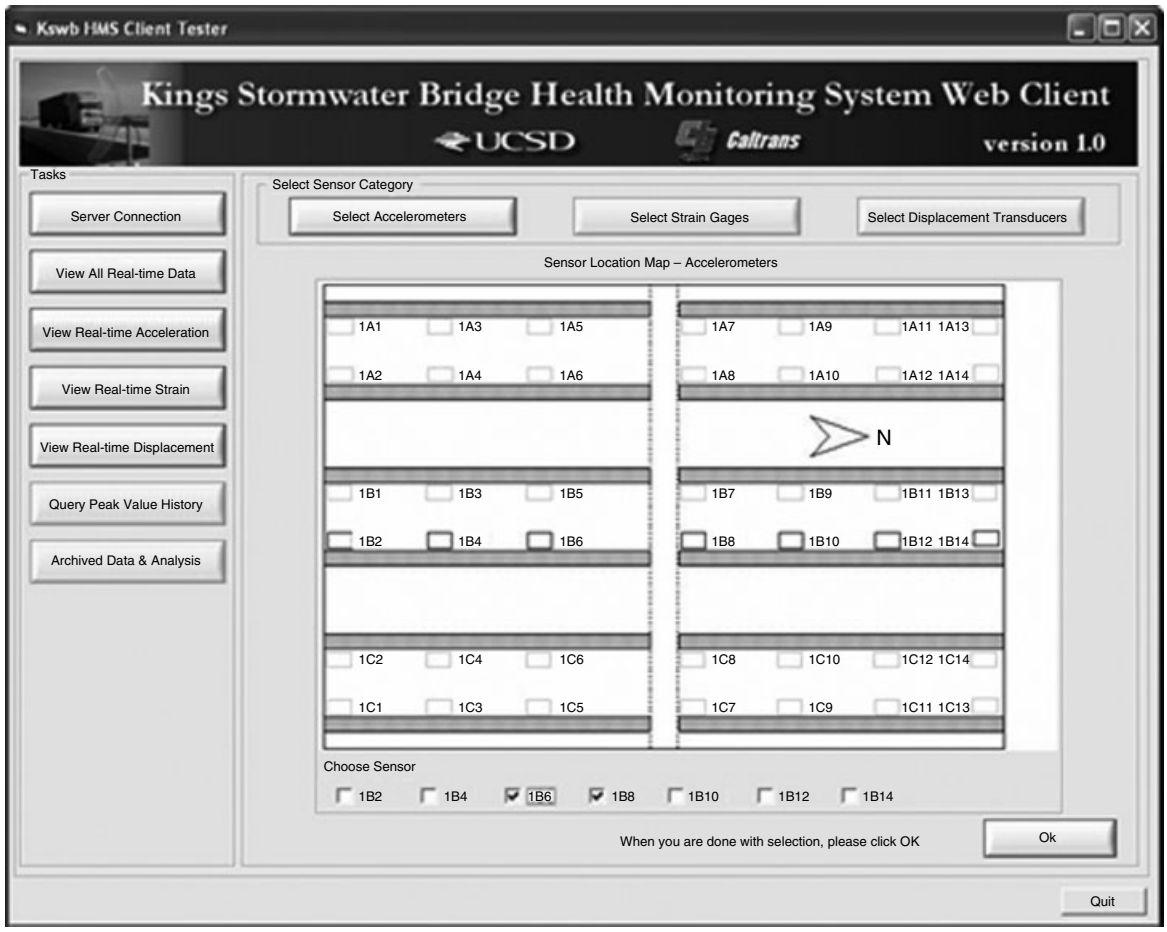

Figure 9. Example of map showing sensor locations.

multiple sensors selected by location. Results can then be viewed in real time (Figure 10a), with the capability of zooming in on details of any sensor (Figure 10b).

In addition, historical records can be assessed to compare peaks with current measurements, such as in Figure 11(a) for displacements, and in Figure 11(b) for strains.

3.4 Sample results of diagnostic analysis

At the current level of development, the vibration-based damage diagnostics information is supplemented by results from a finite-element model of the entire bridge (including deck panels, girders, deck-girder connections, cap beam, column/piers, and abutments), giving the user the capability of comparing structural response characteristics determined through the use of sensor measurements to FEA-based "ideal" or "updated" characteristics, as well as to predetermined response thresholds that signify bounds of acceptable structural behavior. The model was developed in ANSYS using design and construction drawings, and manufacturing specifications for the FRP composite components. The deck panels were modeled using elastic shell elements with equivalent properties, while the girders were modeled as beam elements. Connections between girders and deck panels were modeled as rigid constraints. The concrete barrier was also modeled using beam elements connected to the deck panels, while the connections to the abutments and the cap beam were modeled as rigid connections. The frequencies of the first five modes obtained from the initial FEA model are listed in Table 1 together with corresponding frequencies from a baseline forced

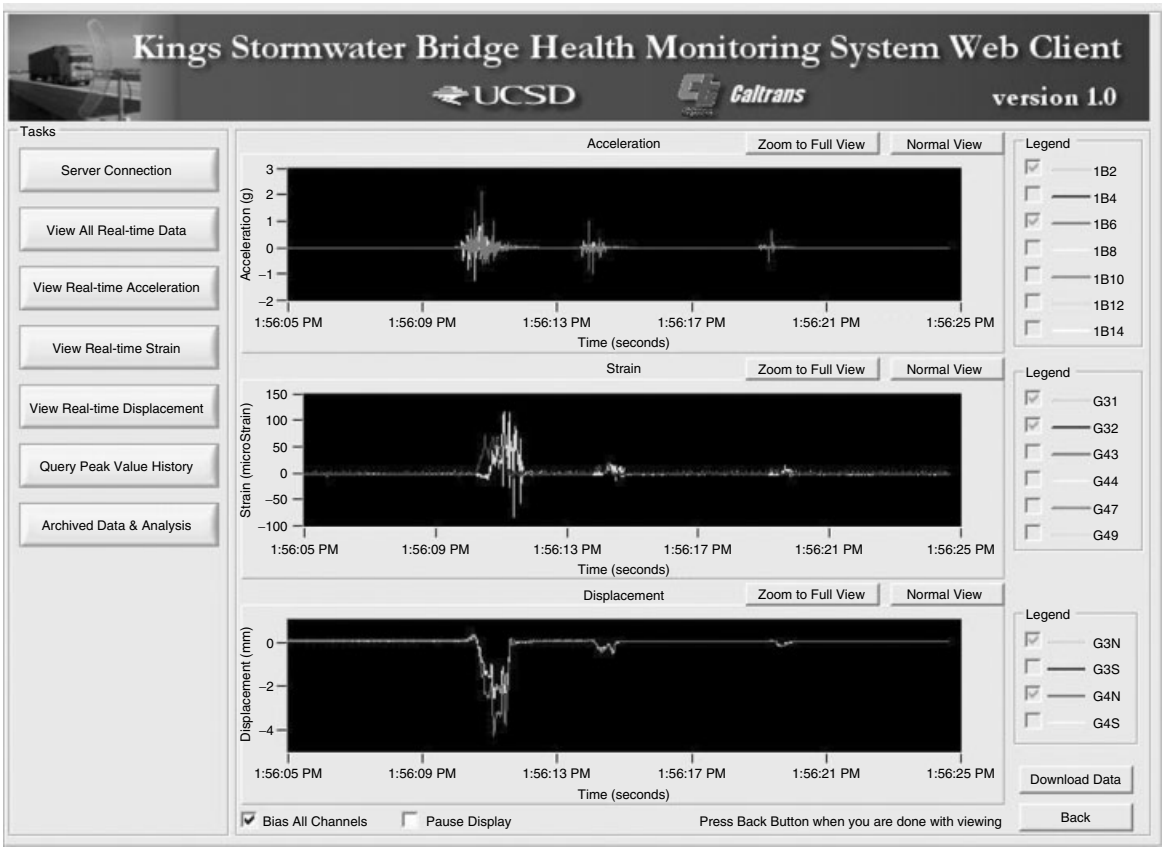

Figure 10a. (a) Real-time view of sensor-based response measurement. (b) "Zooming in" on data.

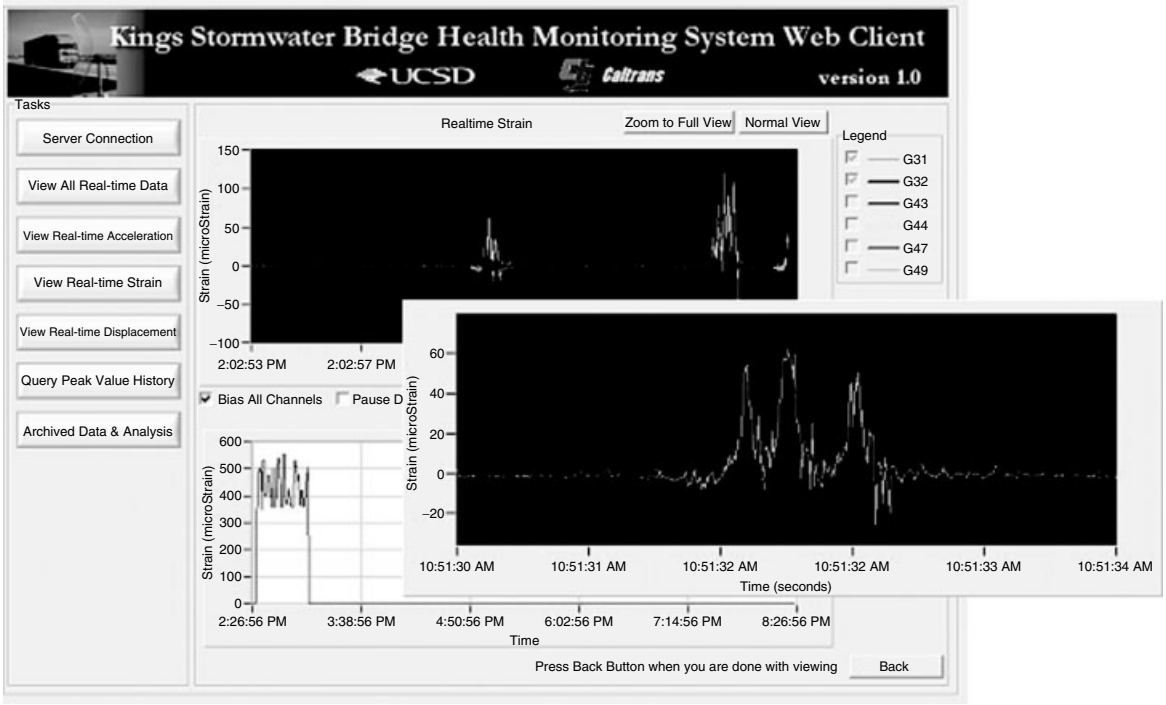

Figure 10b. *Continued.*

vibration test conducted just after the bridge was opened to traffic. A model updating process is then used to adjust the material properties used in the FEA model to better match the experiment results. The frequencies of the updated FEA model are also listed in Table 1 for comparison. This set was used as the initial baseline representative of the as-built nonaged structure. Figure 12 shows the mode shapes of the first two modes from the "baseline" finite-element model. Both the frequencies and the mode shapes are used hereafter for assessment of response as a function of time.

Shifts in natural frequency and the change of mode shapes provide an indication of stiffness changes in the structure. Four different data sets, collected in October 2001, June 2002, January 2003, and August 2003, respectively, are used as an example to show the time-related variations in modal parameters and the value of the methodology presented as a means of SHM. For each data set, the TDD algorithm was applied after the corresponding frequency ranges were determined. The change in natural frequencies is quite obvious when plotted out in Figure 13, which shows a decreasing trend of natural frequencies of both modes.

It should be noted, however, that there was a significant initial drop till June 2002 after which there appears to be very little change, especially considering the effect on response accruing from the changes in temperature. During this time period, some horizontal debonding at the saddle between the deck and girders was noticed, in addition to vertical cracking of the polymer concrete saddles in local areas with associated leakage of water through the deck joints and the cracks in the saddle, causing discoloration and streaking on the girder. This deterioration, in addition to the cracking and distress in the joints between decks, can be shown through FEA to lead to the change in frequencies, validating the experimental observations [6].

Although the changes may not be as clear when viewed in terms of mode shapes (Figure 14), a shift in peak location and magnitude can be noted on comparison of the August 2003 data with data from two other time periods.

Table 1. Comparison of frequencies of initial FE model and experiment

Mode number	Frequency (Hz)		
	Experiment	Initial FE model	Updated FE model
1	11.03	12.32	11.12
2	13.11	13.97	12.98
3	15.36	15.92	15.01
4	16.92	17.82	17.11
5	19.01	19.65	19.34

It is noteworthy that the analytically simulated mode shapes based on FEA models compare well with the experimental results, again showing the value of FEA use for both comparison at the threshold levels and for purposes of prediction. Translating the results into structural stiffness, this means the structure is becoming more flexible, i.e., decreasing structural stiffness with respect to time.

Use of the damage index method allows for determination of magnitude of damage indicators, which can provide assessment of damage in the structure. Changes in these indicators can be seen in Figure 15, and it is noted that the region with the highest damage indicator magnitude is concentrated around an area about 3.3 m (10 ft) on either side of the cap beam, which correlates with visual observation of damage through deterioration of the construction joint between deck panels. It is of interest to note that the increase in damage indicators in these

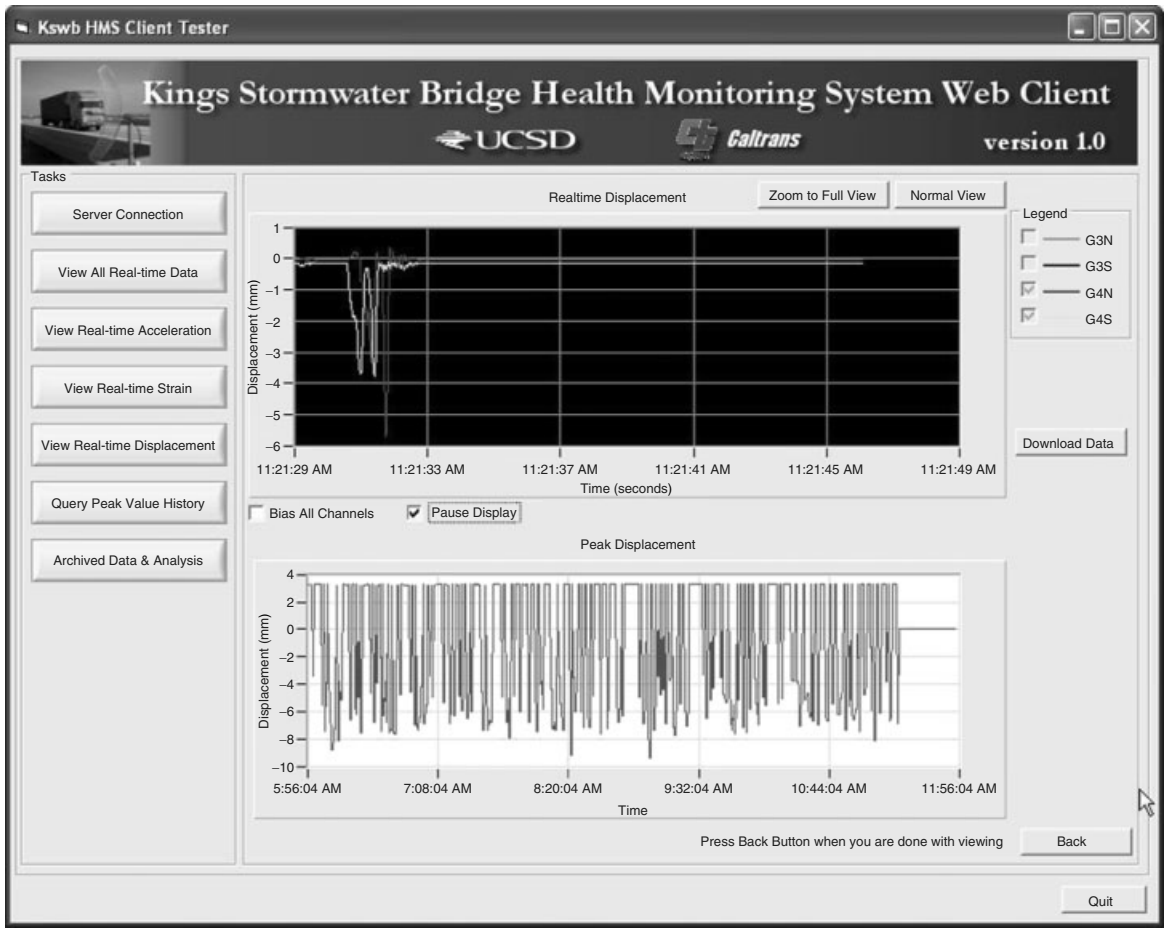

Figure 11a. (a) Access to peak displacements. (b) Access to peak strains from the overall data record.

