The use of continuous Lamb waves leads to results, which can be hard to interpret whether real structural parts are likely to induce reflections, mode conversions etc. Such elements can be fasteners, stringers, rivets, etc. or simply the plate edges. In particular, these effects are important in metallic structures for which the attenuation of Lamb waves is very low. To avoid this inconvenience, it is more convenient to generate short bursts and to follow their propagation [32]. Some modifications have to be introduced relative to the wave imaging mode: only one laser stroke is used per burst and its firing is delayed according to the propagation stage one wants to image. The second surface state is simply obtained by reversing the transducer input voltage.

In its simplest way of application, the shearographic camera views the structure perpendicularly to its surface, and then only the out-of-plane displacement is detected (present results). Nevertheless, it is possible to visualize the in-plane displacement, and this can be useful for Lamb wave imaging [33, 34].

5.2 Illustrative examples of shearographic imaging of Lamb waves

Figure 5 presents the visualization of the interaction of Lamb waves with a delamination in a C/epoxy plate [31, 32]. The coupon, equipped with a PZT emitter, is the one already used for the vibrothermographic experiment. The detection and localization are unambiguous and feasible on both front and rear faces of the plate. The interaction between the incident wave and the delamination is a diffraction phenomenon. It is possible to detect, although not so easily, this diffraction (emergent wave) around the damaged area (in particular, in Figure 5c).

Figure 6 presents an interaction in a more complex configuration: an artificial defect in a composite sandwich structure of a radome [35]. The defect is a lack of material, representative of a debond between the outer skin (glass/epoxy composite) and the core made of low-density foam. There is an interaction only in the outer skin, which allows us to delimit the extent of damage. No interaction is produced in the inner skin, which is thicker, because its dispersion curves are almost identical to that of the full sandwich.

The demonstration of the possibility of imaging the propagation of Lamb wave bursts has been achieved too [32]. Figure 7 presents the images of

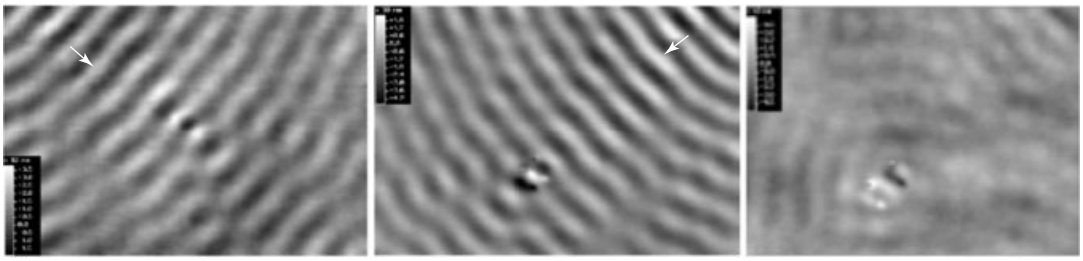

Figure 5. Interaction of Lamb waves (S_0 mode, 68 kHz) propagating in the C/epoxy plate described in the section on vibrothermography. The dimensions of images are $17 \times 12\,cm^2$ and their dynamic range is near to 50 nm. The electric power injected in piezoelectric emitter is 1 W. In figure (a) the shearographic image of the front face obtained with a shear distance equal to half the wavelength shows both incoming and diffracted waves. This is also the case for the image of the rear face given in figure (b). In figure (c) the image of the rear face obtained with a shear distance equal to the Lamb wavelength only shows the diffracted waves. [Reproduced with permission from Ref. 32. © EDP Sciences, 2006.]

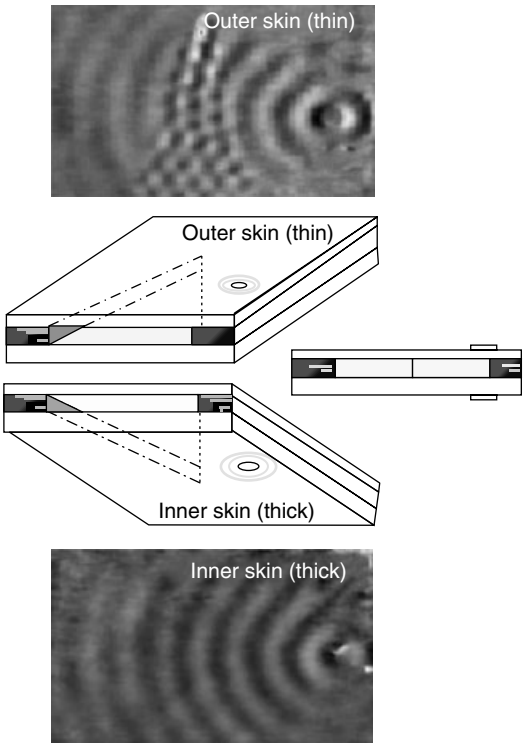

Figure 6. Shearographic visualization of the interaction of Lamb waves (A_0 mode, $f = 20\,\text{kHz}$) with a defect in the core (lack of foam) in a composite sandwich of a radome.

the displacements recorded on the impacted sample previously monitored (Figure 5) for three different delays after the burst emission. In the first image, the Lamb wave front is still upstream from the impact defect and in the second image the burst has already passed the defect. Again a 30° wide wake with a 180° phase delay appears downstream. In the last image, a circular diffracted wave is seen around the defect. Five-period bursts have been used, with windowing, and this unavoidably induced higher frequency content for the mechanical excitation. Modes other than S_0 with different velocities and wavelengths could thus be present. Together with the fact that the bursts are repetitively emitted, this could explain why the defect already appears before the burst reaches it. Indeed small amplitude ripples can be seen in front of and behind the burst.

6 IMAGING INTERACTIONS OF LAMB WAVES WITH DAMAGES USING SCANNED LASER ULTRASONICS AND EMBEDDED PZT RECEIVERS

6.1 Principle

The concept of the third technique (Figure 1c) proposed by Takatsubo and colleagues from AIST (Japan) [13], is based on the fact that when ultrasonic waves propagate between two points using one emitter and one receiver having the same frequency characteristics, the same waveform would be detected if the emitter and the receiver replaced each other. The technique uses a pulsed laser generating ultrasounds by thermoelastic effect and a piezoelectric receiver. The waves detected by the piezoelectric sensor at a point B and generated by the laser at a point A would be almost the same as the waves detected at point A issued from the laser generation at point B. This visualization is based on the reversibility of the propagation of ultrasonic waves.

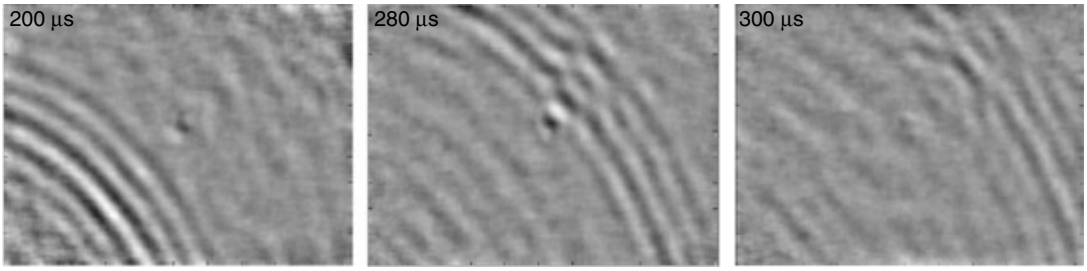

Figure 7. Shearograms of burst propagation in a delaminated C/epoxy plate (5-J impact) obtained for three delays after the burst. Transducer driven with repetitive five-period bursts (68 kHz). [Reproduced with permission from Ref. 32. © EDP Sciences, 2006.]

Let us consider now that the laser impact is scanned on the structure surface. Then, the train of waveforms detected by the fixed-position piezoelectric sensor during the laser scanning will be the same as those obtained by detecting the waves generated by directing the laser beam toward the position of the piezoelectric sensor while scanning the sensor on the structure surface. Therefore, images may be created by the waveforms detected during scanning of the laser. Displaying these images consecutively in the order of the measurement times produces an animation showing the propagation pattern that would be generated by a laser generation of ultrasounds at the location of the piezoelectric receiver. These authors have experimentally demonstrated that this principle is still valid if a defect is present in the propagation path [13].

The technique has several remarkable advantages: (i) it allows visualization of ultrasonic waves propagating in a complex-shaped 3D structure with curved surfaces, steps, and dents; (ii) there is no need to adjust the laser incidence angle and the focal distance; (iii) high detection sensitivity is obtained; and (iv) noncontact wide-field imaging of complex structures is made possible.

6.2 Practical applications

The technique has been applied to the detection of various types of structures and defects: holes and flaws in curved metallic pipes, slits in metallic plates, and debonding in a carbon fiber reinforced plastic (CFRP) structure. Figure 8 presents an illustration of the possibilities of the technique for detecting debonding between the skin and a hat stringer in a CFRP structure (airplane wing). The pulsed laser was a yttrium aluminum garnet (YAG) (1064 nm) delivering 5-mJ, 10-ns pulses with a repetition rate of 20 Hz. The laser is fixed on two rotation axis stages controlled by a PC. The image results from the impact of the 2-mm-diameter laser beam onto

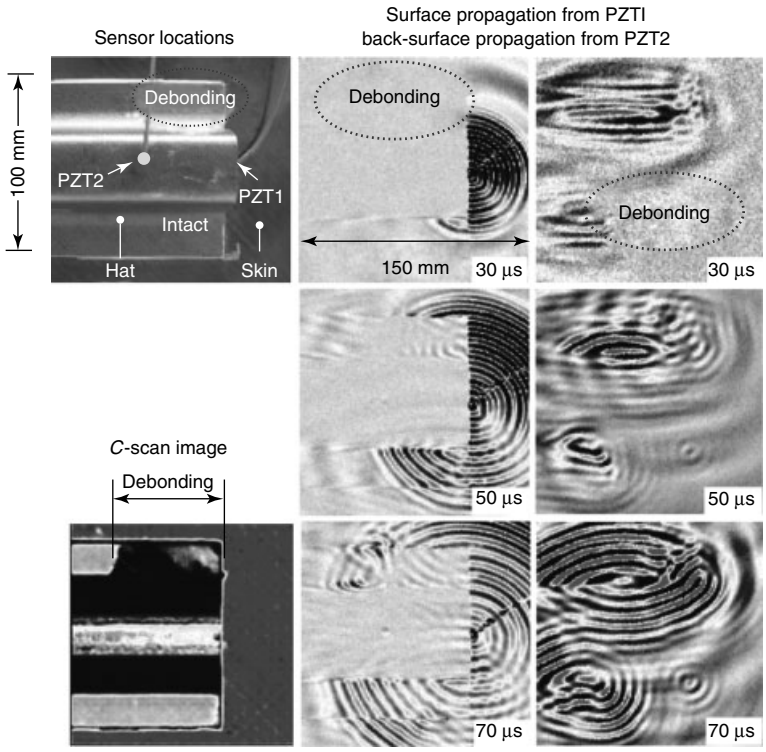

Figure 8. Detection of a debonding between skin and hat stringer of a CFRP structure. [Reproduced with permission from Ref. 13. © Takatsubo, 2006.]

100×100 points on the structure. For each impact, the PZT receiver signal is recorded. Thanks to the reversibility, the amplitudes of the recorded trains of waveforms at a given time correspond to the displacements of the ultrasounds at the irradiation points. Images can be created whose intensities are determined by these amplitudes. When displayed consecutively, the propagation at the surface of the structure of the ultrasonic waves can be observed, allowing the detection of damaged areas. Using Fourier analysis, it is possible to construct monofrequency images. The visualized signal in Figure 8 is a single-frequency (300 kHz) ultrasound signal, so there is very little velocity dispersion in the propagation image since such a dispersion depends on frequency. The debonding forms a thin air layer, and ultrasonic waves hardly propagate across it. The debonded part and the intact part can thus be clearly distinguished.

7 CONCLUSIONS

The concept of NDECS has been defined and proposed as a third possible way between the classical NDE and SHM. From the analysis of the present evolution of techniques in NDE and SHM fields, it has been deduced that the best NDECS solutions could be the combined use of Lamb waves and optical noncontact detection or emission systems. Three NDECS configurations have been described on the basis of the combined use of embedded PZT transducers with the following techniques: stroboscopic shearography, lock-in infrared thermography, and scanned laser ultrasonics. To demonstrate that these solutions are applicable in the short term, promising experimental results have been presented.

Chapter 76

On the Way to Autonomy: the Wireless-interrogated and Self-powered "Smart Patch" System

Stephen C. Galea, Stephen Van der Velden, Scott Moss and Ian Powlesland

Air Vehicles Division, Defence Science and Technology Organisation (DSTO), Melbourne, VIC, Australia

1 INTRODUCTION

The application of bonded composite patches or doublers to repair or reinforce defective (secondary) metallic structures is becoming recognized as an effective and versatile repair procedure for many types of problems [1]. However, the application of bonded composite repairs to cracked aircraft primary structure is generally acceptable only on the basis that a margin on design limit-load (DLL) capability is retained in the event of loss (total absence) of the repair [2]. However, assuming that the static requirements and quality-assurance processes are satisfied, one approach to certify full credit for the patch in slowing crack growth could be justified by a *continuous safety-by-inspection approach.* This approach is based on the continuous self-assessment of the patch system integrity using a *smart patch* approach [2, 3], by incorporating *in situ* sensors to continuously monitor the structural condition of the patch system and associated remaining damage in the parent structure. The need to follow approved patch design, fabrication, and quality-assurance procedures is unchanged; this approach simply allows a relaxation of the probability of failure requirements, particularly in relation to environmental degradation. However, the viability of any *smart patch* or *in situ* structural health monitoring (SHM) approach now depends on establishing its reliability or probability of damage detection, which is similar to

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 Commonwealth of Australia. ISBN: 978-0-470-05822-0.

the problem of probability of detection in Non-Destructive Inspection (NDI), and should include system self-checking and redundancy to provide the required level of confidence.

To demonstrate and evaluate the feasibility of the *smart patch* concept, the Australian Defence Science and Technology Organisation (DSTO) has developed two SHM systems to interrogate the structural health of a boron/epoxy (b/ep) doubler (or reinforcement) on an F/A-18 inboard aileron hinge, as shown in Figure 1(a). One system, the battery-powered *smart patch* (BPSP), uses a lithium ion-based battery as the power source and measures load transfer from the structure to the patch, using conventional strain gauges, to monitor patch health. The patch health data is uploaded by the operator via an infrared (IR) link. The other concept, the self-powered (wireless) *smart patch* (SPSP), involves more technical risk and consists of a piezoelement-based self-powered sensing system powered by an array of piezotransducers, which convert structural dynamic strain to electrical energy, and monitors damage in the patch via piezoelectric film strain sensors. In this system, the patch health data is uploaded by the operator using a magnetic transceiver. The instrumented aileron was installed on a Royal Australian Air Force (RAAF), Aircraft Operation Support Group (AOSG) F/A-18 in early 2006 and was flown for 12 months.

This article describes some of the critical issues associated with the development, evaluation and implementation of the self-powered *smart patch* system, including system design, functionality and certification testing, and installation. The article gives a brief overview of the various available power-harvesting techniques and discusses several key issues when designing and developing the self-powered *smart patch* system, viz., (i) demand—power requirements, (ii) supply—energy generation from vibration or strain-based sources, and (iii) conversion—issues and efficiencies associated with energy conversion from mechanical to electrical energies. Flight data from the SHM system and lessons learned during the program are also presented.

2 BACKGROUND

2.1 General system specifications

The initial idea was to evaluate the *smart patch* concept on a bonded composite patch/reinforcement designed for an F/A-18 aluminum aileron hinge with a propensity to cracking [5] (Figure 1a). During the initial system design phase, the RAAF decided to refurbish the ailerons and, in so doing, replaced the aluminum hinges (Figure 1b) with redesigned titanium hinges (Figure 1c), thus eliminating the cracking problem. However, in consultation with senior RAAF engineering managers, it was decided to proceed with the *smart patch* demonstrator on a titanium aileron hinge.

The first phase of the project was to establish the operating envelope of the system, including temperature, strain, and vibration at the aileron hinge and, flying time and elapsed time between system installation and removal from the aircraft. All these issues are critical when designing and implementing such a system. These general specifications are listed below [6]:

- The expected operational temperature range was -40 to $+70\,^{\circ}$C.
- No strain time history data was available for the titanium aileron hinge; however, flight loads and design data for the aluminum aileron hinge indicated that the operational peak strains were of the order of $1500\,\mu\varepsilon$ at an excitation frequency of between 8 and 42 Hz.
- Flight times were expected to vary between 40 and 60 min per sortie.
- The system was expected to be operational for an elapsed time of one year, which would entail between 100 and 200 sorties.

2.2 Concept development and high-level system design

In general, the *smart patch* concept needs to continually inspect regions of the reinforcement likely to suffer disbond damage [2]. There are several methods of achieving this goal and providing an indication of structural health. One method involves subjecting the structure to a known excitation and then measuring a response at the "interrogation" time (*see* **Development of an Active Smart Patch for Aircraft Repair**; **Design, Analysis, and SHM of Bonded Composite Repair and Substructure**). An alternative would be to use some form of "in-service" excitation (*see* **Design, Analysis, and SHM of Bonded Composite Repair and Substructure**). In this case, in-flight loading is used as the excitation mechanism and in-flight strain response as the damage indicator. A finite element (FE) analysis of the hinge is undertaken to determine the most likely regions of damage and to assist in developing the most appropriate damage indicator (see Section 3.1) [6].

An autonomous remotely accessed patch health monitoring (*smart patch*) system was the final objective. As discussed previously, the full *smart patch* demonstrator consisted of two, developed concurrent, wireless SHM systems, namely, the BPSP and the SPSP. However, even though the BPSP system is a lower risk solution it does suffer from the limitation of a finite power supply and would require occasional maintenance to replace the battery. The SPSP offers significant advantages over the BPSP since it is maintenance-free and therefore facilitates rapid acceptance by operators, maintainers, and certification authorities and would incur minimum additional through-life-support costs. This latter approach would enable minimum interruption to relatively rigid and well-established logistic and maintenance procedures associated with aging aircraft. In addition to monitoring the health of bonded patches, this approach would facilitate SHM of structural "hot spots" in "difficult-to-access" locations. Therefore, to encourage acceptance by operators and maintainers, a fully autonomous system design was chosen with no batteries. This self-powered system had the following major hardware components; (i) power-harvesting elements, (ii) electronics to manage power harvesting, interrogate the sensors, calculate/store patch health, and allow data download, (iii) sensing elements, (iv) system wireless interrogation, and (v) handheld data gathering unit. Issues associated with the selection and design of these components are discussed in Section 3.

2.2.1 Energy harvesting

DSTO is exploring structural power-harvesting techniques for use on defence platforms [7]. The

main driver for this research is the development of powering systems for autonomous distributed sensor networks (DSN) applied to airframes for SHM. Using "smart" sensor concepts, damage and damage growth in the airframe, and other structural life-related problems, would be continuously monitored on board the aircraft to provide real-time damage assessment. This technology could potentially permit a safe reduction in inspection and regular maintenance costs with substantial impact on the through-life costs. Using a DSN for SHM has only recently become feasible because of advances in micropower electronics and microelectromechanical system (MEMS); however, there are still a number of issues to overcome.

One of the main hurdles to the use of a DSN is powering. It is unsatisfactory to use the conventional approach of running power through copper wires on a central power/data bus because of

1. certification issues;
2. the added mass of wiring;
3. the drain on the limited electrical power available on an aircraft;
4. the wiring occupying significantly more space on the aircraft than the sensors themselves;
5. the fact that the DSN is no longer unobtrusive on the airframe and would interfere with maintenance procedures;
6. installation of the DSN itself would be complicated, time consuming, and expensive;
7. the significant reliability and durability issues with excessive wiring.

An alternative to the central power/databus is to have a ubiquitous network of autonomous sensors with independent power supplies. One option is to use batteries as the primary power source; however, replacing batteries in a DSN would be a considerable maintenance overhead and therefore, alternative approaches for powering such systems are required. Because of the low-power nature of MEMS systems, the concept of self-powering a DSN via harvesting power from the local environment becomes an intriguing possibility. On an airframe, in particular, there can be significant accelerations and dynamic strains available that lend themselves to the power-harvesting concept. Power harvesting has the potential to

- reduce the logistical burden and costs incurred by replacing a number of battery-powered systems;
- increase system availability due to the longevity of a device that is "self-powered" (compared with a battery-powered device); and
- power large numbers of tiny sensors in a network that may be difficult (or impossible) to power any other way.

Power harvesting itself is the process of energy scavenging from the local environment. Depending on the operational environment, various energy sources may be available [8] (*see* **Energy Harvesting and Wireless Energy Transmission for SHM Sensor Nodes**), for example: vibration, kinetic, solar, thermal (*see* **Energy Harvesting using Thermoelectric Materials**), chemical, and biological. On an aircraft, some or all of the first four sources could be available, depending on the location of the sensors. Within DSTO, the focus has been on the use of piezoelectric elements (both ceramic and polymer) for power-harvesting applications [9] using vibrational energy.

There is significant worldwide activity in the area of power harvesting, and a number of reviews of the literature are available [10]. Eggborn [11] discusses optimization of power harvesting from the piezoelectric/cantilever combination. Defense Advanced Research Projects Agency (DARPA) supported a "micro power generation" program that funded a number of energy harvesting investigations, for example, the "piezoelectric eel" project [12] and the "thermoelectric generator" [13]. Perhaps the best-known example of power harvesting is the Massachusetts Institute of Technology (MIT) piezoelectric shoe [14]. In 1996, Starner [15] discussed the possibility of using the everyday actions of the human body as a source of potentially harvestable energy. Starner calculated that one of the best prospects for power harvesting from the human body is walking—an average 68-kg person, walking with an average human gait of two steps per second, generates 67 W of "heel strike" power. Paradiso, at the MIT Media Lab [16], investigated the possibility of parasitic "shoe scavenging" and the result was a piezoelectric shoe-based power-harvesting system [17]. Both PVDF (polyvinylidene fluoride) piezoelectric films and PZT (lead zirconate titanate) piezoelectric ceramics and the associated harvesting electronics were placed in a running shoe. As the shoe wearer walked, the piezoelectric

deformed, generating piezoelectric voltage that was then (through the power-harvesting electronics) used to charge a storage capacitor. The storage capacitor was then used to drive a radio frequency (RF) transmitter.

There are a number of other MEMS power harvesting examples available in the literature, for example, El-hami *et al.* [18] describe a micromachined magnet/coil power harvesting device. The so called smart dust being developed at the University of California, Berkeley is a significant MEMS-based project, which involves the development of a "self-powered" device [19]. More recently, Beeby unveiled a MEMS-based energy harvester with practical volume $0.15\,\mathrm{cm}^3$ capable of producing $46\,\mu\mathrm{W}$ in a $4\,\mathrm{k}\Omega$ load from vibration levels of $0.59\,\mathrm{m\,s}^{-2}$ at the device resonance frequency of 52 Hz [20].

However, for the self-powered system that was implemented on the F/A-18 aileron hinge, time and resource limitations led to the development of a relatively simple power-harvesting system based on the conversion of strain energy to electrical energy (charge) via two different electromechanical coupling devices, PVDF piezoelectric films, and PZT piezoelectric ceramics. The combination provided a degree of robustness in terms of mechanical and thermal durability. Also, since the operational strains in the titanium aileron hinge were not well understood, the combination of PVDF and PZT power harvesting elements ensured that enough electrical power would be generated to power the system. PVDF elements are durable, have an adequate operating temperature range, up to about $80\,^{\circ}\mathrm{C}$, and are chemically inert. The PZT wafers have better strain/electrical energy conversion efficiency than PVDF and have a better operating temperature range, up to $\sim 180\,^{\circ}\mathrm{C}$, but are not as mechanically durable as PVDF (i.e., low strain to failure of 0.1–0.2% strain).

2.2.2 System operation and information flow

The basic operation and information flow issues can be summarized as follows:

- When in flight, a combination of piezoelectric film (chosen for its durability) and piezoelectric ceramic (chosen for its higher output) elements are used to power up the system.
- A patch health measurement is taken by the piezoelectric film sensors when power is available and the temperature and strain are within a selected range. As damage growth is slow, the relatively sparse sampling is considered adequate.
- The reading is used to refine the current health estimate stored in a nonvolatile memory.
- A handheld interrogator, placed in close proximity to the hinge, powers the circuitry of the self-powered system via inductive coupling and allows readings to be downloaded via the same inductive link. Inductive coupling was chosen as it is able to carry power and information through a thin barrier (in this case, the plastic aileron hinge cowl, although transmission through thin aluminum is also possible).

3 DETAILED DESIGN

3.1 Damage detection scheme

The FE model of the hinge with a b/ep reinforcement, which is shown in Figure 2(a), was used to assess the proposed damage detection techniques [21]. Two load cases were considered in the FE analysis, viz., load case WO39 a tensile design ultimate load condition and WO42 a compressive design ultimate load condition [5]. Figure 2(b) shows the peel and shear stress distribution in the adhesive of the reinforcement, respectively, for load case WO39, and indicates that two critical regions exist, namely, the tapered region at the end of the patch on the hinge strut ($x \sim 200\,\mathrm{mm}$) and the region of high adhesive peel stresses in the concave portion of the reinforcement ($x \sim 70\,\mathrm{mm}$). The BPSP monitored damage in the former and the SPSP monitored damage in the latter. In both cases, damage was detected by monitoring the change in ratio of critical region strains to far-field strains (referred to here as the *patch health indicator*) [22]. The discussion below focuses on the analysis associated with the damage detection approach for the SPSP system.

In this case, the damage was simulated by a 10 mm-long disbond in the adhesive layer at the high peel stress region (at $x \sim 70\,\mathrm{mm}$) of the patch. The surface longitudinal strains (ε_x) plotted in Figure 2(c) for the tensile load case, WO39, show significant increases in surface strains when the damage is introduced,

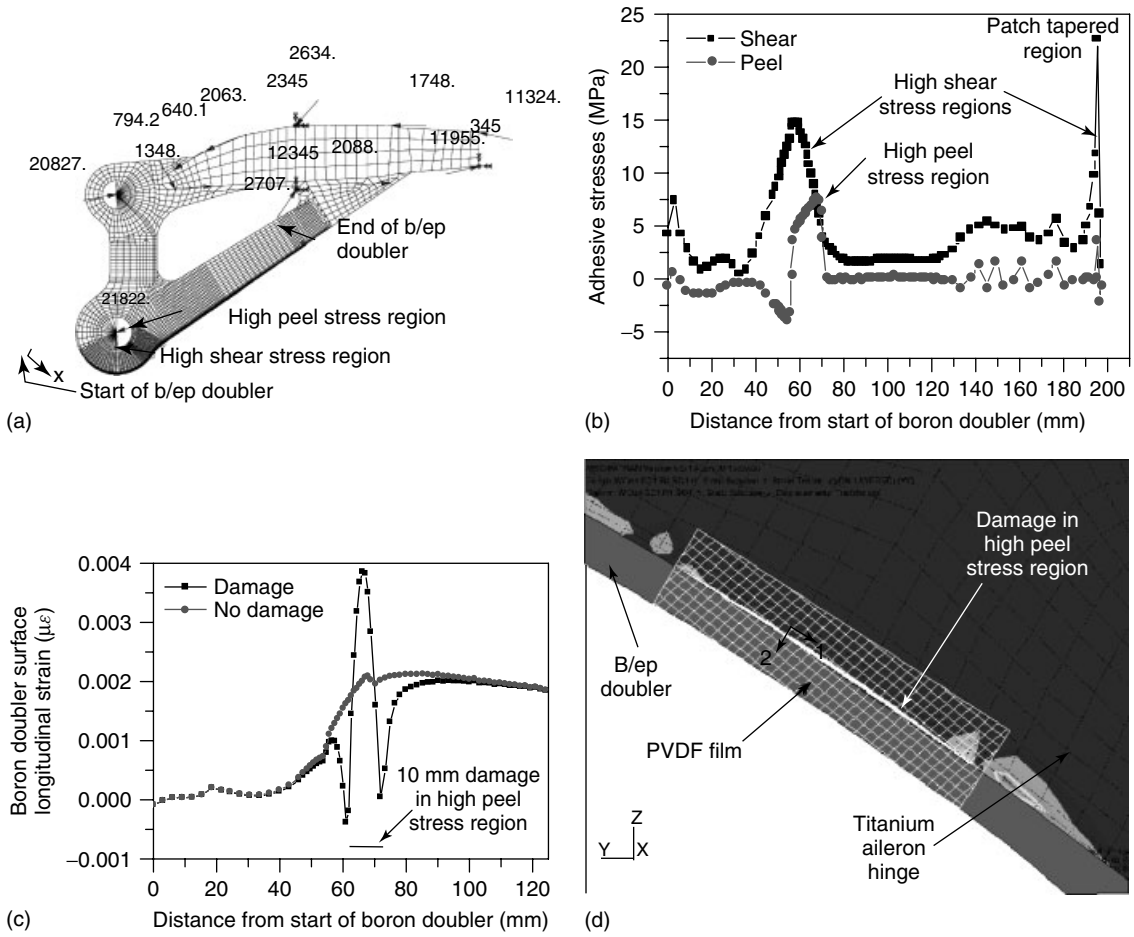

Figure 2. (a) Finite element model of titanium aileron hinge with b/ep doubler. (b) Predicted adhesive stresses in the reinforcement system with no damage present (load case WO39). (c) Longitudinal surface strain profile on b/ep doubler due to a 10 mm disbond in the adhesive high peel stress region. (d) FE displacement plot and damage detection scheme for damage in the high peel stress region.

indicating that damage detection is possible using surface strain sensors. However, the distinctive sharp peak/trough in the surface strains (over a 10 mm length) means that the probability of detection is very sensitive to the sensor size and proximity to the damage site. Thus sensors will only detect the damage if the sensing length is small, compared to the strain gradient length, and if the sensors are positioned over or very close to the damage or when the damage reaches a substantial size. Also, it is possible that the damage will initiate on one side of the strut before growing, through the width, to the other side of the strut. Therefore, to have a reasonable chance of detecting damage, one approach would be to use an array of short gauge length strain sensors on both sides of the b/ep reinforcement. However, this would require several dual-channel devices or one multichannel device to monitor a reasonable length of about 10–20 mm. A more simplistic (in terms of the electronics and number of sensors required) approach is to make use of the disbond opening under load (Figure 2d).

In this application, piezoelectric film sensors were proposed for measuring strain, or, more specifically, to measure strain produced in the film bridging the disbond as it opens. Piezoelectric film sensors

Table 1. Voltage outputs for two piezoelectric film sensors

Result case	$\int \varepsilon_x \, dS$ (mm^2)	$\int \varepsilon_y \, dS$ (mm^2)	$\int \delta u \, dy$ (mm^2)	PVDF output (V)	Ratio V_{dam}/V_{nodam}
No damage case (4 mm × 15 mm sensor covering the anticipated damage)	0.0899	0.0345	0	2.7	2.5

generate a charge when strained rather than conventional electrical-resistance foil strain gauges, which *require* electrical power to measure strain. Thus the use of such sensors also reduces the system power requirements. In this case, a piezoelectric film sensor covering the edge of the aileron hinge strut (over the edge of the patch, adhesive layer, and the titanium strut), as shown in Figure 2(d), was used to detect disbond opening. FE studies for two sensor configurations, one 2 mm × 15 mm long and the other 4 mm × 15 mm long, were undertaken [23]. The area integral of the longitudinal (ε_x) and transverse (ε_y) strains of the sensing area is tabulated in Table 1 for various sensing conditions, i.e., no damage, the entire sensor covering the damage, and only half the sensor covering the damage. Table 1 also includes the area integrals of the crack opening ($\int \delta u \, dy$) and the predicted electrical voltage calculated from the overall area integral of strain [24]. The results show that the 2 and 4 mm wide (by 15 mm long) sensors will have a 2–4 and 1.5–2.5 fold increase in response, respectively, due to a 10 mm disbond, when compared with the undamaged case. The piezoelectric film sensor (see Figure 3) was manufactured from 28 μm thick PVDF sheet where the silver ink electrodes were removed using a grit blasting process and a mask was placed over the sheet to protect the sensing regions during grit blasting.

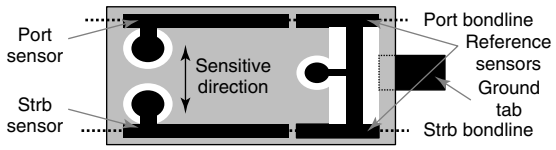

Figure 3. PVDF sensor configuration (hatched area indicates silver ink electrode on top surface and gray is the silver electrode on the lower surface).

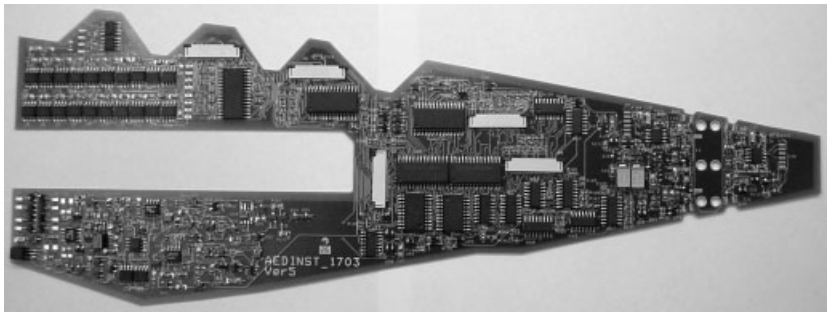
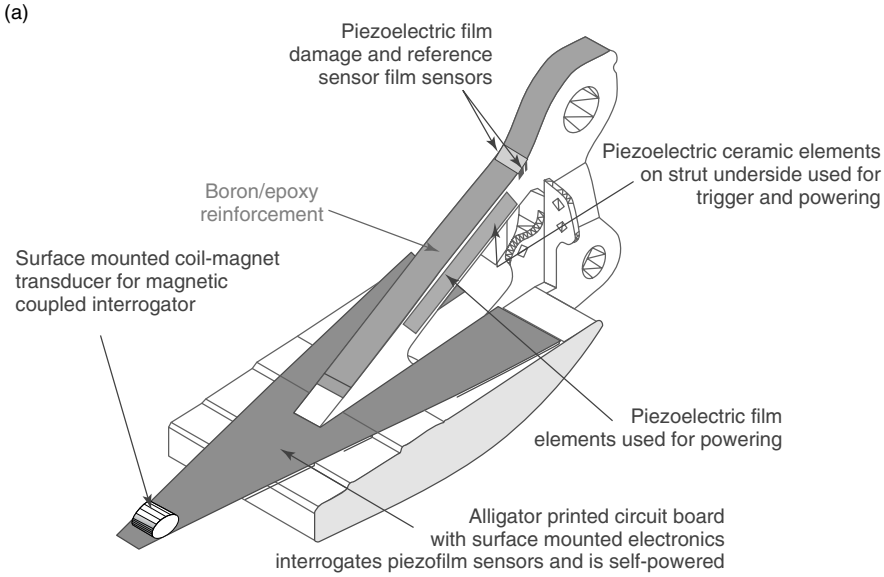
3.2 Electronic design and power (demand) requirements

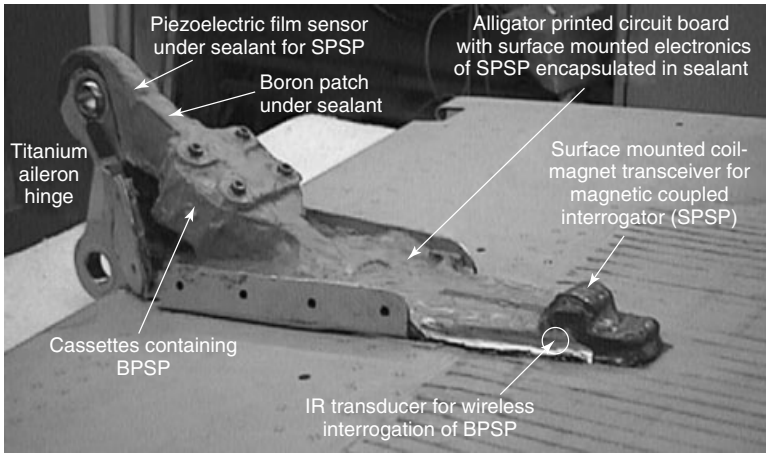
Geometric constraints and limitations in strain level and frequency response limit the amount of power available while using piezoelectric elements to fractions of a milliwatt. Since it is difficult to get a reasonable amount of signal processing done on this kind of power budget, the harvested power was stored in a capacitor. Consequently, a reading was taken only once the following conditions were met: (i) sufficient energy was available for a complete reading/computation/store cycle, (ii) the structure was experiencing significant strain (within a given window), and (iii) the temperature was also within a given window. Budget and time constraints necessitated a fairly large A-shaped printed circuit board (APCB) footprint with surface-mounted commercial off the shelf (COTS) electronic components, shown in Figure 4(a).



(a)



(b)



(c)

Figure 4. (a) Photo of the SPSP printed circuit board, (b) schematic of self-powered *smart patch* system, and (c) photograph of the installed *smart patch* system on an F/A-18 aileron hinge. (SPSP and BPSP are self-powered and battery-powered *smart patch* configurations, respectively.)

Figure 4(b) and (c) show the mounting arrangement of the *smart patch*, including the BPSP, and the location of the transducers on the aileron hinge. However, the design is such that it should be a relatively straightforward process to reduce the unit to very small proportions using standard complementary metal oxide semiconductor (CMOS) technology—this would have the added benefit of quite substantially reducing the energy requirements and overall weight.

To keep the energy requirements of the circuit as low as possible, it was necessary to minimize the number of components. This is illustrated in Figure 5 for the analog section and Figure 6 for the digital section. Figure 5 shows that the analog section consists of a small number of building blocks: (i) a power harvester (ii) a power controller (with temperature lockout), (iii) a trigger, (iv) a signal conditioner, (v) two logarithmic analog to digital converters, and (vi) an interrogation transceiver. It can be noted from the actual circuit, inserted under the block diagram, that there are, indeed, only a few components.

To minimize energy usage, the digital section, depicted in Figure 6, uses as few components as is practicable. The building blocks are (i) a flash to binary converter, (ii) a computation unit, (iii) data storage, (iv) a finite state machine, (v) a clock control, (vi) an interrogation control, (vii) a data output unit, and (viii) programming/testing ports. Items (i)–(iv) are all implemented in ferroelectric nonvolatile random access memory (FRAM) to reduce power requirements and to reprogram the circuit function; this proved extremely valuable in the test and verification stage of the system design.

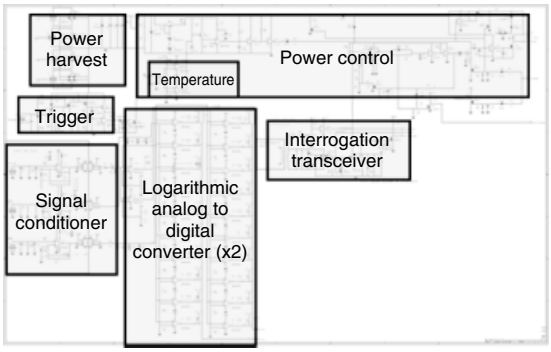


Figure 5. Electrical schematic block diagram—analog section.

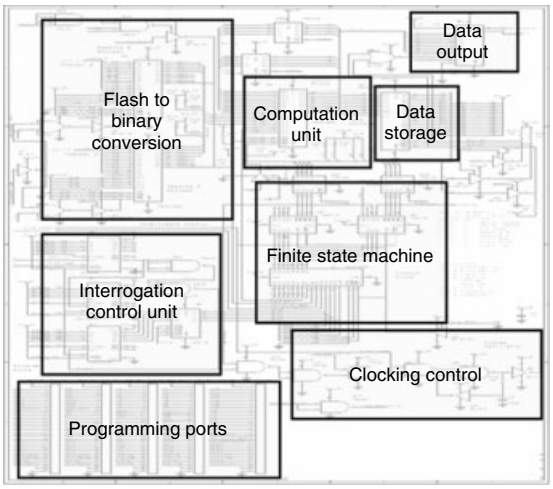

Figure 6. Electrical schematic block diagram—digital section.

As discussed previously, PVDF film was proposed as the sensing material because of the fact that it requires no excitation power. Other advantages with piezoelectric film sensors are their very good fatigue life and strain to failure properties, simple signal conditioning requirements, good high-frequency response; they are also light weight and conform easily to complex shapes. Some limitations with PVDF sensors that need to be considered are their limited operating temperature, poor thermal sensitivity, poor response in the low-frequency regime, and also the extreme care that is required to ensure the correct sensor polarity during installation. As there is a high probability of a substantial amount of strain being generated at low frequencies, it was considered important to ensure that the frequency roll-off characteristics were fairly accurately matched, especially in adverse environments. This in itself can be tedious, but as high impedances are involved, the greater challenge is ensuring that they remain matched in adverse environments. To assist with this problem, buffer amplifiers with low input leakage were incorporated, but the need for thorough protection against moisture ingress remained a critical issue. Considerable care was taken to reduce the risk of moisture ingress creating a shunting effect that would adversely affect this matching.

To minimize system power requirements, the patch health measurement was a ratio obtained using an

analog technique, where the signal from the "reference" transducer was fed through a divider chain and compared with the signal from the active transducer (i.e., sensor over the damage region) via a chain of 10 comparators (with 10% resolution). Each digitizer/divider "reading" uses about 100 nJ (i.e., typically 2.5 μW per comparator, with a 1.2 ms power-up time for 10 comparators plus resistive chain). One advantage of this technique is that it has a frequency response in the kilohertz region, and minimal possibility of time skew problems between the two readings forming the ratio. A disadvantage is the relatively long (1.2 ms) "switch on" settling time of the comparators (and amplifiers). This necessitated a two-stage power supply, where the analog and digital circuits were powered for milliseconds and a few microseconds, respectively. Also, since the PVDF sensors could not be calibrated before installation, owing to time and resource constraints, it was likely that the sensor readings from the undamaged critical region might not exactly match those from the reference; consequently, perfect patch health readings might not result in a ratio value of unity.

The device was designed to measure two ratios, one on the starboard and the other on the port side of the strut, with respect to a common reference and to a 10% resolution. Each reading, taken when the conditions previously described were met, was recorded in FRAM, wrapping back to the initial position in storage after approximately 16 million readings. FRAM was chosen primarily because of its relatively low access energy requirement, which is in the region of 1 nJ/bit compared typically with a few microjoules per bit for electrically erasable programmable read-only memory (EEPROM) devices, and its tolerance of extended temperatures. The parallel variant was chosen, as the higher access speed helped in minimizing system energy requirements. Unfortunately, at the time of design, only the 5 V supply variant of these parts was available, thus to keep the design simple, most of the circuit operates at this relatively high voltage. The high-level choice of FRAM as the storage medium dictated that the device required some digital circuitry, and the choice of input transducers dictated analog input circuitry.

Besides the storage function, the other aspects of the electronic design that were chosen to be implemented in digital technology were sections of the computation and most of the interrogation functions. A programmable logic device (PLD) was originally chosen on the grounds it provided low operating power with maximum flexibility. However, further investigation revealed a large and potentially problematic start-up energy requirement. As standard cell and custom integrated circuits (IC) were beyond our budget it was decided to use medium scale integration (MSI) CMOS as the most appropriate option. The information stored was two (4 bit) ratios and one (24 bit) integer indicating the number of reading cycles. A temperature-dependent lockout was fitted to the supply circuit to prevent any operations being attempted if the operating temperature was outside specified temperature limits. The limits set were quite tight, within a window range of 10–40 °C, to ensure that readings were not influenced by thermal effects. This was considered an acceptable option in this application as the data required was a very small number of samples and not considered to be particularly dependent on temperature.

In the most elementary case, the only value needed would be the last worst patch health indicator reading. However this was considered not to be sufficiently robust, since a single noise "spike" could cause a misleading reading. This led to the conclusion that filtering and some other confidence-building indicators were required. A time stamp was considered, but this would necessitate a permanent power source to keep the clock running. Also, since the aim was for "indefinite" operation, a reading counter was chosen as a compromise. Unfortunately, the only place to maintain the count is in the nonvolatile memory, thus necessitating a "measurement cycle" to consist of (i) reading the memory, (ii) taking the measurement, and (iii) writing the updated information back into memory. In an attempt to reduce the effects of spurious spikes, a simple slew rate filter algorithm was employed. This was thought to be appropriate as the damage is expected to grow relatively slowly with respect to the reading rate, and even if the patch suddenly failed this would be indicated after only 10 reading cycles at most. During a reading cycle, the system is synchronized to an internal ~1 MHz clock, the speed being basically chosen to minimize the energy required.

Measurements of the overall system indicated the prototype consumed about 210 nJ of energy to perform the digitizing and dividing function, 60 nJ to perform the storage and retrieval function, and 10 nJ

for clocking. Hence, the total energy required of the system to make a reading, retrieve and store data, and undertake simple real-time data processing is approximately 280 nJ.

3.3 Power harvesting—energy harvesting and conversion issues

On the supply side, there were two PVDF stacks, each stack having three PVDF elements electrically in series, with poling directions perpendicular to the loading direction. The individual PVDF elements had a nominal thickness of 52 μm, and a manufacturer-rated capacitance of 5.7 nF [25] from which the PVDF relative permittivity $\varepsilon_R \sim 11.3$ was calculated. The PVDF elements were laminated prior to installation, bonded together into a stack using Hysol EA9309 adhesive, and found to have a fairly consistent measured series capacitance of ~1.9 nF. Care was taken to ensure that PVDF electrodes of similar potential (while under cyclic loading) were colocated to minimize capacitive coupling. Insulation resistance was measured to be in excess of 50 GΩ, so both dc and low ac frequency dielectric loss appeared to be negligible for PVDF.

Using the typical published piezoelectric coefficient for PVDF (d_{31}) of 23 pC/N and assuming a simple one-dimensional piezoelectric case with no losses, the predicted peak voltage due to a peak strain of 300 με was ~32.1 V across a stack of three PVDF elements in series. Each PVDF stack fed power through a separate bridge rectifier, which incorporated BAS70 [26] diodes to minimize electrical loss. Each diode had a typical forward voltage drop of 0.22 V (at relevant current levels) and 3 nA of leakage current. The PVDF stacks were directly bonded to the aircraft structure and had a calculated output of ~0.1 V/με (open circuit). The PVDF stack capacitance of 1.9 nF meant that about 0.19 nC (0.1 V × 1.9 nF)/1 με of charge could potentially be generated.

The energy harvesting power supply was a simple diode bridge (Figure 7a) and capacitor, which can be thought of as having two states, diode conduction "ON" and "OFF" as shown in Figure 7(c). The circuit was designed for a nominal operating voltage of about 5.2 V. Thus the first 5.2 V/(0.1 V/1 με) = 52 με of mechanical load excursion did no work on the electrical load (assuming the previous excursion reached the conducting state) and, in fact, incurred a slight leakage current loss while it was occurring. At the nominal operating point, the storage capacitor holds an electrical potential energy of $E = 1/2\ \text{C}\ \text{V}^2 = 0.5 \times 1\,\mu\text{F} \times (5.2\ \text{V})^2 \approx 14\,\mu\text{J}$.

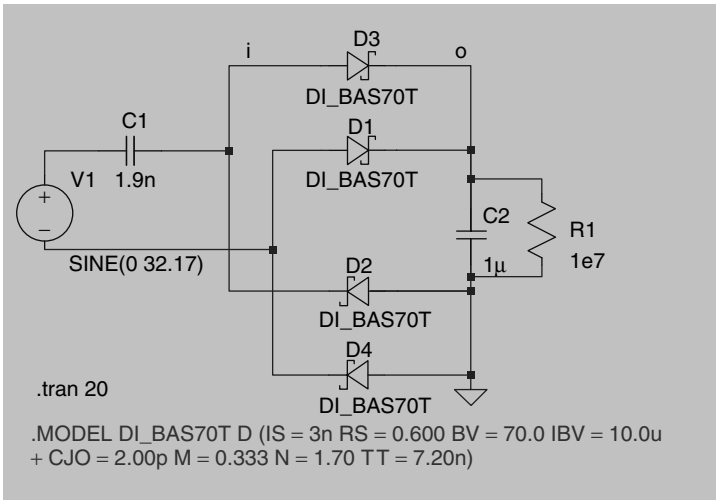
Once the diodes turn "ON", the voltage can be thought of as being approximately constant (assuming the storage capacitance is much larger than the PVDF stack capacitance, 1 μF vs. 0.0019 μF in our case) and each 1 με would add energy of $1/2 \times 1.9\ \text{nF} \times [(5.2\ \text{V} + 0.1\ \text{V})^2 - (5.2\ \text{V})^2] \approx 1$ nJ (not allowing for losses).

With this type of system the primary "losses" associated with the diodes is because of leakage when the diode is reversed biased, and forward drop when the diode is conducting. The power "loss" associated with leakage can be approximated by multiplying the leakage current by the (mean) reverse voltage and by the fraction of time the device is reverse biased. The forward loss can be approximated by the ratio of forward voltage drop to load voltage.

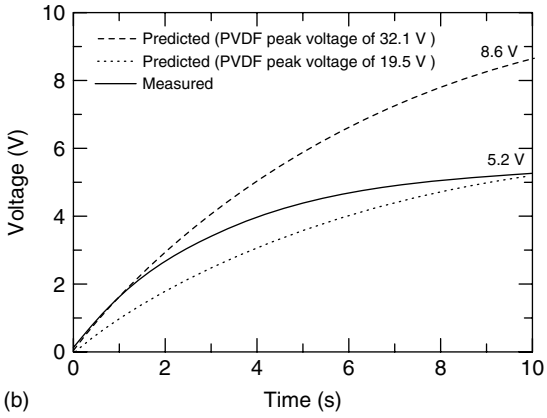
As mentioned, the energy harvesting circuit implemented had a working load voltage of about 5.2 V and since the diodes had a forward voltage drop of about 0.22 V, the diodes of the full bridge (two diodes on at a time) would have dissipated about $100 \times (2 \times 0.22\ \text{V}/5.2\ \text{V}) \sim 8\%$ of the incoming power while in the conducting state.

If the input was truly sinusoidal, then it is expected that the diodes would be reverse biased for about half the time. Given that the leakage of the rectifying diodes was about 3 nA at the operating voltage of 5.2 V and with at least one pair being reverse biased at any point in time, then the expected drain would be about $(2 \times 3\,\text{nA}) \times 5.2\text{V} \approx 31.2\,\text{nW}$ while in operation. Should the excitation amplitude reduce for a period then this value is expected to double, since all four diodes would be reverse biased. Hence, a minimum of 31.2 nW/1 nW ≈ 31 με of "active" strain excursion would be required per second to replenish diode losses. This figure was kept low by the use of low-leakage diodes. If BAT54 diodes with 600 nA leakage [27] had been chosen, then an "active" strain excursion level of $\sim 6200\,\mu\varepsilon\,\text{s}^{-1}$ would be required. Here the term *active* refers to the part of the strain excursion that occurs while the diodes are "ON".

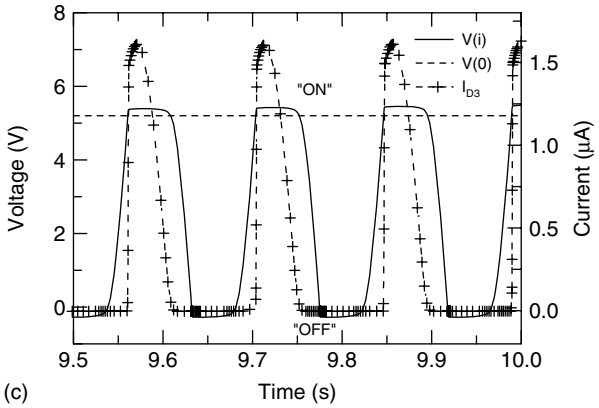
The energy harvesting process was modeled via LTSpice [28] simulation, as shown in Figure 7(a),



(a)



(b)



(c)

Figure 7. (a) Model of PVDF/diode rectifier energy harvesting circuit. (b) Measured versus predicted storage capacitor voltage. Predictions were made using two PVDF peak voltages viz., 32.1 and 19.5 V. The measured voltage was for a 1 µF storage capacitor being charged using a PVDF stack subject to a sinusoidal strain with a peak value of 300 $\mu\varepsilon$ at a frequency of 7 Hz. Storage capacitor voltage was ~5.2 V after 10 s, and ~5.36 V after 14 s. (c) The current for diode D3 (I_{D3}) versus time for a PVDF peak voltage of 19.5 V and a storage capacitor voltage near the operation point of 5.2 V.

which incorporates the BAS70 full bridge diode rectifier, a 1.9 nF PVDF stack, and a 1 μF storage capacitor with a 10 MΩ parallel resistance to model a 10X oscilloscope probe (at low frequency, the probe capacitance of ~13 pF was considered irrelevant). The model assumes that the energy harvester and aircraft structure are effectively decoupled, i.e., actions of the harvester have negligible effect on both the bulk and local strains in the aircraft structure. The PVDF is modeled as a 1.9 nF capacitor in series with an ac voltage source of 7 Hz with peak voltage 32.1 V. The manufacturer states that the BAS70 diode leakage is 3 nA (at 25 °C and 5 V reverse voltage); this was confirmed experimentally (the diode measured was from the same diode batch that was later flown) and hence the saturation current "I_s" in the LTSpice diode model was adjusted to 3 nA. LTSpice modeling showed that after 10 s of charging, from a sinusoidal strain excitation of 300 με peak strain at 7 Hz, the storage capacitor dc voltage should be ~8.6 V assuming only diode losses.

Figure 7(b) also shows a comparison of the LTSpice simulation with the measured voltage of a 1 μF storage capacitor during the charge up phase, using a PVDF stack (viz., one stack of three 52 μm thick by 156 mm long by 19 mm wide PVDF elements) subjected to a sinusoidal strain with a peak value of 300 με at a frequency of 7 Hz. In this case, the PVDF stack is a similar configuration to those flown on the flight demonstrator. The storage capacitor voltage achieved was ~5.2 V after 10 s, and after 14 s the final storage capacitor voltage was 5.36 V.

Given the stated mechanical loading conditions (7 Hz at a peak strain of 300 με), a comparison between the final simulated storage capacitor voltage (8.6 V) and the measured storage capacitor voltage (5.2 V), as shown in Figure 7(b), indicates that the inefficiencies (losses) totaled about $100 \times (32.1 - 19.5/32.1) \sim 39\%$. Three mechanisms have been postulated for this energy harvesting loses. In decreasing order of importance they are

1. the effect of Poisson's ratio, a tensile stress in the 1 direction will produce ~1/3 compression in the 2 direction, which will reduce the piezoelectric output voltage by ~1/3 (assuming $d_{31} \sim d_{32}$);
2. a "shear lag" effect that is the combination of bondline mechanical compliance issues and, more importantly, the reduction of strain in the PVDF elements that are located furthest from the metallic substructure due to the compliance of the piezoelectric film; since the PVDF elements are quite compliant, not all the strain is transferred from the metallic substructure through these elements to the ones above—the larger the stack the less strain will be transferred to the top elements;
3. the effect of capacitive coupling between the PVDF metallization layers.

It appears that Poisson's ratio effect alone cannot explain the 39% efficiency decrease measured. Using the measured storage capacitor voltage of 5.2 V (at $t \sim 10$ s) generated by a single PVDF stack, the energy stored in the 1 μF capacitor after 10 s was approximately,

$$E = \frac{1}{2} C\ V^2 = 0.5 \times 1\ \mu F \times (5.2\ V)^2 \sim 14\ \mu J \quad (1)$$

This means 14 μJ of energy could be harvested every 10 s from each side of the strut, resulting in 1.4 μW, which was sufficient energy for the device to operate when attached to the aluminum hinge configuration.

The limited flight strain data available for the aluminum aileron hinge configuration, indicated that the strain loading scenario (i.e., 300 με peak at 7 Hz) should be easily achieved at the aileron aft hinge strut. Note also that the 7 Hz used in this experimental study is quite conservative since the in-flight strain and acceleration data indicate that structural resonances occurred at about 14, 30, and 55 Hz, as shown in Figure 8. These higher frequencies would produce more energy for harvesting within a given time period.

The replacement of the aluminum aileron hinge with the titanium hinge meant that there was a significant reduction in the operational strain levels on the hinge. FE studies indicated that the strains were reduced by about a factor of about 2. The maximum surface strains on the b/ep doubler, for load condition WO39, were reduced from 5000 με for the aluminum to 2100 με for the titanium hinge [21, 23]. Therefore, it was decided to add additional power-harvesting PZT elements on the lower side of the hinge strut, as shown in Figure 4(b). The PZT power-harvesting elements consisted of two 32 mm long by 12.5 mm

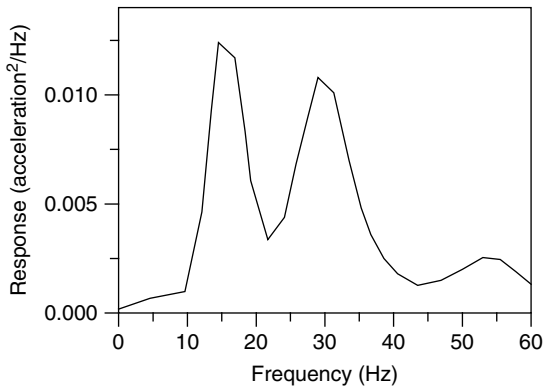


Figure 8. Typical acceleration frequency spectra measured on in the aileron hinge region.

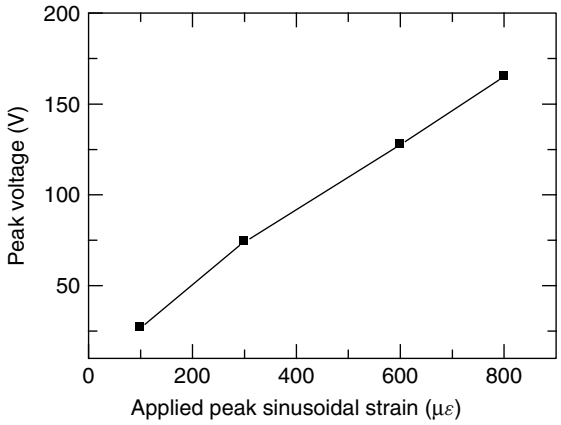

Figure 9. Peak strain versus open-circuit voltage for a T226-A4-303Y PZT-5A bimorph subjected to a sinusoidal peak strain (10–30 Hz).

wide Piezo Systems T226-A4-303Y bimorph transducers, consisting of a 0.12 mm thick brass shim sandwiched between dual parallel poled 0.27 mm thick PZT wafers [29]. The calculated capacitance of the PZT-5A bimorph was 12.4 nF compared with the measured capacitance of approximately 9.2 nF.

When a load equaling 300 $\mu\varepsilon$ was applied to the PZT-5A bimorph the calculated open-circuit voltage was ~115 V, assuming no losses or inefficiencies. To experimentally confirm that the voltage produced by the PZT-5A bimorph was as expected, a specimen was manufactured from 4340 steel plate with dimensions 260 mm × 75 mm × 4 mm. The PZT-5A bimorph element was bonded to the plate using silver-loaded epoxy with a resultant bondline thickness of less than 200 μm. The top surface of the bimorph was also coated with silver-loaded epoxy to approximate the bonding conditions that the bimorph would experience in service.

As shown in Figure 9, when the PZT-5A bimorph was subjected to a sinusoidal 300 $\mu\varepsilon$ peak strain (at excitation frequencies between 10 and 30 Hz), the recorded peak voltage produced by the bimorph was about ~75 V across a 10 MΩ oscilloscope probe, which is an $100 \times (115\,\text{V} - 75\,\text{V}/115\,\text{V}) \approx$ 35% efficiency decrease. The difference between the calculated and measured PZT-5A bimorph voltages appears to be almost entirely explainable by the Poisson's ratio effect.

For the purpose of energy harvesting, the output from each of the PZT bimorphs was fed into a separate bridge rectifier that was effectively working in a half-wave manner. The main benefit of the half-bridge approach was that it allowed one electrode of each of the PZT-5A bimorph to be bonded to, and hence, electrically grounded with, the aircraft structure.

To summarize, assuming no mechanical or electrical losses, the individual PVDF elements appeared to be rated at ~2.5 nJ/(m^2·$\mu\varepsilon$) and the PZT-5A bimorphs at ~4.4 μJ/(m^2·$\mu\varepsilon$). Maintaining the assumption of no mechanical or electrical losses, and also assuming 100% strain transfer efficiency and with no maximum placed on voltages, with a constant sinusoidal mechanical loading of 7 Hz at 300 $\mu\varepsilon$ peak strain, it was calculated that

1. ~0.96 μW of power could be harvested from a single PVDF element, resulting in a total of ~5.8 μW harvestable from the two PVDF stacks;
2. ~2.2 mW from a single PZT bimorph, resulted in a total of 4.4 mW from the two PZT-5A bimorphs attached to the aileron strut; and
3. the overall minimum harvestable power from the PVDF stacks and the PZT bimorphs was ~4.406 mW.

As can be seen, the two PZT-5A bimorphs were capable of producing significantly more power than the two PVDF stacks; however, there was a risk that the ceramic PZT-5A bimorphs might not have been robust enough to cope with the stresses induced by operational flight loads.

Further expanding upon the energy harvesting efficiency and loss factors discussed above, we arrive at the following results:

1. Dielectric loss: this appears to be sufficiently small as to be considered negligible for both for both PVDF and PZT-5A bimorphs. For example, a PVDF charged to 5 V, with 50 GΩ insulation resistance, has a continuous dc power loss of $\sim(5\,\mathrm{V})^2/50 \times 10^{12}\ \Omega = 0.5$ pW, and assuming low-frequency structural vibration, ac power loss to the dielectric will also be negligible.
2. Geometrical strain compliance between the underlying structure and the piezoactive material: this is an efficiency loss due to the single sided mechanical coupling that is normally used to attach a piezoelectric element to the structure.
3. Diode loss: the diode loss in the bridge rectifier is caused by both the forward voltage drop across the diode and the diode leakage current, both of which produce real energy losses via heat production. Generally speaking, the peak currents produced by the energy harvesting process are small, and assuming no losses, the peak currents will be $<3\,\mu$A for the PVDF stack and $<50\,\mu$A for the PZT-5A bimorph. The Schottky diodes used in the rectifiers must be carefully chosen; however, it is not a trivial task to determine the best diode because the LTSpice diode models provided by manufacturers are generally quite inaccurate when currents are small (i.e., 100 μA or less), so accurate diode losses cannot be simulated. For energy harvesting from low-frequency structural excitations the authors consider diode leakage to be the main diode loss component. A laboratory testing program appears to be the most efficient method of determining the best rectification diodes for the particular energy harvesting task.

At this point it should be noted that the simple energy harvesting circuits implemented on the *smart patch* may not have been optimal since the voltage across the piezoelements, and hence the electrical component of the force was rather low. On the other hand, having very small forces feeding back from the energy harvester in the aircraft structure is conservative from a structural dynamics point of view. In any case, circuit board space and design time limitations prevented us from using a more elaborate circuit.

It is difficult to assess the exact mechanical and electrical losses in the harvesting system during any particular flight because of the

1. lack of low current fidelity in the diode spice models provided by manufacturers;
2. action of the diode bridge rectifiers during the energy harvesting process being nonlinear; and
3. mechanical loading of the aileron hinge during flight being unknown.

However, for a specific sinusoidal loading condition of $300\,\mu\varepsilon$ peak strain at 7 Hz, measurements have shown (Figure 7b) that a PVDF stack can charge up a 1 μF capacitor to the operational load voltage of 5.2 V in ∼10 s. Under the same loading conditions, taking into account the inefficiencies and loss mechanisms discussed above, LTSpice simulation calculated that a PZT-5A bimorph will charge up a 1 μF capacitor to the operating load voltage of 5.2 V in ∼0.57 s. Given that the time to charge the 1 μF storage capacitor to the operating load voltage 5.2 V is known, the expected power-harvesting level for the combination of the two PVDF stacks $(2 \times [0.5 \times 1\ \mu\mathrm{F} \times (5.2\ \mathrm{V})^2/10\ \mathrm{s}] \approx 2.8\,\mu\mathrm{W})$ and the two PZT-5A bimorphs $(2 \times [0.5 \times 1\ \mu\mathrm{F} \times (5.2\ \mathrm{V})^2/0.57\ \mathrm{s}] \approx 90\ \mu\mathrm{W})$ was estimated to be ∼93 μW, meaning that ∼0.55 s of time was required to generate enough energy to power the electronics outlined in Section 3.2.

3.4 Interrogation

During the information uploading operation, the circuit was both powered and clocked by an alternating magnetic field provided by the interrogator. This field was modulated with a serial representation of the reading information, which was continually repeated until the interrogator received several identical samples at which time it accepted the data.

The antenna consists of a coil of copper wire wound on a ferrite core. The device is energized by the current produced in the coil in response to a low-frequency magnetic field produced by the interrogator. The data is modulated on this carrier by changing the reflected impedance. The data rate

is derived as a submultiple (1/16th) of the carrier frequency.

4 SAFETY-OF-FLIGHT AND FUNCTIONAL TESTING

A number of testing activities were undertaken, during the development of the *smart patch* system, to cover two main aspects:

1. safety-of-flight issues, which required testing on a prototype *smart patch* system to characterize the system response from specified mechanical vibration/shock, electromagnetic and pressure/temperature environments;
2. system functional testing consisting of both bench-top testing of the electronic components (including interrogator) and a prototype *smart patch* system on an "original" aluminum aileron hinge component (removed from an F/A-18 aileron).

4.1 Safety-of-flight testing

The vibration test on a system mock up consisted of a resonance search test, and a low-frequency swept sine, a low-frequency sine dwell and a high-frequency random vibration test, and finally a shock test in each of the three principal axes. Testing requirements are based on specifications given in [30, 31]. Visual inspection of the test article after testing did not reveal any deformation, delamination, fragmentation, or breakage [32]. Results of the tests showed that the system survived all vibration and shock testing without failure and that the equipment performed normally after the test.

Temperature and altitude testing included temperature cycles between -40 and $+80\,^{\circ}$C with concurrent altitude pressure cycles from sea level to 9000 m. No adverse structural or chemical problems were encountered; however, significant variations in the coefficient of thermal expansion between the potting compound and the wiring caused solder joints to fail—these issues meant that a more compliant potting compound needed to be used for the in-flight demonstrator.

The electromagnetic test consisted of a radiated emissions test in accordance with MIL-STD-461E [33] and Boeing requirements [34] for RF susceptibility from 1 MHz to 18 GHz. No emissions were detected from the *smart patch* when it was optically isolated from the interrogator and monitor computer [35].

4.2 Functional testing

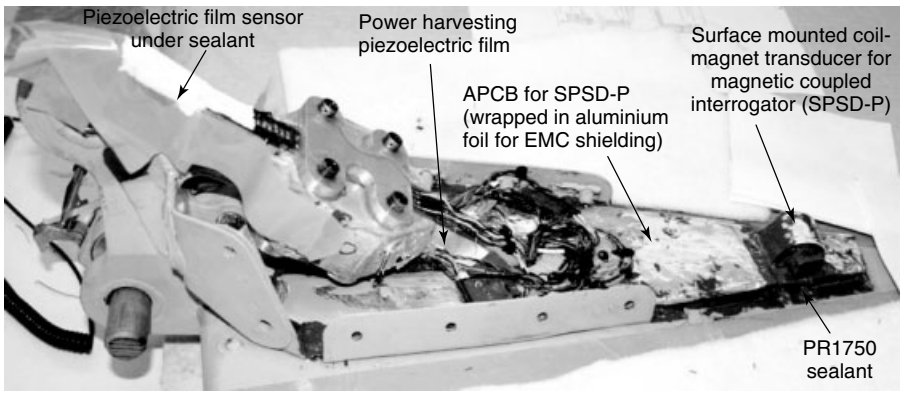
Electronic components (such as the APCB and handheld interrogator) were bench tested using simulated voltage inputs for the piezoelectric film sensor and power-harvesting elements. A trial installation was also performed on a subcomponent "original" aluminum aileron hinge taken from an F/A-18 aileron, similar to the component shown in Figure 1(b) and then subjected to functional and environmental testing. That was undertaken to "fine tune" and validate the installation procedure and evaluate the performance of the *smart patch* after adverse environmental (i.e., hot/wet/cold) loading. The environmental testing involved placing the subcomponent in an environmental chamber and subjecting it to several moderate and severe thermal cycles of -30 to $40\,^{\circ}$C and -40 to $70\,^{\circ}$C, respectively. All thermal cycling was undertaken at the maximum relative humidity of the chamber (which was about 100%), and each temperature extreme was maintained for at least 30 min, to ensure condensation would occur on the subcomponent during the environmental cycling; the aim was to ensure that the environmental cycling would comprehensively test the protective coating process. The specimen was then installed in the testing machine to perform a number of functional tests. This testing program was extremely useful and outlined several electronic and installation deficiencies, involving the environmental protection [6]. The main issues were problems associated with the FRAM units, as well as issues with the protective coating process associated with the electromagnetic shielding layer bonding to the protective polysulfide PR1750 sealant. Polysulfide PR1750 was used for the environmental protection for the electrical components and piezoelectric transducers, as well as to bond the APCB to the aileron hinge surface. Electromagnetic shielding was achieved by wrapping aluminum foil around the APCB, after applying the PR1750, and wiring. Care needed to be taken to ensure that air pockets were removed between the foil and the

PR1750. A coating of conductive paint provided the final electromagnetic protective layer.

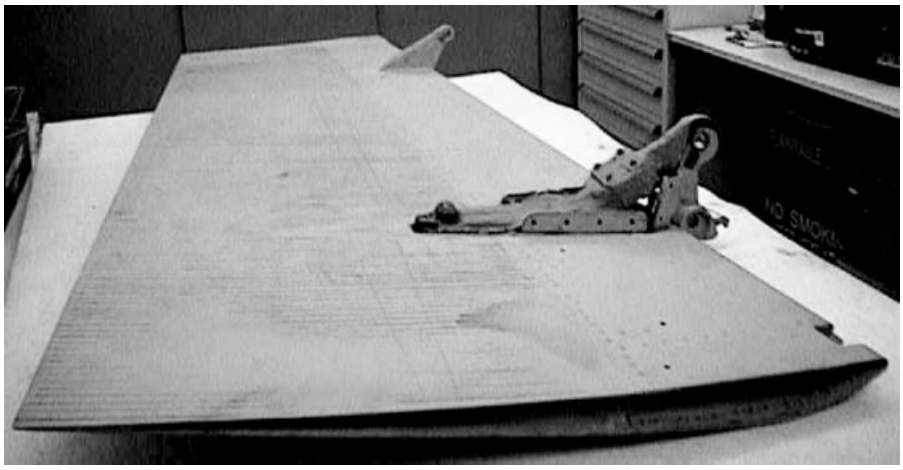
5 SYSTEM IMPLEMENTATION AND FLIGHT TEST RESULTS

A comprehensive installation procedure was written and approved by the appropriate airworthiness authorities [6]. The system was then installed on an Aircraft Research and Development Unit (ARDU), Flight Test Squadron (AFTS) aileron, over about a two-week period in November 2005. The aileron with the installed *smart patch* is shown in Figure 10.

The instrumented aileron hinge was installed on Hornet A21-101 in February 2006. The patch health information was to be downloaded by ground personnel from the instrumented aileron using a handheld unit, as shown in Figure 11, at the end of every week. No downloads were attempted if the aircraft did not fly during the week or if operational requirements meant that the aircraft was located at another base. After each download, the handheld unit was connected to a nearby docking station, which ensured that the handheld device was fully charged and allowed the patch health data, in the handheld unit, to be downloaded via a GSM mobile (cell) phone link for analysis. A plot of this data is shown in Figure 12.



(a)



(b)

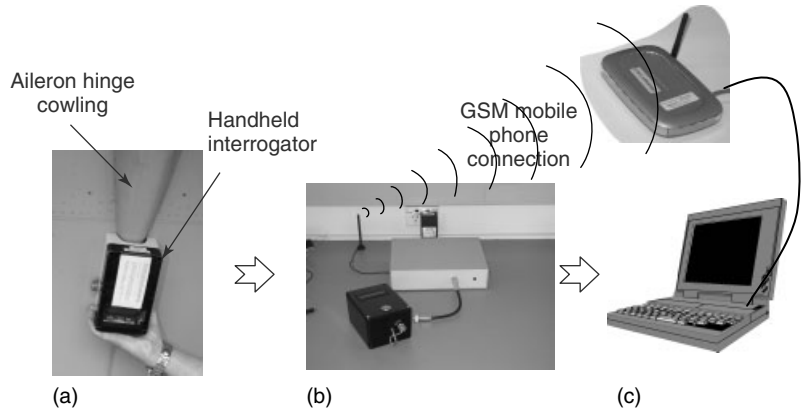

Figure 11. Patch health data download from *smart patch* (a) using handheld interrogator, (b) connecting handheld interrogator to docking station, and (c) download data to base station via GSM mobile phone link.

The trial ended in late February 2007 after 110 flights had been completed. During this time, the self-powered unit had registered 178 valid readings. The patch health indicator readings stored in FRAM, from the starboard and port piezoelectric film sensors, were initially set to an arbitrary low health value of about 0.8 and 0.1, respectively, as shown in Figure 12(a). Both patch health readings exhibited similar trends toward their respective perfect patch health ratio. As discussed previously, the PVDF sensors were not calibrated before installation and, as a result, the port and starboard ratios may settle to a nonunity ratio. The starboard sensor converged to a ratio of about 1.0 after 14 flights (37 readings) and then maintained a consistent value until the end of the trial. Therefore, any divergence from this value would indicate damage in the patch on the starboard side. The port sensor converged to a different ratio of about 0.63 after 97 flights (134 readings). As mentioned above, 178 valid readings were recorded after a total of 110 flights, as shown in Figure 12(b). The figure shows a steady increase in valid readings, of between one and two readings per flight, which was another indication that the device was working correctly.

6 DISCUSSIONS—LESSONS LEARNED

Considerable experience in low-power electronic design, design and implementation of packaging, as well as understanding issues associated with the design and implementation of a strain-based power-harvesting techniques has been achieved during the development of this demonstrator. One significant lesson learnt was to be cautious in the choice of electronic components that have only recently been released. This is because the project suffered considerable delays in the early part of the program due to the early adoption of immature COTS electronics, in particular, early versions of the Ti430 and a nonoperational FRAM chip. The use of COTS surface-mounted electronic components necessitated a large printed circuit board (PCB) footprint, making the installation complicated, cumbersome, and time consuming. Also, working with polysulfide PR1750 sealant to provide environmental protection, provided an additional level of complexity mainly due to the fact that the sealant was difficult to work with and required 24 h to cure, besides posing health and safety concerns. Hence, it would be desirable to eliminate the use of this sealant during any future *smart patch* installations.

Overall, there is a need to simplify the installation process into as few steps as possible. If the electronics were miniaturized (on a single chip), then this would greatly assist with packaging and installation, as well as reducing energy requirements, improving robustness, and reducing weight. A vibration-based energy harvesting approach would have also been feasible in this situation and would have facilitated in simplifying packaging and installation. This is because the system could be installed as a self-contained device thus eliminating the need

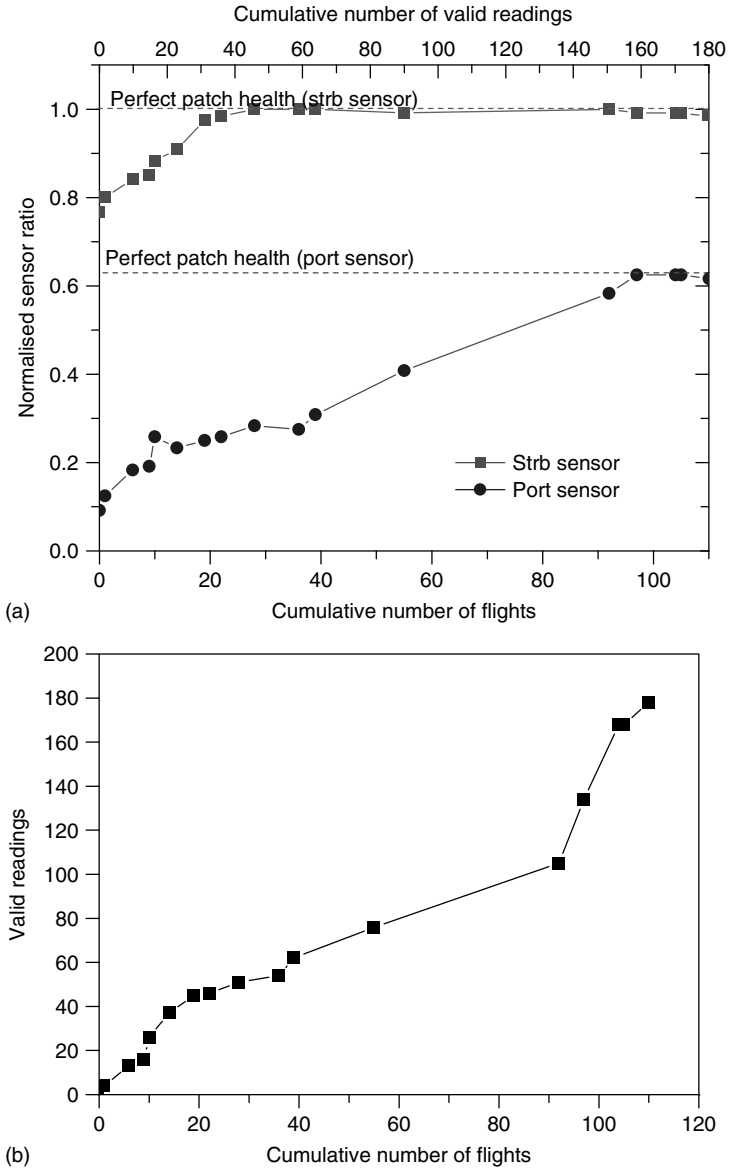

Figure 12. (a) Variation of *smart patch* normalized sensor ratios (patch health indicator readings) with increasing number of flights (from Mar 2006 to Feb 2007). (b) Plot shows the number of valid readings for the self-powered system with increasing number of flights.

to install separate power-harvesting piezoelectric elements, which required a significant footprint, to the structure.

After the instrumented aileron was removed from the aircraft, the *smart patch*, including the b/ep reinforcement, was removed from the aileron. Before removing the b/ep reinforcement from the aileron hinge, a standard tap test was undertaken, indicating no disbonds were present in the patch. Removal of the sensors, power-harvesting elements, PCB, and electromagnetic shielding indicated no significant adverse environmental effects on the various components.

However, it was observed that, in some regions, the PR1750 had not adhered to the shielding, suggesting that care needs to be taken when handling the shielding. Also, some of the PVDF layers in the power-harvesting stacks had disbonded. This observation reinforced the fact that more durability and robustness testing of the various sensing and power-harvesting elements would be required if the system were to be installed for a longer period.

7 CONCLUSIONS

The *smart patch* approach, which, in this case, is based on a self-powered *in situ* SHM system, would assist in alleviating certification concerns associated with implementing bonded composite repairs to primary aircraft structures. This approach relies on the ability to autonomously detect disbonding in the patch and is basically a continuous safety-by-inspection approach for the bonded repair. The main aspects of a self-powered *in situ* patch health monitoring system, applied to a composite bonded reinforcement on an operational F/A-18 aircraft, were outlined in this article. The system incorporates piezoelectric film PVDF sensors and is designed to operate using the electrical power generated by an array of PVDF and PZT power-harvesting piezoelements, which convert structural dynamic strain to electrical energy. The system was successfully installed on an operational RAAF F/A-18 aircraft. Patch health information downloaded from the *smart patch* system after 12 months of operational flying has indicated that the device is performing as expected and that the patch has "good" health. This was confirmed by applying a standard tap test to the composite bonded patch.

The system was designed with the focus on minimizing power requirements. This meant that issues such as the type of sensor, the amount and type of patch health information stored, electronic design/components including memory type and the interrogation technique were chosen from the standpoint of minimizing overall energy consumption. Owing to time constraints, the self-powered approach was strain-based, rather then vibration-based, since this required minimal development time even though it significantly complicated the installation process. To further lower risk, two types of power-harvesting piezoelectric elements, polymer and ceramic, were used in the system. This ensured adequate durability while ensuring enough power was generated at the reduced strain levels anticipated in the refurbished titanium hinges. The *smart patch* approach also demonstrated to the operators and maintainers of the aircraft that the interrogation of such systems required minimal interruption to their current maintenance routine.

ACKNOWLEDGMENTS

This program was undertaken under a RAAF sponsored task with support from Aircraft Structural Integrity-Directorate General Technical Airworthiness (ASI-DGTA) especially Officer-In-Charge ASI WGCDR Jason Agius and Dr Madabhushi Janardhana. Also, significant support was provided by AOSG, Aerospace Systems Engineering Squadron, especially Chief Engineer WGCDR Greg Young, Mr Des Cass, SGT Gavin Jones and SGT Andrew Schutz. The authors would like to also acknowledge Andrew Rider for development of the surface treatment procedure for the titanium aileron hinge and Ivan Stoyanovski for the application of the composite patch to the hinge; David Rowlands for assistance in installation of the *smart patch* and fabrication of the handheld interrogation unit; Keith Muller, Rodney Gray, Carlos Rey and Bruce Crosbie for assistance in mechanical testing; Peter Virtue and Howard Morton for undertaking the NDI of the aileron; Anthony Walley for assistance in developing the installation procedure and testing the PZT elements; Mike Konak, Quang Nguyen, Peter Smith and Sami Weinberg for assistance in circuit design and software development; and Richard Callinan for undertaking FE analysis. Support from Richard Chester and Alan Baker during the program is also gratefully acknowledged. Significant technical support from Aerostructures Technologies Pty Ltd is also gratefully acknowledged—Bryan Stade and Karmal Gill for designing the attachment and mounting arrangements; Mathew Goldstraw, Greg Rowlinson, Simon Maan and Ron Westcott for undertaking the FE analyses.

1 INTRODUCTION

A typical structural health monitoring (SHM) system consists of three basic components: (i) actuators and/or sensors, (ii) diagnostic software, and (iii) integrated hardware to monitor the "health state" of in-service structures [1–4]. Many research activities have been done to evaluate new sensor technologies for health monitoring of structures, such as optical fibers [5], piezoelectric materials [6], magnetostrictive materials [7, 8], and microelectromechanical system (MEMS) [9]. Among various types of transducers, piezoelectric materials are being widely used for SHM because they can be used as either actuators or sensors due to their piezoelectric effect and vice versa (*see* **Piezoelectric Wafer Active Sensors**; **Piezoelectric Paint Sensors for Ultrasonics-based Damage Detection**). In the active-sensing mode, both wave propagation and impedance-based SHM methods have been developed [10–15]. In the passive sensing mode, the piezoelectric sensors are used as sensors that continuously monitor external impact events [16]. In the wave propagation-based SHM, guided waves, such

as Lamb and Rayleigh waves, are most widely used for damage detection in metallic and composite structures. Guided waves used for damage detection are introduced into a structure at one point by a piezoelectric actuator and sensed by another piezoelectric sensor at a different position. A key advantage of using piezoelectric elements is that a larger area of the structure can be monitored with fewer transducers, which is vitally important for the monitoring of large-scale structures. Other sensors, like optical fiber-based types, can only scrutinize smaller, specific areas, thus leaving larger areas of a structure unmonitored.

However, it is well understood in the field of SHM that the network of transducers plays a key role in the performance of the SHM system. The ability of sensors and actuators in the network to communicate with each other establishes the intelligence of the system. The type, location, and number of sensors and actuators critically affect the sensitivity of the SHM system.

As the number of sensors increases, the integration of such a network with a structure can be very challenging or become impractical. Obviously, for SHM, the network sensors must be able to

1. integrate/adapt easily within/onto the structure;
2. accommodate any structural configuration;
3. carry a minimal weight; and
4. operate under variable environments.

Stanford multiactuator–receiver transduction (SMART) Layer technology, originally developed by Lin and Chang [17], can overcome these major challenges listed above. In this article, the progress of the SMART Layer technology is summarized in terms of its adaptability for practical applications.

2 SMART LAYER

2.1 SMART Layer design

An important part of the SHM system is the proper integration/adaptation of the sensors with the structure. Sensors permanently mounted onto structures provide the capability to monitor the condition of these structures throughout their service life. The SMART Layer is a unique and cost-effective method for integrating a network of piezoelectric elements with a structure [17, 18]. The layer is made of a thin dielectric film with an embedded network of distributed piezoelectric elements that can be used as either actuators or sensors. The novelty of the SMART Layer lies in its networking capabilities with any type of sensor that enhances its monitoring capabilities and eliminates the need to place each type of sensor individually on the structure. The major features of the SMART Layer include

- actuating and sensing capabilities;
- built-in sensor network for area sensing;
- signal consistency and sensor reliability;
- multiple wires from every transducer to improve reliability of the circuit;
- shielded layer to reduce electromagnetic (EM) noise;
- "hardwired" sensors for direct hardware diagnostic;
- ease of installation.

As shown in Figure 1, the SMART Layer utilizes a layered construction: a circuit layer, an insulation layer, and a sensor layer. In the sensor layer, PZT (lead zirconate titanate) discs with a diameter of 6.35 mm and a thickness of 0.25 mm are most often used, while other PZTs of different shapes and sizes can also be included in the layer as needed. Typical properties of the SMART Layer are given in Table 1.

2.2 Double/multiwire SMART Layer

The SMART Layer can be designed and manufactured in different configurations based on the requirements of the application. To increase the reliability

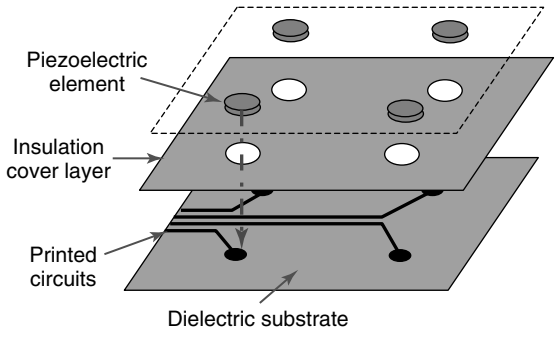

Figure 1. Overview of SMART Layer.

Table 1. Typical properties of SMART Layer

Network sensors	Dielectric material	Thickness of the layer	Temperature range	Environment
PZT-5A disc $D = 6.35$ mm $T = 0.25$ mm	Polyimide	~0.15 mm thick at the area without PZT	−54 to 121 °C for continuous operation	Coated SMART Layer passed salt fog and humidity tests

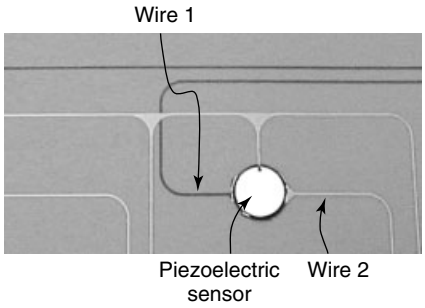

Figure 2. A double/multiwire version of SMART Layer.

of the layer, multiple printed circuitry has been developed for the layer design. With a single-wired layer, a small cut caused by impact or damage in the circuit can break the communication between the sensor and the diagnostic hardware system, rendering it worthless. The method of placing multiple circuits on the layer has been developed so that if one circuit breaks, the other could still be used. Figure 2 shows a picture of the sample of a layer with double wires for each sensor that has been manufactured in this way. Each sensor/actuator is connected via double wires to the final terminals.

This wire redundancy design in the layer eliminates the "fear of breakage of the wires" and makes the layer more reliable. This concept can be extended to any number of wires emanating from a single piezoelectric sensor. The circuit is designed so that the wires emanating from the same piezoelectric sensor are as far away from each other as possible. This design aspect ensures that any damage to one circuit does not damage the other circuit as well.

2.3 Layer for 3D structures

The SMART Layers can be fabricated in different shapes for integrating with different contours of structures. They vary in complexity ranging from a simple flat strip with one or two sensors to a complex 3-D "shell" with more than 50 sensors [18]. For structures with multiple curvatures and complex geometry, SMART Layers can be custom designed with special shapes and cutouts to provide a perfect fit. Two innovative manufacturing methods are described below.

One method of fabricating three-dimensional complex-shaped SMART Layers is to use mechanical locks at preselected locations and then shape the layer based on the required geometry. Upon curing, the layer will hold its shape. A schematic of this concept is presented in Figure 3.

A two-dimensional SMART Layer can also be fabricated through a compressed molding process into a layer with a three-dimensional configuration. A typical fabrication process for a three-dimensional SMART Layer was developed [19] and is briefly outlined as follows (Figure 4):

1. A two-dimensional SMART Layer is first fabricated based on a sensor location map from the 3-D structure.
2. Upon completion of the manufacturing process of the 2-D layer, appropriate cutting, trimming, and scissoring may be applied to conform the layer into the shape of the targeted structure.
3. The 2-D layer is then placed between the molds and subjected to a required processing temperature and pressure.
4. The pressure is maintained during the cooling cycle. After cooling down to room temperature, the layer can be removed from the molds and maintains its 3-D shape.

Figure 5 shows a 3-D layer that was fabricated on the basis of the procedures from items 1 to 4 outlined above, to conform to a composite mold. The 3-D layer was then embedded into a composite frame through

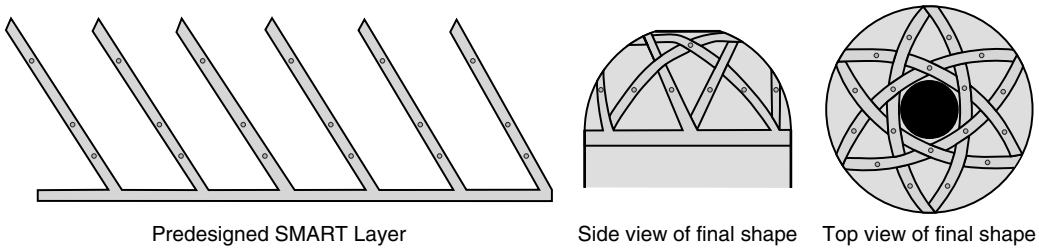

Figure 3. Fabrication method for 3-D SMART Layer.

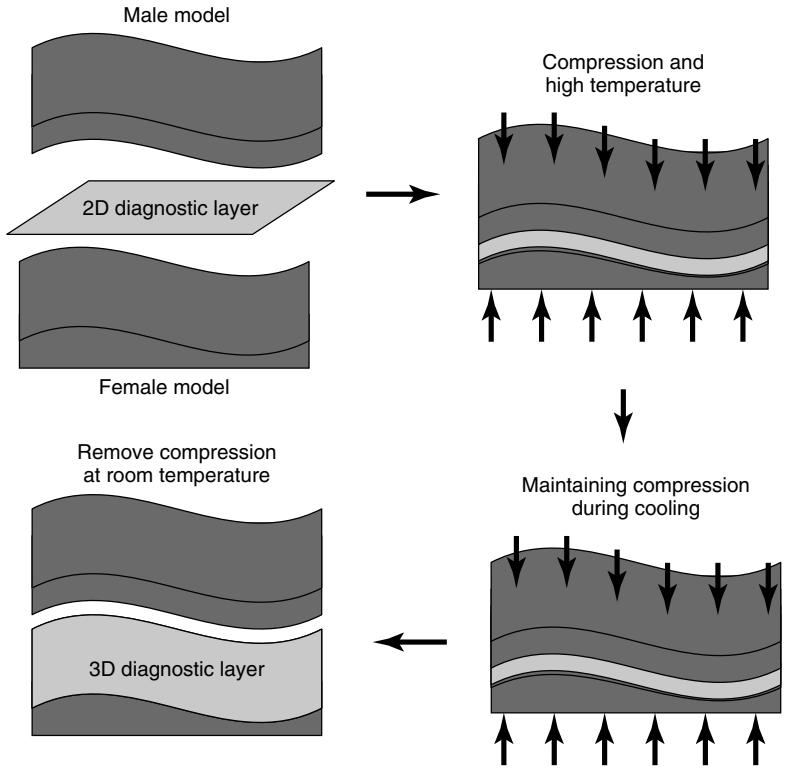

Figure 4. Conversion process of 2-D SMART Layer to 3-D.

a resin transfer molding process, which is described in the next section.

2.4 Hybrid SMART Layer

The SMART Layer can also accommodate other types of transducers along with piezoelectric elements. For instance, techniques have been developed to incorporate optical fibers into the layer. As shown in Figure 6(a), fiber Bragg grating (FBG) sensors are incorporated in the same layer with piezoelectric elements to create a hybrid piezoelectric/fiber-optic SMART Layer. Typical procedures for manufacturing such a diagnostic layer and the physical principles of the hybrid system can be found in the literature [20]. There is another article in the same section of this Encyclopedia that describes the hybrid SHM system (*see* **Hybrid PZT/FBG Sensor System**). Similarly, other types of sensors, such as strain gauges, MEMS, and temperature sensors can also be incorporated in

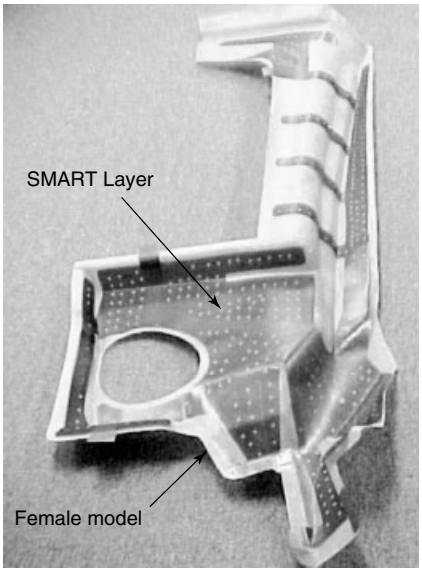

Figure 5. 3-D SMART Layer with 50 piezoelectric elements embedded.

the SMART Layer. Figure 6(b) shows a PZT/strain gauge hybrid layer mounted on a composite panel.

3 INTEGRATION OF SMART LAYER WITH A HOST STRUCTURE

In an SHM system, a sensor network needs to be permanently mounted onto the host structures. As shown in Figure 7, the SMART Layer can either be surface-mounted onto an existing structure or embedded into a composite structure during fabrication.

3.1 Surface Mounting the SMART Layer

As an example of a surface mounting the SMART Layer, the design and installation of the layers on bonded repairs on an F-16 airplane [21] (*see* **Flight Demonstration of a SHM System on a USAF Fighter Airplane**) is briefly described here. The center keel area of the F-16 fuselage station 341 bulkhead is susceptible to fatigue crack growth due to a maintenance-induced initiation site. The bulkhead is a large single-piece machined structure, and replacement of a damaged bulkhead is time consuming and costly. A system of adhesively bonded repairs was developed by Southwest Research Institute and applied to the keel structure as a potential alternative to replacing the bulkhead. To assess the health of the bonded structure as the airplane continues to be used, a health monitoring system was developed to inspect the bonded repairs.

Structure in the keel area of the F-16 station 341 bulkhead is complex, with material interfaces, fastened joints, and system penetrations. Figure 8 shows two views of the area in the main landing gear wheel well of the airplane that will be repaired and monitored. To ensure that the sensors would fit on the airplane and still provide adequate coverage of the repair area, a full-scale paper mock-up of the sensor layer, including positioning the transducers, routing

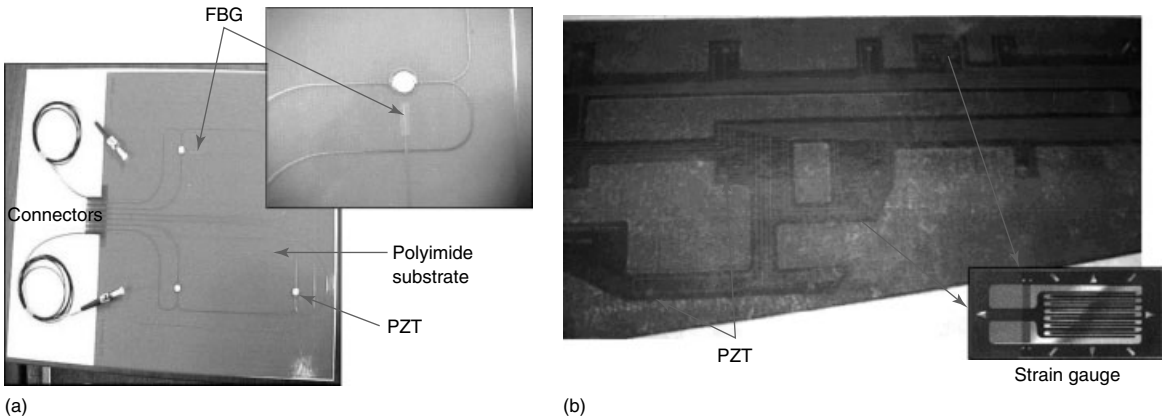

Figure 6. Hybrid SMART Layer.

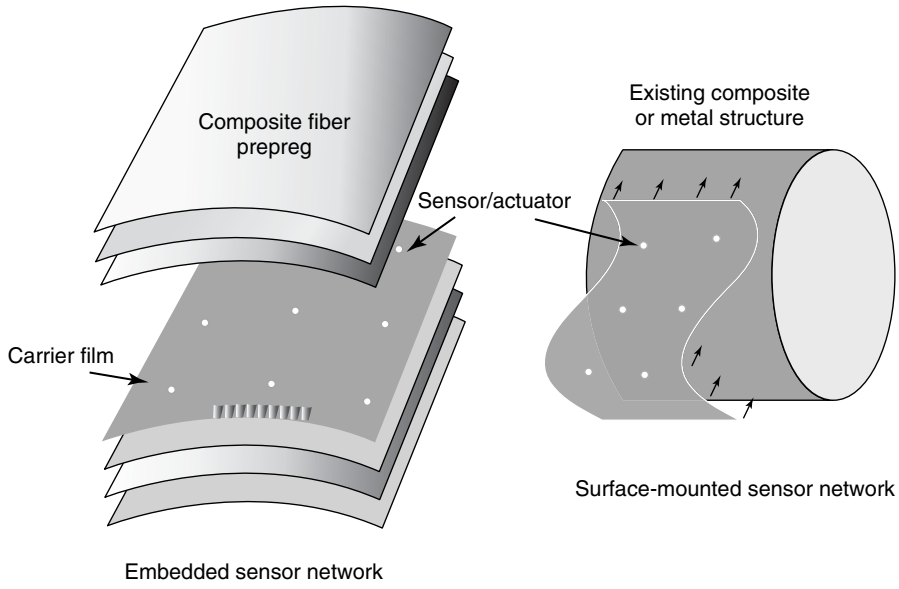

Figure 7. Diagnostic layer integrated with structure.

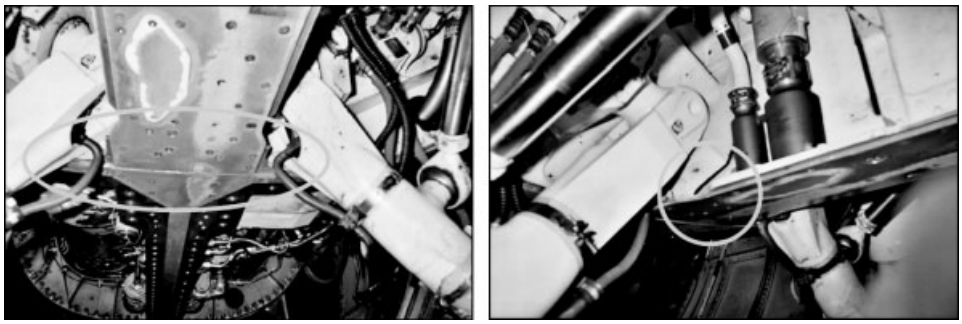

Figure 8. The main landing gear wheel well of an F-16 contains complex structures and multiple system installations [21].

the wiring, and finding an accessible but protected location for the connector, was created by using the F-16 at the US Air Force Museum. A SMART Layer was fabricated to match the paper mock-up. Figure 9 shows the layer prior to installation. The completed system consists of three separate layers and an integral connector.

The installation was performed at Hill Air Force Base in Ogden, Utah. Hysol EA 9394 epoxy adhesive was used to bond the sensor layer on the structure. As shown in Figure 10(b), the layer was adhered to the structure and fixed temporarily with clamps and Kapton tape. After room temperature curing, the tape and clamps were removed, and an overcoat of epoxy adhesive was brushed on the exterior of the sensor layer.

3.2 Embedding SMART Layer within composite

Methods for integrating a SMART Layer into a composite structure during different fabrication processes have been developed, including hand layup of prepregs or wet layup of fiber cloth, the resin transfer molding (RTM) process, and the filament-winding process. For hand layup of prepregs, the layer is simply treated as an additional ply laid

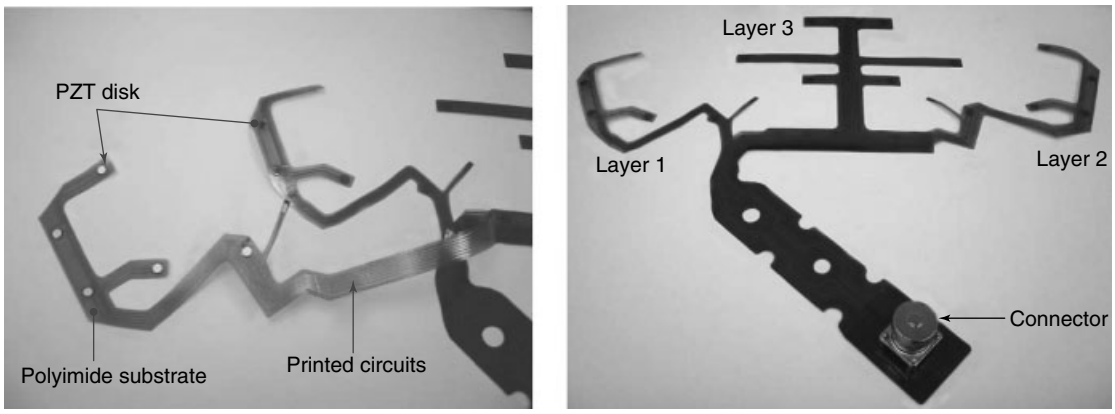

Figure 9. SMART Layer designed for monitoring the bonded repairs of F-16 [21].

Figure 10. The SMART Layers were mounted on the three repairs installed in the keel area of the station 341 bulkhead. (a) In-service F-16, (b) installation, and (c) mounted SMART Layer with surface coating [21].

down during layup. When inserting the layer inside composites, the sensor side preferably should face the thicker side of the laminate to account for the extra thickness of the sensors. For most of the cases, no other adhesive is needed when cocured with composite. Examples for integrating SMART Layers inside composites with RTM process and filament-winding process are given below.

3.2.1 Diagnostic layer integrated into composite during the RTM process

In this section, the study for integrating a sensor network into a three-dimensional composite foam core structure during the RTM process is presented [19]. RTM, which is a popular composite manufacturing process, is a low-pressure, closed molding process, where a mixed resin and catalyst are injected into a closed mold containing a fiber pack or preform. After the resin has cured, the mold can be opened and the finished component can be removed. The inclusion of a SMART Layer inside composite structure during RTM process is shown in Figure 11. The layer is inserted in the mold as an extra preform.

As an example, the 3-D layer shown in Figure 5 was inserted into the interface of the composite and foam core during the RTM manufacturing process. The open sides of piezoceramic disks on the diagnostic layer were oriented toward the composite. The cured composite sandwich structure with sensor network integrated is shown in Figure 12.

3.2.2 Sensor network integrated into filament-wound structure

Filament winding is the process of winding resin-impregnated fiber or tape on a mandrel surface in a precise geometric pattern. This is accomplished by rotating the mandrel while a delivery head precisely positions fibers on the mandrel surface. It is used for the manufacture of parts with high fiber volume

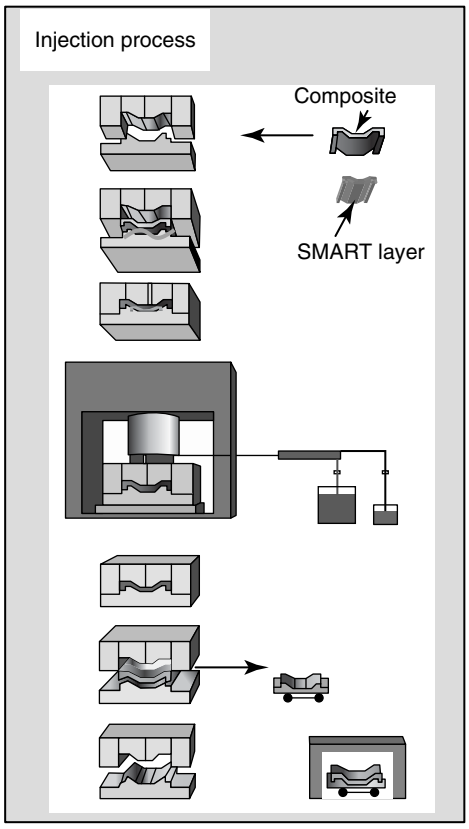

Figure 11. Composite RTM process and inclusion of SMART Layer.

fractions and controlled fiber orientation. To monitor the integrity of filament-wound composite structures, such as solid rocket motors and liquid fuel bottles, a way to embed a sensor network into a filament-wound composite structure was investigated [19, 22].

The composite bottle measures 500 mm in length and 381 mm in diameter. For the composite filament-winding process, the layer was designed in the shape of a thin flat strip with a row of piezoelectric elements. The PZT is 6.35 mm in diameter and 0.25-mm thick. There were five piezoceramic disks on each strip. To reduce EM noise, the connection circuits were shielded on one side by a solid copper foil. As shown in Figure 13, eight strips were used for the composite-wound bottle. This provided a sensor spacing of slightly less than 153 mm in the hoop direction. The result is an approximate square grid of sensors distributed over the bottle. The design of the bottle has five hoop composite layers and two helical composite layers in the cylindrical section, but only two helical layers in the dome sections.

Figure 14 shows some pictures of how the strips of SMART Layer were incorporated into the composite bottle during the filament-winding process. The main process involves winding composite prepreg tows onto an aluminum liner mandrel in either a hoop direction or a helical pattern. First, a hoop layer was wound onto the cylindrical section of the bottle. Four sensor strips were then placed on the top of the hoop layer and held in place by Teflon tape affixed on the dome part. Then two hoop layers were wound over the cylindrical section again. Next, the tapes used to fix the location of the four strips were removed before winding two helical layers over the entire bottle. Then, another hoop layer was wound over the cylindrical section. Next, the four outer sensor strips were placed on the bottle, held in place by Teflon tape. Finally, a hoop layer was wound on the top of the cylindrical section, leaving the outer strips exposed on the dome part. All the open

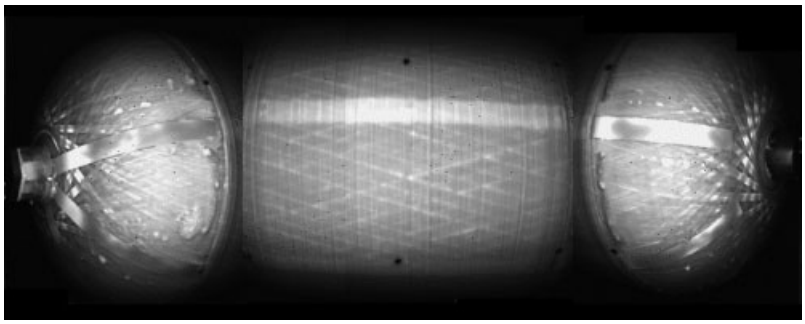

Figure 15. Finished bottle and thermographic image showing embedded SMART Layer.

sides of piezoelectric elements on the strips were oriented toward the thicker side of the composite: the piezoelectric elements on the inner strips face outward and the piezoelectric elements on the outer strips face inward. Since the composite material used to fabricate the bottle is a prepreg, i.e., has both fiber and resin in it, no epoxy resin was transferred into the bottle prior to cure. Since a vacuum bag was not used during curing, Teflon tape was used to push the part of four sensor strips on the outer surface of the dome to stick with the dome surface. The composite bottle was then cured at 177 °C (350 °F) for 2 h in the oven. During curing, the bottle was rotated continuously to obtain an even flow of resin and to eliminate any resin pools.

Figure 15 shows the finished bottle and the corresponding image from a thermographic scan (for thermal imaging techniques, *see* **Thermal Imaging Methods**). The imager used was an Indigo Merlin running under Thermal Wave Imaging software. The heating source was a TWI Flash System. Prior to scanning, the outer surface of the bottle was painted flat black [23]. From the thermographic image, the strips looked well bonded to the composite. This clearly demonstrated the compatibility of the SMART Layer with the filament-winding process typically used for the manufacturing of composite rocket motor cases.

4 SURVIVABILITY AND RELIABILITY OF BUILT-IN SENSOR NETWORK

The reliability of the sensor network for SHM must be entirely guaranteed through the life of structures. But the environments, such as mechanical loading, temperature, and chemicals, can significantly degrade the performances of sensors due to the nature of sensor materials [24] (*see* **Integrated Sensor Durability and Reliability**). A series of tests have been conducted to determine the survivability and functionality of the SMART Layer and its sensors under the different environment conditions. These tests include

- static and fatigue tests;
- temperature tests;
- vibration tests;
- salt fog and humidity tests.

4.1 Characterization of loading effect on the performance of PZT

4.1.1 Mechanical tests on coupon specimens

Tensile tests were conducted on three types of specimens: (i) aluminum specimens with SMART Layer mounted on the surface; (ii) composite specimens with SMART Layer mounted on the surface; and (iii) composite specimens with the layer embedded in the plies [25]. There were two PZT disks on each SMART Layer. For the composite specimens, the layer was cocured one ply down or on the surface of the specimen at 180 °C in an autoclave, while for the aluminum specimen the layer was bonded with an epoxy adhesive film Hysol EA 9696 and cured at 120 °C. During the test, the actuating signal was a five-cycle sinusoidal tone burst with an amplitude of 50 V and a frequency of 50 kHz. The performance of

PZT was studied by the difference between the amplitudes of sensing signals taken at different load histories. The piezoelectric property of PZT was evaluated at intervals of certain strain with and without loading.

Figure 16 shows the results of monotonic tensile tests. As shown in Figure 16(b) and (c), for the PZTs bonded on the composite specimens, the amplitude, η/η_o (η_o is the amplitude of the signal before loading), was almost constant up to the failure strain of PZT, $\varepsilon = 0.1\%$. The difference between the surface-mounted and embedded sensors was negligible except for the region of high strain. However, as shown in Figure 16(a), the amplitude, η/η_o, was almost constant up to about $\varepsilon = 0.3\%$, which is much larger than the failure strain of PZT.

The PZTs mounted on the aluminum specimen could survive much higher tensile strain because of the compressive prestress applied to the PZT during the adhesive mounting process of PZTs [25]. It is clear that the performance of PZT remains unchanged when the applied strain does not exceed the static failure strain of PZT, whereas the degradation of PZT occurs when the applied strain exceeds the static failure strain of PZT.

In addition, it can be concluded that the performance of PZT depends not on the materials of the host structure but on the thermal residual strain induced during the cure cycle. It is important to note that the PZT embedded in the structure can be used without any degradation even if the applied strain to the host structure exceeds the failure strain of PZT by introducing compressive prestress via a specific cure cycle.

The fatigue loading tests were carried out by controlling the strain applied to the specimen on the servo-hydraulic testing machine. The frequency of loading was 10 Hz and the ratio of minimum strain to maximum strain was 0.1. Figure 17 shows the results of fatigue loading tests. For the aluminum specimens, the amplitude, η/η_o, remained unchanged after 10^6 cycles when the maximum strain did not exceed 0.3%. The critical point of the onset of degradation in the fatigue loading tests of aluminum specimens, $\varepsilon = 0.3\%$, agreed with that in the monotonic tensile

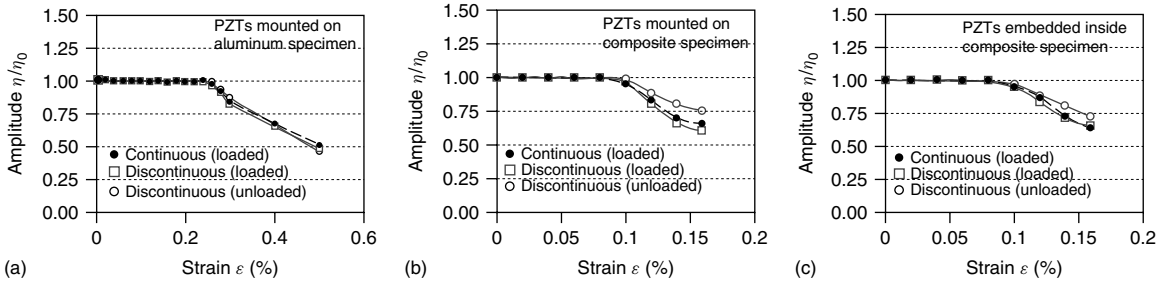

Figure 16. Results of tensile test for (a) aluminum specimen, (b) composite specimen with surface-mounted layer, and (c) composite with embedded layer.

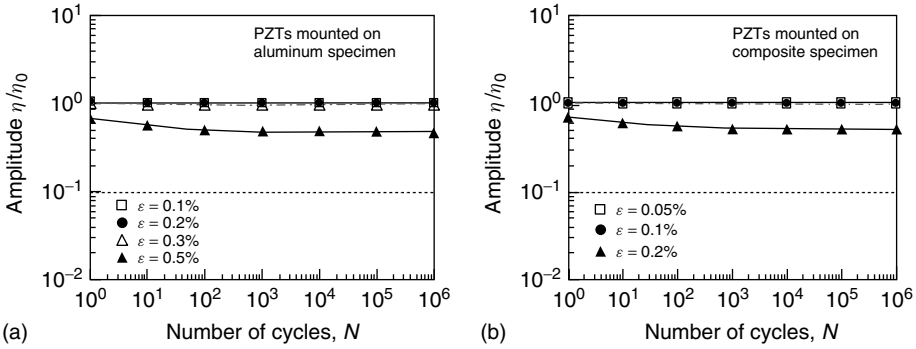

Figure 17. Effect of fatigue loading on the performance of PZT: (a) aluminum and (b) composite.

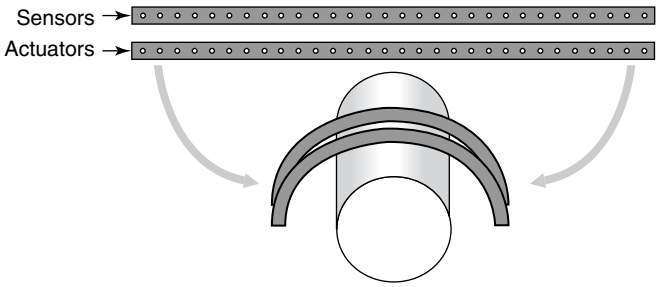

Figure 18. Thirty actuators and 30 sensors on two SMART Layers.

tests. For composite specimens, the amplitude, η/η_o, was almost constant for maximum $\varepsilon < 0.1\%$ when increasing the number of cycles up to 10^6. From the results, it can be concluded that the performance of PZT is not degraded under fatigue loading when the applied strain does not exceed the static failure strain of PZT, whereas the degradation of PZT is considerably stable after the first or several cycles of loading when the applied strain exceeds the static failure strain of PZT.

4.1.2 Fatigue test on a Thunder Horse steel pipe sample

The purpose of the test was to demonstrate the ability of SMART technology to detect and monitor the growth of a fatigue crack at the girth weld of a steel pipe used in offshore industry, and also to investigate the reliability and survivability of PZTs under fatigue load for real-world applications.

Test article

A Thunder Horse steel pipe sample was used in the test. The pipe, consisted of two 3-m-long segments joined together with a girth weld, has a 324-mm outer diameter with a wall thickness of 40 mm. Two 30-sensor SMART Layer strips were mounted on either side of the girth weld as shown in Figures 18 and 19. The sensors used in the strips were PZTs, each having a diameter of 6.35 mm and a thickness of 0.76 mm.

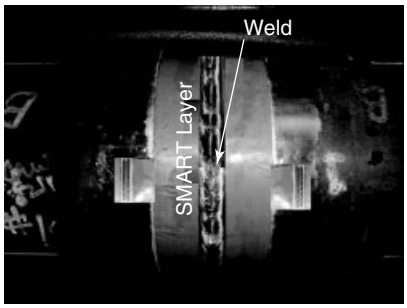

Figure 19. SMART Layers were mounted right up against the cap of the girth weld.

Test procedures and results

The testing was conducted with 2.8 MPa (400 psi) internal pressure and the fatigue cycling ran at ±206 MPa (30 ksi) at 27 Hz. For this test, the 30 piezos on one strip were used as actuators while the 30 piezos on the other strip were used as sensors. Each actuator, in turn, was excited with a five-peak modulated sine wave burst. The excitation generates stress waves that propagate through the structure and these are recorded by the sensor directly across from the actuator. Data was collected at 25 different intervals during the test. The test was stopped at about 12 300 000 cycles because a through-wall crack was observed in the pipe. All sensors were functioning when the tests were stopped.

The effect of cycling electric loading on the performance of PZTs was also investigated. The maximum voltage, which a 0.25-mm PZT can survive, is 70 VAC. Both surface-mounted PZTs and embedded PZTs inside the composite were tested. In each cycle, five-peak modulated sine wave bursts with maximum amplitude of 50 V were input to the PZT actuators at 10 different frequencies (50, 100, 150, 200, 250, 300, 350, 400, 450, and 500 kHz), respectively. The amplitude of sensor response to the excitation generated by the actuator is employed to evaluate the performance of the actuator. Test results that showed sensor signals for their actuator–sensor paths remained unchanged after 10^7 cycles for all PZTs on both specimens.

4.2 Effect of temperature and vibration

4.2.1 Temperature effect

Owing to the temperature dependence of material properties of the PZT, adhesive, and host structure, the sensor signals responding to the same voltage input to the actuator are temperature dependent. Figure 20 shows the temperature dependence of piezoelectric coefficients of PZT. It is expected that the sensor signal will change when the temperature changes. Tests on both metal and composite structures were conducted to investigate the temperature effect on the performance of SMART Layer. The SMART Layers were mounted on the structures with Hysol EA 9396. Hysol EA 9396 is a low-viscosity room temperature curing adhesive system with excellent strength properties at temperatures from −55 to 177 °C (−67 to 350 °F). Before mounting the SMART Layers on the structures, the surfaces of the structures were well prepared. The adhesive was cured at room temperature, followed by a post-curing of 1 h at 93 °C (200 °F).

Sensor signals from the SMART Layers on both metal and composite structures were recorded at different temperatures and cycles within the temperature range from −51 to 93 °C (−60 to 200 °F). Typical sensor signals from the SMART Layers on an Alloy 718 duct are shown in Figure 21. On the basis of the results, it is clear that the sensor signals for all frequencies tested here are repeatable at the same temperature after several temperature cycles. However, both amplitude and phase of the signals are different at different temperatures. According to the signals recorded from the SMART Layers on the metal structures, it can be seen that the amplitude of the signals slightly changed when the temperature changed. Also the phase of the signals shifted. However, the amplitude of signals from the layer on the composite panels significantly reduced when the temperature increased from −51 to 93 °C (−60 to 200 °F), depending on the resin used in the

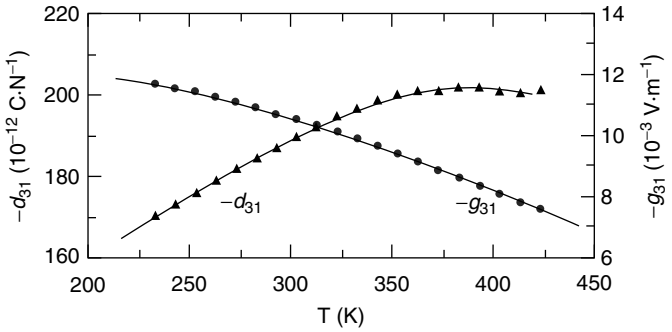

Figure 20. Temperature dependence of piezoelectric coefficients (d_{31}, g_{31}) of PZT (APC 850).

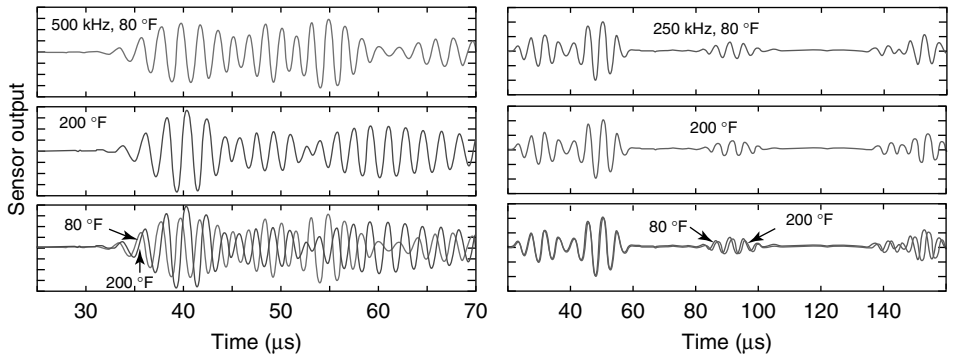

Figure 21. Typical sensor signals recorded at different temperatures.

composites. It can be concluded that the SMART Layer works well within the temperature range from −51 to 93 °C if the host structure can survive the environment [26].

For some specific applications, such as monitoring crack growth in a liquid rocket engine pipe, the sensor network must be able to survive a much harsher environment. Acellent has conducted the tests to determine the ability of the current SMART Layer to survive the extreme cold temperatures and high pressures of rocket engines. The test procedures and results are described in the following section [27]. From the successful application of composite manufacturing process monitoring, it demonstrated that the SMART Layer indeed survive high temperatures up to 200 °C [18].

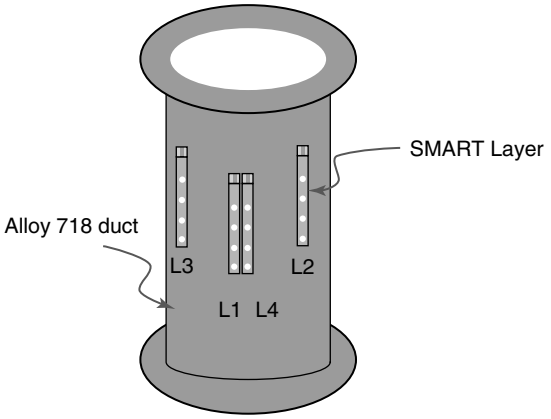

Figure 22. Schematic of the test specimen with SMART Tapes mounted.

4.3 Performance of SMART Layer under combined cryogenic temperature and vibration environment

This section describes how the physical robustness of the SMART Layer as well as operational survivability and functionality were verified with a duct simulator, conditioned to flight vibration and shock environments on a simulated large booster LOX-H_2 engine [27].

4.3.1 Test specimen and setup

Two layers (L1 and L3) with four piezoelectric single crystals on each were fabricated and mounted on the surface of an Alloy 718 duct with a diameter of 152 mm and length of 406 mm, as shown in Figure 22. The other two layers (L2 and L4) with PZTs were also manufactured and mounted on the duct to compare the performance of different piezoelectric materials. The low-temperature adhesive EP29LPSP was used to bond the layers on the Alloy 718 duct.

As shown in Figure 23, the duct with flanges was bolted between two aluminum "bookend" fixtures on the shaker machine. Liquid nitrogen (LN_2) flowed into one flange, through the duct, and out of the other flange. The vibration was controlled via an arithmetic average between accelerometers on each bookend. The test environments were derived from operational measurements on large booster LOX-H_2 engines during engine hot-fire testing. The defined random and sine environments represent an average of the data from the large propellant duct with the highest overall vibration level.

4.3.2 Test procedure

The duct assembly was installed in the test setup and a functional checkout of the sensors was conducted to verify their pretest operational condition. Test instrumentation was installed, including the triaxial response accelerometer and two temperature-monitoring type-K thermocouples. After completion of the flat random characterization run and instrumentation checks, the duct assembly was chilled down and attempt made to perform the same characterization at cryogenic temperatures. Following the completion of 30 min at 0 dB for the cryogenic test, four shock pulses were applied to the test setup at 0 dB.

Pitch–catch signals for both types of piezoelectric sensors were taken at ambient and cryogenic temperatures prior to applying the dynamic environments, during full-level vibration testing, and after completion of full-level testing.

4.3.3 Measurement results

Figure 24 shows some typical sensor signals at different stages. The sensor signals for piezoelectric sensors after the full-level test are the same as the signals before the test. It demonstrated that the piezoelectric sensors could withstand the operational

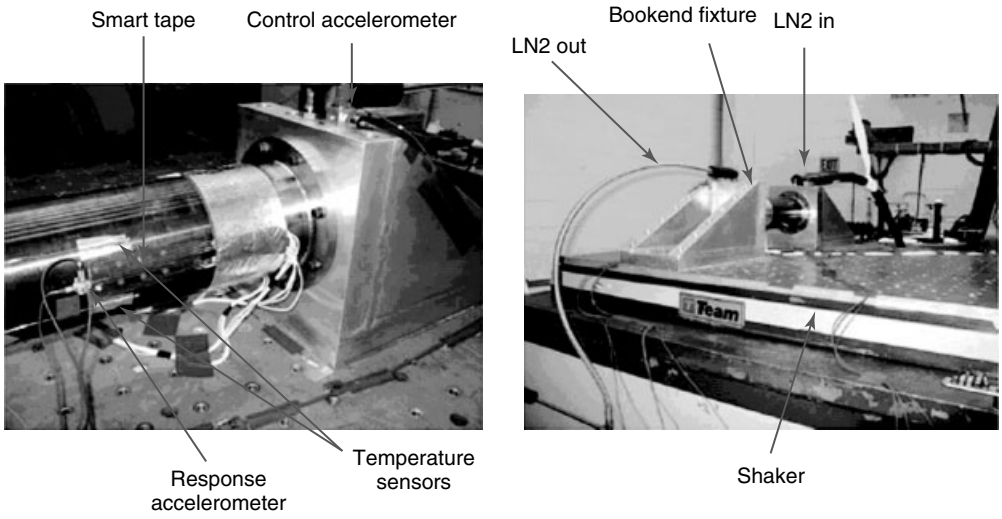

Figure 23. Setup for the combined cryogenic temperature and vibration test.

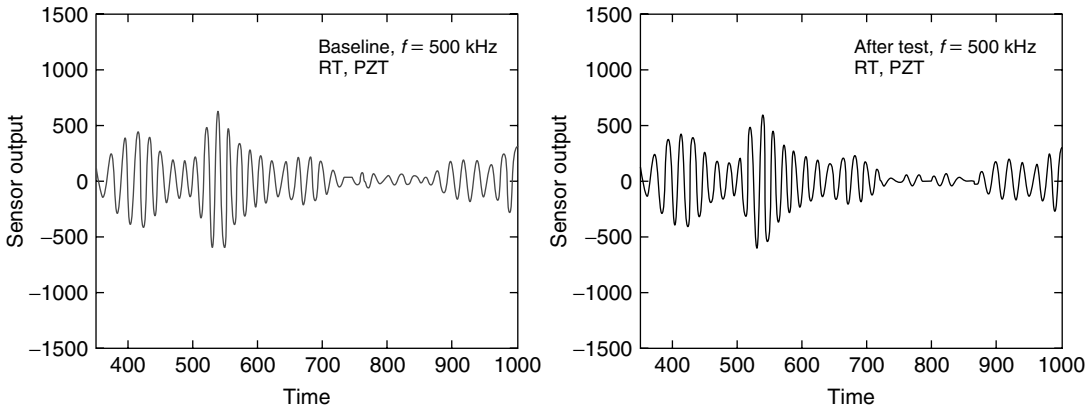

Figure 24. Comparison of 500-kHz signals from PZTs at room temperature before and after the full-level test.

levels of vibratory and shock energy on a representative rocket engine duct assembly within a restricted frequency band in laboratory testing.

4.4 Effect of moisture and aggressive chemical environment

Generally, the piezoelectric materials and polyimide used in the SMART Layer do not have a very good durability in high humidity or aggressive chemical environments. Protective coatings or encapsulation is recommended if the layer is used in high humidity or aggressive chemical environments. To evaluate the effectiveness and quality of protective coatings for the SMART Layer, both humidity testing and salt fog testing were conducted in a humidity chamber and a salt fog chamber per MIL-STD-810F, respectively. The coating tested is an epoxy primer per MIL-PRF-23377, Class C, which is then top coated per MIL-C-46168, Class H. The thickness of the epoxy primer is 15–25 μm, while the thickness of the top coating is 45–75 μm.

The comparisons of signals for the specimens before and after the salt fog test are shown in Figure 25. Test results showed that the SMART

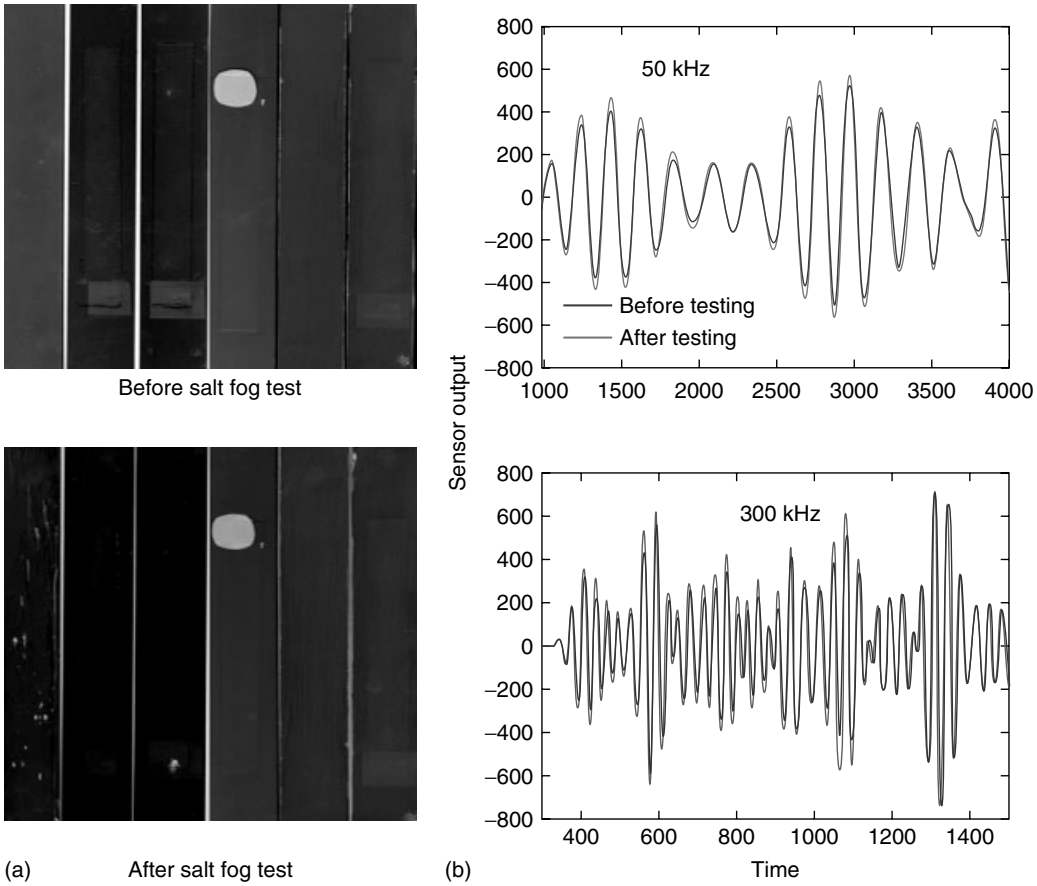

Figure 25. Salt fog test results: (a) aluminum specimens with protective coatings and (b) sensor signals.

Layers can survive humidity and salt fog exposure with proper surface treatment (sanding or chemical treatment), bonding the layers on the surface with Hysol EA 9396, and use proper coatings (epoxy primer per MIL-PRF-23377, class C, which is then top coated per MIL-C-46168, class H). Note that there is no protective coating necessary if the layer is embedded inside a composite.

5 EFFECT OF SMART LAYER ON STRUCTURAL INTEGRITY

When the SMART Layer is embedded inside a composite structure, the effect of the layer on the structural integrity is a concern. It is important to investigate the performance of the composite structure with embedded SMART Layer. Mechanical tests on composite coupon specimens with and without embedded polyimide layer were conducted to assess the change in structural integrity due to inclusion of the SMART Layer.

5.1 Quasi-static impact test

To determine the effects of embedding a SMART Layer into a composite, measurements of the damage tolerance of composites to transverse impact are needed. Quasi-static impact tests were used to simulate a low velocity impact and create a delamination. The tests were performed on both woven graphite/epoxy composites and toughened prepreg carbon–fiber/epoxy composites.

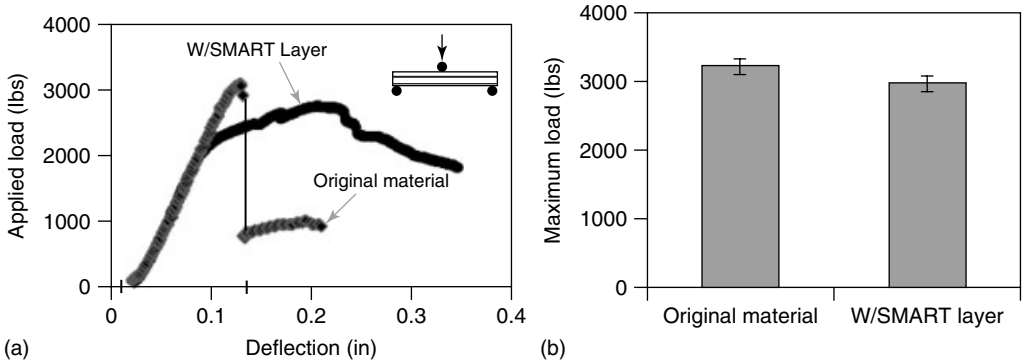

Figure 26. Mechanical test results of specimens with and without embedded SMART Layer (1 lb = 0.45 kg, 1 in. = 25.4 mm). (a) Load–deflection curve and (b) strength comparison.

5.1.1 Woven graphite/epoxy composite

The woven graphite/epoxy coupon specimens tested have a $[0_4/90_4/0_4]$ stacking sequence, specifically designed to promote delamination at the two ply-group interfaces. The specimens measured $140 \times 76 \times 5.2\,\text{mm}^3$. A SMART Layer was placed at the lower 0/90 interface. The thickness of the layer was 0.15 mm, while the thickness of the coupon specimens was 5.2 mm. For testing, the specimens were simply supported on two sides by steel rods spaced 90.0 mm apart and loaded in the center by a 12.7-mm diameter spherical indenter. The specimens were loaded at a displacement rate of $0.127\,\text{mm}\,\text{min}^{-1}$ ($0.05\,\text{in.}\,\text{min}^{-1}$). Test results on these specimens are presented in Figure 26. The test results indicate that the presence of the SMART Layer does not noticeably affect the strength of the host composite structure.

An examination of the cross section of the specimens corroborates these findings. Magnified views of the cross sections of the specimens are shown in Figure 27. It is clear that delamination in the specimens without the embedded SMART Layer occurs at the lower 0/90 interface, as expected, because of the high interfacial shear stress at the ply-group interface. However, in the specimens with an embedded SMART Layer at the lower 0/90 interface, there is no delamination. The actual delamination occurs one or two plies away from the interface, indicating that the SMART Layer does not promote delamination.

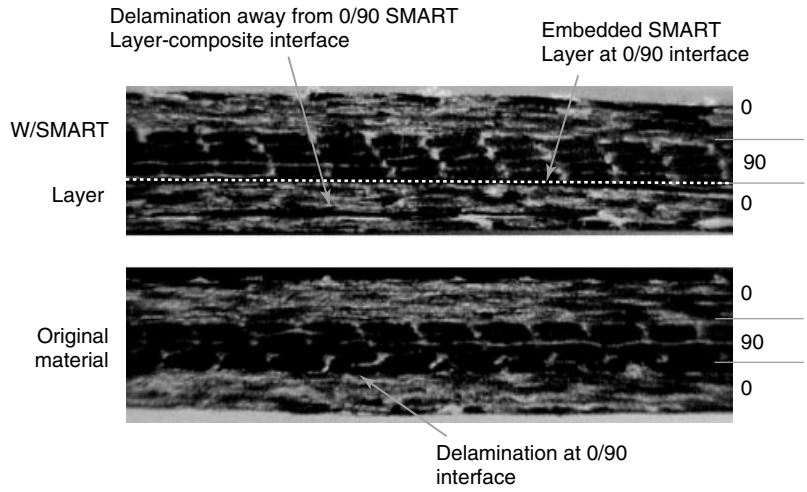

Figure 27. Cross-sectional view of test specimens.

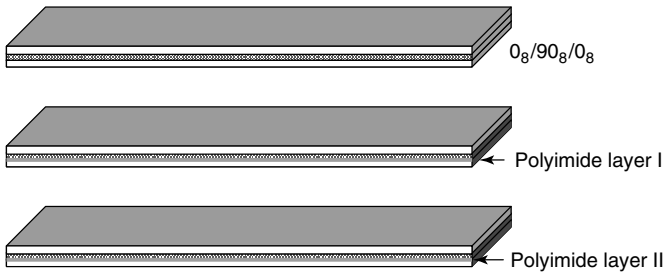

Figure 28. EX-1522 composite coupon specimens with or without polyimide layer inserted at the 0/90 interface.

5.1.2 Toughened carbon–fiber/epoxy composite

The toughened carbon–fiber/epoxy (EX-1522) composite coupon specimens used for quasi-static impact test have a layup $[0_8/90_8/0_8]$. For the embedded specimens, a 0.076-mm-thick polyimide layer I or a 0.152-mm-thick polyimide layer II is inserted at the interface to determine the effect of the thickness of SMART Layer on delamination growth, as shown in Figure 28. The specimens measured $130.0 \times 24 \times 4.0\,\text{mm}^3$. Similar to the woven graphite/epoxy composite, the specimens were supported on two sides by steel rods spaced 75.0 mm apart and loaded in the center by a 12.7-mm diameter spherical indenter. The specimens were loaded at a displacement rate of $01.27\,\text{mm}\,\text{min}^{-1}$. Test results on these specimens are presented in Figure 29.

The effect of embedding a SMART Layer on the damage tolerance of T300 and T800 composites to transverse impact was also studied by Lin and Chang [17]. Typical X-ray photographs for the tested specimens with $[0_8/90_8/0_8]$ stacking sequence were shown in Figure 30. As indicated by the X-ray photographs, the delamination area is actually smaller for the specimens with an embedded polyimide bondply; except in the case of the Toray T800H/3900–2 material, which is a resin system with a very high toughness, that it showed a slightly larger delamination. The improvement in impact resistance for most materials is attributed to the fact that the ductile polyimide layer toughens the interface and reduces matrix cracking, thus suppresses delamination.

5.2 Short beam shear test

Short beam shear tests on toughened carbon–fiber/epoxy (EX-1522) composite coupon specimens with and without polyimide layer were conducted. As shown in Figure 31, three types of specimens with unidirectional layup were tested: regular specimen

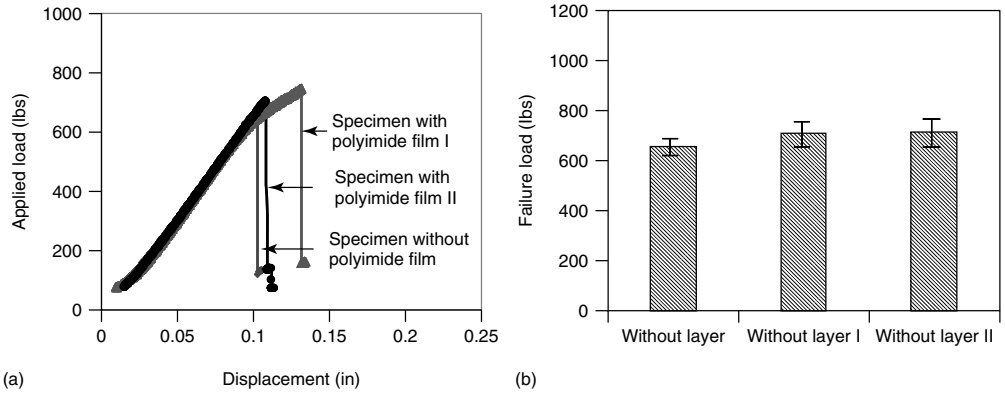

Figure 29. Three-point bending test results of layup $[0_8/90_8/0_8]$ with and without polyimide layer embedded at 0/90 interface. (a) Typical load–deflection curve and (b) strength comparison.

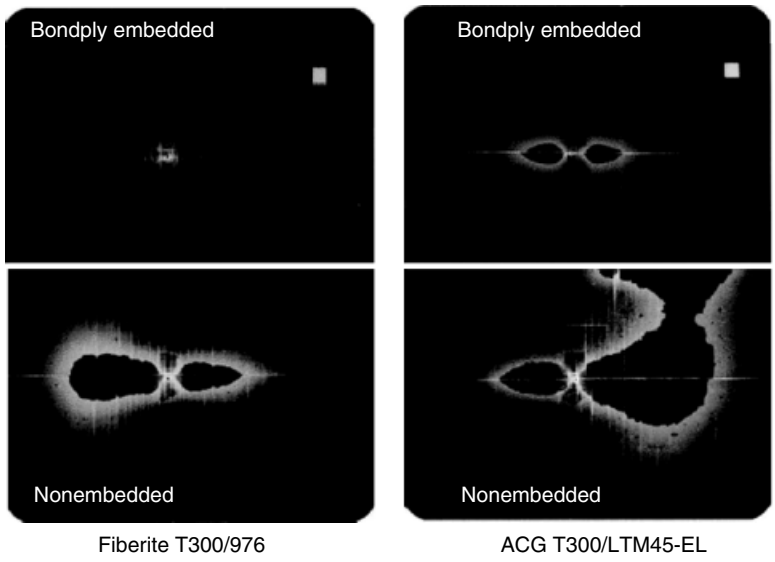

Figure 30. X-ray photographs of delaminations created by the impact test.

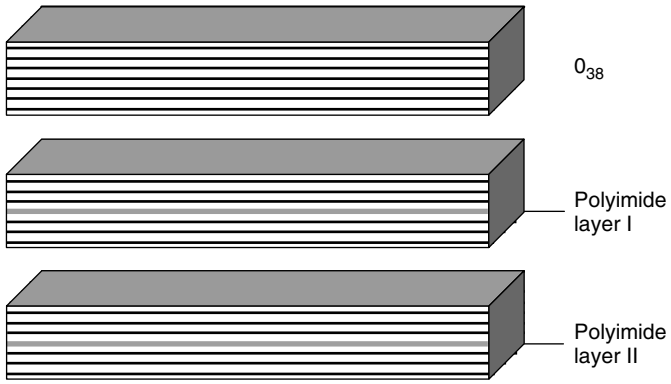

Figure 31. Short beam shear test specimen configurations. Polyimide layer was inserted in the middle plane of some specimens.

without polyimide embedded (Beam 1), specimen with 0.076-mm-thick polyimide layer I embedded (Beam 2), and specimen with 0.152-mm-thick polyimide layer II embedded in the middle plane (Beam 3). The specimens with a layup $[0_{38}]$ measured $40 \times 6.35 \times 6.35\,\text{mm}^3$. The specimens were loaded under three-point bending with a 25.4-mm span. A loading rate of $0.127\,\text{mm}\,\text{min}^{-1}$ was applied. Test results on these specimens are presented in Figure 32.

As shown in Figure 32, there is not much difference between the short beam shear strength of composite with and without polyimide layer. All types of specimens failed in a similar fashion—multiple simultaneous shear cracks between plies, i.e., delamination.

Once again, the test results indicate that the presence of the SMART Layer does neither noticeably affect the strength of the host composite structure nor promote delamination. Besides the studies mentioned above, more investigations on the change in structural integrity due to inclusion of the layer can be found in the literature [17, 28–30]. Results showed that the embedded layer would not decrease either the stiffness or strength of a composite structure.

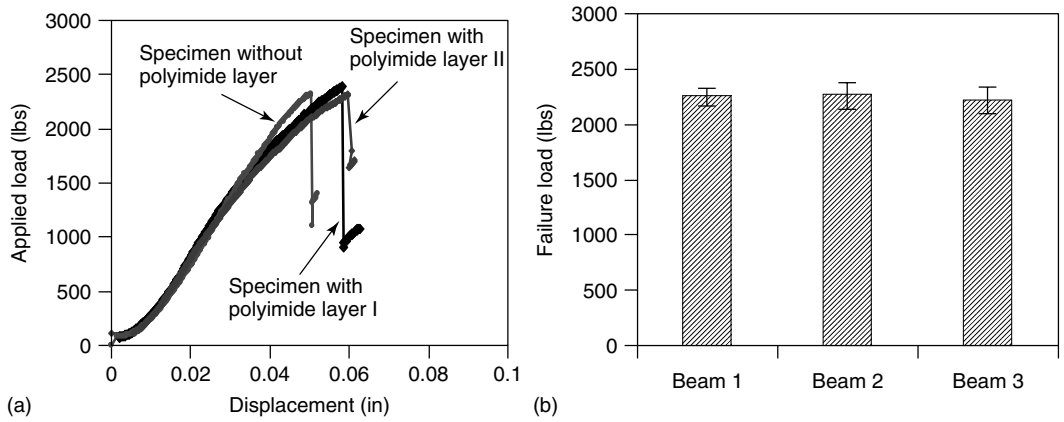

Figure 32. Short beam shear test results of unidirectional layup specimens with and without polyimide layer embedded in the middle plane. (a) Typical load–deflection curve and (b) strength comparison.

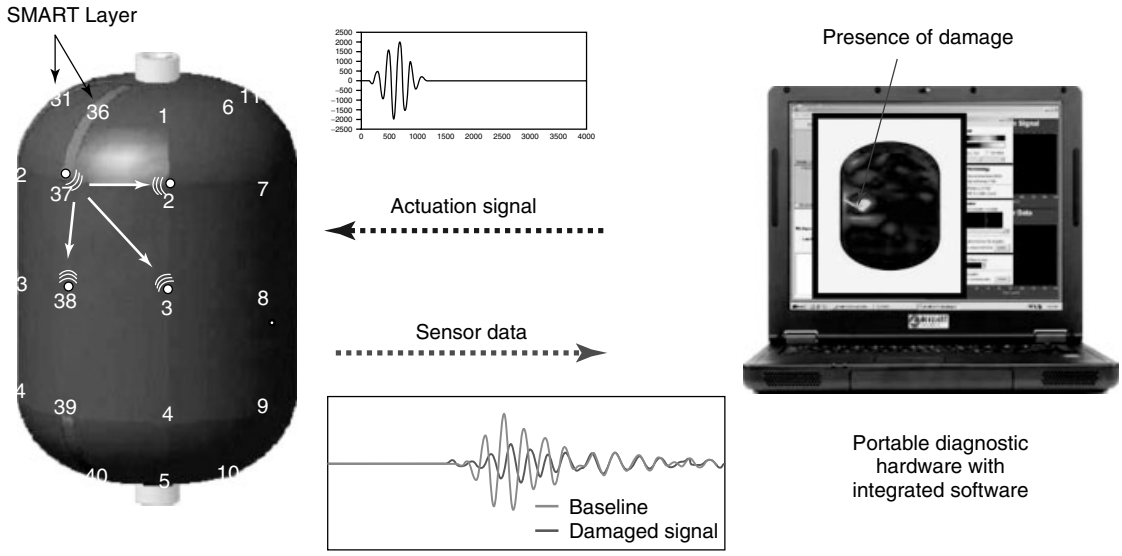

Figure 33. Diagram of Acellent's active-sensing system.

6 SENSOR NETWORK-BASED STRUCTURAL HEALTH MONITORING SYSTEMS

The SMART Layer integrated with a structure can be used for both active and passive sensing. The functioning of the active-sensing system is analogous to that of a built-in acousto-ultrasonic nondestructive evaluation (NDE) with a network of miniaturized piezoelectric transducers. The signal generator of the diagnostic hardware produces a diagnostic signal capable of propagating in structures with minimum distortion while being sensitive to any induced damage. Figure 33 shows the principles of Acellent's portable SHM system. The signal wave generated by the diagnostic hardware drives the actuator to produce a stress wave that propagates across the structure and is measured by the sensors.

When a propagating stress wave encounters a discontinuity in the geometry or material property of the structure, the wave is reflected or scattered.

The methodology used in the diagnostic process is based on the comparison of the current sensor responses with previously recorded sensor responses (baselines) from the undamaged structure. The differences between the two sets of signals are what contain the information about any existing damage or other anomalies. Some applications of the active sensing system can be found in the literature [31–34].

The passive sensing can be used in real time to detect impact events including both impact location and energy. The passive sensing system is set up to continuously listen for impacts at all times. When a sufficiently large force strikes the structure, the piezoceramic sensors that are bonded onto the structure pick up the stress waves traveling through the surface of the structure. A trigger mechanism enables software control to determine the trigger condition, which could be related to a specific set of features of the sensor measurements. As an example, to monitor the safety of a thermal protection system (TPS), a built-in passive sensing system is being developed for detecting the impact location and impact force in real time on TPS panels supplied by Lockheed Martin Space Systems [35].

7 DAMAGE DETECTION IN COMPOSITE STRUCTURES

A SmartComposite system based on SMART Layer technology has been developed to handle some practical issues for the application of SHM on composite structures in real world [36]. Regardless of the application, there are a number of elements that are essential to the practical usage and implementation of any SHM system. These elements can be grouped into three main categories: (i) the system must be easy to use, (ii) it must provide a well-defined resolution, and (iii) it must be very reliable. The essential elements for each category are listed below:

- Easy to use
  - the sensor installation should be straightforward with minimal training;
  - the system should have simple calibration procedures—preferably automated;
  - all data analysis shall be automated;
  - results should be output in standard formats.
- Well-defined resolution
  - the system must provide a quantifiable probability of detection (POD);
  - when damage is detected, the system must indicate size/severity along with the measure of uncertainty.
- High reliability
  - the system must be able to compensate for environmental changes;
  - the system must have built-in test for hardware and sensor self-diagnostics;
  - the sensors must survive extreme environmental conditions;
  - in the event of damage to a sensor, the system must be repairable.

Each element listed above has, by itself, been studied by many researchers and developers for a variety of applications. But there has been little work conducted to combine all the essential elements into a common framework. On the basis of the SMART Layer technology, Acellent has addressed this issue by focusing on all of the above elements, customizing each one for composite structures, and then unifying all of them into an integrated system called *the SmartComposite System*.

The key features of the system include sensor self-diagnostics and an adaptive algorithm to automatically compensate for damaged sensors, reliable damage detection under different environmental conditions, and generation of POD curves. In addition, state-of-the-art techniques to optimize sensor placement, automated calibration, and automated damage detection with no user interpretation of data make it an efficient and user-friendly system. A few of the features are discussed in the following sections.

7.1 Self-diagnostics

If one or more sensors are degraded, damaged, or missing, the SHM system may not function properly and can give false indications of structural damage. Measuring the impedance of each channel can be used to find an open or short circuit. This can indicate a missing sensor or damaged connection/wiring.

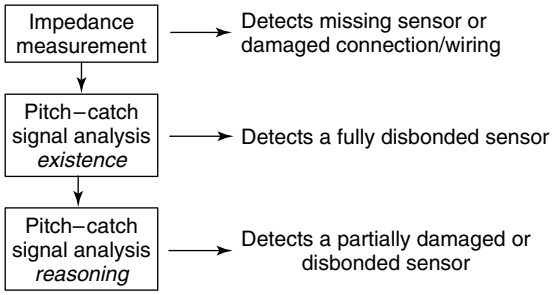

Figure 34. Integrated three-step method to automatically detect faulty sensors.

But a degraded or damaged sensor may go undetected using the impedance method. To resolve this, a reasoning process using the active sensor signals has been developed and implemented to detect degraded or damaged sensors that the impedance method may miss.

An integrated three-step method shown in Figure 34 has been developed to automatically detect

- faulty sensors caused by a missing sensor or damaged connection/wiring;
- a sensor that is still connected to the electronics, but is disbonded from the structure; and
- a partially damaged or disbonded sensor.

The impedance measurement of each channel can be used to find an open or short circuit. If a sensor is flagged as degraded, damaged, or missing, all signal data from the faulty sensor are removed from the analysis routines.

7.2 Temperature compensation

Current state-of-the-art damage detection methodologies rely on the use of baseline data collected from the structure in the undamaged state. The methodologies are based on comparing the current sensor responses to the previously recorded baseline sensor responses, and using the differences to glean information about structural damage. However, it is known that environmental effects, such as temperature differences, will also cause changes in the sensor signals, and will thus interfere with most damage detection schemes.

Acellent has developed a calibration technique utilizing multiple baselines that can be employed to mitigate the effects of environmental changes. The technique has been tested and verified for both global and local changes in temperature and can be used to compensate for global temperature changes in the structure as well as temperature gradients [36].

With this method, data is collected from the healthy structure at various temperatures and stored in a so-called baseline space. The baseline signals from each temperature can be used to create a baseline surface for each actuator–sensor path. At a later time, when a sensor scan is performed to search for damage, the newly recorded signals are compared with the

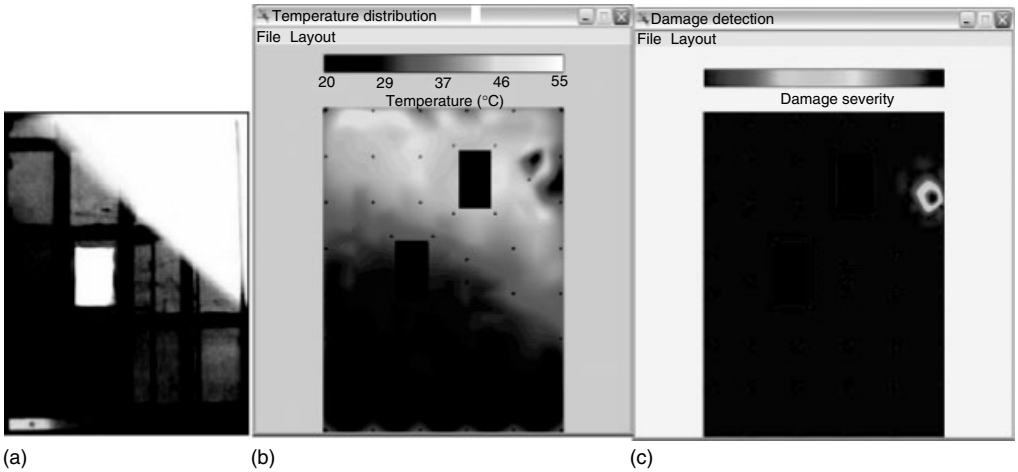

Figure 35. Environment compensation to eliminate temperature effect on a composite panel. (a) Structure in sun, (b) temperature distribution, and (c) detected damage.

corresponding baseline surfaces to determine a best fit along the temperature axis. An example of the temperature compensation is shown in Figure 35. The specimen shown in Figure 35 is a 1.5 m × 1.5 m fiberglass stiffener panel with surface-mounted SMART Layers containing a total of 50 actuators/sensors.

8 CONCLUSION

SHM offers the promise of a paradigm shift from schedule-driven maintenance to condition-based maintenance of assets. SMART Layer technology is a viable and cost-effective means of monitoring the structural condition and detecting damage while structures are in service. The techniques for fabricating the diagnostic layers and the methods for integrating the layer into structures are developed. The performance of the piezoelectric elements embedded in the SMART Layer under different loading and environment conditions was investigated. Other practical issues, such as the self-diagnostics of the embedded network and environmental compensation, are also discussed. On the basis of the study, the following remarks can be made:

1. Using SMART Layer, large sensor (and actuator) networks can be easily integrated with metal/composite structures. The characteristic features of the diagnostic layer include (i) ease of installation; (ii) adaptation to any structure with complex geometry; (iii) use of an area sensing network; (iv) actuation and sensing capabilities; (v) signal consistency and sensor reliability; and (vi) shielding to reduce EM noise.
2. The performance of PZT remains unchanged when the applied strain does not exceed the failure strain of PZT and the electric cycling input is below the maximum voltage.
3. The SMART Layer is functional within a wide temperature range. Proper protective coatings can effectively isolate the layer from the moisture and aggressive chemical environment when the layer is mounted on the surface of a structure.
4. Test results showed that the presence of the SMART Layer does neither noticeably affect the strength of the host composite structure nor promote delamination.
5. A SmartComposite system based on SMART Layer technology has been developed to handle some practical issues for the application of SHM in real world. The major features of the system include sensor network self-diagnostics, environment compensation, and POD curves with quantified damage size.

Chapter 80
The HELP-Layer® System

Michel B. Lemistre
Laboratoire SATIE/CNRS, Ecole Normale Supérieure de Cachan, Cachan, France

1 INTRODUCTION

The major risk for composite materials is the creation of delaminations resulting from impacts being often associated by fiber breaking. Besides, other types of damages can be caused by thermal aggressions, inducing pyrolysis of the polymeric matrix and by liquid ingress linked to aggressive environments. The most current structural health monitoring (SHM) system (based on fiber-optic sensors and acousto-ultrasonics), well suited to damages of mechanical origin, are unfortunately poorly sensitive to these last two types of damages. Assuming that all damages can affect the main electrical properties of structures such as electrical conductivity and dielectric permittivity, a measurement of these two parameters may allow detecting all kinds of damages. This is the reason why a new SHM system has been developed. This system, based on the interaction between a low-frequency electromagnetic field and the composite structure, allows the electrical characterization of materials. As shown here, this method detects and characterizes all kind of damages with a good sensitivity.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

2 THE HELP-Layer® SYSTEM

2.1 Short recall of the principle

The HELP-Layer® system [1, 2] is a low-frequency electromagnetic technique (*see* **Electric and Electromagnetic Properties Sensing**) applied to an SHM concept for composite structures. Its principle is based on a simple concept: a carbon fiber reinforced plastic (CFRP) structure is a double medium made, on the one hand, of a conductive medium (carbon fibers of conductivity $\sigma \approx 10^4\,\mathrm{S\cdot m^{-1}}$) and, on the other hand, of a perfectly dielectric medium (the polymeric matrix). The electromagnetic behavior of the first medium is sensitive to conductivity variations and the second medium to the orientational polarization phenomenon. So, one can define a polarization vector $\mathbf{P}$ linked with the local electric field E_1 by the following relation:

$$\mathbf{P} = \chi_e \varepsilon_0 E_1 \tag{1}$$

where ε_0 is the dielectric permittivity of the free space ($8.84 \times 10^{-12}\,\mathrm{F{\cdot}m^{-1}}$) and χ_e is the electric susceptibility, itself linked with the relative dielectric permittivity ε_r by the following expression:

$$\varepsilon_r = 1 + \chi_e \tag{2}$$

After induction of eddy currents in the structure, the measurement of the reflected electric field E_r gives access to both electrical parameters σ and ε_r, by the following relation:

$$E_r = \frac{J}{\sigma} + E_l\left(\varepsilon_r - 1\right) \tag{3}$$

with J being the eddy current density. This method allows for detection of a possible local variation of σ and/or ε_r. Therefore, all damages inducing a local variation of one or both these parameters will be detected.

In the case of a glass fiber reinforced plastic (GFRP) structure, the induction of eddy currents being impossible, one excites the structure with an electric field. So, only one parameter is measured, the relative dielectric permittivity ε_r.

2.2 Technology used

The HELP-Layer® system is a complete system having two parts. The first part is the sensitive layer itself. The second part is the associated electronics having in charge the excitation for inducing eddy currents (or electric field) in the structure, and the data reduction process to extract the relevant information and to build an image of the structure where the damages clearly appear.

The sensitive layer is made of a printed circuit on a 200-μm-thick dielectric substrate including a double network of crossed wires; this layer is bonded or embedded in the structure under test. Figures 1 and 2 respectively present the principle of the layer and a photo of a carbon/epoxy plate equipped with such a layer. By scanning these networks, one can perform local measurements of the electric field, with each analyzed zone having a dimension of 20 mm × 20 mm corresponding to the distance between two successive wires of each network (Figure 1). The first network, called the *inductive network*, is short-circuited at one end (or in open circuit in the case of a GFRP structure);

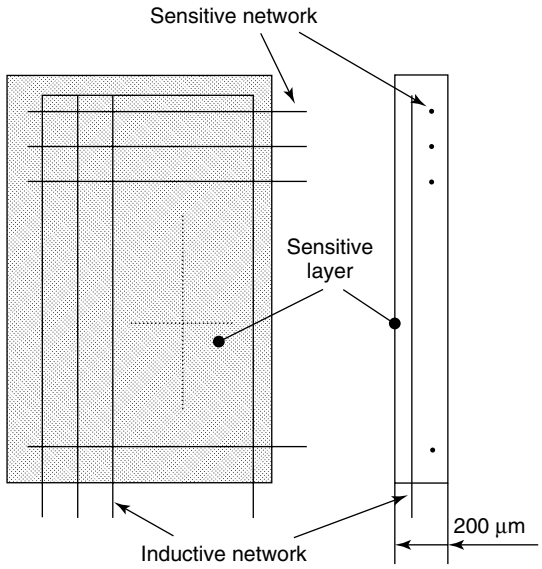

Figure 1. Geometry of the sensitive layer.

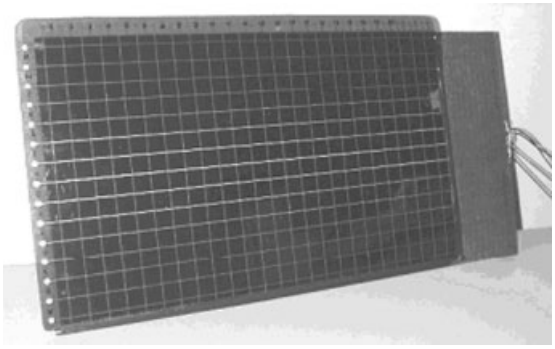

Figure 2. Instrumented structure.

each pair of wires represents a loop of induction (or a capacitance in the case of a GFRP structure). The second network, called the *sensitive network*, is not short-circuited, and each pair of successive wires can be considered as a capacitance allowing the in-plane component of the electric field perpendicular to the wires to be measured. Furthermore, each wire of this network can be considered as an elementary antenna, measuring the in-plane component of the electric field parallel to the wires (Figure 3). There are two possible exploitation methods of this technique. The first one consists of using only the modulus of the in-plane electric field to build an image of the damaged structure. The second one exploits separately the two in-plane components of the electric

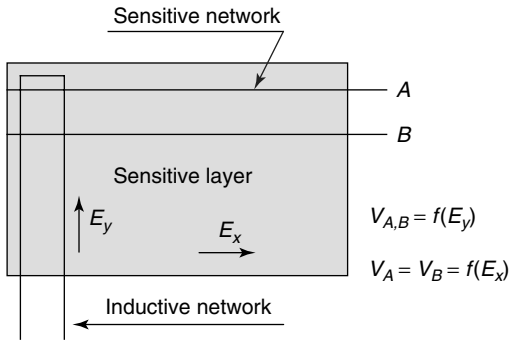

Figure 3. Measurement of the electric field components.

field and allows computation of the new values of the electric parameters to fully characterize the damages and to estimate their severity. This second method of exploitation is explained in the following subsections.

2.3 Example of application

An example of results obtained with the first method of exploitation is shown in Figure 5. Figures 2, 4, and 5 respectively present a photograph of an instrumented structure (a 16-ply orthotropic carbon/epoxy plate $[0_2, 90_2]_{2s}$ of dimensions: 610 mm × 305 mm × 2 mm), the types and locations of the damages in the structure (as seen from the opposite face of the plate), and the electromagnetic image obtained. The plate has been damaged by six different defects: a 4 J impact (I2) inducing a severe delamination with fiber breakage, a 2 J impact (I1) inducing a light delamination, and four local burns produced by "high energy sparks" (30 V, 5 A) of various duration, delivering energies of 40 J (B2), 80 J (B3), 120 J (B1), and 400 J (B4) (Figure 4).

In Figure 5, one can see that all damages are perfectly detected except the lower 2 J impact, probably because of the fact that there is no fiber breakage, so there is no variation of electric properties inside the structure under test. The inductive network has been excited by a continuous signal having a frequency of 700 kHz. The data reduction process is based on a multiresolution processing, using wavelet transform [3–5].

3 NUMERICAL SIMULATION

3.1 Basic principle

The numerical simulation method used is a concept developed at the Ecole Normale Supérieure of Cachan/France, called *distributed point source method* (DPSM) [6–8]. The main originality of this method is that, contrary to a classical finite

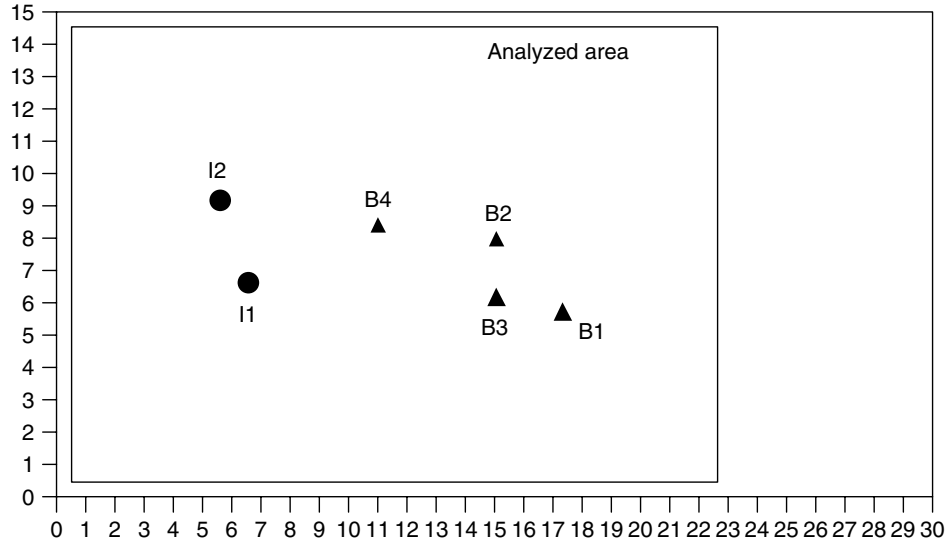

Figure 4. Damaged structure.

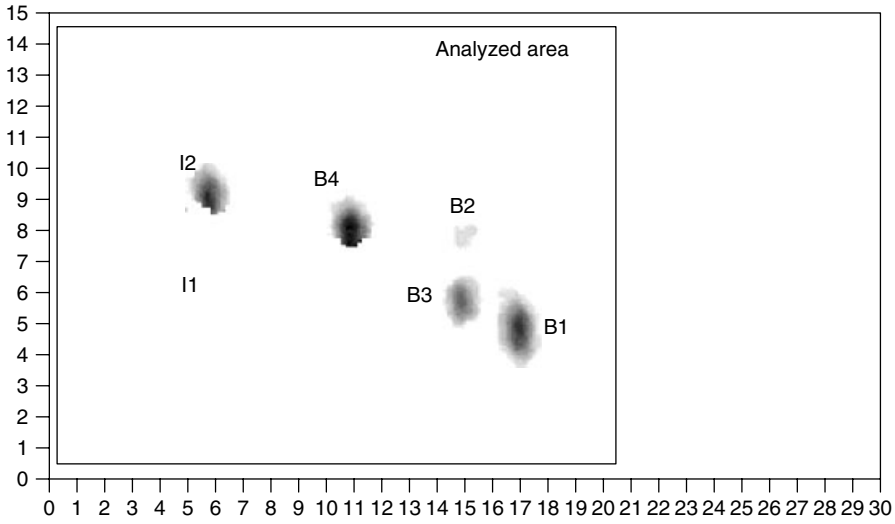

Figure 5. Electromagnetic image of the damaged structure shown in Figure 4.

elements method, it is not necessary to mesh the totality of the computation volume, but only the surface of interest. The implementation of the model simply requires discretization of the active surface of the transducer or the interfaces to obtain an array of point sources, so that the initial complexity is changed into a superposition of elementary problems. The active surfaces like transducers, emitters, or interfaces reflecting a part of an incident field, are discretized into a finite number of elementary surfaces, a point source being placed at the centroid of every elementary surface. It is interesting to note that the energy (or the power) radiated by such a system is the product of a scalar quantity by the flux of a vector (or the time derivative of the flux, for power). Let us call the scalar quantity θ_k the scalar potential, and ϕ_k the flux emitted by the source k, the vector being the field $\boldsymbol{V}$. For magnetic systems, θ_k and ϕ_k represent the magnetic potential and the flux of magnetic induction for the N elementary sources (Figure 6). For instance, one can calculate the potential θ at point M by superposition of elementary charges as follows:

$$\theta(M) = k\left(\sum_{n=1}^{N} \frac{q_n}{R_n}\right) \tag{4}$$

where R_n represents the distance between the source k and the point M, and q_n is the elementary charge at the point n (i.e., the charge generating the source k).

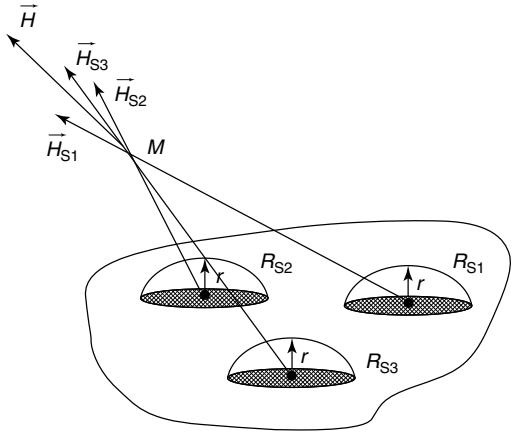

Figure 6. Discretization of a sensor surface into a finite number of hemispherical surfaces.

However, it is necessary to calculate the potential θ at the top point of each hemispherical surface (contribution of each elementary source toward others) by the following equation:

$$\begin{bmatrix} \theta_1 \\ \theta_2 \\ \vdots \\ \theta_n \end{bmatrix} = k \begin{bmatrix} F_{1,1} & F_{1,2} & :: & F_{1,n} \\ F_{2,1} & F_{2,2} & :: & F_{2,n} \\ :: & :: & :: & :: \\ F_{n,2} & :: & :: & F_{n,n} \end{bmatrix} \cdot \begin{bmatrix} q_1 \\ q_2 \\ \vdots \\ q_n \end{bmatrix} \tag{5}$$

where the function F represents the inverse of the distance R between the charge q_n and the calculation

point. From matrix $[F]$, which is a regular matrix, it is possible to calculate the elementary charges by the following relation:

$$[q] = \frac{1}{k}[G] \cdot [\theta] \tag{6}$$

with

$$[G] = [F]^{-1} \tag{7}$$

One can thus calculate the three quantities θ, V, and ϕ in each point of the space by using the knowledge of the elementary sources. If we place a target at point M, one can calculate the same quantities on its surface by using the matrix of reflection coefficients. A major issue of this method is that the surface of interest is meshed uniquely and the thickness of the target is taken into account by the matrix of reflection coefficients. This method allows the behavior of the HELP-Layer® system to be simulated.

3.2 Simulation conditions

As shown before, the HELP-Layer® system includes two crossed conductive networks. One of these networks is in charge of inducing eddy currents inside the carbon structure and appears in the form of parallel lines, with a spacing of 20 mm, and is short-circuited at one end. To induce significant eddy currents inside the structure (i.e., a significant electric field), it is necessary to sequentially inject a current of 1 A into each line of the inductive network. The frequency of excitation is chosen taking into account the depth of the structure (i.e., the skin effect). To simplify the problem, only one element of the HELP-Layer® of 60 mm × 60 mm is modeled, including only one inductive line. The structure is set at 0.1 mm above the HELP-Layer®. The current source is an inductive line of 60-mm length located in the xy plane at $x = 30$ mm and $y = 0$–60 mm, meshed by 60 current elements *Idl* (Figures 7 and 8). This current source is called *DPSM primary sources JAp*. The formulation used is the DPSM/Green's formulation [9].