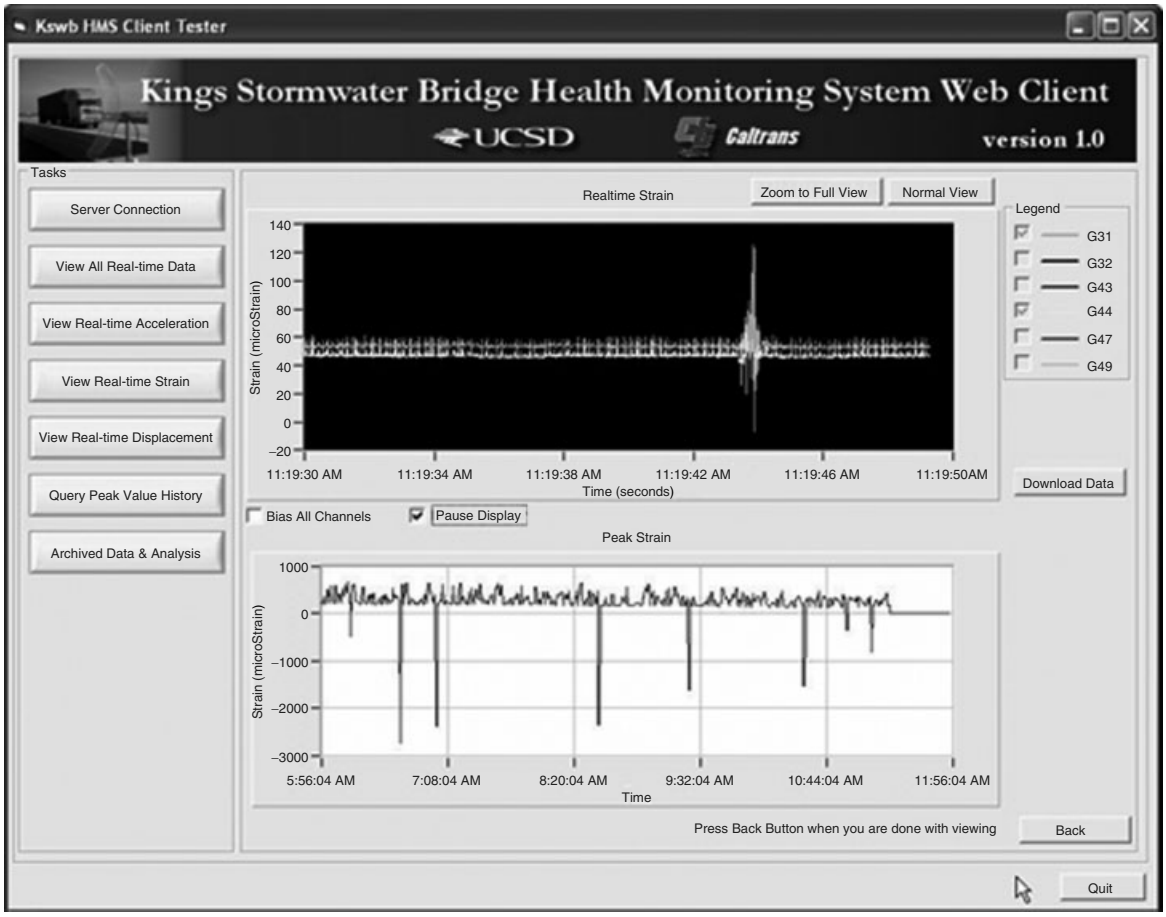

Figure 11b. *Continued.*

regions was noticed ahead of visual identification of the distress, emphasizing the value of such a health monitoring system in not just monitoring response but also in providing advance warning of deterioration.

4 SUMMARY

The design of components and structures is predicated on uncertainties related to a number of factors including those related to load, materials, and service environment. The lack of detailed knowledge in some of these has led conventionally to the use of intrinsically high factors of safety. While the use of an SHM system can provide, at the minimum, data that can be used to assess structural integrity in a manner allowing for provision of early warning of impending failure, it can also serve as a means of assessing reliability and, perhaps, even remaining characterizing capacity and remaining life on a continuous basis. In its development as a web-based system, it thus not only serves as a means of NDE but also as a means of collecting detailed records of response that will enable not just better designs of new structures but also the basis of better assessment and prediction of reliability of components and entire systems enabling better, and more timely, allocation of resources based on age, deterioration, and level of importance of the structure in terms of a local and regional context. Web-based SHM thus provides for the development of an *in situ* system similar to the system used by the federal aviation administration

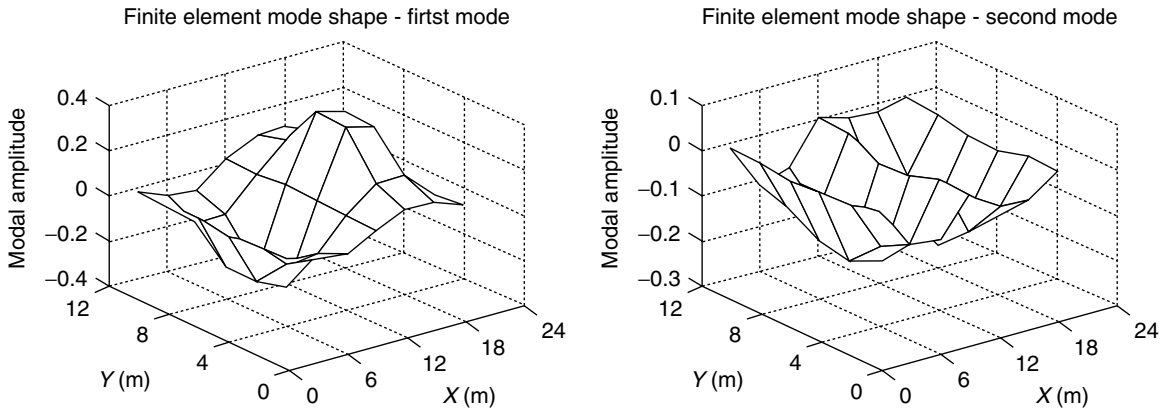

Figure 12. Mode shapes from the FEA model.

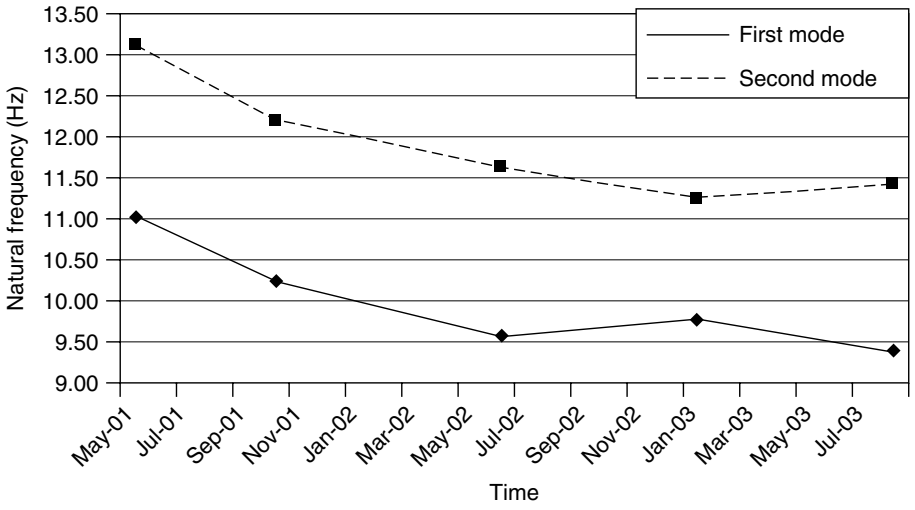

Figure 13. Change in frequency as a function of time.

(FAA) in tracking flights in the air, but based on fixed objects whose "health" varies and can be tracked in time.

The SHM system presented in this article provides an example of implementation of a system amenable to the use of autonomous monitoring. The system not only enables the collection and presentation of data from a suite of sensors but also provides for the assessment of the data in terms of structural characteristics, which can be compared to analytical results derived from an FEA model, which is calibrated to the initial response. This allows for the setting of response thresholds that would provide warnings to the user/owner when exceeded. In the current form of implementation, the web-based system has data transferred both in real time and in packages at preset intervals across a wireless network. Data is interrogated using a damage prognosis algorithm that provides indicators of damage severity and allows for comparison between response and damage state at various points in time. Thus subtle changes in bridge response, which may not be seen easily through just inspection of modal parameters, such as deterioration in

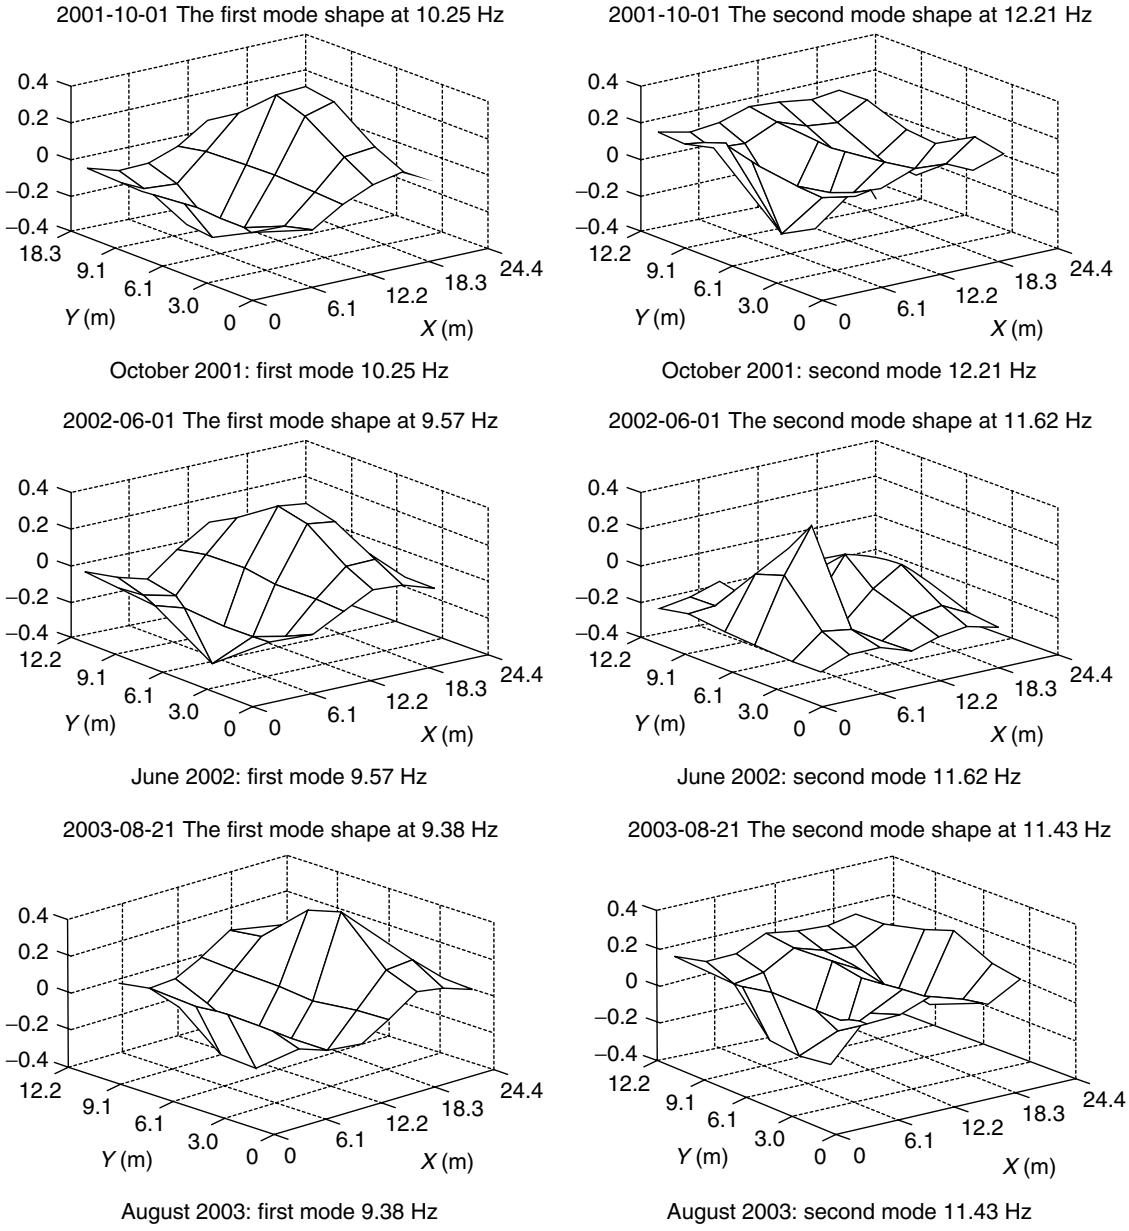

Figure 14. Changes in mode shapes over time.

expansion joints over time, can be easily determined. It is expected that the further development of such systems will lead to the establishment of a comprehensive methodology for autonomous health monitoring of structural systems to the point where true condition-based physical inspection and monitoring would become a reality. The integration of damage identification and finite-element-based tools further provides assistance to the engineer in assessing health immediately rather than having to resort to expensive closures while assessments are made off-line.

1 INTRODUCTION

While traditional nondestruction evaluation (NDE), ranging from simple visual inspection to methods based on electrical properties, electromagnetic properties and acoustic or ultrasonic wave, has provided effective means in evaluating structural performance [1], it is understood that the application of structural health monitoring (SHM) has led to a paradigm shift in thinking from event-based structural evaluation to continuous on-line *in situ* monitoring. Such a philosophy may potentially reduce cost significantly without compromising performance and reliability of engineering structures such as airframes [2, 3] and bridges [4, 5]. It provides critical information of long-term structural performance for life cycle maintenance and management [6]. As one example, SHM has been introduced into a maintenance policy by the US Department of Defence, known as *Condition-Based Maintenance Plus* (*CBM+*), to reduce the cost in maintenance by a schedule-based approach [7].