The first computation consists of calculating the electromagnetic field on the surface of the structure ($\vec{E}$ and $\vec{H}$) or, more precisely, the magnetic vector potential $\vec{A}_1$ in medium 1 (free space) computed by superimposing the effect of current sources *JAp* and *JA*1 (DPSM virtual sources; see Figure 8. The magnetic vector potential in medium 2 (the structure) $\vec{A}_2$ is only defined by the current sources *JAs* and called *DPSM secondary sources*, the boundary

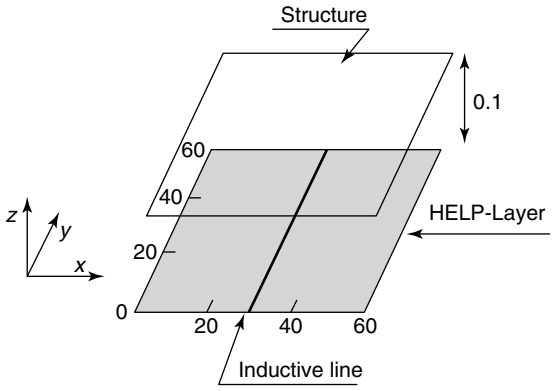

Figure 7. Geometry of the simulation (dimensions are given in millimeters).

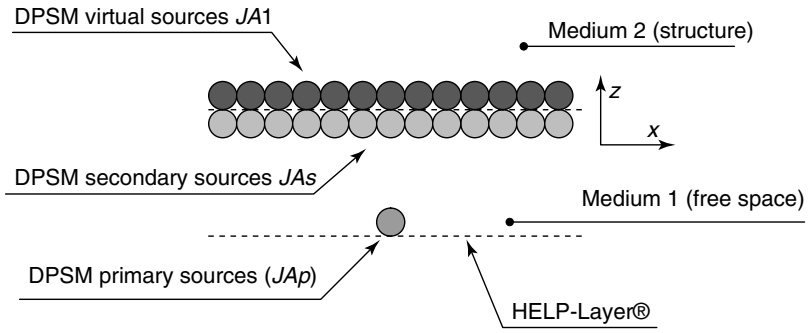

Figure 8. DPSM current sources.

conditions being the continuity on the vector potential and its first derivative along the z axis:

$$\begin{cases} \vec{A}_1 = \vec{A}_2 \\ \dfrac{1}{\mu_1}\dfrac{\partial \vec{A}_1}{\partial z} = \dfrac{1}{\mu_2}\dfrac{\partial \vec{A}_2}{\partial z} \end{cases} \tag{8}$$

In the case of harmonic excitation, one can compute the electric field by the following relation:

$$\vec{E} = -j\omega\vec{A} \tag{9}$$

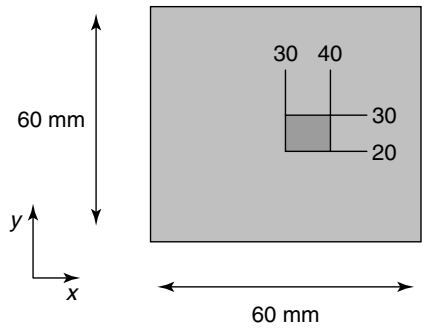

Figure 9. Location of the virtual damage.

3.3 Validation with experimental data

A computation of the in-plane component of the electric field E_y for three kinds of materials allows the results obtained for the same values measured to be compared by the HELP-Layer® system. Table 1 shows this comparison.

3.4 Modeling a damage inside the structure

Assuming that the defect is located at 1-mm depth inside the structure for $x \in (30, 40)$ mm and $y \in (20, 30)$ mm (Figure 9), generating a variation of one electric parameter of the structure (i.e., σ or ε). The first step is to construct the secondary sources *JAs* inside the structure. After that one performs the same process as presented previously, with new virtual sources *JA*2 and new secondary sources *JAs*2, medium 2 being the structure and medium 3 being the damaged zone of the structure (Figure 10). Note that we do not solve the global problem but a new elementary problem with new DPSM sources *JAs*2.

Two kinds of damages (damage 1 and damage 2) have been simulated, by variation of the local electrical conductivity σ and by variation of the local relative dielectric permittivity ε_r, respectively. Table 2

Table 1. Comparison between computed values and experimental values of the E_y component of the tangential electric field

Type of structures	E_y component ($\mathrm{V{\cdot}m^{-1}}$): computed values	E_y component ($\mathrm{V{\cdot}m^{-1}}$): experimental values	ΔE_y (%)
$[0_2, 45_2, 90_2, -45_2]_S$	1.59	1.65	+4
$[0_2, 45_2, 90_2, -45_2]_{2S}$	1.40	1.40	−3.5
$[0_2, 90_2]_{2S}$	1.60	1.65	+4

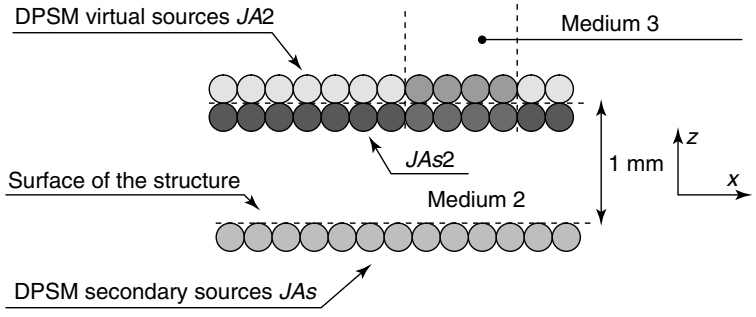

Figure 10. New DPSM sources.

Table 2. Numerical values of σ and ε_r for each kind of damage

Kind of damage	Sound area		Damaged area	
	σ (S·m^{-1})	ε_r	σ (S·m^{-1})	ε_r
1	10^4	4	5×10^3	4
2	10^4	4	10^4	2

shows the numerical values of these two parameters for each kind of damage.

Figure 11(a) and (b) present the modulus of the resulting electric field $|E_y|$ and $|E_x|$, respectively for the damaged structure 1. Figure 12 (a) and (b) present the same parameters for the damaged structure 2. These electric fields expressed in volts per millimeter represent for each one of the damaged structures (i.e., 1 or 2) the difference between the electric field obtained from a perfectly sound structure and the electric field obtained from the damaged structure.

One can see that in the case of a damage generating a variation of the electric conductivity σ, the y component of the electric field is dominating. In Figure 11(a) and (b), showing $|\vec{E}_y|$ and $|\vec{E}_x|$ respectively, the maximum value of the y component is 10^{-3} V·mm^{-1}, whereas the maximum value of the x component is only 1.3×10^{-7} V·mm^{-1}. On the contrary, in the case of a damage generating a variation of the dielectric permittivity ε_r, the major contribution on the electric field is given by the x component (Figure 12a and b): i.e.,

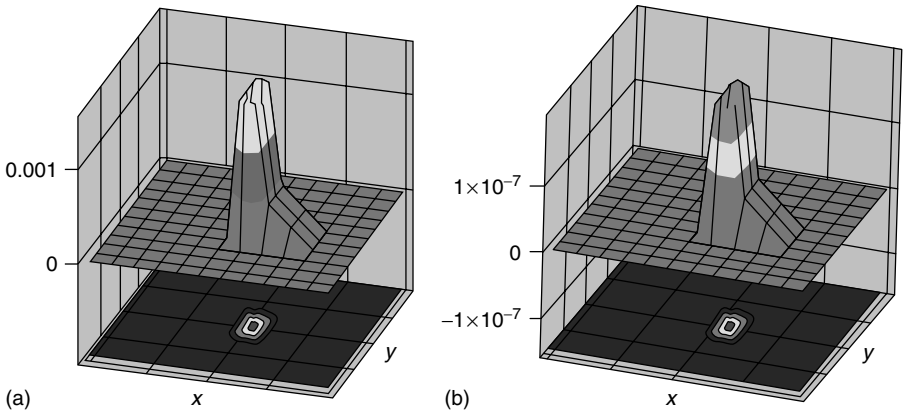

Figure 11. Electric fields resulting from a damaged structure 1. (a) Modulus of the E_y component and (b) modulus of the E_x component.

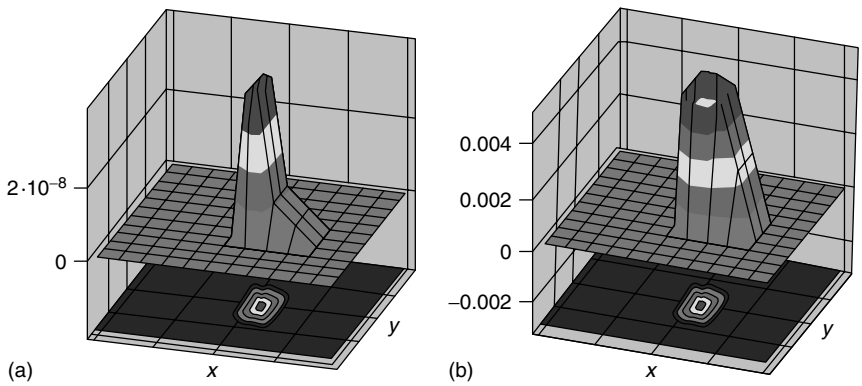

Figure 12. Electric fields resulting from a damaged structure 2. (a) Modulus of the E_y component and (b) modulus of the E_x component.

the maximum value of the y component is only $2.5 \times 10^{-8}\,\mathrm{V{\cdot}mm^{-1}}$, while the x component is $3 \times 10^{-3}\,\mathrm{V{\cdot}mm^{-1}}$. This is a very important result because it allows a kind of damage (i.e., the origin of the damage, *see* **Electric and Electromagnetic Properties Sensing**) to be determined.

3.5 Solving the inverse problem

To solve the inverse problem (i.e., computation of the new values of σ and ε_r, and determination of the kind of damage), the preceding remarks allow an algorithm to be developed (Figure 13). The first step helps to determine if the modulus of the x component of the electric field measured by the HELP-Layer® system E_{x_m} is significant (i.e., whether $>10^{-3}\,\mathrm{V{\cdot}m^{-1}}$). If the E_{x_m} component is not significant, the damage has a mechanical origin (delamination, fiber breaking, crack); so, one computes the modulus of the E_y component (resulting from the difference: sound structure—damaged structure) with variation of the σ value and compares it to the experimental E_{y_m} component. When the computed E_y value is equal to the experimental E_{y_m} value, the last value of σ is the local conductivity of the structure due to the damage. If the E_{x_m} component is significant, the damage has no mechanical origin, but may be due to burning, liquid ingress, etc. One compares the computed E_x value with the experimental E_{x_m} value and determines the local permittivity ε_r due to the damage, by the same process. To determine the possible local variation of σ one can then perform the same process with the E_y components.

The first evaluation concerns a quasi-isotropic plate of 2-mm thickness $[45_2, 0_2, -45_2, 90_2]_S$, including various delaminations generated by calibrated impacts (impact energies of 0.75, 2, 2.5, 3, and 4 J). The HELP-Layer® system measures the two components of the electric field (i.e., E_{x_m} and E_{y_m}), while the simulation program computes the values ε_r and σ on the damaged area corresponding to the same electric field component variations. For a sound structure, the electrical parameters are $\varepsilon_r = 4$ and $\sigma = 10^4\,\mathrm{S{\cdot}m^{-1}}$. Table 3 shows the results obtained. One can see that a delamination resulting from an impact of energy lower than 2.5 J does not cause a fiber breakage and consequently cannot induce a variation of σ that would detect the fiber breakage. The threshold of detection for this kind of defect is a delamination resulting from an impact of about 2.5 J for a 2-mm-thick plate of such a composite.

The second evaluation concerns a 2-mm-thick orthotropic plate $[0_2, 90_2]_S$, including various burning generated by electric sparks, for electric energies of 10, 40, 80, and 120 J. The field variations measured are given in Table 4. Assuming the same sound material properties as in the first case, the simulation

120	0.80	2×10^{-3}	NV	3.39

[a] Nonsignificant variation (see subsection 3.5).

leads to values of ε_r and σ as given in this table. Here an extra hypothesis was necessary. It was assumed that in the case of light burning, the low variation of the conductivity of the resin is masked by the relatively high conductivity of the carbon and that in the case of a fiber breakage phenomenon induced by hard burning, the increase of σ in the resin because of pyrolysis and the decrease of σ in the carbon fiber bundles would compensate each other. On the basis of these considerations, it has been assumed that only the permittivity ε_r was affected. In fact, it would have been more accurate if the two parameters, ε_r and σ, could have been varied. However, that would require the establishment of a new experimental procedure allowing the identification of both parameters. This improvement of the method is an objective for future development.

4 CONCLUSION

This article has been dedicated to an original system of structural health monitoring called the *HELP-Layer® system*, which is based on the interaction of an electromagnetic field and materials such as dielectric or conductive composite structures. The system shows that it is perfectly possible to detect, localize, and characterize various damages in a composite structure by using electromagnetic methods. Simulations allow validation of this electromagnetic method for use in a SHM system such as the HELP-Layer®, based on the analysis of electrical properties of materials. They also permit to distinguish between two types of damage (e.g., mechanical and thermal damage). The main interest of this method lies in its high sensitivity to "nonmechanical" damages such as resin pyrolysis and liquid ingress.

Work in progress consists in determining the effect of electrically qualified damage on the residual mechanical behavior of the composite material linking directly the HELP-Layer® system measurements to the degradation of structural performance, which, in fact, is the most interesting point.

1 INTRODUCTION

Damage detection techniques have been studied intensively in almost every aspect of engineering. In recent years, tremendous progress has been made. This is apparently a response to the high demand for safer structures and lower cost. Technological progress on novel smart actuators and sensors, such as piezoelectric transducers (lead–zirconate–titanate—PZTs) and fiber-optic sensors (fiber Bragg grating—FBG), has paved the way for the development of structural health monitoring (SHM) technology [1, 2]. Owing to their advantages, piezoelectric ceramics have been widely employed in noise and vibration control and active and passive sensing [3–6]. However, when the piezoelectric sensors are used in the active-sensing mode, such as using Lamb wave in pitch–catch manner to detect structural damage with a highly integrated diagnostic system, crosstalk between PZT actuation signals and sensor signals is always a problem. Further, electronic signals from PZT sensors to the data storage or processing unit may attenuate significantly during long-distance transmission, for example, from a bridge deck to its monitoring and control center. FBG sensor systems have offered an attractive solution to the problem of making strain measurements, as they have the advantages of small size, high resolution, high multiplexibility, electromagnetic immunity, and potentially high-density quasi-distributed measurements. FBGs serving as strain sensors have recently been used

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

in numerous harsh field environments, such as civil structures [7–9], aerospace vehicles [10], and ships [11] (*see* **Fiber Bragg Grating Sensors**).

A hybrid piezoelectric/fiber-optic sensor system offers the best decoupling of actuator and sensor signals (minimum interference), because the two devices use different mechanisms for signal transmission: the piezoelectric actuators use electrical channels while the FBG sensors use optical means [12, 13]. However, building a hybrid system is not simply a matter of putting the devices together. One of the most important issues arises from their different characteristics. PZTs are often used to actuate structures or detect dynamic responses, while FBG sensors are mainly used for quasi-static measuring or relatively low-frequency responses. This does not mean that FBG sensors cannot measure dynamic responses. But there are some issues relating to such sensors needed to be investigated, such as the relationship between sensitivity and grating length, the part of the optical fiber on which gratings are engraved, strain resolution, frequency range, and also the signal-to-noise ratio. Udd [14] demonstrated the capability of FBG sensors to detect acoustic emission and ultrasonic stress waves. Ogisu *et al.* [15] reported damage detection with the FBG sensor/PZT actuator hybrid system. Minardoa *et al.* [16] gave the full characterization of the ultrasonic waves by wavelength shift detection, indicating that the measurement can be achieved only if the grating length is smaller than the ultrasonic wavelength. Pierce *et al.* [17] successfully demonstrated the technique of damage inspection for CFRP (carbon fiber–reinforced plastic) plates with both fiber-optic Michelson interferometer and fiber-optic Mach–Zehnder interferometer using ultrasonic Lamb waves. However, this technique is not capable of multiplexing. Betz and his colleagues [18–20] have done a thorough study on both theoretical analysis and experimental validation of using PZT/FBG hybrid system to sense acoustic stress wave for damage detection.

In this article, a general review of the hybrid piezoelectric/fiber-optic SHM systems is presented, which includes the ultrasonic stress wave detectability study based on both experimental demonstration and theoretical analysis, the integrated hybrid PZT/FBG active diagnostic system and the applications, as well as the demonstrations of damage detection in both metallic and composite structures.

2 FBG AS ULTRASONIC STRESS WAVE SENSORS

2.1 Experimental demonstration

FBG is a selective reflector that reflects optical signals of a certain wavelength called the *Bragg wavelength* λ_b, according to the physical state of the gratings. An FBG consists of a series of periodically located cross sections with a higher refractive index (RI) at the core of a length of optical fiber. At each of the RI steps, a small fraction of the optical signal is reflected. With variations of temperature and strain, the fiber's physical properties change. This results in a change of the RI (n) and the period of the Bragg grating (Δ_0) and causes a Bragg wavelength shift (λ_b). This shift in the Bragg wavelength can be measured by an optical spectrum analyser (*see* **Acoustic Emission**; **Piezoelectric Wafer Active Sensors**; **Stanford Multi-actuator–Receiver Transduction (SMART) Layer Technology and Its Applications**).

$$\lambda_b = 2n_{\text{eff}_0}\Delta_0 \tag{1}$$

There are several methods for interrogating the FBG signals to effect quasi-static or low-frequency multisensor measurements [21]. Micron Optics fiber Fabry–Perot tunable filter (FFP-TF), developed by Micron Optics, is commonly used. It utilizes a Fabry–Perot etalon that passes wavelengths that are equal to integer fractions of the cavity (etalon) length; all other wavelengths are attenuated according to the Airy function [22]. However, for high-frequency measurements up to $\sim 10^5$ Hz or higher, another interrogation scheme, developed by Udd [14], is well suited. As shown in Figure 1, a matched fiber grating filter is employed instead of FFP-TF.

Udd and his coworkers presented a systematic study on acoustic emission detection using FBG sensors. In the first test, they attached an FBG sensor onto a PZT actuator and designed an interrogation scheme shown in Figure 1, in which a tunable matching FBG filter was employed to interrogate the

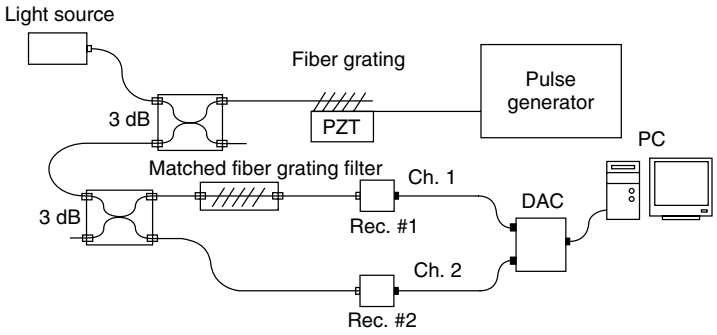

Figure 1. Schematic diagram of the FBG system with matched fiber grating filter. [Reproduced with permission from Ref. 14. © SPIE, 2001.]

optical response signal. Data were taken in the form of photoreceiver voltage response to the light signal. The ratio of signal from channel 1 to channel 2 can be correlated to the corresponding strain under measurement. From their experimental investigation, a lower detection limit has been established for acoustic emission (AE) detection using FBGs. They also carried out tests to study the capability of Lamb wave detection by FBGs on an aluminum plate. The detection results showed that the sensitivity of the FBG sensor varied according to the distance between the FBG sensor and the ultrasonic transducer. Furthermore, the directional dependency of the detection sensitivity was also studied.

2.2 Theoretical analysis

Minardoa *et al.* [16] investigated the response of an FBG to the dynamic strain induced by a symmetric mode Lamb wave theoretically and presented numerical simulation results. They studied the interaction between a uniform FBG of length L, written into the core of a standard single-mode fiber, and an ultrasonic wave. The FBG that is not subjected to any external stress is described by a modulation of the effective RI of the fundamental guided mode along the fiber axis z.

$$n_{\text{eff}}(z) = n_{\text{eff}\,0} - \Delta n \sin^2\left(\frac{\pi}{\Lambda_0} z\right) \tag{2}$$

where Δn is the maximum index change and Λ_0 is the grating pitch. The Bragg wavelength, as determined by applying the Bragg condition, is given by equation (1).

They assumed an ultrasonic plane wave, with the acoustic wavefront normal to the optical fiber. Strain field is modeled by a longitudinal strain wave propagating along the fiber axis. In addition, the time dependence is assumed to be sinusoidal and can be expressed as

$$\varepsilon(z, t) = \varepsilon_m \cos(k_s z - \omega_s t) \tag{3}$$

Here, ε_m denotes the strain wave amplitude, ω_s its angular frequency, and k_s its wave number related to its wavelength by $k_s = 2\pi/\lambda_s$.

The strain wave influences the Bragg grating response by modulating its geometrical and physical properties, which is the same as quasi-static measurement using FBG sensors. Then the new effective RI of the Bragg grating under the ultrasonic wave action can be evaluated as the sum of two contributions. The first one is a mechanical contribution, due to the modulation of the grating pitch under the strain wave, which can be determined by the deformation along the z axis of the grating; the second one is an optical contribution due to the change in RI via the elasto-optic effect. Through the study the sensitivity of FBG response has been shown to decrease when reducing the ratio between the ultrasound (US) wavelength and the grating length. Moreover, a significant spectrum shape distortion has been shown to occur for high-power ultrasonic waves. It also showed there are essentially three main operating regions that can be distinguished. The first region, when $\lambda_S/L \ll 1$, the wavelength shift sensitivity S_λ approaches zero, and so no apparent Bragg wavelength modulation occurs. In the second region, corresponding to $\lambda_S/L \approx 1$, S_λ increases with the ratio λ_S/L, and in the third region,

corresponding to $\lambda_S/L \gg 1$, S_λ approaches the static value $S_m \approx 0.78$.

3 DAMAGE DETECTION

3.1 Lamb wave source location

Betz and Lamb [18] suggested a fit function to predict the directivity dependence of FBG sensors.

$$\hat{A}(\alpha) = a_2 \sin^2\left(\pi \frac{\alpha - a_1}{180}\right) \tag{4}$$

where $\hat{A}$ is the normalized amplitude of the strain amplitude, α is the angle between the direction of FBG sensors and the longitudinal wave propagation, and a_1 and a_2 are fit parameters that can be determined by test. He designed a test scheme to obtain those parameters and then used the inverse of equation (4) to calculate the direction of the Lamb wave, and by two sets of FBG sensor rosettes the location of the Lamb wave source can be found.

3.2 Acoustic emission detection

Udd [14] and his coworkers studied the acoustic emission detection ability of FBG sensors. However, a further study was carried out by Baldwin and Vizzini [23]. Baldwin and Vizzini successfully demonstrated the ability of an FBG sensor to detect a pencil lead break event, metal to metal impact events, and AE events from composite specimens with loosely mounted and embedded FBG sensors using a similar interrogation technique as Udd adopted.

3.3 Composite delamination detection

Ogisu *et al.* [15] reported damage detection with hybrid FBG sensor/PZT actuators using small diameter FBG sensors. They proposed a novel FBG sensor signal interrogation system capable of detecting frequencies of up to 1 MHz. The system employs an arrayed wave guide grating (AWG)-type filter to obtain a high-sensitivity filter characteristic for detecting small displacements in the grating of the FBG sensors. Furthermore, the AWG-type systems are also capable of interrogating multiple sensors at the same time. The sensor length in their study was less than one-seventh of the wavelength of the Lamb wave to ensure sensitivity. They also carried out double-lap joint-type composite coupon tests with the proposed method to demonstrate the damage detection capability.

4 ACTIVE HYBRID PIEZOELECTRIC/FIBER-OPTIC SHM SYSTEM

To take the advantages of both PZT and fiber-optic sensor, an active hybrid piezoelectric/fiber-optic SHM system has been developed recently [13]. With this system, the emerging concept of SHM can become a commercially viable option in structural engineering, allowing a new generation of safer, more reliable, and lower maintenance structures. As shown in Figure 2, the developed structural diagnostic system can permit quantitative characterization and event determination pertaining to aerospace and civil structures in hostile service environments. More specifically, the hybrid system can potentially be used to perform:

- *in situ* material property characterization;
- detect material and structural defects;
- detect damage including delaminations and corrosion; and
- characterize load environments (fatigue, overload).

4.1 Principle of the PZT/FBG hybrid active structural health monitoring system

The hybrid diagnostic system uses piezoelectric actuators to input a controlled excitation to the structure and fiber-optic sensors to capture the corresponding structural response. The system consists of three major parts: a diagnostic layer with a network of piezoelectric elements and fiber gratings to offer a simple and efficient way to integrate a large network of transducers onto a structure; diagnostic hardware consisting of an arbitrary waveform generator and a high-speed fiber grating demodulation unit together with a high-speed data-acquisition card to provide actuation input, data collection, and

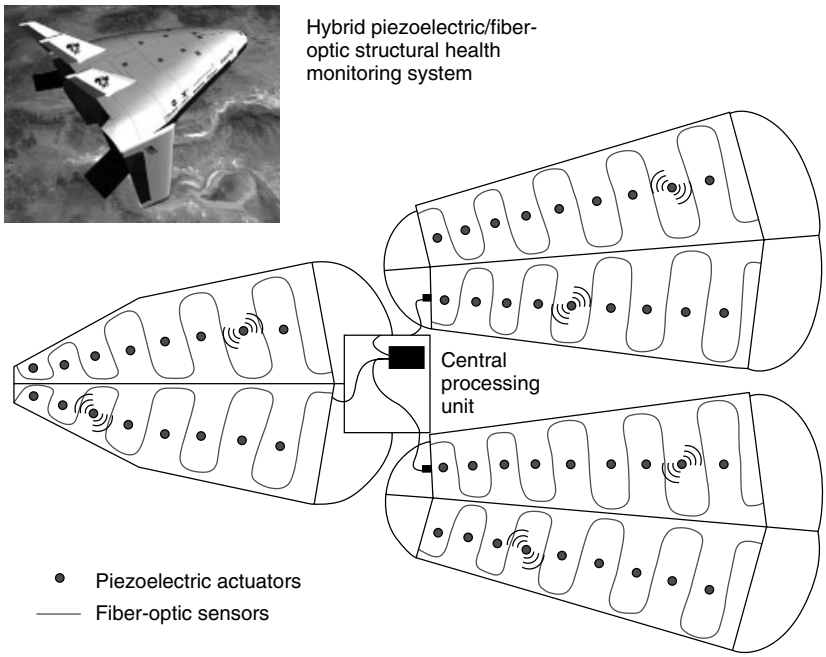

Figure 2. Schematic of a hybrid piezoelectric/fiber-optic structural health monitoring system for aerospace vehicles. [Reproduced from Ref. 13. © Institute of Physics Publishing, 2005.]

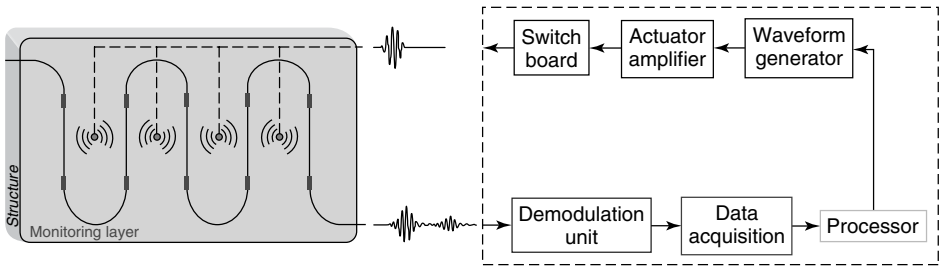

Figure 3. Piezoelectric/fiber-optic hybrid sensing system scheme. [Reproduced from Ref. 13. © Institute of Physics Publishing, 2005.]

information processing; and diagnostic software to determine the condition of the structure. Figure 3 shows a schematic diagram of this system.

One major advantage of the hybrid diagnostic system is that it offers the best actuator/sensor decoupling (minimum interference between actuation input signal and sensor output signal) because the transducers use different mechanisms for signal transmission: the piezoelectric actuators use electrical channels while the fiber-optic sensors use optical means. Since they use two separate mechanisms for transmitting signals, there is virtually no interference between them.

4.2 Hybrid piezoelectric/fiber-optic sensor sheets

Hybrid piezoelectric/fiber-optic (HyPFO) sensor sheets have been developed [13, 24]. The concept of a HyPFO sensor sheet is a generalization of the concept of a SMART layer [25], which is a device that comprises a thin dielectric film containing an embedded network of distributed piezoelectric actuator/sensors. Such a device can be mounted on the surface of a metallic structure or embedded inside a composite material structure during fabrication of the structure. Besides the piezoelectric

and fiber-optic sensors, other types of sensors, such as strain gauges, MEMS (microelectromechanical systems) and TRD (time-rate-of-decay) temperature sensors, can also be integrated in the sensor layer. The advantages of a hybrid sensor layer include the following:

- It is not necessary to install each sensor individually on a structure. Sensors are embedded in thin, flexible films that can easily be mounted on structures in minimal amounts of installation time.
- Multiple measurements can be performed. For example, fiber-optic sensors can be used to measure temperatures, PZTs can be used to measure concentrations of hydrogen, and sensors of both types can be used to monitor acoustic emissions.

4.3 Demonstration of damage detectability of the system

In order to demonstrate the damage detection capability of the active hybrid diagnostic system, tests were conducted on both aluminum and fiber-reinforced composite plates.

4.3.1 Damage detection on an aluminum plate

Damage detection tests were performed on an aluminum plate with a dimension of $500 \times 500 \times 1.5\,\text{mm}^3$. Four PZT actuators, each having a diameter of 6.35 mm and thickness of 0.25 mm, and a single grating sensor were mounted on the top surface of the aluminum plate. The single FBG is written at the center wavelength of 1550 nm and has a gauge length of 10 mm. The layout of the PZT actuators and the FBG sensors is shown in Figure 4. In the tests, five-peak burst waveforms were used to excite the structure [26].

To demonstrate the ability of the hybrid PZT/FBG system to detect damage, a $50 \times 8 \times 2\,\text{mm}^3$ small stick-on patch was attached to the path between actuators and fiber grating sensors to simulate damage. Using the same five-peak burst waveforms as above, a series of tests with different frequencies of actuation signal were carried out. The sensor output was recorded and compared with the baseline taken before a stick-on patch was put on the aluminum plate. The typical test results are shown in Figure 5.

There are many modes of Lamb waves that can be actuated in a plate with a PZT. In our test, according to the product of frequency and thickness, only two kinds of modes were activated, i.e., A_0 and S_0. When

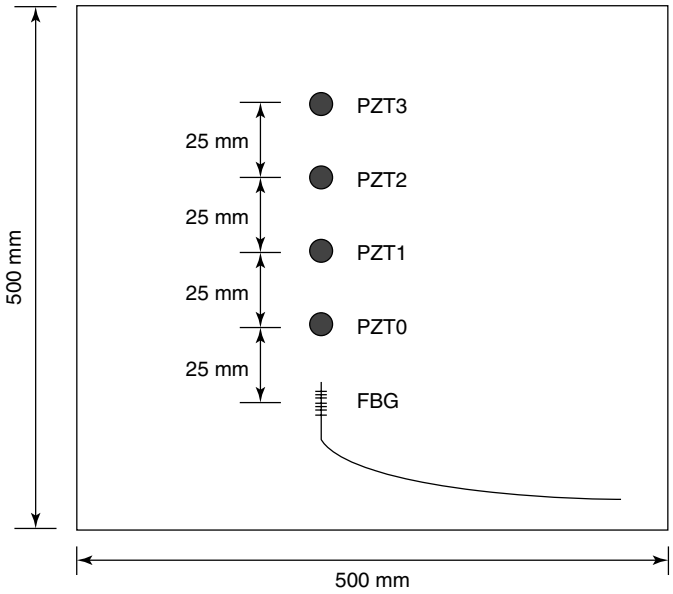

Figure 4. Layout of PZT actuators and the FBG sensor on the aluminum plate.

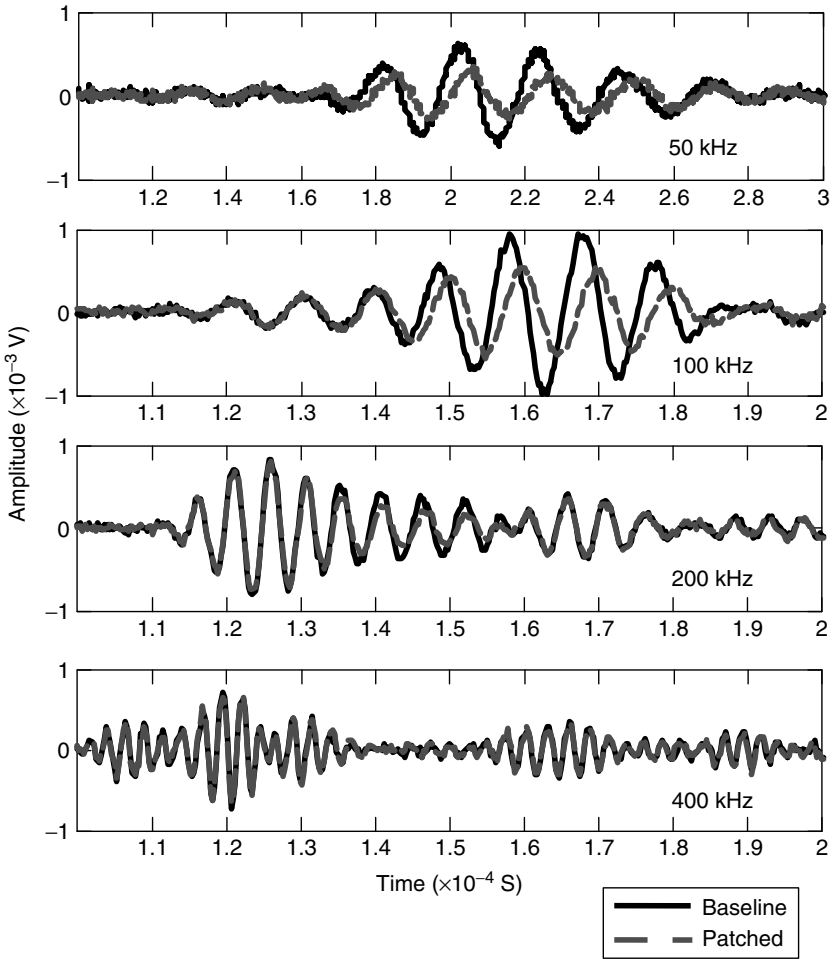

Figure 5. Damage detection test results from the aluminum plate.

the wavelengths are large in relation to the thickness of the plate, the fundamental symmetric mode and the fundamental antisymmetric mode are equivalent to the extensional and flexural waves, respectively.

The data presented in Figure 5 were signals actuated by PZT1 and collected by the FBG, the direction of which is parallel to the path of signal transmission. It was demonstrated that the signal amplitude is related to the distance and the cross angle between the signal transmission path and the FBG's direction [25]. From the signals we obtained, it can be seen that both A_0 and S_0 mode waves are detected. S_0 mode waves travel faster in this case, so they arrive first. When the center frequencies of the actuation signal are 50 and 100 kHz, respectively, S_0 mode waves carry less energy and are not significant. When the center frequency of the actuation signal is 200 kHz, S_0 mode waves and A_0 mode waves are both significant. We cannot see apparent changes in S_0 mode waves owing to the stick-on patch. However, we can see significant changes in both amplitude and phase in A_0 mode waves, which arrived later than S_0 mode waves. The results are consistent with established theories. The A_0 mode flexural waves show high sensitivity to weight added on their transmission path. The simulated damage was thus clearly identified. When the center frequency of actuation signal is 400 kHz, there are no A_0 mode waves showing up in the sensor signal, which is caused by the limitation of FBG sensors. When FBG sensors are utilized for stress

wave detection, they cannot pick up a clear signal when the wavelength of the stress wave in question is smaller than the gauge length of the FBG sensor. In the case of 400 kHz, the wavelength of the A_0 mode decreases to about 6 mm, which is less than the 10-mm gauge length of the FBG. As Minardo [16] has demonstrated, no A_0 mode stress wave could be detected. There are only S_0 mode signals detected in this case, which are extensional waves and not sensitive to weight added on its traveling path, and hence the signal after damage and baseline signal are almost identical.

4.3.2 A quasi-distributed damage-detection scheme for composite plates

A damage detection scheme for a composite plate was implemented using the hybrid PTZ/FBG active-sensing system. The configuration of the specimen tested is given in Figure 6. Two PZT actuators and three FBG sensors (engraved on the same optical fiber) were embedded in a Hybrid SMART layer [13], which was then bonded onto the composite plate.

A delamination damage was introduced by repeated impacts on the center of the zone covered by the sensor network. A pitch–catch test was then carried out with a five-peak wave actuation signal of 100 kHz. Typical signals are shown in Figure 7. It can be seen that there are significant changes in both the amplitude and phase of the detected signals due to the delamination damage. To locate and evaluate the extent of damage, a damage index can be employed. When multiple paths are affected by the damage area, which results in big damage indices for these paths, their effects add up to show a heightened intensity of colors. This display technique can be used as a fast imaging method to help visualize the approximate location and extent of damage [28], as shown in Figure 8.

The extent of delamination damage in the composite plate was examined by an ultrasonic scan. The results clearly showed that severe damage was inflicted on the center area of the zone. The damage detected with the hybrid system is consistent with the result of the ultrasonic scan and X-ray image of the impact damage. In summary, it has been demonstrated that debond in composite structures can be conveniently identified by the proposed hybrid PZT/FBG active-sensing scheme [26].

4.4 Potential application for monitoring a large area

As described in [29], there is a major challenge in the networking of a multitude of piezoelectric sensors applied to physically large structures because of a large number of connection wires and big signal noise from long-distance communication. The hybrid system could be a potential solution for the applications of SHM on large structures, such as the health monitoring of bridge and long pipeline structures [27].

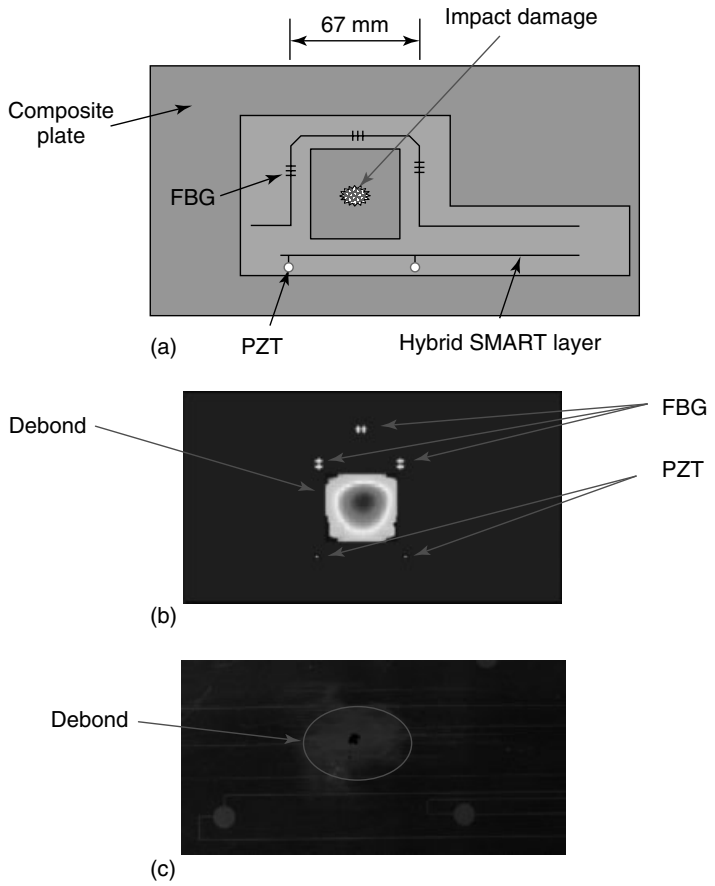

Figure 8. Hybrid sensor network used for damage detection. (a) Hybrid layer mounted on the surface of a composite plate, (b) diagnostic image of impact damage on the composite plate, and (c) X-ray image of the damage on the composite plate.

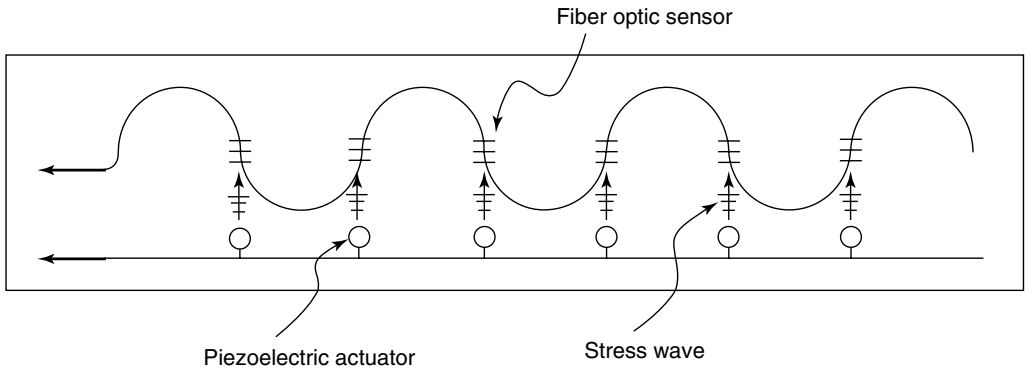

Figure 9. A typical design of hybrid piezoelectric/fiber-optic sensor network. [Reproduced with permission from Ref. 27. © 2006, Qing *et al.*]

Figure 9 shows a typical design of hybrid piezoelectric/fiber-optic sensor network used in the SHM system. In the network, all piezoelectric actuators are connected to a diagnostic instrument through a shielded cable. The distributed FBGs are used as sensors. The piezoelectric actuators can be simply connected together in series or in parallel, and then they generate stress waves in the structure simultaneously. By using a set of control wires, each piezoelectric actuator can also be used to generate stress wave in the structure individually. The smart cable with piezoelectric actuators and the optic fiber with distributed gratings can be placed on a thin carrier film, and then will be permanently bonded on the composite or metal structure to be monitored. The changes caused from the degradation of material properties (or corrosion) around all diagnostic paths will be identified. The design is particularly good for global damage monitoring of large composite or metal structures, such as fuel storage tanks for space ships, bridges with composite repairs, and metal pipelines. The advantages of this design include the following: (i) simpler wiring; (ii) long-distance sensor signal transmission; and (iii) capability to detect ultrasonic stress waves, quasi-static strain, and impacts. With all those features, an ideal health management solution based on hybrid FBG/PZT network can be offered by monitoring multiple physical parameters using the same system. At first, strain, temperature, and impact can be monitored continuously using FBG sensors, which can provide environment loading information and is critical to structural heath assessment. Then, when there is any abnormal sign, such as high stress or impact at certain locations, the active system can be triggered to send out diagnostic signals using the PZT actuators to detect whether any damage occurred.

5 CONCLUDING REMARKS

In order to resolve some issues in the piezoelectric sensor–based SHM system, such as coupling between sensors and actuators and long-distance signal transmission for large structure applications, extensive research on the development of hybrid piezoelectric/fiber-optic diagnostic systems has been conducted. A general review of the efforts made is presented in the article. An integrated hybrid active system and its application approach are also introduced, and damage detection capability with the system is demonstrated. One of the key issues for the hybrid PZT/FBG systems is the interrogation technique for FBG sensors, which dominates the sensitivity and dynamic range of the system. Besides, the fabrication technology of FBG sensors also needs to be improved to achieve high sensitivity for ultrasonic stress wave, which requires smaller grating length compared to quasi-static strain measurement.

1 INTRODUCTION

The concept of developing completely self-power electronics has received significant interest over the past decade partially fueled by the recent advances in wireless and structural health monitoring (SHM) technology [1]. As described in earlier articles, SHM is an integrated process of data acquisition, signal processing, and statistical inference used to track and assure the safety and performance of a structure. SHM has immediate benefits and market potential. However, because of the need for a widely dispersed sensor network to effectively monitor large civil structures and the need to dispense with increasing wiring harnesses in vehicle applications, it has been realized that wireless SHM sensors should be used to reduce the system complexity (*see* **Wireless Sensor Network Platforms**). However, when using wireless sensors it is necessary that a portable power supply be used, such as batteries. Because batteries must be periodically replaced, the use of batteries to power wireless sensors greatly restricts sensor placement and location. For instance, it is often necessary to embed the sensor in the structure to achieve the desired response or to be close to areas of high damage probability. By implementing methods of obtaining ambient energy from the sensors surroundings, a wireless device could be designed to function indefinitely. Additionally, one major use of SHM systems would be to quickly inspect civil structures or military vehicles after catastrophic events, which typically cause widespread power outages thus making the use of wired power sources impossible.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

The recent advances in low power electronics and wireless technology have made the hardware necessary to perform the required tasks available, but an effective power source has yet to be identified. Therefore, the development of wireless SHM systems revolves around the ability to capture ambient energy surrounding the device and convert it into usable electrical power. In many studies, piezoelectric materials have been utilized to capture the ambient vibrations around a system and convert them into electrical power [2] (*see* **On the Way to Autonomy: the Wireless-interrogated and Self-powered "Smart Patch" System**). However, the energy generated by piezoelectric materials is typically far too small to directly power most electronic devices. The issue of too little energy can be compensated for by using energy storage methods to accumulate sufficient energy to power the electronics in short bursts. A second and more developed method of obtaining energy from ambient sources is through the use of thermoelectric generators (TEGs), which capitalize on thermal gradients. TEGs use the Seebeck effect [3], which describes the current generated when the junction of two dissimilar metals/semiconductors experiences a temperature difference. Using this idea, numerous *p*-type and *n*-type junctions are arranged electrically in series and thermally in parallel to construct the TEG. Thus, if a thermal gradient is applied to the device, it will generate an electrical current that can be utilized to power other electronics. By implementing power harvesting devices, autonomous portable systems can be developed that do not depend on traditional methods for providing power, such as the battery, which has a limited operating life.

TEGs are an established technology and have been used for capturing ambient energy in various applications. Lawrence and Snyder [4] suggest a potential method of retrieving electric energy from the temperature difference that exists between the soil and the air. To test their concept, a prototype was built without the TEG and the heat flow was measured to estimate the amount of power that could be obtained. The results showed that a maximum instantaneous power of approximately 0.4 mW could be generated by the thermoelectric device. Rowe *et al.* [5] investigate the ability to construct a large TEG capable of supplying 100 W of power from hot waste water. The system tested used numerous thermoelectric devices placed between two cambers, one with flowing hot water and the other with cold water flowing in the opposite direction thus maximizing the heat exchange. With a total of 36 modules, each with 31 thermocouples, 95 W of power could be generated. Fleming *et al.* [6] investigated the use of TEG to provide electrical power in micro air vehicles. A TEG was mounted on the exhaust system of an OS max 61 internal combustion engine and was shown to generate 380 mW of power.

Several authors have studied the use of TEGs for obtaining waste energy from the exhaust of automobiles. Birckolz *et al.* [7] worked with Porsche to develop a TEG unit that would fit around the exhaust pipe of the 944 engine. The unit was experimentally tested and found to generate an open circuit voltage of 22 V and a total power of 58 W. Similarly, Matsubara [8] constructed an exhaust system using ten TEG modules and a liquid heat exchanger to maximize the thermal gradient. The system was tested on a 2000-cc class automobile and shown to produce 266 W of power. Bass *et al.* [9] investigated the placement of a TEG in the vertical muffler of a class 8 diesel truck. The system generated 1 kW of power, thus allowing it to be employed as a substitute for the truck's alternator. By removing the alternator from the engine, the power delivered to the driveshaft was increased by 3–5 hp, providing an increase in fuel efficiency and a reduction in emissions. For more information on TEG applications in automobiles, see Vázquez *et al.* [10]. A review of previous research in TEGs shows that there are several key parameters that dictate the amount of energy generated; the most important of these are the surface area in contact with the thermal source, temperature gradient across the device, and the thermal conductivity between the TEG and the source.

The idea to use thermoelectric devices to capture ambient energy from a system is not new. However, TEGs have typically been used simply to determine the extent of power capable of being generated rather than investigating applications and uses of the energy. Furthermore, most previous research efforts have utilized liquid heat exchangers or forced convection to significantly improve heat flow and power generation, but require complex cooling loops and systems. These previous studies also commonly do not consider the amount of energy applied to the cooling system and therefore only report gross levels of power. In this article, the use of TEGs

as power harvesting devices that do not have an active heat exchanger, but function as a completely passive power scavenging system with SHM applications, is reviewed. The motivation for investigating a passive power generation device stems from the need to identify effective power sources for the development of self-powered wireless SHM systems. These systems could be placed in a desired location without regular replacement of batteries or maintenance, as most wireless devices currently do. Because of the remote placement of the TEG, it becomes impossible to incorporate active heat exchangers into the system.

When deploying a wireless SHM network, the sensors are placed in a variety of locations, some of which have ambient vibration and others that have ambient thermal gradients. Because the ambient source of energy may vary around the structure, it is important to have a variety of methods to capture the energy. In the case of vibrating structures such as a bridge or tall building, piezoelectric materials may form the ideal energy harvesting device, but if ambient vibration is not present, then alternative power generation devices must be studied. Here two potential locations for a wireless SHM system that does not have significant vibration are examined: first, those that are exposed to the sun but do not vibrate, such as a dam; and second, structures that are subjected to high temperatures, such as a boiler, rocket, or combustion engine. When performing SHM, it is typically not necessary to continuously check its integrity, but rather to perform an analysis once a day or perhaps a week. Therefore, the energy harvesting device should be able to store the energy until it is needed by the electronics. The ability to store the generated energy from piezoelectric materials in a rechargeable battery has been shown by Sodano *et al.* [11, 12]. Here two TEG systems are discussed in the context of using them to recharge a completely discharged nickel–metal hydride battery and the relative charge time will be compared with that of piezoelectric-based power harvesting systems.

2 BASIC THEORY

TEGs use the Seebeck effect, which describes the current generated when the junction of two dissimilar metals experiences a temperature difference. This effect is also responsible for the current generated by a thermocouple. Using this idea, numerous p-type and n-type semiconductor junctions are arranged electrically in series and thermally in parallel to construct the TEG. Thus, when an electrical current is applied to the TEG a thermal gradient is generated, allowing the device to function as a small solid state heat pump. Inversely, if a thermal gradient is applied to the device, it will generate an electrical current that can be utilized to power other electronics. The simplest model of TEG is

$$V = \alpha \Delta T \tag{1}$$

Here V is the voltage generated, ΔT is the temperature difference (gradient) across the TEG and the constant of proportionality α is called the *Seebeck coefficient*. Thus the basic TEG model produces a dc voltage proportional to the temperature difference across the device. If the TEG is connected to a load, then one simple model is to consider the TEG electrically as a voltage source with some internal resistance applied to some resistive load. This is illustrated in Figure 1. In the figure V_{TEG} is the voltage generated according to equation (1), R_{TEG} is the internal electrical resistance provided by the TEG material and R_{load} is the electrical resistance provided by an external load to the TEG. The load resistance is that of the electrical resistance associated with a direct use device or the resistance offered by a storage device (either a capacitor or battery). For the case when R_{load} is a battery or a capacitor being charged, a diode must be included in this circuit between the generator and the load to prevent a backflow of energy from the battery to the TEG when ambient energy is not being harvested. As a general rule, the power delivered is maximized when the load resistance or impedance is equal to the internal resistance of the TEG.

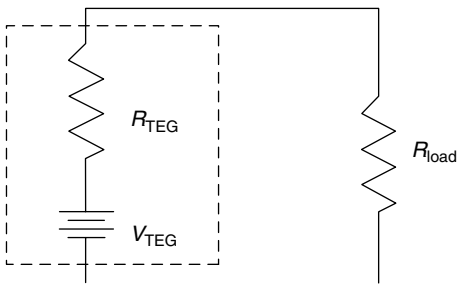

Figure 1. Simple electric circuit model of a TEG.

Practical TEG devices consist of many *pn* junctions connected electrically in series and thermally in parallel (so the same thermal gradient appears across each *pn* pair) as illustrated in Figure 2. If n is the number of such junctions, then the voltage can be modeled simply as

$$V = n\alpha\Delta T \tag{2}$$

Therefore, the voltage or power output is increased by increasing the number of junctions. Traditional thermoelectrics are built by physically assembling discrete blocks of n-doped or p-doped thermoelectric elements onto electrical circuits as illustrated in Figure 2. The circuits are typically on ceramic plates that have metal lines to route the electrical current. The thermoelectric elements are placed onto the ceramic plates using pick-and-place assembly equipment and attached to the metal lines on the ceramic plates using solder. On the basis of this method of manufacturing, the ability to scale the size of the thermoelectrics to smaller scales has been limited.

Scaling thermoelectric devices to a smaller size is desirable because the power density (watts per square centimeter that it can generate) is inversely proportional to the length (height in Figure 2) of the thermoelectric element. By scaling to smaller geometries, higher power densities can be achieved, leading to a more efficient device. This advantage has spawned a rapid growth of research into microelectromechanical system (MEMS) thermoelectric devices constructed using thin-film technology. Thin-film thermoelectric materials can be grown by conventional semiconductor deposition methods, and devices can be fabricated using conventional semiconductor microfabrication techniques. The resulting TEG devices can be produced in large quantities with small dimensions, allowing them to be easily integrated into the SHM sensing platform.

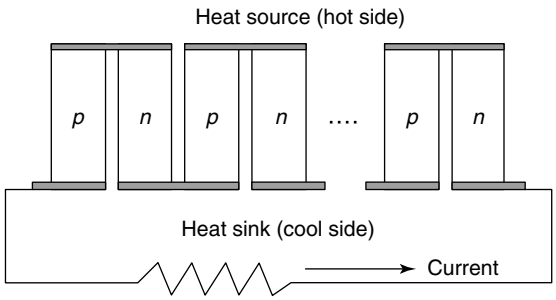

Figure 2. Arrangement of a thermal electric generator device.

3 EXAMPLES

Two thermoelectric systems will be presented here to determine their ability to convert solar energy and waste heat into electrical energy and its storage in a conventional rechargeable battery. The results will be compared with energy harvesting using photovoltaic materials (solar cells). The first system developed used solar radiation to heat one side of the TEG, while the cold side was bonded to a metallic structure that functioned as a heat sink with a large thermal mass or capacity. Because direct solar energy was not sufficient to heat the hot side of the TEG, the idea of a "greenhouse" was combined with a solar concentrator to elevate the temperature. A greenhouse functions by allowing visible light emitted by the sun to pass through the transparent surface, thus heating the objects inside and converting the visible light into thermal infrared waves that cannot penetrate the surrounding medium to exit, causing the heat to build up. Because dark objects do not reflect much visible light, but rather convert almost all of it into thermal energy, a blackbody heat sink was placed inside the container to increase the thermal energy stored. To further increase the amount of thermal energy applied to the hot side of the heat sink a solar concentrator was used. A solar concentrator focuses a large area of sunlight onto a smaller area, thus increasing the thermal energy stored in the greenhouse. A schematic describing the layout of the system is shown in Figure 3. This system does not preclude the use of a solar cell, but could be applied with one to capitalize on both the incident light as well as the thermal energy released.

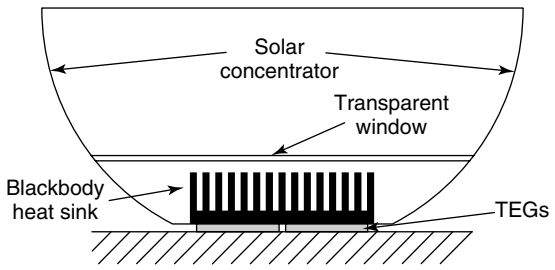

Figure 3. Schematic of solar harvesting device.

The second method of capturing ambient energy was from waste heat that would be available from combustion engines, boilers, or furnaces. To simulate the energy available in these locations, a hot plate was used. A heat sink was attached to the hot plate to allow more energy to be removed from the cold side of the TEG and facilitate a larger power output. To investigate completely passive power harvesting methods, the systems did not include a means of providing forced convection, which would greatly increase the energy produced by the TEG, but would require additional energy for the active cooling systems.

4 EXPERIMENTAL TESTING

A prototype of each power harvesting system was constructed and experimentally tested to identify their ability to capture thermal energy, convert it to electrical power and then use the electrical output to charge a discharged nickel–metal hydride battery. Both systems used eight Melcor thermoelectric coolers (model HT-4-30) to generate the electrical signal. The physical properties of this device are shown in Table 1. The first system used solar energy to develop a thermal gradient over the TEG. To increase the amount of solar energy applied to the power harvesting device, an aluminum parabolic solar concentrator was used to reflect the visible light onto a black body aluminum heat sink ($7.62 \times 7.62 \times 3.175$ cm). The heat sink was painted flat black to allow more of the visible light to be converted into thermal energy. Above the heat sink was a Plexiglas window that trapped the thermal energy, thus allowing it to accumulate and increase the thermal gradient over the TEG. The solar concentrator, heat sink, and TEGs were bonded to a steel plate, which acted as the host structure; this setup is shown in Figure 4.

Table 1. Dimensions and electrical properties of the TEG

Property	Value
Dimensions ($w \times l \times h$)	30 mm × 34 mm × 3.2 mm
Maximum temperature difference	77 °C
Number of thermocouple junctions	127
Device resistance	3.78 Ω
Resistivity	1.37 Ω cm^{-1}

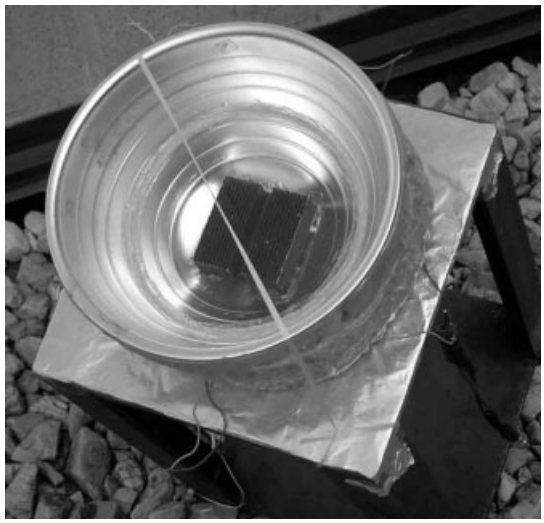

Figure 4. Experimental setup of the solar harvesting system.

The second source of ambient thermal energy tested here is simply a structure with an elevated temperature available from aircraft engines, Heating Ventilation and Air Conditioning (HVAC) systems, boilers, or furnaces. To simulate the energy available in these locations, a hot plate was used. Because the purpose of this study is to investigate completely passive power harvesting methods, the systems did not include a means of providing forced convection, which would greatly increase the energy produced by the TEG, but would require additional energy for the active cooling systems. A prototype of the power harvesting system was constructed and experimentally tested to identify its ability to capture thermal energy, convert it to electrical power, and then use the electrical output to charge a discharged nickel–metal hydride battery. The setup used eight Melcor thermoelectric coolers (model HT-4-30) to generate the electrical signal. To simulate this environment, the TEGs were fixed between a heat sink and a thin aluminum plate, which was then attached to a hot plate using thermal grease. The experimental setup is shown in Figure 5. To monitor the temperature of the hot and cold sides of the TEG, Omega CO-1 thermocouples were used. Because the thermocouple was only 0.13-mm thick, it could be bonded to the hot and cold sides of the TEG.

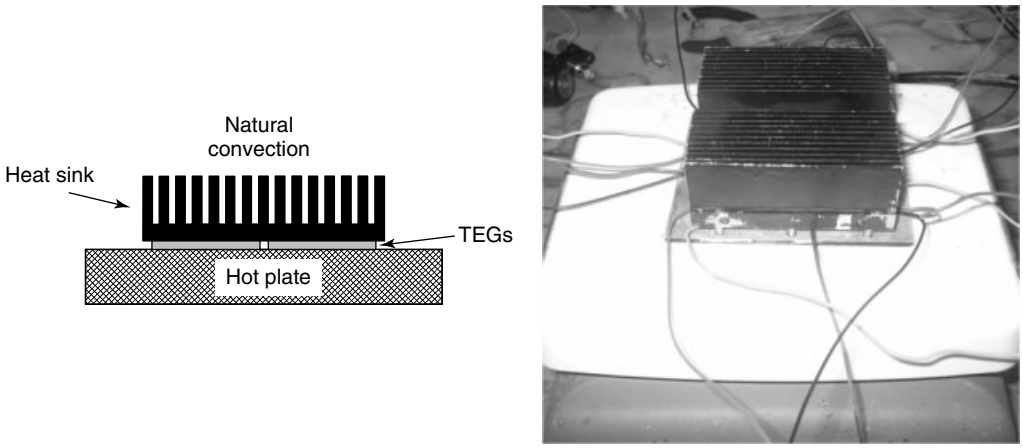

Figure 5. Experimental setup of the energy harvesting system.

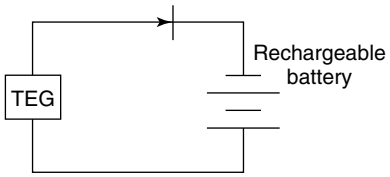

Figure 6. Diagram of circuit used to recharge batteries.

When an SHM system is applied, it is often only necessary that the integrity of that structure is not monitored continuously, but rather only periodically—every day, week, or even month. Continuous testing is not necessary because in many cases, damage will occur over an extended period of time from aging or fatigue. If the SHM system operates only for a small percentage of the time, the energy generated by the power harvesting system must be stored until needed by the electronics. The storage of the electricity is also necessary to ensure that when the electronics are switched on, sufficient power is available. Typically, if energy is to be stored for an extended period of time, it is more effective to use a rechargeable battery. Therefore, a simple circuit can be been constructed to take the electrical energy generated by the two power harvesting devices and store it in a nickel–metal hydride battery. The circuit used in this study is shown in Figure 6. The diode is a necessary piece of this circuit because it forces current to only flow in one direction. If the diode is not present, the TEG would draw power form the battery during times when the voltage generated was less than the voltage of the battery or if the thermal gradient is reversed. Because the output of the TEG is a dc signal, it does not require a means of rectifying, which is a source of energy loss in piezoelectric power harvesting.

5 RESULTS

To experimentally illustrate the power generated by the TEG, it is placed on a hot plate, thus allowing the applied temperature to be accurately monitored. For the system of eight TEGs electrically in series used in this power harvesting device, the Seebeck coefficient is not defined and therefore was fit using experimental data and equation (2). To determine this coefficient, the voltage output of the TEG was measured as the temperature of the hot plate was varied for two different configurations of the TEG modules. A schematic of the different TEG configurations is provided in Figure 7. The resulting voltage output for each configuration and the linear fits for each case are shown in Figure 8. From this figure, it can be see that the Seebeck coefficient for the two different configurations varies. The change in the Seebeck coefficient occurs because the stacking of the TEG modules causes variation in the thermal gradient over each module and in the heat sink's ability to remove energy from the cold side due to a change in surface area in contact with the thermal source. The effect of the configuration on the heat sink's performance can be

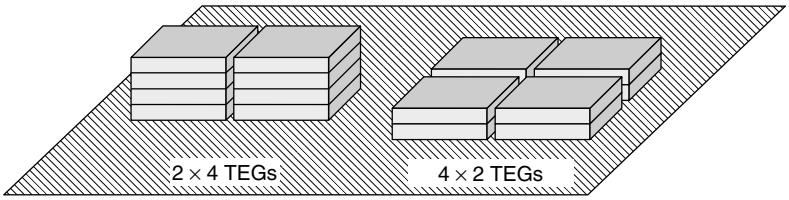

Figure 7. Three different configurations of the TEGs with the hot plate, the footprint is 20.4 cm^2 with two TEGs and 40.8 cm^2 with four TEGs.

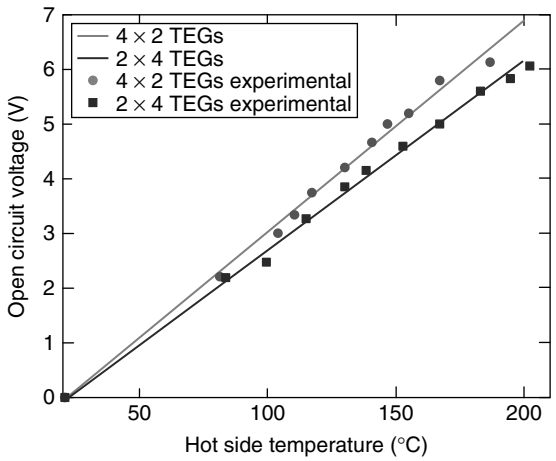

Figure 8. Output voltage of the thermoelectric generator as a function of the hot side temperature.

illustrated by the air temperature around the heat sink. When the heat sink is close to the hot plate, the temperature of the air surrounding it is higher and thus reduces the total thermal difference between the hot and cold sides. However, if too many TEGs are stacked, the gradient between the hot plate and heat sink is divided over each TEG and a large portion of energy is allowed to be transmitted from the sides of the stack, thus reducing the overall power output. The resulting Seebeck coefficient of the configuration using two layers of four TEGs and four layers of two TEGs are 2.96×10^{-4} and 2.68×10^{-4} V K^{-1} respectively.

The current output for each of these systems can now be found using the following relationship [12]:

$$I = \frac{G\alpha D_T}{2\rho} \tag{3}$$

where I is the current output, G is the area per unit length of the thermoelectric element, and ρ is the resistivity. Now the power generated by each system can easily be determined by equating the power output of the energy harvesting system to the product of the output voltage and current. The results show that the power harvesting module does indeed vary linearly and the thermal gradient or number of modules necessary to generate a particular amount of power for an electronic device can be easily determined. Furthermore, the amount of power that can be generated from TEGs when placed on a 200 °C surface can be as high as 40 mW without any form of convective heat transfer, as shown in Figure 9. As a comparison, when a piezoelectric device subjected to the level of vibration typically found in an automobile engine, it can only generate a maximum of 2 mW [10]. This point illustrates the substantial difference in the power available from TEGs and the idea that more powerful electronics can be powered when using them.

After the amount of power generated by the TEG for various hot side temperatures had been quantified, the ability of each device to recharge a nickel–metal

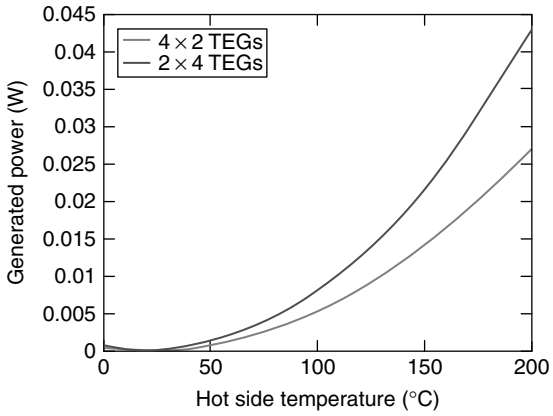

Figure 9. Power generated by the thermal harvesting system as a function of the hot side temperature.

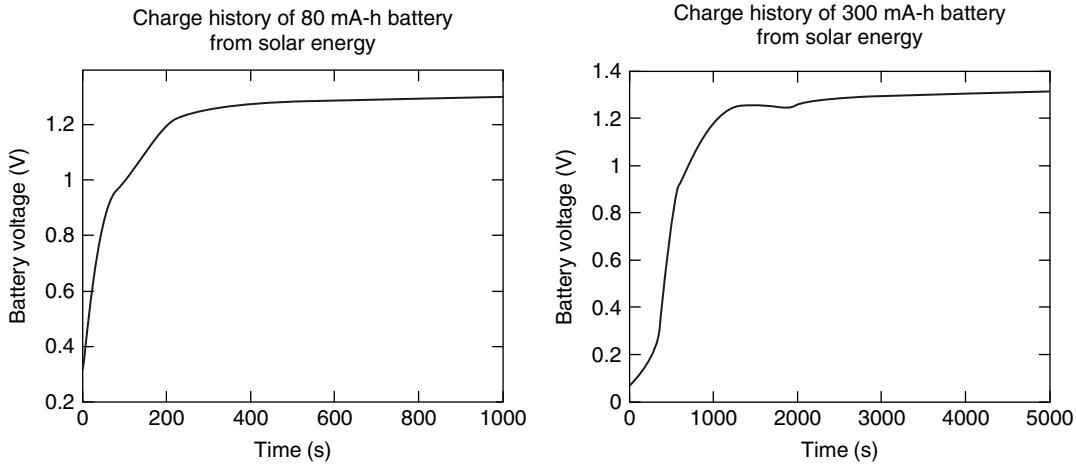

Figure 10. Charge histories of rechargeable batteries from solar harvesting system for an 80 mA·h battery and a 300 mA·h battery.

hydride battery was determined. The circuit layout shown in Figure 6 was used to collect the electrical output of the TEG and store it in the rechargeable battery. For this study, an 80 and a 300 mA·h battery were tested with the solar harvesting system and only a 300 mA·h battery was tested for the waste heat device. (The unit milliampere-hour "mA·h" indicates the capacity of a battery: an 80 mA·h capacity implies the battery will last for 1 h if subjected to 80-mA discharge current.) An 80 mA·h battery is roughly the size of a watch battery and a 300 mA·h battery is slightly less than half the size of a typical AAA battery.

First, the solar harvesting device was investigated by placing the system in direct sunlight with an ambient temperature of 29.4 °C. Both batteries were charged on the same day with relatively short time between each test, therefore limiting the variation between tests. The hot side temperature of the solar harvesting device was measured to be approximately 52.8 °C. The resulting charge times for both batteries are shown in Figure 10. From these figures it is apparent that the TEG system developed in this study can effectively harvest solar radiation and use that energy to quickly recharge a discharged battery. Next, the waste heat system was tested and the resulting charge time is shown in Figure 11. Once again, it is clear that the TEG is very capable of storing converted energy in a battery.

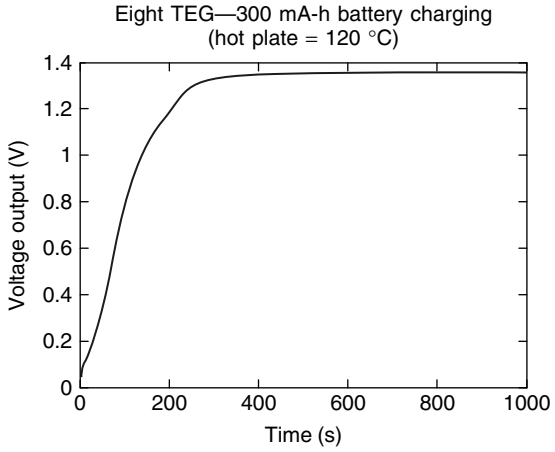

Figure 11. Charge history of a 300 mA·h nickel–metal hydride battery from waste heat harvesting system.

6 COMPARISON OF HARVESTING TECHNOLOGIES

After identifying the ability to use a TEG for the purpose of recharging small batteries, the results were compared with those found using piezoelectric materials by Sodano *et al.* [11]. The time required for each system to charge the battery to a cell voltage of 1.2 V was the measure in each case and the results are provided in Table 2. The charge time listed for the TEG devices are from Figures 10 and 11,

Table 2. Time needed to achieve the battery's cell voltage by a TEG with solar energy and waste heat, and for a piezoelectric material experiencing random vibration [11]

Capacity of the battery (mA·h)	Charge time from solar energy (min)	Charge time from waste heat (min)	Charge time from vibration using piezoelectric materials (h)
80	3.3	NA	2
300	17.3	3.5	5.8

NA, Not Available

while the charge time for the piezoelectric system are for a PZT patch excited at an amplitude and random frequency measured from a typical automobile [11]. The results from charging a battery using piezoelectric materials are only provided to give an idea of the results from previous studies performed under realistic conditions and do not represent that a TEG will always outperform piezoelectric materials. (Note: this comparison is not intended to imply that piezoelectric materials are less effective or efficient than a TEG and these tests were performed on two very different systems.) The charge times in Table 2 may seem to be lower than possible; the time listed is simply to achieve the battery's cell voltage and not a full charge. The time needed to take the battery up to capacity would be longer, however, the times listed for both the piezoelectric and the TEGs both represent the time required to reach the cell voltage from a fully discharged state. To determine the time needed to provide a complete charge to the battery, a charge controller would be needed. The TEG is capable of quick recharge times because of its large current output, whereas the piezoelectric material supplies a very high voltage at a low current. To give an idea of the difference in these two devices, the impedance of one TEG is approximately 3 Ω while that of the piezoelectric device is approximately 10 000 Ω. Owing to the lower impedance of the TEG, eight modules had to be connected electrically in series to boost the output voltage to the required 1.2 V of the battery; however, this lower impedance also makes the TEG far more suited for use with rechargeable batteries, which charge faster with larger currents.

7 CONCLUSIONS

The usefulness of wireless SHM systems is established in many articles in this encyclopedia. Energy harvesting is an enabling technology for SHM. The long term goal of many SHM systems is to develop a completely self-powered electronic module that may be placed in a remote location without the concern of replacing the power supply. Generating energy from ambient sources using piezoelectric materials to harvest the vibration energy surrounding a system is one approach. For those cases where the structure in question does not experience sufficient vibration to generate the power levels needed to sustain the operation of the electronics, thermoelectric harvesting may be appropriate. This article has focused on using TEGs to generate an electrical signal from ambient thermal gradients. Two potential examples of this technology are presented: harvesting of solar radiation and harvesting of waste heat. For each application, an experimental prototype was constructed and tested to determine the effectiveness in recharging a discharged nickel–metal hydride battery.

Each application of the thermal generator was implemented such that only conductive heat transfer was present. Most of the previous studies have utilized an active heat exchanger to increase the energy output. However, the use of active convection causes the net power output to be reduced due to the energy applied to the heat exchanger. Therefore, this article has focused on demonstrating that with fairly small thermal gradients and only conductive heat transfer the thermal electric generator can form an effective power harvesting source. The results indicate that TEG does produce significantly more power than a piezoelectric device and that the time needed to recharge a battery is significantly lower. Thus in applications where thermal gradients are present, TEGs make a suitable choice for powering SHM applications [12].

Chapter 85
Loads Monitoring in Aerospace Structures

Steve Reed
QinetiQ, Farnborough, UK

1 INTRODUCTION

The aim of this article is to describe the philosophy behind operational loads monitoring (OLM) in aerospace structures, within the context of in-service structural health monitoring (SHM). In-service OLM or measurement can be defined as *a structural usage substantiation activity*. This activity involves the capture, analysis, and reporting of representative, directly measured strain data or derived loads and associated flight parameters from a sample of suitably instrumented in-service air vehicles within a fleet. Within this article, the principle aims of loads monitoring programs are described. Thereafter, the basic approaches taken and the use of data captured within these programs are outlined. Readers are referred to **Operational Loads Sensors**; **Nondestructive Evaluation/Nondestructive Testing/Nondestructive Inspection (NDE/NDT/NDI) Sensors—Eddy Current, Ultrasonic, and Acoustic Emission Sensors**; **Eddy-current *in situ* Sensors for SHM**; **Fiber-optic Sensor Principles**; and **Directed Energy Sensors/Actuators** for further information on sensor technologies. Furthermore, although military usage papers dominate the loads monitoring literature (*see* **Fatigue Monitoring in Military Fixed-wing Aircraft**; **Agile Military Aircraft**; **Flight Demonstration of a SHM System on a USAF Fighter Airplane**; **Operational Loads Monitoring in Military Transport Aircraft and Military Derivatives of Civil Aircraft**; **Health and Usage Monitoring Systems (HUM Systems) for Helicopters: Architecture and Performance**; and **Aerospace Applications of SMART Layer Technology**), there is a growing realization of the importance of such programs in the civil arena and this is reflected in **Commercial Fixed-wing Aircraft**; **History of SHM for Commercial Transport Aircraft**; **Video Landing Parameter Surveys**; and **Landing Gear**.

OLM is related to flight loads measurement (FLM) or flight loads survey (FLS) activity; however, these are distinct activities with differing aims. FLM or FLS programs are primarily associated with the substantiation of loads models where instrumented aircraft

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

are flown to particular points in the flight envelope, whereas OLM is concerned with substantiating the usage of the aircraft in service.

2 AIMS OF LOADS MONITORING PROGRAMS

The aims of the loads monitoring program dictate the measurands, conduct, and output from the program. An illustration of the most common aims is provided in Figure 1.

2.1 Substantiation of design and qualification fatigue usage spectra

During the design of an aircraft a great many assumptions about the usage of the aircraft. These assumptions are drawn from a variety of sources including data from previous aircraft types in similar roles with adjustments made for changes in capability and data from operators specifying intended usage, role, and stores carriage for the new type. Nowadays, a large proportion of major military aircraft programs are multinational projects for which design and qualification spectra are generally developed from a combination of intended usages. Furthermore, in response to rapidly changing military threats, it is highly unlikely that an aircraft will be used solely within its originally intended role throughout its life.

The fatigue spectra derived from these assumptions and used in the design and qualification of the aircraft cover a wide range of loading actions including maneuver-driven symmetric and asymmetric aerodynamic and inertia loads, gust loading, buffet loads, landing impact loads, ground handling loads, thermal loading, and engine thrust or propeller torque loading.

The increased use by the military of modified civil aircraft adds further issues to consider. Usage in a military environment may be considerably different to that assumed in civil design. Also, the modifications made to the aircraft (e.g., conversion from a passenger aircraft to an air-to-air tanker or refueling aircraft; *see* **Operational Loads Monitoring in Military Transport Aircraft and Military Derivatives of Civil Aircraft**) may introduce significant changes in local loads within the structure and an associated change in the usage of the aircraft in service.

Therefore, one of the essential initial elements of the loads monitoring program is to capture the

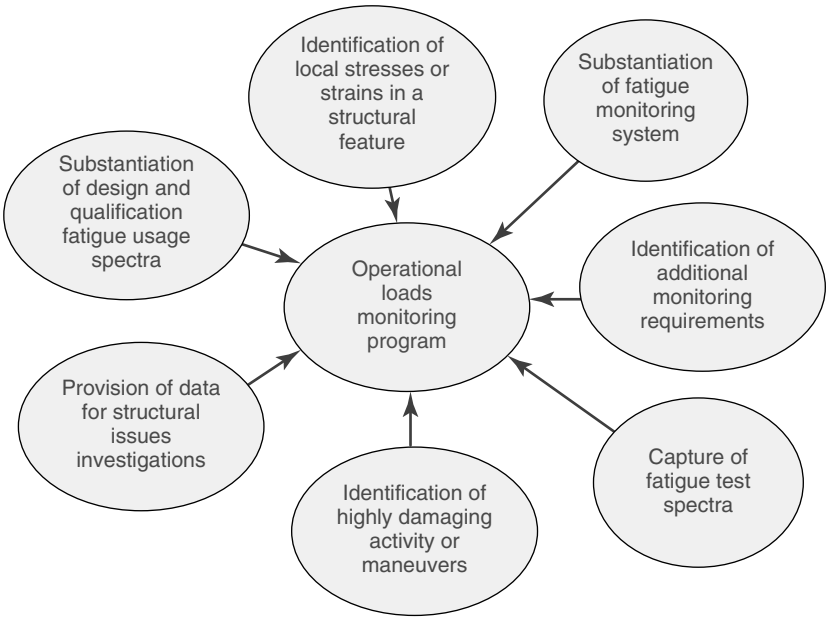

Figure 1. Aims of loads monitoring program.

fatigue design and qualification spectra and identify appropriate methods of assessing these spectra against in-service usage [1]. Thereafter, it is necessary to identify which of these spectra can be substantiated by the loads monitoring program and how this will be done. Direct measurement of loads or strains using electrical resistance strain gauges [2, 3] has generally been the preferred method of substantiating fatigue spectra. However, there are circumstances where measuring strains may not be practicable and substantiation of spectra using parametric methods or a combination of strain and parametric data may be required.

From a safety perspective, it is essential that any usage spectra more severe than assumed in design are identified and remedial action put in place. Secondly, usage more benign than assumed has the potential for life extension or to accommodate increases in usage severity in the future.

2.2 Identification of local stresses or strains in a structural feature

OLM may also be required to determine the local stresses or strains in a structural feature from overall forces and moments, often in association with finite element or boundary element modeling. This scenario might occur when a feature cannot be exercised adequately on a fatigue test and hence comparison with test loading would not be appropriate.

2.3 Substantiation of fatigue monitoring system

The usage of all aircraft is tracked in some way (*see* **Usage Management of Military Aircraft Structures**). This ranges from counting flight cycles or flying hours to full aircraft monitoring using strain-gauge fits installed on every aircraft in a fleet. All of these tracking methods contain usage assumptions and even the most sophisticated SHM systems cannot measure usage in all structural components of the aircraft directly and hence assumptions have to be made. Although OLM substantiation of a structural monitor can expose lack of understanding of the loading actions, generally it is the usage assumptions that prove to be in greater error.

2.4 Identification of additional monitoring requirements

A prime function of the loads monitoring program is often to identify the need for any additional monitoring requirements where there are insufficient margins of safety or unacceptable levels of risk, using the initial tracking measurands. Where the tracking of these unmonitored structural components, using these simple measurands, such as flight cycles, does not correlate sufficiently with fatigue damage accrual or where there is insufficient margin of safety, then additional monitoring options may need to be considered.

Novel aircraft types where there are no historical data (such as unmanned air vehicles (UAV)) are likely to have a significant level of uncertainty in their design usage data. Also, projects that use civil-designed aircraft in military roles are most likely to face uncertainty in usage or deviation in usage from that assumed in design. Challenging fatigue-life requirements or targets, limited fatigue testing, and an aim to reduce inspection burdens may drive the designer to consider additional monitoring to invoke the reduced safety factors associated with monitored structure. In these cases, OLM data can be used to support monitor development.

2.5 Capture of fatigue test spectra

One of the aims of an OLM program can be the generation of fatigue test spectra and additional data to validate these spectra (e.g., detailed stresses, accelerations, and pressurization cycles). Where this is a requirement, this will become a significant design driver for the OLM program and will necessitate a Skopinski-type [4] calibration in a loads rig (discussed later). Such calibration allows the OLM data to be described in global loading terms of shear, bending moment, and torque for fatigue test load spectra generation.

2.6 Identification of highly damaging activity or maneuvers

Identification of highly damaging activities or maneuvers is a key aim. Comparisons between maximum and minimum load/stress or strain conditions should

be made with limit-load and maximum fatigue allowable conditions. If such risks are identified, then either additional evidence should be required to support an increase in the loads envelope or appropriate limitations may need to be introduced into the operational release for the aircraft.

Secondly, the aim is to identify the structural cost, in fatigue damage terms, of activities or maneuvers. This information can then be used by operators to make informed decisions as to the need to undertake these maneuvers. These data can also be used to assist in the education of aircrews in methods of reducing fatigue consumption without significantly affecting mission capability.

2.7 Provision of data for structural issues investigations

OLM programs have frequently been used to provide data to support structural investigations and to exploit potential fleet life extension. In reality, structural issues or exploitation of life extension potential have often been the catalyst needed to initiate an OLM program for a fleet.

3 OLM MEASUREMENT SYSTEM DESIGN

3.1 Review of flight loads measurement and previous OLM installations

The OLM measurement requirements should be driven by the program aims. As previously discussed, OLM is, to a certain extent, a natural progression from FLM or FLS. Generally, FLM instrumentation will be far more extensive than can be justified for an OLM program and FLM installations are often not sufficiently robust to be used in-service. However, FLM experience should be invaluable in establishing the most suitable elements of the instrumentation, strain range, and sample rate data for inclusion in the OLM fit and the FLM data should be reviewed with this aim in mind.

3.2 Strain-gauge installations

Although electrical resistance strain gauges have been in use for over 50 years [2, 3], they are still the mainstay of instrumentation used in OLM data capture. Fiber-optic strain sensors (*see* **Fiber-optic Sensor Principles**; **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**; **Fiber Bragg Grating Sensors**; **Novel Fiber-optic Sensors**; and **Reliable Use of Fiber-optic Sensors**) have made inroads into civil and marine application and aerospace technology demonstrators (*see* **The Character of SHM in Civil Engineering**; **Monitoring Marine Structures**), and it is highly likely that these systems will be used for in-service aerospace applications in the near future [5]. Electrical resistance strain gauges rely upon the Wheatstone bridge principle, whereby a strain change in the structure to which the measuring arms of the bridge are attached causes an imbalance of resistance across the bridge and generate an output voltage. This voltage is measured, conditioned, and converted to a measure of the strain/stress/load in the structure, using appropriate calibration equations (discussed later). Strain-gauge bridges can be arranged in several different configurations, such as a 1/4 bridge, a 1/2 bridge, a full bridge or rosette depending on the measurement requirement [6].

Where the aims of the program include fatigue spectra substantiation, strain gauges will have to be located and configured to meet this aim. For example, for direct comparison with a full-scale fatigue, the OLM installation would be a subset of the fatigue test strain-gauge fit based upon knowledge from analysis of the loads paths, strain responses, and constraint effects of the test article. If the test does not exercise a feature thoroughly, the probability of that feature failing at the end of test is extremely small. Hence, for unfailed features, when in-service data are captured and if the OLM spectra are more severe than the test spectra, low-fatigue lives will be identified and supplementary evidence will be required to support a fatigue-life clearance.

Also, although assessment in terms of fatigue damage (or crack growth rate) is the ultimate fatigue-life currency, this can often be quite a blunt tool. Damage comparison is only really valid when the stress or strain spectra are similar shapes. Therefore, if the strain range or spectrum shape seen on the fatigue test is highly dissimilar to that seen on the in-service aircraft, a direct damage comparison may not be appropriate and the feature may not be substantiated by the test. Therefore, once data are available,

test and in-service spectra comparison, in addition to fatigue damage comparisons, should be undertaken.

Alternatively, if the aims of the OLM program were to include provision of data for assembly of fatigue test load spectra, then OLM strain gauging would have to be located and configured so that the outputs from the strain-gauge bridges can be combined to produce bending moment, shear force, and torque values in the structural components required to be tested and suitable loads calibration methods would be required (discussed later).

Where program aims include substantiation of fatigue monitoring systems, strain-gauge installation would have to be located to capture the prime loading in the critical features protected by the monitor. For wing fatigue monitoring, this has generally been wing-to-fuselage or wing center-line joint features, but the critical features will be aircraft specific.

In practice, most OLM programs will have several of the aims described above and a combination of configurations will be required. Where there is some leeway or options to be considered for locating strain-gauge installations, they should be located in regions of low strain gradient. Locations should be chosen to avoid vulnerability to in-service damage from maintenance traffic and general use. Historically, the reliability of strain-gauge installations across OLM and direct strain-based fatigue monitoring systems has been mixed. Poor access for installing gauges does increase the risk of a poor-quality bonding and the associated risk of repair being required. Surface preparation is essential to obtain a high-quality bond [6]. For most applications, the in-service temperature range will require elevated temperature cure for gauge epoxy-based (or similar) adhesives. A temperature survey will be required to identify heat sinks in the structure to ensure accurate curing temperatures for the strain-gauge adhesive. Twisted-pair wiring lengths from the strain gauge to the signal conditioning unit should be kept to a minimum to reduce the effects of cable resistance and interference. The use of distributed master/slave data acquisition unit (DAU) connected by digital signals is often recommended to combat excessive cable lengths. Additionally, the path of strain gauge and instrumentation cables should be considered from an interference perspective to avoid sources such as high-power electric motors. Finally, where required, the method of calibrating the strain-gauge arrangement should be considered. For example, for easily removable components, loads calibration undertaken on static test machines represents an attractive and cost-effective option, although consideration has to be given to end constraints and stiffness. It is efficient practice to install secondary or backup gauges during installation, where a similar response from primary and secondary systems is expected.

3.3 Parametric and discrete measurands

The instrumentation most commonly used in OLM programs to obtain parametric and discrete data include accelerometers, synchros, potentiometers, tachogenerators, gyroscopes, flow meters, switches, thermometers, and pressure transducers. The requirements for parametric data captured within an OLM program should again be driven by program aims and applicable aircraft environment standards [7, 8]. Traditionally, the prime role of the parametric data has been to provide a basis for understanding the strain/stress/loads. A simple example of this would be comparing an inner wing bending moment plot with the normal acceleration parameter. Combinations of parameters, such as airspeed, altitude, accelerations, roll, and pitch rates, can be used to identify a flight condition or particular maneuvers. This may be essential in cases where airborne calibration or check calibration of strain gauges is required. Furthermore, where direct strain monitoring of a feature is impractical, it may be necessary to use parametric data or a combination of strain and parametric data to substantiate the fatigue spectra. Substantiation of the performance of an aspect of the parametric monitoring systems, such as normal acceleration-based systems, is also generally undertaken using flight test instrumentation standard accelerometers.

3.4 Capturing parametric data from data bus systems

The majority of modern aircraft used in military roles are fitted with data bus systems. Military aircraft generally use Mil Std 1553B or similar data bus systems and civil-derived aircraft tend to use ARINC 429 or similar systems. Many of the parameters needed to support an OLM program may well already

be available on these data bus systems. Although capturing the data stream from a data bus is an attractive option, care should be taken to ensure that the parameter provided on the bus is fit for the purposes of OLM in terms of sample rate, refresh rate, processor prioritization effects, time synchronization, accuracy, and resolution of the source sensor.

3.5 Capturing parametric data from aircraft instrumentation

Where an aircraft is not fitted with a data bus or where the required parameters are not available or suitable on the bus, tapping into existing aircraft instrumentation or the installation of OLM-specific instrumentation will be required. From a design, qualification, and through-life support perspective, use of existing aircraft instrumentation represents a far more cost-effective approach. However, tapping into primary flight instrumentation systems, such as pilot's altimeter, should generally be avoided owing to the increased risk to these systems. Additionally, as with data bus systems, an understanding of the specification and output signal format of the instrumentation is essential. Also, consideration has to be made as to whether the tapping loads up the signal. Where aircraft are fitted with accident data recorders (ADRs) or crash survivable memory units (CSMUs) tapping into input or output ports for these systems can also be considered for OLM data capture. Interfacing with ADR systems has generally been discouraged in the past owing to the risk of interfering with these systems; however, modern systems, in particular, are often fitted with output data ports and these options should be considered.

3.6 Introducing OLM-specific instrumentation

It is most likely that OLM-specific instrumentation will be required (such as accelerometers). Consideration should be given to equipment reliability, vulnerability in the operational environment, long-term support, additional data-acquisition signal conditioning requirements, as well as fitness for the purpose. Furthermore, experience has shown that even short-term OLM programs last considerably longer than ever envisaged at the outset and long-term support of the installation should be considered.

3.7 Numbers of instrumented aircraft

Historically, instrumentation of around 10% of a large fleet, ideally with a minimum OLM fit of two aircraft for small fleets, has proven a reasonable proportion for planning OLM installations. However, each program should be judged on a case-by-case basis and the factors considered should include program aims, fleet size and disposition, roles within the fleet, fleet-within-fleet issues (including structural build standard), OLM installation capability and reliability, cost, likely attrition, and volume of data required against collection time.

3.8 Data acquisition

The purpose of the data-acquisition system is to take measurements of the parameters (e.g., acceleration, velocity, or displacement) and provide data, which are used for analysis. The basic block diagram, as illustrated in Figure 2, illustrates the essential elements of an instrumentation system. The parameter is sensed by a transducer, which in turn produces data, often in the form of an analog voltage. These raw data are passed to the signal conditioning unit to be processed into a suitable form having been scaled, filtered, and usually converted into digital data. Thereafter, the data are transmitted to a data recorder unit.

3.9 Data sampling rate and antialiasing filters

Experience has shown that data should be sampled at a minimum of 10 times the highest frequency of the structurally significant modes, with appropriate antialiasing filters, to have confidence in capturing a close approximation to the strain peaks and troughs in the time history. Where there is insufficient data to identify the highest significant structural mode with confidence, an initial data sampling plan should be introduced with significantly higher rates than are likely to be needed and only reduced when analysis of the time histories shows that the sample rate can be reduced safely. Methods such as subsampling

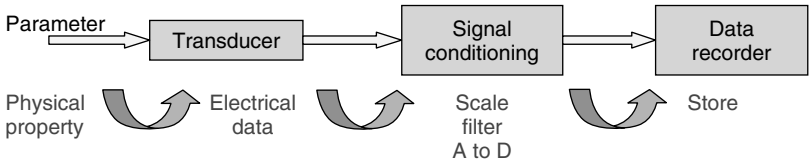

Figure 2. Data-acquisition cycle.

and repeat damage sums as well as identification of maximum and minimum values of subsampled data will identify when the sample rate reduction is significantly affecting the data capture. This is illustrated in Figure 3. Some may argue that to capture the frequency content in a signal it only needs to be sampled at twice that frequency. While it is correct that the frequency content will be identified, the magnitude of the peak and trough of a cycle cannot be reliably captured by only two points in the cycle. Regions particularly vulnerable to higher frequency dynamic loading, particularly for combat and associated trainer aircraft, may include the following:

- tailplane/foreplane/canard
- fin
- rear fuselage
- outer wing
- flying controls and lift devices (e.g., rudder, airbrake, slats, flaps, ailerons leading edges devices, and leading edge root extensions)
- external stores and pylons
- undercarriage and support structure.

4 CALIBRATION

Calibration refers to the process of determining the relation between the output (or response) of a measuring instrument and the value of the input quantity or attribute. Calibration can be undertaken using various methods with different aims and it is imperative that the calibration tests performed are relevant to the program aims and produce data consistent with these aims. Some of the more commonly used calibration methods, primarily for loads to fatigue test

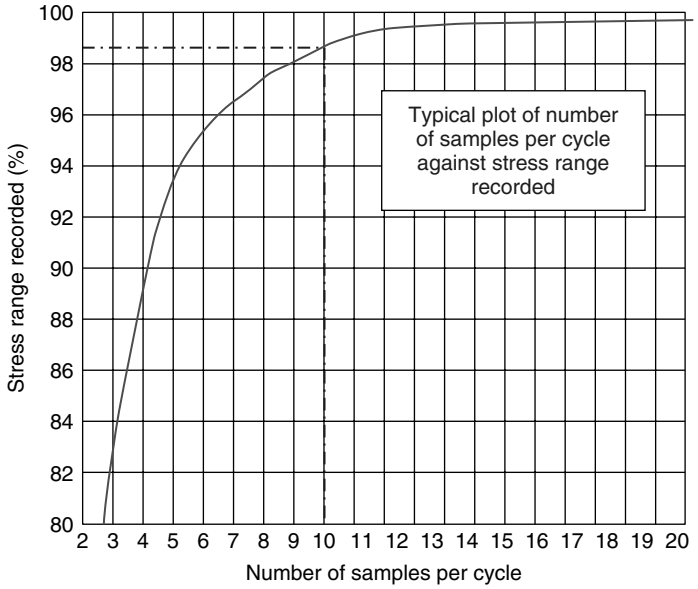

Figure 3. Identification of sample rate effects.

or loads input to a stress model, are discussed in the following sections.

4.1 Setting of physical datum values

Irrespective of the method of calibration used, there will be a need to establish the appropriate physical loading condition that corresponds to the zero output from the strain-gauge installation. Strain-gauge bridges are frequently balanced to give zero output in the calibration state with no external load applied. Bridge balancing can sometimes be achieved with the instrumented component in a zero load state but, in general, the "zero position" of a gauge installation output has to be set to a physical known output or datum before analysis can proceed. Frequently, ground conditions are used in this exercise since mass information is likely to be readily obtainable and an expected output can be derived from suitable models.

4.2 On-aircraft strain-gauge load calibration

Where the aims of the OLM program require the identification of loads, such as in the determination of fatigue test spectra, a more complex approach to calibration is required. As previously mentioned, the methods generally used for loads calibration are developed from the work undertaken at NACA (forerunner of NASA) in the early 1950s and published by Skopinski *et al.* [4]. Load calibration is a method that permits the measurement in flight of the shear, bending moment, and the torque on the principal lifting or control surfaces of an aircraft. Although it is accepted that the stress in a structural member may not be a simple function of the three loads of interest, processes have been developed for numerically combining the outputs of several strain-gauge bridges in a way that the loads may be obtained. A simple typical installation for a two-spar structure, using four-active-arm strain-gauge bridges is presented in Figure 4.

Ideally, gauges would be placed so that a bending moment bridge would respond only to bending and a shear bridge would respond only to shear and, so on. However, this is only true for an elementary truss-type beam arrangement and, in practical structures, more complex interactions between loading mechanisms exist. With care, gauge locations can be chosen and configured so that the bending bridge output contains predominantly bending moment effects and, so on. The loads on the surface of a wing, for example, can be specified by three orthogonal forces, normal forces, longitudinal forces, and lateral forces (Figure 5) and by three orthogonal moments, bending moment, torque, and in-plane bending. Thereafter, loads models are used to transfer these overall loads to local loads within the structure.

The strain in a structural member or component can therefore be expected to be some function of these six quantities and this strain response must be taken into account in any method of relating strain-gauge bridge output to load. In real structures, these relationships can be complicated further as the strain in a wing root, for example, may be affected not only by the loads outboard of the measurement station but also by loads on the opposite wing or inboard of the measurement station. This *carryover effect*, as it is

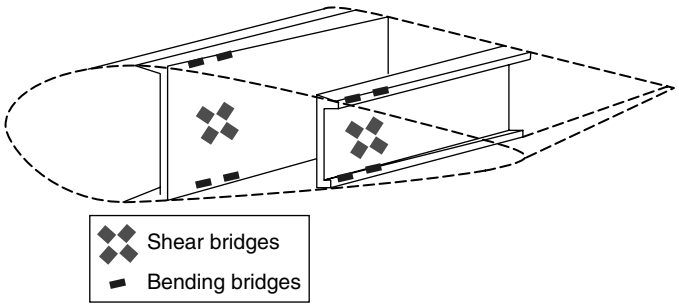

Figure 4. Example of strain-gauge bridges for loads calibration.

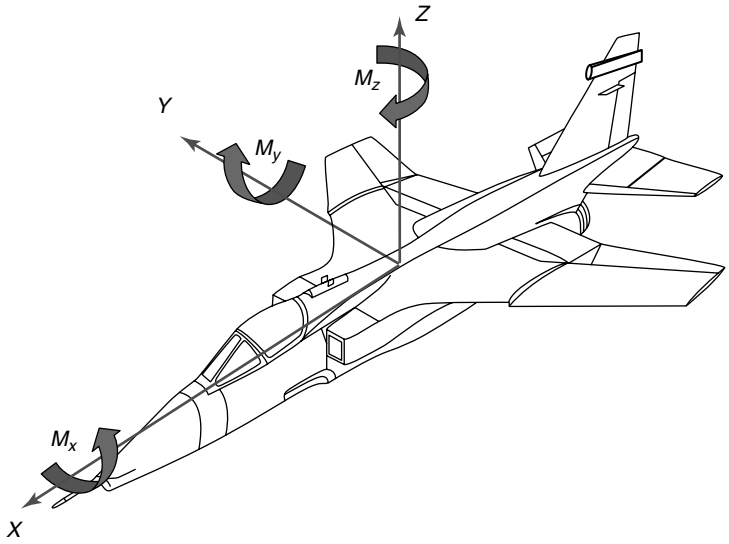

Figure 5. Forces and moments acting on an aircraft.

termed, can be particularly significant for unsymmetrical loading actions [4]. However, certain simplifications to these six quantities can be made. For a wing structure, the stress in the structural member and hence the output from the strain gauges mounted upon that structure may be taken to be a function of the three principal terms of aerodynamic load investigation, shear, bending moment, and torque. Additional loading actions may need to be considered for other structural features; for example, drag loads are generally highly significant for external stores and hence may need to be considered.

For major lifting surfaces, the method of obtaining the relationship between the output of the strain-gauge bridges and the shear, bending moment, and torque loads is by applying a series of point loads and employing the principle of superposition. This assumes that the strain at a particular location due to loads applied simultaneously at several points on the structure is the algebraic sum of the strains due to the same loads applied individually. This is the fundamental basis of Skopinski-type calibrations. Developments from Skopinski's methods have been used widely and include the application of distributed loads to produce check cases [9].

In theory, load calibration to limit-load conditions is desirable. However, in practice, application of a point load anywhere near limit-load condition is likely to cause significant local damage to the structure. Furthermore, the extent of loading achievable is often determined by how an aircraft can be constrained within the loads rig and how these constraint loads can be reacted within the structure. Therefore, detailed design and analysis are required to ascertain achievable load ranges. Loads should generally be applied at regions with local reinforcement, such as spar and rib intersections, or at external load application points, such as aileron or rudder hinges, to prevent local damage. Major attachment locations, such as wing, fin, and tailplane mounts, engine mounts, slinging points, and undercarriage attachments, are generally used as reaction points.

Methods such as influence coefficients can be used to identify the response of individual bridges to changes in the applied load location. If the normalized bridge output (bridge output/applied load) remains relatively constant with change in location of applied load, then the bridge is more sensitive to shear. If the normalized bridge output varies linearly with variation in the span-wise location of the applied load, then the bridge is sensitive to bending moment. However, if the output varies with chord-wise location of the load, then the bridge is responsive to torque.

Once the bridge-to-load equation has been optimized, where practicable, this may be cross-checked

by predicting the distributed load cases and determining the percentage accuracy. R values of 0.995 or R^2 values of 0.990 are realistic aims for shear and bending moment load calibrations. Such high levels of correlation are often difficult to achieve in practice for torque values. This is partly because the torque value can often be a relatively small number but driven by the difference between two large numbers (i.e., front and rear spar shears).

Loads calibration is a complex and potentially costly exercise. There are many potential pitfalls and experience has shown that, the more checks that can be introduced into the process, the more likelihood there is of retaining a high level of confidence in the results of the exercise.

4.3 Off-aircraft loads calibration

It may not be necessary to calibrate the component or structure on the aircraft in a full rig facility; wing attachment links are a good example of such a component. Great care has to be taken with off-aircraft calibration methods to ensure that the loading applied to the component during the calibration exercise can be related directly to the loading seen by the component in service.

4.4 Strain-gauge correlation to fatigue test damage

Where program aims are to compare in-service usage directly with fatigue test spectra, a method of correlating the strain outputs from the OLM aircraft to the damage introduced into the fatigue test can be used. In this method, strain-gauge bridge arrangements on the fatigue test are replicated on the OLM aircraft and the fatigue analysis is fitted to either test failure points or the end of test, with appropriate safety factors applied. The fitting factor (stress factor applied to the test spectra to predict a failure criterion at the end of test) is then applied to strain-gauge bridge output from the OLM aircraft. Thereby, in-service flying can be compared directly with that replicated on the fatigue test.

4.5 Strain-gauge airborne and on-ground calibration

Airborne and on-ground calibration methods have been used in several programs as either prime calibration or as backup or confidence checks in support of loads calibration or calibration to test damage methods. Airborne calibration is most likely to be chosen as an alternative method where Skopinski-type loads calibration is deemed prohibitively costly. The principles of this method are relatively simple, but the application in practice can be highly problematic and the method is considered unlikely to be successful for all applications.

The method requires the aircraft to be flown in several predetermined flight conditions or maneuvers or data corresponding to these conditions be extracted from OLM data. For example, for an airborne calibration of a wing root bending bridge on a combat aircraft, a range of symmetric pull-up and push-over maneuvers over a range of normal acceleration values and a series of wind-up turns[a] could be used to develop slope and offset correction (i.e., $y = mx + c$) for the bridge in question.

With sufficient data and a good knowledge of the global and local loads or stress distributions within the aircraft, airborne calibration is feasible for wing locations and possibly fuselage locations driven by bending loads, for example. However, having confidence in the application of this method to a tailplane and, in particular, a fin, where relationships between flight conditions and stresses in the component are more complex, is considered highly challenging and a high-risk strategy. Parametric and discrete OLM instrumentation should be subject to manufacturers' recommended calibration procedures.

5 DATA ANALYSIS

5.1 Data capture and analysis

As with so many aspects of an OLM program, capture and processing of the OLM data is a technically complex function. The analysis aims will be program specific, but a typical top-level process is illustrated in Figure 6.

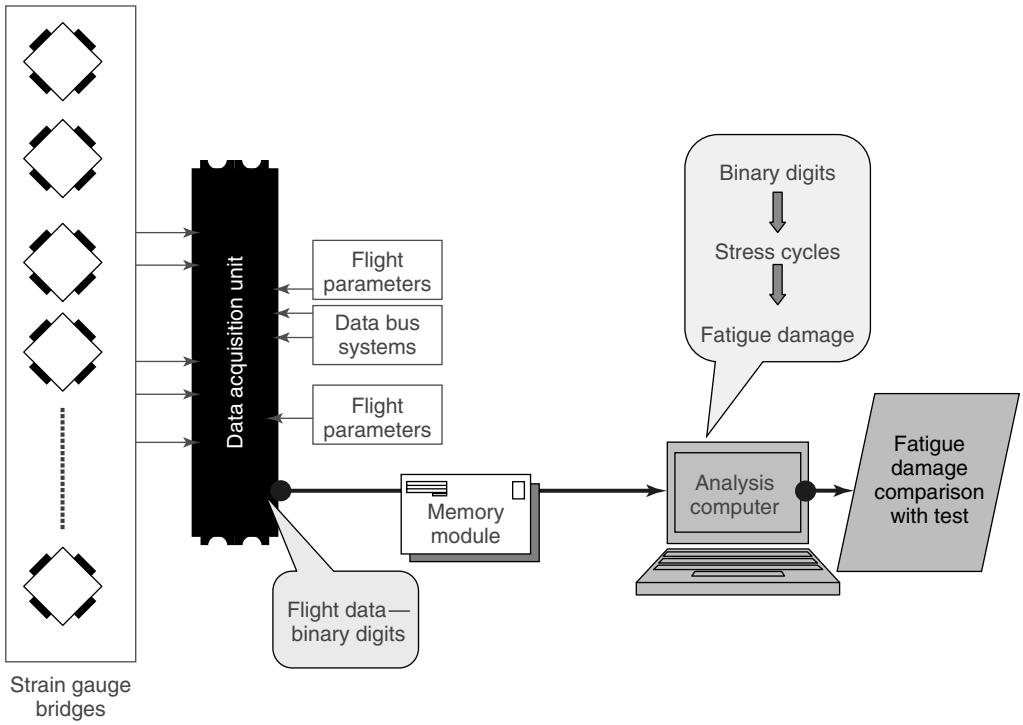

Figure 6. Example of top-level capture and analysis process.

5.2 Analysis process

An example of data analysis process is illustrated in Figure 7. The fatigue analysis process and postprocessing activity, such as comparison of OLM data with fatigue test spectra, will again be program-aim specific and there is insufficient space within this article to describe the various methods used. However, there are key functions required irrespective of program-specific aims and these are described briefly within this section.

5.3 Data anomaly and confidence checks

Retaining the integrity of the OLM data is essential to the success of any OLM program and anomaly and confidence checks generally include the following:

- identification of any regions of lost data;
- identification of bit failures;
- identification of error flags;
- collation and reporting of DAU-produced data health reports;
- identification of provisional data status against established criteria (e.g., data loss $<2\%$);
- check to ensure data loss does not coincide with highly damaging events (e.g., high-g);
- data replacement and identification process for minor losses (e.g., last known good value);
- exceedances of channel maximum and minimum expected strain/stress or load values;
- excessive rate of change values (where practicable) compared with performance data;
- failure of correlation between measurands expected to have a high degree of correlation;
- mismatch between flight record and OLM data;
- data trending checks with similar sortie descriptors;
- outlier analysis of known condition values (Figure 8);
- comparison with expected theoretical values for flight conditions (Figure 9).

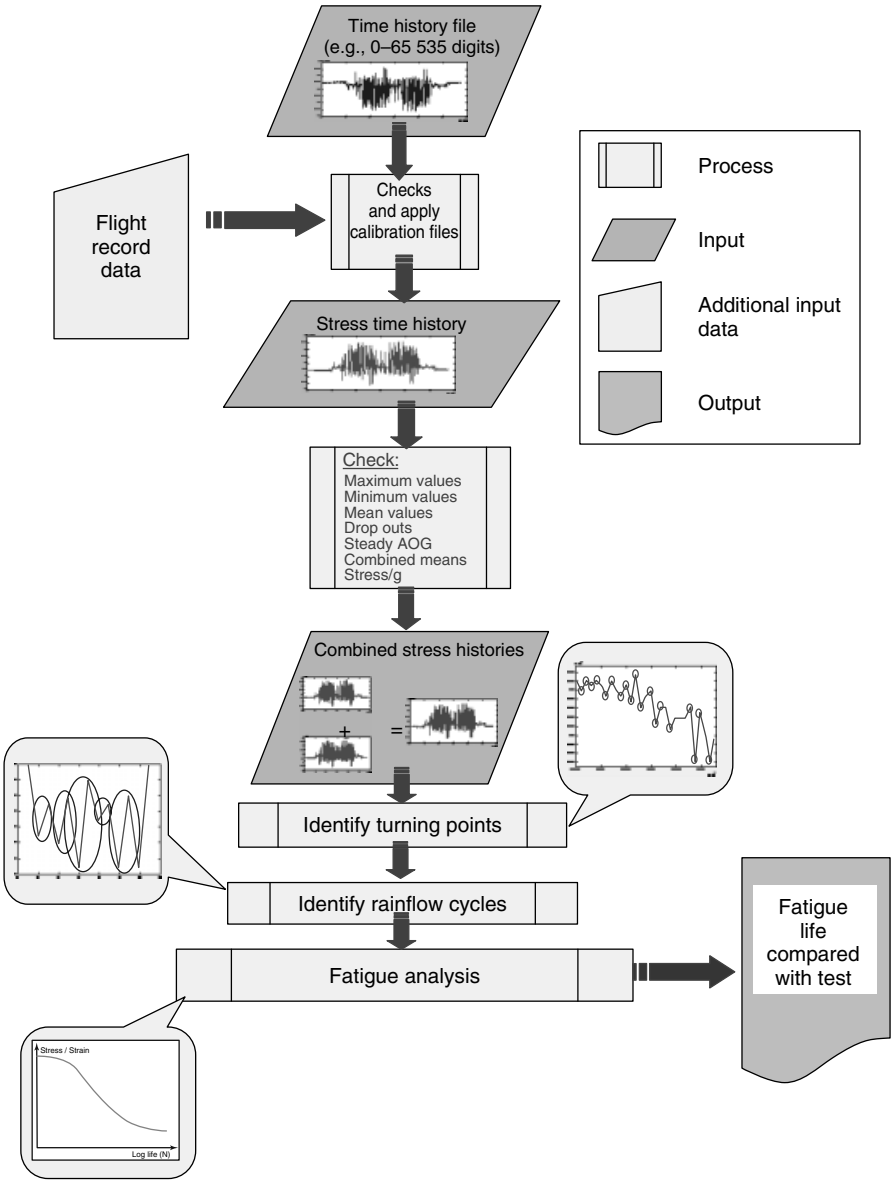

Figure 7. Example of data analysis process schematic.

5.4 Data representation

In-service time history data are analyzed in various ways to undertake a comparison with design and qualification spectra. The method used should be consistent with the fatigue design process. Traditionally, cycle data have often been presented in a cycle frequency of occurrence matrix or FOOM, usually by cycle range and mean or amplitude and mean. An example of FOOM data representation is presented in Figure 10.

Exceedance diagrams are a frequently used method of data reduction and permit comparison between data sets, e.g., test and usage spectra. An example of exceedance diagram is reproduced in Figure 11.

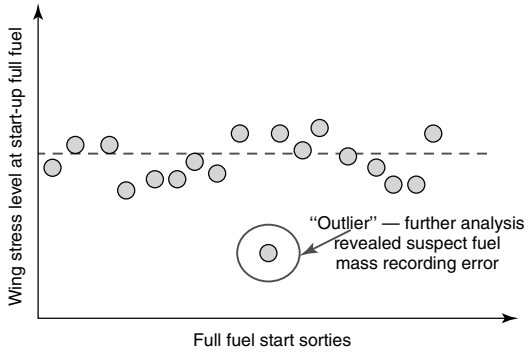

Figure 8. Illustration of trending of wing stress during start-up.

Care should be taken when using exceedance diagrams and the method chosen to reduce each data set should be consistent with the method used to produce the comparison data initially. Users also need to be aware of the effects of the loss of cycle mean stress information.

5.5 Fatigue data presentation

Assessments of in-service usage in fatigue damage terms are usually undertaken using data expressed in standard forms (i.e., per 1000 flying hours or per 1000 sorties). Additionally, fatigue damage or crack

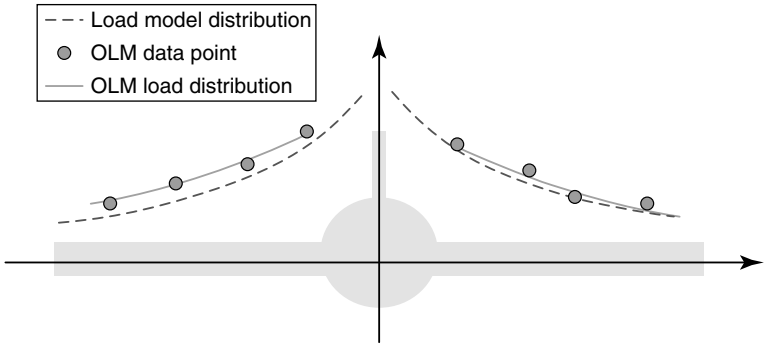

Figure 9. Example of span-wise load distribution plot.

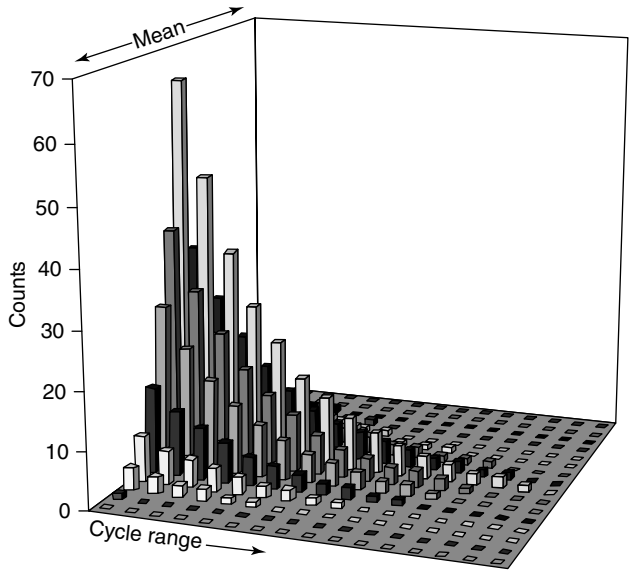

Figure 10. Example of FOOM Representation (16 × 16 FOOM illustrated—generally larger).

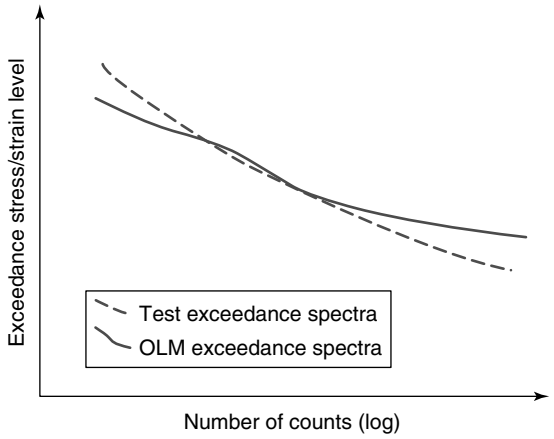

Figure 11. Example of exceedance diagram comparing test and OLM spectra.

growth accumulated through sorties on a flight-by-flight basis provides a valuable indication of highly damaging maneuvers or flight regimes. Examples of typical wing bending stress/strain time histories and corresponding damage accumulations are presented in Figure 12 for a combat/trainer aircraft and in Figure 13 for a transport aircraft.

6 DATA CAPTURE PROGRAM

6.1 Criteria affecting data capture

Even for fleets well provided with OLM aircraft, OLM data will rarely account for more than 2% of flying. For many fleets with few OLM aircraft and only periodic recording, OLM will represent significantly lower percentages of overall flight data. Therefore, the aim of detailing a data capture program is to ensure that the program aims are met with representative data.

6.2 Identification of data capture requirements

Data capture requirements should be specified for the initial OLM program. A review of available sortie

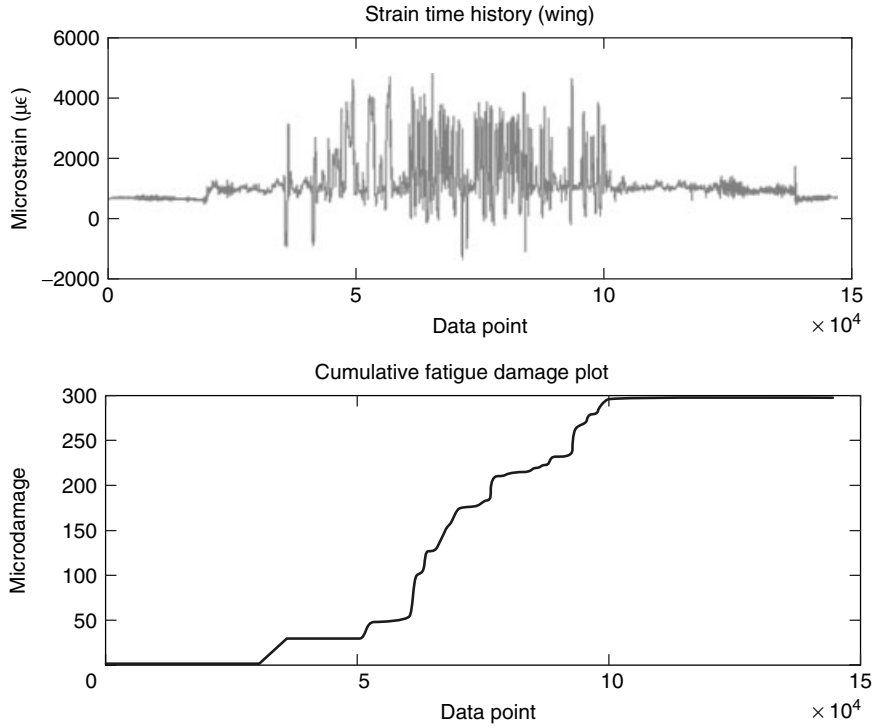

Figure 12. Example of combat/trainer aircraft wing strain/stress time history and fatigue damage accumulation plots.

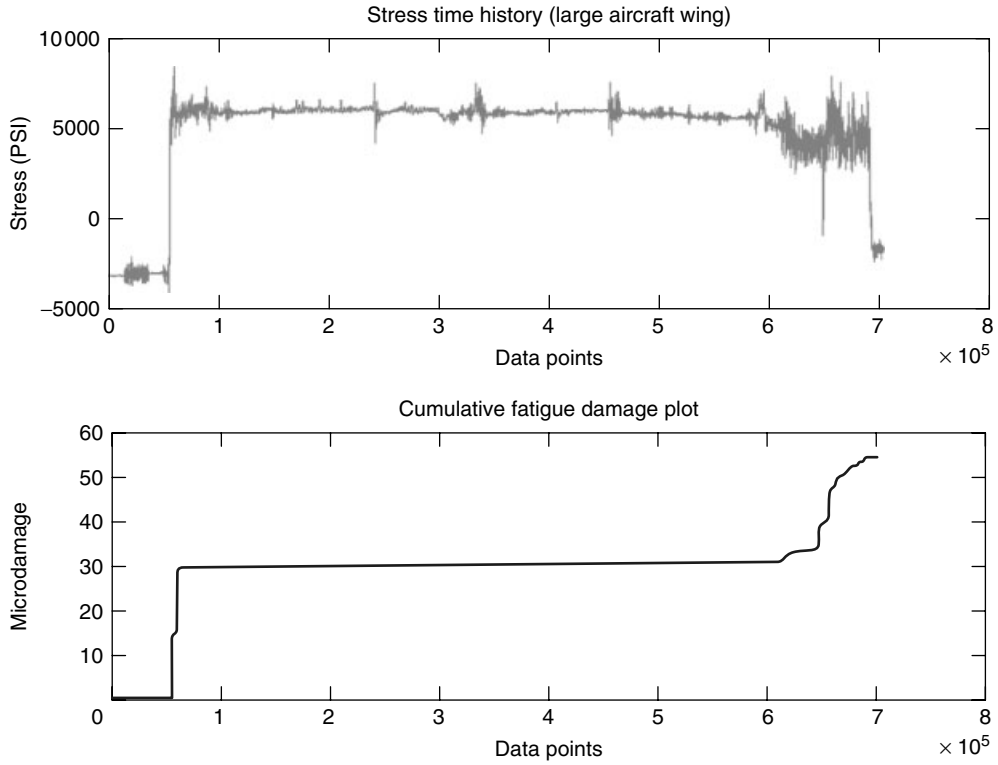

Figure 13. Example of transport aircraft wing strain/stress time history and fatigue damage accumulation plots.

usage data (or data from previous aircraft in the role) should be undertaken as the basis for the data capture requirements and the factors that should be considered in determining the program should include the following:

- program aims (i.e., need for test spectra, for example, may be first priority);
- sortie-type distribution flown by the fleet;
- likely variance within sortie type (e.g., air test—low variance, air combat—high variance), based upon cumulative average data from monitoring system if available;
- *a priori* fatigue damage distribution across sortie type (e.g., from monitoring system);
- fleets-within-fleets and matching OLM capability;
- fleet distribution, deployments, maintenance, and modification program;
- initial simplification or stores and role equipment variations;
- seasonal and syllabus variations (at least one year's data should be captured);
- impact of scheduled maintenance on data capture.

Where usage data are available for a fleet and the fleet is fitted with even a rudimentary monitoring system, these data can be used to provide an estimate of the number of sorties required within each sortie type. A simple time ordered cumulative average fatigue damage plot (Figure 14); can provide an indication of the minimum number of sorties needed in each sortie type to gain a reasonable representation of that sortie type *a priori*. (It is accepted that this heuristic method depends upon the monitor being reasonably accurate or at least relatively consistent.) Where no usage data exist, first-cut estimates can be developed from previous aircraft types in similar roles.

Once data capture commences and damage or crack growth[b] data are available, these initial estimates of the minimum data capture requirements could be refined using OLM-derived damage or crack growth rates by sortie profile code and by major structural component. In addition, where scatter is found to

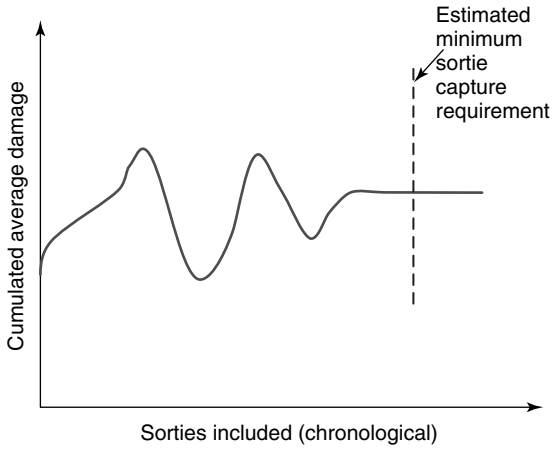

Figure 14. Example of cumulative average fatigue damage plot.

be larger in a particular sortie type than expected, particularly where that sortie type contributes highly to fatigue damage accrual, a greater number of sorties will be needed to provide representative data.

7 REPORTING

7.1 Post-air-test/initial analysis and report

Following the air test or initial flying after the installation of the OLM system on each OLM aircraft, postflight analysis should be undertaken promptly. This analysis should include the following:

- identify the serviceability status of all data channels;
- identify any data losses or anomalies;
- compare channel values with expected values;
- compare character of data with that expected for channel;
- check channel ranging values in engineering units;
- check frequency content for channels susceptible to high-frequency loading;
- review channel sample rates;
- recommend remedial action as required;
- check analysis software.

Having confidence in the data provided from an OLM program is essential in ultimately achieving the aims of the program. Where confidence in the data is lost, remedial action to recover the situation can be extremely costly and wasteful. Therefore, rapid initial analysis and reporting following initial sorties is required.

7.2 Interim and final reporting

At a point determined by the program aims, interim and final reports should be raised. The final report, in particular, should form a natural progression from the interim reports but should be considered as the definitive historical record for the program and hence should be a stand-alone document but with references to lower-level detailed reports generated during the course of the program. The final report should include details of the following:

- program aims
- OLM installation
- calibration process
- data analysis process
- data capture program
- data capture achievement
- data quality
- data analysis
- conclusions by program aims
- recommendations for remedial airworthiness action or further work
- OLM report references
- lessons identified
- future OLM recommendations, including data capture, system enhancements, or care and maintenance requirements.

ACKNOWLEDGMENTS

The author is pleased to acknowledge the contribution of OLM practitioner colleagues throughout the UK aerospace industry, who provided valuable input to the recently produced UK OLM guidance paper [10], on which some of the content of this article is based. In particular, the author wishes to acknowledge the contribution of his coauthor on that project, Mrs Dorothy Holford.

END NOTES

[a.] Wind-up turn: In a wind-up turn, the aircraft is rolled into a turn at each test condition and, keeping the speed and power constant through the maneuver by allowing the height to vary around the nominal test altitude, the normal acceleration is increased progressively until a defined limiting condition is reached.

[b.] Linear elastic fracture mechanics methods assume that the crack elongation is a function of its original length as well as the incremental applied stress/load spectrum, whereas the stress–life approach considers the incremental damage contribution from the spectrum to be independent of the *a priori* damage accumulation. Meaningful comparison of crack growth increments on a flight-by-flight basis will require calculation from a standard initial crack length.

Chapter 140
Loads and Temperature Effects on a Bridge

Ming L. Wang
Department of Civil and Materials Engineering, University of Illinois, Chicago, IL, USA

1 INTRODUCTION

Bridges are an essential part of a highway network. They are open to traffic, resistant to natural disaster, and subjected to millions of loading cycles per year. However, they are quite expensive to maintain and do occasionally fail [1]. The fact that many bridges are carrying greater average loads than predicted during their design has significantly increased the need to monitor bridge performance over the past few years. To effectively manage bridges today, there is a great need to monitor the real-time conditions of bridges, and the deterioration rates of their components, so that efficient and proactive measures can be taken [2–5]. By using the latest state-of-the-art technologies, it is possible to utilize health monitoring systems on highway bridges to determine their behavior and condition, and assess maintenance and inspection needs [6, 7]. Bridge health monitoring systems have historically been implemented for the purpose of understanding bridge behavior under various loads and environmental effects [8–13].

The Kishwaukee Bridge is a five-span precast, posttensioned segmental concrete box girder bridge across the Kishwaukee River in Rockford, Illinois. The structure has been under increasingly stringent inspection since extensive cracking adjacent to the piers in the webs was observed [14–18]. To this end, the author has developed instrumentation that continuously monitors the bridge on the basis of local strain, displacement, temperature measurements, and global frequency measurements [17, 19].

The ultimate focus of the instrumentation is the measurement of permanent deformations in the web at key locations that may indicate yielding of the steel shear reinforcement and consequent changes to the load-carrying capacity. This is accomplished through local and global monitoring, for maximum redundancy. The local monitoring relies on strain gauge pairs installed on the web faces in the middle of each main span to estimate the loads on the bridge, and by two linear variable displacement transducers (LVDTs) displacement-strain rosettes that were installed at the location identified during prior static load tests as having the most severe reinforcement stresses. The global measurements are derived from ambient vibration accelerometer records.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

Frequency measurements are relatively insensitive to deterioration of shear capacity. However, they are analyzed for two reasons. First, measurements were obtained during 1999–2000; despite visual inspections, these data are directly relevant to assessing long-term changes in the structure [20], although recent experience clearly indicates the need for a more thorough understanding of thermomechanical effects [21]. Secondly, both the benchmark frequency measurements and the current data are available at high resolution and accuracy, and the requisite sensitivity of frequency shifts can be explored through finite element method (FEM) analysis [22]. Moreover—and relevant to this article—these two factors enable the use of bootstrap methods to develop quantitative change-point criteria for automated alarm monitoring. This is an important step, given the time and expense for manual analysis of data. These frequency data thus complement the interpretation of long-term strain and displacement measurements from moving ambient loads, data which can be beset with possible drifts and large uncertainties. Temperature correlation was performed after noting that the average lag between internal and external free air temperatures was roughly 5 h.

This article provides a supplement to the current research on bridge health monitoring and improves the understanding of bridge behavior. Specifically, load and temperature effects are addressed in detail.

2 KISHWAUKEE BRIDGE MONITORING

2.1 Background

Kishwaukee River Bridge (Rockford, IL) is a posttensioned, precast segmental concrete box girder bridge opened to traffic in 1980. The bridge has five spans with lengths of $51.8\,\text{m} + 3 \times 76.2\,\text{m} + 51.8\text{m}$. As the first generation of segmental structures, the Kishwaukee Bridge engineers chose the design of a single shear key joint usually located close to the center of gravity of the cross section. These joints are quite vulnerable especially during polymerization of the glue.

Problem arose during and after the completion of the bridge. The epoxy applied between segments was not hardened properly in some joints. The epoxy was unable to carry the shear stress fully and was instead acting as a lubricant that caused reduction of shear resistance capacity. Therefore, a substantial part of the shear force was concentrated at the shear keys [16]. As shown in Figure 1, the inclined cracks went through only for the length of one segment but not continuously to the next segment. Many steel pins were inserted to the webs between segments to stop the propagation of shear cracks. It has proved to be effective in successfully slowing down the progress of cracking. However, there is

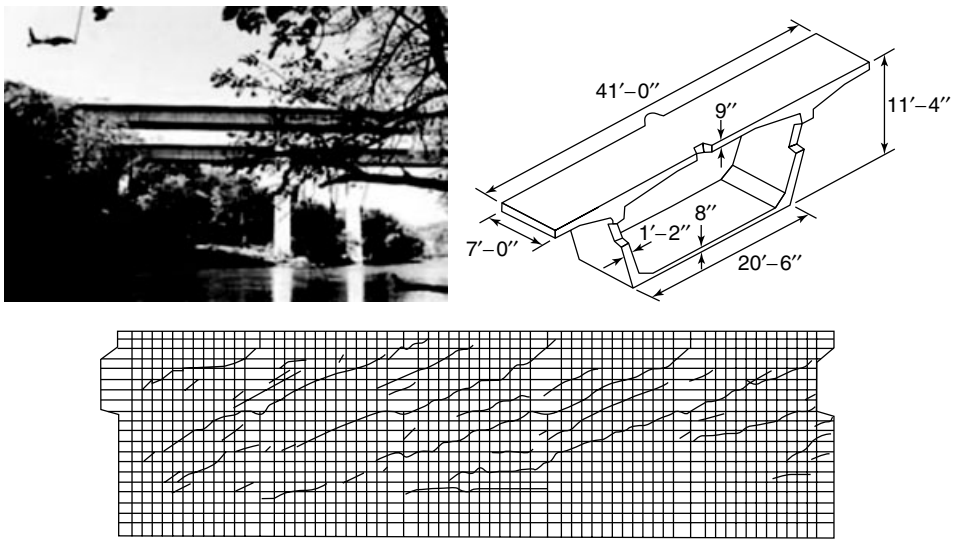

Figure 1. Shear cracks on the webs of Southbound Kishwaukee Bridge.

a need to know current shear carrying capacity as well as the extent of propagation of cracks. A long-term monitoring program is therefore imperative for structural surveillance of Kishwaukee Bridge to provide continuous health records for the bridge management department [23].

Since the major problem of Kishwaukee Bridge is shear cracks on the webs, a specifically designed structural health monitoring system was installed on the Kishwaukee Southbound Bridge in 2003 [24]. This system monitors and records the strain, crack opening displacement (COD), and acceleration of the bridge, as well as the temperature outside and inside the bridge girder. Using shear strain measured through a rosette of three CODs across cracks, its corresponding shear resistance capacity can be predicted. Thus, the operation and management for this bridge is transformed into a more objective and quantitative process. This process provides for optimal integration of experimental, analytical, and informational system components [25]. In addition, the outcome of the process provides valuable information for current evaluation of structural integrity, durability, and reliability [19]. Using this information, composed from the sensory system, data-acquisition system, and health assessment system, the bridge owner and maintenance authorities can make rational decisions in assigning the budgets for both maintenance and repair.

2.2 Static load test

In order to determine the actual health status of Kishwaukee Southbound Bridge and set up the baseline for the following long-term health monitoring, we did two static load tests in 2000. The bridge was tested for service loading conditions. The weight of the trucks was comparable with a weight of the design truck defined in AASHTO LRFD Bridge Design Specifications. The design weight of the truck (72 kips) was amplified by a dynamic factor of $\delta = 1.320$. Four different positions of the trucks were proposed on the bridge, as shown in Figure 2.

Visual inspection of the shear cracks determined the most damaged webs in the bridge. Web SB2-N4-E was chosen for *in situ* measurement of deformation due to shear forces. Three LVDTs were installed at the interior surface of the web, close to the neutral axis, as shown in Figure 3. Measured displacements were used for estimation of the web's shear stiffness. The load stage using trucks located in position 2 (second load) was selected for assessment, because neither transverse bending moments nor vertical axial stresses accompanied the imposed load in the web of segment SB2-N4. Shear forces generated by trucks located in position 3 (second load) were used for calculation of the steel stress increment in reinforcement.

Average shear strain and shear stiffness of the cracked web can be assessed by equations (1) and (2):

$$\Delta\gamma_{Lt} = \frac{2[\Delta\varepsilon_{\alpha} - \Delta\varepsilon_{L}\sin^2(\alpha) - \Delta\varepsilon_{t}\cos^2(\alpha)]}{2\cos(\alpha)\ \sin(\alpha)} \quad (1)$$

$$(GA)_{ir} = \frac{\Delta V}{\Delta\gamma_{Lt}} \quad (2)$$

To determine the global flexural stiffness of the bridge, strain gauges were installed at the webs of segments located next to the closures. Measured concrete strains were used for the calculation of curvature in equation (3) and evaluation of the modulus by equation (4):

$$\Delta\chi_{\text{meas}} = (\Delta\varepsilon_{\text{upper}} - \Delta\varepsilon_{\text{lower}})/d_{gs} \quad (3)$$

$$E_c = \Delta M/(\Delta\chi_{\text{meas}}\ I_i) \quad (4)$$

The assessed value of modulus was still in the range of 35 000–40 000 MPa. This value is very similar to the design value, while the tangent shear modulus has been reduced about 50–55% by shear cracks. Therefore, the change of bridge shear stiffness has little influence on its flexural stiffness. Dynamic tests and FEM simulation also corroborate the negligible effect of shear stiffness on flexural stiffness.

2.3 Half-scale experiment of concrete girder

In order to determine the shear carrying capacity of Kishwaukee Bridge, a half-scale I-beam model was cast in the laboratory. The following parameters are measured in this experiment: deflection of the end of cantilever, flange strains, web strains, reinforcement

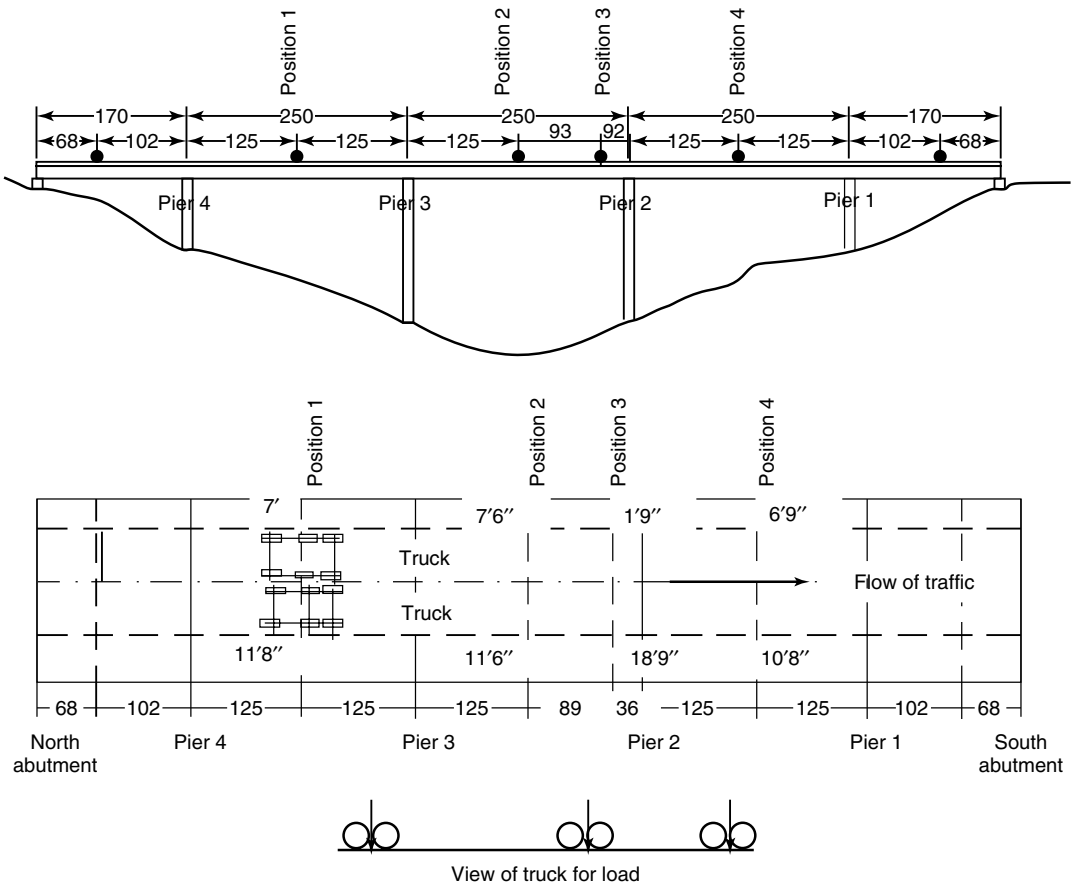

Figure 2. Static diagnosis load test on the southbound Kishwaukee Bridge.

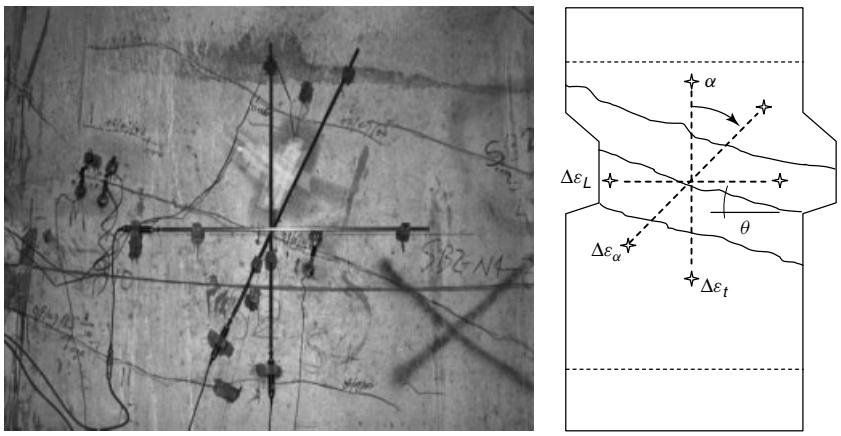

Figure 3. LVDT sensors installed on the inner surface of the web.

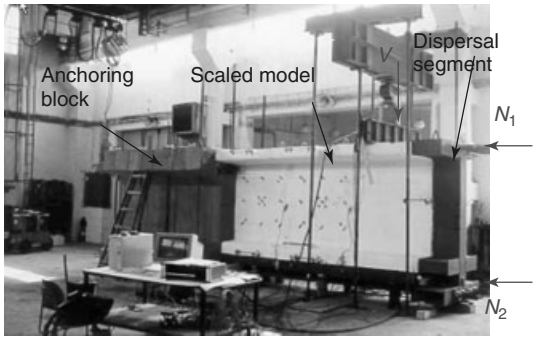

Figure 4. Arrangement of half-scale experiment.

strains, prestressing force, and elongation of the strands.

Figure 4 presents the arrangement of the half-scale experiment. The three half-scale I-beam segments were put between the anchoring block and the dispersal segment. The friction between the joints of three segments was reduced to a certain degree to simulate the unhardened epoxy problem on the southbound Kishwaukee Bridge. The prestressing reinforcement was low relaxation strands with a high yielding point of 1800 MPa. The upper prestressing force N_1 was applied with eight 3-strand tendons on the top flange while four 4-strand tendons were used to apply the lower prestressing force N_2 on the bottom flange. The shear force V was applied with a hydraulic jack.

The propagation of shear cracks on the I-beam webs is shown in Figure 5. According to the visual inspection records, the type and inclination of these shear cracks are similar to the actual cracks on the Kishwaukee Bridge as shown in Figure 1. It indicated that the experiment successfully simulated the actual damage condition of Kishwaukee Bridge. The relationship between shear stress and shear strain is shown in Figure 6. The original tangent shear modulus G_c was 15 000 MPa. After the linear elastic phase, the concrete cracked and the steel reinforcement carried much of the shear force itself, which is evident from the graph. About the yielding point of shear reinforcement, the reduced tangent shear modulus G_{ct} was roughly 5300 MPa. According to the analysis of the static load test, the current tangent shear modulus is approximately 6740 MPa at the

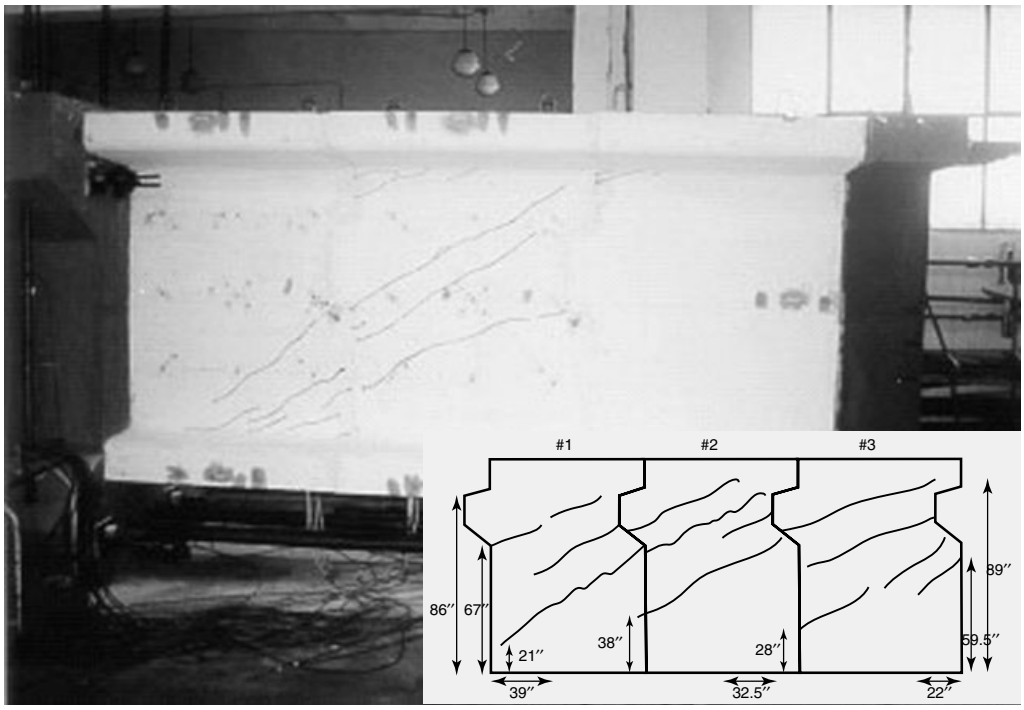

Figure 5. Propagation of shear cracks on the specimen.

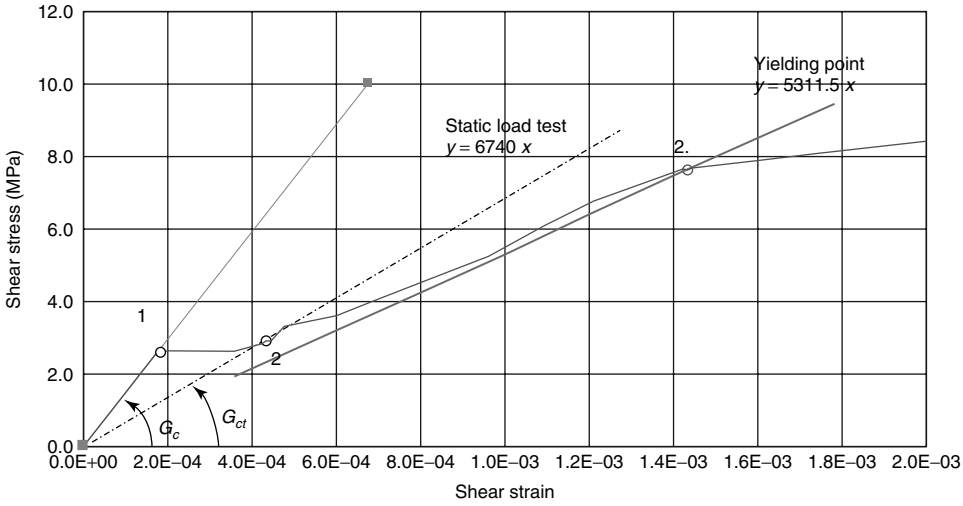

Figure 6. Relationship between shear stress and shear strain measured from half-scale experiment.

worst location (SB2-N4) of the southbound Kishwaukee Bridge. This means the shear steels are still in the safe region of stress–strain curve. However, more strict regulations should be encouraged so that no overweight truck passes over the bridge, which might induce further damage.

2.4 Real-time global and local health evaluation

Kishwaukee Bridge monitoring system has been collecting and processing data and generating evaluation and health reports for five years. The system can analyze the frequency distribution, COD, shear strain in the web, and traffic information in real time. Automated warning/alarm system is in effect to warn against any further local structural damage on the bridge, system problems, sensor dysfunction, and data errors.

Subsequent to temperature compensation and local-in-time change-point, detect the second step in the analysis strategy is to compare the current population with off-line reference data sets, which have been preserved for this purpose. Our strategy using the bootstrap has been discussed previously [23].

After establishing the baseline of bridge health, a long-term monitoring system can be used to provide the continuous health information of a bridge. For concrete bridges, cracks, especially the shear cracks, act as the main role of local damage and the global health information of a bridge can be represented with the bridge stiffness. Both global and local conditions of bridges need be evaluated in order to determine their in-service behavior and justify rehabilitation and repair plans. The global health information can be provided by dynamic measurement, while the local damage can be captured by sensors such as strain gauges and LVDT. The raw acceleration data are collected and preprocessed to obtain the natural frequencies in a sensor substation. Then the acceleration and frequency data are transferred into the database server via the Internet in real time, as shown in Figure 7(a). After that, the application server will analyze the data to get the hourly bootstrap mean and its confidence intervals, as shown in Figure 7(b).

On the basis of dynamic tests from 1999 to 2000, the global dynamic characteristics of the bridge are obtained from the acceleration data with the related temperature values. These structural parameters are set up as the baseline of global health assessment. Temperature has a significant influence on the natural frequencies of a structure. Hence, it is important to derive the relationship between temperature and natural frequencies, i.e., how much the frequency will change owing to the variation of 1 $^{\circ}$C. To a certain degree, this relationship can represent the change in the bridge bending stiffness due to the temperature variation.

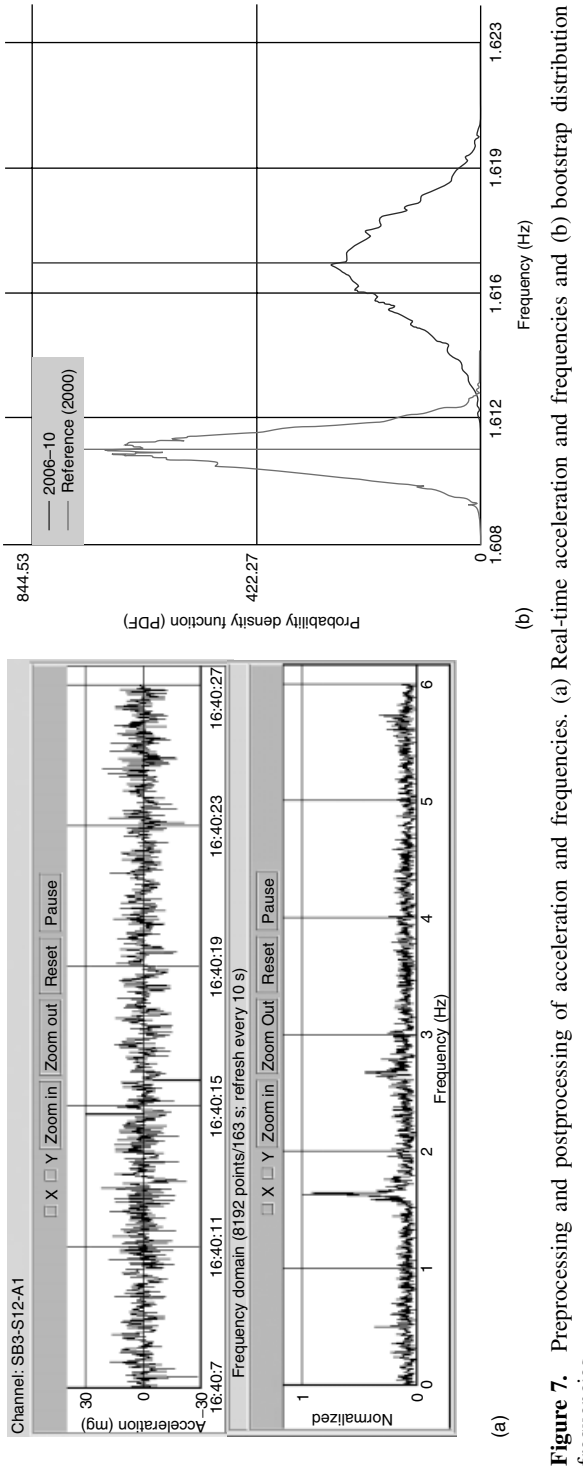

Figure 7. Preprocessing and postprocessing of acceleration and frequencies. (a) Real-time acceleration and frequencies and (b) bootstrap distribution of frequencies.

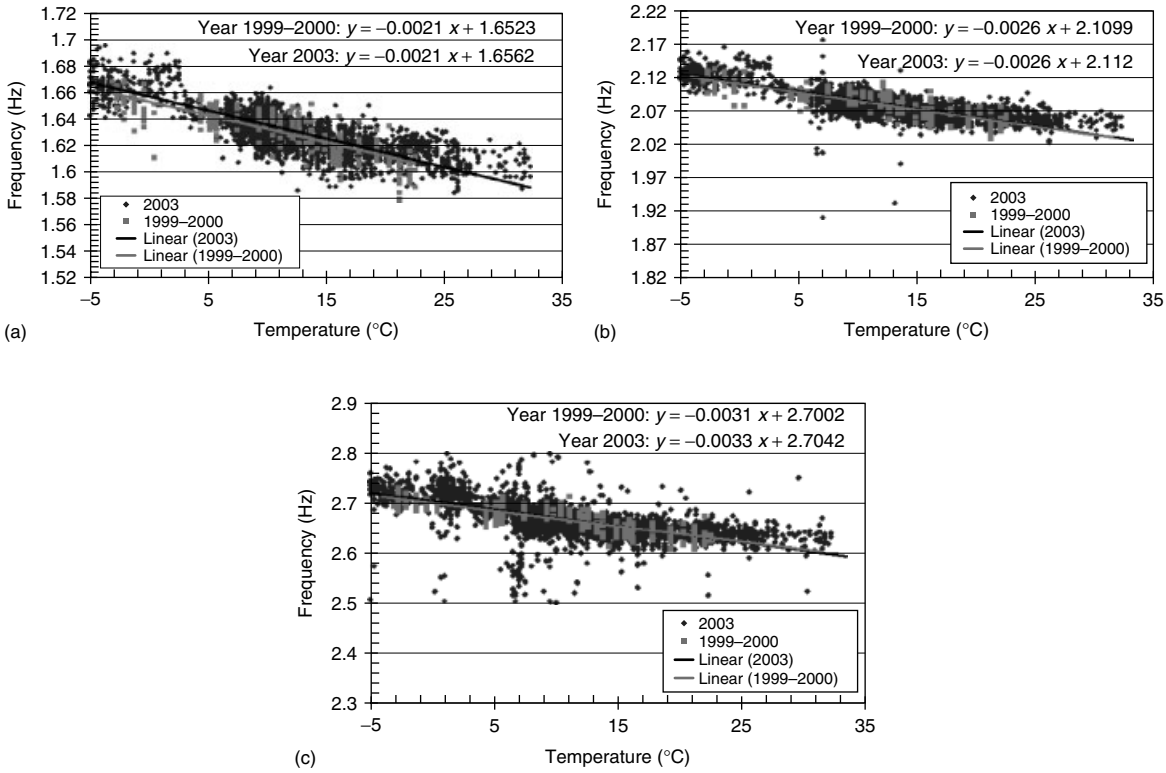

Figure 8. Relationship between temperature and first three modes; (a), (b), and (c) corresponding to mode 1, mode 2, and mode 3, respectively.

Figure 8 provides the temperature-related regression curves and parameters of the first three modes from 1999 to 2003. As shown in the figure, the changes in the first two modes due to the variation of 1 °C during 2003 are almost the same as the baseline (1999–2000). However, the analysis about mode 3 during year 2003 shows a little increase in the frequency change due to the unit temperature variation.

According to the theory of dynamic analysis, the changes in higher modes usually reflect the development of local damage. In order to verify the result of global health assessment and inspect the state of local damage, it is necessary to carry out the specific local health evaluation.

The raw data of COD are preprocessed in sensor substation and transferred into the database server via the Internet, as shown in Figure 9(a). Then, based on the hourly record of CODs, the application server will analyze these data to obtain their bootstrap distribution and confidence intervals. The result is shown in Figure 9(b).

In order to find out whether the shear cracks propagated during 2004, it is necessary to analyze the relationship between temperature and CODs, i.e., to find how much the COD will change due to a variation of 1 °C.

On the basis of the data of five years, the analysis result of CODs (A) is given in Figure 10 according to their locations. In five years, the CODs (B) excluding the temperature effect show some differences between the west web and the east web. As shown in the graph, on the west web, the total accumulated COD is about 120 μm. However, on the east web of SB2-N4, the corresponding COD is about 75 μm. Both values indicate accumulation of damage in terms of increases in COD. The difference between the west web and the east web is possibly due to the heavier traffic on the west side of the southbound bridge.

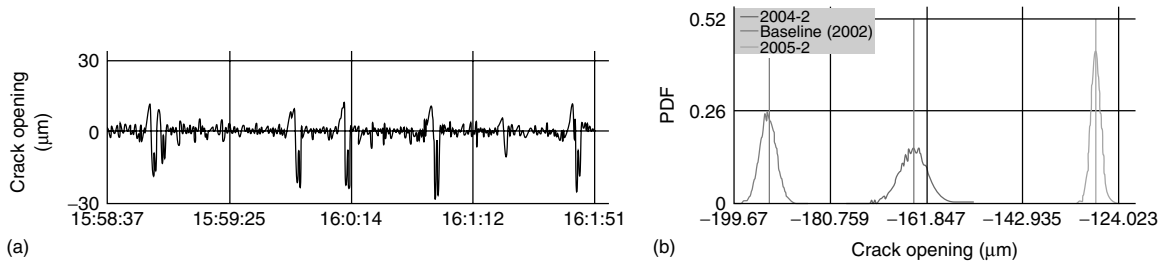

Figure 9. Preprocessing and postprocessing of crack opening displacement. (a) Real-time crack opening displacement and (b) bootstrap distribution of COD.

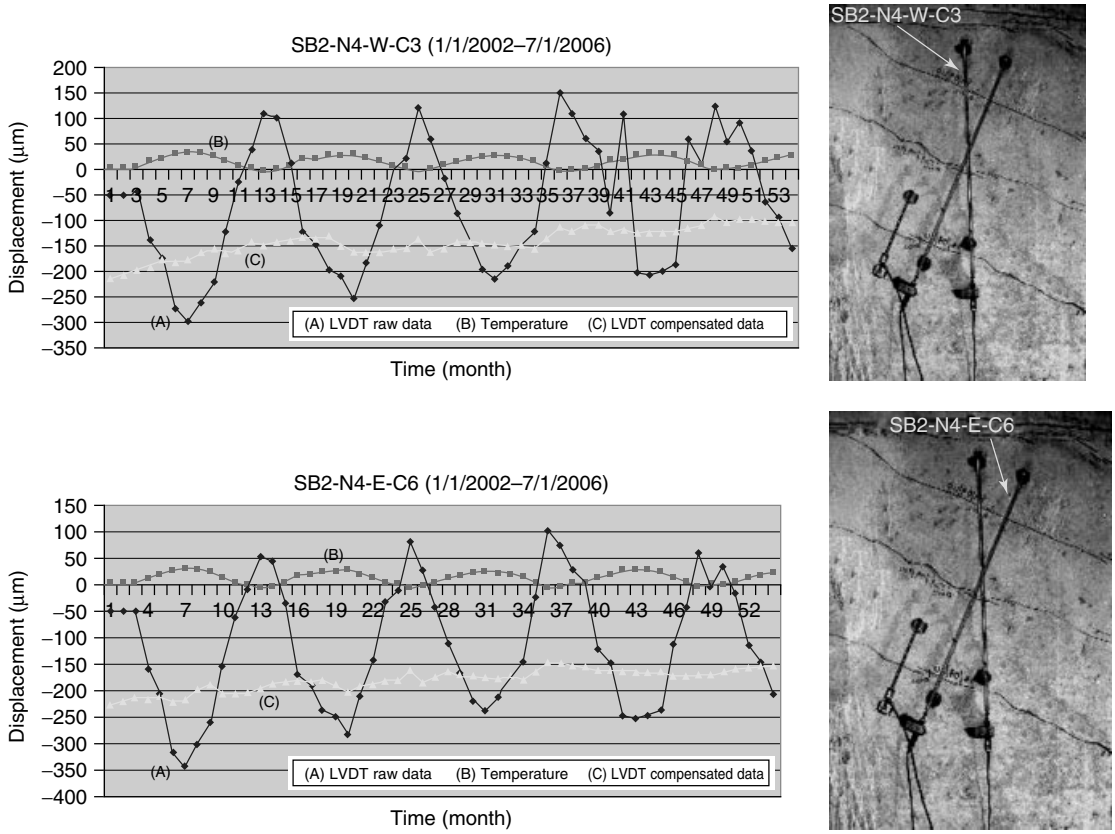

Figure 10. Relationship between crack opening displacement and temperature.

This result conforms to the visual inspection of Illinois Department of Transportation. According to the analysis on COD, we can evaluate the average shear strain of the cracking webs.

On the basis of the global and local measurements, the rule-based expert system gives the shear carrying capacity of the bridge with ductile mode of failure. Figure 11 presents the shear stress–shear strain curve of the cracked web at segment SB2-N4. As shown in the graph, the monthly maximum shear strain is over the baseline of the static load test in 2000. However, this value is still far below the yielding point. It indicates that the most damaged segment (SB2-N4) is still working in the nonlinear elastic zone.

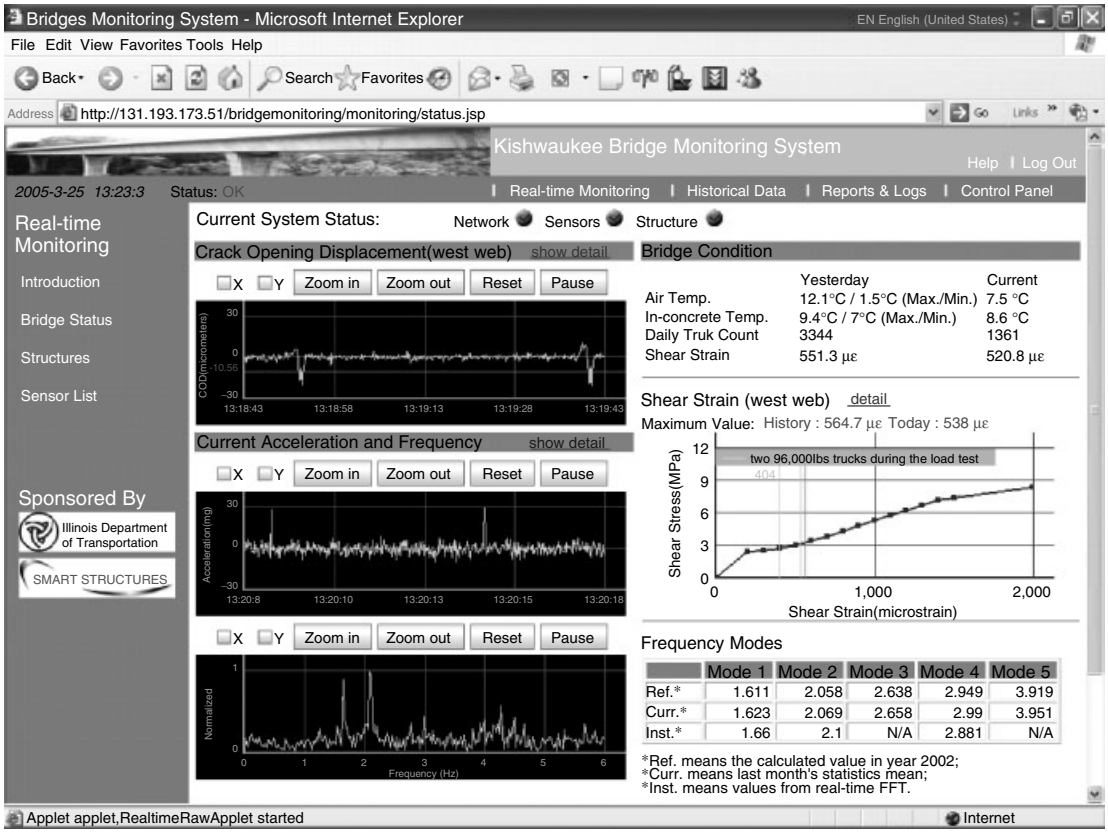

Figure 11. Main interface page.

2.5 Temperature effect

Measurements obtained from the monitoring system are available continuously and with greater precision; data studied in this article are given in Figure 12. The new data allow comparison with theory to better estimate characteristic thermal times and the effect of heat transfer on modal estimates. A reasonable 1-D model for transient heat conduction is given by equation (5),

$$\overline{T}(x,t) = \sum_{n=1}^{\infty} c_n(\beta_n) X(\beta_m, x) \mathrm{e}^{-Fo_n} \qquad (5)$$

where $\overline{T}$ is normalized temperature, $\beta_n = f(h,k)$ are the eigenvalues (with units of m^{-2}), Fo_n are Fourier numbers, c_n depends on a uniform initial condition of unity, and $X(\beta_m, x)$ are the eigenfunctions. Heat transfer at interior surfaces is neglected.

For long times (several hours), the sum is well approximated by the first term, $\overline{T} = c_1 X_1 \mathrm{e}^{-Fo_1}$ (with $c_1 X_1 \sim 1$–1.2 here). Transport properties of concrete were based on suggested values [26, 27]; the largest unknown is the heat transfer coefficient h, which was estimated from data when the free stream temperature, T_5, was nominally constant, as shown in Figure 13(c). Frequency variations for mode 1 and mode 3 are shown in Figures 13(a and b). A characteristic thermal time for a $1/e$ change to propagate through the thickness of the webs is then obtained from $Fo_n \sim \alpha\beta_1^2\tau \equiv 1 - e^{-1}$. For the case $h = 10$, $\tau = 14.2$ (h); for $h = 25$, $\tau = 8.4$ (h), corresponding times for average temperature, $\overline{T}_{\mathrm{avg}} = L^{-1}\int_0^L \overline{T}(x,t)\,\mathrm{d}x$, are 13.5 and 7.5 (h), respectively. The corresponding values of the Biot number $Bi = hL/k \sim 1$–5 together with τ indicate the presence of

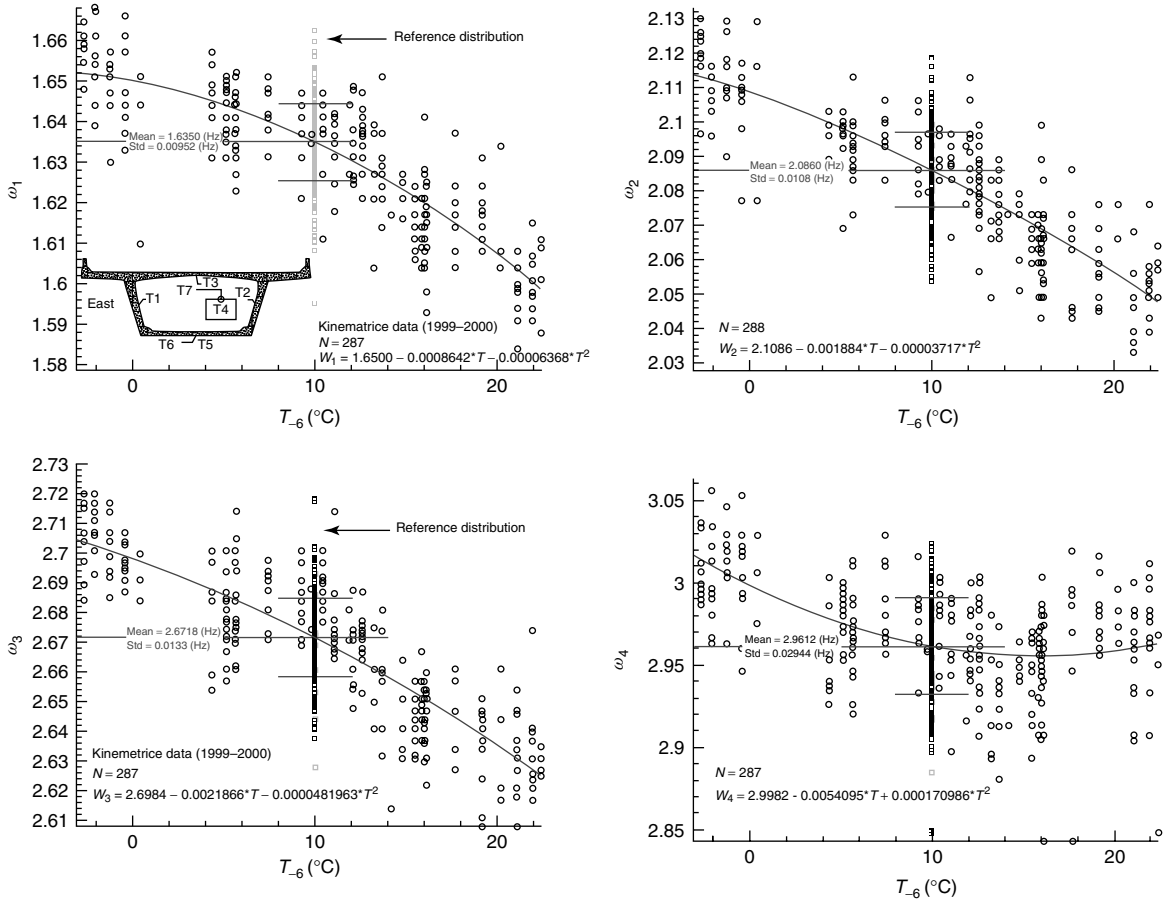

Figure 12. Open circles denote reference frequency data obtained from 1999 to 2000 for the Southbound Kishwaukee Bridge (primarily between 1600 and 2200 h). Deterministic temperature bias inferred from T_5 (delayed 5 h) was identified using least squares regression, and all frequency estimates were adjusted to a common reference temperature, $T_{\text{ref}} = 10(^{\circ}\text{C})$, according to the equation, $\omega_{i,\text{corr}} = \hat{\omega}_i(T_i) - [\hat{\omega}_i(T_i) - \omega(T_{\text{ref}})]$. (Open squares denote data obtained at 1600 h from 4 December 2003 through February 2004).

large thermal gradients and stresses [28]. The analysis and new data indicate that thermal equilibrium is rare for this structure.

2.6 Traffic effect

In this study, we have measured COD of shear crack in real time. The average COD subjected to a truck loading was about 25 μm as shown in Figure 9(a) of a real-time plot. The average COD due to temperature in a day was about 40 μm which is only about two to three times of the displacement due to traffic. In general, temperature effect could be 10 times more than the traffic effect if the member is free of damage [7]. However, it is difficult to separate the accumulation of damage that is due to traffic or temperature cycling. It is estimated that the average number of trucks passing daily is about 3000 using real-time data as shown in Figure 14. Figure 15(a, b) show the yearly COD cycles due to temperature.

Figure 15(c, d) are the estimated effects due to traffic. These are obtained by subtracting the temperature effect and permanent accumulation of damage due to fatigue as shown in Figure 16 from the original data as shown in Figure 17. We knew overall

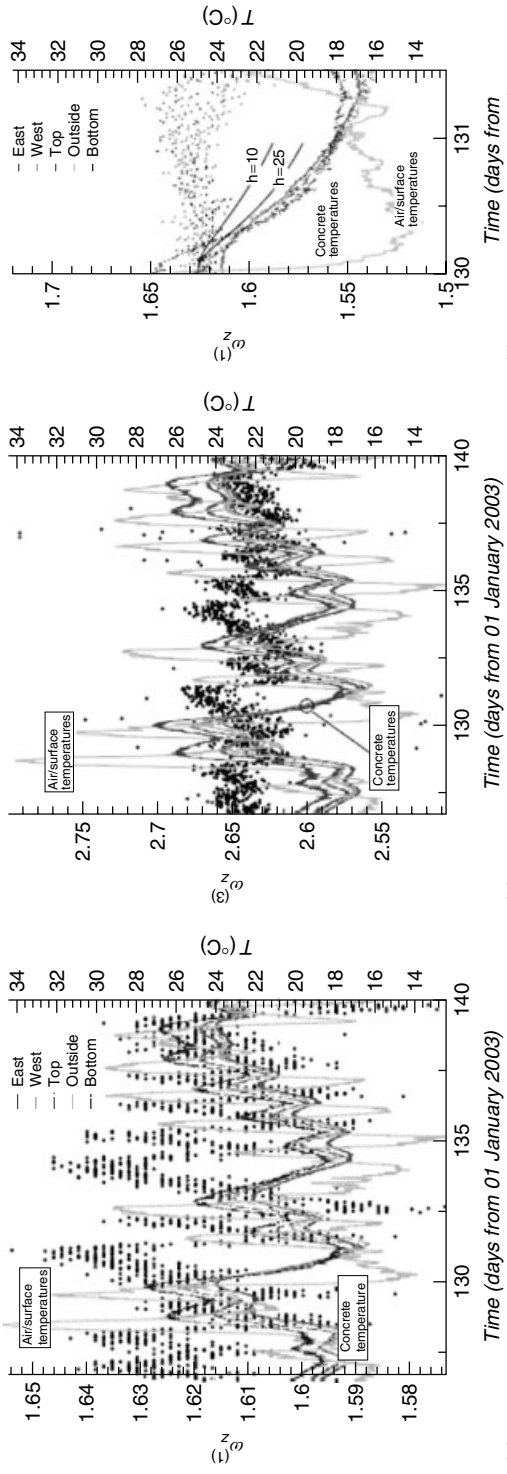

Figure 13. FFT estimates from May 2003: (a) time variation of $\omega_z^{(1)}$ and temperatures; (b) time variation of $\omega_z^{(3)}$; and (c) estimates of heat transfer coefficient based on concrete thermal properties $k = 3\,\mathrm{W\,m^{-1}\,K^{-1}}$, $\rho = 2242\,\mathrm{kg\,m^{-3}}$, and $c = 1000\,\mathrm{J\,kg^{-1}\,K^{-1}}$ [23].

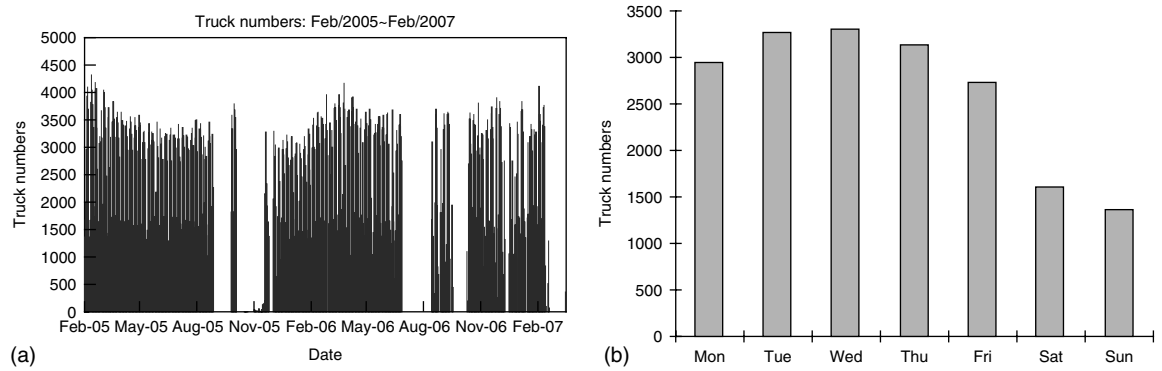

Figure 14. Average number of trucks in two years. (a) Passing daily and (b) average for each day of the week.