SHM is a technique that uses sensors, on site or remotely, to collect information on structural, mechanical, or physical behavior, either continuously or periodically, for the diagnosis and prognosis of structural integrity and performance. It was comprehensively reviewed by many researchers [8–10]. Generally speaking, an SHM system may be specified

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

in terms of its functionality, sensing system design, and information acquisition and interpretation.

1.1 Functionality

An ideal SHM system should be capable of indicating structural health at four levels hieratically:

- level one: the occurrence of an adverse event to structure, affecting structural performance and functionality;
- level two: the location where an adverse event to structure occurs;
- level three: scale or severity of the adverse event to structure;
- level four: residual service life of structures or structural components to maintain required minimum performance and functionality with such an adverse event;

where an adverse event to structure can generally be considered as a consequence arising from an interaction between structures and their environment, which may include mechanical (loading, wind, impacts, and shock, etc.), chemical and biological (chloride, water, bacteria, etc.), thermal (radiation, heating, thermal shock, etc.), and so on. The consequence can be any form of damage or degradation in relation to performance and functionality of structures, such as crack, fatigue, buckling, delamination, dislocation, disconnection, etc.

1.2 Sensing system design

An appropriate sensing system is of vital importance to capture authentic signals to quantify the structural performance and identify any degradation in the performance. Much akin to the nerve cell of human beings, the sensor is a device for detecting the variation in physical, chemical, or biological properties, and, by proper transduction, transforming the measurands into interpretable information. Sensor technology is seen as a basic element in SHM. Basically, an ideal sensor system for SHM meets the following requirements: (i) veridical acquisition of changes in local or global structural responses; (ii) faithful delivery of captured changes; (iii) possibly less intrusion to host structure; (iv) endurance for general structural service conditions with its service life not less than that of the host structure; and (v) ease in handling, attachment, integration, and operation. In some demanding situations, e.g., for aerospace applications, the sensor should also feature small size, light mass, extremely high sensitivity and reliability, low cost and power consumption, little deterioration with aging, remote data transmission, robustness for noise, reduced wire, or even wireless, etc. While it is difficult to design a sensing system strictly satisfying all the requirements indicated above, an optimal design may be reached for a specific application by considering its most desired needs.

There are many sensing options including ultrasonic probe, acoustic emission sensor, magnetic sensor, eddy-current transducer, accelerometer, strain gauge, laser interferometer, optical fiber, electromagnetic acoustic transducer (EMAT), etc. In particular, piezoelectric elements have been generating a lot of interest for SHM, especially because of their potential of being used as either sensors or actuators [1–15].

By virtue of the utility of piezoelectric elements, an active sensing scheme can be designed on the basis of the assessment of electromechanical impedance spectrums (*see* **Electromechanical Impedance Modeling**). It is implemented by measuring the electric current in response to the voltage imposed on the piezoelectric element integrated with structures. The electromechanical impedance is directly related to structural dynamics [16], and therefore any structural change will, in principle, lead to variation in the impedance. Applications of such a scheme include detection for bridge joint deterioration [17, 18], disbond in composite repair patch [19], loose joints in pipelines [20], and cracks in a concrete beam [21].

The active sensing can also be achieved by using Lamb waves. Lamb waves have been widely explored [22] since 1961 when they were introduced as a means of damage detection [23]. Lamb waves, made up of a superposition of longitudinal and shear modes, are available in a thin plate or shell structures. The mode of a Lamb wave can be either symmetric or antisymmetric, and can be excited by a variety of means [10]. Details can also be found in Section 2 (*see* **Fundamentals of Guided Elastic Waves in Solids**). Piezoelectric elements are capable of generating and acquiring Lamb waves,

and are particularly suitable for integration into a host structure as an *in situ* actuator and sensor, as a result of their low mass, good mechanical strength, wide frequency band, low power consumption and acoustic impedance, as well as low cost. Theoretically, a sensing system can be designed on the basis of the concept to relate damage-modulated Lamb waves signal to damage location, size, or severity, offering an SHM system featured with functionality at all four levels.

1.3 Signal acquisition and interpretation

Signal acquisition is designed to capture any information related to structural health status, which can further be interpreted at the four levels of functionality required by an SHM system. The concept to apply piezoelectric elements for identifying structural damages by assessing Lamb waves can be schematically described by Figure 1. As seen, one piezoelectric element is used as an actuator to generate Lamb waves, and the other as a sensor to collect signals. With the occurrence of damage, the original signal is considerably modulated by the damage, as in the example described in Figure 2(a) and (b). In comparison with Figure 2a, without the effect of structural damage, Figure 2(b) shows that a structural damage such as delamination in a composite laminate induces a *shear horizontal* (SH) mode wave [24], and there is a time lag between the SH wave and the symmetric mode (S) wave.

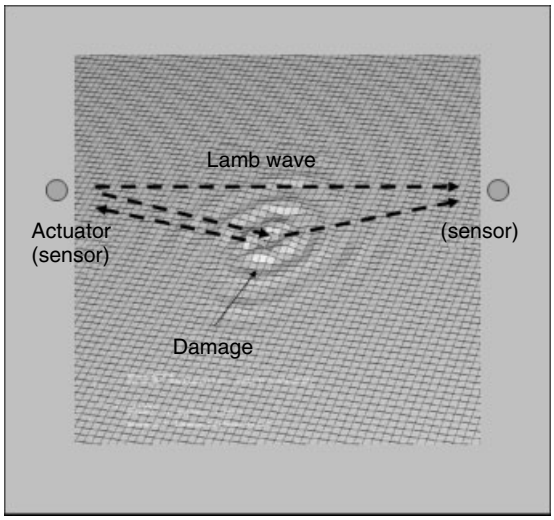

Figure 1. Active sensing scheme with Lamb waves.

Basically, there are two approaches to interpret the signals acquired by a sensor in an active sensing scheme based on Lamb waves:

- using *time of flight* (TOF) of damage-modulated Lamb waves between recipient wave and the damage-reflected wave, to identify a damage event and quantify the location of damage—the functionality at levels one and two required by a SHM system;
- correlating features of damage-modulated Lamb waves to identify a damage event, quantify

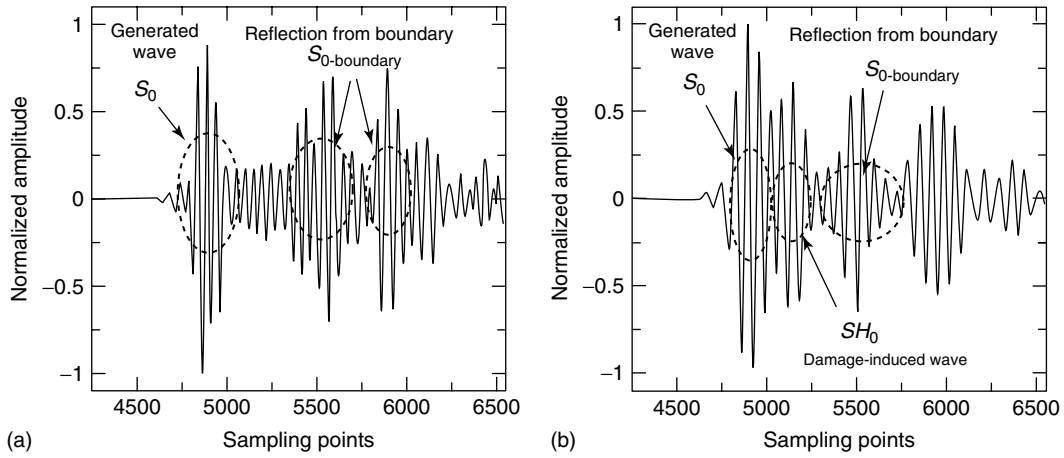

Figure 2. Acquired Lamb wave signals: (a) without damage modulation and (b) with damage modulation.

damage location, and size or severity—the functionality at levels one, two, and three required by an SHM system.

A proper sensing system design into network may also extend the first approach to achieve functionality at level four. The features mentioned in the second approach can be obtained in the time domain [25], but it is more common to analyze features in the frequency domain by approaches such as the fast Fourier transform (FFT) [26–28]. It is more reasonable to combine the analyses in both the time and the frequency domains so as to avoid any information loss in either of these domains, i.e., the time–frequency domain analysis. The joint time–frequency domain analysis is exemplified by the *short-term Fourier transform* (STFT) and the *Wigner–Ville distribution* (WVD) [29]. Recently, *wavelet transform* (WT) has become more popular in feature extraction for SHM [30–32], such as denoising a signal to facilitate feature extraction in the time domain [33].

2 ACTIVE SENSING

Active sensing design using piezoelectric elements has created great potential to advance the development of SHM techniques, especially in applications pertaining to plate and shell structures that largely exist in airframes, marine vehicles, containers or tanks, pipelines, and so on. An active piezoelectric sensing system is capable of both generating interrogative signals and capturing structural-modulated responses, which reflect the condition of structures, over *an area* instead of at *a point*. However, the identification of structural condition is normally shown as a typical inverse problem that represents the solution (structural condition) in terms of a *hidden* physical phenomenon to be obtained or estimated from *observed* signal from sensors. Mathematically, it often shows that the process is highly ill-conditioned or not well-posed that requires, (i) a solution to exist, (ii) the solution to be unique, and (iii) the solution to continuously depend on the observed data. Complication of structural damages, such as occurring at multiple locations, may impose even more difficulties to obtain the solution correctly. While a simple active piezoelectric sensing system may potentially monitor a broad structural area, it also creates uncertainties in signal interpretation caused by noises and signal scattering as a result of environment, structural boundary, and discontinuity interference. Distinguishing the damage-induced signal variation from noises, particularly in engineering practices, is very challenging.

Intrinsic problems in seeking an inverse solution as well as practical issues in view of system operations require a new path to increase the robustness and reliability of SHM. Artificial intelligence techniques can be adopted to reproduce human cognitive processes for the identification of structural abnormality and derive *beliefs* at the level of an individual sensor, which is essentially a part of a decentralized or distributed sensor network. An overall *decision* or consensus on structural condition becomes available by combining the *beliefs* within a group and then subsequently among groups of individual sensors in the network in multiple steps, known as *a multilevel fusion process*, which may considerably increase the robustness in obtaining inverse solutions and reduce uncertainties in damage identification for SHM. How to design a distributed active sensing system to suit the needs of a multilevel decision fusion process becomes important.

3 DISTRIBUTED SENSING SYSTEM AND DECISION FUSION

Neurological study [34] indicates that signals to different senses are initially segregated at the neural level and neurons do not interact with each other on what they sense until the signals are transmitted to the brain, where the sensory signals converge on the same target to supply perceptions and orient behavior. It is understood that there are three critical steps involved in such a process: (i) distributed sensing, (ii) information fusion, and (iii) establishing perception and orienting behavior. Extending the concept to SHM, sensors can be designed in a distributed way—not only in terms of a spatial network but also in terms of their functions—implying that they are able to sense different physical parameters at many locations in a specific pattern. Distributed sensors may firstly form their individual beliefs that represent their own interpretation of data or "the world" they sense.

Secondly, a fusion process then combines all their beliefs following conjunctive, disjunctive, or compromising rules to form a consensus about the view on "the world"-health status of the structures. The advantages of using a distributed sensor network include the combination of all kinds of information sources that can be the same type or completely different, the enhancement of the awareness of targets with superior system reliability and robustness [35], and the reduction in dependence of final perception/decision on the information from a single sensing source.

3.1 Distributed active sensing structure

Figure 3 gives a representative unit in a distributed active sensing structure, including the following four elements: (i) active sensor node, (ii) passive sensor node, (iii) sensor controller, and (iv) sensing path. The active sensor node plays an active role by generating an interrogative signal propagating through a sensing path and forming its belief about structural health on the basis of the response of the passive sensor node. The passive sensor node is used to receive a signal transmitted through structures from the active sensor and provide feedback to the active sensor node by the sensor controller. The sensor controller decides which sensor node takes an active role, relays and processes feedback to establish a belief for the active sensor node. The sensing path is the possible pathway of interrogative signal traveling from the active sensing node to the passive sensing nodes within a structure.

A distributed active sensing structure can be designed in a centralized format, as shown in Figure 4, where sensors may rotate to take an active role to generate interrogative signals and get feedback

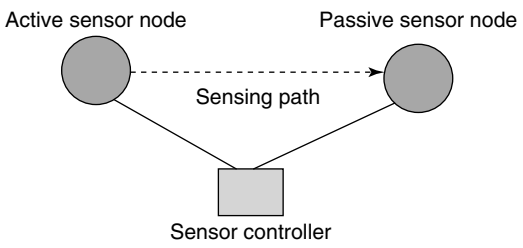

Figure 3. Sensor nodes, controller, and sensing path.

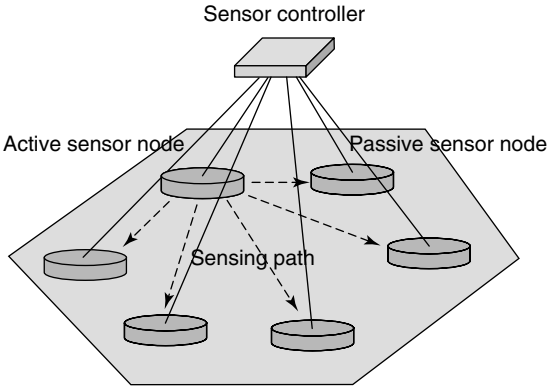

Figure 4. Centralized active sensing structure.

from all other (passive) sensors only through one sensor controller. All feedbacks then become inputs to form a belief of the active sensor group in regard to structural health status. It should be indicated that the entire process is controlled by one sensor controller, know as *a centralized structure*. Figure 5 shows a hierarchical structure, which has an extra sensor controller at a higher layer. As mentioned in the centralized structure, each sensor may have its own belief on the status of structural health. The sensor controller at the low layer may form a belief of a sensor group on the basis of the beliefs of individual sensors through the second level of the fusion process. In the hierarchical structure, the high-layer sensor control subsequently establishes a belief of entire sensor groups by fusing the beliefs formed at the low-layer sensor controllers.

Different from the hierarchical structure, the autonomous active sensing structure, as shown in Figure 6, does not possess any high-layer sensor controller. Sensor controllers are independent of each other, but maintain communication among themselves. Note that the belief of entire sensor groups is established at each sensor controller by acquiring information from all the others with their own rules, which are not necessarily the same.

More complex active distributed sensing structures can be established on the basis of the basic structures discussed above. One example is the hybrid structure, which is intended to integrate the features of centralized, hierarchical, and autonomous structures.

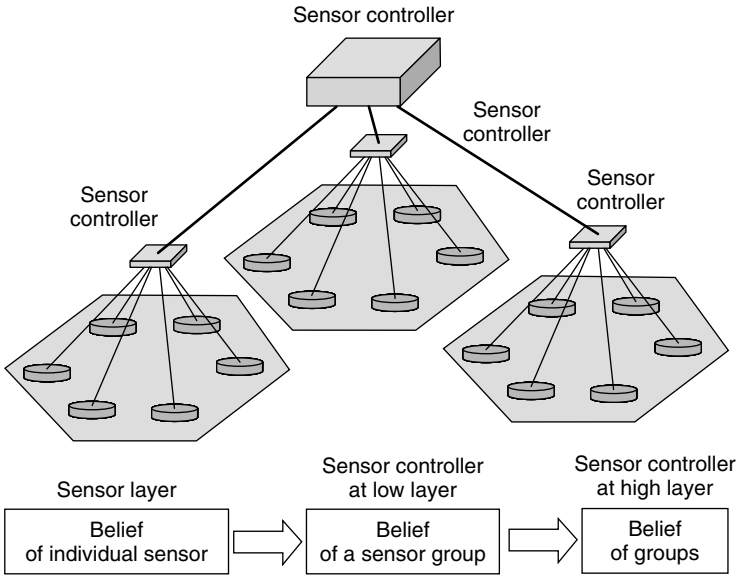

Figure 5. Hierarchical active sensing structure.

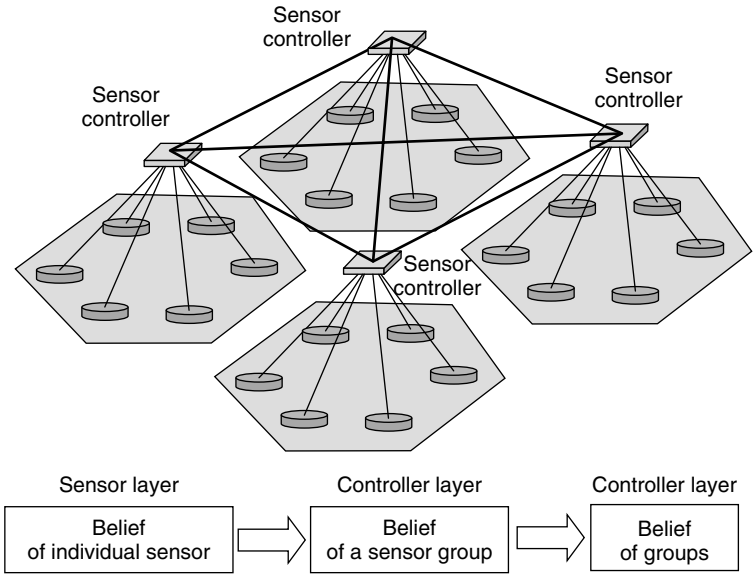

Figure 6. Autonomous active sensing structures.

3.2 Fusion in distributed active sensor network

As discussed previously, the establishment of a belief at each layer, i.e., sensor layer and sensor controller at a low or high layer, has to be implemented via fusion, which basically combines the beliefs at the lower layer to form a new belief or posterior belief at a higher layer. The fusion process is intended to make the posterior brief with less imprecision, uncertainty, and incomplete information, accurately characterizing the structural health status. More precisely, a brief

is described by a degree that represents how certain or possible the perception of a sensor or a sensor controller may enhance such a view or consensus as the occurrence of a series of potential adverse structural health events. A fusion process is described by a projection function, $\Im$, which projects a vector of the prior belief, $\vec{B}_{\text{prior}}$, at a lower layer to a posterior belief, $B_{\text{posterior}}$, at a higher layer presented by

$$\Im: \vec{B}_{\text{prior}} \longrightarrow B_{\text{posterior}}, \text{ for } \vec{B}_{\text{prior}} \in I^n \text{ and } B_{\text{posterior}} \in I \tag{1}$$

where I represents a measure set of the degree of the posterior belief as well as the degree of all subsets of the prior belief given in n dimension. It is normally defined as an interval, for example, [0, 1], where "0" indicates that the prior belief *cannot* enhance the posterior belief or provide information to strengthen the consensus, and "1" represents that the prior belief can enhance the posterior belief.

Character of fusion functions can be divided into three basics [36]. Assuming that there are two prior belief inputs with their degrees described by x and y, and a fusion function is given by $\Im$ with the posterior belief given by $\Im(x, y)$, then

- $\Im$ is conjunctive if $\Im(x, y) \leq \min(x, y)$;
- $\Im$ is disjunctive if $\Im(x, y) \geq \max(x, y)$;
- $\Im$ is a compromise if $\min(x, y) \leq \Im(x, y) \leq \max(x, y)$.

Conjunctive fusion gives the common part among the prior beliefs, reducing the less certain components and giving the smallest measure, as shown in Figure 7(a). Disjunctive fusion covers all possible beliefs, increasing the certainty and giving the greatest measure, as shown in Figure 7(b). Compromise fusion gives an intermediate measure, as in Figure 7(c).

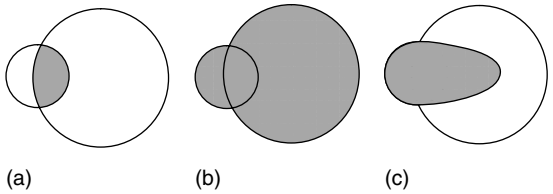

Figure 7. Fusion behavior: (a) conjunctive, (b) disjunctive, and (c) compromise.

In practice, a fusion function can have any one of the function character described above or their mixture, depending on the context of the fusion function. The selection of fusion schemes has to be considered in relation to the data sets and the fusion objectives. The following are a few examples of fusion functions [36]:

- conjunctive fusion functions

$$\Im(x, y) = \{\min(x, y); xy; \max(0, x + y - 1)\}, \quad (x, y) \in [0, 1] \times [0, 1] \tag{2}$$

- disjunctive fusion functions

$$\Im(x, y) = \{\max(x, y); x + y - xy; \min(1, x + y)\}, \quad (x, y) \in [0, 1] \times [0, 1] \tag{3}$$

- compromising fusion functions

$$\Im(x, y) = \left\{ \frac{2xy}{x + y}; \sqrt{xy}; \frac{x + y}{2}; \sqrt{\frac{x^2 + y^2}{2}} \right\}, \quad (x, y) \in [0, 1] \times [0, 1] \tag{4}$$

More fusion techniques include the voting scheme, Bayesian inference [37], Dempster–Schafer theory [38, 39], and fuzzy logic [40].

3.2.1 Fusion based on voting scheme

In a fusion based on voting scheme, the posterior belief is formed according to the voting index [37]:

$$\Im(\vec{Y}_i) = \sum_{j=1}^{n_i} w_{ij} Y_{ij} \tag{5}$$

where n_i is the total number of prior beliefs from all sensors used to assess the ith location ($i = 1, \ldots, N$), and Y_{ij} is the prior belief degree of the jth sensors on the structural condition at the ith location. Typically, it equals one when supporting a tested consensus and zero when against it. In equation (5), w_{ij} represents the voting weight of the jth sensor in relation to the ith location, and $\sum_j w_{ij} = 1$. The fusion based on voting scheme is compromising.

3.2.2 Fusion based on Bayesian theory

In Bayesian fusion, with multiple inputs, E_i, from a distributed sensor network, the posterior probability of the belief, $\Theta = \theta_i$, is given by [37]

$$P(\Theta = \theta_i | E_1, \ldots, E_j, \ldots, E_m) \sim P(\Theta = \theta_i) \prod_{j=1}^{m} P(E_j | \Theta = \theta_i) \quad (6)$$

where $P(\Theta = \theta_i)$ is the prior probability of the belief of $\Theta = \theta_i$; $P(\Theta = \theta_i | E_i)$, $(i = 1, \ldots, m)$ is the posterior probability of the belief of $\Theta = \theta_i$, given inputs $E_i (i = 1, \ldots, m)$; and $P(E_i | \Theta = \theta_i |)$ is the likelihood of the occurrence of E_i at the assumption of $\Theta = \theta_i$. The fusion based on Bayesian theory is conjunctive.

3.2.3 Fusion based on Dempster–Shafer rule

Assuming mass functions $m_j(B_j)(j = 1, \ldots, m)$ that represent the degree of belief of the sources (e.g., sensors) on the proposition B_j, the Dempster–Shafer rule for the fusion of belief degree on the proposition Θ, where $\Theta = B_1 \cap \ldots B_j \cap \ldots B_m$, is then given by [38, 39]

$$m_1 \oplus \ldots m_j \oplus \ldots m_m(\Theta) = \frac{\sum_{B_1 \cap \ldots B_j \cap \ldots B_m = \Theta} m_1(B_1) m_2(B_2) \ldots m_m(B_m)}{1 - k} \quad (7)$$

where

$$k = \sum_{B_1 \cap \ldots B_j \cap \ldots B_m = \emptyset} m_1(B_1) m_2(B_2) \ldots m_m(B_m) \quad (8)$$

where k is a measure of conflict between sources, reflecting the imprecision of information; and $B_1 \cap \ldots B_j \cap \ldots B_m \cap \ldots = \emptyset$ implies the scenario with null intersection among all $B_j (j = 1, \ldots, m)$. The fusion based on Dempster–Shafer rule is conjunctive.

3.2.4 Fusion based on fuzzy interference

Assuming membership functions, $\mu_{A_j}(x)(j = 1, \ldots, m)$ that define a fuzzy set of beliefs on the proposition, such as damage occurrence at a location, the fusion through fuzzy conjunction is given by [40]

$$\mu_{A_1 \cap A_2 \ldots \cap A_m}(x) = \min\{\mu_{A_1}(x), \mu_{A_2}(x), \ldots, \mu_{A_m}(x)\} \quad (9)$$

where x is the universe of discourse related to the degree of prior beliefs. To defuzzificate the combined fuzzy conclusion in equation (9), the centroid defuzzification method is applied by using the following equation:

$$\bar{x} = \frac{\sum_{j=1}^{m} \mu_{A_j}(x_j) x_j}{\sum_{j=1}^{m} \mu_{A_j}(x_j)} \quad (10)$$

where $\bar{x}$ is the posterior belief through fusing degree of prior beliefs, on the proposition of damage occurrence.

3.2.5 Fusion with neural network

A neural network consists of one input layer with α elements (im), two hidden neural processing layers respectively possessing λ and η computing elements (referred to as *neurons*), and one output layer containing β variables (ov). Mathematically, the ith output variable in the network is formularized as

$$ov_i = T_3\left(\left(\sum_{q=1}^{\eta} w_{q-i}^3 \cdot T_2\left(\left(\sum_{r=1}^{\lambda} w_{r-q}^2 \cdot T_1 \times \left(\left(\sum_{p=1}^{\alpha} w_{p-r}^1 \cdot im_p\right) + b_r^1\right)\right) + b_q^2\right)\right) + b_i^3\right) \quad (11)$$

where im_p denotes the pth input element. $w_{p-q}^r (r = 1, 2, 3)$, defined as *weight*, represents the linkage joining the pth input element/neuron in the rth layer with the qth neuron/output variable in the next layer. Similarly, b_q^i, called *bias*, is an offset constant for the qth element in ith layer, $(q = 1, 2, \ldots, \lambda/\eta/\beta$ for the first/second-processing/output layer). $T_s (s = 1, 2, 3)$ is the transfer function in the network [41]. In the fusion with a neural network, the inputs may be the features related to prior beliefs, while outputs are the parameters related to posterior beliefs.

4 DISTRIBUTED SENSOR NETWORK FOR DAMAGE DETECTION OF COMPOSITE STRUCTURES

The following gives a few examples to demonstrate the applications of distributed sensor network and one/multiple level of fusion in damage detection of composite structures, as shown in Figure 8. The simulation is concentrated on a representative active sensing unit (RASU), extracted from structures with a complex distributed sensor network.

In a distributed active sensor network, each sensor takes a role of Lamb wave generator (active sensor) or receiver (passive sensor). The information fed back to the active sensor from a passive sensor within a sensing path is represented using a set of digitalized signal features, termed digital damage fingerprint (DDF) in a study [42] pertaining to structural conditions. DDF is a kind of characteristic of a scattered Lamb waves signal that are extracted from the wavelet filter-processed signal and energy spectrum by gradually screening the noncharacteristic components and using principal signal components only, as described by a simple example shown in Figure 9.

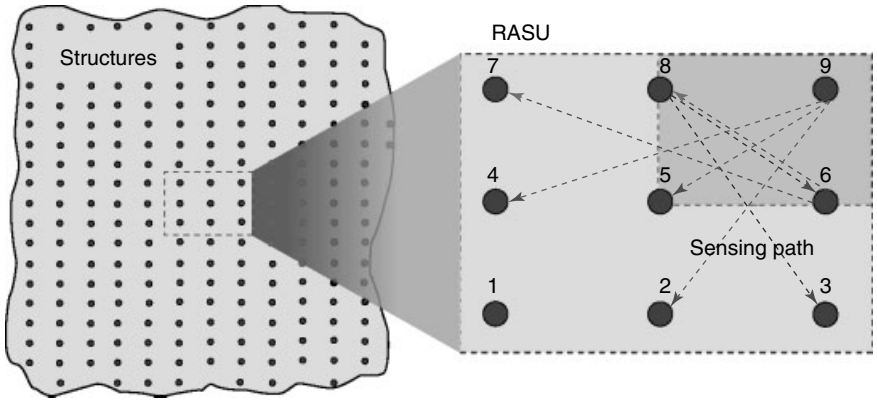

Figure 8. Representative active sensing unit (RASU) from structures.

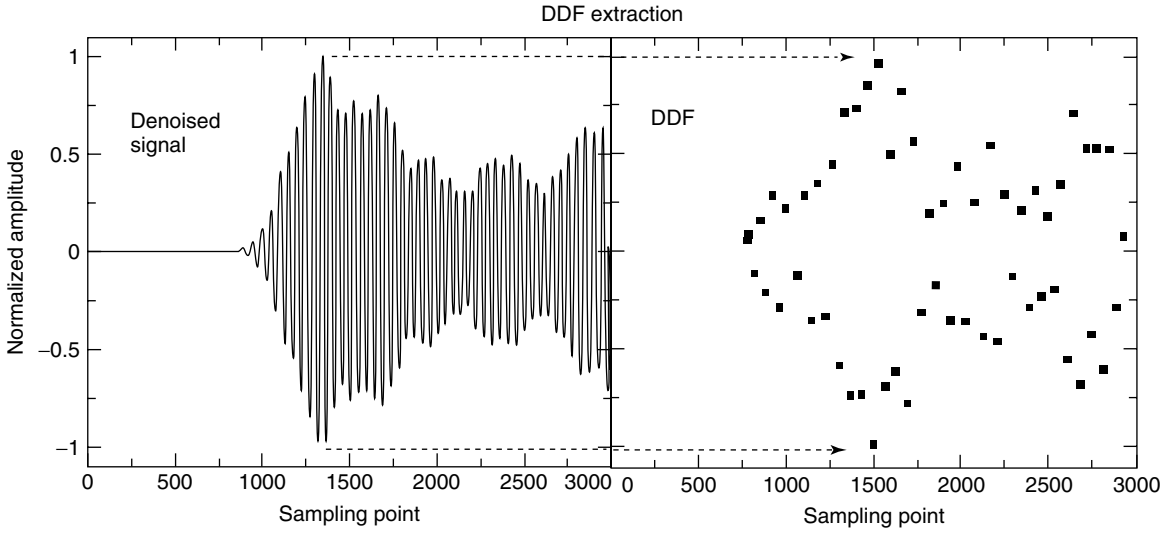

Figure 9. An example of DDF extracted from a denoised signal by a wavelet filter.

The one or multiple level fusion process is strongly related to DDF.