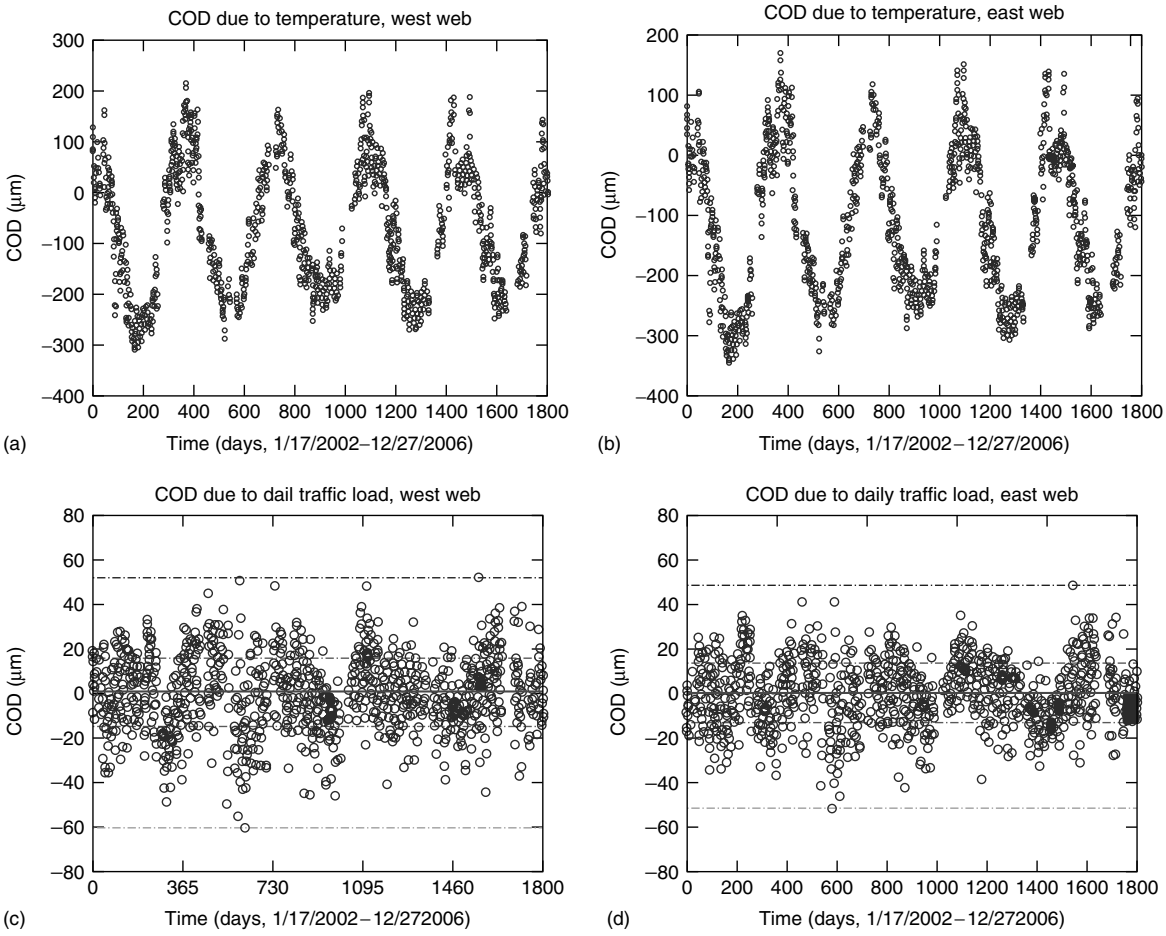

Figure 15. Crack opening displacement: due to temperature for west web (a) and for east web (b); and traffic load for west web (c) and for east web (d).

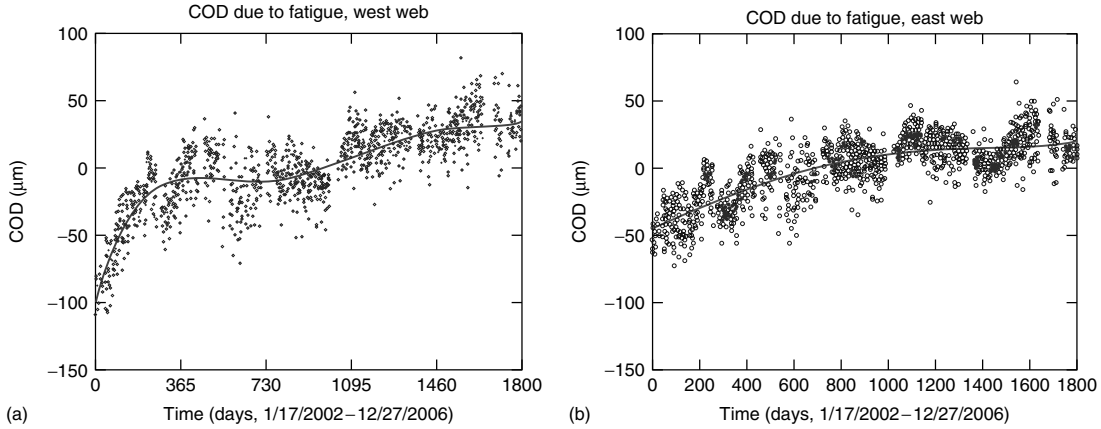

Figure 16. Crack opening displacement due to fatigue for west web (a) and east web (b).

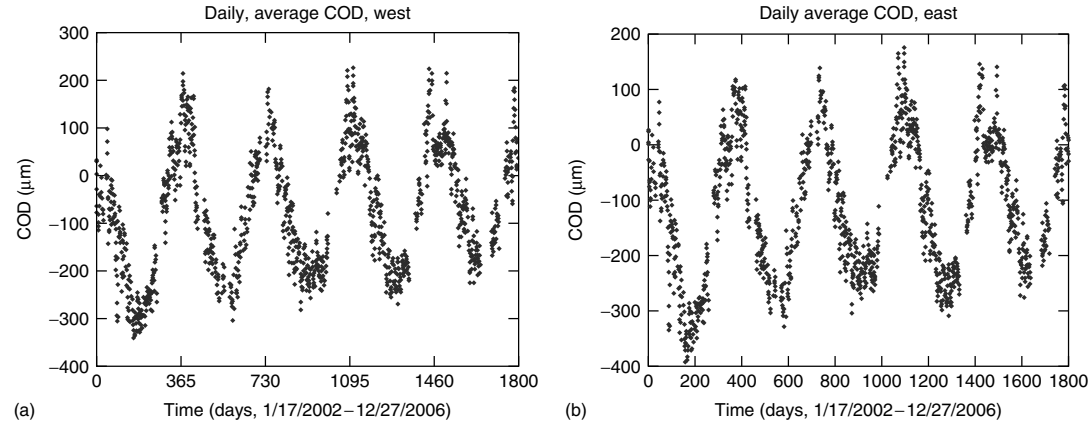

Figure 17. Crack opening displacement (raw data) for west web (a) and east web (b).

accumulation of damage in terms of COD is about 120 μm in five years from 2002 to 2006. Therefore, one can conclude, although temperature effect is about two to three times of traffic effects in terms of COD values, the accumulation of damage may be attributed mainly to truck loadings because of their sheer number of cycles over the years. Overweight trucks are usually cleared by State Highway Department. Unexpected loadings that produced very large COD are frequent. Upon inspection of all data gathered, it is seen that the cracks are active and progressing in a slow pace. Overall, the shear stiffness has reduced by 50%. However, bending stiffness and frequency have not shown the same trend and proportion. On the contrary, frequency has shown negligible effect from continuing local shear cracking.

3 CONCLUSION

A real-time bridge monitoring system includes a real-time data acquisition, a real-time data analysis, and a health reporting system. It should provide the current health status of the bridge in real time. It should be able to determine the current strength and resistant capacity of a structure. The key point is to use the minimum number of sensors to collect, process, and analyze the real-time dynamic and static data from the most critical positions of the bridge.

A large-scale real-time monitoring system can generate huge amount of data every day. The excessive information will overwhelm and decrease the productivity of the bridge engineers if there is no integrated program of data preprocessing and health

diagnosis in the monitoring system. All the real-time raw data shall be preprocessed in the bridge to increase the speed of data transmission, save the capacity of database, and improve the efficiency of health assessment.

The effect of the structure in terms of COD due to temperature is about two times the effect due to traffic loadings in terms of their daily magnitude. However, the accumulation of damage due to fatigue may be mainly attributed to traffic loadings because of the sheer numbers of cycle.

Automatic measurement should not be considered to be the be-all and end-all of bridge health monitoring. Its place is firmly entrenched in assisting engineers to conveniently carry out the damage detection, analysis, and evaluation of bridges. A retrofit mechanism was recommended for Kishwaukee Bridge. Retrofit is underway.

1 INTRODUCTION

It is a fundamental requirement of engineering structures and systems that they operate within limits specified by the environment in which they will be used. At the design stage, the loading of the structure is defined and appropriate material choices are made on the basis of their properties. Prototypes may be built and stringent experimental testing may be carried out. Because of limitations of the experiments and approximations made in any numerical models developed, a true picture of the behavior of a structure is not available until it is in service.

In the past, engineers designed ideal structures, i.e., making the assumption that at all points through the life cycle the structure was damage free. The design philosophy here is the *safe-life* philosophy. The assumption is that the structures or components in question have *no* margin for failure. The safe life of the structure is estimated and safety factors are applied to support the fatigue analysis. The safe operating life is "guaranteed" by selecting a large margin of safety. This overdesigned approach usually leads to high costs and/or poor performance, and structural failures are statistically still possible because of, among other things, unpredicted loads. With the pressure to introduce new lightweight structures, this concept is no longer valid and new design philosophies have emerged. One might consider a *fail-safe* approach, which allows for crack initiation in

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

individual components on the condition that the entire structure operates safely until the cracks are detected. This philosophy will lead to cost reductions and better performance, but will entail increased maintenance. Arguably, the most desirable approach to structural design is the *damage tolerant* approach [1]. This assumes that structural damage is inevitable. The damage size is estimated from load sequences and fracture mechanical models. The main assumption is that the damage location is known, damage initiation can be reliably detected, and the damage severity can be monitored. It is clear that this approach requires reliable monitoring methods. In response to this requirement, the discipline of structural health monitoring (SHM) has emerged.

In the field of condition monitoring (CM) of machinery, there has been a transition in the maintenance philosophies from *run-to-breakdown maintenance*, through *time-based maintenance* to *condition-based maintenance* over the years, and each of the steps has entailed more comprehensive monitoring capabilities.

All these points indicate the desirability of implementing a reliable monitoring strategy. The basis of this article is to establish the requirements for such a monitoring system and it is argued that this necessarily has to be an *intelligent* monitoring system. If intelligent monitoring systems are incorporated, then structures can be designed to operate at the margin of safety without extended periods of inspection, and in the case of components that are overdesigned, material costs would be significantly reduced.

Where the type of health monitoring described in the paragraphs above is in a sense "safety critical", i.e., life by monitoring with no margins, such systems are currently prohibited from incorporating "intelligence" by regulatory bodies (such as the UK Civil Aviation Authority (CAA) and the US Federal Aviation Authority (FAA)). It is not a simple matter to overcome such objections, but the potential benefits of doing so justify the effort. Having said this, there are substantial benefits to be obtained from monitoring that addresses noncritical failures, where monitoring is used to convert unplanned to planned maintenance. This falls outside the scope of the safety-critical regulations, which could greatly accelerate the acceptance of intelligent systems.

In devising an intelligent fault detection system, the primary consideration is an unambiguous definition of damage as a prerequisite to providing a unified approach to damage evaluation across all the engineering disciplines. This requires a taxonomy for the relevant concepts, i.e., a precise definition of what constitutes a fault, damage, and defect. A specification for operational evaluation is an essential feature; the proposed approach makes use of a hierarchical damage identification scheme. An approach to sensor prescription and optimization must also be defined; in the present article issues such as placement and validation are covered. Finally, a data-processing methodology is required—in the current approach, this is based on a data fusion model. Recently, it appeared possible to summarize much of the received wisdom from the field of SHM in a series of axioms [2]. These axioms encode much information, which may provide guidance in designing an effective monitoring system.

The purpose of this article is to set down all the issues involved in progressing to intelligent fault detection and to suggest an overall approach. The authors believe that a holistic approach is required for intelligent fault detection. The structure and the sensors must be treated as one, i.e., at the design stage, provision should be made for fault detection. The holistic approach can be implemented on existing structures, so the issues discussed in the article should not be regarded as only relevant to new structures. The basis of the holistic approach is that not only should the structure be monitored but so should the sensors; hence dealing with sensor failure is a primary concern.

2 TAXONOMY

To fully explore what is meant by intelligence in the context of SHM, first of all, it is imperative to define in an unambiguous manner exactly what constitutes damage and when a system is considered to no longer be operational. The following discussion establishes what the authors consider to be coherent and workable definitions of faults, damage, and defects:

- A *fault* is when the structure can no longer operate satisfactorily. If one defines the *quality* of a structure or system as its fitness for purpose or

its ability to meet customer or user requirements, it suffices to define a fault as a change in the system that produces an unacceptable reduction in quality.

- A *damage* is when the structure is no longer operating in its ideal condition, but can still function satisfactorily, i.e., in a suboptimal manner.
- A *defect* is inherent in the material, and, statistically, all materials contain some unknown amount of defects; this means that the structure can operate at its design condition if the constituent materials contain defects.

The above definitions allow a hierarchical relationship to be developed; i.e., defects lead to damage, and damage leads to faults. In the proposed approach, it is necessary to introduce monitoring systems to obtain a damage tolerant structure, so that it can be decided when the structure is no longer operating in a satisfactory manner. This means that a fault has to have a strict definition, e.g., the stiffness of the structure has deteriorated beyond a certain level. In some cases, a simple definition based on one parameter may not be sufficient. A good example of this is when a crack is propagating in a stable manner, there is an increase in strain in the component and hence a reduction in component stiffness. Once the strain has increased above a certain level, a decision may be made to take the component out of service. On inspection it may be observed that the crack is growing in such a direction that the component will fail safe, so service could have been prolonged. So along with a strain monitor, it would be useful to monitor the direction of crack growth. With this in mind, it is clear that the choice of the fault monitoring system needs to take into account the material type and the operating environment. This approach ensures that the quality of the measurement is optimized and hence an overarching issue is the limitations of the sensor. From the above, it can be seen that the question—*what is a fault*—is based on not only the structure's operating environment but also the type of monitoring system that is used.

Another consideration is the level of damage tolerance required. Some systems may not require any damage tolerance. An example of this is the crumple zones in a car; these are designed to fail on impact in order that the energy is absorbed by the structure and not the driver and passengers. There would be little point in monitoring these areas in a car and the crumple zones could be defined as *areas with infinite fault tolerance*.

Finally, a means of identifying procedural faults must be included in any intelligent fault monitoring system. If a structure is being incorrectly used, this may cause a fault; however, it is important to distinguish between this type of fault and the more general *systemic* fault. An example of a procedural fault would be mode of operation that increases the load beyond the design load for a limited period of time. The increase in load does not cause immediate failure, but significantly reduces the product life. A type of alarm system that triggers when the design loads are exceeded could be used; this would alert the operator that there is a problem and hence prevent a repeat of the incident and thus increase the product life. An alternative monitoring philosophy is in current use in the aircraft industry. Health and usage monitoring systems (HUMS) do not just consider overloads, but record or examine all loads and modify the remaining life in the light of usage.

3 INTELLIGENT FAULT DETECTION

The discussion can now proceed to matters of detection and how it can be achieved with intelligence. The first observation one might make is that fault detection is, in a sense, trivial, as a fault is defined as a change in the condition of the structure that produces an unacceptable reduction in quality. By implication, such a change will be evident. Thus, *intelligent* fault detection actually entails detecting the damage that will, if not corrected, lead to a fault.

Detection of damage is a facet of the broader problem of *damage awareness* or *damage identification.* The objective of a monitoring system must be to accumulate *sufficient* information about the damage for appropriate remedial action to be taken to restore the structure or system to high-quality operation or at least to ensure safety. Also, efficiency demands that only the *necessary* information should be returned by the monitor. With this in mind, it is helpful to think of the identification problem as a hierarchical structure, in the same way as one can think of the evolution of the fault as a hierarchical structure. This

train of thought began with Rytter in his PhD thesis [3]. The original specification cited four levels, but an additional one is given here—that of classification. The modified structure is

1. detection: the method gives a qualitative indication that damage might be present in the structure;
2. localization: the method gives information about the probable position of the damage;
3. classification: the method gives information about the type of damage;
4. assessment: the method gives an estimate of the extent of the damage;
5. prediction: the method offers information about the safety of the structure, e.g., estimates a residual life.

While the location of the classification step is arguable—some might put it before localisation—few would argue that the structure above summarizes the main issues in damage identification. The vertical structure is clear; each level largely requires that all lower-level information is available (with the proviso just mentioned). Note that the damage identification scheme should, if possible, be implemented on-line, i.e., during operation of the structure; in this case, prediction must also be understood as an estimate of the residual safe life of the structure obtained during operation. For an aircraft in flight, for example, this is critical. If the diagnostic system signals serious damage, but fails to indicate that there is time to land, the aircraft may be lost needlessly and at great expense, when the crew bail out.

Classification is added to the original scheme because it is important, if not vital, for effective identification at level 5 and possibly at level 4. Level 5 is distinguished from the others in that it cannot be accomplished without an understanding of the physics of the damage, i.e., characterization. Level 1 is also distinguished in the following sense—it can be accomplished with no prior knowledge of how the system will behave when damaged. To explain this, a slight digression on pattern recognition (PR) or machine learning is needed.

Many modern approaches to damage identification are based on the idea of *pattern recognition*. In the broadest sense, a PR algorithm is simply one that assigns to a sample of measured data a class label, usually from a finite set. In the case of damage identification, the measured data could be vibration mode shapes, full-field thermoelastic data, scattered wave profiles, etc. The appropriate class labels would encode damage type, location, etc. To carry out the higher levels of identification using PR, it is almost certainly necessary to construct examples of data corresponding to each class. That is, to establish that a given set of measurements from a composite panel shows the presence of a delamination, the algorithm must have prior knowledge of what data from a delaminated panel looks like as opposed to one with, say, a resin-rich area. Each possible fault class should usually have a *training set* of measurement vectors that are associated uniquely with it. Many PR algorithms work by *training* a diagnostic, for example, a neural network can learn by example; it is shown the measurement data and asked to produce the correct class label; if the result differs from the desired label, the network is corrected. Typically, many presentations of data are required. This type of learning algorithm in which the diagnostic is trained by showing it the desired label for each data set is called *supervised learning*.

If supervised learning is required, there will be serious demands associated with it; data from every conceivable damage situation should be available. The two possible sources of such data are computation or modeling, and experiment. Modeling presents problems if the structure or system of interest is geometrically or materially complex, for example, finite element (FE) analysis of structures requiring a fine mesh can be extremely time consuming even if the material is well understood. Structures with composite or viscoelastic elements may not even have accurate constitutive models. The damage itself may be difficult to model; it may also make the structure *dynamically* nonlinear, i.e., an opening–closing fatigue crack, which also presents a formidable problem. Unfortunately, the situation is no better for experiment. To accumulate enough training data, it would be necessary to make copies of the system of interest and damage it in all the ways that might occur naturally; for high-value structures like aircraft, this is simply not possible. This is arguably the main problem associated with data-driven approaches to SHM.

Fortunately, there is an alternative to supervised learning—*unsupervised learning*. However, this

mode of learning only applies to level 1 diagnostics, i.e., it can only be used for detection.

The techniques are often referred to as *novelty detection* or *anomaly detection* methods [4–6]. The idea of novelty detection is that only training data from the normal operating condition of the structure or system is used to establish the diagnostic. A model of normal condition is created; later, during monitoring, newly acquired data is compared with the model, and if there are any significant deviations, the algorithm indicates novelty. The implication is that the system has departed from normal condition, i.e., acquired damage. The advantage of such an approach is clear. If the training data is generated from a model, only the unfaulted condition is required, and this simplifies matters considerably. From an experimental point of view, there is no need to damage the structure of interest. Although novelty detection is only a level 1 approach, there are many situations where this suffices, i.e., safety-critical systems where any fault on the system would require it to be taken out of service.

It is an important qualifier that the novelty detectors should flag only *significant* deviations from normal operating condition. All real systems are subject to measurement noise and usually operate in a changing environment; the monitor must be able to distinguish between a statistical fluctuation in the data and a real deviation from normality. This means that of the various flavors of PR existing [7], the most appropriate one is *statistical pattern recognition* (SPR). Another important observation is that there may be variations in the normal condition that are not statistical, i.e., the characteristics of the structure may vary with changing environmental conditions, and this must be addressed. In general, it is important that the algorithms used for damage identification should account properly for sources of uncertainty and variation in the data. The algorithms should also, as far as possible, return a confidence interval with their diagnosis.

The term *normal operating condition* requires some discussion. As stated in the previous section, defects are always present in a structure to some extent. The normal operating condition therefore means a state of the system when there is some assurance, statistical or otherwise, that the system is fit for purpose. In some cases, there may be macroscopic damage, i.e., a fatigue crack; however, if it is known that the crack will not grow under, for example, the standard loadings on the system, the state qualifies as in a normal operating condition. Novelty detection will then look for new cracks or unexpected growth of the old crack.

The discussion above is intended to show that there is often a trade-off between the level of a diagnostic system and the expense of training it adequately. Given this fact, the main requirement of an *intelligent* fault detection system then is that it should return information at the apposite level for the context. It should measure the appropriate data and process this with the appropriate algorithm. It should take proper account of uncertainty in the data and return a confidence level in its diagnosis.

4 SENSOR ISSUES

4.1 Operational evaluation

The first demand of an intelligent fault detection system is that it should measure the appropriate data. This simple statement hides a multitude of problems. The holistic approach to fault identification requires that the diagnostic system should be carefully designed with the objectives in mind. This means that, at the very least, decisions must be made about the type of sensors to be used and the placement of those sensors. Before this, a preplanning or evaluation stage is desirable, like the *operational evaluation* stage defined by Farrar and Doebling [8]. This requires the architect of the monitoring system to first

- provide economic and/or life-safety justifications for performing the monitoring;
- define system-specific damage including types of damage and expected locations; e.g., failure modes effects analysis (FMEA) and failure modes effects and criticality analysis (FMECA) [9];
- define the operational and environmental conditions under which the system functions;
- define the limitations on data acquisition in the operational environment.

Each of these requirements can substantially support the design process. The second of the four raises two important issues. First, as observed in the previous section, a supervised learning scheme

for the diagnostic requires training data; to build a model or specify an experimental program to generate training data, one must specify the expected damage classes (type, severity, location, etc.). Secondly, given *a priori* information about likely damage locations, one can make an informed choice of whether to design for *local* or *global* monitoring, or a hybrid of the two. For example, if certain "hot spots" on a structure are identified as critical regions, they can be inspected using a high-resolution local method like active ultrasound, leaving the rest of the structure to be monitored using a less sensitive, but global, vibration-based method.

Environmental conditions must be considered when designing a monitoring system. Consider the novelty detection methods described in the last section; if the data used to characterize the normal operating condition does not span the whole range of operational and environmental conditions observed in practice, it is likely to signal novelty when a previously unseen condition occurs. The system then erroneously diagnoses a fault. Examples of systems where this occurs abound: an offshore structure changing its mass due to oil storage or marine fouling, an aircraft before and after dropping a store, and a bridge in a desert area undergoing substantial temperature changes as day changes to night.

There are likely to be obstructions to implementing the optimum monitoring system. This places constraints on the optimization problem for sensor placement. In situations where the monitoring system is needed for a preexisting structure, certain useful, if not critical, locations may be inaccessible. For a truly holistic approach to damage monitoring, the monitoring system should be designed as an integral part of the structure or system. In the case of control, a minimum requirement for the sensor system is to measure the current state of the plant during normal condition. This may be insufficient for fault detection as the deviations from normal condition may be orthogonal to the measured dimensions. It is clearly necessary, therefore, to anticipate this during the design process; FMEA may give sufficient guidance for expected faults.

If one is taking a unified approach to damage identification, where the problem may be to monitor a civil engineering structure, a machine, or a chemical process, one should add a further requirement to the operational evaluation stage:

- identify context-specific features and decide the appropriate level for monitoring.

This should be the first or second consideration.

4.2 Sensor placement

The most critical issue in the specification of a monitoring system is the type and location of the sensors; there can be no monitoring without the appropriate sensors. Specification of the type of sensors is arguably a matter of operational evaluation; knowledge of the expected damage types is valuable if not crucial there. Also the question of local versus global monitoring must be settled at this stage. The optimal positioning of the sensors is critical for true intelligence in monitoring. In principle, this problem can be solved using an optimization scheme; various approaches are discussed in **Sensor Placement Optimization** in this volume.

4.3 Sensor validation and failure safety

The holistic approach to health monitoring demands that the sensor network be an integral part of the structure or system. It immediately follows from this that damage to the system may manifest itself as damage to the sensor network. A fault in the sensor network—which must be regarded as a systemic fault—will have undesirable consequences, whether or not the integrity of the overall structure is compromised. A sensor failure that causes an unnecessary alarm may cause the system to be needlessly taken out of service. A sensor failure that causes a fault to go unnoticed may have severe cost or safety implications—the monitoring system might as well not be present. The implication of this argument is that the sensor network itself should be monitored. Redundancy or diversity should be built in, if necessary, to avoid the monitoring system itself making a significant contribution to fault reporting.

There are essentially two approaches to monitoring the sensors. First, the individual sensors can be self-monitoring. This is the approach taken by Henry and Clarke in the SEVA program [10]. This is currently only an option with larger sensors—the Coriolis mass flow meter described in the SEVA work can

accommodate a communications bus. The sensor is capable of self-diagnostics and also returns the on-line uncertainty of the measurements. The alternative for sensors like accelerometers, which cannot accommodate substantial electronics, is to allow the sensors to monitor each other as described, for example, by Kramers [11, 12]. The crucial feature of the latter approach is that the sensor outputs are correlated, i.e., there is *redundancy* in the sensor network. Kramers' approach not only allows the identification of errant sensors but also generates an approximate version of what the deviant sensor *should* read. The development of smart sensors like piezoceramics and piezopolymers also opens up possibilities. The ability of piezoelectrics to act as both sensors and actuators allows the possibility of active validation, i.e., each sensor, in turn, can act as a signal generator, and the consequent readings on the remaining sensors can be compared with a template to give a health report.

The question of redundancy has been raised. This should also be a requirement of an intelligent monitoring system. If a sensor is diagnosed as defective, the information that would have been delivered by the sensor should be available elsewhere. This issue should be considered during the design stage and made part of the sensor optimization. In the future, it may be possible to perform on-line reallocation of the sensors; at present, the only option is to include backup sensors. The simplest approach is to collocate sensors at critical points, but to keep only one active at a given time; redundant sensors are switched in when damage occurs to an active sensor. This approach is clearly suboptimal. Also certain causes of damage, e.g., impact, are likely to affect the collocated pairs. Another approach is to overdesign the sensor network in such a way that damage to a single sensor still leaves a network that is optimized for monitoring in some sense. This approach to fail-safe sensor optimization is discussed in [13, 14].

Finally, it must be stated that sensors alone do not suffice for any real level of damage identification. The one possible exception is for level 1, in situations where novelty detection amounts to exceedance of a sensor reading above a given threshold. In all other cases, some form of data processing is required; intelligent use of signal-processing algorithms is essential, and a principled strategy for this is discussed later.

5 DATA PROCESSING FOR DAMAGE IDENTIFICATION

Once the operational evaluation stage has passed and the sensor network has been designed, the health monitoring system can begin to deliver data. The choice and implementation of algorithms to process the data and carry out the identification is arguably the most crucial ingredient of an intelligent fault detection strategy. Before even choosing the algorithm, it is necessary to choose between two complementary approaches to the problem:

- damage identification is an inverse problem;
- damage identification is a PR problem.

The first approach usually adopts a model of the structure and tries to relate changes in measured data from the structure to changes in the model; sometimes, locally linearized models are used to simplify the analysis. The algorithms used are mainly based on linear algebra or optimization theory, and an excellent survey of the dominant methods can be found in [15] (*see* **Modal–Vibration-based Damage Identification**).

The second approach is based on the idea described in Section 3, whereby measured data from the system of interest are assigned a damage class by a PR algorithm. This is the approach that is chosen here for detailed discussion. There is no implied criticism of the inverse problem approach; the authors are simply concentrating on the framework with which they are most familiar. For a critical appraisal of inverse problem approaches to damage identification, the reader can refer to [16].

The data-processing element of a monitoring system consists of all actions on the data upstream from the point of acquisition by the sensors. The ultimate product of the analysis is a decision as to the health of the system. The analysis has been neatly summed up by Lowe [17] as the D2D (data to decision) process. The principled approach—the intelligent approach—to the D2D process is based on ideas of *data fusion* (*see* **Data Fusion of Multiple Signals from the Sensor Network**).

Sensor and data fusion as a research discipline in its own right emerged largely because of various defense

organizations attempting to formalize procedures for integrating information from disparate sources. There are many definitions of data fusion, but one of the first—which has endured—came from the North American Joint Directors of Laboratories, who were charged by the US military to establish a standard data fusion terminology [18]. Their definition of data fusion was as follows:

> A multilevel, multifaceted process dealing with the automatic detection, association, correlation, estimation, and combination of data from single and multiple sources.

The object of the exercise was to determine a battlefield situation and assess threat on the basis of data from various sources. The philosophy of data fusion was quickly recognized to have broader applications: initially in the fields of meteorology and traffic management, but later in the medical field and in nondestructive evaluation (NDE). The first models of the D2D process were couched exclusively in military terms, but as time wore on, a more general terminology was adopted. One of the first general models for data fusion was the *waterfall model* developed in DERA, the UK Defence Evaluation Research Agency [19]. It is no longer widely used; however, it suffices to illustrate the main stages of the D2D process. The model is illustrated in Figure 1.

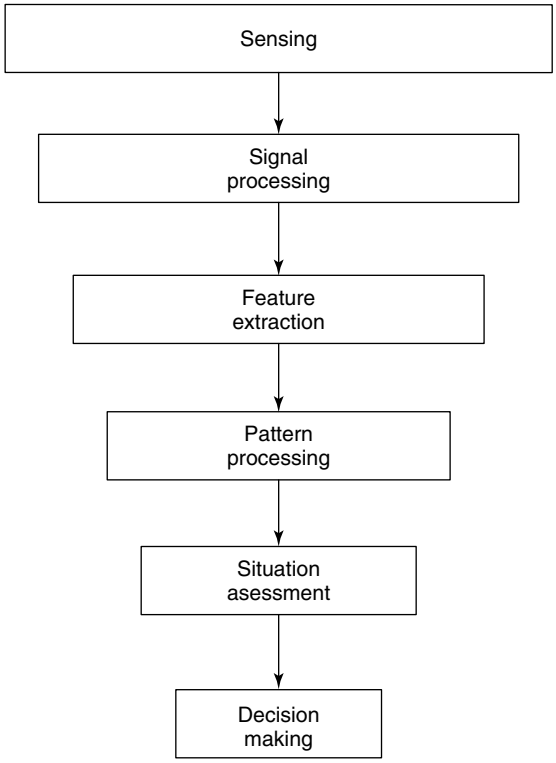

Figure 1. The waterfall model.

Apart from the situation assessment stage, which is an artifact of the old military terminology, all the important processing stages for SHM are present in the model.

Beyond the sensor level, which generates the raw data, the first stage is *signal processing*. This should more properly be called *preprocessing*. The purpose is to prepare the data for feature extraction, but this is dealt with in detail later. The preprocessing stage can encompass two tasks. The first of these is *data cleansing*. Examples of cleansing processes are filtering to remove noise, spike removal by median filtering, removal of outliers (care is needed here as the presence of outliers is one indication that the data is not from normal condition), and treatment of missing data values. The second (optional) preprocessing stage is a preliminary attempt to reduce the dimensions of the data vectors and further denoise the signal. For example, given a random time series with many points, it is often useful to convert the data to a spectrum by Fourier transformation. If the signal is divided into contiguous blocks before transformation and the resulting spectra are averaged, the number of points in the spectrum can be much lower than in the original time history and noise is averaged away. Another advantage of treating the time signal this way is that the data vector obtained should be independent of time. If the original time series is random, it makes little sense to compare measurements at different starting times. The preprocessing is usually carried out on the basis of engineering judgment and experience. At this stage, the aim would be to reduce the dimension of the data set from possibly many thousands to perhaps a hundred.

The second stage is *feature extraction*. The term *feature* comes from the PR literature and is short for *distinguishing feature*. Recall that the fundamental problem of PR is to assign a class label to a vector of measurements. This task is made simple if the data contains dominant features that distinguish it from data from other classes. In general, the components of the signal that distinguish the various damage classes

are hidden by features that characterize the normal operating condition of the structure, particularly when the damage is not yet severe. The task of feature extraction is to magnify the characteristics of the various damage classes and suppress the normal background. Suppose the raw data from the sensors is a time series of accelerations from the outside of a gearbox casing. Further, suppose that the time data has been preprocessed and converted into an averaged spectrum. Feature extraction, in this situation, could be extracting only the spectral lines at the meshing frequency and its harmonics, as these lines are known to be sensitive to damage. So feature extraction can be carried out on the basis of engineering judgment also. Alternatively, statistical or information theoretic algorithms like principal component analysis (PCA) can be used to reduce the dimension. The resulting low-dimensional data set is the *feature vector* or *pattern vector* the PR algorithm will use to assign a class. The aim of this stage would be to generate a feature vector of dimension less than 10. A low-dimensional feature vector is a critical element in any PR problem as the number of data examples needed for training grows explosively with the dimension of the problem. Care must be taken at this stage that the information discarded in the dimension reduction is not relevant for diagnosing the damage. Feature extraction should only discard components of the data that do not distinguish the different system states and thus concentrate the information about damage.

The next stage is *pattern processing*. This is the application of an algorithm that can decide the damage state on the basis of the given feature vector. An example would be a neural network that has been trained to return the damage type and severity when presented with say, condensed spectral information from a gearbox. Three types of algorithms can be distinguished depending on the desired diagnosis.

1. Novelty detection
As discussed earlier, the algorithm must simply indicate whether the data comes from normal operating condition. This is a two-class problem, which has the advantage that unsupervised learning can be used. Methods for novelty detection include outlier analysis [20], kernel density methods [5], autoassociative neural networks [21], Kohonen networks [22], growing radial basis function networks [23], and methods based on SPC control charts [24].

2. Classification
In this case, the output of the algorithm is a discrete class label. To apply such an algorithm, the damage states must be quantized, i.e., for location, the structure should be divided into labeled substructures. In this case, the algorithm could only locate to within a substructure, so resolution of what is essentially a continuous parameter may not be good unless many labels are used. However, this type of algorithm is useful in the sense that the algorithms can be trained to give the probability of class membership; this gives an inbuilt confidence factor in the diagnosis. In the case, where the desired diagnosis is from a discrete set, e.g., for diagnosing damage type, this class of algorithms are singled out. Examples of algorithms include neural network classifiers trained with the *1 of M* rule, linear and quadratic discriminant analysis, kernel discriminant analysis, and nearest neighbor classifiers. A comparison of some of these approaches on a damage classification problem is given in [25].

3. Regression
In this case, the output of the algorithm is one or more continuous variables. For location purposes, the diagnosis might be the Cartesian coordinates of the fault, and for severity assessment, it could be the length of a fatigue crack. The regression problem is often nonlinear and is particularly suited to neural networks. As in the classification case, it is often possible to recover a confidence interval for a neural network prediction [26].

In all cases, the pattern processing is subject to an important limitation. There is a trade-off between the resolution of the diagnosis and the noise rejection capabilities of the algorithm. Put simply, if the data is always noise-free, there will be very little fluctuation in the measurement from normal operating condition; in this case, small damages will cause detectable deviations. If there is much noise on the training data, it will be difficult to distinguish fluctuations due to noise and deviations due to damage, unless the damage is severe. One of the tasks of feature extraction is to eliminate, as far as possible, fluctuations on the normal condition data. This optimization for

performance is a requisite feature of intelligent fault detection.

The concepts of PR and machine learning have been applied in the framework of fault detection on many occasions. Detailed discussions can be found in this volume (*see* **Statistical Pattern Recognition**; **Machine Learning Techniques**; **Artificial Neural Networks**; **Novelty Detection**).

The final stage in the D2D chain for the waterfall model is the *decision*. This is a matter of considering the outputs of the PR algorithm and deciding whether action needs to be taken, and what that action should be.

The waterfall model is a fusion model in the sense that it allows for a sensor network with different types of sensors, all of which generate relevant information that can be fused together at the preprocessing or feature extraction stages. In general, fusion models also allow information to be combined at the pattern level or the decision level. The objective, at all times, is to reach a decision with higher confidence than can be reached using any of the information sources alone.

A better fusion paradigm than the waterfall model is the *omnibus* model. This is illustrated in Figure 2.

This has several advantages over the waterfall model. First of all, it includes the possibility of *action*. In the context of SHM, this could be repair. In the event of a sensor failure, this could entail the reallocation of sensors or the switching in of redundant sensors. The model has a loop structure

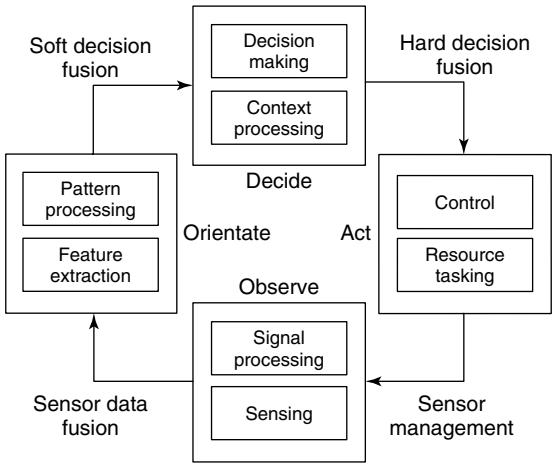

Figure 2. The Omnibus model for data fusion.

that makes clear the fact that action need not interrupt the monitoring process, but may enhance it.

6 THE AXIOMS OF SHM

On the basis of information published in the extensive amount of literature on SHM over the last 20 years [15, 27], the authors feel that the field has matured to the point where several fundamental axioms, or accepted general principles, have emerged. They are presented here in the spirit that they should guide the design and implementation of an SHM system. At the risk of repeating a little of the material discussed earlier, the axioms are discussed in some detail below. The material follows the discussion in [2] very closely. The said paper can be consulted for detailed case-study material relating to each axiom.

The word "axiom" is being used here in a slightly different way to that it is understood in the literature of mathematics and philosophy. The word "axiom" here is used to represent a fundamental truth at the root of any SHM methodology. However, the axioms are not sufficient to generate a given methodology. First of all, the authors are not suggesting that the axioms proposed here form a complete set; it is possible that there are other fundamental truths that have been omitted here. Secondly, the axioms here do not specify the "operators" for SHM; to generate a methodology from these axioms, it is necessary to add a group of algorithms that will carry the SHM practitioner from the data to a decision. It is the belief of the authors that these algorithms should be drawn from the discipline of SPR and algorithms of this type are used in the illustrations throughout this article.

The structure of the following discussion is simple: each of the following sections discusses the proposed axioms in turn.

Axiom 1. *All materials have inherent flaws or defects.*

Metals are never perfect single crystals with a perfect periodic lattice. Broberg [28] provides an excellent account of the inception and growth of microcracks and voids in the *process region* of a metal. In fiber-reinforced plastics (FRPs), defects can also occur at the macrostructural level because of voids produced in manufacturing. These defects compromise the

strength of the material, as coalescence of defects in extreme loading regimes will lead to macroscopic failure at the component level and subsequently at the system level. However, engineers have learned to overcome the design problems imposed by the inevitability of material imperfections by adopting design philosophies like those discussed in the introduction here.

In many engineering materials, the effects of nano-/microstructural level defects can be subsumed into the average material properties such as yield stress or fatigue limit and are not typically considered as "damage". However, in other circumstances, like in composite materials, this may not be the case, and the void content of the material should be regarded as initial "damage". There is no way (under dynamic load) of preventing damage evolution from voids and the associated degradation of the material properties.

As all materials contain imperfections or defects, the difficulty is to decide when a structure is "damaged". This is where the taxonomy of Section 2 comes into play. The strict definition of failure coupled with a monitoring system allows one to consider the concept of prognosis. Here prognosis means the prediction of the structure's future operational life given some assessment of its current condition and some prediction of its anticipated future operational environment.

Axiom 2. *The assessment of damage requires a comparison between two system states.*

This is possibly the most basic of the proposed axioms. It is necessary to state it explicitly as it is sometimes stated that some approach or other "does not require a baseline". It is argued here that this statement is simply never true, and any misunderstanding lies with the assumed meaning of "baseline". In the usual PR approaches to SHM, a training set is required. In the case of damage detection where novelty detection approaches can be applied, the training set is composed of samples of features that are representative of the normal condition of the system or structure of interest. For higher levels of diagnosis requiring estimates of damage location or severity, the training data must also contain samples of normal condition data, but also must be augmented with data samples corresponding to the various damage conditions. In this case, there is no argument that the normal condition data constitutes the "baseline". As discussed earlier, the basic level of damage identification is detection and this can be accomplished using novelty detection algorithms. All novelty detectors in current use rely on the acquisition of a normal condition training set; this includes autoassociative neural networks [21], probability density estimators [5], and, more recently, negative selection algorithms [29].

The necessity of Axiom 2 is not confined to damage detection methods based on PR, but it is also a requirement of the large class of algorithms based on linear algebraic methods. It is perhaps most obviously needed in the case of FE updating methods [30], a class of algorithms that have proved successful at the higher levels of damage identification, i.e., in the location and quantification of damage [31, 32]. The FE updating methodology is based on the construction of a high-fidelity FE model of the structure of interest in its normal condition. To assure that the model provides an accurate description of the virgin-state system, it is usually updated on the basis of experimental data, i.e., the parameters of the FE model (e.g., stiffness indices) are adjusted to bring it into closer correspondence with the experimental observations. The process of damage identification then proceeds by further updating the model on the basis of monitored data. Clearly, any further need for parameter adjustment will arise because the system has changed, and this change is assumed to be caused by damage. The particular elements adjusted will pinpoint the location of the damage and the size of the adjustment provides an estimate of the severity of the damage.

Several approaches claim to operate without a baseline data, which might be interpreted as implying that they do not to require a comparison of systems states. It is argued here that this is just a matter of terminology. One such method is the strain energy method of Stubbs and Kim [33]. This approach appears only to operate on data from the damaged structure. Roughly speaking, an estimate of the modal curvature is used to locate and size the damage. In fact, one might argue that there is an implicit baseline or model for this data on the assumption that the undamaged structure behaves as an Euler–Bernoulli beam. Also, the feature computed—the curvature—cannot be used without a threshold of significance, which is computed on the understanding that most of

the estimated curvature data comes from the rest of the structure that is undamaged.

The fact that damage detection algorithms require a comparison of system states is at the root of one of the main problems in SHM. If the normal condition or baseline state changes because of environmental or operational variations, the application of a novelty detection algorithm may yield a false-positive indication of damage. This issue is discussed in more detail when Axiom 4 is considered. The choice of baseline is one of the issues that may be addressed during the operational evaluation phase.

Axiom 3. *Identifying the existence and location of damage can be done in an unsupervised learning mode, but identifying the type of damage present and the damage severity can generally only be done in a supervised learning mode.*

The statistical model development aspect of SHM is concerned with the implementation of the algorithms that operate on the extracted damage-sensitive features to quantify the damage state of the structure. The algorithms used in statistical model development usually fall into three categories. When data is available from both the undamaged and damaged structure, the statistical PR algorithms fall into the general classification referred to as *supervised learning. Group classification* and *regression analysis* are categories of supervised learning algorithms and are generally associated with either discrete or continuous classification, respectively. *Unsupervised learning* refers to algorithms that are applied to data not containing examples from the damaged structure. *Outlier* or *novelty detection* is the primary class of algorithms applied in unsupervised learning applications. All of the algorithms analyze statistical distributions of the measured or derived features to enhance the damage detection process.

As previously discussed, the damage state of a system can be described in hierarchical terms as in Rytter's structure discussed in Section 3.

Answers to the questions posed in the damage identification hierarchy in the order presented represent increasing knowledge of the damage state. When applied in an unsupervised learning mode, statistical models can typically be used to answer questions regarding the existence and location of damage. As an example, if a damage-sensitive feature extracted from measured system response data exceeds some predetermined threshold, one can conclude that damage has occurred. This conclusion also must rely on the knowledge that the change in the feature has not been caused by operational or environmental variability. Many approaches to damage detection in rotating machinery, such as those that examine change in the kurtosis values of the acceleration amplitude response to identify bearing damage, are based on such outlier analysis [34]. Similarly, changes in features derived from relative information obtained from an array of sensors can be used to locate the damage as is done in many wave propagation approaches to SHM [35]. In general, these statistical procedures cannot distinguish between possible damage types or assess the severity of damage without additional information.

Axiom 4a. *Sensors cannot measure damage. Feature extraction through signal processing and statistical classification are necessary to convert sensor data into damage information.*

Sensors measure the response of a system to its operational and environmental input. Therefore, there is nothing surprising about the fact that sensors cannot *directly* measure damage. In a more basic context, it is similarly impossible to measure stress. The solution is to measure a quantity—the strain—from which one can infer the stress. (In fact, things are a little more indirect than this. The important point is that the sensor yields a value linearly proportional to the physical quantity of interest. Knowledge of the material properties then allows one to infer the stress from the strain measure.) In other words, the stress σ is a known function of the strain ε,

$$\sigma = f(\varepsilon) \tag{1}$$

In this case, the function f is known from observations of basic physics and is particularly simple. The situation is a little more complicated for damage. Suppose, for the sake of simplicity, that the damage state of a given system is captured by a scalar D. The first objective of damage identification is to measure some quantity, $\mathbf{x}$, usually vectorial (or alternatively—multivariate), which is a function of the damage state,

$$\mathbf{x} = \mathbf{f}(D) \tag{2}$$

The main difficulty for SHM is that the function **f** is generally not known from basic physics and must usually be *learned* from the data. The data in question may often be of high dimensionality such as a computed spectrum or a sampled wave profile.

The main problem associated with the machine learning or PR techniques used to learn the function in equation (2) is their difficulty in dealing with data vectors of high dimensionality. This limitation is sometimes termed the *curse of dimensionality*. If one considers methods depending on the availability of *training data*, The curse is simply that, to obtain accurate diagnostics, the amount of training data theoretically grows explosively with the dimension of the patterns [36].

From a pragmatic point of view, there are two solutions to the problem. The first is to obtain adequate training sets. Unfortunately, this will not be possible in many engineering situations, because of the limitations on the size and expense of testing programs. The second approach is to reduce the dimension of the data to a point where the available data is sufficient—this is the feature extraction discussed earlier. However, there is a vital caveat: the reduction or compression of the data must not remove the influence of the damage. (Also, one should be aware that if the high-dimensional features are insensitive to damage, no amount of dimension reduction will help.) This caveat means that the feature extraction must be tailored to the problem. This approach may be feature selection based on engineering judgment as in selecting the meshing harmonics from gearbox vibrations. More principled approaches to dimension reduction may be pursued, but care should be taken. For example, if one uses PCA one certainly obtains a reduced dimension feature; however, this vector is obtained using a criterion that may not preserve the information from damage.

Axiom 4b. *Without intelligent feature extraction, the more sensitive a measurement is to damage, the more sensitive it is to changing operational and environmental conditions.*

This section discusses what are called *intelligent feature extraction*. The concern being addressed here is that the features derived from measured data will not only depend on the damage state but may also depend on an environmental and/or operational variable. Temperature θ is used here for illustrative purposes. Equation (2) then becomes,

$$\mathbf{x} = \mathbf{g}(D, \theta) \tag{3}$$

The machine learning problem is complicated by the fact that one wants to learn the dependence on D, despite the fact that some of the variation in the measurand is likely to be caused by variation in θ. The problem of feature extraction is then to find a reduced dimension quantity that depends on the damage, but not the temperature.

An alternative approach to the problem posed in this section is to learn both the dependence on damage and the environment (D *and* θ). Note that as this learning problem is a mixed one, supervised learning is used to obtain the temperature dependency, but unsupervised learning is used to detect the damage. This approach is not considered here, but a discussion can be found in [37]. Finally, the simplest approach to the overall problem here would be to directly select features that are sensitive to damage, but not to environmental and operational variations. This is not easy, in general; an interesting example of this strategy in the context of wave propagation features can be found in [38].

Axiom 5. *The length and timescales associated with damage initiation and evolution dictate the required properties of the SHM sensing system.*

Axiom 1 introduced the concept of the length scales associated with damage and pointed out that defects are present in all materials beginning at the atomic length scale and spanning scales where component and system level faults are present. In terms of timescales, damage can accumulate incrementally over periods of time exceeding years, such as that associated with some types of fatigue or corrosion damage accumulation. Damage can also result on fraction-of-second timescales from scheduled discrete events such as aircraft landing impacts and from unscheduled discrete events such as blast loadings and natural phenomena hazards like earthquakes.

Axiom 4a states that a sensor cannot measure damage. Therefore, the goal of any SHM sensing system is to make the sensor reading as directly correlated with, and as sensitive to, damage as possible. At the same time, one also strives to make the

sensors as independent as possible from all other sources of environmental and operational variability. To best meet these goals for the SHM sensor and data-acquisition system, the following sensing system properties must be defined:

1. types of data to be acquired;
2. sensor types, number, and locations;
3. bandwidth, sensitivity, and dynamic range;
4. data acquisition/telemetry/storage system;
5. power requirements;
6. sampling intervals (continuous monitoring vs monitoring only after extreme events or at periodic intervals);
7. processor/memory requirements; and
8. excitation source (active sensing).

Fundamentally, there are five factors that control the selection of hardware to address these sensor system design parameters:

1. the length scales on which damage is to be detected;
2. the timescale on which damage evolves;
3. how varying and/or adverse operational and environmental conditions will affect the sensing system;
4. power availability; and
5. cost.

The development of a damage detection system for the composite wings of an unmanned aerial vehicle (UAV) can be used as an example. In one case, damage is assumed to be initiated by foreign object impact on the wing surface. Such damage is often very local in nature and may manifest itself on a length scale of the order of $10\,\mathrm{cm}^2$ or less. Accurate characterization of the impact phenomena occurs on a microsecond to millisecond timescale, which requires the data-acquisition system to have relatively high sampling rates (greater than 100 kHz). This damage may then grow to a fault after being subject to numerous fatigues cycles during many hours of subsequent flight. The timescales associated with the damage initiation and evolution influence sensing system properties 2–5 above.

This example clearly demonstrates that the length and timescales associated with damage initiation and evolution drive many of the SHM sensing system design parameters. *A priori* quantification of these length and timescales will allow the sensing system to be designed in an efficient manner.

Axiom 6. *There is a trade-off between the sensitivity to damage of an algorithm and its noise rejection capability.*

This axiom is self-evident in many ways. To detect small damage, a set of features combined with a PR algorithm must be very sensitive to the structure of the data. Under those circumstances, it is reasonable to assume that the presence of noise in the data would be likely to bias the results of the algorithm.

A pragmatic consequence of this axiom is that one should attempt to reduce the level of noise in the measured data or the subsequently extracted features as much as possible; this can be accomplished by many means including wavelet denoising, analog or digital filtering, or even simple averaging.

Axiom 7. *The size of damage that can be detected from changes in system dynamics is inversely proportional to the frequency range of excitation.*

In the field of ultrasonic nondestructive testing, the diffraction limit is often associated with the minimum size of flaw that can be detected as a function of ultrasonic wavelength. This limit may suggest that flaws of a size comparable with half a wavelength are detectable. The diffraction limit is actually a limit to the resolution of nearby scatterers, i.e., if two scatterers are separated by more than a half-wavelength of the incident wave, they will be separable. In fact, a flaw will scatter an incident wave for wavelengths below this limit and this amount of scattering decreases with increasing wavelength. This result means that, if instrumentation is available to detect arbitrarily small evidence of scattering, i.e., arbitrary small reflection coefficients, then arbitrarily small flaws can be detected. However, as described above, scattering is always substantial when the size of the flaw is comparable with the wavelength, and so it is advantageous to use small wavelengths to detect small flaws.

The wavelength λ is related to the wave phase velocity v and frequency f by

$$\lambda = \frac{v}{f} \tag{4}$$

From this simple relationship, it is clear that for constant velocity the wavelength will decrease as the frequency increases, which in turn implies that the damage sensitivity will increase.

Evidence for damage detection well below the diffraction limit for the size of the flaw can be found in numerous places in the literature, e.g., in [39] and [40].

The relationship between damage sensitivity and wavelength can be extended to more general types of vibration-based damage detection methods. In these applications, the wavelength of the elastic wave traveling through the material is replaced by the "wavelength" of the standing wave pattern set up in the structure, which is interpreted as a mode of vibration. The technical literature is replete with anecdotal evidence that such lower-frequency modes are not good indicators of local damage [15, 27]. The lower-frequency global modes of the structure that have long characteristic wavelengths tend to be insensitive to local damage. For the case of civil engineering infrastructure such as suspension bridges, these mode-shape wavelengths can be on the order of hundreds of meters [41], and flaws such as fatigue cracks that must be detected to assure safe operation of the structure are of the order of centimeters in length. Even if one allows for the fact that the cracks may have influence over a larger distance than the crack dimensions, this distance is still small compared to the mode-shape wavelengths.

The observations regarding the relationship between the characteristic wavelength and the flaw size have led research to explore other high-frequency active-sensing approaches to SHM. These methods are based on Lamb wave propagation [39], impedance measurements [42], high-frequency response functions, and time reversal acoustics [43]. In these applications, the excitation frequency can be as high as several hundred kilohertz and the corresponding wavelengths are on the order of millimeters. However, as the frequency increases and wavelength decreases, scattering effects (e.g., reflection of elastic waves off grain boundaries and other material interfaces) will eventually increase the noise in the measurements and place limits on the sensitivity of the damage detection process. Optimal frequency ranges for damage detection can be determined on the basis of the wavelength of the standing wave pattern and the condition that the damage is located in areas of high curvature associated with the deformation of the wave pattern.

Finally, there will generally be an increased energy requirement necessary to maintain a comparable amplitude excitation at the higher frequencies; this is because higher frequencies have higher attenuation. As a result, higher frequency excitation procedures are typically associated with more local damage detection procedures.

7 CHALLENGES AND BARRIERS TO SHM IMPLEMENTATION

The discussions of the previous sections have thrown light on various aspects of the design of SHM systems. However, one should recognize that there are still some significant barriers to the general implementation of damage identification systems. Some of these barriers are discussed in this section.

7.1 Structural monitoring versus structural health monitoring

Many sensor systems currently being deployed on real-world structures are actually structural monitoring systems as opposed to SHM systems. They are simply sparse arrays of sensors deployed with no definition of the damage to be detected and no definition of the methods for feature extraction and statistical classification that will be used to identify damage. Many bridge monitoring systems currently being deployed are examples of such systems that are often referred to as *SHM systems*. It is the authors' opinion that a true SHM system will have a quantified and predefined definition of the damage to be detected, as well as a predefined and validated approach to feature extraction and statistical classification of the features. Such a system would have performed false-positive studies where the chance of misclassification of damage has been quantified.

7.2 Local versus global damage detection

The need for quantitative global damage detection methods that can be applied to complex structures has led to the development of, and continued research

into, methods that examine changes in the vibration characteristics of the structure. The basic premise of vibration-based damage detection is that damage will alter the stiffness, mass, or energy dissipation properties of a system, which, in turn, will alter the measured global dynamic response properties of the system. Although the basis for vibration-based damage detection appears intuitive, its actual application poses many significant technical challenges [16]. The most fundamental challenge is the fact that damage is typically a local phenomenon and may not significantly influence the lower-frequency global response of a structure that is normally measured during vibration tests, particularly those where the response to ambient excitation is measured.

More recently, researchers have been studying hybrid multiscale sensing approaches to SHM [42]. Such approaches rely on active-sensing systems for local damage detection and then the same sensors are used in a passive mode to measure the influence of damage on the global system response. Here, the term *active* refers to systems where actuators are incorporated with the sensing system to provide a known input that is designed to enhance the damage detection process.

Fundamentally, there will always be a trade-off between the cost associated with deploying a local sensing system over a large area of the structure and the lack of fidelity associated with more global sensing systems. For most applications, some hybrid system will most likely be employed, which is based on *a priori* knowledge of specific areas on the structure that are most likely to experience damage, but such systems are still in the development and validation state.

7.3 Defining damage *a priori*

The success of any damage detection technique will be directly related to the ability to define the damage that is to be detected in as much detail as possible and in as quantifiable terms as possible. Here the definition of damage can include issues such as the type of damage to be detected (e.g., fatigue crack), the threshold level of damage that must be detected (e.g., 5-mm-long, through-thickness crack), the critical level of damage that produces failure or that will no longer allow for a planned safe shut down of the system (2-cm-long crack), locations where the particular type of damage accumulates in the structure (e.g., welded beam-to-column connections), and the tolerable or anticipated rate of damage growth.

In the examples cited above, the damage is quantified in terms directly related to the type of failure. There will be cases where the damage will be quantified in an indirect manner. As an example, damage may be defined as *delamination of a composite aircraft wing component*. The critical level may be defined as *an amount of damage that produces a certain change in the flutter characteristics of the aircraft*.

Because of the costs, system level testing to failure for the purpose of defining the damage to be detected is rarely done. Instead, these definitions are often based on prior observed behavior of damaged systems. Component level testing is a more cost-effective experimental approach that can also be used to develop such damage definitions. At other times, numerical simulations of the damaged system will be used to establish these definitions. Finally, there will be many cases where these definitions will be developed in an *ad hoc* manner based on the experience and intuition of people familiar with the equipment.

Large complex structural systems are usually made up of numerous components. Typically, there will be multiple damage mechanism that will be of concern. However, an SHM system that is optimal for detecting one type of damage may not be useful for detecting an alternate damage condition. Also, there will be cost limitations on the development and deployment of the SHM system. Therefore, it is imperative to define the various possible damage scenarios and to establish a priority for detecting damage associated with these scenarios. Such prioritization will be based on some study of the relative probability of occurrence associated with the various damage scenarios versus the consequences of the respective damage scenarios. With such a prioritization established, the SHM system can be designed to address the most critical damage concerns, which will make optimal use of a given SHM budget.

The definition of damage is the first step in identifying the required data-acquisition system capabilities, the candidate features to be extracted for damage detection, and the statistical models that are to be employed for the feature discrimination. To date,

many SHM studies suffer from taking the approach where the damage detection process is first developed and then the procedure is studied in an effort to define the damage that it can detect.

7.4 Defining the requisite sensing system properties

A significant challenge for SHM is to develop the capability to define the required sensing system properties before field deployment and, if possible, to demonstrate that the sensor system itself will not be damaged when deployed in the field. The first line of attack is clearly the establishment of an appropriate sensor network that can adequately observe the system dynamics for suitable signal processing and feature extraction. Sensor networks, generally speaking, contain three main components: the sensing unit itself, communications, and computation (hardware and, as appropriate, software control and processing algorithms).

As discussed earlier in relation to Axiom 5, the goal of any SHM sensor network system is to make the sensor reading as directly correlated with, and as sensitive to, damage as possible. At the same time, one also strives to make the sensors as independent as possible from all other sources of environmental and operational variability, and, in fact, independent from each other (in an information sense) to provide maximal data from minimal sensor array outlay. To best meet these requirements, various design parameters must be defined as in the first numbered list in discussion of Axiom 5 in Section 6. The five fundamental issues that control the selection of hardware to address these sensor system design parameters are also discussed in that section.

In addition, the feature extraction, data normalization, and statistical modeling portions of the process can greatly influence the definition of the sensing system properties. Before such decisions can be made, two important questions must be addressed. First, one must answer the question, "What is the damage to be detected?" (Section 7.3) Second, an answer must be provided to the question, "What are the environmental and operational sources of variability that must be taken into account?" To answer this question, one does not only have to have some ideas about the physical sources *per se*, but one also should have thought about how to accomplish data normalization. Typically, data normalization is accomplished through some combination of sensing system hardware and data interrogation software. However, these hardware and software approaches will not be optimal if they are not done in a coupled manner.

7.5 Accounting for operation and environmental variability

When deployed on a structure outside of a controlled laboratory setting, the damage detection process will have to deal with structures that experience changing operational and environmental conditions. These changing operational and environmental conditions will produce changes in the measured system response and it is imperative that these changes are not interpreted as indications of damage. Varying temperature and moisture levels are two common environmental conditions that must be accounted for during the damage detection process. Changing mass is a common operational variable that results from fuel usage and varying payloads. Running equipment or vehicles at varying speeds and through varying maneuvers are other operational parameters that can significantly influence kinematic quantities that are being measured as part of the damage detection process.

Often sensors will have to be added to monitor the changing operational and environmental conditions in an effort to develop a procedure that normalizes the data to remove trends caused by these effects. Also, the sensors themselves will have environmental and operational limitations under which they will function properly.

7.6 Need for long-term proof of concept studies

There are very few long-term SHM studies ongoing on real-world structures. These studies are difficult to perform because of costs and the rapid evolution of sensor technology. However, such studies are needed before structure owners and regulators will accept SHM as an acceptable means of condition-based maintenance. Research funding agencies will need

to feel that such studies are of merit. Without such studies, it will be difficult to develop the appropriate data normalization procedures that are needed to address the environmental and operational variability issues discussed in Section 7.5. To date, most SHM studies are performed in well-controlled laboratory settings.

7.7 Lack of data from damaged systems

As discussed in earlier sections, another fundamental challenge for SHM is that in many situations feature selection and damage detection must be performed in an unsupervised learning mode. That is, data from damaged systems is not available. Unsupervised approaches typically look for outliers from an established baseline condition and such changes can result from many things other than damage. Few system owners will allow engineers to damage their structure in an effort to validate a damage detection approach. Even if such studies were allowed, in almost all cases damage is introduced in an artificial manner and it is questionable if such "damage" is truly indicative of the actual damage that will be encountered in the field.

7.8 Time scales associated with damage evolution

Damage can accumulate over widely varying timescales, which poses significant challenges for the validation of SHM sensing systems in the field. In the case of civil engineering, infrastructure damage evolution can occur on timescales that are comparable to the career of the maintenance engineer. This challenge is supplemented by many practical issues associated with making accurate and repeatable measurements over long periods of time on complex structures often operating in adverse environments. There are few studies that have examined the long-term issues associated with the field deployment of such sensing systems.

7.9 Nontechnical issues

In addition to the challenges described above, there are other nontechnical issues that must be addressed before SHM technology can make the transition from a research topic to actual practice. These issues include convincing structural system owners that the SHM technology provides an economic benefit over their current maintenance approaches using quantified benefit–cost analyses and convincing regulatory agencies that this technology provides a significant life-safety benefit. In the case of intelligent damage detection systems, it will be necessary to overcome the current barriers to certification for safety-critical systems.

In general, the multidisciplinary nature of SHM system development makes it a more costly technology development to undertake. It requires people with diverse technical expertise and a significant amount of technology integration and validation. Such costs have to be quantified and addressed when performing initial benefit–cost studies for the SHM system development. These issues are coupled with short research time horizons in many industries, which are on the order of a 12–18-month time to market.

8 SUMMARY

In summary, assuming that this article has managed to convince the reader of the desirability of an intelligent monitoring system, the requirements for such a system are as follows:

- It should be designed from a holistic viewpoint, ideally at the design stage of the structure of interest. At the very least, an operational evaluation stage is necessary to establish the baseline requirements for and restrictions on the monitoring.
- The sensor distribution should be optimal. This means the smallest number giving the required resolution should be active at any given time. Note that the optimization may well be constrained. It should, for example, take account of inaccessible regions, and any upper limits on weight or power consumption. If failure safety is desired—and it should always be recommended—the distribution should include inactive units that can be switched on in the event of sensor failure. This implies that the sensors themselves should be monitored. This can be accomplished by using self-validating sensors or sensor

networks. Active and inactive units should be installed at the optimal locations.

- Data processing should be dictated by an optimal fusion model designed to give the most robust and confident decision process given the available sensor resolutions and confidences. Where possible, algorithms that are provably optimal should be employed.
- As far as the "axioms" discussed in this chapter are to be considered fundamental truths, they should be considered as valuable guidance in the design process, they give information on what is, and is not, feasible. The barriers to implementation discussed here are also to be considered in deciding what is feasible or, indeed, practical.
- If control is part of the system requirements, the actuator distribution should be optimal. The smallest number of actuators giving the required control actions should be employed and these should be located optimally.
- Feedback should be part of the process. If the decision process identifies an information gap and the system is capable of sensor/actuator redeployment, this should be implemented by whatever means available. This may be as simple as switching in inactive units, or could, in the future, entail physical movement of units.
- There should be a strategy for planning and implementing repair or replacement of the system or of subsystems. This may or may not go as far as specifying a backup system, depending on cost constraints.
- Monitoring should be as continuous as possible, with all levels of the D2D process updated as frequently as cost/technology constraints allow.

Some of these requirements are not currently within the reach of available technology. However, the purpose of this article has been, amongst other things, to specify a paradigm for intelligent fault detection. If the community considers that the pursuit of intelligent SHM systems is desirable, then many, if not all, of these requirements will be realized. However, the problem of global SHM is so significantly complex and diverse that it will not be solved in the immediate future. Like so many other technology fields, because of the issues discussed above and difficulties in surmounting them, advancements in SHM will most likely come in small increments over long periods of time.

Significant future developments of this technology will need to come by way of multidisciplinary research efforts encompassing fields such as structural dynamics, signal processing, motion and environmental sensing hardware, computational hardware, data telemetry, smart materials, and SPR, as well as other fields yet to be defined.

Chapter 83
Design Principles for Aerospace Structures

Jens Telgkamp
Structure Design Principles, Airbus, Hamburg, Germany

1 INTRODUCTION

SHM is a promising technology for application to metallic and composite structures. Current and future structures will benefit from the use of SHM in several ways. While the SHM system developers bring several technologies closer to maturity, the business case for the application is becoming clearer; a general development is that for newly developed aircraft it is becoming more and more important to integrate the idea of SHM in the early design phase: SHM will provide its full benefit only when it is incorporated at an early development stage, while only a part of this benefit will be available if the idea is introduced after the structural design is already fixed.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

2 AIRCRAFT STRUCTURE DESIGN—A MULTIDISCIPLINARY CHALLENGE

Aircraft structures have, since the beginning of powered flight more than 100 years ago, undergone tremendous development. To give an example of the enormous performance increase over that period, Figure 1 gives an overview of the relative aircraft weight (related to range and payload) of aircraft structures from 1920 to today, where each dot marks an

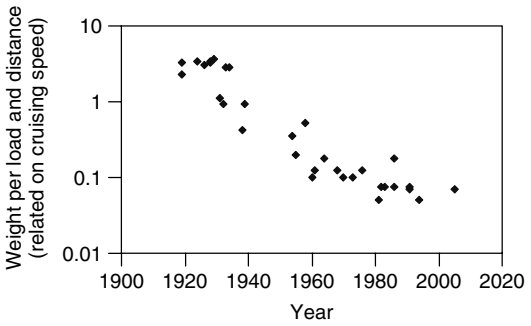

Figure 1. Relative weight of typical civil aircraft structure, from 1920 to today.

aircraft type typical of the relevant year's state of the art. Note that the scale is logarithmic, i.e., the structural performance has increased by a factor of roughly 100 over that time.

Up to current times, rapid development has continued wherein the market sets the development targets. Some general challenges are the requirements regarding

- range;
- size/capacity;
- cruising speed;
- cost (recurring/nonrecurring cost);
- need and responsibility to design environment-friendly aircraft.

However, these challenges partially contradict each other, so the ultimate challenge is to use the technologies and materials available to meet the best compromise to obtain the aircraft demanded by the market.

During the whole aircraft design process, the aircraft designers are influenced by a variety of factors. Some major factors are as follows:

- available materials and technologies;
- airworthiness regulations;
- environmental considerations;
- general aircraft requirements (mission profile, maintenance, operating cost, etc.);
- specific requirements for structural details;
- manufacturing capacities and capabilities;
- NDI (nondestructive inspection) and NDT (non destructive testing) capabilities, depending on the available mature technologies for NDI/NDT;
- design costs.

In aircraft design, there is an ongoing competition between metallic and nonmetallic materials, mainly composites. The composite materials have, during

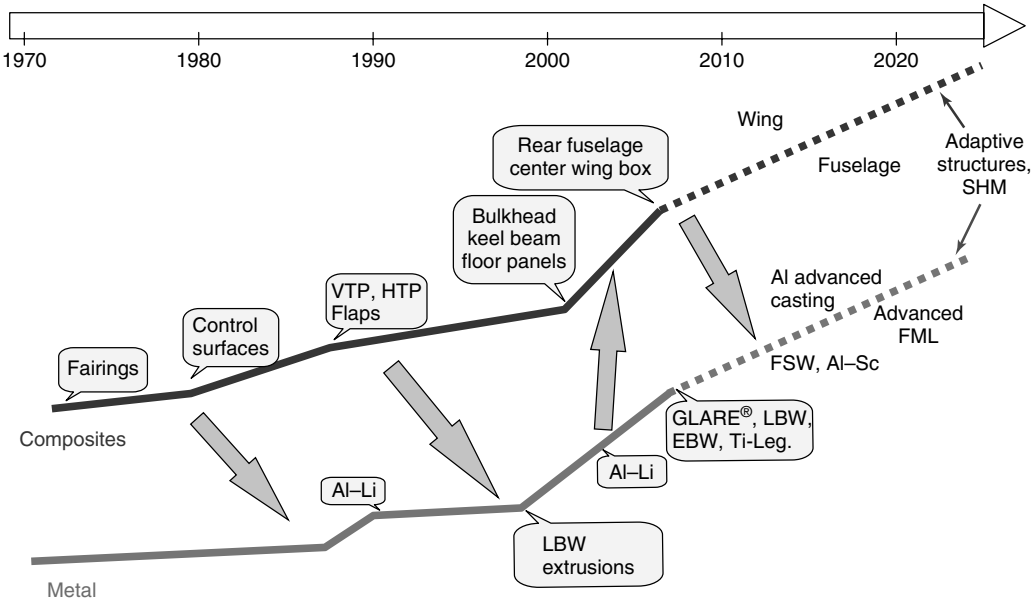

Figure 2. Application and technology introduction at Airbus for typical metallic and composite structures over time.

recent years, undergone a rapid development challenging the community developing metallic materials and new manufacturing processes for metals. Figure 2 displays some materials and technologies introduced by Airbus into their products from 1970 to today together with an anticipated technology extrapolation into the future. It is clear that the metallic and composite communities stimulate each other and the airframe manufacturer selects the best technology for the relevant aircraft under development.

In addition to the monolithic metallic materials and fiber–resin composite materials, fiber–metal laminates have also been used, for example, the GLARE® material on the Airbus A380, which combines some of the advantages of metallic designs (e.g., repairability, static behavior) with those of composite materials (e.g., tailoring of fiber layer orientations). The GLARE® fiber–metal laminate is a sandwich consisting of some thin aluminum sheets with fiber/prepreg layers in between. Figure 3 gives an overview of some of the main strengths and drawbacks of metallic materials, composites (here, carbon fiber reinforced plastics), and fiber–metal laminates.

Although aircraft designers continue to seek the technically best solution for each application, the general trend is in the direction of extended use of composites. Figure 4 displays the use of composites (relative to the overall structural weight of the aircraft) over the years in Airbus aircraft structures: from less than 10% in the Airbus A300 (first flight 1972) to over 50% in the A350 XWB, one of the designs currently under development at Airbus.

The choice of material for each structural application depends, of course, on the local loading and other design requirements at the location under consideration. To explain typical loading of the structure, an example is used: Figure 5 shows a stylized aircraft fuselage structure under in-flight and pressurization loading. The cylindrical barrel is a very strongly simplified model of an aircraft fuselage design (a typical design of real cylindrical fuselage structure is depicted in Figure 6). The pressurization causes tensile stresses in the fuselage skin in the circumferential as well as in the longitudinal directions. Additional mechanical load to the structure comes from the fuselage bending: The lifting force is introduced into the fuselage center at the location of the wing attachments—in the center of the fuselage. Gravity acts on the fuselage structure, causing down-bending in the forward as well as in the rear fuselage. On top of that, the resulting aerodynamic force acting on the horizontal tailplane (downward force in cruising condition) causes an additional down-bending of the rear fuselage.

Although this is only a simplified model of fuselage loading (and it takes into account only in-flight loading in cruising condition), it is clearly evident that different local loads put forth different challenges on the choice of materials and manufacturing technologies at the different locations: The upper shell is mainly characterized by biaxial tension load

	Strengths	Drawbacks
Metals (Al alloys)	• Standardization • Reparability • Static behavior • Improvement potential	• High density • Fatigue behavior • Corrosion behavior • High costs of new alloys
Composites (CFRP)	• Fatigue behavior • Low density • No corrosion • Best suited for smart structures	• Impact behavior • No "plasticity" • Reparability • Recycling
Fiber–metal laminates	• Improved fatigue • better tailoring • Higher fire resistance • Less corrosion (compared to Al alloys)	• Lower stiffness • Higher density (compared to CFRP) • Less industrialized process (compared to CFRP)

Figure 3. Main strengths and drawbacks of metallic, composite, and fiber–metal laminate structure.

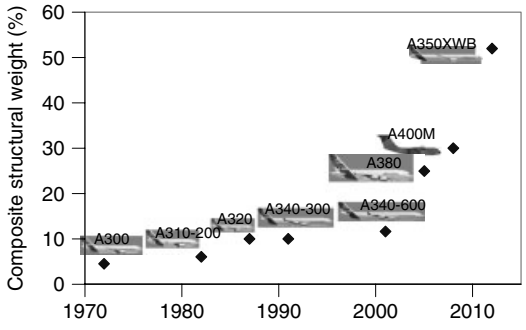

Figure 4. Composite structural weight fraction of Airbus aircraft programs over time.

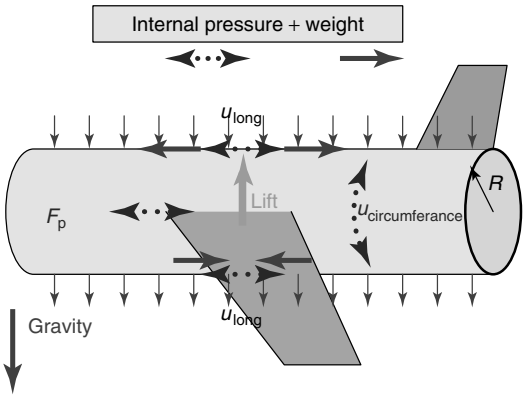

Figure 5. Simplified model of an aircraft fuselage structure in cruising condition with main loads coming from gravity and internal pressure.

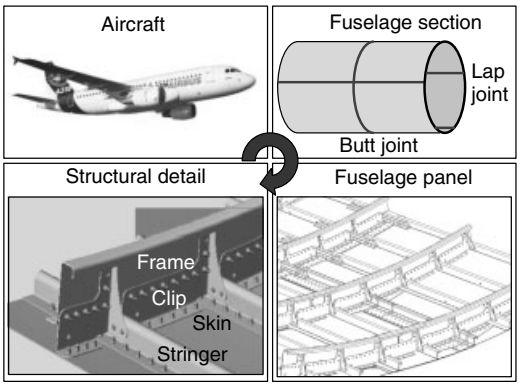

Figure 6. Aircraft fuselage structure in four different levels of detail.

(from pressurization and bending), while the lower shell areas are characterized by tensile loading in the circumferential direction (from pressurization) and compressive loading in the longitudinal direction (from fuselage bending). Therefore, the upper shell areas tend to be dimensioned by fatigue/crack growth, while the lower shell areas may be dimensioned, instead, by static stability.

It is once more emphasized that this example of fuselage bending and compression is an extremely simplified model, since it takes into account only one load case and a very simple structure modeling. However, it is obvious that in this simple model a number of areas with different local requirements of the materials and choice of tech can be identified. The final design and dimensioning has to take into account a variety of additional factors such as a long list of load cases, needs of system installation and passenger doors/windows, corrosion protection, repairability, inspectability, and many others.

Figure 7 displays a simplified Airbus A380 fuselage with colors/grayscales indicating dimensioning criteria. In the lower part of the same figure, the material choice for the fuselage is indicated, and shows some correlation to the dimensioning criteria: While the GLARE® and 2524 materials show good performance mainly in fatigue and crack-growth areas, the 6013 material has a high stiffness and therefore, exhibits good stability against buckling in the stiffened panels; the 7475 alloy shows strong static strength.

In summary, it is important to emphasize that aircraft structure design is a multidisciplinary challenge where aircraft top-level requirements, structure loading, and materials/technology selection influence each other [1, 2]. The final set of dimensioning criteria also dependent upon the material choice and only the right material/technology choice will finally deliver good structural performance. This article gives examples of how this performance can be further improved by integrating SHM technology into the structural design.

3 OVERVIEW OF POTENTIAL SHM APPLICATION TO AIRCRAFT STRUCTURE

This section gives an overview of possible ways to integrate SHM into the structure so that the operator of the aircraft will benefit from the technology. It

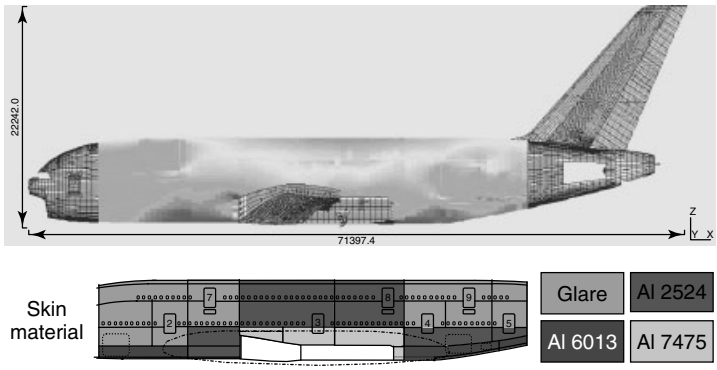

Figure 7. Schematic plot of dimensioning criteria for fuselage skin and material choice for the Airbus A380-800 aircraft.

is evident that for all these ideas the business case and the cost–performance trade-off have to be looked at in detail before taking any concrete decision for an individual aircraft application. However, some examples for potential applications are discussed.

3.1 Concepts for applying SHM to aircraft structure

Figure 8 gives an overview of some applications of SHM to aircraft structures.

According to this, the main benefits of SHM to aircraft structures can be subdivided as follows:

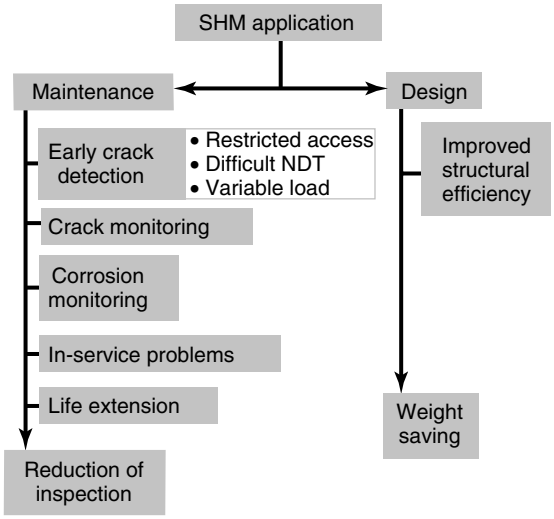

Figure 8. Different applications of SHM in civil aircraft structure.

- Applications related to maintenance
  - **Early crack detection**
    SHM can be used as an alternative to conventional NDI/NDT. This is especially beneficial either in areas where conventional inspection is very challenging and therefore, financially penalizing, or in areas of the structure where physical access to the area to be inspected is difficult.
  - **Damage monitoring**
    This means monitoring of known damage (cracks or delaminations) on individual aircraft. In this case, care must be taken in regard to the question of what it means, in practice, to operate a structure with a known flaw. In today's world (without SHM being used in series aircraft), it is the current policy not to operate aircraft with known flaws.
  - **Corrosion monitoring**
    Since all aircraft structures contain a certain percentage of metallic components, the possibility of corrosion development will always have to be taken into account in the aircraft design. In particular, the topic of galvanic corrosion needs to be looked at, since this type of corrosion is likely to develop in interfaces between metallic components and carbon fiber components. Therefore, Airbus is looking at technologies to monitor the metallic components in aircraft structure for corrosion. In the first generation, the application seems especially beneficial for "hot-spot"

areas, where possible corrosion issues have been identified in service.

– **In-service problems (mainly related to fatigue, damage tolerance)**
Sometimes, when a fleet of aircraft is already in operation, problems are detected either on in-service aircraft or on the full-scale fatigue test of the aircraft type (which, for civil transport aircraft, is normally not yet finished when the first aircraft enter into service). An example of this is given in Section 4.2.

– **Life extension**
Sometimes, in the case of aging aircraft fleet, the airframe manufacturer decides to certify and allow a longer service life than originally planned for the aircraft type. In some cases, SHM may help in future with this challenge. An example of this situation is discussed in Section 4.3.

- Applications related to design improvement
Generally, it is expected that including the use of SHM on a newly designed aircraft structure can be beneficial because it will help avoid design conservatism without compromising safety. Examples of this are given Section 5.

3.2 Some SHM technologies considered for potential application to aircraft structure

This section gives a compact overview of some of the technologies that are considered by Airbus. Airbus do not consider themselves as SHM technology developers, but they develop concepts for integrating SHM into their structure and therefore adapt commercially available technologies according to their needs.

Some technologies under investigation at Airbus are

- comparative vacuum method (CVM™);
- optical fiber sensors (mainly fiber Bragg gratings);
- Lamb waves (guided waves);
- foil piezoelectric (PVDF sensor);
- eddy-current foil sensors (ETFS);
- foil crack wire;
- acoustic emission.

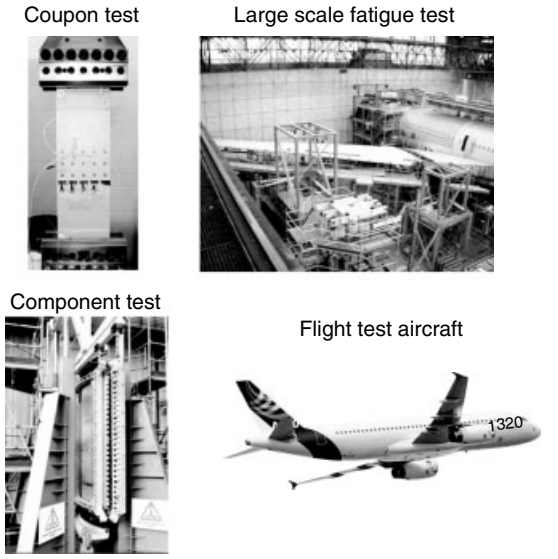

Figure 9. Four different levels of testing aircraft structure.

This list is not exhaustive, but only intended to give some examples. Details can be found in [3–5].

As already mentioned above, Airbus are not developing SHM technologies themselves, but they have to ensure there is enough practical experience with the individual SHM systems under consideration for use on aircraft. To do so, the technologies are being tested at various levels (Figure 9), such as

- coupon tests (small lab specimens);
- component tests (for example, shear/compression shells or curved panel tests);
- full-scale tests (full-scale static and fatigue tests as they are a part of a new aircraft structure certification);
- flight test aircraft.

4 IMPROVING AIRCRAFT STRUCTURE MAINTENANCE THROUGH USE OF SHM

4.1 Early crack detection in areas difficult to access or difficult to inspect

To ensure integrity and the safe operation of the aircraft structure, an inspection program is defined

for each individual aircraft type. Generally, these inspections are penalizing because of the following reasons:

- The inspections have to be performed by the operator (airline) of the structure, using their own resources and material.
- The inspection plan forces the operator to perform logistics to have each individual aircraft in the service routine at the appropriate time.
- During the inspection of an individual aircraft, this aircraft cannot be used for scheduled flights and does not give any benefit for the operators.

Analyses of individual maintenance examples have shown that the latter point is often the most penalizing one. The downtime due to inspection puts an economic burden on the operator, which is in many cases, is more penalizing to the operator than the cost of performing the maintenance action itself.

One example of an area that is difficult to access is the "frame feet" of a metallic fuselage structure. These are the areas where the frames are connected to the structure below (e.g., a center wing box fitting), as illustrated in Figure 10. If a scheduled inspection of this area turns out to be necessary, the inspection will be penalizing to the operator—even if the inspection itself is relatively simple. The main reason is that

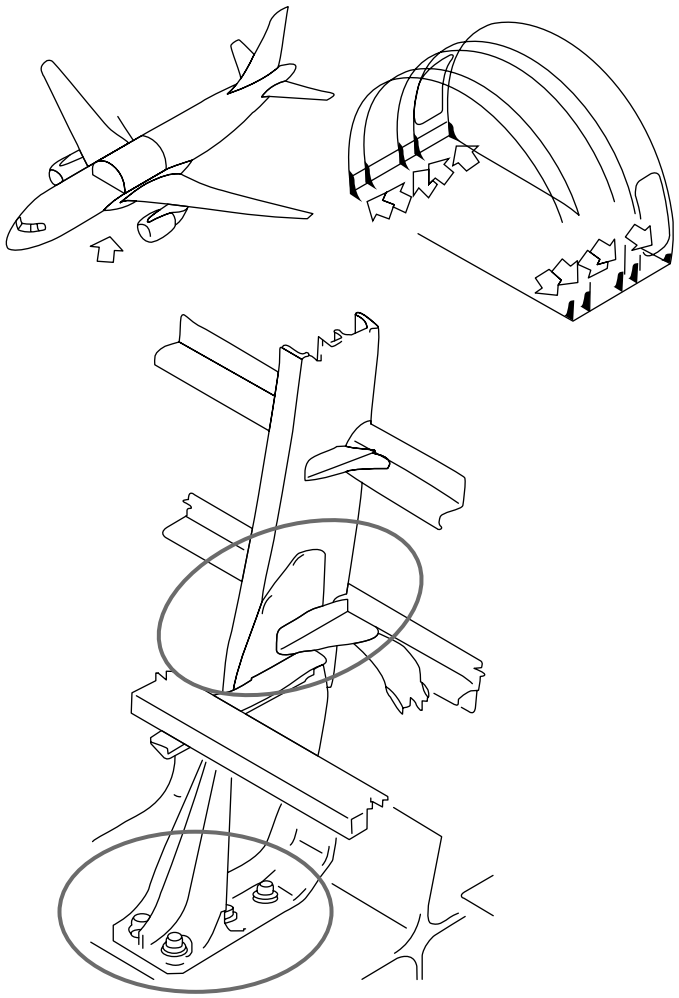

Figure 10. Connection of fuselage frames to center wing box.

the area under consideration is not easy to reach by an inspector to perform conventional NDI/NDT, and therefore significant effort and time are necessary to access the area. The result is additional work and, especially, additional downtime to perform the inspection. A suitable SHM-based solution would enable monitoring of the area without the need to access the area directly, because the sensors would be permanently installed on the structure.