By way of illustration, a CF/EP (T650/F584) laminate was supported on all its four sides with a stacking sequence of $[45/-45/0/90]_s$ and measuring $500\,\text{mm} \times 500\,\text{mm} \times 1.275\,\text{mm}$ [43]. A sensor network of nine piezoelectric elements was surface-bonded on the laminate, sensors being numbered Pi $(i = 1, 2, \ldots, 9)$, similar to the one in Figure 8. The laminate was pretreated with damage (hole or delamination) during fabrication. Without losing generality, the damage was presumed elliptic, defined with six parameters: presence (0 or 1), location (ξ, ζ), semimajor/minor axes (α, β) and orientation of θ, although it is very often that not all of those details are required. Knowledge about digital damage fingerprints DDFs in relation to each sensing path under a specific damage was obtained through FEM simulation. Owing to the symmetric character in the discussed examples, only the area as shadowed in Figure 8, surrounded by sensors 5, 6, 9, and 8, was considered for the location of damage, though sensors 1 to 9 were all used in the damage identification process to identify damages. In establishing the knowledge, the cases of damage (location, shape, and orientation of holes/delamination) assumed are shown in Figure 10.

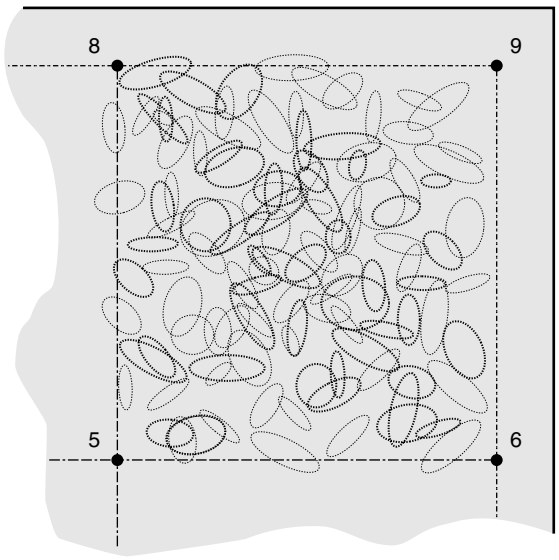

Figure 10. Samples of damages for acquiring knowledge of relevant DDFs.

4.1 Centralized sensing structure and one-level fusion process

In this example, the sensing structure was designed to be centralized, with one sensor controller to regulate one of sensors to generate Lamb waves and the others to collect signals, as shown in Figure 4. Feedback from all passive sensors became inputs to form a belief of structural condition status via a fusion process. Neural network was applied to implement the fusion process. The prior belief was described by the knowledge of delamination characteristics (location, shape, and orientation) in relation to DDFs obtained through FEM simulation. That knowledge was then employed to train a neural network and to establish the relation between DDFs and delamination.

In experiments, a delamination was pretreated as shown in Figure 11(a). DDFs were obtained on the same sensing paths as those utilized to train the neural network. A one-level fusion process was then carried out by combining all obtained DDFs as inputs of the trained neural network. The posterior belief about delamination was then established, as shown in Figure 11(b). The belief about the damage is reasonably close to the actual one.

4.2 Hierarchical distributed sensing structure and multilevel fusion

The belief of the sensors on structural damage status can also be quantified by correlating real-time acquired DDFs with preestablished knowledge about the DDFs, which are obtained from FEM simulation in association with specified damage patterns, illustrated in Figure 10. As a result, corresponding to each sensing path, there is one correlation coefficient C_{ij}^k, which can be considered as the degree of belief of an active sensor i within a sensing path $\vec{ij}$ on a specific damage pattern D_k defined in the preestablished knowledge. Theoretically, when there are N sensors, there exist $N-1$ sensing paths for one active senor i, or $\vec{ij}(j = 1, \ldots, i-1, i+1, \ldots, N)$. The level-one fusion is required to consolidate the correlation coefficients $C_{ij}^k(j = 1, \ldots, i-1, i+1, \ldots, N)$ to form a belief, $Bel(k; i)$, of the active sensor i on the damage patterns $D_k(k = 1, \ldots, M)$, or

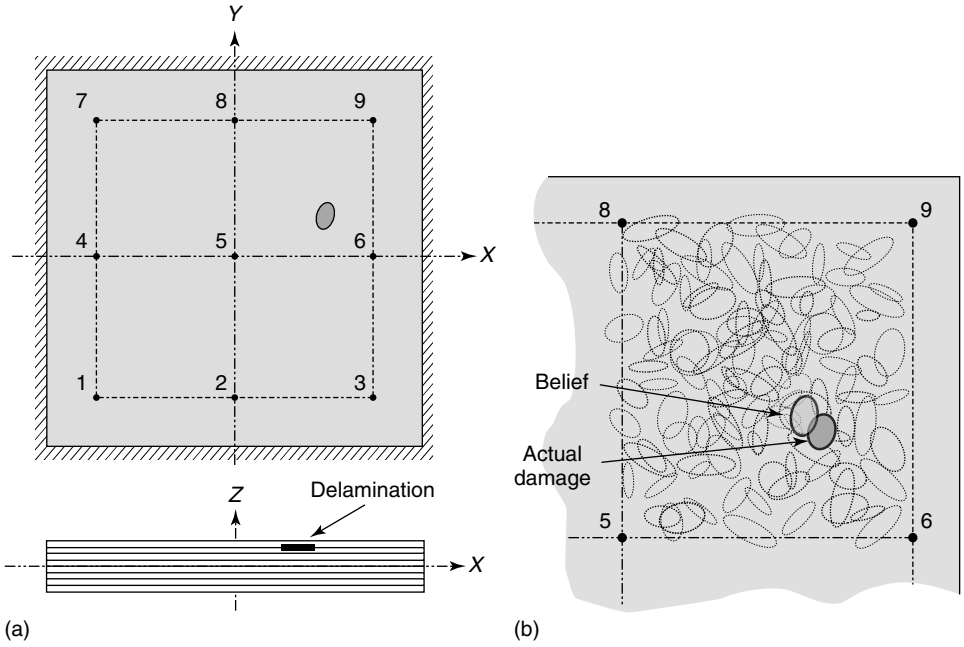

Figure 11. Experiment and identification: (a) A CF/EP laminate with a pretreated delamination and (b) comparison of the actual pretreated delamination with the belief on the damage formed on using an artificial neural network (ANN) [43].

described by

$$\Im_1(k) : C_{ij}^k \longrightarrow Bel(k;i), \text{ for } C_{ij}^k \in [0,1]^{N-1} \quad (j = 1, \ldots, i-1, i+1, \ldots, N) \quad \text{and } Bel(k;i) \in [0,1] \tag{12}$$

Meanwhile, all sensors may form their own beliefs, $Bel(k;i)(i = 1, \ldots, N)$, on each damage pattern. The level-two fusion is required to combine all beliefs of sensors to establish a belief of a group of sensors, which is normally at a sensor controller layer in the hierarchical active sensing structure as discussed previously. The fusion function for a sensor group p is described by

$$\Im_2(k) : Bel(k;i) \longrightarrow Bel(k;p), \text{ for } Bel(k;i) \in [0,1]^N (i = 1, \ldots, N) \quad \text{and } Bel(k;p) \in [0,1] \tag{13}$$

When there are groups of sensors, or there are groups of fusion approaches for one sensor group, that are used to form a posterior belief, the level-three fusion, $\Im_3(k)$, has to be implemented at a higher layer in the hierarchical structure, but very much similar to the one described in equations (12) and (13).

With fusion processes based on Bayesian theory and voting scheme [44], the belief about damage can be identified through level-one fusion, as shown in Figure 12(b) and (e), and level-two fusion, as shown in Figure 12(c) and (f). The actual damage is highlighted by a dotted circle. It is shown that the belief about the damage from one sensing path, as shown in Figure 12(a) and (d), is very vague, and actually cannot identify the damage. The belief after level-one fusion increases the confidence of belief about the damage, while the accuracy in identifying damage improves significantly after level-two fusion.

It is interesting to find that the contrast of the result from the Bayesian theory is much better than the one from the voting scheme. As discussed previously, the fusion based on the Bayesian theory is conjunctive, which may reduce uncertain components in the fusion process and provide a smallest measure. The fusion based on the voting scheme is compromising, which take an intermediate measure, implying that it could not reduce uncertain data as good as the fusion

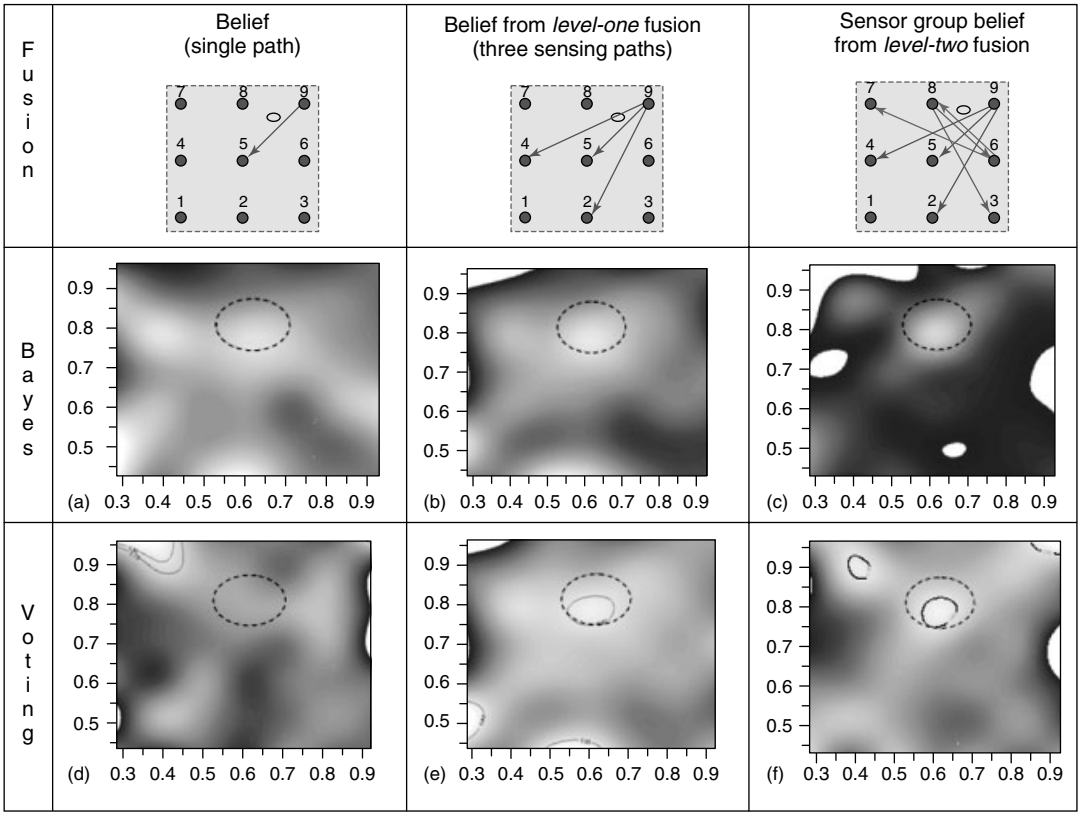

Figure 12. Damage identification by a fusion process, (a), (b), and (c) were obtained by fusion based on Bayesian theory, (d), (e), and (f) were obtained by fusion based on voting scheme (results of (c–f) extracted from [44]). The gray scale is equivalent to the probability of damage occurrence with the lighter corresponding to the higher possibility.

process based on the Bayesian theory. Therefore, the proper selection of fusion process is important.

5 SUMMARY

Design of a sensing network, and subsequently the interpretation of data acquired from sensors within the structure, are two critical issues in SHM for practical applications. It is understood that the process to identify structural health status is basically an inverse problem, which is often mathematically ill-posed or ill-conditioned creating considerable barriers to offer a robust and reliable identification algorithm, especially based on a simple sensor structure.

Active sensor network is designed to deal with the problems of health monitoring, capable of providing richer and sometime redundant information for structural condition identification by spatially distributed sensing structure. The sensing structure can be centralized, hierarchical, or even autonomous, in correspondence to the requirements of data interpretation.

The challenges faced by data interpretation for distributed active sensing network is how to consider information from all the sensors. The information from each sensor may be consistent or conflict with each other, and sometimes, meaningless. The combination of all information becomes crucial in the interpretation of data during the process of SHM. Data fusion can be utilized to implement the task. There have been a wide range of approaches in data fusion, including those algorithms based on voting scheme, Bayesian theory, Dempster–Schafer rules, fuzzy inference, and neural network. The behavior of data fusion operation can be conjunctive, disjunctive,

compromising, or a mix of them. It determines the quality of fusion process, which is often involved with imprecision, uncertainties, and incompleteness. An example has been demonstrated to see the difference of results from a fusion process based Bayesian theory and voting scheme.

Fusion can be considered as a process to establish a posterior belief about a set of propositions, such as structural damage events, on the basis of a set of prior beliefs that are possessed by physical elements such as sensors. Basically, a data fusion process is utilized to increase robustness and reliability of an SHM algorithm by reducing imprecision, uncertainties, and incompleteness as much as possible, through rich information from distributed sensor network.

Chapter 75

Energy Harvesting and Wireless Energy Transmission for SHM Sensor Nodes

Kevin M. Farinholt, Gyuhae Park and Charles R. Farrar
Engineering Institute, Los Alamos National Laboratory, Los Alamos, NM, USA

1 INTRODUCTION

The management of energy resources is an essential component in the success of any structural health monitoring (SHM) system. With applications that span aerospace, civil, and mechanical engineering infrastructure, it is necessary for sensors and sensor nodes to be both physically robust and energy efficient. In many applications, a sensor network must be installed in locations that are difficult to access, and often these systems have a desired operation life span that exceeds the capabilities of conventional battery technologies. To augment or replace the need to manually recharge or replace batteries within sensors, it is desirable to utilize ambient energy sources that are present within or around the structure being monitored. This process of extracting energy from the environment or a surrounding system and converting it into usable electrical energy is known as *energy harvesting*. Recently, there has been a surge of research in this area, brought about by advances in wireless technology and low-power electronics such as microelectromechanical system (MEMS) devices.

In many SHM applications, there is a considerable amount of ambient energy present within the structure under analysis. This ambient energy is typically in the form of mechanical vibrations induced through environmental or operational conditions, or thermal gradients that develop throughout the day from solar heating or the operation of machinery. The purpose of this article is to provide an up-to-date assessment of available energy harvesting methods suitable for potential SHM sensing applications. This article is not intended to provide an exhaustive literature review, as this area is very broad and useful review articles are already available in

 ISBN: 978-0-470-05822-0.

the literature (*see* **On the Way to Autonomy: the Wireless-interrogated and Self-powered "Smart Patch" System**; **Energy Harvesting using Thermoelectric Materials**). Instead, this article provides a concise introductory survey on the topic and outlines the current status of energy harvesting as applied to relevant themes in SHM. In the second part of the article, a recent alternative to energy harvesting based on vibrations and thermal gradients is presented with more details, using radio frequency (RF) signals to wirelessly deliver electrical energy to operate SHM sensing systems. In this approach, both energy and data interrogation commands are conveyed via a mobile host to each sensor node in order to perform the individual interrogation. Power does not have to reside at the sensor node, relaxing battery, or other such powering requirements. This article also discusses such a prototype system, which is used to interrogate piezoelectric impedance-based sensors on a full-scale bridge.

2 ENERGY HARVESTING

The source of ambient energy can take various forms, including sunlight, thermal gradients within a material, human motion and body heat, vibrations, and ambient RF energy. Several articles reviewing possible energy sources can be found in the literature [1–7]. Fry *et al.* [1] provide a survey of power supplies such as thermoelectric generators (TEGs), mechanical vibration devices using piezoelectric transducers, wind turbines, solar cells, and other exotic portable power sources that utilize ambient electromagnetic radiation, as well as traditional portable supplies such as batteries and fuel cells. While this report is concerned with sources for the US military special operations requirements, it provides insight on the future research trends in energy harvesting.

Roundy [2] compared the energy density of available and portable energy sources. He concludes that, for the device whose desired lifetime is in the range of 1 year or less, battery technology alone is sufficient to provide enough energy. However, if a device requires a longer service life, which is often the case, then the energy harvester can provide a better solution than the battery technologies. Paradiso and Starner [3] point out that the battery technology has evolved very slowly in mobile computing, with only a threefold increase in the battery energy density since 1990. At the same time, the disk storage density has been increased by 1300 times and the CPU speed by nearly 800 times. Park *et al.* [4] summarized several energy harvesting techniques that have been used in SHM applications. The summary also includes the issues associated with power-efficient hardware design and issues with energy harvesting system integration. Glynne-Jones and White [5], Qiwai *et al.* [6], and Mateu and Moll [7] also summarized the basic principles and components of energy harvesting techniques, including piezoelectric, electrostatic, magnetic induction, and thermal energy. A common suggestion listed in these articles is the combined use of several energy harvesting strategies in the same devices so that the harvesting capabilities in many different situations and applications can be increased. Furthermore, energy consumption can be minimized in an effort to close the gap between required and harvested energy [7].

2.1 Electrical energy from mechanical vibrations

One of the most effective methods of implementing an energy harvesting system is to use mechanical vibration to apply strain energy to the piezoelectric material or displace an electromagnetic coil. Energy generation from mechanical vibration usually uses ambient vibration around the energy harvesting device as an energy source, and then converts it into useful electrical energy. The research in this area has made use of mechanical vibration in order to quantify the efficiency and amount of energy capable of being generated and converted, as well as to power various electronic systems. Active materials, usually ceramic- or polymer-based, may be fabricated into a variety of shapes and sizes amenable to various applications. Some examples are shown in Figure 1.

The concept of utilizing piezoelectric material for energy generation has been studied by many researchers over the past few decades, which is well summarized in [8–10]. Piezoelectric materials form transducers that are able to interchange electrical energy and mechanical motion or force. These materials, therefore, can be used as mechanisms to transfer ambient vibration into electrical energy that

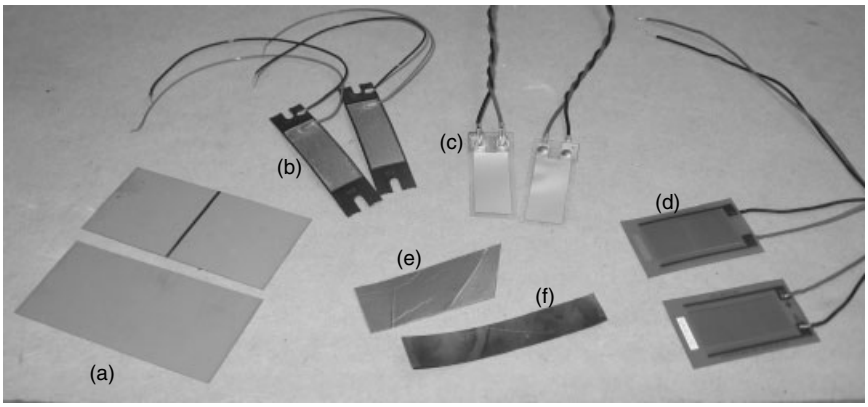

Figure 1. Some typical sensor/actuator materials: (a) PZT 5A4E from Piezo Systems; (b) thunder actuator from FACE International; (c) PVDF transducers from Measurement Specialties; (d) MFC actuators from Smart Material; (e) ionic polymer transducers from Discover Technologies; and (f) ionic polymer–metal composites from Environmental Robots.

may be stored and used to power other devices. A full description of the piezoelectric effect and the methods used to model the behavior of these materials is beyond the scope of this article. However, a significant number of journal articles and conference proceedings develop accurate models and discuss the fundamentals of these materials in great detail [11–13].

Basically, a variety of piezoceramic devices and piezo films have been examined in various settings to try and capture ambient vibration energy [14–16]. Most of them have been laboratory demonstrations and experiments. Some have focused on the electronics in an attempt to optimize the energy transferred from mechanical motion to electrical energy [17, 18]. Others have focused on using various different electrode patterns and packaging to optimize the electromechanical coupling [19]. Studies have also focused on using tuning to try and maximize the amount of energy transferred [20]; however, most of them have dealt directly with the random nature of mechanical energy. In all cases, the goal is to maximize the amount of energy flowing from the mechanical motion of vibration into usable electrical energy. The second feature addressed in the literature is, what should be done with the harvested energy. Some efforts examine storage through capacitors, immediate use, and storage through charging batteries [16, 21]. Other articles examine various applications of harvested power for powering the small electronics including SHM strain-sensing [22, 23] and environmental-sensing systems [24].

2.2 Electrical energy from thermal sources

A second method of obtaining energy from ambient sources is through the use of TEGs that capitalize on thermal gradients. TEGs use the Seebeck effect (Figure 2), which describes the current generated when the junction of two dissimilar metals experiences a temperature difference. Using this principle, numerous p-type and n-type junctions are arranged electrically in series and thermally in parallel to construct the TEG. Thus, when an electrical current is applied to the TEG, a thermal gradient is generated, allowing the device to function as a small solid-state heat pump. Inversely, if a thermal gradient is applied to the device, it will generate an electrical current that can be utilized to power other electronics.

TEGs have been used for capturing ambient energy in various applications. Lawrence and Snyder [25] suggest a potential method of retrieving electric energy from the temperature difference that exists between the soil and the air. To test their concept, a prototype was built without the TEG and the heat flow was measured to estimate the amount of power that could be obtained. The results showed that a maximum instantaneous power of approximately 0.4 mW could be generated by the thermoelectric device. Rowe *et al.* [26] investigate the ability to construct a large TEG capable of supplying 100 W of power from hot waste water. The system tested used numerous thermoelectric devices placed between two

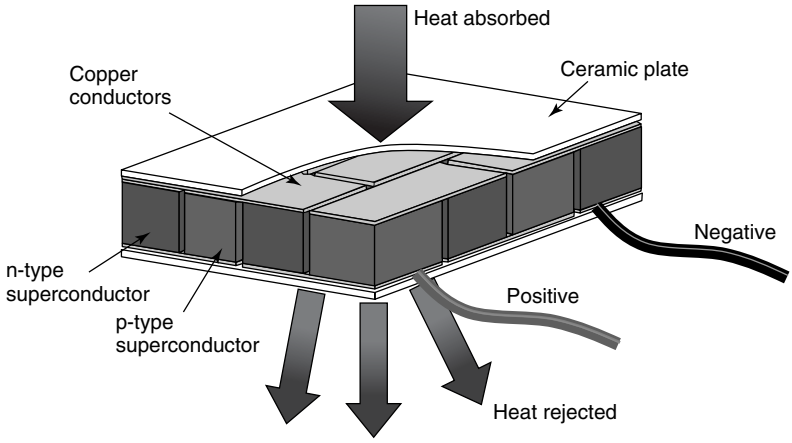

Figure 2. Schematic of the Seebeck effect.

chambers, one with flowing hot water and the other with cold water flowing in the opposite direction and thus maximizing the heat exchange. With a total of 36 modules, each with 31 thermocouples, 95 W of power could be generated.

As described, the idea of using thermoelectric devices to capture ambient energy from a system is not a new concept. However, in many cases, the research efforts utilize liquid heat exchangers or forced convection that significantly improve heat flow and power generation, but require complex cooling loops and systems. Therefore, Sodano *et al.* [27] investigated the use of TEGs as power harvesting devices that do not have an active heat exchanger, but function as a completely passive power scavenging system. Two potential applications are investigated, utilizing solar radiation and harvesting of waste heat. For each application, an experimental prototype was constructed and tested to determine the effectiveness in recharging a discharged nickel–metal hydride battery. The results showed that the TEG does produce significantly more power than a piezoelectric device and that the charge time needed to recharge a battery is significantly lower. This study is presented in more detail in **Energy Harvesting using Thermoelectric Materials**.

The TEG is a mature technology and a reliable energy converter with no moving parts compared to vibration-based harvesters. The TEG has been actively studied for the last three decades and the literature in this area is extensive. One of the drawbacks of this technology is low efficiency (<5%) if there is low temperature gradient present. Further, the fabrication cost is high, and the volume and weight are still too large for microscale sensing systems. Therefore, with the recent advances made in nanotechnologies, the fabrication of MEMS-scale TEG devices has been actively studied [28–30]. For instance, 0.5 cm^2 of a new thermoelectric thin film developed by Applied Digital Solution produces 1.5 μW of power with only a 5 $^{\circ}$C temperature gradient [31].

2.3 Current and future efforts in energy harvesting

Although extensive research work has been focused on energy harvesting, the amount of harvested energy appears to fall significantly behind that required by SHM sensing systems. The power requirement (not counting telemetry) for active-sensing SHM sensor nodes ranges in the order of tens to hundreds of milliwatts. Therefore, the major limitations facing researchers in the field of power harvesting revolve around the fact that the power generated by piezoelectric materials is far too small to power SHM devices. Therefore, methods of increasing the amount of energy generated by the power harvesting device or developing new and innovative methods of accumulating the energy are the key technologies that will allow energy harvesting to become a practical source of power for wireless SHM systems. Innovations in power storage must be developed before power

harvesting technology will see widespread use. The energy harvesting materials have typically been used to determine the extent of power capable of being generated rather than investigating applications and uses of the harvested energy. However, some limited research has focused on field applications of energy harvesters in SHM systems, one example being the intelligent repair application discussed in **On the Way to Autonomy: the Wireless-interrogated and Self-powered "Smart Patch" System**. The practical applications for energy harvesting systems, such as wireless self-powered SHM sensing networks, must be clearly identified with emphasis on power management issues. Application-specific, design-oriented approaches are needed to help the practical use of this technology. Finally, the long-term reliability of energy harvesting devices under the field operating condition should be extensively studied and validated before the full-scale deployment can take place.

3 RADIO FREQUENCY WIRELESS ENERGY TRANSMISSION

Another potential solution for powering SHM sensor nodes and networks is the use of wireless energy transmission. This approach relies on the use of electromagnetic radiation to charge a capacitor or battery that is embedded within or near a sensor network. At short ranges (∼cm) this method is highly efficient owing to inductive or capacitive coupling through magnetic or electric fields [32]. At longer ranges, the efficiency decreases as the electromagnetic radiation is transmitted in the form of visible or near-infrared light, or microwave radiation in the gigahertz range [33, 34]. While the efficiency of short-range coupling mechanisms is ideal, the close proximity that is necessary between source and receiver makes this option difficult to implement in many SHM applications. At longer length scales, the use of visible or near-infrared light provides an effective method for transmitting energy from the source to the target because of the ability to focus light. Unfortunately, the inefficiencies in current photovoltaic cells are detrimental as the conversion capabilities are on the order of 12%. Some experimental triple-junction cells have been developed with efficiencies of 30–40%; however, they require a highly concentrated light source to operate effectively [35].

Another transmission mechanism that is being considered is microwave radiation. In this case, power is generated elsewhere and transmitted to a sensor node by some form of RF radiation. This concept can utilize two different RF energy sources, ambient or controlled RF sources. Previous studies showed that electronics can be used to efficiently capture the ambient radiation sources and convert them to useful electricity. Harrist [36] attempted to charge a cellular phone battery by capturing ambient 915 MHz RF energy. Although he was not able to fully charge the battery, he observed 4 mV s^{-1} charging time from a typical cellular phone battery. Although there are several electronics that may derive their required power from ambient RF sources, the amount of captured energy is extremely low, typically in the range of a few microwatts. Therefore, the technology that has received the most attention is the microwave transmission with a controlled or so-called beamed RF sources, and has been significantly improved in the last several decades. A source antenna transmits microwaves across the atmosphere or space to a receiver, which can either be a typical antenna with rectifying circuitry to convert the microwaves to dc power, or a rectenna (rectifying antenna) that integrates the technology to receive and directly convert the microwaves into dc power.

A pair of excellent survey articles was written to discuss the history of microwave power [37, 38]. With the use of rectennas, efficiencies in the 50–80% range of dc-to-dc conversion have been achieved. Significant testing has also been done across long distances and with kilowatts power levels [39]. The study showed the feasibility of the wireless energy delivery systems for actuating large devices, including dc motors and piezoelectric actuators. Briles *et al.* [40] invented an RF wireless energy delivery system for underground gas or oil recovery pipes. The RF energy is generated on the surface, and travels through the conductive pipe acting as an antenna or a waveguide. The sensor module in the bottom of the pipe captures this energy and uses it to power the electrical equipment. With a 100-W transmitted power from the surface, it was estimated that around 48 mW of instant power can be captured after traveling 1.6 km along the pipe.

The fundamental limitation in this approach is the dispersion of microwaves, since they cannot be focused as readily as light. However, this loss

from dispersion during transmission is made up for in the increased efficiency with which this RF energy can be converted into electrical energy. Relative to the photovoltaic cells, the conversion of RF energy is more efficient than the highest performing photovoltaics. To further improve the efficiency of the microwave transmission, larger arrays of receiving antennas can be assembled to harvest more of the transmitted energy. Current research efforts in RF wireless energy transmission focus on improving the conversion efficiency and attempt to maximize the output power by designing efficient antennas and rectennas. In particular, circular polarized antennas are being implemented in the rectenna design because it avoids the directionality of other antenna designs [41–43]. An array of rectennas is increasingly used to improve the output power [44] and several new rectenna design schemes are proposed [45, 46]. Different elements are also used for efficient rectification [47, 48] in an attempt to obtain optimum output power, and these research trends are similar to those typically pursued in the energy harvesting arena.