An example of an area where the NDT inspection itself is difficult is illustrated in Figure 11: In a lap joint between a door panel and the surrounding fuselage structure panels, some signs of scratches were discovered. Since these scratches are possible sources of fatigue cracks, regular inspections of the area are necessary. However, the area is not easy to inspect with conventional inspection technologies because of the difficult local geometry. A suitable SHM solution would give the benefit of replacing the difficult (and therefore time-consuming and cost-intensive) inspection by an automated action.

The above-mentioned examples are only two possible benefits SHM may have when applied to structural areas, which are difficult to access or difficult to inspect. It is clear that a variety of different application cases can be defined and that each individual application will have to be investigated in regard to the benefit resulting from the SHM application, and also in regard to possible technologies to realize an SHM solution.

4.2 SHM application as a retrofit solution to in-service aircraft

This section is dedicated to the situation where a potential problem of an individual structural area is detected after a fleet of aircraft has already entered into service. This can happen in several ways. For example:

- A damage finding can occur on the full-scale fatigue test when some aircraft of the relevant type are already in service, since this test is, in most cases, not completely finished at the time when the scheduled service of the relevant aircraft type starts.
- A damage finding is identified on one or several aircraft of the in-service fleet.

In both cases, the question about the impact of the damage on the whole in-service fleet is immediately raised.

According to the state of the art, the damage is analyzed with regard to its impact and the result may be one of the following scenarios:

1. The operators have to modify the component on all in-service aircraft of the relevant type because a safe continued operation of the aircraft is no longer possible with the nonmodified structure.
2. The operators have to perform additional inspection actions on the relevant structural area for the whole fleet of that aircraft type, and for the whole remaining lifetime.

Sometimes, the operators are not forced to one of the two options above, but instead they are given the option to choose between them, i.e., each operator can choose between modifying all aircraft of the fleet or agreeing to an inspection plan for all aircraft.

Instead of modifying the structure immediately or agreeing to scheduled extra inspections, the operator may, in future, have the opportunity to decide on a third option with SHM: the maintenance workers have to get access to the structural area under consideration once to install the SHM technology. The inspections would then be carried out in an automated way by the SHM system, if necessary, for the whole remaining lifetime of the aircraft.

The main advantages of this option are as follows:

- The operator has to access the area only once: to install the SHM system. Further access for inspections will not be necessary since the system is locally installed and the inspection can be carried out without direct physical access.
- Also the downtime for the inspections is significantly reduced by using SHM inspection instead of conducting conventional inspections.

On the other hand, the business case is very dependent on the individual damage scenario examined. Normally, a probabilistic analysis needs to be carried out to calculate the probability that a significant part of the fleet will be affected by the damage, which was observed on one aircraft or on the full-scale test cell.

Figure 12 illustrates, in a simplified way, the comparison of cost between the classical options

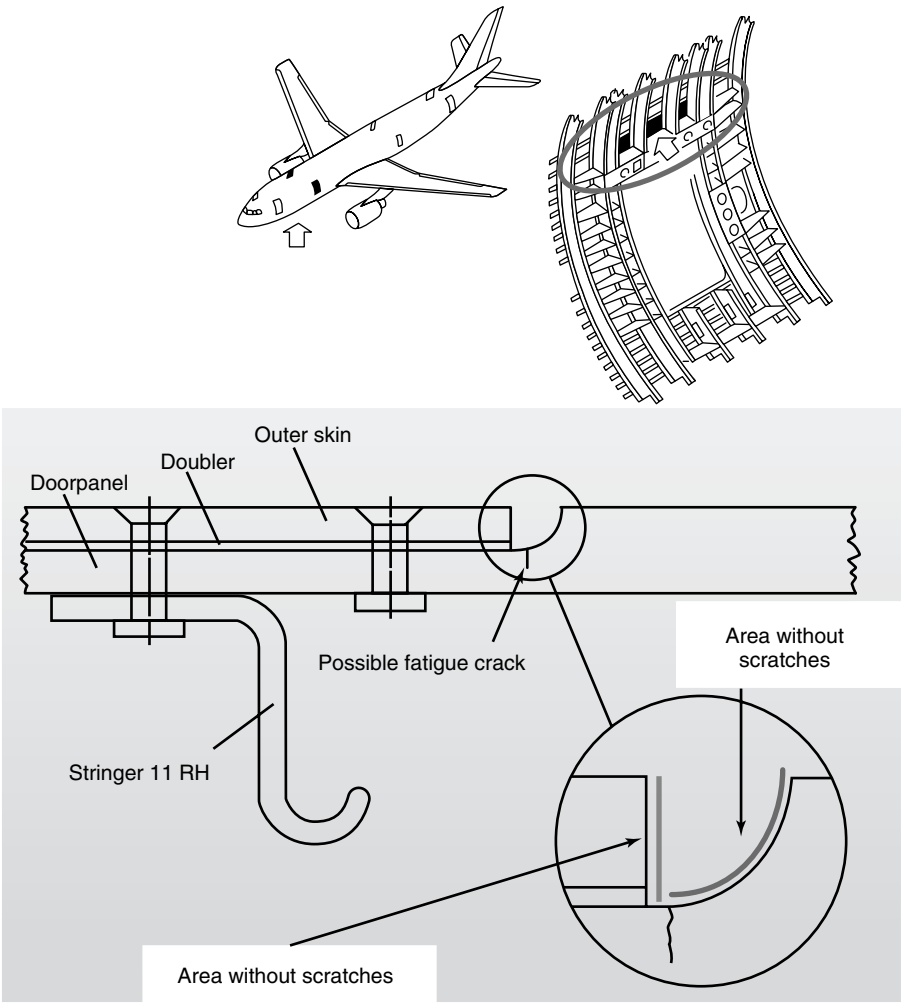

Figure 11. Chemically milled radius above a passenger door.

(structure modification or inspection requirements) on the one hand and the SHM alternative, on the other. In case of a conventional maintenance philosophy (without SHM), the aircraft manufacturer would either decide to have mandatory inspections for all fleet (case 1), or inspection requirements only (case 3), or a combination of both by giving the operator the freedom to chose (case 2).

- For mandatory modification, the cost for the operator is the cost for modification of the whole fleet, including additional cost for downtime, etc.
- In the case of inspection requirements, the costs for the operator are the cost for performing the scheduled extra inspections on the whole fleet. However, it may happen that some aircraft of the fleet will show a damage finding during the inspection. For these aircraft, the modification/repair has to be performed after the finding.

For the option using SHM in future, it is clear that the trade-off between the conventional solution and the SHM option depends strongly on the probability of the damage occurring on an aircraft during the service life. Therefore, probabilistic analysis is necessary before deciding on the business case for the application.

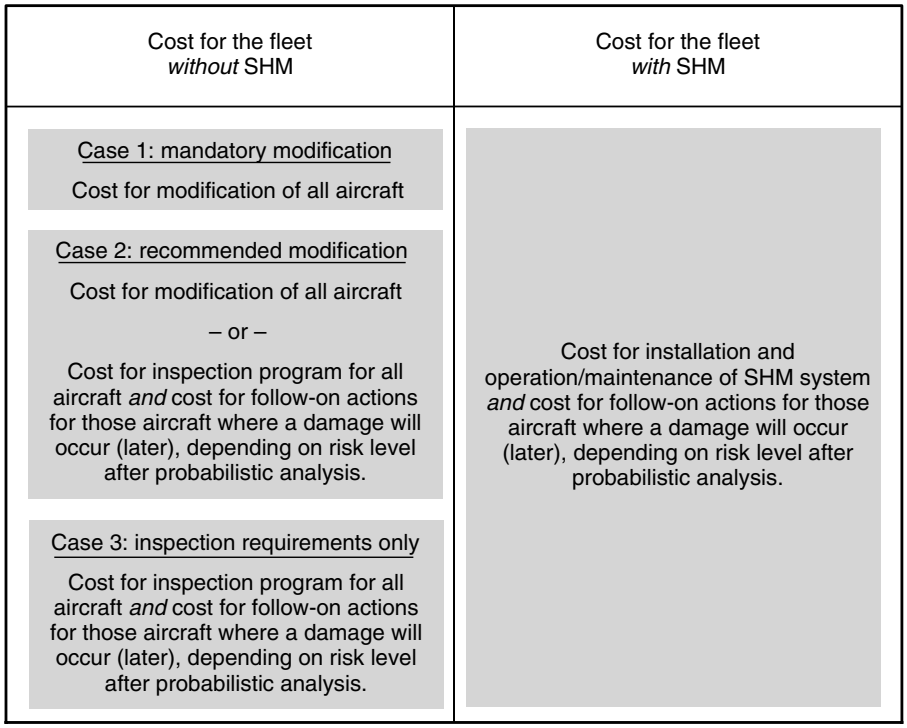

Figure 12. Cost comparison for in-service damages without and with SHM.

For example, if damage is found during a full-scale fatigue test, it is likely to happen after the design service goal of the aircraft, since the duration of a full-scale test is higher, e.g., 2.5 or 3.0 aircraft lifetimes. In that case, probabilistic analysis has to be carried out to identify how likely it is that the damage will occur on individual aircraft during the in-service life of one aircraft. This probability will indicate which fraction of an in-service fleet of aircraft will show the damage before reaching its design service life. If the damage is likely to occur on a significant fraction of the fleet, it may be more beneficial for the operator to decide for modification of the whole fleet at the beginning. If, however, the damage is expected to occur only on a small percent of the fleet, the operator may prefer to install the SHM system for monitoring the hot-spot area under consideration. The operator would then not be required to perform additional conventional inspections and the SHM (automated) inspections would not be penalizing to the operator. Only a small fraction of the fleet (if any) would show the damage later and only these aircraft would then need to be modified.

4.3 SHM application in aircraft life extension programs

It may happen that the aircraft manufacturer decides to operate an aircraft type that has proven to be reliable and robust for an extended service life i.e., for more flight cycles compared to what was planned when the aircraft was originally designed, certified, and entering into service. During the process of service life extension, the aircraft manufacturer has to demonstrate to the airworthiness authorities that the structure of the aircraft fleet can withstand the extended service goal. To do so, he has to demonstrate by calculations and/or tests that all components of the aircraft structure are sufficiently well designed to meet the extended requirements, for example, the "crack-growth" and "fatigue" requirements.

It may, of course, happen that some components do not have sufficient dimensioning reserves to withstand the new requirements, or at least cannot withstand them without additional inspections, modification, or component replacement. All of these options are clearly penalizing to the operator. As described in

the section above (application to in-service aircraft), it may be beneficial to include suitable SHM retrofit solutions to the structure. Again, the detailed business case for the SHM alternative depends strongly on the specific application under consideration and on the available SHM solution.

5 IMPROVING AIRCRAFT STRUCTURE DESIGN THROUGH USE OF SHM

This section is mainly dedicated to the possibility of improving aircraft design by using SHM. The idea is to exploit the aircraft structure in a more efficient way by having the benefit of knowing about the structure integrity throughout the service life rather than only during scheduled conventional inspections. In addition, structural information can be retrieved from areas that are not accessible with conventional NDT.

However, it must be clearly stated that this family of applications is complex: it requires suitable and very reliable SHM technologies and the certification of the optimized structure will depend on the SHM system. The certification of a structure, which has been weight optimized with the SHM benefit, would rely on the presence of permanent monitoring. In other words, the structure, in general, will not be allowed to operate without the SHM system.

5.1 General possibility of design improvements using SHM

The overall idea is to obtain a structural benefit from the use of SHM in the sense that some structural components may be sized in a less-conservative way compared to conventional design strategy but without compromising on safety. The design conservatisms mentioned before result from the fact that at present the operator performs scheduled inspections at rather large intervals, because very frequent inspections would be too penalizing. This has to be taken into account in the component's sizing in the sense that undetected damages between two inspections or growth of damages between two inspections have to be proved as not likely to turn into a dangerous scenario. This philosophy can, of course, be challenged if an automated inspection through SHM is performed permanently, or at least at small intervals compared to the conventional inspection. In any case, it is evident that the dimensioning of the component and the inspections performed are linked to each other.

The new philosophy would also fulfill the airworthiness requirements, but following a different strategy compared to that the conventional method. Therefore, the high level of safety can clearly be maintained.

An additional aspect comes from the fact that the dimensioning of the component will then only be valid as long as the SHM system is reliable and available throughout the whole structure service life. However, care must be taken not to penalize the aircraft operator by the new process of sizing and certifying the structure. For example, if the SHM system should fail during the aircraft operation, the operator should be able to continue operation for at least a fixed "grace period", so the operator can reach a hub or service center before he finally fixes the SHM system. Therefore, the justification has to show that no dangerous damages can grow even when operating the structure without SHM for a limited (and short) grace period.

These considerations put some strong requirements on the SHM systems considered for this application:

- The system has to find the relevant structural faults at extremely high mean time between failures (MTFB).
- For safety and certification reasons, it is clear that the system has to be equipped with self-diagnostic capabilities, i.e., the SHM system will give an indication if the system itself has a defect and cannot continue to ensure reliable monitoring.
- The system has to withstand a long lifetime, which has to be equal to or longer than the lifetime of the structure itself. Hence, the system has to be robust in the sense that environmental effects in service (including exposure to temperature differences, water, fuel, hydraulic fluids, etc.) should not compromise the reliability and durability of the system.
- False-positive indications have to be very rare, which means that only in very unlikely cases the SHM system will indicate a structural failure

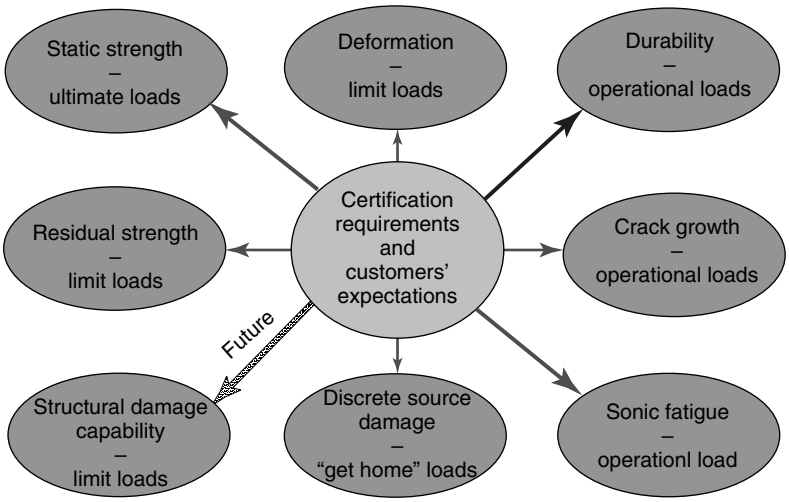

Figure 13. Main dimensioning criteria for aircraft metallic primary structure.

although the structure is intact. A false-positive indication would not compromise the safety of the structure, but it would force the operator to perform an additional conventional inspection to clarify the situation and therefore be a significant economic drawback on the operator.

Furthermore, it is clear that any application targeting a less-conservative dimensioning will have to be taken into account in the early design stages of the structure, in contrast to other applications, which may be also beneficial as retrofit solutions to existing aircraft [6, 7].

5.2 Example for metallic structure: monitoring stiffeners

During the design of aircraft structures, a wide range of aspects have to be considered to reach sufficient static strength, high durability, and excellent fatigue and damage-tolerance behavior. The end result of the iterative calculations is an optimized design regarding weight, costs, and aircraft performance. Figure 13 gives an overview of the major design criteria based on certification requirements and customers' expectations. These criteria and further aspects such as corrosion, repairability, and inspectability have to be applied to all structures and also to major modifications and repairs.

The fatigue and damage-tolerance regulations including the corresponding advisory circulars have to be met for certification. Fatigue and damage-tolerance analyses and complementary tests have to be performed for the whole primary structure to demonstrate high fatigue life, slow crack growth, and large damage capability for the structure. The major aspects of the fatigue and damage-tolerance regulation FAR 25.571 are summarized below:

- An evaluation of the structure has to show that a catastrophic failure due to fatigue, corrosion, or accidental damage, will be avoided throughout the operational life of the airplane.
- A structural inspection program has to be developed, considering probable damage locations, crack initiation mechanisms, crack-growth time histories, and crack detectability.

Figure 14 shows, in principle, the damage types to be considered during the fatigue and damage-tolerance analysis. Since the fuselage and wing structures for in-service aircraft are mainly externally inspected, the analysis assumes a skin crack above a broken internal stiffener, e.g., stringer or frame. Monitoring of the internal stiffener by SHM allows the application of a less-stringent crack scenario, i.e., the assumption of a skin crack above an intact stiffener. This leads to a reduced stress intensity delta K at the crack tips, which results in a slower crack growth and a longer critical crack length in the skin.

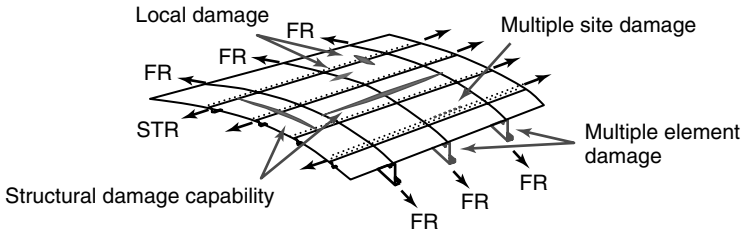

Figure 14. Damage types to be considered in fatigue and damage-tolerance justification.

The benefits due to SHM mentioned above exist in metallic areas dimensioned by damage tolerance, i.e., mainly by crack growth. The question of which areas of the structure are dimensioned by these criteria cannot be answered in a generalized way: the local dimensioning criteria for each structural area are dependent on the aircraft type, design criteria, mission profile, inspection program, and material. An example of aircraft structural area that is typically designed for damage tolerance/slow crack growth, are the skin panels in the upper metallic fuselage structure.

There are four different possibilities of SHM application at the fuselage structure:

- monitoring of stringers—to detect stringer cracks or failures;
- monitoring of frames—to detect frame cracks or failures;
- monitoring of skin—to detect circumferential skin cracks;
- monitoring of skin—to detect longitudinal skin cracks.

The idea discussed in this example is to challenge the "crack-growth" criterion for the aircraft fuselage skin by monitoring stiffeners (stringers and frames). Before going into detail, the principle of the crack-growth evaluation is briefly explained: The basic idea is that during the certification of a new airframe structure, the developers have to demonstrate to the certification authorities that any crack in the metallic structure growing during the operation of the aircraft will, in any case, be detected within the framework of the inspection program before it grows to a dangerous size. Figure 15 illustrates this principle: The calculated crack curve (crack length over number of flight cycles) is indicated, as well as the detectable and critical crack length. The aircraft manufacturer has to demonstrate that the crack-growth interval

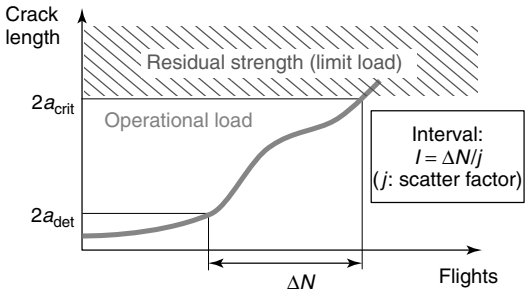

Figure 15. Schematic display of crack-growth calculation and determination of inspection interval.

from detectable to critical length is lower than the relevant inspection interval, divided by a scatter factor.

Figure 16 contains an example of an SHM application for the fuselage structure. It is assumed that the fuselage stringers are permanently monitored by SHM, whereby the skin is visually inspected from outside. The assumed crack scenario is the less-stringent damage scenario, i.e., a skin crack above an intact stringer. This crack scenario is compared with the traditional scenario, i.e., a skin crack above a broken stringer. The figure shows a significantly slower crack growth resulting from the application of SHM. The period over which the crack grows from $2a = 75\,\text{mm}$, which is detectable by general visual inspection, to the critical crack length is increased by a factor of roughly 2.5. This would either allow an increase in the intervals for general visual inspection of the skin by this factor or an increase in the allowable stress level by more than 15%. In analyses, it has turned out that for typical fuselage shells the calculated crack growth after a 15% stress increase with SHM still gives a better inspection interval than that reached without SHM and the original stress level in the skin. This significant improvement is not possible

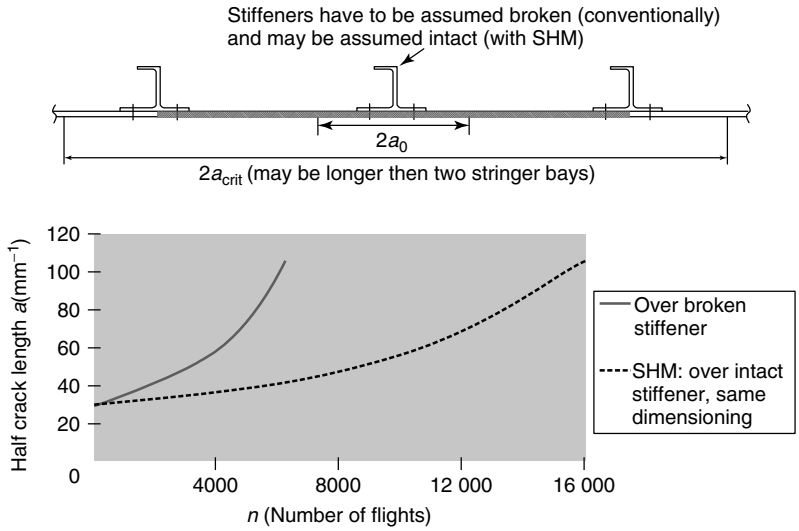

Figure 16. Calculated crack-growth curves for skin cracks, assuming broken or intact internal stiffeners (stringers).

for areas dimensioned by other design criteria, e.g., static strength. Every specific structural component has to be checked in detail for the extent to which a design/weight benefit would be possible by monitoring with an SHM system.

One example of a concept that integrates SHM technology into the structural design is presented here and is related to metallic components, e.g., stiffeners such as stringers or frames. A cavity is included into an extruded profile during the extrusion process. During operation of the component, this cavity is used to monitor the integrity of the component itself using the comparative vacuum monitoring (CVM™) method.

The CVM™ technology is based on the idea of maintaining a vacuum inside small cavities. The sensor consists of a foil or a film including the cavities and is applied to the structure in such a way that the structure surface forms a part of the cavity's boundary (Figure 17). A crack in the structure would now cause a leak in the vacuum, which can be detected by the relevant system attached to the sensor. Details can be found in **Comparative Vacuum Monitoring (CVM™)** and [4].

The Airbus VSI (Vacuum Sensor Integrated) concept takes advantage of the CVM™ principle. Figure 18 illustrates this idea. The cavities are included in the metallic component itself and are later connected to the relevant CVM™ technology (*see* **Comparative Vacuum Monitoring (CVM™)** and [4]). When a crack appears in the component (as indicated in the lower part of Figure 18) the leakage at the crossing points between cavities and crack will be detected.

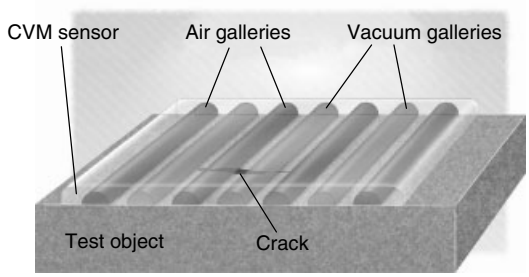

Figure 17. Basic principle of the CVM™ technology. [Reproduced with permission. © SMS Ltd.]

In the application described, the sensor and structural component are, in fact, one and the same part. This has two major advantages compared to conventional, surface-mounted sensors:

- The solution is very robust in the sense that the integration of the sensor (which is the cavity itself) into the profile makes it impossible to destroy the sensor without destroying the component itself. When using conventional surface-mounted sensors, care must be taken that the installation is robust to withstand roughly 30 years of service life (including humidity, temperature,

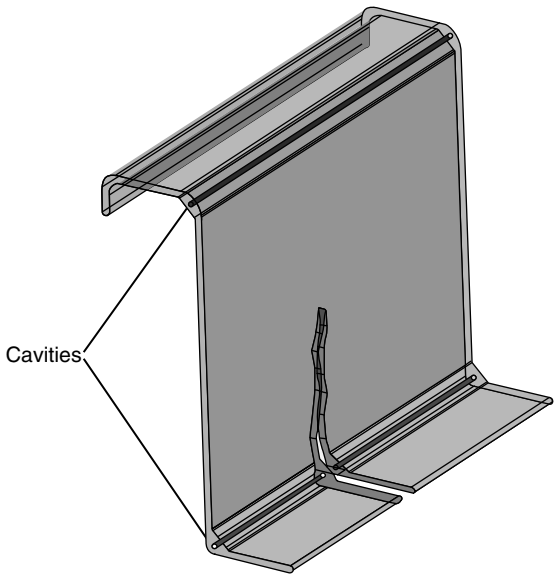

Figure 18. Schematic display of an extruded stiffening profile with integrated cavities for vacuum monitoring.

and hydraulic fluid exposure, workers stepping over the component, etc.).

- One of the main requirements for SHM systems is that the lifetime of the sensor must be at least as long as the lifetime of the structure that it is monitoring. Since the new component proposed here integrates the structural component and sensor, this requirement is always fulfilled by definition.

5.3 Example for composite structure: monitor for delaminations

In case of composite structures, some design conservatisms exist that may be challenged by using SHM technology without compromising on safety or reliability.

For example, composite structures are designed to withstand all required loads in a damaged status, as long as these damages cannot be easily found. If an internal delamination in a composite structure can exist in service, possibly because of an impact event on the component, the delamination will, often, not necessarily be found during operation. Consequently, the aircraft manufacturer has to design the whole structure to withstand the required loads in this damaged state. In general, this delamination damage could potentially exist anywhere on the structure.

If an SHM technology could be installed on the component guaranteeing to find delamination damage above a certain size, the structural dimensioning described could be challenged. The structure would be continuously monitored and could be designed to avoid the above-mentioned design conservatism, at least to a certain extent.

Figure 19 illustrates some of the damage types that can exist in composite structures, and can, above a certain size, be detected by conventional NDI methods such as ultrasonic inspection. When making the transition to SHM monitoring, instead of conventional inspections, the damage has to be detected by

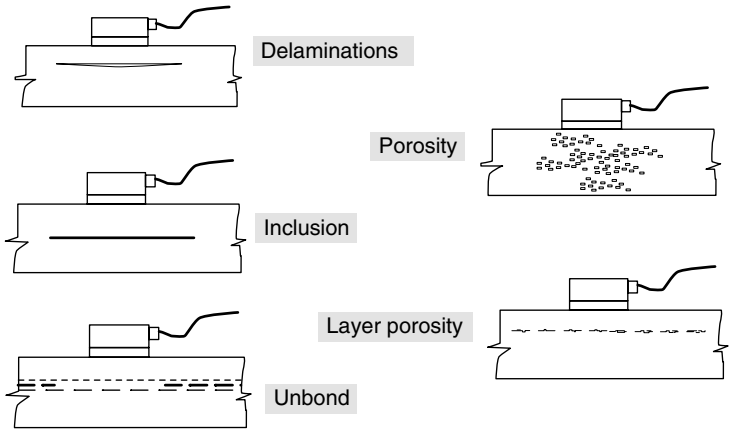

Figure 19. Different damages to be detected in a composite laminate.

suitable SHM technology. If the envisaged SHM solution is capable of finding even smaller cracks than what the conventional inspections can find, the benefit will be increased.

One method by which an SHM system can detect damage in composite laminates is to include sensing fibers (e.g., fiber Bragg gratings) into the laminate itself during manufacture (see [8, 9]). As in the example of metals above, the stringent requirements for the SHM system, such as reliability, lifetime, robustness, etc., also have to be fulfilled for this application. In addition, the repair aspect has to be considered as soon as the SHM system is embedded into the structural component itself instead of being applied on the surface. If the structural component is damaged and the damage is indicated by the SHM system, the structure will, of course, have to be repaired. For composite components, repair strategies are available today. However, if the operability of the structure depends on SHM, the repair of the SHM system itself is also necessary before the operation of the structure can be continued. The development of repair principles for this type of structure will therefore need to take into account both the repair of the structure and the SHM system, which would mean additional effort in the case of embedded sensor systems.

5.4 Improving global architecture through SHM

In this section, an example is given for the optimization of the global architecture by locally monitoring parts of the structure, using SHM. There are areas in the design where the installation of systems, tubings, pipes, etc. is determined by the inspectability of the structure, for example, when a highly loaded fitting is designed with consideration to special inspection requirements. The aircraft architects will then probably decide not to locate any system components in such a way that the structure inspection will be made more complicated. For the operator, it would be a significant economic burden to remove system components for each inspection of the structural component "hidden" behind it. Therefore, architects would have to consider a trade-off between "hiding" the structural area to be inspected behind the system and changing the installation of the system. A change of installation would then, most likely, not be the optimal from the system point of view, e.g., additional/longer tubings and pipes, and from global architecture point of view, e.g., additional space allocation through the system with a further impact on space-allocation planning.

An SHM solution for the structural component would solve the problem in the sense that with SHM permanently installed during the structure assembly, the inspections could be carried out in an automated way throughout the aircraft life without the need of getting direct physical access to the structural area. The system's architecture could then be optimized, leading the above-mentioned trade-off to an optimal solution, which would not be realistic without the SHM installation. As with previous examples, in this application, the detailed business case depends strongly on the details of structure and system installation needs of the particular area under consideration.

6 OUTLOOK AND CONCLUSIONS

With the growing maturity of SHM technologies and solutions, more and more applications are seen for civil aircraft. The "first generation" applications in Airbus are mainly related to replacing conventional inspections by SHM solutions and to retrofitting existing aircraft with SHM.

However, in future generations, more ambitious applications will be possible. One example for this is the idea of making the structural dimensioning less conservative, leading to a weight saving. Examples have been discussed for metallic as well as for composite structures, but it has to be kept in mind that the requirements for the SHM technology are extremely high and that the new technology has to first prove its reliability before use. This proof of reliability has to occur not only on a lab-scale, but also on flying aircraft before it can be considered to be used for "weight saving" type of applications.

The general development, which is foreseen for the future, is that multidisciplinary development of new structural solutions will become more important, integrating the disciplines of material development, stress/calculation, design, global architecture, technology development, and others to find the best solution for each relevant structural component. One future trend may be to look for more integration of structural components and SHM technologies.

The technology developers need to be triggered to work in the right direction to be able to deliver the right solutions for the structural concepts being developed. In addition, it is emphasized that only an early introduction of the new technologies into the aircraft planning and predesign process will finally deliver the optimum benefit for the new generation aircraft structure.

Chapter 84
Design Principles for Civil Structures

Vistasp M. Karbhari
University of Alabama in Huntsville, Huntsville, AL, USA

1 INTRODUCTION

Structures associated with the built infrastructure are traditionally designed conservatively to ensure extremely small levels of risk associated with their sudden failure. The level of acceptable risk is orders of magnitude lower than that associated with structures more commonly associated with advanced technology applications such as aircraft and spacecraft. Melchers [1], for example, shows orders-of-magnitude difference in the risks associated with air and automobile travel than those associated with structural failure of the built infrastructure. The reason for this is threefold: (i) the built infrastructure interacts daily with man and hence forms the backbone of society and, consequently, is expected to be a stable anchor without probability of failure; (ii) unlike aircraft, automobiles, and machinery, which are extensively tested at the level of prototypes and are manufactured multiple times in exactly the same configuration, a majority of the built infrastructure is unique and therefore presents neither the opportunity for extensive prototype testing (except for ongoing tests on the structure during its service life) nor, to date, the means of accurately predicting future response, and is therefore designed without the same knowledge base; and (iii) the ambiguity and degree of uncertainty related to the actual life of the structure and the potential increases in load and usage, in the future, force the use of an extremely conservative design.

Classically, structures are designed by considering the relationship between the *capacity* of the components of the structure, and of the assembled system, to the *demand* anticipated for that structure. Since times immemorial, engineers have designed structures using a fairly simple method that requires that

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

the maximum stress due to anticipated loads on the structure are a fraction of the maximum stresses that the structure can withstand. The ratio of the stress at "failure" to the actual level determined for the structure under conditions of service is the factor of safety, which is generically a sufficiently large number, both due to the need for safety at the component level and due to the amassing of component-level factors of safety at the systems level.

This methodology has been used in various forms to develop codes and specifications based on the working stress, or allowable stress, design method. While the methodology has served fairly well for centuries, it does have some major disadvantages. First, the method is built on an approximation of deterministic values for load events, material characteristics, and a linearly equivalent model of structural response, which intrinsically removes all considerations of a statistical and probabilistic nature. Secondly, it leads to structures of the same class, but different configurations, being designed with nonuniform factors of safety. For example, the use of the same specifications for the design of short- and long-span bridges leads to long-span bridges having substantially higher factors of safety since the long-span bridges are governed by dead loads that can be determined with a high degree of certainty than the live loads that would govern the design of short-span bridges. Since the 1970s, this has led to the development of modern design codes and specifications that consider the concepts of structural reliability through limit-state and load and resistance factor design (LRFD) methods. In the LRFD method, which is still being developed in the United States, and is perhaps used more extensively on bridges than on other structures, the factor of safety is quantified by a reliability index, β, which relates the statistical characteristics of the combination of loads with those of the resistance of the components of the structure. In general, bridge codes are calibrated to a value of $\beta = 3.5$, which corresponds to the probability of failure of a component of the structure of 1 in about 2000 during the service life of the bridge (which has a nominal extent of 75–100 years).

Notwithstanding the use of a reliability basis for design, there is still significant conservatism since the value of β relates only to the notional failure of a component with the failure of the system itself having a much smaller probability of failure. In addition, the methodology does not provide a means for addressing the challenges associated with the uniqueness of each system and the lack of data regarding its anticipated service-life response. Additionally, there are challenges both in estimating the remaining life of a structure in service as well as in the real-time assessment of the optimum time to conduct repairs based on the currently used visual method of inspection.

2 SHM AND CIVIL ENGINEERING

Notwithstanding the design methodology initially used, all structures, including critical civil infrastructure facilities like bridges, pipelines, transmission systems, and highways deteriorate with time. This deterioration is due to various reasons including fatigue failure caused by repetitive traffic loads, effects of environmental elements and aging on the materials of construction, and extreme events such as an earthquake, hurricanes, and floods. In order to maintain the safety of the structures, various cognizant authorities prescribe methods of routine inspection. For example, in the case of "lifeline" structures such as highway bridges, the states are mandated by the National Bridge Inspection Program to periodically inventory and inspect all highway bridges on public roads. The National Bridge Inspection Standards [2], first implemented in 1971, prescribe minimum requirements for the inspection of highway bridges in the United States. A substantial amount of research has been conducted in this area to improve the speed and reliability of such inspections. According to a recent survey performed by the Federal Highway Administration [3], although visual inspection is slow and costly and has unproven reliability, it is still the primary tool used to perform these inspections. The implementation of these inspections consists of scheduled field trips to bridge sites at routine intervals, usually once every several years. If a significant increase in distress between inspections is noted, the period between inspections is decreased and the level of inspection is increased till such time that the distress has been corrected by replacement or repair. Not only is this method of time-based inspection inefficient in terms of resources, because all bridges are inspected at the same frequency, regardless of the condition of the bridge, but there is also a

potential danger that serious damage could happen to the bridge in between two inspections, thus posing a hazard to public safety. The adoption of structural health monitoring (SHM) principles assists in decreasing these effects.

With the increasing importance of lifelines, such as highways, to the national economy and the well-being of a nation, there is a need to maximize the degree of mobility of the system. During inspections, issues such as serviceability, reliability, and durability need to be answered in precise terms. More specifically, the owners (the Federal Highway Administration, State Departments of Transportation, etc.) need to be able to answer the following questions: (i) Has the load capacity or resistance of the structure (serviceability) changed? (ii) What is the probability of failure of the structure (reliability)? and (iii) How long will the structure continue to function as designed (durability)? [4]. This requires not just routine, or critical event (such as an earthquake)-based inspections, but rather a means of continuous monitoring of a structure to provide an assessment of changes as a function of time and an early warning of an unsafe condition using real-time data.

Although the term SHM has gained prominence recently, its basis and motivation can be traced to the very earliest endeavors of man to conceptualize, construct, worry about deterioration, and then attempt to repair (or otherwise prolong the life) of a structure. Thus, it represents an attempt at deriving knowledge about the actual condition of a structure, or system, with the aim of not just knowing that its performance may have deteriorated, but rather to be able to assess remaining performance levels and life. In its various forms, over the years, it has been represented as the process of conventional inspection, inspection through a combination of data acquisition and damage assessment, and more recently, as the embodiment of an approach enabling a combination of nondestructive inspection and structural characterization to detect changes in structural response. In recent years, it has often been considered as a complementary technology to systems identification and nondestructive damage-detection methods.

Most work, to date, on SHM systems for civil structures, has been useful, but resembles existing bridge management systems. These management systems focus on processing collected data, but are unable to measure or evaluate the rate of structural deterioration for a specific bridge. Housner *et al.* [5] provide an extensive summary of the state of the art in the control and monitoring of civil engineering structures, and the link between structural control and other forms of control theory. They also define SHM as "the use of *in situ* nondestructive sensing and analysis of structural characteristics, including the structural response, for detecting changes that may indicate damage or degradation". While most ongoing work related to SHM conforms to the definition given by Housner *et al.* [5], this definition also identifies the weakness associated with these methods. A health monitoring system, which detects only changes that may indicate damage or degradation in the civil structure without providing a measure of quantification, is of little use to the owner of that structure. For example, while data from the Strong Motion Instrumentation Program (SMIP) in California provides very important seismograph data related to the shaking of ground and structures during earthquakes through a sensor network through California [6] (which is used to both enhance the understanding of earthquakes and to improve design and construction methods), it does not assist engineers/inspectors in discerning whether structures should be kept open or closed after an earthquake—this has still to be done through manual inspections. While researchers have attempted to integrate quantitative nondestructive testing (NDT) with health monitoring, the focus, to date, has primarily been on data collection, and not on evaluation. It could be concluded that these works have produced better research tools than approaches to bridge management. It is only recently that the emphasis has been on the implementation of efficient approaches to not only collect data from a structure in service but to also process the data to evaluate key performance measures, needed by the owner, such as serviceability, reliability, and durability. For the current work, the definition by Housner *et al.* [5] is modified and SHM is defined as the use of *in situ*, nondestructive sensing and analysis of structural characteristics, including the structural response, for the purpose of estimating the severity of damage and evaluating the consequences of damage on the structure in terms of response, capacity, and service life. More simply, SHM represents the implementation of a Level IV [7] nondestructive damage-evaluation method, and for the purposes of use in civil infrastructure then it must have the ability to collect, validate,

and make accessible operational data on the basis of which decisions related to service-life management can be made [8].

On the basis of this, a more effective "condition-based" approach is the option considered for implementation, in which, the condition of the structure is constantly monitored using an appropriate nondestructive evaluation (NDE) technique without requiring the inspector to actually be on site, with the "in-person" visual inspection only being performed when necessary. The word "constantly" is used to indicate that the assessment of a structure's condition would be performed at much shorter intervals than would be possible using current visual inspection procedures. More importantly, the condition assessment would include more content than could be provided by a visual inspection. The following assessment, for example, would be typically desired by the bridge management authority: (i) damage to the structure and changes in the structural resistance, (ii) probability of failure or of the structure's performance falling below a certain threshold, and (iii) estimation of the severity of damage and the remaining service life. Condition-based monitoring can thus not only reduce resources needed for inspection but, when combined with advances in sensor, computational, and telecommunications technology, could also provide for continuous and autonomous assessment of the structural response.

With the increasing age of the world's built environment and the criticality of infrastructure systems and lifelines to the well-being and progress of society, there is an immense value in the efficient implementation of SHM—enabling, in an utopian world, the autonomous management of systems to prevent failure while simultaneously minimizing the cost of maintenance, reducing or eliminating downtime, and even upgrading structural systems as necessary. It must be noted that a critical feature of such systems is embedded in the concepts of durability and damage tolerance as developed in the aerospace world, and as shown schematically in Figure 1. It should be noted that while the concept is depicted in terms of residual static strength and damage size, it could just as easily be expressed in terms of another residual performance characteristic, or even remaining life and deterioration as measured through characteristics other than physical damage size.

3 CRITICAL NEEDS AND DESIGN PRINCIPLES

SHM intrinsically includes the four operations of acquisition, validation, analysis, and management. For the SHM system to operate as designed, key issues as identified in Figure 2 need to be addressed during the design of the SHM system itself prior to its implementation in the field. Also, the concept of monitoring prescribes that it be an ongoing process, albeit in some cases it could be used at preset intervals of time, or when activated by a threshold event (such as earthquake excitation, and overload). Thus, SHM is essentially the basis for condition-based rather than time-based monitoring, and the system should be

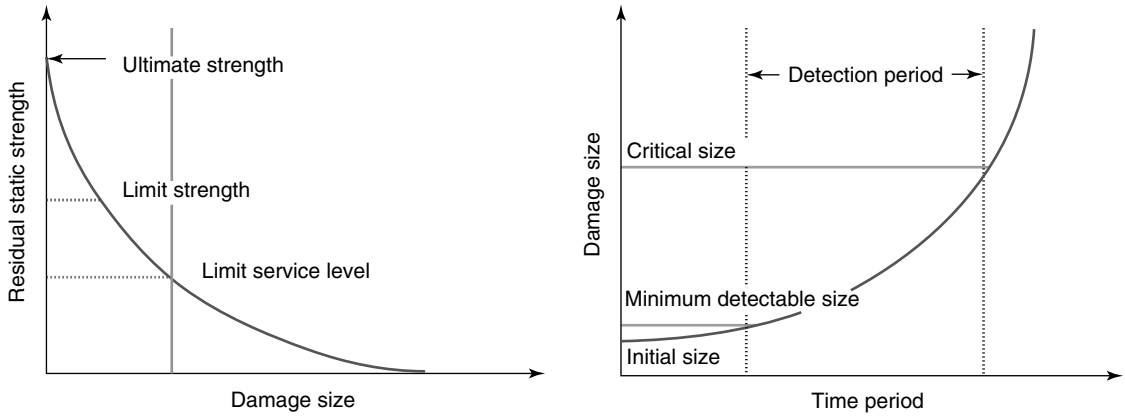

Figure 1. Schematic showing the application of concepts of durability and damage tolerance to design.

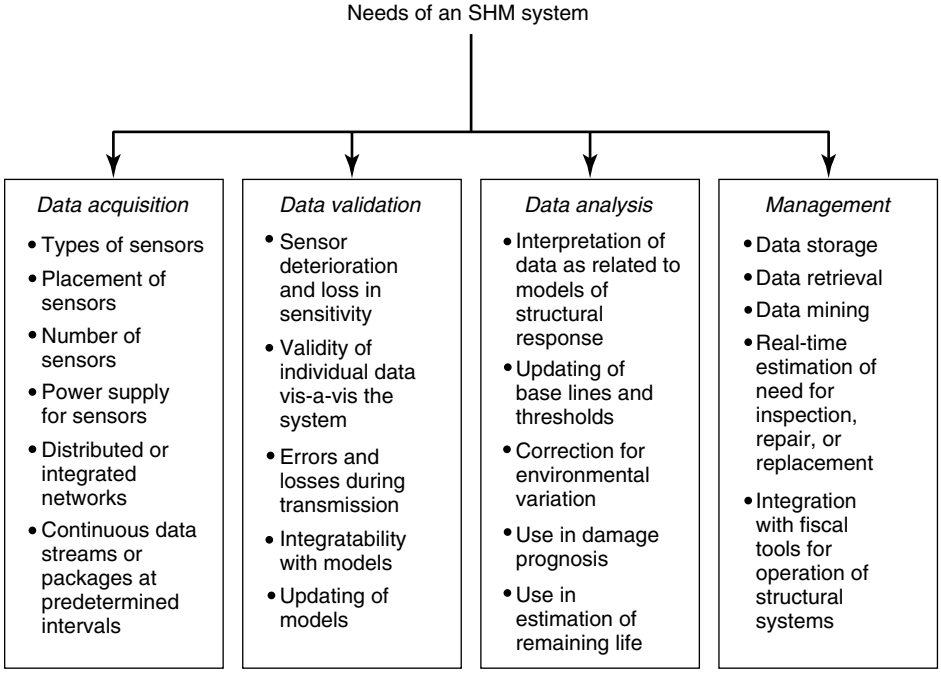

Figure 2. Critical components in the design of an SHM system.

capable of integrating real-time data on aging and degradation into the assessment of structural integrity and reliability. It should be noted that mere monitoring systems, i.e., those that just collect data, do not use an integrated approach to the design, implementation, and operation of the SHM system, resulting in the benefits of the system not being fully realized. Too often, a disproportionate emphasis is placed on the collection of data rather than on the management of this data and the use of decision-making tools that would support the ultimate aim of using the collected data to effect better management of the infrastructure system. Typically, even well-planned systems collect data on a continuous or periodic basis and transmit the data to a common point. The data is then compared with the results from a numerical model. The weakness lies in the fact that the systems may not attempt to update the model to reflect aging and deterioration, or changes made through routine maintenance or even rehabilitation. This can be done through the incorporation of a system's identification or nondestructive damage-evaluation algorithm to rapidly process the data with the ultimate goals of estimating capacity and service life.

Through a review of a large number of existing SHM projects on components of the built infrastructure, the following primary aspects can be identified as being crucial to the design of a viable SHM system:

- definition of clearly defined goals for the system;
- appropriate care in the selection of instrumentation and method of operation;
- predetermination of appropriate rates of usable (i.e., valid) data;
- development of approaches for real-time analysis of the validated data; and
- development and seamless implementation of tools for appropriate data interpretation and result implementation.

A brief discussion of each of the five aspects is given below.

SHM systems are often used on the basis of technology push rather than applications pull based on a clearly defined objective. While the enhancement of systems safety (through use of SHM as a mechanism of warning of failure) is desirable, SHM systems by themselves cannot ensure a higher level of safety, or even a better method of maintenance. SHM systems

by themselves also cannot decrease the level of maintenance, or even increase the periods between maintenance. If appropriately designed, however, they can reduce the amount of unnecessary inspections and ensure that deterioration/degradation is tracked such that the owner/operator has consistent and updated estimates of deterioration (quantity and general location), capacity, and remaining service life. While developing a design for an SHM system, a comprehensive examination of the structural characteristics and expected response of the structure to be monitored should first be considered. In addition, it is crucial that the requirements of the system be clearly identified, especially as related to the characteristics that are to be directly measured. In the case of a bridge, for example, the following aspects would need to be considered as the initial aspects in the design of the SHM system:

- type and class of bridge (the requirements and design principles will differ based on not only span but also the class of bridge—cable stayed, suspension, slab-on-girder, box girder, etc.);
- materials used in the fabrication of bridge (aspects to be monitored in steel bridges could be different from those in bridges fabricated of structural concrete);
- criticality of specific components of the bridge, their vulnerability to load and extreme events, and level of redundancy;
- forces that need to be considered in evaluating the bridge response (e.g., traffic load, wind load, temperature-induced loads, wave loads, seismic forces, etc.);
- determination of the characteristic parameters and response under static, normal load, load combinations, and extreme load events. This will provide the crucial basis for the selection of instrumentation;
- level of average daily traffic (ADT) and consideration of "permit" loads; and
- interaction of superstructure with substructure.

Thus, *in toto*, the design has to consider the three interacting aspects of working conditions/environment, structural configuration and state, and structural response. These must be considered in light of "hazards" that could cause changes in structural response, ranging from aging and deterioration of materials to the effect of events such as earthquakes and floods. Table 1 lists some of the aspects that should be considered during the design phase of SHM systems for different types of infrastructure.

While a large number of sensors are now available ranging in size, sensitivity, method of measurement,

Table 1. Examples of aspects for consideration in designing SHM systems

Class of infrastructure	Considerations
Bridges	Materials deterioration, time-dependent losses (creep, shrinkage, relaxation), corrosion, fatigue and cyclic load related changes, overstress, environmental extremes, unintentional damage, vandalism, soil–structure interaction, earthquake and wind forces, wave action
Buildings	Materials deterioration, corrosion, overload, use in unintended manner, wind and/or snow load, earthquakes, vandalism
Industrial (manufacturing-related) facilities	Materials deterioration, corrosion, overload, use in unintended manner, wind and/or snow load, damage due to earthquakes, vandalism, stress/damage due to manufacturing activities, vehicular impact
Energy generating facilities	Materials deterioration, corrosion, overload, wind/snow load, earthquakes
Offshore facilities	Materials deterioration, corrosion, overload, wave action, debris impact, ice-related damage, explosions (offshore oil platforms), machinery-related impact
Pipe lines	Materials deterioration, corrosion, overload/overstressing, blockage, temperature extremes, wind/wave/snow and earthquake loads
Dams, waterways	Materials deterioration, corrosion, overload, water pressure, soil–structure interaction, earthquakes
Port- and harbor-related facilities	Materials deterioration, corrosion, overload, vessel impact, wave action, debris impact, soil–fluid–structure interaction

and ability to work in a hard-wired and/or wireless mode, the intrinsic challenge still remains the same—appropriate selection (based on actual need, operational environment, and expected service life) and placement, and appropriate design of the system. A good review of different types of sensors crucial for use in civil infrastructure is given in [9]. On the basis of the characteristics of the structural system under consideration and the needs of the monitoring system, various devices/sensors can be used which measure either the absolute, or relative, value of characteristics such as deflections/deformations, strains, accelerations, temperature, moisture content, acoustic emission, electrical resistance or potential, load, etc. The sensors should clearly be selected on the basis of their ability to not only measure the specific characteristics needed but also do that at the appropriate level of sensitivity and with the reliability level needed in the exact operating environment. When used in a civil engineering environment, special care has to be taken to ensure compatibility with the changing environment and the vagaries of nature. This is of special importance when sensors are bonded or otherwise placed on surfaces, which may be subject to extremes of temperatures, large temperature variations (both daily and over seasons), moisture (ranging from humidity and precipitation to actual immersion such as when flash floods cause overtopping of bridges), and UV radiation. Compensation for temperature variation is well established for bonded resistance strain gauges and accelerometers. Yet, false alarms are often seen due to fast transient temperature changes especially in low-frequency accelerometers and this must be kept in mind during sensor selection and deployment. In cases where the sensors are bonded onto the concrete or steel substrates, care needs to be taken to ensure that the bond itself does not deteriorate with exposure and time, and further that deterioration and/or changes at the level of the substrate do not cause recording of erroneous measurements. While these aspects may appear to be trivial, they are of extreme importance in ensuring the long-term reliability of data. There are special concerns related to the use of SHM in cold regions beyond those associated with increasing brittleness of the materials used in the sensors, leads, and connections. Rime is a form of ice that forms when supercooled droplets, such as those in fog, freeze on contact with surfaces already below freezing point and this causes sensors to literally freeze. Also, this can cause brittle rupture of components themselves, or stretching, fracture, or even pullout of the connectors and leads. In addition, the overall design of the system must take into account the effect of accidental impact such as that from floating debris (Figure 3), which can effectively cause severe damage as a result of repeated impact. It is critical that sensor and system selection is based not just on considerations of sensitivity and durability but also on robustness and reliability, especially if the SHM system is expected to be in operation over an extended period of time. In this vein, it should be noted that although fiber-optic systems have good sensitivity and fairly good short-term durability, the drift can be significant if intended to be used continuously over long periods of time at very high levels of sensitivity. In addition, even though these systems have shown very good performance in extremely harsh environments (such as when mounted in automotive cylinders subject to instantaneous gas temperatures as high as 1500 $^{\circ}$C and continuous temperatures up to 300 $^{\circ}$C with pressures up to 300 bar), their reliability, to date, rarely exceeds 10 years. It must be emphasized that this is only a fraction of the expected service life of a bridge, thus pointing out the need for monitoring of the SHM system itself to ensure that parts are replaced prior to the end of their service lives.

All too often the small size, relative cost, or just the inability of the users to design a system results in the overuse of sensors. The mere capability of placing a million sensors on a structure does not automatically ensure a better SHM system. Rather, it almost always ensures failure since attention has not been paid to

Figure 3. Floating debris in the form of a tree trunk and roots.

design, nor of how to access and interpret data. Just as materials deteriorate under environmental exposure, through use, sensors can also degrade and this fact is often completely forgotten, resulting in expensive and highly complicated systems either delivering invalid, or no data, in very short periods of time. At the minimum, the expected service life of the SHM system must be in excess of that of the structural system being monitored. It is also important to keep in mind that unlike aircraft and spacecraft, which can be expected to be routinely brought in for thorough inspection, civil structural systems remain in the environment in which they were constructed for extremely long periods of time with significantly lower levels and extent of maintenance, and with long anticipated service lives (30–75 years or even more). Thus, even if the durability of the SHM system cannot be guaranteed for these long periods, there has to be a very high level of surety that a replacement system (or components) can be easily installed (at a reasonable cost) to continue the monitoring.

It must be emphasized that even in times when sensor costs can reasonably be expected to decrease substantially there is a fallacy in the argument that "more is better". In fact, it can easily be shown that the opposite is true—the increase of data channels not only complicates the issue of data transmission and synchronization but also increases the complexity of data validation. The mere possession of data of points in the structure that are unimportant and do not provide any characterization of response is a waste. Thus, there is a major challenge in minimizing (i.e., optimizing) the number of sensors based on the actual need and ability to characterize pertinent aspects of response.

Beyond the selection of the sensors themselves are the critical design principles of placement and arrangement. Although it is conceivable that a very large number of sensors could be placed on a structure such that the determination of the exact location was unimportant in reality, it is critical that sensors are placed at locations where one anticipates the signal representing the characteristic being measured shows an important value. Thus, it is essential that a comprehensive study of structural response is conducted prior to positioning the sensors so as to enable the identification of crucial locations. These could be locations of the highest stress or strain, nodes at which inflexion of deformation took place, structural connections or locations at which failures were anticipated to occur, etc. In addition, the layout needs to be designed so as to optimize the number of locations used and the accuracy of information available both through direct measurement and through interpolation. In the case of long-span bridges, for example, the following design principles could be used:

- Sensor arrangements should be such that the deformation of the superstructure is clearly determined. In the case of box-girder-based bridges, this would necessitate the determination of deflections of both the top and bottom surfaces.
- Sensor arrangement should be mapped as a function of traffic lanes and prior determination of locations of maximum load under different load combinations. Placement under the wheel-line or at locations such that determination of wheel-line effects is possible is important.
- When wind load is an important consideration, the sensor positioning must take this into account by considering the measurement at midspan of decks where deformations are likely to be the highest and at the top of towers, if the bridge design includes towers. In the case of long-span bridges where spans are long enough to show significant wind force response, positioning of sensors at quarter or eighth span is advantageous.
- In areas of seismic activity, it is important to not only have accelerometers positioned to accurately measure dynamic response but there also needs to be placement in the vicinity of the bridge at locations where ground motion can be measured isolated from the effects of structural response. It should be noted that the positioning to capture structural response of the bridge also needs to be able to capture the dynamic response of the bridge under excitation from ambient vibration such as traffic.
- Temperature and humidity effects are best measured at midspans and extreme locations. In addition, there is the need to be able to determine gradients between the top and bottom surfaces of decks and between the top and base of towers.
- While corrosion can take place at any location, areas where there is a change of section, joints and connections, high stresses, etc. are important points for location.
- The overall configuration (geometry) of the structure should also be mappable.

The challenge of assessing the validity of data is similar to the challenge of selection of the sensor and its placement. While large data streams may seem impressive to the routine observer (and unfortunately all too often even seem to be the ultimate goal of experienced engineers and scientists, without concern regarding the usefulness of the data), what is important is the ability to validate the data in real time, and thereby separate signals due to nonresponsive sensors from those providing the actual measurement of response. All too often, a structure or system has been declared severely damaged or conversely totally undamaged after an extreme event, because the validity of data streams was not checked. There are two generic approaches to validation—analytical redundancy and hardware redundancy. In the first approach, a mathematical model that allows for comparison of static and dynamic responses of the sensor to determine the anticipated value has to be implemented. Unfortunately, this requires addition of sensors, and increases time and complexity. In the case of hardware redundancy, validation is done through selection of data that is common to a majority of sensors. Again, for reliability, the number of sensors has to be increased, but depending on the structure even this may not ensure validation of the data stream. Further, this results in overall loss in sensitivity since the result is necessarily a statistical approximation. The obvious solution, albeit with significant implementation challenges, is the development of a knowledge-based system that applies reason through genetic algorithms, fuzzy logic, or other such tools to infer the right solution. This would enable validation in real time (unlike the two previously described approaches) through the use of reasoning under uncertainty. However, again, the major challenge is to find the right compromise between performance and precision [10, 11].

While it is useful to be able to both see data streams in real time and to archive them for future use, the real purpose of the data is to allow interpretation and analysis. If the system is set up such that there are large streams of data, but none of them can be accessed in real time, the system must be considered a failure. Obviously, data pertaining to damage done due to seismic excitation is largely useless if it is only accessible in a time period equivalent to that over which visual inspection shows that the bridge has collapsed. If one assumes that a large percentage of available data is valid, then the benefits are still substantially curtailed if a preliminary assessment and characterization of response cannot be completed almost in real time.

Unfortunately, the greatest challenge is that most SHM systems are designed merely to collect data, rather than to provide a means for its efficient management and interpretation. It is critical that the system provide a means not just of recording (and displaying) response but also (and more importantly) of characterizing the response and comparing it to an appropriately updated model to enable assessment of the critical aspects of capacity and service life. Thus, overall, the major principles for design initiate with the development of an appropriate plan for SHM, and continue through the selection and placement of the sensors, collection and transmission of data, checking of its validity, and finally to the actual use of the data in a manner required by the owner/operator of the structure. In reality, the primary aspect of design of such systems is in moving past the mere attractiveness of a sensor network to the actual development and implementation of a system capable of serving as a true tool for health monitoring—i.e., not just being able to state that the "patient" is sick, but rather of being able to pinpoint the location and reason, as well as the effect of the incapacity.

4 SUMMARY

Although the field of SHM as applied to civil structures is still in its infancy, it is already demonstrating significant advantages not only in the assurance of integrity of built infrastructure and its predicted serviceability but also in paving a new path for both a better understanding of structural response and for the development of design codes. It is expected that the further developments of SHM systems will result in the establishment of a comprehensive methodology for autonomous health monitoring of structural systems to the point where true condition-based physical inspection and monitoring would become a reality. The integration of sensing networks with the development of robust and effective tools for real-time data interpretation and use in developing measures of performance (such as capacity) and remaining service life provide useful tools for inspection and assessment of the health of our infrastructure. The integration of damage identification

and finite-element-based tools, as being currently developed, can further provide assistance to the engineer in assessing health immediately rather than having to resort to expensive closures while assessments are made off-line. While attention needs to be paid to the relevant principles associated with the design of such systems, it is also useful to consider additional advantages that would conceivably alter the design in minor ways. While the field of structural response is a mature one there are still significant ambiguities in our understanding of long-term response, especially as related to dynamics of assemblies and systems under combined natural forces. The use of an appropriately designed SHM system would enable further understanding of response through data analysis and interrogation, which would lead to better and more refined methods of structural design. In addition, the use of real-time data enables immediate updating of risk and resource allocation, thereby linking design, construction, and service-life maintenance together and enabling the development of a new paradigm for future development of design codes and specifications—one not based on the use of inordinately high factors of safety due to uncertainty, but one based on a continuous assessment and monitoring of risk and health. This would reenvision civil structural design and maintenance, leading to the development of a modern field of civil infrastructure systems.

1 INTRODUCTION

1.1 Design and management considerations for the incorporation of monitoring

This chapter explores the rapidly evolving field related to incorporating information obtained through structural health monitoring (SHM) into the design and management of civil structures. Herein, the employment of monitoring technologies is investigated with respect to the following topics:

- development of a strategic, top-down monitoring approach;
- collecting the most critical information, at the right time, with the right instrument;
- probabilistic formulation of the analysis;
- conducting structural assessment;
- updating with monitoring information;
- life-cycle costing; and
- inclusion of risk.

In particular, this area of study is somewhat complex and challenging, but is timely, needed, and offers great potential to improve current practice. Emphasizing its youth, references on maintenance principles themselves (in the absence of SHM) are relatively sparse and graduate courses on service-life design or life-cycle maintenance management (LCM) are rarely part of engineering curriculua. For the interested reader, references [1, 2] serve as an excellent resource to get started. Although new, the field is one of significant activity across research centers, professional publications, associations, and conferences worldwide. Several examples of research centers at major universities include ATLSS (Advanced Technology for Large Structural

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

Systems at Lehigh University), LIST (Laboratory for Intelligent Structure Technology at the University of Michigan), CIMSS (Center for Intelligent Material Systems at Virginia Tech), SSTL (Smart Structures Technology Laboratory at the University of Illinois at Urbana-Champaign), CIBrE (Center for Innovative Bridge Engineering at the University of Delaware), SFB477 (Collaborative Research Center on Life-Cycle Assessment of Structures via Innovative Monitoring at the Technical University of Braunschweig, Braunschweig, Germany), SFB398 (Cooperative Research Center for Lifetime Oriented Design Concepts at the Ruhr-University Bochum, Germany), ISIS (Intelligent Sensing for Innovative Structures centered at the University of Manitoba, Canada), SISTeC (Smart Infra-Structure Technology Center at Kaist, Korea), EMPA (Swiss Institute of Materials Science and Technology, Dubendorf, Switzerland), and several others. Some examples of professional journals include *Structural Control and Health Monitoring* [3] edited by Lucia Faravelli, *Structure and Infrastructure Engineering* [4] edited by Dan M. Frangopol, and *Structural Health Monitoring* [5] edited by Fu-Kuo Chang. Several professional associations dedicated to this topic include IABMAS (International Association for Bridge Maintenance and Safety), ISHMII (International Society for Structural Health Monitoring), IALCCE (International Association for Life-cycle Civil Engineering), and SAMCO (European network of Structural Assessment Monitoring and Control).

Traditional structural design, or purchasing in general, usually focuses on obtaining the least cost solution that fulfills specified requirements. Over the past several decades, efficiencies have been gained through reductions in structural weight as material properties, construction methods, and design software technologies have improved. Although it is implied that a concrete structure will require repair, roofs will need to be replaced, and paints will need to be reapplied, the intended service life of a structure is often left unspecified. In such cases, project bids consider only the initial costs of design and construction and upon completion the structure is turned over to the owner with the absence of a maintenance plan. Maintenance and repair activities are then likely to become an *ad hoc* reaction whenever a defect manifests itself, at which time a maintenance program is developed [1]. Unfortunately, in terms of expense, research in the field of life-cycle management (LCM) has shown that the costs of inspecting, maintaining, and repairing a structure over its useful life span often dwarf those associated with the initial design. This is compounded by the frequent desire to extend the service life of a structure beyond that originally intended. Against this backdrop, monitoring technologies have the potential to improve the design and management of civil infrastructure in several ways: (i) performance-based design can be conducted by recording site-specific conditions such as wind, load demands, or temperature; (ii) inspections can be scheduled on an "as needed" basis driven by structure-specific data when indicated by monitoring data; (iii) the accuracy of structural assessments can be improved by analyzing recorded structural response data; (iv) as a result of more accurate information provided as input to analytical models, maintenance, repair, and replacement activities can be optimally scheduled, which results in cost savings; and (v) performance thresholds can be established to provide warning when prescribed limits are violated. However, these benefits also come with an associated life-cycle cost as monitoring systems must be purchased, installed, and maintained and their information processed and assessed. As a result, a truly optimal and efficient design needs to consider and evaluate the costs and benefits of different strategies and approaches. An oversimplified example highlights some of these considerations and issues.

Example 1 A tenant in a second floor apartment complex requests permission to construct a large wood balcony and agrees to share costs evenly with the building owner. Two estimates that meet local design requirements are provided by construction companies qualified to do the work. Company A bids \$13 000 and states that the balcony will need replacement every 20 years. Company B bids \$15 000 and states that the balcony will need replacement every 30 years by using higher quality wood. A safety inspection is required at 10-year intervals (excluding the years at which the balcony is replaced) at a cost of \$500 for each inspection. The apartment has an intended service life of 60 years at which time a major rehabilitation is planned. Assuming good inspection results, which company should get the work?

Answer As a temporary user, the tenant can immediately select the lower initial cost solution, Company A. As the long-term owner, the apartment manager must do more work and consider the life-cycle costs of each solution. Undiscounted, hiring Company A appears to cost \$40 500 with two rebuilds and three inspections and hiring Company B appears to cost \$32 000 with one rebuild and four inspections. However, the timing of the payments is important. In order to make a valid comparison, all costs must be converted to the net present value of money using

$$NPV = \frac{FV}{(1+r)^n} \tag{1}$$

where NPV is the net present value, FV is the future value, r is the discount rate, and n is the year in which payment occurs. Assuming a discount rate of 4% results in:

Company A

$$NPV = 13\,000 + \frac{13\,000}{(1+0.04)^{20}} + \frac{13\,000}{(1+0.04)^{40}} + \frac{500}{(1+0.04)^{10}} + \frac{500}{(1+0.04)^{30}} + \frac{500}{(1+0.04)^{50}} = 22\,203 \tag{2}$$

where the NPV is in dollars.

Company B

$$NPV = 15\,000 + \frac{15\,000}{(1+0.04)^{30}} + \frac{500}{(1+0.04)^{10}} + \frac{500}{(1+0.04)^{20}} + \frac{500}{(1+0.04)^{40}} + \frac{500}{(1+0.04)^{50}} = 20\,365 \tag{3}$$

where the NPV is in dollars.

In this analysis, it appears that Company B is the best choice. However, it must be noted that the result is extremely sensitive to the discount rate. The owner may wish to consider the impact of different discount rates or the disruption caused by multiple rebuilds in his/her decision.

Example 2 The apartment manager in the above example selects Company B and learns of some wood preservation strategies. A sealer is recommended with a cost of material and labor of \$750. The company suggesting this sealer claims this product will extend the service life of the wood well beyond 60 years as long as the sealer is kept in good condition. The sealer is expected to last from 5 years to 10 years at which point sanding and reapplication is recommended. The purpose of the sealer is primarily to keep water out of the wood. If the moisture content of the wood is kept below 22%, wood-destroying fungi cannot grow. Separately, the manager learns of some monitoring strategies for the deck. Small disks that turn color if the moisture content of the wood rises above 20% are available for a cost of \$50 each. These disks would be affixed to the wood underneath the sealer coating. Strain alarms are also available that indicate if a member surpasses a critical strain threshold. These alarms cost \$100 each and can be used to determine if the deck has been overloaded or if members are no longer distributing loads as originally intended. These monitoring actions could potentially replace the 10-year safety inspection requirement. What purchases should the manager make?

Answer Clearly, this becomes a more complicated analysis and the answer depends on how the structure and the different products perform. Although there is not enough information to completely answer this question yet, some significant insights can be obtained. For the sealer, a net present value calculation (as previously indicated) yields a present value cost of \$19 622 if the sealer is replaced every 5 years and a present value cost of \$17 974 if replaced every 10 years. The preventive maintenance strategy is cost effective and the sealer should be purchased. The moisture content disks have the potential to indicate when to reapply the sealer and thus optimize its usage. However, the number of disks utilized and the future performance of the sealer will determine if they are cost effective. To determine the quantity of disks required, spatial effects must be considered (i.e., where to place the disks on the structure). False positive readings are possible as are false negative readings. Further investigation requires a statistical analysis. The use of strain alarms also provides unique opportunities and challenges. Use of such gauges would require the selection of critical structural members and a determination of how many of these members to monitor. Although these

gauges could alter or replace the 10-year inspection requirement, their most significant contribution comes from an increased level of safety (and corresponding decrease in the probability of failure) through the knowledge that the structure has operated within specified limits. The owner may be interested in such an approach specifically to reduce the likelihood of a lawsuit associated with a structural collapse. In order to account for the utility (cost–benefit) of the strain alarms, risk-based decision making must be employed or the cost of failure incorporated into a life-cycle cost analysis.

These two examples highlight some of the differences between a traditional design approach, which only accounts for the initial cost of a structure, and a life-cycle approach which accounts for all costs over the useful life of the structure. At some point, for this second-story balcony, the apartment manager would likely decide that this particular type of structure is not critical enough to warrant a full-scale monitoring solution. Although increased information enables better decision making, increased information also requires that more decisions be made, as well as the creation of systems dedicated to the collection and processing of the information itself. In contrast, for other types of structures such as a large bridge, dam, or building, this type of approach may be fully justified and necessary.

1.2 Importance and timeliness

Treatment of the inclusion of SHM into LCM must address the question of "why now?" This question can be best answered in two parts: (i) because we can and (ii) because we must. We can, because technological development of sensors, power generation, more efficient batteries, more powerful computational platforms, and wireless capabilities are making it feasible to obtain site-specific response data cost effectively. Although many of these technologies and ideas have existed for some time, especially in the aircraft industry, they have typically required a controlled environment, hard wired cables, and immense effort to obtain data. Although reasonable for the design and testing of new aircraft, application for the assessment of civil structures in the field has been infeasible. We must address this challenge now because of the current and impending condition of existing civil infrastructure, which warrants further explanation.

Sustainable economic growth, productivity, and the well being of a nation are intimately linked to the reliability and durability of civil structures such as buildings, bridges, dams, and transportation networks [6]. To this end, comparisons across countries in varying stages of development can be used to show that Gross Domestic Product (GDP), life expectancy, and infrastructure development are highly correlated. As a result, society relies on its engineers and government to design, maintain, and regulate structures that are safe and perform as intended over their service lives. In terms of magnitude, new civil engineering construction is the largest industry in the world, representing approximately 10% of annual GDP. Of this 10% of GDP spending, an estimated 5–10% is the result of the failure (not necessarily collapse) of existing structures [1]. For most countries, existing structures and civil infrastructure are their most valuable assets and their upkeep represents one of their most significant investments. Unfortunately, these assets are deteriorating at an alarming rate due to overuse, overloading, aging, or damage [7].

Highway bridges provide an excellent example of the problem. Many of the bridges constructed in the United States as part of the Eisenhower Interstate expansion in the 1950s, 1960s, and 1970s are approaching the end of their planned service lives. Bridges, in particular, are vulnerable to and are constantly subjected to aggressive environments, which include chemical attack from de-icing salts, environmental stressors such as wind, temperature, and water, as well as continuously increasing traffic volumes and heavier truck loads [8]. It is undesirable, if not impossible, to replace these bridges simultaneously without severely impacting commerce and productivity. It is estimated that hundreds of billion ton-miles of goods and materials along with several trillion passage-miles are transported on highway networks in the United States every year [9] and that this connectivity has made significant contribution to the Nation's economy and quality of life [10].

The deterioration of highway bridges in North America, Europe, and Japan is well documented and publicized. In the United States, 25.8% of the 596 808 existing bridges were structurally deficient or functionally obsolete as of the end of 2006 [11].

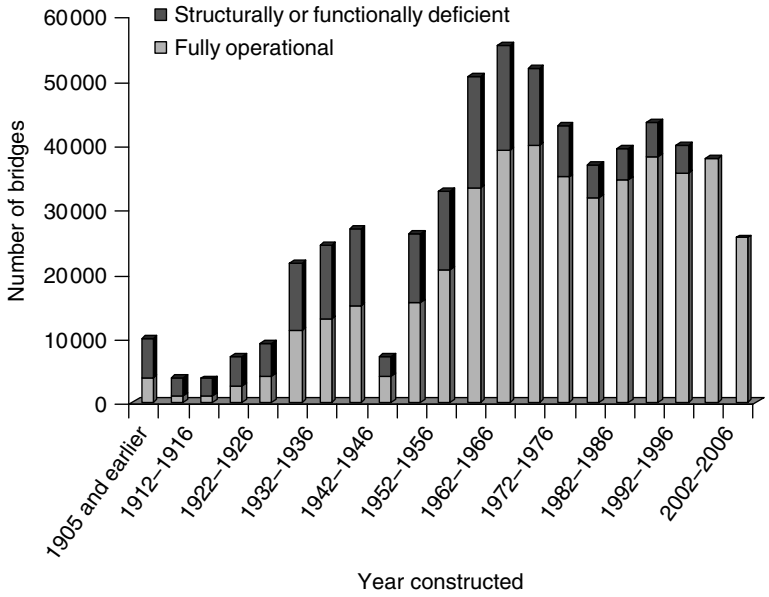

Figure 1. Quantity and classification of US bridges by year constructed. [Adapted from National Bridge Inventory Statistics.]

Figure 1 shows the quantity and classification of US bridges by the year constructed. Aside from the current number of deficient bridges, this figure shows the trend that, as bridges become older, a larger percentage become deficient. Because the majority of US bridges were constructed during the 1950–1980s, we are approaching what some describe as the age of "mass maintenance." Similar trends and results have been reported in Europe and in Asia [12, 13]. To resolve this problem in the United States, an estimated annual investment of $9.4 billion for the next 20 years is required [14]. Because so many structures need maintenance, repair, or replacement simultaneously, there is a great need for methods and technologies that accurately assess these structures, prioritize repairs, and enable the efficient allocation of funds.

2 WHAT TO MONITOR: DEVELOPING MONITORING STRATEGIES

The intent of this section is to offer some ideas for the formulation of monitoring strategies. Here, a top-down approach is developed, which is in sharp contrast to how SHM is typically utilized today. Currently, monitoring is most often used as a bottom-up diagnostic tool in response to an existing problem or defect. Equipment is brought to the site, measurements are recorded, the equipment is removed, and the data is studied. In time, as technologies, metrics, and methods are developed that are convincingly cost effective, the use of permanent (or systematic) monitoring systems will become more common. The formulation of a monitoring strategy should consider (i) historical failures and current assessment of the type of structure of interest; (ii) how the structure fits within a larger network; (iii) the type of measurement desired (global vs. local) and what sensing mechanisms are most appropriate; and (iv) what type of analysis is being conducted and what monitoring data will best improve the analysis. Across these considerations, cost effectiveness is imperative. Because maintenance demands will likely outpace available resources for the foreseeable future, infrastructure managers will likely not invest in monitoring unless it either becomes code driven or there is a return on their investment. Otherwise, money spent on monitoring will simply reduce the funds available for maintenance and repair.

2.1 Past failures and condition of existing structures

Historically, albeit unfortunately, structural failures and collapses have acted as the catalysts that have shaped design codes, construction methods, and management practices. Several notable studies have been conducted in this area and serve as an excellent resource. Matousek and Schneider [15] studied 800 reported failures and errors in the field of structural engineering across several classes of structures. Stewart and Melchers [16] summarized parts of a number of studies involving structural failures. Blind [17] analyzed initiating events and causes for dam failures. Bertrand and Escoffier [18] studied the failures of offshore structures; Anderson and Misund [19] studied the initiating events for the failures of pipelines; and Scott and Gallaher [20] studied the failure of components and systems in nuclear power plants. Perhaps, the most recent and applicable study to one of the most pressing needs today is a 2004 analysis of the reasons for reconstruction across 1691 bridges in Japan [21]. The results of this study are shown in Figure 2.

From this study, it might be concluded that monitoring strategies for concrete may be of particular interest for bridge managers as slab failure and concrete spalling/cracking accounted for most of the superstructure failures.

Although past failures certainly provide insight, the current condition and classification of existing structures must also be considered when developing a monitoring strategy. Maintained by the Federal Highway Administration (FHWA), the National Bridge Inventory (NBI) is a database of statistics for bridges in the United States [11]. The database has been created from construction records and over 40 years of bridge inspections, and provides bridge type, classification, location, age, and current condition. Statistics are also available that detail replacement, rehabilitation, and new construction projects as part of the Highway Bridge Replacement and Rehabilitation Program (HBRRP). Combining this data better enables the design of monitoring approaches for assessing existing structures, as well as those newly constructed. Using information from the NBI as of 2006, Figure 3 details (a) the makeup of the NBI by bridge type, (b) the makeup of deficient bridges by type, (c) the makeup of newly constructed bridges (2003 and 2004), and (d) the makeup of bridge replacement and rehabilitation projects (2003 and 2004).

From these statistics one can conclude that (i) most of the existing bridges in the United States are concrete; (ii) steel bridges represent the largest proportion of deficient bridges; (iii) most new construction is concrete, and (iv) most of the rehabilitation projects are of steel. Because steel bridges are generally older, it is not surprising that these bridges are disproportionately deficient. Additionally, since steel bridges make up the bulk of rehabilitation projects, it is reasonable to assume that many of these older bridges are located in urban areas where new construction is difficult without significantly disrupting traffic flow. From these statistics, if monitoring is viewed from the perspective of forming national priorities, effort should focus on concrete SHM for new construction and upon steel SHM for structures being assessed.

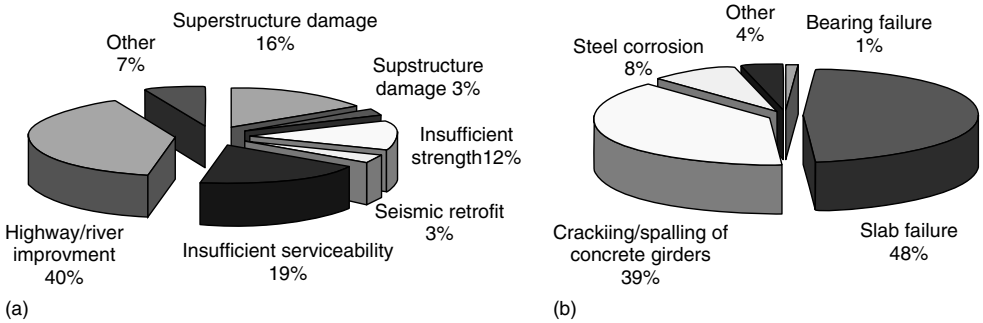

Figure 2. Study of 1691 recent bridge reconstruction projects in Japan: (a) reasons for reconstruction for all bridges and (b) for the bridges reconstructed due to superstructure damage, the primary cause of that damage. [Adapted from Ref. 21.]

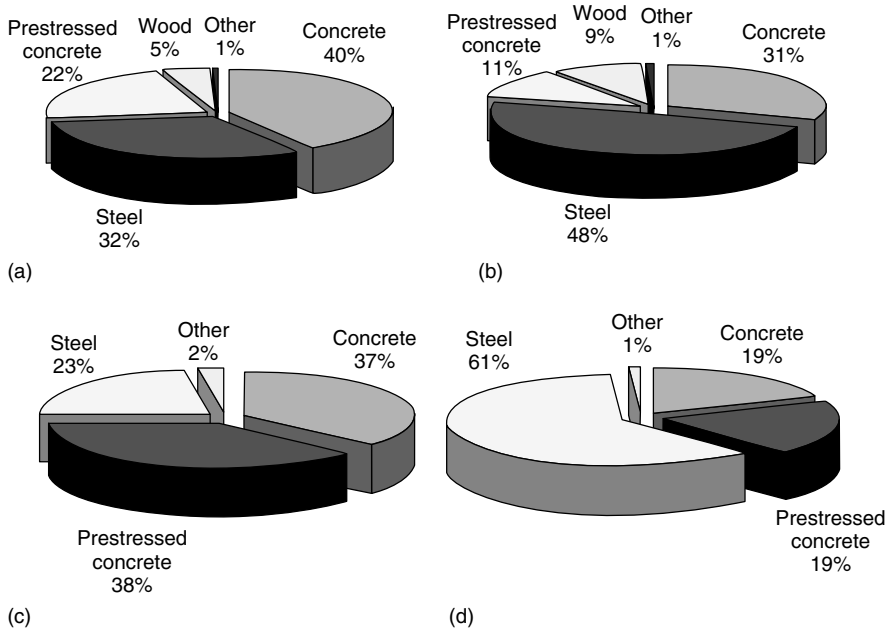

Figure 3. National Bridge Inventory (NBI) statistics of interest for developing national level monitoring priorities. (a) NBI bridge makeup, (b) deficient bridges by type, (c) newly constructed bridges (2003–2004), and (d) replaced and rehabilitated bridges (2003–2004). [Adapted from Ref. 11.]

2.2 Consideration of structures within a network

Rarely is the management of a structure considered in isolation. Whenever possible, inspections, assessments, and maintenance actions should be taken in context of where the allocated resources will provide the most benefit.

Example 3 A bridge manager of a network of 14 bridges (see Figure 4 and Figure 1 in Akgul and Frangopol [22]) located near Denver, Colorado, has $100 000 available for SHM technologies and desires to make the best use of these funds. Where should monitoring effort be focused and on what should money be spent?

Answer Clearly, not enough information is provided, but immediately, several questions and competing interests become apparent. Bridges within the network are of different types, ages, spans, and traffic characteristics. Most of the bridges are concrete. Since chloride ingress into concrete is best detected by embedded sensors installed during construction, the analysis is most likely limited to cracking of concrete, steel fatigue, or an assessment of load versus capacity through strain measurements, unless concrete decks are being resurfaced, in which case, embedded sensors might be a good investment. Noticeably absent from the provided information is any information concerning the current condition and/or safety classification of each bridge. Age directly correlates to the amount of deterioration and the average daily truck volume is the primary cause of fatigue through the number of accumulated strain cycles imparted upon the structure. Here, the bridge with the highest average daily truck traffic (ADTT) is also one of the newest bridges showing the necessity to consider age and ADTT in context. Even if condition and safety assessments were provided, the structure with the worst levels may not warrant monitoring priority if other bridges are more important to the overall performance of the network. Metrics to make such an assessment could range from the extra travel distance required if a particular bridge became non-operational, additional travel time associated with a loss of functionality (lane reduction), the highest cost of failure or consequence in the event of collapse, political importance, or historical/cultural value.

Bridge characteristics in Colorado highway network

Bridge name	Number of spans	Bridge length (m)	Year built	Average daily truck traffic
Prestressed concrete				
E-16-MU	1	34.1	1994	810
E-16-LA	2	77.9	1983	450
E-16-DM	2	44.5	1990	390

* Adapted from [22]

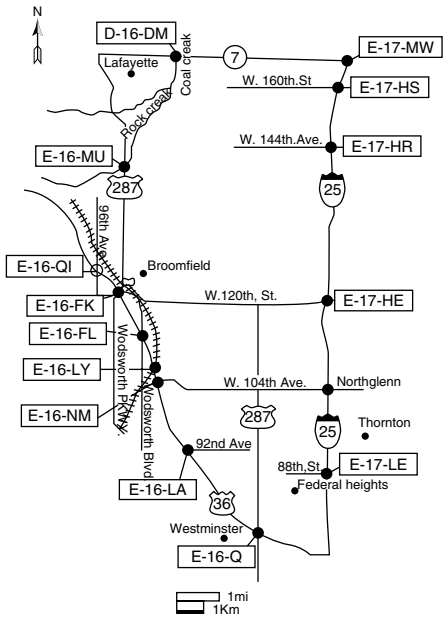

Figure 4. An existing bridge network near Denver, Colorado. [Reproduced with permission from Ref. 22. © American Society of Civil Engineers, 2003.]

Fortunately, some of these issues have already been addressed by researchers developing techniques for the reliability-based maintenance management of bridge networks based upon network theory. Akgul and Frangopol [22] established the network configuration and reliability analysis for the Denver area network depicted in Figure 4. Liu and Frangopol [23] used this network to introduce the bridge reliability importance factor (RIF) as

$$RIF_i = \frac{\partial \beta_{\text{net}}}{\partial \beta_{\text{sys},i}} \tag{4}$$

which relates the change in the reliability of the bridge network to the change in reliability of any particular bridge within that network. The bridge for which a change in reliability has the largest impact upon network performance will have the highest RIF. Liu and Frangopol [24] expand this work to include network connectivity and user satisfaction. Then, in Liu and Frangopol [25], 73 possible network maintenance actions are optimized with respect to life-cycle cost and network reliability. With respect to these approaches, the inclusion of SHM is mutually beneficial. SHM benefits the existing models by reducing uncertainties thus making them more accurate. Conversely, by providing metrics that prioritize bridges by importance, these models indicate where monitoring efforts would have the greatest impact.

2.3 Matching monitoring and analysis strategies: right tool for the right task

Monitoring strategies are broadly categorized into two groups, global and local. Both provide different types of information and, in general, support different analysis types. Figure 5 depicts global and local monitoring strategies, the type of information collected, and the associated measurement types.

Selecting an appropriate strategy might be dictated by the structure, type of analysis, or both. (Several common analysis modeling choices can be found in **Free and Forced Vibration Models**; **Civil Infrastructure Load Models for Structural Health Monitoring**; **Modal–Vibration-based Damage Identification**.) For example, one may be limited to a global monitoring approach when accessibility to specific parts of the structure is impossible. Conversely, one may desire global monitoring methods when working

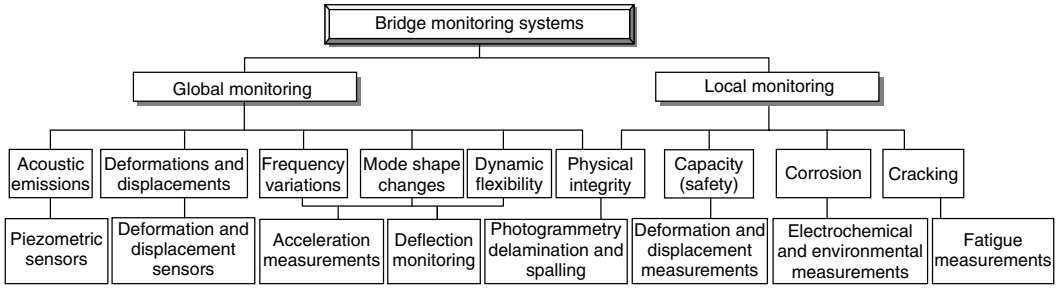

Figure 5. Infrastructure monitoring strategies [Adapted from Ref. 26.]