Originally considered for alleviating the wiring harness in space structures or microaerial vehicles or providing an extremely low power for those typically used in radio frequency identification (RFID) tags in the 1–100 μW range, the application of an RF wireless energy transmission system for powering electronics typically used in distributed sensing networks has not been studied substantially in the past. In particular, the application of this technology for SHM sensor nodes in order to alleviate the challenges associated with power supply issues has never been addressed in the literature. Therefore, recently, a new and efficient SHM sensing network is proposed, whereby the electric power and interrogation commands are wirelessly provided by a mobile agent [49–51]. This approach involves using an unmanned mobile host node to generate an RF signal near sensors that have been embedded on the structure. The sensors measure the desired response at critical areas on the structure and transmit the signal back to the mobile host again via the RF communications. This "wireless" communication capability draws power from the RF energy transmitted between the host and sensor node and uses it to both power the sensing circuit and transmit the signal back to the host, which is schematically described in Figure 3. This research takes traditional sensing networks to the next level, as the mobile hosts (such as UAV) will fly to known critical infrastructure based upon a GPS locator, deliver required power, and then begin to perform an inspection without human intervention. The mobile hosts will search for the sensors on the structure and gather critical data needed to perform the structural health evaluation. This integrated technology will be directly applicable to rapid structural condition assessment of buildings and bridges after an earthquake. Also, this technology may be adapted and applied to damage detection in a variety of other civilian and defense-related structures such as pipelines, naval vessels, hazardous waste disposal

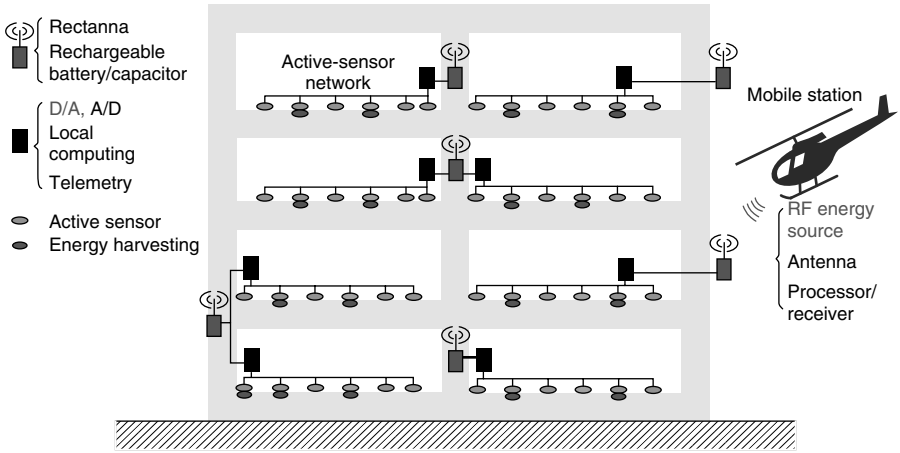

Figure 3. A new sensing network that includes wireless energy transmission and energy harvesting and is interrogated by an unmanned robotic vehicle.

containers, and commercial aircraft. It should be emphasized that this technology can be hybrid in that the sensor node is still equipped with energy harvesting devices and the mobile host would provide additional energy if the energy harvesting device is not able to provide enough power to operate the sensor nodes. Even if the energy harvesting device provides sufficient power, the mobile agent can wirelessly trigger the sensor nodes, collect the information, and/or provide computational resources, which significantly relax the power and computation demand at the sensor node level.

3.1 Patch rectenna design for SHM sensor node

There are two principal components in any wireless energy transmission system: the transmitting antenna and the receiving antenna. The transmitter is driven by an energy source such as a microwave generator and power amplifier, whereas the receiver is coupled with a rectifying circuit that converts the RF energy into usable electrical energy. A supercapacitor can serve as a storage device to collect the received energy and power the associated sensor node.

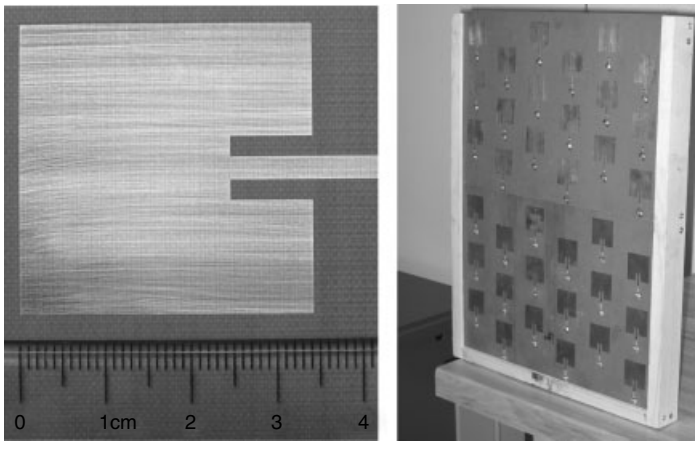
As stated previously, limitations in microwave transmission are associated with the dispersion of the wave as it travels through space. This dispersion can significantly reduce the amount of power received by the rectenna. This loss is seen to be a function of the square of the distance from the transmitting antenna, as seen in the Friis transmission equation:

$$P_{\mathrm{R}} = \frac{G_{\mathrm{T}} G_{\mathrm{R}} \lambda^2}{(4\pi R)^2} P_{\mathrm{T}} \tag{1}$$

where G_{T} and G_{R} are the transmitting and receiving gains, λ is the microwave wavelength in meters, R is the distance between antennas in meters, and P_{T} and P_{R} are the transmitted and received power in milliwatts. For a single microstrip patch antenna, such as the one shown in Figure 4, the power efficiency is calculated to be approximately 1.2% at 1 m spacing [52]. While this level of efficiency is relatively low, it can be increased considerably by assembling a larger array of these microstrip patch antennas as shown in Figure 4. This configuration greatly enhances performance as the array is capable of harvesting more of the incident wave from the source antenna. In this configuration, laboratory tests have shown that the antenna array is capable of charging a 0.1 F capacitor to 3.7 V in 28 s when located at 1.5 m from a source antenna that is emitting 900 mW of microwave power at 2.4 GHz.

3.2 SHM sensor node design for wireless energy transmission

This discussion of energy harvesting and wireless energy transmission is targeted toward one sensor



(a) (b)

Figure 4. (a) A single microstrip patch antenna used to receive microwave energy and (b) a rectenna array of 36 of these patch antennas.

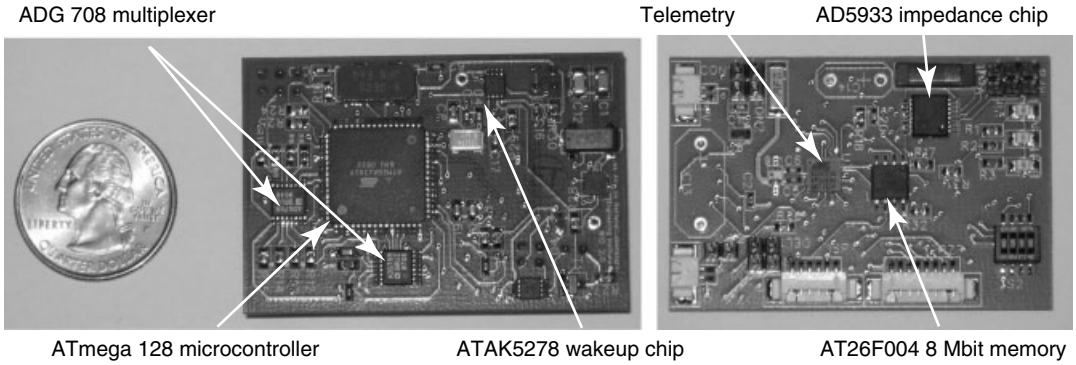


Figure 5. Wireless impedance device (WID2) developed by Los Alamos National Laboratory to measure, process, and transmit electrical impedance data for up to seven piezoelectric sensors.

node that has been developed by researchers at Los Alamos National Laboratory [53]. This system is designed as an active-sensor node that can interrogate the electrical impedance of seven piezoelectric patches, which utilizes impedance-based SHM [54], and is referred to as the *wireless impedance device* (WID2). The principal components of the design are shown in Figure 5, and include an ATmega1281V microcontroller, an AD5933 impedance chip with ADG708 multiplexers, an ATAK5278 wake-up chip, and an AT86RF230 telemetry module.

This sensor node is designed to provide onboard computing and data storage for a variety of SHM schemes. The standard operating condition for the WID2 is the idle mode in which the sensor node operates below 0.65 mA, consuming less than 1.82 mW of power. Proper configuration of the sleep modes should allow us to reduce current draw to 0.01 mA, providing a sensor node that is capable of extended operation at extremely low-power levels. The WID2 can be brought out of this idle mode at specific time intervals through an integrated real-time clock that is capable of waking the WID2 on intervals of 1 s to 1 year. Additionally, the sensor node can be activated through a low-frequency wakeup chip that monitors an integrated inductor for a magnetically coupled wakeup signal. Once the sensor node is activated, the microcontroller measures electrical impedance of each attached piezoelectric sensor, evaluates the status of the sensor, and either stores or transmits the result to a mobile host, which subsequently transmits the data back to the base station. Current and power consumption of the WID2 are outlined in Table 1 for each operational state.

Table 1. Current and power consumption for WID2 in different operational states

State	Current (mA)	Power (mW)
Measure	20	56
Transmit	22	61.6
Idle	0.65	1.82

The measure and transmit operations take a combined time of 10 s to complete. When considering the power consumption, the power requirement of WID2 is within the range of the capabilities of several energy harvesting or wireless energy transmission methods. Under laboratory testing, it was found that a 0.1 F supercapacitor provides sufficient energy for more than 10 s of operation, when it is charged to 3.7 V, which combines energy harvesting and transmission techniques to provide decades of sustainable operation.

3.3 Field testing

In August 2007, this method was field tested on the Alamosa Canyon Bridge near Truth or Consequences, New Mexico. Experiments were designed to test the effectiveness of this wireless energy transmission system when mounted on a mobile host. The source antenna, was mounted on the side of an automobile and the height was adjusted to match the height of the receiving antenna array. The microwave source and power amplifier were powered by a power inverter

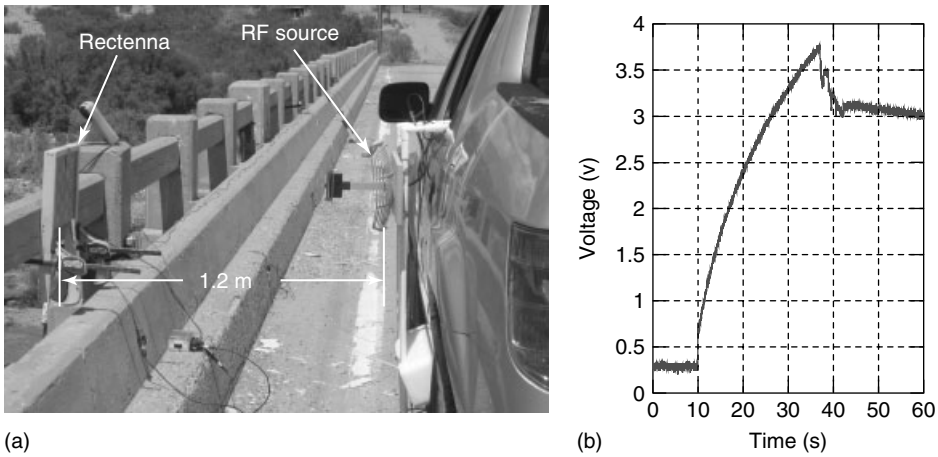

Figure 6. (a) Wireless energy delivery system field tested on Alamosa Canyon Bridge, NM. (b) The RF source was configured to emit 1 W of energy at 2.4 GHz, charging a 0.1-F capacitor to 3.7 V in 27 s.

that was plugged into the automobile's 12 V dc power supply. The receiving antenna was composed of 18 microstrip patch antennas clamped to the concrete side rail of the bridge as seen in Figure 6. This rectenna was used to charge a 0.1-F (P/N: PB-5R0V104) supercapacitor, which was connected to a WID2.0 sensor node and used to monitor the preload in two bolts on the bridge through piezoelectric sensors.

For this test, the automobile was stopped in parallel with the rectenna, as shown in Figure 6. The source antenna was activated and the voltage on the 0.1-F capacitor was visually monitored to prevent the capacitor from charging above 4 V (the WID2.0 operates on a nominal voltage between 2.7 and 3.3 V). During these experiments, the spacing between the transmitting and receiving antennas was maintained at 1.2 m, and the resulting charge time was measured to be 27 s to obtain a voltage of 3.7 V within the supercapacitor. Once charged, the sensor node was used to take measurements from two PZT active sensors, perform the local computing to determine bolt tightness, and then transmit 8 bytes of data back to the mobile host.

4 CONCLUSIONS

Energy harvesting is slowly coming into full view of the SHM and the more general sensing network communities. With continual advances in wireless sensor/actuator technology, improved signal-processing technique, and the continued development of power-efficient electronics, energy harvesting will continue to attract the attention of researchers and field engineers. However, it should be emphasized that energy harvesting still remains in its infancy and only a few successful examples are in practice. Still, a tremendous research effort is required to convert, optimize, and accumulate the necessary amount of energy to power such electronics.

One potential alternative that has shown successful performance in remotely powering sensor nodes is the use of wireless energy transmission. This technique builds upon an already existing technology that has been redirected to focus on low-power SHM systems. Laboratory and field tests have demonstrated that this method is highly effective in powering nodes that are designed to perform discrete measurements of a structure's health. Further development is needed to determine the optimal configuration of the receiving array and to couple this technique with charging electrochemical batteries to provide testing capabilities between charging cycles.

Chapter 72

Nondestructive Evaluation of Cooperative Structures (NDECS)

Daniel L. Balageas

Structure and Damage Mechanics Department, ONERA (The French Aerospace Lab), Châtillon, France

1 INTRODUCTION

The recent evolution of nondestructive evaluation (NDE) techniques used for maintenance of structures is characterized by rapid and dramatic changes. These changes also concern the general philosophy of structure maintenance and monitoring.

Three major evolutions can be highlighted: (i) in the pure NDE field, the ever growing importance of full-field, real-time, noncontact imaging techniques (*see* **Full-field Sensing: Three-dimensional Computer Vision and Digital Image Correlation for Noncontacting Shape and Deformation Measurements**); (ii) the birth and the impressive development of structural health monitoring (SHM), which could be superficially considered as an avatar of NDE, if only seen as a fully integrated NDE; and (iii) the importance of Lamb waves to elaborate SHM systems.

An analysis of these evolutions leads us to consider a possible third way, intermediate between NDE and SHM, called *nondestructive evaluation of cooperative structures* (NDECS). To illustrate this concept, three possible NDECS are presented. The first two techniques result from the combination of localized and embedded Lamb wave generation and noncontact optical detection; the last one combines laser ultrasonics and embedded piezoelectric detection.

2 RECENT EVOLUTION IN NDE, SHM, AND MAINTENANCE PHILOSOPHY

Presently, the maintenance of aerospace structures is based on the use of NDE techniques. One

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

of the characteristic evolutions of NDE and of experimental mechanics techniques is the importance gained by the development of full-field, real-time, noncontact imaging techniques. Such techniques, thanks to charge-coupled device (CCD) cameras, are performing a parallel acquisition of information coming from a very large number of locations. This is achieved by cameras working in various spectral domains: ultraviolet, visible, near, or far infrared, associated with coherent light illumination (interferometric techniques such as electronic speckle pattern interferometry (ESPI) [1]) or incoherent sources (stimulated thermography [2], visible image correlation techniques [3], etc.). These techniques can image fields of displacements, deformation, temperature, etc. of structures submitted to various types of solicitations: loads [4], fatigue [5], vibrations [6, 7], radiant heat fluxes [8], eddy currents [9], electromagnetic fields [10], etc. A high-frequency periodical excitation often used in NDE consists in propagating ultrasounds in the structure. Nevertheless, it has been only very recently coupled to full-field imaging techniques, and more particularly with shearography and thermography.

SHM, which belongs to the domain of smart materials and structures, can be considered as a new form of NDE, characterized by the full integration of sensors, actuators, and intelligence inside the structure during its manufacturing process. It is the reason why the recent growth of SHM community is partially explained by the progressive aggregation of members of the NDE community, while SHM, at its beginning, was mainly done by the mechanical engineering community.

SHM techniques were introduced in the 1990s and show an impressive development [4]. If we look at the SHM literature, we see an increasing importance of Lamb wave-based work and, for this purpose, a prevalent use of piezoelectric patches (*see* **Ultrasonic Methods**; **Piezoelectric Wafer Active Sensors**; **Piezoelectric Paint Sensors for Ultrasonics-based Damage Detection**). This is illustrated by a statistical analysis of the recent publications given in [4, 11].