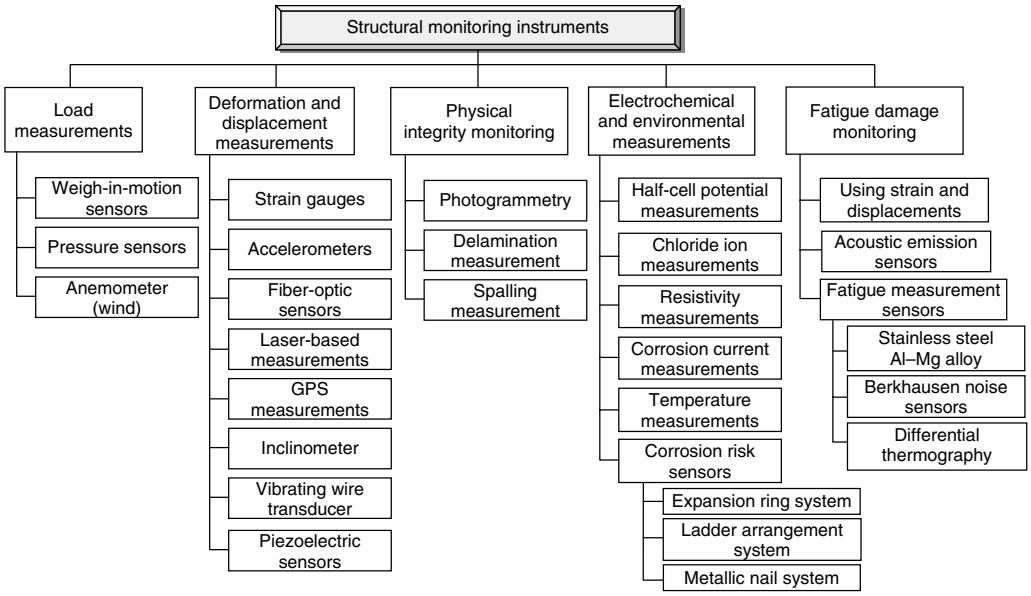

Figure 6. Common structural health monitoring instruments and associated uses. [Adapted from Ref. 26.]

with an analysis that creates an equivalent structure. A common example would be the characterization of the stiffness or modal characteristics in a finite element model. For this, accelerometers would be an appropriate instrument. This would not necessarily be the case when analyzing a specific structural failure mechanism such as flexure, shear, fatigue, or corrosion. In this case, information would be desired about member geometries, material properties, loads being imparted on the structure, and environmental effects. Figure 6 shows common SHM instruments for these types of measurements. A more detailed discussion of several of the most common sensor types can be found in **Fiber Bragg Grating Sensors**; **Microelectromechanical Systems (MEMS)**; **Reliable Use of Fiber-optic Sensors**; **Integrated Sensor Durability and Reliability**.

Example 4 Three options are being considered for the detection of corrosion during the design phase of a new reinforced concrete parking area on the roof of a university lecture hall in a harsh weather environment (Figure 7). The roof replacement is required to remedy existing cracks, leaks, and potential future safety concerns. The approaches under consideration include (i) periodic half-cell potential tests by an inspection team, (ii) embedded corrosion risk sensors 5 cm above rebar level, and (iii) corrosion sensors located on the rebar itself. What advantages and disadvantages should the design firm discuss with

Figure 7. Rooftop parking area being considered for replacement and redesign. [Photo by T.M. Messervey.]

the building owner when the project is still being developed?

Answer Each option implies a different maintenance strategy and different future actions required to be followed by the facility manager. Hence, any such discussion among designer, manager, and owner is positive. Periodic half-cell potential tests, option (i), require scheduling and user disruption during their execution, but are likely the least expensive option and no immediate funding is required. In scheduling such tests, there is the risk to inspect too often, thus allocating more funds than necessary to inspections, and there is also the risk of testing too infrequently and thus not detecting the onset of corrosion as desired. Embedding corrosion sensors above the rebar, option (ii), is intended to detect the deterioration mechanism (presence of chloride ions) before deterioration initiates on the rebar itself and as such is proactive in nature as shown in Figure 8(a). Such an approach lends itself to multiple repairs (resurfacing) of the top concrete layers to preserve the more demanding and expensive replacement of the entire deck. Detecting the presence of corrosion directly on the rebar and corresponding section loss, option (iii), lends itself to the complete replacement of the deck when necessary. Once corrosion has initiated, several models are available to predict the remaining safe life span of the rebar. The intended life span of the parking lot is a critical detail not provided in this scenario. Also left for further investigation are

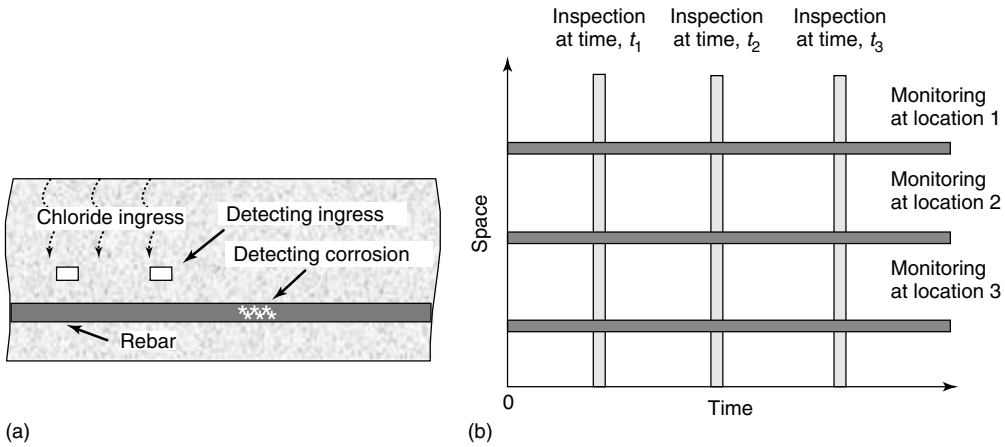

Figure 8. For a reinforced concrete design: (a) detecting the corrosion initiation mechanism versus detecting corrosion itself and (b) spatial and temporal differences between inspections and monitoring (adapted from [26]).

spatial and temporal effects. Generally, inspections or tests provide information about an entire structure at a point in time, whereas monitoring provides information continuously at a specific location over time as depicted in Figure 8(b). To balance these differences, inspections must occur at appropriate intervals of time, and sensors must be placed at the appropriate intervals in space.

2.4 Determining what and when to monitor at the structural level

2.4.1 Aleatory and epistemic uncertainty

Consideration of the uncertainty associated with critical loading and structural parameters is one of the most critical issues in assessing the condition of existing civil infrastructures [27]. The contributors to uncertainty in civil structural systems are discussed by Moon and Aktan [28]. Uncertainty can be considered in two broad categories, aleatory and epistemic. Aleatory uncertainty describes the inherent randomness of phenomenon being observed and cannot be reduced. Natural variations in temperature are an example of this type of uncertainty. Epistemic uncertainty describes the error associated with imperfect models of reality due to insufficient or inaccurate knowledge [29]. Error associated with predicting stresses in a structural member through use of an analytical model is an example of this type of uncertainty, as material properties, geometry, and loads are never deterministic. Both types of uncertainty play an important role in the monitoring of civil infrastructure. System identification, i.e., validating structural parameters through experimental testing, proof loading, or measurements from the structure of interest, all act to reduce epistemic uncertainty by improving the accuracy of model input parameters. Efforts should naturally be focused on the parameters for which better information has the greatest impact on model improvement. In many cases, the recording and inclusion of aleatory uncertainty greatly improves assessment and prediction of structural performance. Including temperature effects is again a good example as temperature significantly contributes to variations in strain or modal characteristics. An example of this approach, using SHM technologies to better estimate condition assessment, is provided in [27]. In this example, temperature effects recorded via SHM are utilized to enhance system identification and an ensuing reliability analysis. In this case, inclusion of this data creates a significant decrease in the component and system reliability indexes.

2.4.2 Structural systems and performance over time

Structures are composed of individual members that form structural subsystems, which interact on a global level to fulfill the desired outcome. How a component functions in a system provides insight on where to focus monitoring priorities [30]. For members in series as shown in Figure 9(a), the critical or weakest member is the one with the highest probability of failure, Member #1. For members in series, the *weakest* member should receive monitoring priority. In contrast, if these same three members are arranged in parallel, as shown in Figure 9(b), then the critical member becomes the member with the lowest probability of failure p_f, i.e., the *strongest* member, Member #3. As such, for members arranged in parallel, the *strongest* member (i.e., the member with the lowest probability of failure) should receive monitoring priority.

Varying rates of deterioration may also affect monitoring priorities or when monitoring is appropriate. Figure 10(a) depicts the reliability profiles of two members arranged in series. Member #1 deteriorates more rapidly than Member #2. As such, monitoring priority would first be given to Member #2 until the reliability indexes intersect at point X after which priority would shift to Member #1. In contrast, if these same two members are arranged in parallel, as shown in Figure 10(b), monitoring priority would first be given to Member #1 and then to Member #2 after the intersection of the reliability profiles. In both cases, the concept of monitoring the weakest member

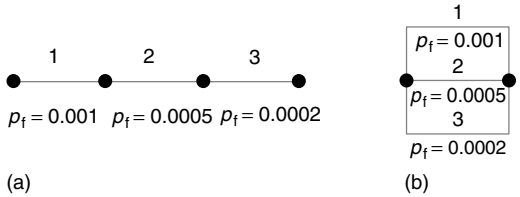

Figure 9. System analysis of members in (a) series and in (b) parallel where p_f = probability of failure.

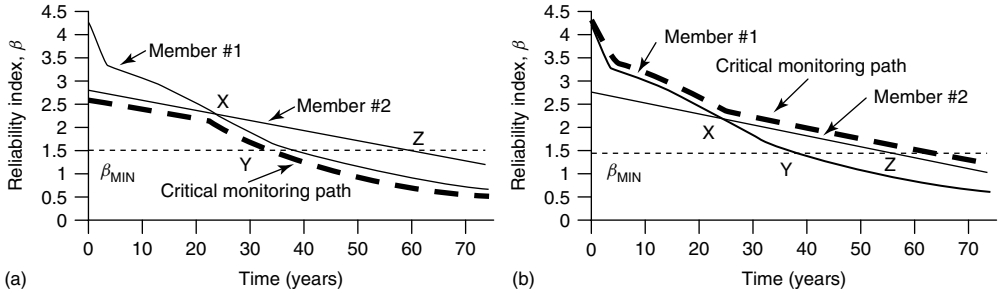

Figure 10. Time-variant system analysis of members in (a) series and (b) parallel.

in series and the strongest member in parallel remain the same, but the critical member changes over time because of varying deterioration rates. Although fairly intuitive for different structural components or components made of different materials, this also finds application among like members with different exposure levels. Examples include exterior steel girders being subjected to a higher corrosion rate than interior girders on a bridge because of a greater exposure to de-icing salts, or exterior versus interior beams and columns in a building.

Such an analysis could also be used to answer the question of when to monitor. Again using the graphs in Figure 10, if a minimum reliability threshold is established, one could conclude that monitoring would be appropriate on Member #1 at the time corresponding to point Y in series and on Member #2 at point Z in parallel given perfect information. Monte Carlo simulation of the model parameters can be used to estimate the earliest possible crossing of the minimum reliability threshold. This would be appropriate for a monitoring system with high operational costs that can be turned on or off, or for a nonpermanent monitoring solution that must be scheduled and brought to the site.

3 INCORPORATING MONITORING DATA INTO DESIGN AND MANAGEMENT

The role of design is to create structures that fulfill their intended purpose over a specified time horizon with the appropriate level of safety in the face of uncertainty. Unfortunately, no structure is perfectly safe, due to the possibility of unforeseen or catastrophic events such as earthquake, fire, flood, or terror. Even if a perfectly safe structure were possible, it would be cost prohibitive. Hence, engineers have the responsibility to reach an optimal balance between safety and cost. Design codes and design methodologies are intended objectively to quantify this balance. As design methods have improved and evolved over time, the role and treatment of uncertainty has changed as well. Allowable stress design (deterministic) accounts for uncertainty through the use of a Factor of Safety. This factor has traditionally come from expert opinion gained over time. In Load and Resistance Factor Design (semi-probabilistic), reliability methods are utilized to calibrate factors that increase loads and reduce resistances. Once these factors are established, the treatment of an individual problem (i.e., the calculations) becomes essentially deterministic in nature. In performance-based design, the engineer is responsible for the appropriate determination and treatment of the uncertainties associated with both loads and resistances in a probabilistic manner. This requires treating loads and resistances as random variables and the characterization of their probability distributions. Performance-based design provides the most flexibility, especially to incorporate newly developed materials, but also places the most responsibility on the designer [31]. Although structural monitoring could be incorporated into any of the design approaches, it is best-suited for a performance-based approach. Because monitoring provides statistical data about a particular structure or the environmental conditions in which it exists, it naturally lends itself to a probabilistic approach for both the design and management of structures. Design considerations for the employment of monitoring can be cross references in **Design Principles for Civil Structures**.

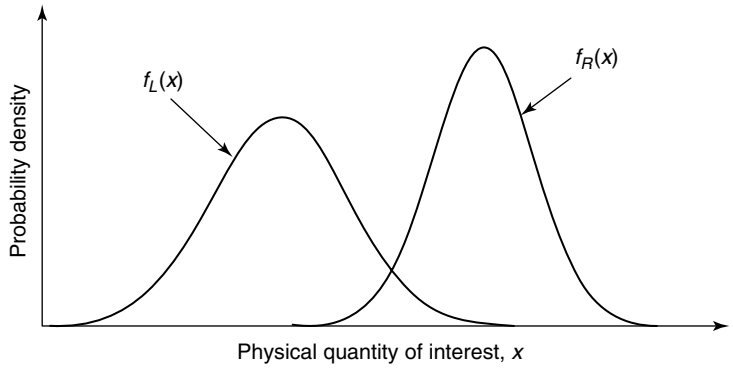

Figure 11. Probability density functions of resistance and load effect.

3.1 Reliability-based assessment of an existing structure using structural health monitoring

Structural reliability is utilized to conduct a probabilistic assessment of the performance function $g = R - L$, where R and L are the resistance and load effect, respectively. Provided that the capacity, R, and load effect, L, are random and can be quantified, the probability of safe performance, p_s, can be expressed as

$$p_s = P(R - L > 0) = \iint_{R>L} f_{R,L}(r, l)\, \mathrm{d}r\, \mathrm{d}l \quad (5)$$

where $f_R(r)$ and $f_L(l)$ are the probability density functions (PDFs) of R and L are defined in Figure 11, and $f_{R,L}(r, l)$ is their joint PDF. Most often, the capacity R and demand L are themselves functions of many other random variables. In such cases, a limit state function $g(\boldsymbol{X}) = 0$, describes the performance of the system in terms of the vector of basic random variables, $\boldsymbol{X}$, and defines the failure boundary, which separates a survival region from a failure region. Formulation of the probability of safe performance p_s then becomes

$$p_s = \int_{g(\boldsymbol{X})>0} f_{\boldsymbol{X}}(\boldsymbol{x})\, \mathrm{d}x \quad (6)$$

which represents the volume integral of the PDF of $\boldsymbol{X}$, $f_{\boldsymbol{X}}(\boldsymbol{x})$, over the safe region $g(\boldsymbol{X}) > 0$. The solution of this integral can quickly become too complex to solve in closed form or using numerical methods, and is typically solved using approximation methods (FORM/SORM) or by using Monte Carlo simulation [32–34]. Commercially available software for such calculations include STRUREL [35], CALREL [36], PROBAN [37], and RELSYS [38].

Typically, the probability of safe performance is a number close to 1, such as $p_s = 0.9772$ which can also be reported in terms of the probability of failure, $p_f = 0.0228$. To make this easier to express, the probability of failure is usually reported in terms of the reliability index, β. In the special case where R and L are independent and normally distributed, the reliability index can be related to the probability of failure as $p_f = \Phi(-\beta)$, where

$$\beta = \frac{\mu_R - \mu_L}{\sqrt{\sigma_R^2 + \sigma_L^2}} \quad (7)$$

where μ_R and μ_L are the mean values of the resistance and load effect respectively, and σ_R and σ_L are the standard deviations. For a probability of failure, $p_f = 0.0228$, the corresponding reliability index is $\beta = 2$, which is sometimes accepted as the lowest acceptable safety level when assessing structures.

Example 5 The Lehigh River Bridge SR-33 was constructed in 2001. During construction, strain gauges were affixed at several key locations as shown in Figure 12 to monitor the strain (i) after erection of the steel truss, (ii) after the emplacement of a concrete deck, and (iii) during the load test of a 326-kN (74 100 lb) design truck. The bridge is constructed of M270 grade 50 W steel with a nominal yield strength of 345 MPa (50 ksi). Strain readings for the key events are transformed to stress based upon

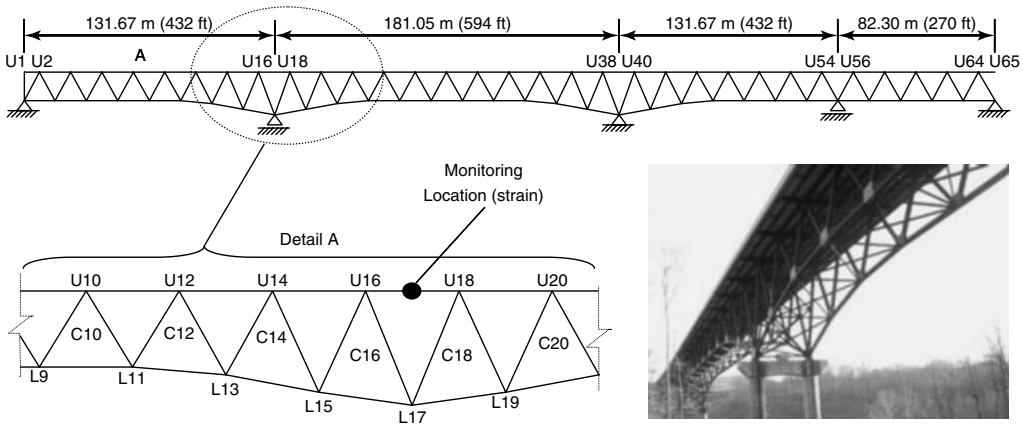

Figure 12. Monitoring of an upper chord on Lehigh River Bridge SR-33. [Adapted from Ref. 39.]

the cross-sectional area of the members as shown in Table 1. Is this member safe?

Answer A deterministic approach to the problem is fairly simple where the Factor of Safety (FS) is calculated as

$$FS = \frac{345 \text{ MPa}}{131.75 \text{ MPa}} = 2.62 \tag{8}$$

Although this approach does quantify a level of safety, incorporating the variability of any of the parameters is not possible. An LRFD approach would incorporate safety through the use of load and resistance factors, but the end result would simply be that the structure was adequate for this particular load with the successful checking of an inequality equation. The best solution is a performance-based approach using structural reliability. For such an analysis, reasonable assumptions must be made to make use of the provided information in a probabilistic manner. Dead loads can vary because of differences in material densities, thicknesses, cover of asphalt, spacing of rebar, etc. Traffic live loads on bridges are typically the most uncertain random variables in a reliability analysis. Quantifying these loads is difficult because they are a function of truck weights, axle spacing, vehicle speeds, and the relative positioning of trucks on the bridge. Ghosn and Moses [40] and Nowak [41, 42] have developed commonly utilized live load models for traffic live loads. Weigh-in-motion (WIM) sensors have the possibility to more accurately capture live load effects through direct measurements. A recent study of over 10 years of WIM data across multiple highways can be found in [43]. Regarding structural capacity, manufacturers typically produce, on average, higher yield strengths than that reported by specification to allow for error in production. A reasonable estimate of the coefficient of variation for the dead load, live load, and yield strength can be taken from Nowak and Yamani's study [42]. Using these coefficients, Table 2 summarizes the descriptors for each random variable. These random variables are also assumed to be normally distributed and independent.

Table 1. Maximum recorded stresses on an upper chord of Lehigh River Bridge SR-33 [39]

	Reason for strain recording	Load type	Total measured strain transformed to stress (MPa)	Incremental stress (MPa)
August 2001	Truss constructed	Dead	61	61
October 2001	Concrete deck emplaced	Dead	109	48
January 2002	Design truck crawl test	Live	131.75	22.75

Table 2. Probabilistic modeling of the provided monitoring data

Variable	Distribution	Descriptors (mean, SD) (MPa)	Coefficient of variation (COV)	Source
Dead load truss	Normal	(61, 3)	0.05	Nowak and Yamani [42]
Dead load concrete	Normal	(48, 2.4)	0.05	Nowak and Yamani [42]
Crawl test live load	Normal	(22.75, 5.91)	0.26	Nowak and Yamani [42]
Capacity: yield strength	Normal	(386, 42.5)	0.11	Nowak and Yamani [42]

Combining the mean values and standard deviations for the load terms yields

$$\mu_L = 61 + 48 + 22.75 = 131.75 \text{ MPa} \quad (9)$$

and

$$\sigma_L = \sqrt{3^2 + 2.4^2 + 5.91^2} = 7.05 \text{ MPa} \quad (10)$$

and solving for the reliability index, β

$$\beta = \frac{\mu_R - \mu_L}{e_s\sqrt{\sigma_R^2 + \sigma_L^2}} = \frac{386 - 131.75}{1.04\sqrt{42.5^2 + 7.05^2}} = 5.67 \quad (11)$$

which corresponds to a probability of failure $p_f = 0.000000007$. In this calculation, a sensor error, e_s, of 4% is included.

It is important to note that this example illustrated only one metric of safety, which best answers the question of *how safe was the structure for the load that acted upon it?* This type of analysis of a crawl test (or proof load) is extremely useful to quantify the benefit or retrofit of repairs through comparison with a previous study [44–46]. Similarly, changes in load distribution or structural performance can be observed. However, this method does not completely address the question of structural safety because time is not taken into account. Using probabilistic modeling, the longer a structure is in service, the more likely that a load from the upper tail of the distribution will occur. Typically, this is taken into account by designing or assessing for the 75-year live load using the statistics of extremes [47].

3.2 Using the statistics of extremes to determine live loading

The design and analysis of civil infrastructure is often concerned with the largest or smallest (extreme values) of a number of random variables. Buildings must withstand maximum wind loads, dams maximum flood levels, and bridges maximum live loads for a given time period [29]. With respect to monitoring, this concept is very useful because it allows the selection of what data to keep. In permanent monitoring approaches, the magnitude of a continuous data stream across hundreds of sensors becomes a management problem in itself. Selecting, logging, and maintaining peak values is one way to efficiently manage data [48].

Extreme values are the largest (or smallest) values from a set of n samples from a known distribution. For example, let X be daily recordings of peak wind velocities. Y_n is then defined as the maximum value from a specified period of time, or number of observations, n. Peak annual wind velocities would come from a set of $n = 365$ samples.

$$Y_n = \max(X_1, X_2, X_3, \ldots, X_n) \quad (12)$$

As the process repeats itself each year, a different peak annual wind velocity is recorded and in turn is itself a random variable. If the underlying distribution has an exponentially decaying upper tail, then the cumulative distribution function (CDF) and probability density function (PDF) of the distribution of the extreme, respectively, are [49]

$$F_{Y_n}(y) = [F_X(y)]^n \quad (13)$$

$$f_{Y_n}(y) = n[F_X(y)]^{n-1} f_X(y) \quad (14)$$

which is to say that the final distribution of the extreme values is a function only of the initial

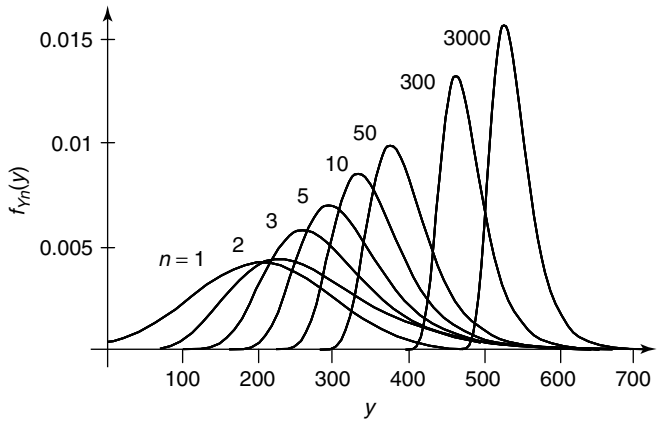

Figure 13. Transformation of a normal distribution to the Type I asymptotic form (Gumbel) for $n = 1$, 2, 3, 5, 10, 50, 300, and 3000. [Reproduced with permission from Ref. 48. © Taylor and Francis, 2007.]

distribution and the sample of size n. This implies that if an extreme phenomenon can be defined in any space (sample size, n, or timeframe), it can be transformed to another desired space. In a physical context, if peak annual wind velocities can be well-defined (given enough yearly observations), then a simple transformation yields the distribution of the 50-year peak wind velocity appropriate for design. Figure 13 depicts the transformation of a normal distribution into the Type I asymptotic (Gumbel) distribution. Each PDF represents the distribution of the extreme value Y_n for the associated sample size.

Using the statistics of extremes can prove useful to monitoring in two ways: (i) once a live load distribution is defined, it can be transformed to an extreme distribution given the number of times sampled and (ii) if extreme values themselves are observed (e.g., maximum daily monitoring values), the extreme value distribution can be defined directly and transformed to the desired time interval.

3.2.1 Live load based upon projected sample size

Given a distribution with an exponentially decaying upper tail, the probability of encountering a value from the extreme tail increases with the number of times the distribution is sampled. Hence, once a sampling rate is established, the distribution of the maximum expected occurrence can be defined for any future time t.

Example 6 The Lehigh River Bridge described in the previous example has an estimated daily crossing rate of 300 trucks. What is the safety level with respect to a 75-year live load requirement?

Answer Assuming a linear relationship between the truck live load and the recorded strain, extreme value statistics can be applied directly to the recorded strain. For a monitored phenomenon with an underlying normal distribution, the distribution for the extreme value for any sample size n is defined by

$$\mu_{Y_n} = \sigma_X \mu_n + \mu_X + \frac{\gamma \sigma_X}{\alpha_n} \tag{15}$$

and

$$\sigma_{Y_n} = \frac{\pi \sigma_X}{\sqrt{6}\alpha_n} \tag{16}$$

where μ_X and σ_X refer to the underlying distribution, μ_n is termed the characteristic value, α_n is a shape factor of the transformed distribution, and $\gamma = 0.5772$ is Euler's number. The shape factor and characteristic value are dependent only on the sample size and are given by

$$\alpha_n = \sqrt{2\ln(n)} \tag{17}$$

and

$$\mu_n = \alpha_n - \frac{\ln[\ln(n)] + \ln(4\pi)}{2\alpha_n} \tag{18}$$

These equations are particular to an underlying normal distribution and are detailed in [49, 50]. Here, for bridge SR-33, with an estimated 300 trucks crossing daily,

$$n = \frac{300 \text{ trucks}}{\text{day}} \times \frac{365 \text{ days}}{\text{year}} \times 75 \text{ years} = 8\,212\,500 \text{ trucks} \quad (19)$$

Applying the above equations first for the shape factor and characteristic value, and then for the mean and standard deviation of the extreme distribution (using $\mu_X = 22.75$ *and* $\sigma_X = 5.91$ from the crawl test) results in

$$\mu_{Y_n} = 53.98 \text{ MPa} \quad (20)$$

$$\sigma_{Y_n} = 1.34 \text{ MPa} \quad (21)$$

for the 75-year live load stress. Combining stresses as before,

$$\mu_L = 61 + 48 + 53.93 = 162.93 \text{ MPa} \quad (22)$$

and

$$\sigma_L = \sqrt{3^2 + 2.4^2 + 1.34^2} = 4.07 \text{ MPa} \quad (23)$$

and solving for an *approximation* of the reliability index, β

$$\beta \approx \frac{\mu_R - \mu_L}{e_s\sqrt{\sigma_R^2 + \sigma_L^2}} = \frac{386 - 162.93}{1.04\sqrt{42.5^2 + 4.07^2}} = 5.02 \quad (24)$$

This is an approximation because error is introduced by the fact that the distribution of the 75-year live load is no longer normal, but Gumbel. This error could be removed through the use of a limit state equation and FORM/SORM analysis.

This approach is an improvement on the previous example with the incorporation of live load effects, which include the consideration of time or multiple truck passages. It finds application in the use of monitoring data obtained by stationary park tests or slow-moving crawl tests. Not yet addressed is the consideration of load combinations. These combinations explore the impact of different loads occurring simultaneously.

3.2.2 Live load based upon in-use monitoring data

Perhaps the best use of monitoring in the assessment of civil infrastructure is the study of long-term data trends. Although this requires some type of continuous monitoring approach, it provides significantly more information. By screening data for peak values, the statistics of extremes can be used to assess live loads. If observed over time, these recordings capture load combinations. Once the extreme distribution is defined in any particular space, it can be transformed to the desired time frame for inclusion in a reliability analysis.

Example 7 An analysis of the performance of connections on the I-39 bridge (Figure 14) spanning the Wisconsin River is desired. Strain gauges are emplaced and maximum daily peak strain values are recorded. Monitoring is conducted for 83 days and strain values are converted to stress via Hooke's law, as reported in Table 3. What is the appropriate live load to assess the structural safety of this connection in a reliability analysis?

Answer Here, sensors were affixed on an existing structure and therefore measurements represent only live loads. Because each reading is the maximum value of hundreds of truck crossings plus environmental effects, it is reasonable to assume that these values follow an extreme value distribution. Type I (Gumbel) and Type II (Lognormal) maximum value distributions are appropriate candidates. Goodness-of-fit tests such as the chi-squared test or the Anderson–Darling test [29] can be used to validate and compare these models. Treating the above values as a univariate data set of extreme values, the mean and standard deviation of these values are calculated as

$$\mu_{Y_n} = 24.67 \text{ MPa} \quad (25)$$

and

$$\sigma_{Y_n} = 4.66 \text{ MPa} \quad (26)$$

For a Type I distribution, the shape factor α_n and characteristic value μ_n can be calculated as [49].

$$\alpha_n = \frac{\pi}{\sqrt{6}\sigma_{Y_n}} = \frac{3.14}{\sqrt{6} \times 4.66} = 0.275 \quad (27)$$

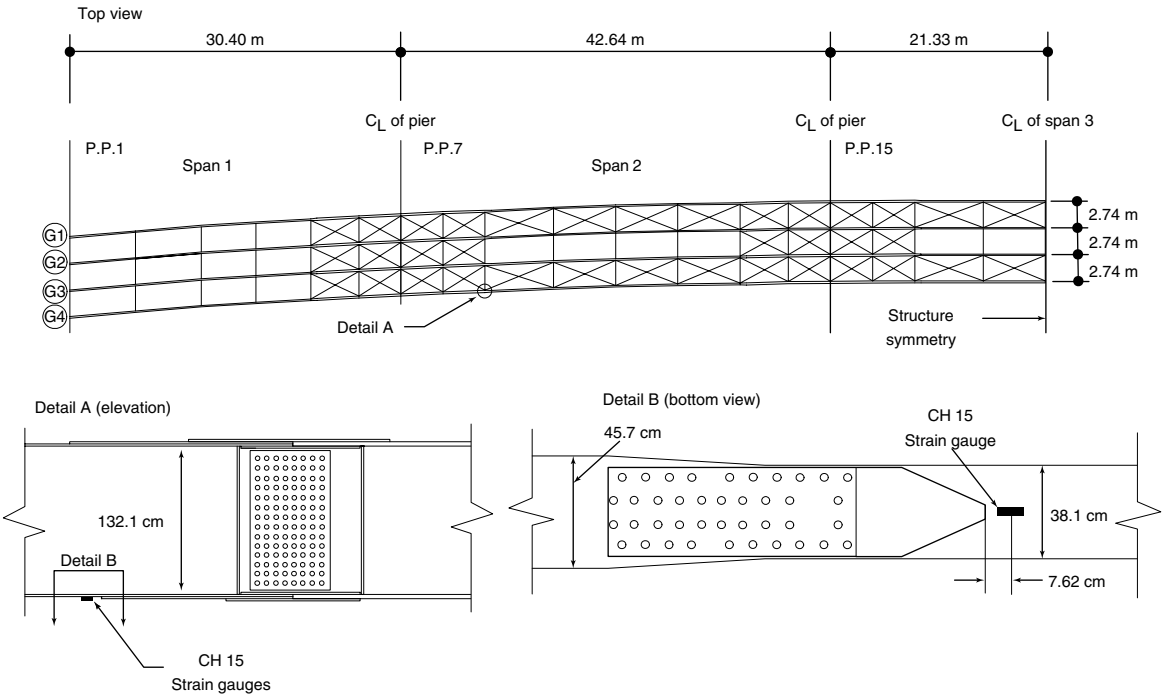

Figure 14. Monitoring of a connection on the I-39 Wisconsin River Bridge. [Adapted from Ref. 51.]

Table 3. Daily recorded peak stresses at monitored connection on the I-39 Wisconsin River Bridge (MPa)

25.27	21.72	19.59	20.62	24.53	22.77	26.11	32.72	39.32	21.48	31.57
30.13	20.81	22.69	23.69	17.07	29.30	22.66	23.44	29.12	30.25	21.32
22.10	34.88	30.64	21.74	31.75	29.31	21.75	24.14	21.16	29.46	22.81
25.86	28.64	22.96	21.12	24.47	28.91	20.36	30.10	24.32	23.87	26.98

29.33	21.66	33.04	22.00	21.25	20.54	16.86	22.53	27.33	20.13	18.94
24.70	30.46	25.02	21.66	29.58	20.50	—	—	—	—	—

$$\mu_n = \mu_{Y_n} - \frac{\gamma}{\alpha_n} = 24.67 - \frac{0.5772}{0.275} = 22.57 \text{ MPa} \tag{28}$$

A Type II distribution does not have a direct solution and requires statistical treatment (best fit empirical distribution function). Here, using the Type I Gumbel, the distribution is defined for daily maximum stress recordings. Owing to the invariance of the asymptotic forms of extremal distributions, this distribution for $t = 1$ day can be transformed to $t = 75$ years using [29].

$$\begin{aligned}\mu_n &= \mu + \frac{\ln(n)}{\alpha_n} \\ &= 22.75 + \frac{\ln(365.25\,\text{days/year} \times 75\,\text{years})}{0.275} \\ &= 59.9\,\text{MPa}\end{aligned} \tag{29}$$

where μ can represent either the mean or characteristic value. In this example, and most commonly, the characteristic value is transformed as it is used along with the shape factor to define the PDF, which takes the double exponential form [49]

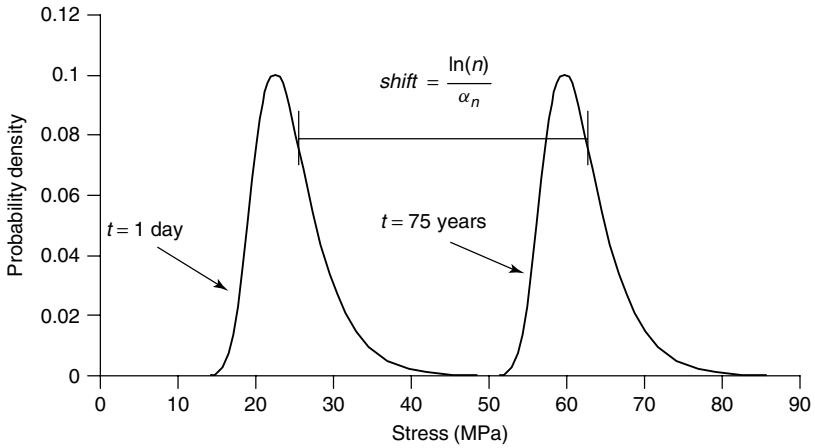

Figure 15. Transformation of a type I (Gumbel) extreme value distribution.

$$f_{Y_n}(y) = n[F_X(y)]^{n-1} f_X(y)$$
$$= \alpha_n e^{-\alpha_n(y-\mu_n)} \exp[-e^{-\alpha_n(y-\mu_n)}] \quad (30)$$

Figure 15 shows the type I (Gumbel) PDFs defined in this example with the associated transformation.

This approach provides the appropriate live load distribution (75-year) to be utilized in a reliability analysis and is useful for monitoring-based safety assessments that consider time effects. Load combinations are also considered if the structure is monitored for a representative period of time as the data will reflect combinations of load demands the structure experiences (e.g. temperature, trucks, wind). Defining what constitutes a representative period of time depends both upon the structure and upon the failure mechanism of interest. Additional information on combinations of extreme events can be found in [52] (*see* **Loads and Temperature Effects on a Bridge**).

3.3 Updating

Monitoring data may not provide the entire basis for the assessment of a structure. More often, there exists some prior belief about the random variable being monitored from codes, expert experience, or experimental tests. In such cases, new information must be combined with existing information in a reasonable manner. When the analysis being conducted is probabilistic in nature and the data sets in question contain variability, Bayesian updating provides a methodology to combine this data.

Assume that $f'(\theta)$ defines an existing (prior) belief of a random variable. The use of monitoring provides sample data that defines this same random variable with a different distribution $f(x)$. The combined (posterior) distribution $f''(\theta)$ is defined as in [50].

$$f''(\theta) = kL(\theta) f'(\theta) \quad (31)$$

The likelihood $L(\theta)$ expresses the conditional probability of observing $f(x)$ given $f'(\theta)$

$$L(\theta) = f(x/\theta) \quad (32)$$

and k is a normalizing factor

$$k = \int_{-\infty}^{\infty} \frac{1}{L(\theta) f'(\theta)\, d\theta} \quad (33)$$

to ensure the area under the PDF is 1. When the information collected is used for updating, two types of information should be distinguished—the equality and the inequality types [47]. Information of the equality type indicates that some basic strength, load, or response variable is measured. Measurement error should be modeled as separate random variable with a mean value of zero (unbiased estimates) and with an appropriate assigned standard deviation. Information of the inequality type refers to observations where it is only known that the observed variable is greater than or less than some limit or threshold: whether

corrosion has initiated, a certain crack width is greater than a prescribed threshold, or a limit state of elastic yielding is reached. In this type of investigation, the uncertainty of the threshold value is taken into account through the use of a probability of detection curve (POD curve). Modeling of POD curves can be found in [53].

Applications for updating in the assessment of civil structures are many. Several include the updating of the expected corrosion initiation time based on chloride penetration levels or presence (inequality), updating the performance of a network based upon success or failure readings at multiple locations (inequality), or including new information about material properties, geometry, or load demands (equality). A number of closed-form solutions for the posterior distribution $f''(\theta)$ can be found in [54–56]. In cases where no analytical solution is available, FORM/SORM techniques [39] may be required or Monte Carlo Simulation may be utilized. A commonly used closed-form solution is the case where both the prior and observed distributions are normal. When this is the case, the resulting distribution of the mean is also normal with the descriptors defined as in [57].

$$E(\theta|x) = \mu'' = \frac{\tau^2}{\tau^2 + \sigma^2}x + \frac{\sigma^2}{\sigma^2 + \tau^2}\mu \quad (34)$$

$$SD(\theta|x) = \sigma'' = \sqrt{\frac{\sigma^2\tau^2}{\sigma^2 + \tau^2}} \quad (35)$$

where, μ represents the prior mean, τ^2 the prior variance, x the monitoring-based mean, and σ^2 the monitoring-based variance. In the updating process, if the monitoring results are scattered or offer little new information, the effect on the prior distribution will be minor. In contrast, if the monitoring data shows only minor amounts of dispersion, the effect on the prior distribution will be large [58].

Example 8 An engineer is involved in a disaster relief reconstruction effort. Wood is extremely difficult to come by and the quality is often poor. Only two stockpiles of fir and pine boards of varied qualities and sizes are available. The engineer does not know exactly what type of fir and pine the boards are and can only estimate a low moisture content based on dry local conditions. An estimate of the modulus of elasticity is obtained for each wood by examining material property tables using likely supplier locations and an estimated moisture content of 10%. The fir modulus of elasticity is believed to be normally distributed with $\mu = 11\,000$ MPa and $\tau = 1500$ MPa. The pine modulus of elasticity is estimated as normally distributed with $\mu = 8000$ MPa and $\tau = 1000$ MPa. Using a strain gauge and known load, the engineer sets up a fairly crude three-point bending test sampling 20 boards of each wood type. The results are both fit to normal distributions and are surprisingly better than anticipated. The sample-based modulus for the fir is $x = 13\,000$ MPa and $\sigma = 3000$ MPa and the sample-based modulus for the pine is $x = 10\,000$ MPa and $\sigma = 500$ MPa. What material properties should the engineer utilize in design?

Answer Because the information available is probabilistic and contains varying degrees of uncertainty, a Bayesian approach is appropriate. For the fir, the posterior distribution is characterized by

$$E(\theta|x) = \mu'' = \frac{1500^2}{1500^2 + 3000^2} \times 13\,000 + \frac{3000^2}{3000^2 + 1500^2} \times 11\,000 = 11\,400 \text{ MPa} \quad (36)$$

$$SD(\theta|x) = \sigma'' = \sqrt{\frac{3000^2 \times 1500^2}{3000^2 + 1500^2}} = 1342 \text{ MPa} \quad (37)$$

For the pine, the posterior distribution is characterized by

$$E(\theta|x) = \mu'' = \frac{1000^2}{1000^2 + 500^2} \times 10\,000 + \frac{500^2}{500^2 + 1000^2}8000 = 9600 \text{ MPa} \quad (38)$$

$$SD(\theta|x) = \sigma'' = \sqrt{\frac{500^2 \times 1000^2}{500^2 + 1000^2}} = 447 \text{ MPa} \quad (39)$$

Figure 16 shows the prior, monitored, and posterior distributions for each type of wood. It should be noted that the posterior distribution is most influenced by the data set containing the best-quality information (least amount of variability). For the pine, because the monitored information contained a high degree

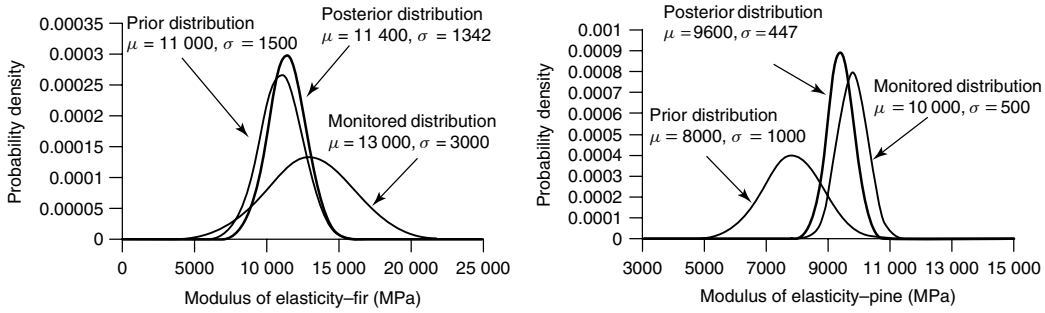

Figure 16. Bayesian updating of the modulus of elasticity of two types of wood.

of variability, it has little effect on the posterior distribution. This is reversed with respect to the fir.

3.4 Time-dependent reliability

Although assessment is a critical step in the management of civil infrastructure, predicting future performance is what allows the efficient scheduling of inspections, maintenance, repairs, and replacements. In fact, such predictions are the basis of LCM methods, durability-based design approaches, and whole-life cost approaches (nearly equivalent terminology). In general, the capacity (resistance) of a structure decreases over time as the structure deteriorates and the load demand increases. Load demand increase in a time-dependent reliability analysis has both a physical and a mathematical sense. In the physical sense, many of the loads being placed on structures have increased, such as the weight of present day trucks compared to those decades ago [43]. Mathematically, as a distribution is repeatedly sampled, the probability of encountering an extreme value increases as previously discussed for live load effects. The deterioration of various materials is a widely researched topic. Enright *et al.* [59] compiled a survey of deterioration models for concrete structures. Deterioration of concrete structures is typically divided into two categories, chemical and physical deterioration mechanisms. Chemical deterioration includes chloride attack, carbonation, acid attack, and alkali-aggregate reaction, while physical deterioration involves freeze–thaw, leaching, erosion, and cracking [26]. For transportation networks, chloride penetration of the concrete and subsequent corrosion of the reinforcing steel is the primary cause of capacity degradation. For steel structures, corrosion models predict where and when corrosion will result in section loss of the steel shape. Albrecht and Naeemi [60] first developed a model for steel girders that was later improved by Thoft-Christensen to include values for random variables [61]. Vulnerability of steel structures to corrosion is largely determined by regional/environmental conditions, proximity of a specific member to exposure, and the presence of aggressive agents. The durability of wood depends largely on environmental conditions, specific wood type, and preservation efforts. Generally, the performance of wood structures decreases over time due to natural weathering, decay, biological attack (fungus or insects), or chemical attack and service life can range from a short period up to 500 years [1].

Much work has been done in the development of reliability-based models to predict structural performance over time [62–64] and in the implementation of structural health monitoring [65–70]. In the most basic sense, these models determine a structure's initial state, model its deterioration, model future demands, and predict future performance. A reliability curve showing structural safety over time as shown in Figure 17(a) is the most common product of such analysis. Because there is uncertainty in (i) initial modeling parameters (ii) rates of deterioration, and (iii) future loads, the performance of the structure at any point of time is also uncertain and requires probabilistic treatment. Monitoring can be introduced at any point in time to reduce uncertainty by improving the accuracy of model input parameters resulting in a change of the reliability index β. Figure 17(b) shows a case in which an initial downward revision in the reliability index would result in the minimum safety threshold, β_{MIN}, being reached sooner.

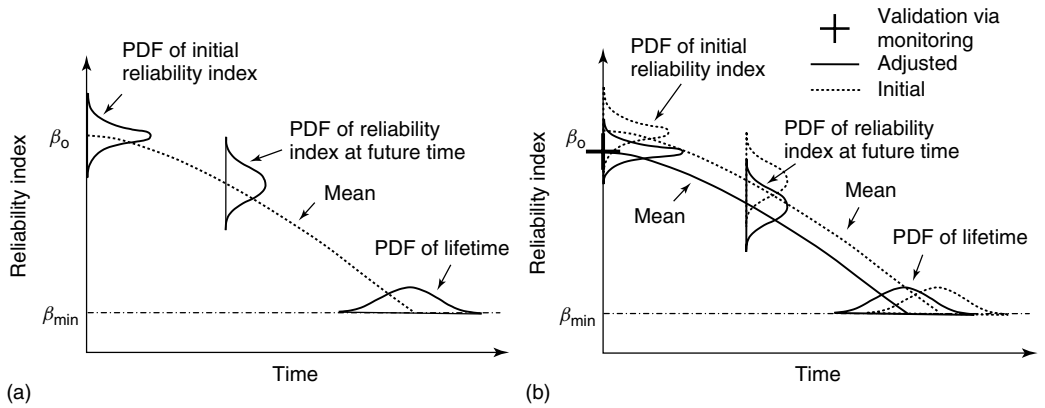

Figure 17. Predicted reliability index (a) without monitoring and (b) after an initial monitoring-based assessment. [Reproduced with permission from Ref. 71. © Taylor and Francis, 2006.]

A natural extension of monitoring at a point in time is monitoring continuously. There is significant benefit to such an approach as (i) the effects of uncertainty compound as one projects further into the future and (ii) permanent monitoring allows for the establishment of performance thresholds that allow a signal to be sent to the asset manager when violated [71]. A framework to introduce continuous monitoring into a reliability-based analysis is shown in Figure 18(a). Figure 18(b) and 18(c) illustrate how multiple or continuous monitoring assessments allow for capturing the rate of deterioration and validation of maintenance actions or repair activities.

3.5 Life-cycle costs with the inclusion of monitoring

The development of a time-dependent reliability-based performance prediction allows for the planning of inspections, maintenance, and repairs. Different combinations of inspection scheduling, preventive or routine maintenance actions, and repair or replacement strategies are typically compared using the metric of life-cycle cost as in [72]:

$$C_{ET} = C_T + C_{PM} + C_{INS} + C_{REP} + C_F \quad (40)$$

where C_{ET} = expected total cost, C_T = initial design/construction cost, C_{PM} = expected cost of preventive or routine maintenance, C_{INS} = expected cost of performing inspections, C_{REP} = expected cost of repairs, and C_F = expected cost of failure. Inclusion of monitoring into this general form results in [30]

$$C^0_{ET} = C^0_T + C^0_{PM} + C^0_{INS} + C^0_{REP} + C^0_F + C_{MON} \quad (41)$$

where C_{MON} = expected cost of monitoring. Because any monitoring solution will need its own management, maintenance, and repair, it is also best treated with respect to life-cycle costs as

$$C_{MON} = M_T + M_{OP} + M_{INS} + M_{REP} \quad (42)$$

where M_T = expected initial design/construction cost of the monitoring system, M_{OP} = expected operational cost of the monitoring system, M_{INS} = expected inspection cost of the monitoring system, and M_{REP} = expected repair cost of the monitoring system. The operational cost of the monitoring system would include the cost of power (battery or electricity), as well as the costs associated with data processing and data management. The benefit, or utility, of the monitoring system, B_{MON}, is then captured through a comparison of the expected life-cycle total cost with and without monitoring:

$$B_{MON} = C_{ET} - C^0_{ET} \quad (43)$$

Close attention must be given to calculating and communicating the utility of monitoring. Because facility managers must prioritize limited available resources, it must be assumed that monitoring would not be utilized unless shown to be cost effective.

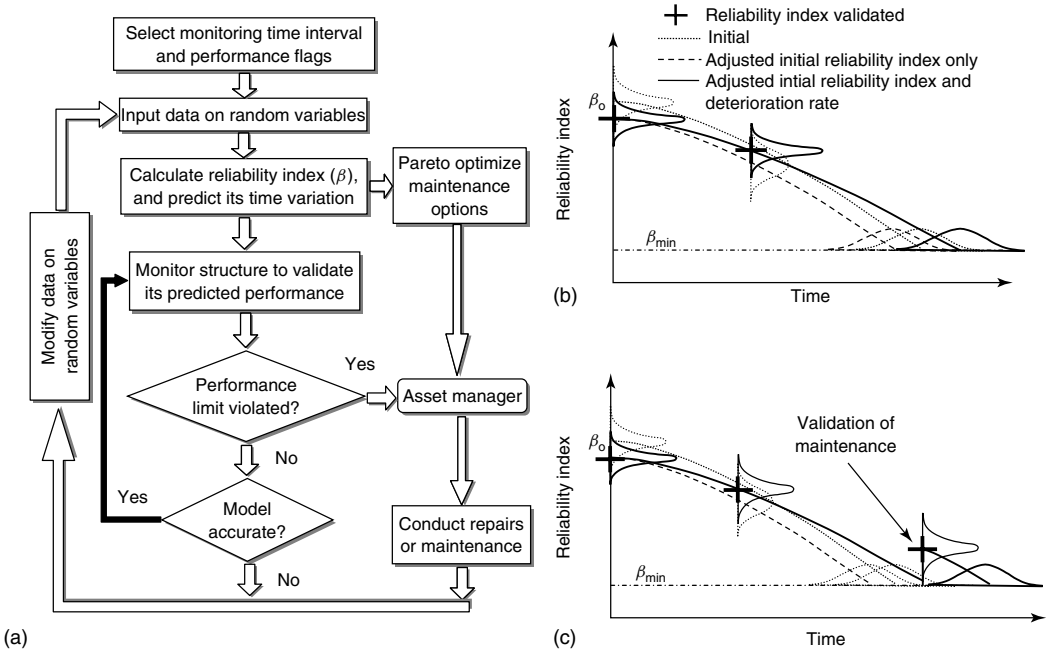

Figure 18. Framework to implement periodic or continuous monitoring. (a) Continuous monitoring framework, (b) validation of deterioration, and (c) validation of maintenance. [Reproduced with permission from Ref. 71. © Taylor and Francis, 2006.]

Example 9 A reliability analysis of a typical short-span highway bridge under corrosion (Figure 19a) yields the reliability index profile shown in Figure 19(b). The engineer believes the model would be significantly improved through a reduction in the uncertainty associated with the section modulus Figure 19(c). In order to investigate this improvement, the standard deviation is reduced, and the analysis was repeated for several alternatives (Figure 19d). Consulting with a monitoring expert, it is agreed that a 50% reduction in the uncertainty associated with the corrosion of the steel girder is feasible via monitoring. Girders are scheduled for replacement when a reliability index threshold of 2.0 is reached at a cost of \$100 000. What is the potential cost benefit associated with the 50% reduction?

Answer The reliability analysis is reconstructed imposing a performance threshold of 2.0 and by projecting the resulting girder replacements when required as shown in Figure 20. In this case, the reduction of model uncertainty results in one less projected repair.

Calculating net present values and assuming a discount rate of 4%,

$$C_{\text{REP}} = \frac{\$100\,000}{(1+0.04)^{25}} + \frac{\$100\,000}{(1+0.04)^{45}} + \frac{\$100\,000}{(1+0.04)^{60}} = \$64\,138 \tag{44}$$

$$C^0_{\text{REP}} = \frac{\$100\,000}{(1+0.04)^{35}} + \frac{\$100\,000}{(1+0.04)^{60}} = \$34\,848 \tag{45}$$

meaning that there is an expected benefit of \$29 290 (i.e., \$64 138 – \$34 848) with respect to the cost of repairs, which can be considered in the design or development of the monitoring solution.

3.6 The incorporation of risk

The answer to the previous analysis is fairly inadequate and can be improved significantly through the incorporation of risk. One of the principle advantages to monitoring should be an increased level of safety through a reduction of uncertainty. Quantifying

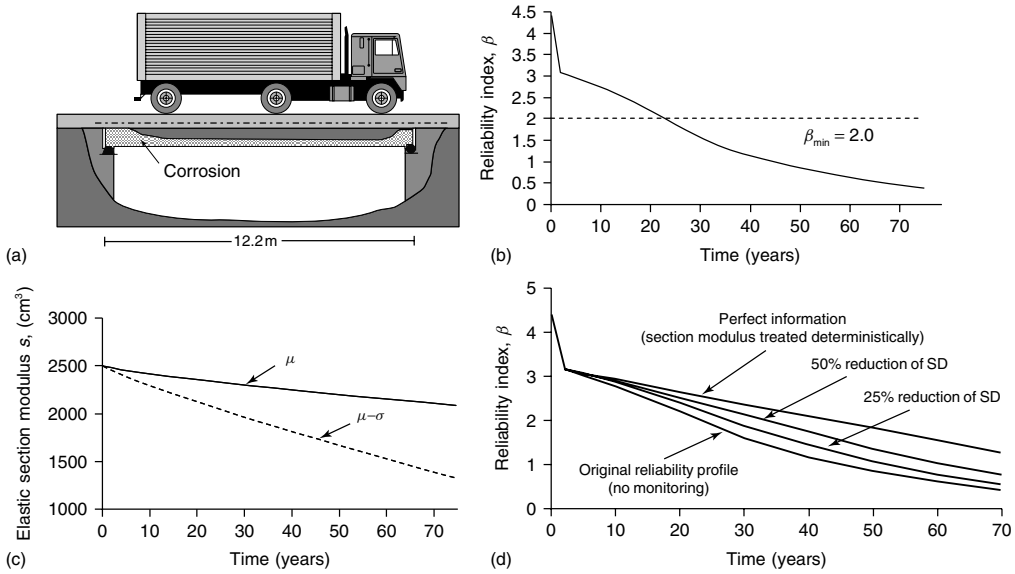

Figure 19. Reliability analysis with respect to flexure of a short-span steel beam highway bridge subjected to live load effects and corrosion over time. (a) Short-span steel girder concrete deck highway bridge, (b) reliability curve with respect to girder flexure, (c) girder average section modulus and deviation, and (d) reliability curve with reduction in section modulus uncertainty. [Reproduced with permission from Ref. 48. © Taylor and Francis, 2007.]

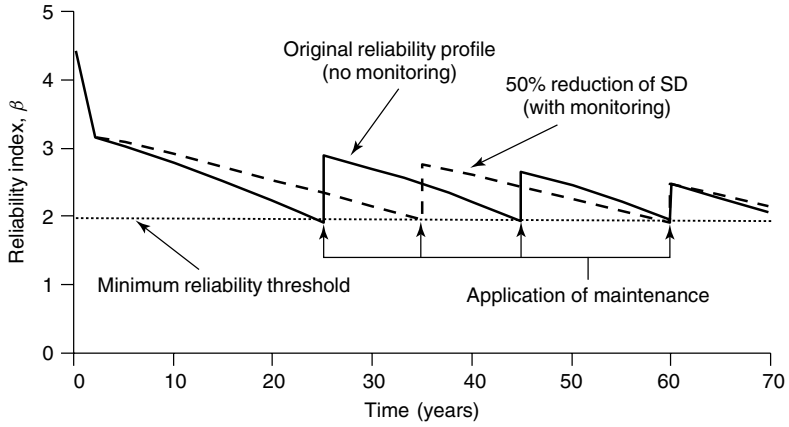

Figure 20. Reliability profile and associated maintenance actions with and without monitoring

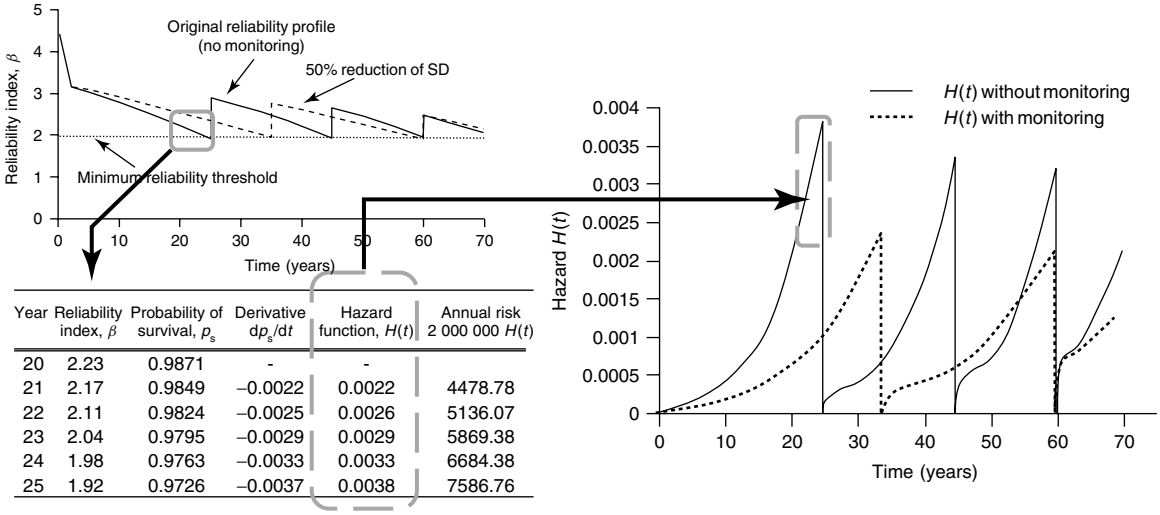
this increased safety in dollars is necessary to appropriately communicate the utility of any monitoring solution. Risk, or the expected cost of failure C_F, can be calculated as the product of the likelihood of an event and the associated consequences given the event occurs as

$$Risk = R = C_F = p_f C \tag{46}$$

Introducing risk into a time-dependent reliability analysis requires the use of a hazard function $H(t)$. This function expresses the conditional probability of failure in time $(t, t + dt)$, given that failure has not already occurred [73].

$$H(t) = -\frac{dp_s(t)}{dt} \times \frac{1}{p_s(t)} = -\frac{S'(t)}{S(t)} \tag{47}$$



Year	Reliability index, β	Probability of survival, p_s	Derivative dp_s/dt	Hazard function, $H(t)$	Annual risk 2 000 000 $H(t)$
20	2.23	0.9871	-	-	
21	2.17	0.9849	–0.0022	0.0022	4478.78
22	2.11	0.9824	–0.0025	0.0026	5136.07
23	2.04	0.9795	–0.0029	0.0029	5869.38
24	1.98	0.9763	–0.0033	0.0033	6684.38
25	1.92	0.9726	–0.0037	0.0038	7586.76

Figure 21. Calculation of the hazard function and associated annual risk. [Adapted from Ref. 73.]

where $p_s(t)$ is the probability that an element is safe at any time t, which is also referred to as the survivor function $S(t)$ and $S'(t)$ its derivative.

Example 10 Assuming a consequence of failure of \$2 000 000 for cleanup, liability costs, design, and reconstruction of a new bridge, calculate the associated cost of failure, C_F, for both options considered in example #8.

Answer The hazard function is created by taking the reliability index β, calculating the corresponding probability of survival p_s, and by calculating the derivative of the probability of survival at each time step for use in the above equation of the hazard function $H(t)$. These calculations are detailed along with the corresponding annual risk for years 20–25 for the option without monitoring (Figure 21).

Calculating the net present value of the annual risk each year and then summing these net present values across the life of the structure for both the options—with and without monitoring yields

$$\begin{aligned} C_F &= \$44\,204 \\ C_F^o &= \$27\,371 \end{aligned} \tag{48}$$

meaning there is an expected benefit of \$16 833 (i.e., \$44 204 − \$27 371) with respect to risk. Combining this result with those in Example 9 yields an expected total benefit of \$46 123 (i.e., \$29 290 + \$16 833) of incorporating a monitoring solution that reduces the uncertainty associated with the section modulus by 50%. Such a monitoring approach would only be cost effective if its life-cycle costs were less than this amount. Such information can be used not only to quantify the utility of monitoring but for use as a monitoring design constraint.

4 CONCLUSIONS

The incorporation of monitoring technologies into the design and management of civil infrastructure introduces a number of challenges often not considered in current practice. Probabilistic modeling, rates of deterioration, predicting costs, sensor placement, information management, and linking this information to accepted design and assessment standards are some of the issues, to name a few—many which have yet to be resolved. This chapter used examples to highlight some of these challenges as an introduction to the topic. Optimization of different monitoring alternatives, treatment of networks of sensors, and acceptance criteria for information obtained from SHM are left for further investigation. Notably present in this chapter, however, is a sharp contrast between SHM being utilized as a response to a discovered structural defect, and SHM being part of an LCM process, where, of course, the latter is preferred. Because of the importance and value of civil infrastructure to the

society it supports, designing better and managing more efficiently is necessary and timely, especially as focus turns to managing existing aging structures. Within this context, monitoring has the potential to significantly aid engineers and managers in making optimal resource allocations by providing site-specific real-time information. To justify the initial and follow-up costs of employing monitoring solutions, the development of metrics that quantify and communicate the utility of monitoring systems are crucial to their acceptance and more frequent use. To achieve this end, engineers and managers must become more comfortable in the assessment and design of civil structures within a performance-based, life-cycle, risk inclusive context.

Chapter 92

Usage Management of Military Aircraft Structures

Rolf H. Neunaber

Industrieanlagen Betriebsgesellschaft mbH, Ottobrunn, Germany

1 INTRODUCTION

An essential requirement in the aircraft (A/C) design is the minimization of the structure weight. Therefore, the structure components are designed only to withstand the cyclic loading of the specified usage profile without any damage (safe-life design) or with damage that can be discovered during in-service inspections before becoming critical (fail-safe design). The structure will be qualified within these boundary conditions for a specific number of allowable flight hours.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

On the other hand, this design enforces that a deviation from the certified usage spectrum during in-service usage has a draw back to the allowable flight hours. This is especially true for aluminum structures, which are particularly damaged by structural fatigue.

For A/C in civil usage, deviations from the certification profile are within narrow limits only (e.g., flight time per flight). In contrast to civil A/C, the missions and outboard store configurations for military A/C change quite often, which results in a high scatter of usage for individual A/C. For a proper assessment of the individual life consumption, the usage of an adapted structural health monitoring (SHM) system is mandatory.

The SHM usage is thereby not restricted to flight safety only. The SHM system is increasingly used for the usage management of the A/C structure. An essential subtask of this is the optimization of maintenance, e.g., inspections and modifications.

2 A/C STRUCTURE CERTIFICATION

Development specifications for military A/C generally require a fatigue test of the entire airframe, or at least its principal components, as proof of structural

integrity. Although test speeds allow the simulation of a large number of daily flights, several years are necessary for the completion of the fatigue test, allowing for interruptions for repair, modification, and inspection. Thus, for reasons of time and money, series production of A/C begins before all results of the fatigue tests on the various fatigue critical areas (FCAs) are known and the necessary modifications made. Individual batches of series production A/C, therefore, still have structural FCAs, albeit with decreasing frequency, whose inherent fatigue life in all probability will not last throughout the planned operational usage.

Hence, necessity to retrofit and repair structural components is unquestionable. The question is, which A/C requires which repair, and when. There are several reasons for asking this question, for example,

- restrictions on operational usage for unmodified structures and
- cost-effective modification.

In order to answer these questions satisfactorily, it is necessary to know the fatigue life ratio of the operational stress spectrum on FCAs to the stress spectrum applied during the fatigue test, i.e., how many operational flight hours are equivalent to a simulated flight hour during testing. Depending on the structural point in question, such spectra comparisons range from

- either a higher or lower operational stress spectrum compared to the test to;
- the stress spectrum simulated during the test not being representative in detail for operational usage.

Thus, it is both useful and essential for the A/C user to have an instrument, which answers the complex questions mentioned above and enables necessary activities to be planned. This task is dealt with by A/C SHM (Figure 1).

3 SHM SYSTEM DESIGN

3.1 System concept

An SHM system is normally composed of the following two essential parts:

- **Onboard**

Load and/or condition data acquisition and processing:

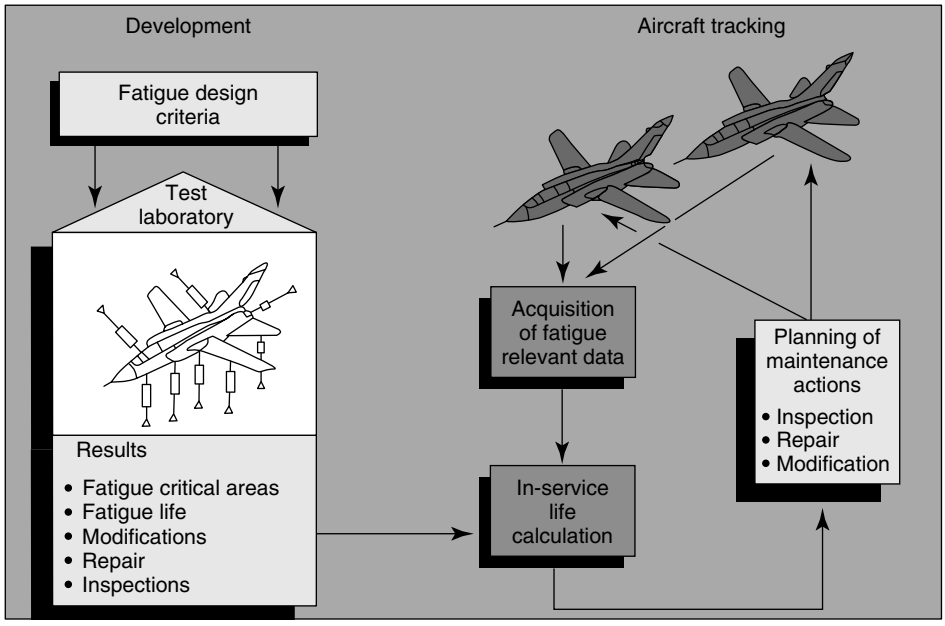

Figure 1. Aircraft structural health monitoring.

The primary function of this part is the acquisition of the load and/or condition data of the FCAs. This part also comprises data processing to a certain extent and data recording for later evaluations on ground.

- **On-ground**

Data processing, evaluation, and fleet management support:

After several input data checks, the milked A/C data are processed with adapted software tools with the aim to generate the load/stress spectra and the accumulated damages for the specific flight of a tail number for each FCA. The processed data are stored together with the relevant identification data for that flight (e.g., flight hours, configuration, and number of landings). This SHM data set forms the basis for the follow-on evaluations required for fleet management.

The onboard/on-ground data transfer is carried out with type-specific designed hand-held terminals. The on-ground station is normally a commercial PC with adapted software tools. Furthermore, the SHM systems can be differentiated according to the following two design variants:

- SHM system is designed and developed together with the A/C itself
  - The SHM system has to be designed to be able to monitor the complete primary structure of the A/C. This is because the FCAs are unknown at this time.
  - If possible, the A/C structure itself can be designed partly as smart structure with the aim to support SHM.
- SHM system has to be retrofitted
  - In case that no FCAs are known, the SHM system has to be designed to be able to monitor the whole A/C primary structure.
  - If the FCAs are known from test or service experience, the SHM system can be designed for the monitoring of those FCAs. In this case, the cost/benefit relation will reach an optimum.

3.2 SHM system types and evaluation

From the acquisition point of view, two types of SHM systems can be differentiated (Table 1).

3.2.1 Load-acquisition systems

- **Flight parameter data**

The available flight control system parameter data (altitude, velocity, normal acceleration, etc.) are

Table 1. Load-acquisition system versus condition-acquisition system

		Load acquisition system	Condition acquisition system
SHM design criteria	– Location of critical area – Type of damage – Stress level/stress spectrum	Selection of relevant flight parameters/strain	Selection of suitable condition acquisition system sensors
	Data acquisition	– Flight parameter/strain versus time – Flight parameter/strain spectra	Sensor and structure condition
In-service usage	Data processing (onboard/on ground)	– Stress spectra generation – Damage calculation	—
	Type of results	– Degree of fatigue degradation – Damage initiation and propagation	Damage initiation and propagation

acquired and stored for stress and damage calculations later on. The data processing is carried out in the following conversion steps:

- parameter history to stress history using specific templates for each FCA;
- stress history to frequency of stress occurrence matrix using a rainflow algorithm and
- frequency of stress occurrence matrix to damage using adapted damage algorithms.

- **Strain data**

The strain data of each local measurement area are acquired and stored for processing later on, analogous to the flight parameter procedure above. The data processing is carried out in the following conversion steps:

- strain history of the measurement point to stress history of the associated FCA using adapted strain to stress algorithms;
- stress history to frequency of stress occurrence matrix as before and
- frequency of stress occurrence matrix to damage as before.

The biggest advantage of the strain sensors is that no templates are necessary for the derivation of the FCA stress history.

In case the fleet is monitored with a flight parameter–based SHM system, additional strain-gauge equipment in a few A/C can be used to derive the necessary FCA templates directly. The equipment mentioned before allows the simultaneous acquisition of flight parameter and strain data as a basis for a correlation analysis according to Figure 2. The results of this analysis are transformed into an FCA template.

3.2.2 Condition-acquisition systems

The condition sensors acquire a change in the structural behavior directly in contrast to the load sensor types. The following condition sensors are examples used in test application and partially in-service:

- comparative vacuum monitoring (CVM)
- fiber Bragg gratings (FBG)
- acousto ultrasonic (AU)
- acoustic emission (AE)
- eddy-current fail sensors (ECFS).

Condition data acquisition during the flight is not necessarily required and/or possible depending on the specific sensor type. Often the after-flight data acquisition is sufficient for the monitoring of a change in the structure's behavior. In this case, the SHM installation equals permanently mounted non destructive inspection (NDI) equipment.

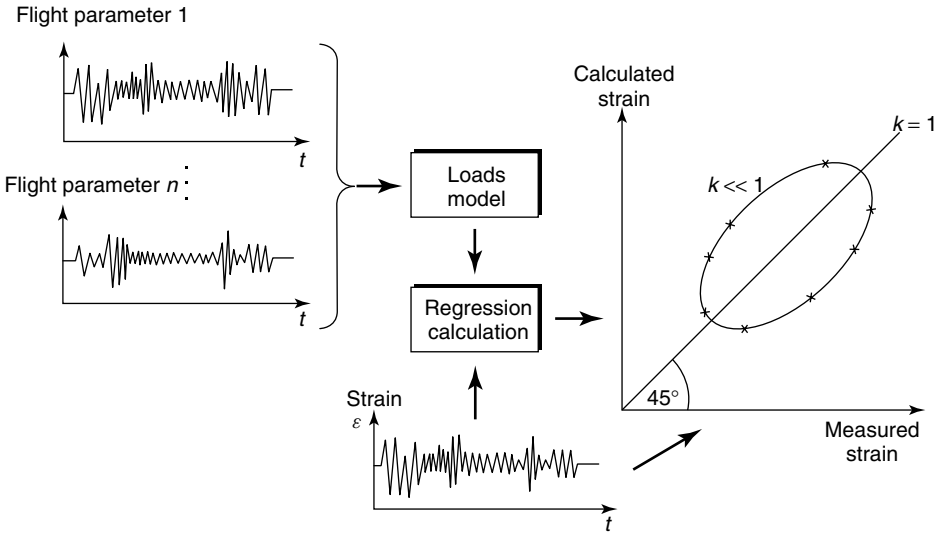

Figure 2. Flight parameter/strain correlation analysis.

3.2.3 Comparison of the SHM systems

- Load-acquisition systems allow better monitoring of the structural degradation especially before crack initiation. Thereby, these systems are used primarily for the planning of preventive measures (inspections or modifications).
- Condition-acquisition systems have the advantage of registering a crack or even crack initiation directly. Compared to load-acquisition systems, no additional safety factor or conservative element needs to be included. This allows the usage of the total individual life capacity.
- Condition-acquisition sensors need to be placed more or less directly on the FCA, which is in many cases not possible.
- Load-acquisition systems are more flexible in usage. This is especially true for flight parameter systems where the necessary FCA parameters (stress templates) need to be developed only once for the whole fleet. In addition, if a new FCA has been uncovered, the generation of one template is sufficient for the monitoring of the whole fleet.

Summarizing the pros and cons, it has to be accepted that the specific application dictates which method is preferable.

4 TORNADO SHM SYSTEM

The Tornado A/C is built mainly out of metallic materials and thereby prone to structural fatigue. The SHM system is designed as a retrofit system primarily used for means of material conservation. The value of this monitoring system thus varies by the ratio of its performance, including such aspects as

- number and importance of FCAs;
- precision of damage calculation per FCA; and
- scope of application for all FCAs of the A/C structure.

to its costs, which include

- investment costs for data acquisition and processing systems and
- recurring costs for data evaluation and report preparation.

Taking the point of view that a number of FCAs must be monitored rather than the entire A/C, the question of optimization of the procedure must be related to the individual FCAs themselves. Most of the Tornado FCAs are located at the center fuselage and wing, where the relevant structure loads are highly influenced by the A/C's normal acceleration.

The tracking concept of the WS Tornado is divided into the three sectors (Figure 3):

- individual aircraft tracking (IAT)
- selected aircraft tracking (SAT)
- temporary aircraft tracking (TAT).

Monitoring is based essentially on flight parameters, which are available on the existing data-acquisition unit of the crash recorder. The following four parameter data sets have been defined according to the concept requirements:

- **Recorder parameter set (RPS)**

The direct acquired flight parameters form the RPS, which is registered by a flight recorder.

- **RPS + strain-gauge data**

During TAT, the strain-gauge data are acquired simultaneously with the RPS flight parameter for the extended data set.

- **Full parameter set (FPS)**

Through differentiations and conversions of several flight parameters, the RPS + data set was transformed to the FPS.

- **Pilot parameter set (PPS)**

To reduce the expense of data acquisition for each individual A/C, an additional severely reduced PPS was defined, containing only the essential flight parameter for stress on the most vital FCAs.

4.1 Temporary aircraft tracking

The key monitoring elements of TAT (Figure 4) are the strain gauges in the various FCAs. They are evaluated by regression techniques to produce a realistic correlation between operational strain in

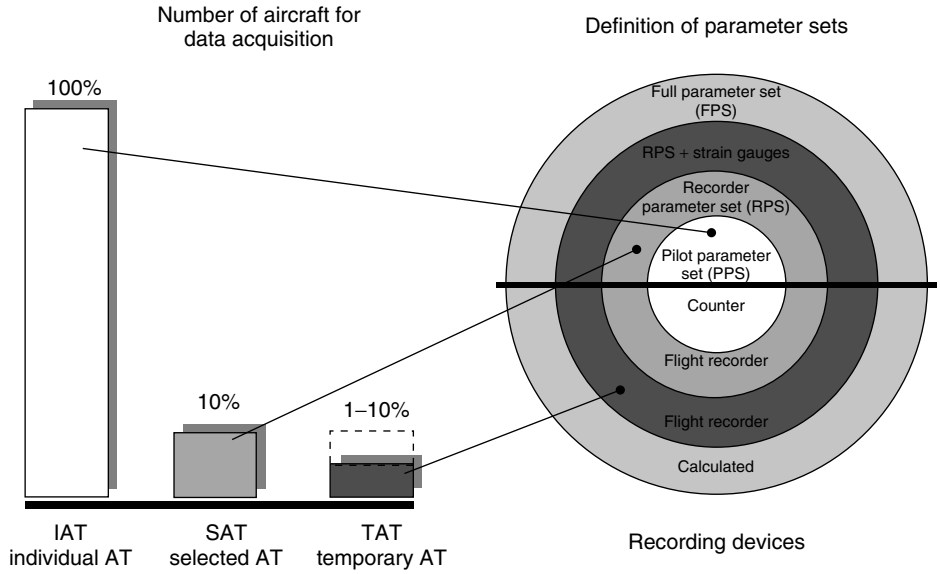

Figure 3. Tracking concept.

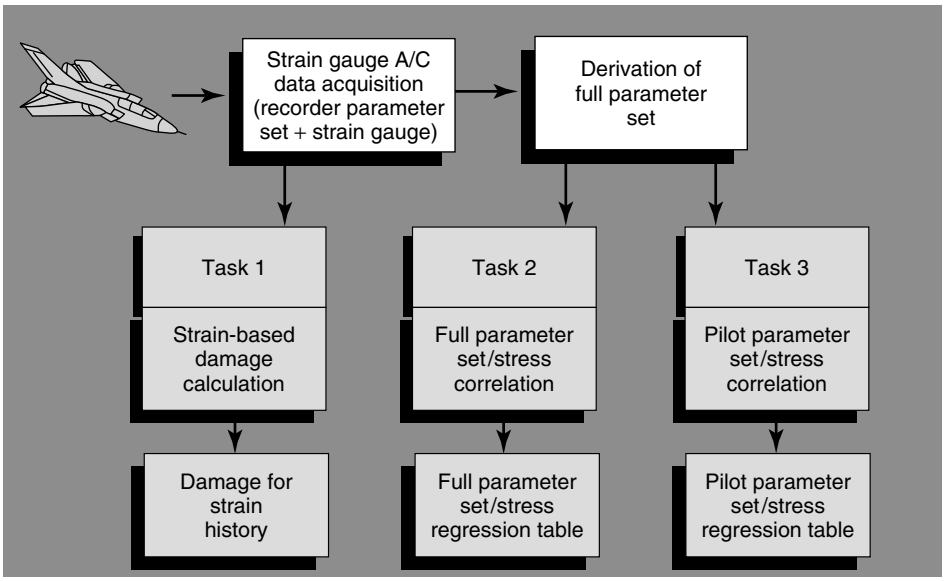

Figure 4. Tornado, temporary aircraft tracking (TAT).

the structure and the flight parameters that cause it. As the strain/parameter correlation is only partially deterministic because of the limited parameter sets, it is cyclically repeated within the TAT segment for the same FCA on several A/C. Hence, mismatches in the parameter algorithms, due to alterations in the A/C configurations and in the operational missions are covered simultaneously.

After transformation of the RPS + strain-gauge data set, the resulting FPS contains all essential influencing variables for mechanical strain (e.g., accelerations and weight).

- **Task 1: Strain-based damage calculation**

Direct conversion of the measured strain history into a frequency of occurrence matrix and calculation of the accumulated damage. The validity is restricted to the A/C observed throughout the measuring period.

- **Task 2: FPS/stress correlation**

Correlation of the FPS with the stress at FCAs obtained from local strain measurement. The correlation analysis extends to a representative number of flights (>100) for a specific A/C configuration and is repeated cyclically.

- **Task 3: PPS/stress correlation**

Correlation of the pilot parameters utilized for IAT with stress at FCAs, calculated from the measured local strain. The correlation analysis extends, as in Task 2, over a representative sample.

4.2 Selected aircraft tracking

The flight recorders are distributed on a statistically representative basis throughout the individual squadrons and register within the RPS the flight parameter spectrum of selected A/C (Figure 5). The derivation of the FPS takes place similarly to TAT, although the recordings do not contain strain-gauge parameters. The generation of the appropriate stress patterns for all FCAs is carried out via the FPS/stress regression table (Task 2 in TAT).

- **Task 4: Flight hour-related damage**

Conversion of the strain history calculated into a frequency of occurrence matrix and, based on that, the calculation of accumulated damage. The applicable safe damage rate per flight hour is calculated on a statistical basis for each squadron.

- **Task 5: Usage spectra survey**

The frequency of occurrence matrices, in a similar manner to Task 4 for selected parameters and stresses, is stored as a basis for the evaluation of further correlated components and structural areas.

- **Task 6: Damage comparison of parameter sets**

The first step simulates IAT, where a stress spectrum is generated with the PPS/stress regression table. In the second step, for the same data sequence, a stress frequency of occurrence matrix is generated with the FPS/stress regression table. In the third step, the

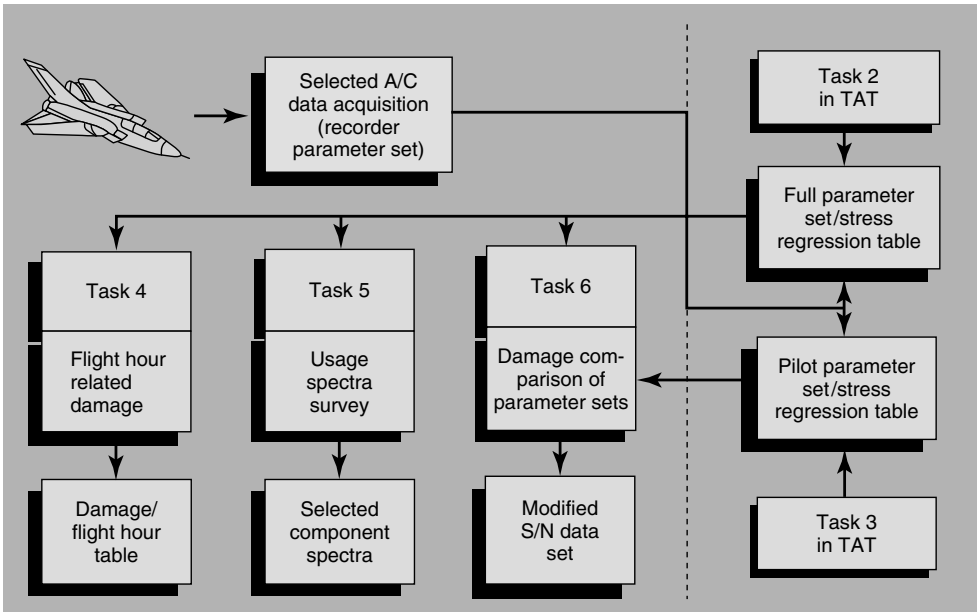

Figure 5. Tornado, selected aircraft tracking (SAT).

resulting damages are compared at individual stress levels. Out of that procedure, the modified stress vs. number of cycles (S/N) data set is generated in order to make the FPS knowledge available for the individual A/C.

Task 4 corresponds to the classic form of SAT, i.e., if the A/C cannot be individually monitored with reference to a specific FCA. This necessarily occurs when the IAT pilot parameters are blind to the stress variation of the FCA. In this case, the scatter of the SAT damage/flight hour is lower compared to the damage calculated with the pilot parameters.

4.3 Individual aircraft tracking

From the conceptual point of view, the IAT permits optimum utilization of the inherent structural life. This naturally presupposes that appropriate sensors (pilot parameters) exist in the individual A/C for the acquisition of stress data. The pilot parameter signals acquired by IAT are converted via the appropriate stress regression table (Task 3 in TAT) into FCA stress spectra and transformed into the individual damage index via the modified S/N data set (Task 6 in SAT).

5 TORNADO USAGE MANAGEMENT

5.1 LEDA Tornado

The Tornado usage management is supported by a software tool named LEDA. LEDA itself is a database, which contains all necessary major inspection actions (including depot inspection) and modification actions for each A/C. The LEDA database is frequently updated with the SHM information from each A/C, which comprises

- flight hours
- A/C configurations
- flown missions
- number of landings
- overall load spectra
- accumulated damage for each FCA.

With the LEDA-internal algorithms, the long and midterm planning of the necessary inspections and modifications for each A/C can be carried out. Several measures can thereby be synchronized for an optimized maintenance schedule.

Beside the LEDA internally processed statistics about the SHM, input data and other calculated data support the fleet management in several decisions. In addition, the LEDA database contains the planning data for other associated programs (Section 6).

5.2 Management actions

As described before, the main aim for A/C monitoring is the optimization of several fleet maintenance tasks, which includes the following:

- Nonperiodic inspection planning (Figure 6)

Planning of usage-dependent inspections of the A/C primary structure. This affects mainly FCAs for which a preventive modification is too expensive at this time and the repair risk is low. The structural safety is thereby established by inspection. The planning of the inspections comprises the initial inspection (threshold) and the follow-on inspections (interval).

For the midterm planning of the nondestructive testing (NDT) inspections at wing box lower panel station XY, Figure 6 shows the relevant A/C tail numbers per calendar year.

- Modification planning (Figure 7)

This planning comprises the necessary preventive modifications of A/C primary structure. Such preventive modifications need to be planned in the long term, because the embodiment requires extensive prerequisites. This includes actions like

  - planning the necessary budget
  - procurement of mod kits
  - adaptation of A/C deployment
  - synchronization with other maintenance actions
  - supply of the required maintenance resources.