These three evolutions (growing importance of full-field real-time imaging techniques, impressive development of SHM, and importance gained by the use of Lamb waves to elaborate SHM systems) are mainly driven by a cost-reduction strategy of maintenance operations (*short-term objective*). The second evolution — development of SHM — aims at the replacement of scheduled maintenance inspections by performance-based or condition-based inspections (*long-term objective*).

3 BETWEEN NDE AND SHM COULD WE IMAGINE AN INTERMEDIATE WAY?

If we consider the progress achieved in both NDE and SHM fields, a third approach seems possible now. This third way could consist in only embedding at well-chosen locations into the structure the stimulation function (actuators or emitters) and leaving the full-field noncontact detection (sensors or receivers) outside, or in adopting an opposite configuration with a full-field noncontact stimulation outside and a localized detection inside. To optimize such systems, Lamb waves could be used in conjunction with full-field noncontact optical techniques. So, using the more recent and promising techniques of both SHM and NDE domains, the proposed approach could be applied in a *short term*, with existing technologies, and would permit time and money saving for maintenance operations. A well-suited appellation for this type of technique could be NDECS.

Such an idea is not totally new. A similar approach has been made by Walsh [12] with a more limited field of application. Walsh proposed to replace conventional ultrasonic testing using surface contact probes by a semiembedded system in which the emitter is inside the structure and the detector is outside, which allows an improved resolution and a larger depth of penetration. Walsh called this concept as *nondestructive evaluation ready material* (*NDERM*) technology.

The NDECS concept proposed here is more efficient and more ambitious. Figure 1 presents a schematic view of what could be an NDECS system. Three possible systems are described using (i) lock-in thermography to monitor the thermal effects resulting from the interaction of the waves with possible damages like delaminations, cracks, or corrosions; (ii) stroboscopic shearography to monitor the full field of the surface displacements created by the Lamb waves; (iii) ultrasounds generated by a

pulse repetitive laser and detected by an embedded piezoelectric receiver. These three imaging techniques are chosen because they seem more promising and they are almost ready to be used, since their feasibility has been proved in laboratory. The two first systems are based on work done at Office National d'Etudes et de Recherches Aérospatiales (ONERA) and were presented as NDECS systems in [11]. The third system is studied by a group at National Institute of Advanced Industrial Science and Technology (AIST) (Japan) [13]. The following sections present the principle and some laboratory results already obtained with these techniques.

4 IMAGING INTERACTIONS OF LAMB WAVES WITH DAMAGES USING LOCK-IN THERMOGRAPHY

4.1 Principle of lock-in ultrasonic vibrothermography

Ultrasonic vibrothermography is an NDE technique based on the application of a modulated mechanical stress on the tested structure, while an IR camera

maps the surface temperature [14]. Thermomechanical coupling (*see* **Thermal Imaging Methods**) is responsible for heat production, which, in turn, is partly responsible for damping. In particular, damaged regions convert energy into heat through enhanced viscoelastic dissipation, collisions, and/or rubbing of internal free surfaces present in delaminations and cracks. Surface defects and internal defects appear hotter when the surface temperature is mapped, a fact that provides the basis for the use of joint mechanical excitation and thermography as a nondestructive technique.

Most of the experimenters have used high-power ultrasound emitters producing simultaneously several uncontrolled waves: mechanical shakers [15], a 500-W ultrasound cleaner [16], ultrasound generators such as sonotrodes (generally designed for plastic welding) with power up to 2 kW [17, 18], etc. The use of such powerful devices may cast some doubt on the nondestructive aspect of the control. The first danger is thus, in the case of polymer composite testing, of overheating the material in the contact area. The second danger is that small tolerable cracks may grow unexpectedly fast when the defect surfaces are submitted to energetic rubbing and/or "clapping".

Ultrasonic vibrothermography can also be performed through video lock-in processing [15] (*see* **Thermal Imaging Methods**) if the high-frequency mechanical excitation is amplitude modulated at a low frequency. In this case, the heat generated by the *high-frequency vibrations* is modulated at this *low frequency* and the thermographic lock-in system is synchronized with this thermal wave frequency. At ONERA it has been proposed to evaluate whether lock-in ultrasonic vibrothermography could be applied by means of small, low-energy piezoelectric transducers embedded or surface bonded to the tested structure, and generating Lamb waves (Figure 2). These transducers are currently used in acousto-ultrasonic SHM systems. This has been successfully demonstrated in the case of C/epoxy plates [14]. This solution presents three main advantages: (i) low-power actuators (less than 1 W) can be used, inducing a low dissipation at the defect location, nevertheless detected, thanks to the lock-in procedure; (ii) embedding or bonding the piezoelectric patches guarantee a coupling constant in time and ascertainable by measuring the electromechanical impedance [19, 20]; and (iii) the use

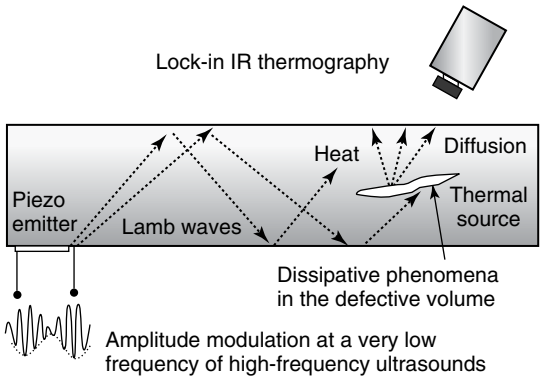

Figure 2. Principle of lock-in ultrasonic vibrothermography applied to the visualization of the interaction of Lamb waves with a damage.

of Lamb wave permits long-distance propagation with moderate attenuation, thus giving an almost uniform sensitivity to the defect detection in the full structure.

The choice of the frequency and the nature of the wave to excite the defects are very important. This has been demonstrated by several experimenters [21–23].

4.2 Low-energy detection of delaminations in composite panels

Following the principle presented in Figure 2, results have been obtained using Lamb waves and very low energies. Temperature mapping was performed using an IR focal plane array camera (Amber 4128, 128 × 128 pixels), with a noise equivalent temperature difference (NETD) of 7 mK. The lock-in technique was applied to demodulate the thermal signal. The ultrasound actuator was fed with a high-frequency electric modulation, between a few tens and a few hundreds of kilohertz, and the amplitude was modulated with a sinus function or a square function at a low frequency (33–300 mHz). By processing 500 images, a temperature modulation amplitude image with an NETD lower than about 0.5–0.6 mK was obtained, making the detection of defects such as delaminations, debonding, microcracking, and macrocracks possible.

The results presented here were obtained with a $[0_4/45_4/90_4/-45_4]_S$ C/epoxy plate of dimensions $70 \times 70\,cm^2$ with a delamination produced by

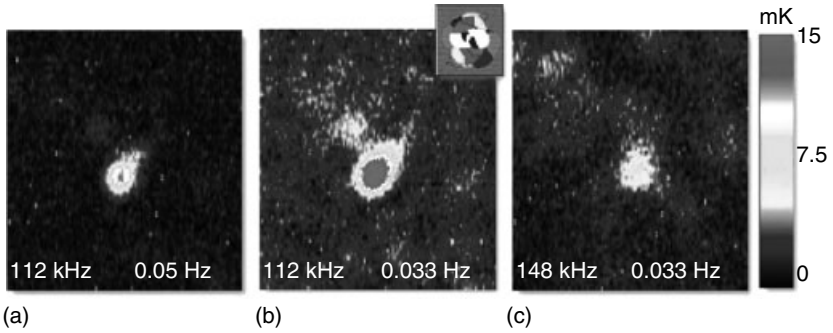

Figure 3. Temperature amplitude map on the front side of the impacted area of a C/epoxy coupon. Influence of the low-frequency modulation for a Lamb wave frequency of 112 kHz: (a) low amplitude modulation frequency of 50 mHz, (b) same as in (a) but with 33 mHz. Influence of the wave frequency (same Lamb mode) with amplitude modulation at 33 mHz: (b) 112 kHz, (c) 148 kHz.

a 5-J impact. The electric power injected in the piezoelectric emitter (disc-shaped, 30 mm in diameter and 200 micron thick) was 1 W. The amplitude of the Lamb waves is modulated at a low frequency (30–300 mHz) to cope with the thermal wave attenuation. In the present case, the delaminations can be detected from front face (impacted face) provided the modulation frequency is lower than 100 mHz. Figure 3(a–b) presents the thermal amplitude images obtained for two modulation frequencies: 50 and 33 mHz. Decreasing the modulation frequency has a beneficial effect on the sensitivity, but results in more blurring. These results highlight the well-known depth probing property of "thermal waves".

With the modulation frequency fixed at 33 mHz to get a good signal-to-noise ratio, several wave frequencies between 50 and 150 kHz were used. The temperature amplitude images obtained after synchronous demodulation are presented in Figure 3(b–c) for 112 and 148 kHz. The highest contrast, i.e. 22 mK, is observed for a frequency of 112 kHz. When the actuator is excited at 148 kHz, the defect is still detectable, but the contrast dropped to about 8 mK. Decreasing the wave frequency has the same detrimental effect. This shows how important the choice of the ultrasound frequency for a safe detection by thermography. For this optimum frequency, the apparent size of the defect is comparable to the image obtained by classical D-scan (see upper right part of Figure 3b).

These experiments show that defects can be detected whatever their depth be, provided that dissipation is high enough and that the modulation frequency is chosen sufficiently low (thick plates need higher mechanical energy and deep defects need lower lock-in modulation frequency to be revealed). The high selectivity of the ultrasound frequency regarding the thermomechanical coupling at the defect location has, however, to be taken into account. This requires some theoretical work to predict, for a given structure and a given defect geometry, which kind of ultrasound wave would lead to maximum dissipation at the defect locus.

4.3 Practical applications

The experimental results just presented concerned delaminations in composite structures. In fact, the field of application of the technique is much wider and ultrasonic vibrothermography has already been applied to real structures presenting realistic damages. These works have been essentially performed with sonotrodes or high-energy lead zirconate titanate (PZT) patches. The types of structures and damages detected until now in these conditions are varied. Let us mention, taken from [17, 22, 23] (i) delaminations in skin and stringer and stringer debondings in composite aircraft panels; (ii) cracks and debonds in metallic structures, hidden corrosions between skin and riveted stringers in aluminum structures; and (iii) heterogeneities in a multilayer C/C–SiC ceramic composite. We can suppose that by choosing tailored Lamb waves, similar results could be obtained with low or moderate energies.

5 IMAGING INTERACTIONS OF LAMB WAVES WITH DAMAGES USING STROBOSCOPIC SHEAROGRAPHY

5.1 Principle of the shearographic imaging of ultrasounds

Shearography is a speckle interferometric technique that appeared in the 1970s [24–26], in which the interfering photons are issued from two closed points of the structure thanks to an optical "shearing" device. This prevents the system from being sensitive to vibrations and solid motions of the structure. The measurement is performed for two successive states of deformation of the structure. By electronic data reduction, a subtraction of the two speckle images produces a resulting image containing information linked to the gradient of deformation between the two states in the direction of the shear. To make the technique quantitative, a phase stepping is required and, from four intensity images corresponding to four phase lags introduced thanks to a controllable mobile mirror, a phase image is obtained, which can be directly graded in gradient of deformation. This differential image is different from the images of deformation given by more classical interferometric techniques like ESPI [1].

To produce two different states of deformation of the structure, it is possible to use depressurization [27], photothermal stimulation [28], or vibrations. To define two states in the case of vibrations, it is necessary to produce a stroboscopic illumination with an acousto–optic modulator in the laser beam [29] as seen in Figure 4(a).

Gordon and Bard [30] were the first to propose and apply this technique to the visualization of ultrasounds. As shown in Figure 4(b), the two states of deformation of the structure correspond to two laser illuminations with a phase difference of 180° with respect to the ultrasounds. The phase stepping

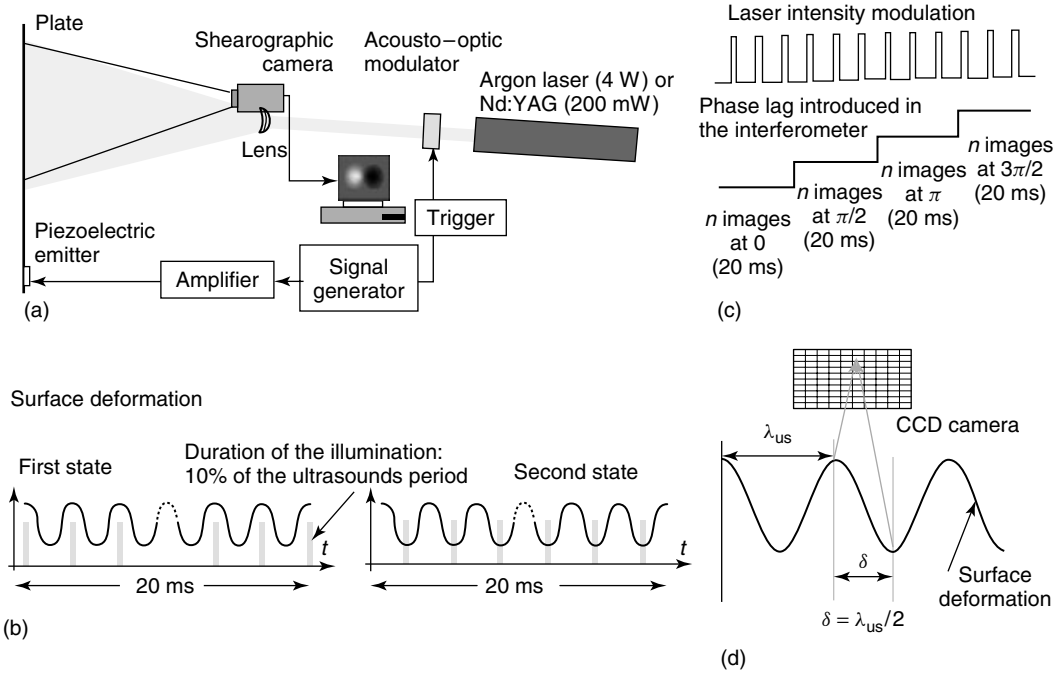

Figure 4. Visualization of Lamb waves by shearography: (a) experimental setup (the shearographic camera contains the three elements of the Michelson interferometer: shearing, phase stepping, and shear control devices). (b) synchronization between the signal feeding the emitter and the laser illumination, producing the stroboscopic effect; (c) synchronization between the laser illumination and the phase lag introduced in the arm of the interferometer (valid for the two states); and (d) shear adjustment (shear distance equal to half the wavelength).

technique is used (Figure 4c) and, to increase the signal-to-noise ratio, for every phase shift, image accumulation is performed for 20 ms. Finally, the better sensitivity is obtained with a shearing distance equal to half the ultrasound wavelength (Figure 4d), producing a difference of displacement between the two interfering points that is maximum. Under these conditions, the shearographic image level is strictly equal to four times the ultrasound amplitude, with a sensitivity of the order of 1 nm. If the shear is equal to the wavelength, then the wave is not seen, the deformation of the interfering points being identical, which can be interesting to visualize the waves diffracted by a damage [31, 32].