Owing to the high number of modification prerequisites, the above planning has to be carried out years before the life of the unmodified structure has been consumed. Bearing that in mind, a load monitoring system has, compared to a condition-monitoring system, the capacity to support long-term planning.

LEDA Tornado

Figure 6. Midterm actions (calendar year).

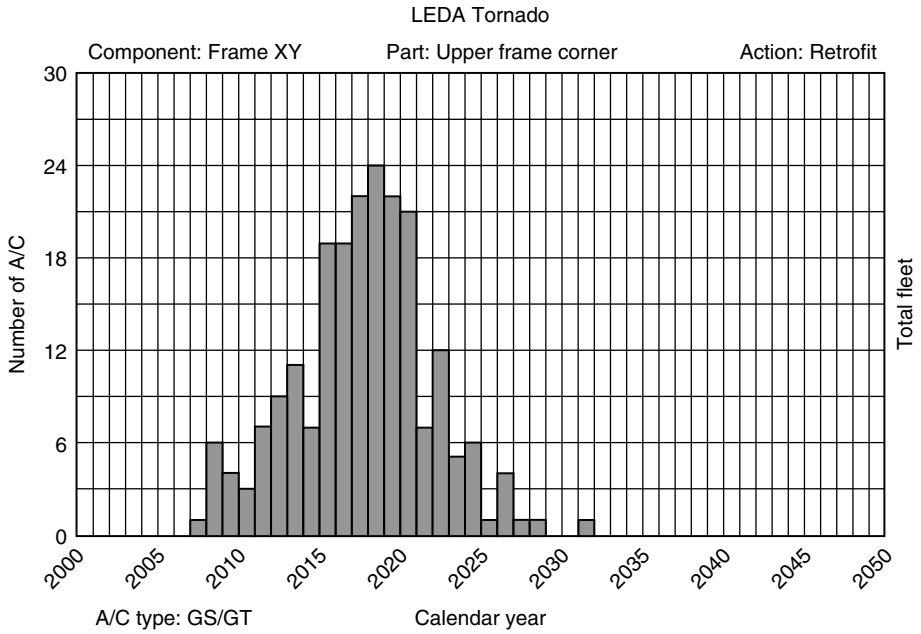

Figure 7. Long-term actions (calendar year).

As an example, Figure 7 shows the long-term planning for the frame XY, upper frame corner retrofit action. The number of retrofit actions per calendar year is presented by graphical methods.

- Fleet management
  - With A/C degradation information, the fleet manager is able to synchronize the operational planning with the maintenance requirements.
  - The A/C degradation information and the maintenance schedule support the fleet manager in the decision on which A/C should be used for specific missions, especially for foreign deployment.
  - If possible, from the A/C configuration point of view, the A/C are rotated between squadrons from time to time based on their accumulated damage. The reason behind that is to reach a balanced degradation over the fleet.

- Out-of-service planning

If for some reasons, A/C have to be retired, then the accumulated damage of the FCAs is one of the selection criteria.

6 ASSOCIATED TASKS

6.1 Analytical condition inspection (ACI)

In addition to the normal periodic inspections, the analytical condition inspection (ACI) program has been defined for the structure and associated equipment to

- find damage in areas, which are normally not inspected due to the required inspection depth or accessibility, sufficiently early, and
- collect information on the technical condition of the fleet leader A/C and to extrapolate the inspection results for follow-on decisions about necessary activities (e.g., modifications) on all A/C.

The ACI program comprises a specific number of A/C per year. The ACI inspection areas are associated with the main structure components (front fuselage, center fuselage, aft fuselage, wing, fin, taileron, and undercarriage).

The LEDA database is the source for the in-depth knowledge of the structural degradation of each A/C. On the basis of this, the ACI candidates are selected (Figure 8).

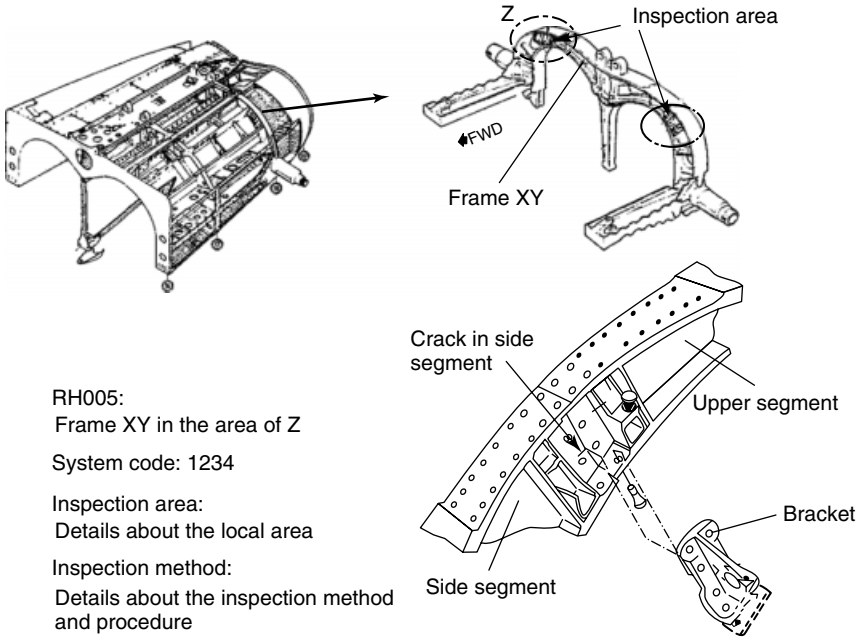

Figure 8. Tornado, analytical condition inspection (ACI).

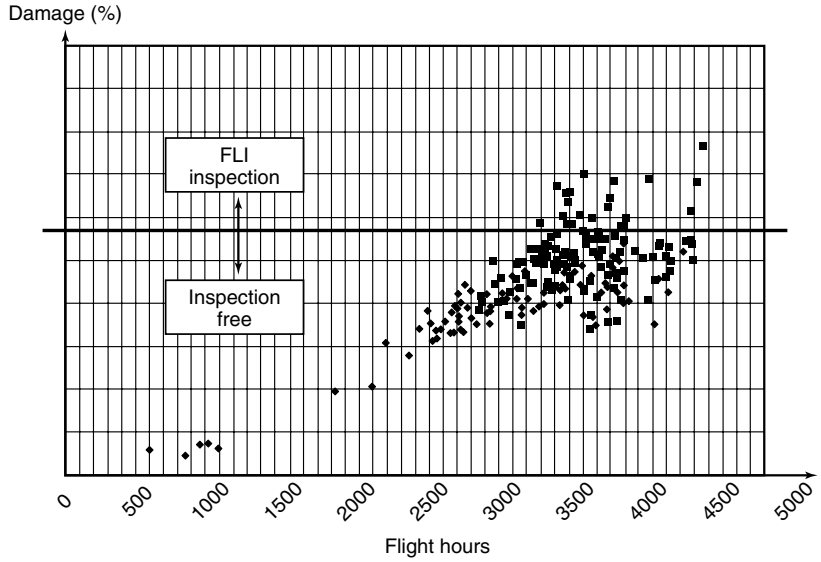

Figure 9. FLI—fleet leader inspection.

6.2 Fleet leader inspection (FLI)

Specific FCAs and their surrounding structure are inspected in the fleet leader inspection (FLI) fleet leader sampling program, which has to be carried out in predefined intervals together with other periodic inspections. The selection of the fleet leader A/C for a specific FCA is based on the in-depth knowledge of the individual FCA damages generated by the SHM system.

To incorporate the influence of several scatter factors, the FLI inspections will be carried out on the most damaged 10% of all A/C. If these A/C are crack-free, it is assumed that the whole fleet is crack-free in this area and the LEDA algorithms are on the safe side (Figure 9).

6.3 Life extension

Germany has decided to extend the Tornado usage from 4000 to 8000 flight hours. This decision was based on the detailed information in the LEDA database about the structure degradation of each individual A/C.

On the basis of LEDA, the necessity for equipment requalification has been derived from the comparison of the actual service usage spectra with the original qualification spectra. If necessary, a requalification has been carried out.

With this knowledge and supported future usage, the main body of the fleet can reach this target with a minimum maintenance overhead.

7 SHM—COST AND BENEFIT COMPARISON

As explained before, the Tornado SHM is carried out primarily for reasons to economize the maintenance effort, e.g., for inspections and modifications. Figure 10 shows a good example for the necessary modification effort of the wing and center fuselage over the complete usage period. The figure differentiates between the costs "without SHM" and "with SHM".

- **Without SHM**

According to the results of fatigue testing, the structural components had to be modified very early within the original design life of 4000 flight hours.

- **With SHM**

Owing to the fact that the in-service FCA stress spectra of the already mentioned structural components are lower than the design spectra, the A/C usage

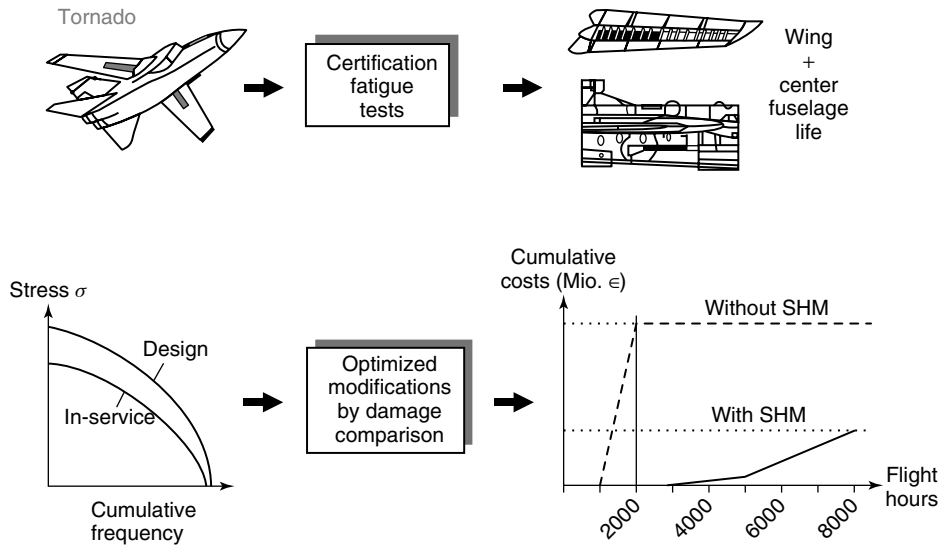

Figure 10. SHM: cost/benefit comparison.

could be extended significantly with very limited modification costs. Even with the life extension to 8000 flight hours, the necessary modifications can be reduced to required packages for the A/C concerned.

This particular example illustrates that modification costs for the case "with SHM" will probably be only one-third of the "without SHM" case. Even if the nonrecurring and recurring costs are considered in addition to the "with SHM" modification costs, the final cost is still considerably less than that for the "without SHM" case.

Chapter 93
Usage Management of Civil Structures

Ayaho Miyamoto
Graduate School of Science and Engineering, Yamaguchi University, Ube, Japan

1 INTRODUCTION

In bridge structures, there are many different unforeseen conditions on which we do not have enough information, because bridges are larger and often need to serve longer—more than 100 years—compared with the other products, such as those in the fields of electrical, mechanical, and systems engineering. And they are subjected to diverse types of deterioration mechanisms such as corrosion, fatigue, carbonation, alkali-aggregate reactions, etc. Although in design code we are forced to consider some parameters or factors affecting structural behavior, there are even more items that we cannot consider them practically. Therefore it is probable to have some risk for not fulfilling the complete standards of safety, so some failure probability is possible. Structural aging, environmental conditions, and reuse are examples of circumstances that could affect the reliability and the life of a structure. Engineers have been visually inspecting, monitoring, and proof testing bridges for centuries. However, presently health and performance are described based on subjective measures that are not universal. In addition, defects, deterioration, and damage are not discovered until it is possible to visually observe the signs they exhibit at which time these would have taken their toll on health. These shortcomings impact the timeliness, effectiveness, and the reliability in any management decision irrespective of any sophistication in the management process. Moreover, even experienced engineers may find visual signs of defects, deterioration, and damage and still not be able to diagnose the causative mechanisms, or their impact on the reliability of the system and global health. The global health of an entire bridge as a system, inclusive of the performance criteria corresponding to each of the limit states, is actually what is needed for effective management decisions. There are needs of periodic inspections to detect deterioration resulting from normal operation and environmental

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

attack or inspections following extreme events, such as strong-motion earthquakes or hurricanes. To quantify these system performance measures, there should be some means of monitoring and evaluating the integrity of civil structures while in service [1]. Then, we need to develop a practical health monitoring system for detecting deterioration phenomenon as early as possible for bridge maintenance.

2 DEFINITION OF HEALTH, PERFORMANCE, AND HEALTH MONITORING OF BRIDGE SYSTEMS

Health can be defined as the reliability of a bridge structure to perform adequately for the required functionalities. Some of these functionalities are as follows [2]:

- utility
- serviceability and durability
- safety and stability of failure at ultimate limit states and
- safety at conditional limit states.

If P_f denotes the probability that the bridge may fail to perform successfully under any likely demand,

$$\text{Health} = (1 - P_f) \text{ for all limit} - \text{state demands/ throughout the life cycle/given as-is condition and symptoms/given the operational and maintenance management} \quad (1)$$

It is not possible to quantify health and reliability of a bridge system for many of the limit states without extensive data that we often do not have. On the basis of a general definition, monitoring is the frequent or continuous observation or measurement of structural conditions or actions [3]. There is another definition that gives more detail: structural health monitoring (SHM) is the use of *in situ*, nondestructive sensing, and analysis of structural characteristics, including the structural response, for detecting changes that may indicate damage or degradation [4]. Figure 1 shows the basic components of a typical structural health monitoring system.

Monitoring is usually carried out in order to achieve one or several goals [2]. The most important goals are as follows:

- structural management
- increase of safety and
- knowledge improvement.

3 STRUCTURAL (BRIDGE) MANAGEMENT

The most safe and durable structures are usually those that are well managed. Measurement and monitoring have an essential role in structural management. The data resulting from the monitoring program is used to optimize the operation, maintenance, repair, and replacing of the structure based on reliable and objective data. Detection of ongoing damage can be used to detect deviations from the design performance. Monitoring data can be integrated in structural management systems and increases the quality of decisions by providing reliable and unbiased information. Many structures are in much better conditions than expected. In these cases, monitoring allows to increase the safety margins without any intervention on the structure. Taking advantage of better material properties, overdesign, and synergetic effects, it is possible to extend the lifetime or load-bearing capacity of structures. A small investment at the beginning of a project can lead to considerable savings by eliminating or reducing overdesigned structural elements.

A few structures might present deficiencies, which cannot be identified by visual inspection or modeling. In these cases, it is possible to increase safety and to decrease managing costs by taking actions before it is too late. Repair will be cheaper and will cause less disruption to the use of the structure if it is done in time. Monitoring can also reduce insurance costs.

The economic impact of structural deficiency is twofold: direct and indirect. The direct impact is reflected by costs of reconstruction, while the indirect impact involves losses in the other branches of the economy. The complete collapse of historical monuments, such as old stone bridges and cathedrals, represents an irretrievable cultural loss for society.

Malfunctioning of civil structures often has serious consequences. The most serious is an accident

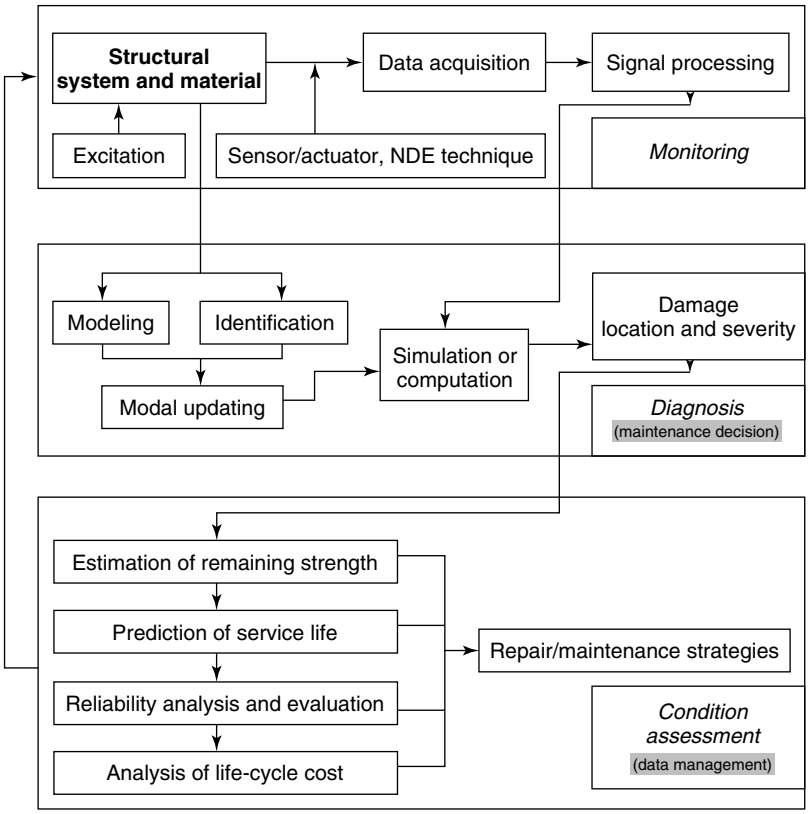

Figure 1. Basic components of a typical structural health monitoring system.

involving human victims. Even when there is no loss of life, populations suffer if infrastructure is partially or completely out of service. Collapse of certain structures, such as nuclear power plants, may provoke serious ecological pollution.

Having permanent and reliable monitoring data from a structure can help to guarantee the safety of the structure and its users.

Learning how a structure performs in real or laboratory conditions will help to design better structures for the future. This can lead to cheaper, safer, and more durable structures with increased reliability and performance. Structural diversity due to factors such as geographical region, environmental influences, soil properties, loads, etc., makes absolute behavioral knowledge impossible: there are no two identical structures.

A good way to enlarge knowledge of structural performance is to monitor their behavior. That is why monitoring during the complete lives of structures, from construction to the end of service, is of interest from the theoretical point of view as well as from the point of view of structure management. Theories need to be tested, and have a better understanding of their health conditions.

In bridge structures, a strategic life-cycle management aided by the latest information technologies, such as network-based database system, intelligent health monitoring, multimedia virtual reality, artificial intelligence, etc., has to be developed to increase their safety and have a better understanding of their health conditions.

4 TECHNOLOGY ISSUES FOR SHM

At present, there are many themes for doing research on SHM. The most important topics are as follows [5, 6]:

- Optic fiber sensing
  - distributed sensors
  - point sensors
  - smart and advanced sensors
- Remote sensing and wireless sensor networks
- Data acquisition
- Data analysis
- Signal processing
- Structural/system identification (SI)
- Damage detection/diagnosis and damage localization
  - forced vibration-based damage detection
  - wind-induced vibration-based damage detection
  - ambient vibration-based damage detection
- Neurocomputing methods for SI and damage detection
  - artificial neural networks (ANNs)
  - fuzzy logic
- Nondestructive structural condition methods and tests
- Structural modeling and simulation by finite-element analysis methods
- Model updating, safety evaluation, reliability, and decision making
- Intelligent materials and structures
- Database and management systems
- System integration
- Health monitoring for special bridges
  - medium-span bridges
  - long-span bridges
    - suspension
    - cable-stayed
- Inclusion of health monitoring system in bridge management system
- Health monitoring of existing and/or new bridge structures
- Life-cycle performance design
- Health monitoring of strengthened bridges with new material or methods like Fiber Reinforced Plastics (FRP).

As is obvious, SHM is a very vast domain of research. It provides benefits to design engineers and practitioners who will have a better understanding of structural behavior and can make feasible decisions. SHM is mainly done to achieve the following objectives:

- detecting the existence of damage;
- finding the location of damage;
- estimating the extent of damage; and
- predicting the remaining fatigue life.

The practical method to investigate the structural condition is getting some results from dynamic responses by using dynamics-based methods. The attractiveness of dynamic responses is due to the fact that we are able to detect and locate damage using them. Dynamic responses are directly related to the global behavior of structure and they can provide rapid inspection of large structural systems. The dynamics-based methods can be divided into four groups:

1. spatial-domain methods
2. modal-domain methods
3. time-domain methods and
4. frequency-domain methods.

Spatial-domain methods use changes of mass, damping, and stiffness matrices to detect and locate damage. Modal-domain methods use changes of natural frequencies, modal damping ratios, and mode shapes to detect damage. In the frequency-domain method, modal quantities such as natural frequencies, damping ratio, and model shapes are identified. In time-domain method, system parameters were determined from the observational data sampled in time.

Moreover, one can use model-independent methods or model-referenced methods to perform damage detection using dynamic responses presented in any of the four domains. The literature shows that model-independent methods can detect the existence of damage without much computational efforts, but they are not accurate in locating damage. On the other hand, model-referenced methods are generally more accurate in locating damage and require fewer sensors than model-independent techniques, but they require appropriate structural models and significant computational efforts. Although time-domain methods use original time-domain data measured using conventional vibration measurement equipment, they require certain structural information and massive computation and are case sensitive. Furthermore, frequency- and modal-domain methods use transformed data, which contain errors and noise

due to transformation. Moreover, the modeling and updating of mass and stiffness matrices in spatial-domain methods are problematic and difficult to be accurate. There are strong development trends that two or three methods are combined together to detect and assess structural damages. For example, several researchers combined data of static and modal tests to assess damages. The combination could remove the weakness of each method and check each other. It suits the complexity of damage detection.

SHM is also an active area of research in aerospace engineering, but there are significant differences in the methods used in aerospace engineering, mechanical engineering, and civil engineering in practice. For example, because bridges, as well as most civil engineering structures, are large in size, and have quite low natural frequencies and vibration levels, at low amplitudes, the dynamic responses of bridge structure are substantially affected by the nonstructural components, and changes in these components can easily to be confused with structural damage. Moreover, the level of modeling uncertainties in reinforced-concrete bridges can be much greater than in the single beam or a space truss. All these make the damage assessment of complex structures such as bridges a still challenging task for bridge engineers.

One of the important problems facing SHM is that very little is known about the actual stress and strains in a structure under external excitations. For example, the standard earthquake recordings comprise recordings of motions of the floors of the structure and no recordings of the actual stresses and strains in structural members. There is a need for special sensors to determine the actual performance of structural members.

SHM requires integrated sensor functionality to measure changes in external environmental conditions, and signal-processing functionality to acquire, process, and combine multisensor and multimeasured information. Individual sensors and instrumented sensor systems are then required to provide such multiplexed information.

4.1 Sensor types

1. Sensor types in structural control and their applications in civil engineering are summarized. In general, there are different kinds of sensors for on-line monitoring, such as piezoelectric transducer, optical fiber sensors, and embedded Brag grating sensors. The reliability and durability of these sensors have been testified in many large bridges and tall buildings. Unlike many mechanical systems, typical civil engineering structures are often large in size and therefore have very low natural frequencies. In addition, the vibration level of the structural responses is quite low very often except under strong earthquake. Therefore, the sensors of a monitoring system must be able to work in a very low-frequency range and they must have a large dynamic measurement range. The industry has made great achievements in developing sensor and is still working forward [4].
2. ISIS Canada, a pioneer research center in the SHM field, has published a report that includes useful information about sensors and sensing systems. It is a very good reference about sensors [7].
3. Now, a new type of sensor, maximum and cumulative displacement memorizing sensor, has been introduced. This sensor is able to measure the maximum, minimum, present, and cumulative displacement without any battery. The sensor system consists of linear potentiometer, rotation potentiometer, transmitter, and noncontact reader (receiver). This sensor system is suitable for memorizing the deformation of aseismic dampers. This system has been installed in several buildings, and its effectiveness is being verified [8].

4.2 Optimum sensor arrangement

The estimation of the parameter values involves uncertainties due to limitations of the mathematical models used to represent the behavior of the real structure, the presence of measurement error in the data, and insufficient excitation and response bandwidth. Although intensive development continues on innovative sensor systems, there is still considerable uncertainty in deciding on the number of sensors required and their location in order to obtain adequate information on structural behavior. In particular, the choice of the number and the location of the sensor in the structure has a major influence on the quality, or

equivalently the uncertainty, of the model parameter estimation. Because complete modal data is impossible for a large flexible structure and measurements yield only partial mode shapes with respect to the total degree of freedom (DOF) corresponding to the finite-element model (FEM), a common practice to bridge the gap is to expand the measured mode shapes or the reduction of freedom in FEM.

Unfortunately, this process unavoidably introduces consequential errors and increases the difficulty in damage detection. One alternative method is to use the measured incomplete mode shapes to detect damage. Then the additional information collected can be used advantageously for damage detection.

1. Methods have been developed to place sensors in an optimal fashion to address the identification and control of dynamic structures by some researchers [9].
2. An effective independence algorithm based on the contribution of each sensor location to the linear independence of the identified modes is proposed. The initial candidate set of sensor locations was quickly reduced to the number of available sensors [10].
3. The effective independence method is extended in an algorithm where sensor placement is achieved in terms of the strain-energy contribution of the structure [11].
4. A methodology for optimum sensor locations is proposed for parameter identification in dynamic systems [12].
5. A rational statistical-based approach is developed for the optimal location of sensor based on Fisher's information matrix (FIM) for the model parameters [13].
6. Using the expected Bayesian loss function involving the trace of the inverse of the FIM, the above-mentioned rational statistical-based approach is extended to treat the case of large model uncertainties expected in model updating [14].
7. An optimal sensor placement is reported for the purpose of detecting structural damage. The prioritization of sensor locations is based on an eigenvector sensitivity analysis of a FEM of the structure [15, 16].
8. Two methods are proposed to determine the optimal or near optimal positioning of sensors. The optimal sensors location is proposed on the FEM associated to the structure to be tested. The first method of location of sensors emphasizes the minimization of the noise effect, and the estimate of the modal coordinates is found in a least-squares sense. The second method is based on the observability Gramian and the optimal sensors location had to ensure observability requirements [17].
9. A method is presented in which the sensor locations are prioritized according to their ability to localize structural damage based on the eigenvector sensitivity method. Numerical examples and test results show that this approach is effective for detecting structural damage directly using optimum and incomplete test modes [18].
10. Measurement selection is proposed in terms of two factors, namely the sensitivity of a residual vector to the structural damage and the sensitivity of the damage to the measurement noise. The advantage of the proposed technique is that it is based on the undamaged state of structure and thus independent of the damaged configuration. Therefore, it is applicable in practice to determine the measurement selection prior to field testing and damage identification analysis [19].
11. A probabilistic advancing cross-diagnosis method is proposed in diagnosis decision making for SHM. It is experimented in the laboratory using a coherent laser radar system and a Charge Coupled Devices (CCD) high-resolution camera. Results show that this method is promising for field application [20].
12. Another new idea is that neural network (NN) techniques are used to place sensors. In an attempt the NN and methods of combinatorial optimization are used to locate and classify faults [21].
13. It has been shown that relatively low-resolution (as compared with the acceleration data) displacement data is now becoming available through Global Positioning System (GPS) technologies, and also potentially through optical technologies [22].
14. A new sensor system is designed for measuring damage indexes and memorizing the data using mechanical memory. Theoretical and experimental studies exhibited excellent performance of the proposed sensor [23].

15. By extensive simulation and experiments for sensor network, it is investigated and verified that the higher the oversampling frequency, the broader the bandwidth and the higher the signal-to-noise ratio (SNR) [24].
16. The problem of locating sensors on a bridge structure is considered with the aim of maximizing the data information so that structural dynamic behavior can be fully characterized. Six different optimal sensor placement techniques, three based on the maximization of the FIM, one on the properties of the covariance matrix coefficients, and two on energetic approaches, are investigated. Mode-shape displacements are taken as the measured data set and two comparison criteria are employed. The first criterion is based on the mean square error between the FEM and the cubic spline interpolated mode shapes. The second criterion measures the information content of each sensor location to investigate on the strength of the acquired signals and their ability to withstand the noise pollution keeping intact the information relative to the structure properties. The results show that the effective independence driving-point residue (EFI-DPR) method provides an effective method for optimal sensor placement to identify the vibration characteristics of the studied bridge. The variance method (VM) gives results very close to the EFI-DPR technique, in terms of the capability to capture the vibration mode shape and signal strength. However, the VM presents unique characteristics in the world of the Optimal Sensor Placement (OSP) techniques, which is the indication of the optimal number of sensors (ONS) [25].

The static and dynamic data are collected from all kinds of sensors that are installed on the measured structures. And these data are processed and usable information is extracted. So the sensitivity, accuracy, locations, etc., of sensors are very important for damage detection. The more information is obtained, the damage identification will be conducted more easily, but the price should be considered. Thus the sensors are determined in an optimal or near optimal distribution. In a word, the theory and validation of optimum sensor locations are still being developed.

5 WHOLE LIFETIME MONITORING OF BRIDGES

The importance of whole life-span monitoring is highlighted in this section [26].

5.1 Monitoring during construction of a new bridge

Construction is a very delicate phase in the life of structures. For concrete structures, material properties change through aging. It is important to know whether or not the required values are achieved and maintained. Defects (e.g., premature cracking) that arise during construction may have serious consequences on structural performance. Monitoring data help engineers to understand the real behavior of the structure and this leads to better estimates of real performance and more appropriate remedial actions.

Important information obtained through monitoring during construction includes the following: Estimation of hardening time of concrete in order to estimate when shrinkage stresses begin to be generated; deformation measurements during early age of concrete in order to estimate self-stressing and risk of premature cracking; and when structures are constructed in successive phases, measurement can help to improve the composition of concrete when necessary. In case of prefabricated structures, sensors may be useful for quality control; optimization between two successive phases of pouring due to evaluation of cure in previous phases; for prestressed structure, deformation monitoring of cables helps to adjust prestressing forces and determine the relaxation; monitoring of foundation settlement helps to understand the origins of built-in stresses; damage caused by unusual loads such as thunderstorm or earthquakes during construction may influence the ultimate performance of structures; optimal regulation of structural position during erection; and knowledge improvement and recalibration of models. The installation of a monitoring system during the construction phases allows monitoring to be carried out during the whole life of the structure. Since most structures have to be inspected several times during service, the best way to decrease the costs of monitoring and inspection is to install the monitoring system from the beginning.

5.2 Monitoring after refurbishing, strengthening, or enlargement of bridge

Material degradation and/or damage are often the reasons for refurbishing existing structures. Also, new functional requirements for the bridge (e.g., enlarging) lead to requirements for strengthening. If strengthening elements are made of new concrete, a good interaction of new concrete with the existing structure has to be assured. Early age deformation of new concrete creates built-in stresses and bad cohesion causes delamination of the new concrete, thereby erasing the beneficial effects of the repair or strengthening efforts.

Since new concrete elements observed separately represent new structures, the reasons for monitoring them are the same as for new structures, presented in previous subsection. The determination of the success of refurbishment or strengthening is an additional justification.

5.3 Monitoring during testing of bridge

Bridges have to be tested before service for safety reasons. At this stage, the required performance levels of structures have to be reached. Typical monitored parameters (such as deformation, strain, displacement, rotation of section, and cracks opening) are measured. Tests are performed in order to understand the real behavior of the structure and to compare it with theoretical estimates. Monitoring during this phase can be used to calibrate numerical models describing the behavior of structures.

5.4 Monitoring during service of bridge

The service phase is the most important period in the life of a structure. During this phase, construction materials are subjected to degradation by aging. Concrete cracks and creeps, and steel oxidizes and may crack due to fatigue loading.

The degradation of materials is caused by mechanical (loads higher than theoretically assumed) and physicochemical factors (corrosion of steel, penetration of salts and chlorides in concrete, freezing of concrete, etc.). As a consequence of material degradation, the capacity, durability, and safety of structure decrease.

Monitoring during service provides information on structural behavior under predicted loads, and also registers the effects of unpredicted overloading. Data obtained by monitoring are useful for damage detection, evaluation of safety, and determination of the residual capacity of structures. Early damage detection is particularly important because it leads to appropriate and timely interventions. If the damage is not detected, it continues to propagate and the structure no longer guarantees required performance levels. Late detection of damage results in either very elevated refurbishment costs or, in some cases, the structure has to be closed and dismantled. In seismic areas monitoring is very critical. Subsequent auscultation of a structure that has not been monitored during its construction can serve as a basis for understanding of present and for prediction of future structural behavior.

5.5 Monitoring during dismantling of bridge

When the structure no longer responds to the required performances and the costs of reparation or strengthening are excessively high, the ultimate life span of the structure is attained and the structure should be dismantled. Monitoring helps to dismantle structures safely and successfully.

6 ANALYSIS TECHNIQUES

The most important issue in practical SHM is, how do we make syntheses assessment for existing bridge condition state based on the collected monitoring data, as the final goal of monitoring?

Recent research and implementation of SHM and damage assessment can be summarized in two main methods:

1. laboratory testing methods and
2. field-testing researches.

Bridge testing methods are mainly static and/or dynamic. Dynamic testing includes ambient vibration testing and forced vibration testing. In ambient vibration testing, the input excitation is not controllable.

The loading could be any load from environment like wind or passing vehicles among others. This type of testing is of interest to the researchers or engineers owing to the convenience of measuring the vibration response while the bridge is being used and also because of the increasing availability of robust data acquisition and storage systems. Since the input is unknown, certain assumptions have to be made. Forced vibration testing involves application of input excitation of known force level at known frequencies. The excitation manners include electrohydraulic vibrators, force hammers, vehicle impact, etc. The static testing in the laboratory may be conducted by actuators and by standard vehicles in the field testing. Here are some recent findings from laboratory and field-testing research on the damage assessment of bridge structures:

1. Slab-on-girder bridges are stiffer than the corresponding calculated values. The floor systems of steel truss bridges may contribute substantially to the combined stiffness of the structure. In most cases, the actual load-carrying capacities are higher than those from calculations [27].
2. Prestressing the concrete deck slab in the vicinity of the pier supports eliminated transverse cracking of the slab, enhanced the natural frequencies, and increased the fatigue life as well as the ultimate load-carrying capacity [28].
3. The ambient vibration method provided approximately the same resonant frequencies and mode shapes as those used in modal analysis [29].
4. Changes in modal frequency and damping (except mode shapes) can be good damage indicators [30].
5. Modal flexibility provided a relevant/reliable measure of structural state [31–34].
6. Changes in the flexibility matrix can be effectively used in detecting and locating damages [35].
7. Ambient excitations were used for the modal testing, which is generated by pulling a model car along the bridges. The results showed that the energy transfer ratio (ETR) is a good indicator of structural damage [36].
8. A modal testing package by using simplified experimental modal analysis and time-domain identification method is also beneficial for monitoring and damage detection system [37].
9. This work represented the first attempt in using the wavelet estimation technique directly on transient data and nor on the impulse response estimates obtained via the random decrement technique [38].
10. The test results are transformed to both strain influence lines and modal flexibility, which have been demonstrated to be a conceptual, quantitative, comprehensive, and damage-sensitive signature [39].
11. A comparison of the ultrasonic pulse velocity (UPV) damage index with the normalized acoustic emission counts revealed that the two methods had different sensitivities at different stages of loading and could potentially complement each other as a hybrid damage assessment tool [40].
12. The integration of a nondestructive damage detection method with an on-site data-acquisition system is done to remotely monitor a conventional concrete slab bridge and a composite bridge utilizing Carbon Fiber Reinforced Plastics (CFRP) and Glass Fiber Reinforced Plastics (GFRP) and evaluate their performance [41].
13. Monitoring system is feasible for the *in situ* monitoring of the stayed cable tension [42].
14. Inclusion of virtual reality and Internet for the development of a platform for SHM shows some benefits in reduction of labor in bridge management systems by automation [43].
15. A flexible videogrammetric technique for structural dynamic measurement by commercial-grade digital cameras. It can capture structural 3-D dynamic trajectories at low cost, to be used for some SI problems. The laboratory results show that this method is capable of providing accepted accuracy for dynamic response measurement, and proved to be a good complement to traditional sensors especially in 3-D vibration measurement [44].

There are many other research works that are similar in some senses to the above-mentioned points. The above-mentioned points are only some result examples that have been found recently. Studying these points show the following results:

- The models in the laboratory are mainly beams, columns, truss, and/or frame structures.

- The location and severity of damage in the models are determined in advance.
- The testing has demonstrated lots of performances of damage structures.
- The field testing and damage assessment of real bridges are more complicated than the models in the laboratory.
- The correlation between the damage indicator and damage type, location, and extent still needs further improvement.
- Advanced numerical methods are capable to help the health monitoring system evaluations.
- There are new technologies emerging in health monitoring systems such as introducing new sensors and sensor networking.
- Multimedia technologies can be useful in health monitoring systems.

The bridge health monitoring and damage detection are both concerned with two fundamental criteria of the bridges, namely,

- the physical condition and
- the structural function.

In structural dynamics, these fundamental criteria can be treated as mathematical models, such as response models, modal models, and physical models. Instead of taking measurements directly to assess bridge condition, the bridge monitoring system and damage detection evaluate these conditions indirectly by application of mathematical models. The health monitoring and damage detection are active areas of research in recent years. For example, numerous papers on these topics appear in the Proceedings of International Modal Analysis. In many journals and conferences, there are many papers and reports about analytical development for bridge health monitoring systems. Some of the methods that are reported in them are as follows:

6.1 Signature analysis and pattern recognition approach

A modal model is characterized by a set of modal parameters, which can be extracted from response model by modal testing techniques. Traditionally, the major modal parameters are natural frequencies, damping ratios, and mode shapes. The modal model can be also used as a vibrational signature. For example, in mechanical engineering, condition monitoring of rotating equipment is typically done by looking for signature changes in a power spectrum of the measured vibrations. The same nonparametric approach could be used for civil structures, but it is more typical to use identified modal parameters to provide the signature characterizing the structure. In order to not only detect damage but also locate its position, observed changes in the signature must be compared with a database of possible changes and the most likely change must be selected. This is a type of pattern recognition where the database of "pattern" is generated by analyzing various damage scenarios or "failure modes". The representative researches on damage detection through a modal model are briefly summarized below.

One approach to detect damage has been to use changes in the modal frequencies. With fiber-reinforced plastics, damage can be detected from a decrease in natural frequencies and from an increase in damping [45]. Performed experiments on a highway bridge demonstrate that the decrease in natural frequencies can be used to detect the presence of damage [46]. The problem of understanding when it is sufficient to measure and use only natural frequencies, thus avoiding the need to measure modal shapes in vibration beams, or beam systems is addressed. The identification procedure was based on the minimization of an objective function that accounts for the difference between the analytical and experimental quantities [47]. Further study demonstrated that the observed changes in natural frequencies, especially the changes in fundamental natural frequencies, were unable to determine the location of crack damage. This occurs because a certain amount of damage at two different locations may produce the same amount of frequency change [48].

Sensitivity analysis has been proposed to improve the sensitivity of natural frequency change to the structural damage. The basic idea behind this was to compare the frequency changes obtained from experimental data collected on the deteriorated structure with the sensitivity of the modal parameters obtained from an analytical FEM of the structure. Accuracy of sensitivity-based methods is dependent on the quality of the FEM used to computer the sensitivities. It should be kept in mind that obtaining an accurate analytical model in itself remains a difficult task.

The uncertainties of analytical model may influence the results of damage detection [30]. Results from some experimental and numerical studies have suggested that the lower vibration modes would probably be suited for damage detection. Using the information from the mode shapes, a method to localize damage by using the pattern-recognition method is reported. The study was on a beam model with known mode shapes, and then generated mode shapes at any location using interpolation. The location of damage compared fairly well with finite-element (FE) analysis.

Finally, this method was applied to the real bridges including 49.7 m plate girder bridges and a two-span simply supported truss bridges (the length of each span is approximately 61.3 m). It was concluded that the method can accurately locate damage though the damage pattern was not quite distinctive [49].

The combination of different modal parameters, especially the combination of natural frequency and mode shapes, has been used by several researchers. It is found that crack propagation in a beam can cause substantial shifts in certain frequencies and mode shapes can be used to locate the damage [50]. With the help of analytical beam models, it is possible to show that the use of changes in the curvature mode shapes is capable to detect and locate damage [51]. A damage indicator called *curvature damage factor* is introduced, in which the difference in curvature mode shape for all modes can be summarized in one number for each measured point. It is applied to a real prestressed concrete bridge, named *Z24*, which crosses the highway A1 between the Bern and Zurich in Switzerland [52]. Another combination in terms of natural frequencies, mode shapes, and modal assurance criteria (MAC) was employed on a scale bridge model test. It is concluded that natural frequencies should be used to detect damage, and mode shapes and MAC values can be further used to identify damage locations [53]. It is possible to compare the transfer function parameter change of the testing system to detect damage and locate the position by using a few sensors [54].

Transmittance functions (TFs) and the sensor–actuator system to detect, locate, and assess damages on a composite beam are introduced. Further work is now under way by using sequential TFs to detect damage on large panel and blade structures using a dense pattern of measurements formal scanning laser Doppler vibrometer (LDV) [55]. Closely spaced frequencies, which cannot be distinguished if the traditional peak picking technique is used, can be identified successfully by eigensystem realization algorithm (ERA). But user expertise is indispensable in this type of analysis [56]. An algorithm to construct a proportional flexibility matrix (PFM) is presented by introducing a dummy structure in relevancy with the real structure.

The PFM is established within a scalar to the flexibility matrix, and the scalar is shown to be the first modal mass. Vectors method is implemented with the PFMs and a multidamage scenario is successfully identified for a simple system. For the algorithm developed, only a very small number of modes are needed to calculate the PFMs with sufficient accuracy and only one reference degree with unchanged mass after damage is needed to make PFMs of predamaged and postdamaged structures to be comparable [57]. The residual wavelet force (RWF), which is expressed in terms of the wavelet transform coefficients of structural-free vibration responses of the damaged structure and the undamaged baseline mass and stiffness matrices, is defined, and then a damage location indicator based on the residual wavelet force (DLIRWF) is presented. The results of the numerical simulations suggest that the proposed method has the ability to localize multiple damages with various extents occurred in structures. Furthermore, the method is well suited to noise-contaminated structures and thus is very promising in practical applications. Moreover, good damage localization results can be obtained when different decomposition scales or different mother functions are used [58].

Changes in the power spectral density (PSD) curvature due to the presence of structural damage have been investigated. The experimental results obtained from a steel bridge model and bookshelf structure demonstrate the usefulness of the changes in PSD curvature as a diagnostic parameter in detecting the damage and locating its position [59]. The results of modal testing present that global low-order natural frequencies of frame structure are insensitive to the local change structural stiffness. The position of stiffness change of frame structure can be detected by the maximum energy high-order mode method proposed in this article with a good accuracy [60].

A damage assessment algorithm is developed for mass density and Young's modulus varied system.

The Latin hypercube sampling (LHS) technique for Monte Carlo simulation is an effective way to deal with variations [61]. Since an optimal and unique algorithm cannot be proposed for damage detection depending on the variety of applications, a multi-algorithm procedure seems to be the only reliable approach for damage detection in the field of continuous static monitoring. For example wavelet transforms identity damage initiation only and not its persistency in time. But proper orthogonal decomposition (POD) procedure overcomes this limitation, because it is able to detect correlation changes between sensors in adjacent sections [62].

A new signal-energy-based damage index is suggested, which releases the limitation of accurate measurement requirement of structural modal parameters involved in the traditional damage indicators. The results demonstrate that the new damage index is capable to identify the existence and location of structural damage of both simple damage (one damage location) scenario and complicated damage (multiple damage locations) scenario [63, 64].

This kind of vibrational signature analysis has been proven to be successful in localizing damage. However, it is not sensitive to most types of damage that occur in bridge structures. Model testing and field testing have shown that the changes of natural frequencies due to local damage are very small, and that mode shapes (especially higher mode shapes) are sensitive to the changes of local stiffness but it is very difficult to measure them accurately. There are similar problems in other vibration signatures, such as mode-shape curvature (MSC), modal flexibility, MAC, etc. None of these can provide sufficient information for the detection of both small and large defects. The successful applications of these modal model methods may rely on the development of test techniques and new findings of model-based approaches.

6.2 System identification (SI) approach

System identification (SI) is the process of constructing or updating an accurate mathematical model of a system based on input and output (I/O) observations. Among other applications, SI can be applied to SHM and damage assessment, e.g., by determining the structural stiffness values and comparing them with previously determined values or originally intended values. Research interest in this subject area has increased steadily over the years.

In the context of civil engineering structures, the first attempt was to carry out SI study by means of a recursive least-square algorithm [65]. Two case studies of state estimate are used to illustrate the use of the Kalman filter and the extended Kalman filter (EKF) [66]. Two SI algorithms, namely, the EKF and iterated linear filter smoother are applied to identify the hydrodynamic coefficient matrices for an offshore structure problem [67]. A weighted global iteration algorithm is proposed to improve the convergence characteristics of the EKF process [68]. The above-mentioned method is subsequently applied in the study of a running load on a beam [69]. In another research, the structural parameters of a damage bridge structure are identified by the EKF [70]. In another investigation, a bridge structure is studied by the EKF. It is also done by another filter-based SI approach considering the incorporation of a memory fading function [71]. Most of the SI studies in structural engineering have dealt with few DOFs and few unknown structural parameters. In practice, however, modeling of engineering structures often requires the contrary. The difficulty and the computational effort required for convergence increase drastically when the numbers of DOFs and unknowns increase. To this end, various means have been proposed in recent years to tackle the numerical problems generally associated with SI of large systems. A substructural identification method is formulated to improve the convergence performance by decomposing the structural system into several smaller subsystems [72–74]. A two-step damage detection and health monitoring approach has been developed for large and complex structures with a limited number of measurements. The first step is initial damage detection, based on the optimal-updating techniques and changes of stiffness. The second is detailed damage detection by the design sensitivity method and linear perturbation theory [75, 76].

In all the above-mentioned works, classical SI techniques were used, such as EKF, recursive least squares, instrumental variable, and maximum likelihood methods; these methods, in one way or another, search the optimal solution by exploiting the previous solution. Treating the problem as an inverse problem, many classical methods require the use of secant, tangent, or higher-order derivatives of

the objective function. As the system of unknowns grows in size, the numerical difficulty increases and often the convergence becomes extremely difficult, if not impossible. Such "exploitation" methods perform point-to-point search and have the danger of converging to local optima. On the other extreme, a random search (e.g., trial and error) may be used to explore the entire search space. To overcome one trial solution with another, an error norm has to be defined as a measure of deviation of the estimated response (computed based on the estimated parameters) from the actual (measured) response. The search continues until the error norm is deemed to be small. Such a blind "exploration" strategy is obviously too time consuming for large systems owing to huge number of possible combinations.

For instance, if there are 10 unknowns to be identified and each unknown is divided into 100 discrete values within its search range, there will be a total of 10^{20} possible combinations—an astronomical figure to work with even for today's powerful computers.

In this regard, a worthwhile attempt is to employ evolutionary algorithms, which have proved in the last decade to be a powerful search and optimization tool. The main features of these algorithms are that they attempt to imitate living things and are stochastic in nature. There are presently four main approaches, namely, genetic algorithms (GAs), evolutionary programming, evolutionary strategies, and simulated annealing. By far the most widely known approach in engineering is perhaps GA. This approach was developed to solve discrete or integer optimization problems as opposed to continuous parameter optimization problems. In the case of parameter identification, this can be tuned into an advantage of controlling the resolution of identified parameters through the (integer) length of the chromosome (number of bits) as explained below.

A GA search is conducted in the modal domain of a much smaller dimension than the physical domain. The objective function was defined based on the estimated modal response in time domain and the corresponding modal response was transformed from the measured response. This method had been shown to work well in terms of mean error (10–15%) for a fairly large system with 50 DOFs and 52 unknown parameters [77]. A GA with real number encoding is applied to identify the structural damage by minimizing the objective function, which directly compares the changes in the measurements before and after damage. Three different criteria are considered, namely, the frequency changes, the mode-shape changes, and a combination of two. A laboratory tested cantilever beam and a frame are used to demonstrate the proposed techniques; numerical results show that the damage elements can be detected by GA, even when the analytical model is not accurate [78].

Structural SI within the linear regions has been well developed and many techniques have been applied to structural damage assessment. However, the question of whether a structure is still linear after the damage remains. This is very important because the dynamical behavior of a nonlinear system can be quite different from those of its associated linear system.

Also if the structural system becomes nonlinear after damage, its dynamical characteristics cannot be estimated by using the linear SI methods.

An attempt has been made to develop methods for the identification of highly localized structural damage in weak nonlinear structures. The damage was defined as either a reduction of stiffness or a change of restoring force characteristics. The location vector method (LVM) is applied to identify the location and type of damage. The fast Fourier transform (FFT) and the least-squares method are used to quantify the damage [79]. The NN is employed to detect the changes in nonlinear systems [80–82]. A frequency-domain modal analysis technique is formulated to apply to weaker nonlinear multidegree of freedom (MDOF) systems. One of the advantages of the method is the ability to determine the response of the nonlinear system at any level once its variable modal parameters has been identified at some reference force level [83]. An adaptive on-line parameter identification algorithm based on the variable trace approach for the identification of nonlinear hysteretic structures is presented. At each time step, this recursive least-square-based algorithm upgrades the diagonal elements of the adaptation gain matrix by comparing the value of the estimated parameter between two consecutive time steps. The effectiveness and efficiency of the proposed algorithm is shown by considering the effects of excitation amplitude, the measurement units, larger sampling time interval, and measurement noise [84]. The vibrations of a clamped beam for two different kinds of nonlinearity are investigated. First, the beam shows

a nonlinear behavior characterized by a piecewise linear stiffness and second, the nonlinearity comes from a bilinear stiffness. The performance of the restoring force surface method together with both the numerical and experimental results is demonstrated [85].

Obviously, the nonlinear SI will be developed by many researchers in the not too far future. When performing vibration tests on civil engineering structures, such as bridges, it is often unpractical and expensive to use artificial excitation (shakers and drop weights). Ambient excitation on the contrary is freely available (wind and traffic). This output-only SI now becomes more and more important [86–88].

Although the regularization increased the popularity of parameter identification owing to its capability of deriving a stable solution, the significant problem is that the solution depends upon the regularization parameters chosen as mentioned below.

A generalized model of differential hysteresis that contains 13 control parameters is developed. Three identification algorithms are developed to estimate the control parameters for different classes of inelastic structure. These algorithms are based upon the simplex, EKF, and generalized reduced gradient method. Novel techniques such as global search and internal constraints are incorporated to facilitate convergence and stability. Effectiveness of the devised algorithms is demonstrated through simulations of two inelastic systems with both pinching and degradation characteristics in their hysteretic traces [89]. A GA with real number encoding is applied to identify the structural damage by minimizing the objective function, which directly compares the changes in the measurements before and after damage. Three different criteria are considered, namely, the frequency changes, the mode-shape changes, and a combination of the two. The technique does not seek to tune the analytical FEM to obtain an improved one in the undamaged and damaged state, but rather to update the FEM so that its model data changes equal the measured modal data changes as closely as possible. Therefore, an accurate analytical model is not needed in the analysis. With proper weights to frequency and mode-shape data, it also accurately detects damages in the symmetric portal frame by using both the frequency changes and the mode-shape changes [90].

In structural SI, different mathematical models introduce different explanations on the result of identification even with the same set of input/output data. The model inaccuracy in structural SI can be categorized into two items:

- the uncertainty due to nonlinear model and
- the completeness of model description (or extract description).

Selecting the exact model becomes one of the important issues for identification. Changes of modal parameters contain the information of structural variations. Thus the sensitivities of four modal parameters, namely, natural frequency, modal shape, the slope, and the curvature of modal shape to flexibility increase are important parameters that should be analyzed [91–93].

A common theme in using SI for SHM and damage diagnosis is to use a model updating approach. Usually, highly accurate and detailed FEMs are required to analyze and predict the dynamical behavior of complex structures during analysis and design. Once the FEM of a physical system is concentrated, its accuracy is often tested by comparing its modes of vibration and frequency response with those obtained from the physical system. If the correlation between the two is poor, then assuming that the experimental measurements are correct, the analytical model must be adjusted so that the agreement between the analytical predictions and the test results is improved. The updated model may then be considered a better representation of the physical structure than the initial analytical model. Any observed local decrease in the stiffness of the model is assumed to indicate the location and severity of damage in the monitored structure. The updated model can subsequently be used with reasonable accuracy to assess the stability and control characteristics and to predict the dynamical responses of the structure. The above process of correcting the system matrices is known as *model updating*.

The methods for FEM update that are used for Nondestructive Evaluation (NDE) can be divided into in the following major categories: mode flexibility methods, optimal matrix update methods, sensitivity-based matrix update methods, eigenstructure assignment methods, changes in measured stiffness methods, combined modal parameters methods, etc. All of these FEM update techniques require that

the user select a subset of the measured modes to be correlated with the corresponding modes of the FEM. Normally, the first few modes of the structure are used in the FEM correlation because they are generally the best identified modes. However, in some situations the higher frequency modes are critical to the location of structural damage, and so it is necessary to include them in the set of modes for FEM correlation. Many modes that are lower in frequency do not undergo significant modification as a result of the damage, so that they contribute to the computational burden without contributing significantly to the location of the damage. The number of modes is limited not only by the computational burden but also by the inherent ill-conditioning and statistical bias associated with large-order update problems. Because of this limit, it is important to have systematic criteria for selecting the modes that are most indicative of the structural damage [94–97].

7 DAMAGE DETECTION METHODS

7.1 Statistical analysis methods

FE modeling provides a complete set of analytical and theoretical modal parameters for a structure, but these parameters are usually not accurate. The experimental data is accurate to some extent, but incomplete, and also intervolved by the noise. Any method to do modal updating must address the mismatch between the level of information in the detailed analytical FEM and the relatively sparse information.

A general Bayesian statistical approach is presented, which treats the uncertainties that arise from measurement noise, modeling error, and possible nonuniqueness in the problem of updating the stiffness distribution [98, 99]. This approach is extended to multiple damage locations [100, 101]. The above approach is used for on-line monitoring, wherein specified modal parameters are identified on a regular basis and the probability of damage for each substructure is continually updated [102].

New approaches that use two set of measured frequency response data to update the analytical system mass and stiffness parameters in order to improve the agreement between the dynamical behaviors of the analytical and actual systems are developed. The algorithm adjusted model without iteration [103]. A similar method to identify multiple damage locations of multistory frame structures and reinforced-concrete bridge column is employed [100, 101].

A reliable damage detection algorithm is presented for framed structures, whose stiffness properties can be explicitly expressed with those of members, by introducing a regularization technique for SI, a parameter grouping technique for locating damaged members and overcoming the sparseness of measured data, a data perturbation method for obtaining statistical distributions of system parameters with a set of noise-polluted measured data, and a statistical approach by a hypothesis test for damage assessment [104].

Unlike most references that focus on the different methods for extracting damage-sensitive features from vibration response measurements, a statistical pattern-recognition paradigm to quantifying the observed changes in these features is introduced. Various projection techniques such as principal component analysis (PCA) and linear and quadratic discriminate operators with the Statistical Process Control (SPC) are employed in an effort to enhance the discrimination between features from the undamaged and damaged structures [105].

A general methodology for structural fault detecting using fuzzy logic is presented, based on the monitoring of the static, eigenvalue, and dynamic responses. Fuzzy logic coupled with principles of continuum damage mechanics is used to identify the location and extent of the damage. This methodology represents a unique approach to damage detection that can be applied to a variety of structures used in civil engineering, machine, and aerospace applications [106]. A probabilistic approach is presented, which examines the eigenvalue problem from a statistical standpoint by considering eigenvalue and eigenvector uncertainty, along with a correlated analytical stochastic FEM to assess the damage. The effectiveness of the proposed technique is illustrated using simulated data on a 3 DOF spring-mass system and on an Euler–Bernoulli cantilever aluminum beam [107].

A Bayesian probabilistic framework for modal updating is adopted and a new probabilistic approach that use the statistic properties of an estimator of the spectral density to obtain expressions for the updated probability density function (PDF) of the modal

parameters is proposed. Examples of single degree of freedom (SDOF) systems and MDOF systems using simulated data are presented to illustrate the proposed method [108, 109].

A statistical method with combined uncertain frequency and mode-shape data for structural damage identification is proposed. The FEM is updated by comparing the measured vibration data before and after damage occurs. The effects of uncertainties in both the measured vibration data and the FEM are considered as random variables in model updating. The statistical variations of the updated FEM are derived with perturbation method and Monte Carlo technique. The probabilities of damage existence in the structural members are then defined. The comparison of results between the calculation and testing show that all the damages are identified correctly with high probabilities of damage existence [110].

The vibration-based SHM problem is addressed as the double task of detecting damages modeled as changes in the eigenstructure of a linear dynamic system and localizing the detected damages within (a FEM of) the monitored structure. The proposed damage detection algorithm is based on a residual generated from a stochastic subspace-based covariance-driven identification method and on the statistical local approach to the design of detection algorithms. This algorithm basically computes a global test, which performs a sensitivity analysis of the residuals to the damages, relative to uncertainties and noises. Damage localization is stated as a detection problem. This problem is addressed by plugging aggregated sensitivities of the modes and mode shapes with respect to FEM structural parameters in the above setting. This results in directional tests, which perform the same type of damage-to-noise sensitivity analysis of the residual as for damage detection [111].

A damage detection method is proposed for SHM under varying environmental and operational conditions. The method is based on PCA applied to vibration features identified during the monitoring of the structure. The advantage of the method is that it does not require to measure environmental parameters because they are taken into account as embedded variables. The number of principal components of the vibration features is implicitly assumed to correspond to the number of independent environmental factors. Since the environmental effects may be effectively eliminated by the proposed procedure, the residual error of the PCA prediction model remains small if the structure is healthy, and it increases significantly when structural damage occurs. Novelty analysis on the residual errors provides a statistical indication of damage. The environmental conditions are assumed to have a linear (or weakly nonlinear) effect on the vibration features, and the PCA-based damage detection method is illustrated using computer-simulated and laboratory testing data [112].

A method based on vector autoregressive volatility (ARV) models is proposed. These models accurately capture the predictable dynamics present in the response. They leave the unpredictable portion, including the component resulting from unmeasured input shocks, in the residual. An estimate of the autoregressive model residual series standard deviation provides an accurate diagnosis of damage conditions. Additionally, a repeatable threshold level that separates damaged from undamaged conditions is identified, indicating the possibility of damage identification and localization without explicit knowledge of the undamaged structure. Similar statistical analysis applied to the raw data necessitates the use of higher-order moments that are more sensitive to disguised outliers, but are also prone to false indications resulting from overemphasizing rarely occurring extreme values [113].

A damage detection method of mechanical system based on subspace identification concepts and statistical process techniques is presented. The aim is to propose a method that is sensitive to small-sized structural damages and suitable for on-line monitoring. Measured time responses of structures subjected to artificial or environmental vibrations are assembled to form the Hankel matrix, which is further factorized by performing singular-value decomposition to obtain characteristic subspaces. It may be demonstrated that the structural responses are mainly located in the active subspace defined by the first principal components, which is orthonormal to the null subspace defined by the remaining principal components. If no structural damage occurs, the orthonormality relation between the subspaces remains valid with small residues when consecutive data sets are compared, and these residues may be evaluated by

the proposed damage indicators. The method is validated using an experimental mock-up of an airplane subjected to different levels of damages simulated. It is also applied in environmental vibration testing of a street lighting device to monitor structural fatigue evolution [114].

A stochastic output error (OE) vibration-based methodology for damage detection and assessment (localization and quantification) in structures under earthquake excitation is introduced. The methodology is intended for assessing the state of a structure following potential damage occurrence by exploiting vibration signal measurements produced by low-level earthquake excitations. It is based upon (i) stochastic OE model identification, (ii) statistical hypothesis testing procedures for damage detection, and (iii) a geometric method (GM) for damage assessment. The methodology's advantages include the effective use of the nonstationary and limited duration earthquake excitation, the handling of stochastic uncertainties, the tackling of the damage localization and quantification subproblems, the use of "small" size, simple and partial (in both the spatial and frequency bandwidth senses) identified OE-type models, and the use of a minimal number of measured vibration signals. Its feasibility and effectiveness are assessed via Monte Carlo experiments employing a simple simulation model of a six story building. It is demonstrated that damage levels of 5 and 20% reduction in a story's stiffness characteristics may be properly detected and assessed using noise-corrupted vibration signals [115].

A novel analytical tool for early detection of fatigue damage in polycrystalline alloys that are commonly used in mechanical structures is presented. Time series data of ultrasonic sensors have been used for anomaly detection in the statistical behavior of structural materials, where the analysis is based on the principles of symbolic dynamics and automata theory. The performance of the proposed method has been evaluated relative to existing pattern-recognition tools, such as NNs and PCA, for detection of small changes in the statistical characteristics of the observed data sequences. This concept is experimentally validated on a special-purpose test apparatus for 7075-T6 aluminum alloy specimens, where the anomalies accrue from small fatigue crack growth [116].

Model updating within a statistical framework appears to be a promising general approach to damage diagnosis and SHM of large civil structures in view of the inescapable data and modeling uncertainties. But many aspects require further research, including optimal location of sensors, the type of damage, which can be reliably detected and located using a given array of sensors on a structure, and strategies for making decisions about possible damage and determining the corresponding probabilities of false alarm and missed alarms, etc.

7.2 Damage index methods

There are some research works using damage index methods. Some of them are as follows:

It is proved that the ratio of the model frequency change between any two models is the function of the damage location only. The ratios were then used as damage indicators, which were calculated from a candidate set of assumed possible damage scenarios. The structural damage was then localized by comparing the predicted ratios with the ratios computed based on measured modal frequencies [117–121].

The modal flexibility involves functions of both the natural frequencies and mode shapes. Some researchers have found experimentally that modal flexibility can be a more sensitive parameter than natural frequencies or mode shapes for structural monitoring and damage detection in bridges [35, 122, 123].

The sensitivity is studied theoretically by comparing the use of natural frequencies, mode shapes, and modal flexibilities for monitoring. The results demonstrate that modal flexibilities are more likely to indicate damage than either natural frequencies or mode shapes [124, 125].

Using the ratio of change in model strain energy in each element can be considered as another damage indicator. The approach requires only the elemental stiffness matrix, the analytical mode shapes, and the incomplete measured mode shapes. The effect of analytical mode truncation, incomplete measured mode, and measurement noise in the damage detection are discussed. Results from the modal simulation and experiment with a two-story partial steel frame indicate that the presented method is effective in localizing damage, but it is noise sensitive in the damage quantification to some extent [18, 126–132].

A sensitivity and statistical-based method is presented to localize structural damage by direct use of incomplete mode shapes. The method is an extension of the multiple damage location assurance criterion (MDLAC) reported in [133], by using incomplete mode instead of model frequency. In general, the damage detection strategy localizes the damage sites first by using incomplete mode shapes, and then detects the damage sites and extent again by using measured natural frequencies, which have a better accuracy than mode shapes [134].

A new modal parameter, the ETR, based on the complex damping theory, is presented and it is proved theoretically that ETR indicator can be much more sensitive to structural damage [135, 136].

A new process of modal parameter identification based on complex modal energy measurement (including the ETR index) is proposed. The damage growth measurement is performed by using the proposed diagnostic technique based on ETR in large-scale structures. The ETR index has been investigated through real steel bridge as a sensitive damage indicator, but it has not been applied on the concrete bridge structures [137].

A method to identify the location of damage in civil engineering structures, which is based on changes in the component transfer functions of the structure, or the transfer functions between the floors of a structure, is proposed. Multiple damage locations can be identified and qualified using the proposed approach. Experimental verification of this approach using a four-story frame structure in the Washington University Structural Control and Earthquake Engineering Lab is also provided [54, 138].

A comparative study of applying various mode-based indices to the structural damage detection of the Tsing Ma suspension bridge with a main span of 1377 m and an overall length of 2160 m is presented. Five mode-based damage indices, including coordinate modal assurance criterion (COMAC), enhanced coordinate modal assurance criterion (ECOMAC), MSC, and modal strain-energy index (MSEI), and modal flexibility index (MFI) are applied respectively for the damage location identification of various simulated damage scenarios in the bridge by 3-D finite-element method. The numerical simulation results show that the applicability and the performance of each index depend on the damage type concerned. On the basis of the performance evaluation, the preferred damage indices in accordance with different damage types are recommended [79].

Structural damage from a known increase in the fundamental period of a structure after an earthquake or prediction of degradation of stiffness and strength for a known damage is estimated. A modified Clough–Hohnston SDOF oscillator is proposed to establish reliable correlations between the response functions in the case of a simple elastic-plastic oscillator. The proposed model has been used to demonstrate that ignoring the effects of aftershocks in the case of impulsive ground motions may lead to unsafe designs [139].

A damage identification technique at an element level is proposed. The element damage equations have been established through the eigenvalue equations on the basis of the changes in frequencies and mode shapes of vibration. Several solution techniques are discussed and compared. Numerical results show that the nonnegative least-squares method can lead to satisfactory results in most cases. An experimental program of the reinforced-concrete beam under static and dynamic loading is used to demonstrate the identification scheme. The adaptation of the FEM is required in this technique [140].

A technique to localize damage in structures is presented. Central to the approach is the computation of a set of vectors, designated as damage locating vectors (DLVs) that have the property of inducing stress field whose magnitude is zero in the damaged elements. The DLVs are associated with sensor coordinates and are computed systematically as the null space of the change in measured flexibility. Numerical simulations carried out with realistic levels of noise and modeling error illustrate the robustness of the technique [141].

A numerical study of the relationship between damage characteristics and the changes in the dynamic properties is presented. It is found that the rotation of mode shape is a sensitive indicator of damage. The numerical results show that the rotation of mode shape has the characteristic of localization at the damaged region even though the displacement modes are not localized. Also, the results illustrate that the rotations of modes are robust in locating multiple damage locations with different sizes in a structure. Furthermore, using the changes in the rotation of

mode shape does not need very fine grid of measurements to detect and locate damage effectively [142].

A methodology to nondestructively locate and estimate the size of damage in structures, for which a few natural frequencies or a few mode shapes are available, is presented. First, a frequency-based damage detection (FBDD) method is outlined. A damage-localization algorithm to locate damage from changes in natural frequencies and a damage-sizing algorithm to estimate crack size from natural frequency perturbation are formulated. Next, a mode-shape-based damage detection (MBDD) method is outlined. A damage index algorithm to localize and estimate the severity of damage from monitoring changes in modal strain energy is formulated. The FBDD method and the MBDD method are evaluated for several damage scenarios by locating and sizing damage in numerically simulated prestressed concrete beams for which two natural frequencies and mode shapes are generated from FEMs. The result of the analyses indicates that the FBDD method and the MBDD method correctly localize the damage and accurately estimate the sizes of the cracks simulated in the test beam [143].

A method to identify and quantify damage in structures, called *residual error method* in the movement equation, is evaluated by a numerical analysis to verify its efficiency when applied to continuous beams and frame structures. This method is based on the alteration, produced by damage, in the dynamic properties of the structures. The location of the damage is performed by observing the error in the movement equation of the intact structures. The structures are discretized in finite elements and the damage is introduced by a stiffness and area reduction of the elements' cross sections. The observation of the obtained results and then its comparison with some other damage detection methods demonstrated that the residual error method in the movement equation is efficient in the damage location and quantification of the studied structures [144].

A procedure for locating variability in structural stiffness is presented. For some types of structures, this variability is directly related to manufacturing defects and/or in-service damage. Unlike many published damage detection methods, the procedure presented here uses only data obtained from the damaged structure. Baseline data and theoretical models of the undamaged structure are not used during the analysis presented here. The procedure locates regions in a structure where the stiffness varies. Only if it is known that the structure, in its undamaged state, is homogeneous with respect to stiffness, the procedure will detect the areas of inhomogeneity that are caused by the incipient damage. For nonhomogenous structures, some knowledge of the structural details (for example, engineering drawings or a baseline test) is required in order to discriminate damage. The procedure is a two-dimensional generalization of a previously published one-dimensional gapped smoothing method, whereby local features in vibration curvature shapes are extracted using a localized curve fit (i.e., smoothing). A variability index is generated for each test point on the structure. Increased variability is due either to structural stiffness features or damage. A statistical treatment of the indices enables discrimination of areas with significant stiffness variability. Provided that the damaged areas are sufficiently small compared to the total surface area, their indices will be statistical outliers. The procedure can either analyze mode-shape data or frequency-dependent operating displacement shape data. The procedure is demonstrated with a FEM of a plate, and by performing experiments on composite plates with deliberately induced multiple delaminations. Finally, the method is demonstrated on data taken from a large composite hull structure. In all cases the procedure successfully located the damaged regions [145].

A methodology to identify damage in a structure is presented. The method utilizes a new form of damage index based on the changes in the distribution of the compliance of the structure due to damage. The changes in the compliance distribution are obtained using the mode shapes of the predamaged and the postdamaged state of the structure. The validity of the method is demonstrated using numerically generated data from beam structures and experimental data from a free–free beam structure with inflicted damage. In the numerical and experimental examples, the damage identification performance of the proposed method is compared with that of the existing strain-energy-based method. The results of the numerical and experimental studies indicate that the proposed compliance-based damage index method can be used in damage identification of the structure [146].

The wavelet packet transform (WPT) is a mathematical tool that has a special advantage over the

traditional Fourier transform in analyzing nonstationary signals. It adopts redundant basis functions and hence can provide an arbitrary time-frequency resolution. A damage detection index called *wavelet packet energy rate index* (WPERI) is proposed for the damage detection of beam structures. The measured dynamic signals are decomposed into the wavelet packet components and the wavelet energy rate index is computed to indicate the structural damage. The proposed damage identification method is first illustrated with a simulated simply supported beam and the identified damage corresponds with assumed damage. Afterward, the method is applied to the tested steel beams with three damage scenarios in the laboratory. Despite the presence of noise factor in the real measurement data, the identified damage pattern is comparable with the tests. Both simulated and experimental studies demonstrated that the WPT-based energy rate index is a good candidate index that is sensitive to structural local damage [147].

A vibration-based damage evaluation method that can detect, locate, and size damage utilizing only a few of the lower mode shapes is proposed. The proposed method is particularly advantageous for beamlike structures with uncertain applied axial load, mass density, and foundation stiffness. On the basis of a small damage assumption, a linear relationship between damaged and undamaged curvatures is revealed in the context of elasticity. It turns out that the resulting damage index equation inherently suffers from singularities near inflection nodes. The transformation of the problem into the multiresolution wavelet domain provides a set of coupled linear equations. With the aid of the singular-value decomposition technique, the solution to the damage index equation is achieved in the wavelet space. Next, the desired physical solution to the damage index equation is reconstructed from the one in the wavelet space. The performance of the proposed method is compared with two existing damage detection methods using a set of numerical simulations. The proposed method attempts to resolve the mode selection problem, the singularity problem, the axial force problem, and the absolute severity estimation problem, all of which remained unsolved by earlier attempts [148].

A vibration-based damage monitoring scheme to give warning of the occurrence, the location, and the severity of damage under temperature-induced uncertainty conditions is proposed. Experiments on a model plate-girder bridge, for which a set of modal parameters were measured under uncertain temperature conditions, are performed. Then a damage warning model is selected to statistically identify the occurrence of damage, by recognizing the patterns of damage-driven changes in natural frequencies of the test structure and by distinguishing temperature-induced off-limits. A frequency-based damage index method based on the concept of modal strain energy is implemented in the test structure to predict the location and the severity of damage. In order to adjust the temperature-induced changes in natural frequencies that are used for damage detection, a set of empirical frequency correction formulae are derived from the relationship between temperature and frequency ratio [149].

A dynamic-based damage detection method for large structural systems using the Hilbert–Huang transform (HHT) has been proposed. The proposed method has been verified numerically by implementing the scheme on a model of wingbox. In the implementation process, the following steps have been identified as being important: (i) axis-symmetry signal extension methods in order to solve the end effect problem of empirical mode decomposition (EMD), (ii) finite-element modeling for the purpose of establishing the base line, and (iii) a feature index vector for structural damage detection. The obtained results show that the damage feature index vector is more sensitive to small damage. The effect of noise is also considered. Examination of the results confirms that the proposed damage detection method is very robust [150].

There may be other damage indices to indicate the locations and extent of damage. For real civil structures, only one damage index may not be enough. Until now, the relationships between damage type and damage index are not clear. A lot of further research is needed in this area.

7.3 Static data methods

Static parameter estimation is based on measured deformations induced by static loads such as a slowing moving track on a bridge. There are many instances in which static loadings are more economical than dynamic loading. Many applications require

only element stiffness for condition assessment. In these cases, static testing and analysis can prove simple and more cost-effective [151–159].

Since the natural frequencies, mode shapes, and static responses of a structural system are functions of structural parameters, these parameters may be identified by comparing the dynamic and static characteristics predicted from the mathematical model with those values determined by test. One of the consequences of the development of damage is the decrease in local stiffness, which in turn results in changes in some of the responses. It is therefore necessary that the dynamic and static characteristics of the structure be monitored for damage detection and assessment.

On the basis of the above-mentioned concept, an improved method that can identify a FEM of a structure capable of providing structural characteristics that are consistent with those measured in static and dynamic tests (e.g., the curvature of mode and the static displacement data) is proposed. The detection of damage in a member with stronger influence on the higher modes is more difficult. Thus, the use of static displacements obtained by a loading condition that simulate higher modes is proposed as a solution to this problem [160].

A new method for parameter identification is presented based on the strain and displacement data from static testing, in which Gauss–Newton, gradient, and Monte Carlo formulas are compositely employed to solve the ill-condition and uncertainties. Furthermore, based on the formula of the algorithm of static responses, a complex approach is also proposed, where combined static strain and displacement with dynamic response (e.g., mode shape) are used to localize damage and identify the severity of damage. Several algorithms are compositely applied to improve the sensitivity of parameter identification and enhance the reliability of solution process. The static and dynamic responses are utilized to calibrate the confidence of identification [161].

A structural damage identification algorithm using both the static test data and changes in natural frequencies is proposed. A proper definition of measured damage signature (MDS) and predicted damage signature (PDS) is presented and matched to detect the location of damage. After obtaining the possible damage location, an iterative estimation scheme for solving nonlinear optimization programing problems, which is based on the quadratic programing technique, is used to predict the damage extent. A remarkable characteristic of the approach is that it can be directly applied in the cases of incomplete measured data. Two examples are presented and the results show that the algorithm is efficient for the damage identification [162].

The SI method is used to identify structural parameters in a FEM by minimizing the error between measured and analytical computed responses. A regularization scheme is applied to alleviate the ill-posedness of an inverse problem by adding a regularization function to the primary error function. Two different algorithms depending on the type of measured response have been developed to assess damage. Static displacements from static loading and modal data from impact vibration are measured through laboratory experiments on a grid-type model bridge. Damage is simulated by saw-cutting the cross section with various depths and identified as the reduction in the structural stiffness of the elements around the crack. Through the experimental works, the applicability of the SI-based damage assessment algorithms has been rigorously investigated [163].

A structural damage detection algorithm using static test data is presented. Changes in the static response of a structure are characterized as a set of nonlinear simultaneous equations that relate the changes in the static response to the location and severity of damage. Damage is considered as a reduction in the structural stiffness parameter (axial and/or flexural). An optimality criterion is introduced to solve these equations by minimizing the difference between the load vector of the damaged and the undamaged structure. The overall formulation leads to a nonlinear optimization problem with nonlinear equality and linear inequality constraints. A method based on stored strain energy in elements is presented for selecting the loading location. Measurement locations are selected based on the FIM. Numerical results for a plane truss demonstrate the ability of this method to detect damage in a given structure with the presence of noise in the measurements [164].

The estimation of nonlinear autoregressive moving average with exogenous input (NARMAX) models for vibrating multilayer composite plates is presented and used to assess internal delamination in the plates. Both static and dynamic tests are carried out to investigate the nature of the nonlinearity of the composite system. The nonlinear nature and order

of nonlinearity are then approximated, and used to restrict the search space of the potential NARMAX model. After the structure and terms of the NARMAX model are identified, all coefficients are calculated for the intact plate. Delamination in the plate is assessed according to the coefficient variations in the model using the measured input/output data for the damaged system. Results show that the model output prediction is in agreement with the test data. The proposed method is available to discover and assess severity and location of delamination in the composite plates [165].

An on-line and real-time detection system is developed through the concept of inverse analysis. In this system, the detectors are selected based on natural frequencies and static strains whose relations with material properties can be obtained from analytical solution or commercial finite-element software or experimental data. By transferring their relations into training patterns of ANNs, the elastic properties of composite wing structures can be determined on-line with frequency and strain sensors embedded into structures. Test results show that the material properties determined through this on-line system well agree with the values obtained from the conventional testing methods. The difference is that the present method determines the properties on-line and in real time without any specimen being obtained from the structures and tested in the laboratory [166].

Modal updating by finite-element method is often used to identify the changes of damage using static testing data. Because the errors caused by FEM may be greater than changes of damage, the FEMs should be first calibrated using the measured modal properties and experimental data. Only the FEMs are reliable, and the results from modal updating by finite-element methods are valuable.

7.4 Substructure analysis methods

In the model updating approach, it is common only to update stiffness correction factors for selected substructures rather than for individual structural members. The goal is to reduce the number of stiffness parameters to be updated so that the ill-conditioning and nonuniqueness are kept within tolerable levels. Considering smaller substructures where damage has occurred is desirable so that better localization and assessment of its severity can be performed as follows:

A substructural approach to estimate the stiffness and damping coefficients from the measurements of dynamic responses is proposed. The structures are decomposed into several smaller subsystems for which state and observation equations are formulated and solved by EKF method with a weighted global iteration algorithm [72]. A research work is reported on the substructural identification in frequency domain for the identification of frequency-dependent systems such as soil–structure interaction systems [167]. A substructural identification method is proposed using autoregressive and moving average with stochastic input NARMAX model and the sequential prediction error method. Since the damage locations are not known *a priori*, adaptive substructuring is useful [74]. A damage detection and assessment algorithm is developed based on the parameter estimation with an adaptive parameter grouping scheme from static response [159]. A SI-based approach for analysis and diagnosis of structures under operating conditions is developed. Of interest in this work is the separation of diagnosis into global damage alarm and damage detection. A simplified algorithm is presented for measurement of the statistical likelihood of damage. This statistical test does not attempt to quantify potential damage, but only provides an intelligent alarm, which takes into account all individual changes of modal frequencies and shapes and compares them to their confidence domain to evaluate whether the changes might be significant. The global alarm concept is perhaps more achievable than damage detection for complex and uncertain civil structures [168]. Two complementary methods are reviewed for model-based damage detection with applications, i.e., the substructural flexibility method and the substructural transmission zeros method [169]. A computational procedure for extracting substructure-by-substructure flexibility from global frequencies and mode shapes is presented. The proposed procedure appears to be effective for structural applications such as damage localization and FEM reconciliation [170, 171]. A damage identification algorithm termed as *constrained submatrix factor adjustment* is proposed. Further this algorithm is extended by using both static and dynamic measurements [172].

For damage detection and condition assessment of large and complex structural systems, substructural identification may be an effective way.

7.5 Neural network approaches

The model updating approach described in the last subsection is based on a parametric structural model. Health monitoring techniques may rely on nonparametric SI approaches, in which *a priori* information about the nature of the model is not needed.

Nonparametric models can be used to detect damage, although it is more difficult to use them for localization of damage. NNs are one of the nonparametric identification approaches that have been receiving growing attention recently. NNs do not require information concerning the phenomenological nature of the system being investigated, and they also have fault tolerance, which makes them a robust means for representing model-unknown systems encountered in the real world. NNs do not require any prior knowledge of the system to be identified. It can treat both linear and nonlinear systems with the same formulation. A number of investigators have evaluated the suitability and capabilities of these networks for damage detection purposes.

NNs are trained to recognize the frequency response characteristics of healthy and damaged structures in which the properties of individual members are adjusted to reflect varying levels of damage [173, 174]. A FEM is used to develop failure patterns that are used to train a NN so that it can later diagnose damage in the reference structure [175]. A NN approach is presented based on mapping the static equilibrium requirement for a structure in a finite-element formulation, with the assumption that structural damage is reflected in terms of stiffness reduction. All of these exploratory studies indicate that NNs offer a powerful tool for assessing the condition of structures with inherent damage [176].

Another study complements the work of other investigators by concentrating on a class of problems where knowledge of the failure states is not available. In other words, the potential failure modes of the test structure are so varied and so unpredictable that it is not feasible to train the NN by furnishing it with pairs of failure states and corresponding diagnostic response. Without postulating or searching among limited set of expected failure modes, the approach of this study can be applied equally well to determine whether the underlying structural response is linear or not. However, such an approach has the disadvantage that detectable changes in the signature of the analyzed response measure of the structure are not directly attributable to a specific failure mode, but simply indicate that damage has been sustained by an element or unit of a structure that has a dominant contribution to the response measure being analyzed [81].

A new method of dynamic FEM updating is proposed using NNs. Because all practical experimental data will contain noise, so it is desirable to develop an updating method that is resistant to noise. It is widely known that NNs tend to be robust in the presence of noise and are able to distinguish between these random errors and the desired systematic outputs. Hence, it seems natural and appropriate to apply NNs to this field. In this method, the experimental data are first prepared by using modal analysis on the frequency response functions (FRFs), and then the resulting model shapes and natural frequencies are assembled into an experimental vector. Another advantage of the proposed approach is the avoidance of the common problem of coordinate incompleteness; i.e., the NN updating method is capable of working with a limited number of experimentally measured DOFs and modes. The proposed updating method is tested on a simple cantilever beam, with promising results. The main drawback is that this method is computationally expensive, and it will fail if FEM has repeated modes. However, it would seem that there is significant potential for this model updating method to work with practical structures [177].

In another research FRFs are implemented to identify faults in FEMs. Modal properties and FRFs are implemented simultaneously to identify faults [178, 179]. An adaptive NN method is proposed for model updating and damage detection. The NN model is first trained off-line and then is retrained during iteration if needed. Numerical simulation of suspension bridge model updating demonstrates the effectiveness of the proposed method [180]. The measured FRFs are used as an input data to ANNs to detect structural damage. The results show that, in all cases considered, it is possible to distinguish the changed states with good accuracy and repeatability [181].

A committee of NN techniques, which employs FRFs, modal properties (natural frequencies and model shapes), and wavelet transformation (WT) data simultaneously, is established to identify damage in structures. The committee approach assumes that the errors given by the three individual approaches are uncorrelated, a situation that becomes more apparent when using measured data rather than simulated data. The committee approaches are used in parallel to diagnose faults on a 3 DOF structure and a population of cylindrical shell. It is demonstrated that the committee procedure is more reliable than using each procedure individually. The disadvantage of the committee is that it requires more than one trained network [181, 182].

In another work the main focus is on evaluating the efficiency of model-unknown identification approaches such as NNs for detecting modifications in the characteristics of the underlying physical systems. Such methods would be particularly useful in assessing intricate mechanical systems whose internal states are not accessible for measurements. In particular, these methods address the issue of low-sensor spatial resolution, unknown system topology, and measurement noise well. The system is tested in its "virgin" state as well as in "damaged" states corresponding to different degree of parameter changes. It is shown that the proposed method is a robust procedure and a practical tool for the detection and overall quantification of changes in nonlinear structures whose constitutive properties and topologies are not known [82].

Multinovelty indices are developed to detect the damage region based on vibration measurement. First, a bridge is partitioned into a set of structural regions and it is assumed that there are vibration transducers at each region. For each region, a NN based on novelty detector is formulated by using the global natural frequencies and the localized modal components. Then the modal flexibility values are used to train an autoassociative NN and to obtain a novelty index. The applicability of the proposed method for structural damage region identification is demonstrated by taking the Tsing Ma Bridge and the Ting Kou Bridge as examples [183].

To diagnose faults in engineering structures in the situations where the excitation signals are unavailable or inaccessible, response-only data, transmissibility function, are utilized to train NNs. The technique is verified with two examples based on two different structural systems. The NN classifiers clearly deliver the diagnostic indications of the faults introduced into the structural systems, which suggests that the transmissibility function is a sensible response-only data source for structural fault diagnosis [184]. ANN is used as a tool in soft computing to determine the dynamic characteristics of a structural system from its dynamic responses. Then the modal parameters of the structural system are directly estimated from the weighing matrices in the NN [185].

A novel NN-based strategy is proposed and developed for the direct identification of structural parameters (stiffness and damping coefficients) from the time-domain dynamic responses of an object structure without any eigenvalue analysis and extraction and optimization process that is required in many identification algorithms for inverse problems. The proposed strategy is extremely efficient in computation and thus has potential of becoming a practical tool for near-real-time monitoring of civil infrastructures [186]. A NN-based damage detection method using the modal properties is presented, which can effectively consider the modeling errors in the baseline FEM from which the training patterns are to be generated. The differences or the ratios of the mode-shape components between before and after damage are used as the input to the NNs in this method, since they are found to be less sensitive to the modeling errors than the mode shapes themselves. Results of laboratory test on a simply supported bridge model and field test on a bridge with multiple girders confirm the applicability of the present method [187].

A damage detection procedure, using pattern recognition of the vibration signature, is assessed using a FEM of a real structure—a suspension bridge more than 100 years old. Realistic damage scenarios are simulated and the response under moving traffic is evaluated. Feature vectors generated from the response spectra are included in two unsupervised NNs for examination. It is shown that the sensitivity of the NNs may be adjusted so that a satisfactory rate of damage detection may be achieved even in the presence of noisy signals [188].

A Bayesian probabilistic approach is presented for smart structure monitoring (damage detection) based on the pattern matching approach utilizing dynamic data. ANNs are employed as tools for

matching the "damage patterns" for the purpose of detecting damage locations and estimating their severity. It is obvious that the selection of the class of feed-forward ANN models, i.e., the decision on the number of hidden layers and the number of hidden neurons in each hidden layer, has crucial effects on the training of ANNs as well as the performance of the trained ANNs. This approach presents a Bayesian probabilistic method to select the ANN model class with suitable complexity, which is usually overlooked in the literature. An example using a five-story building is used to demonstrate the proposed methodology, which consists of a two-phase damage detection method and a Bayesian ANN design method [189].

By using the advanced modeling method of element stiffness matrix modification, the order of the global stiffness matrix can be kept invariable in establishing the model of intact and damaged structures. Then, eigenvalue perturbation theory is introduced to obtain the eigenvalues and eigenvectors of the damaged structure for reducing the computation load. Two ANNs are trained based on the response data simulated using finite-element modal (FEM) and perturbation theory enhanced finite-element modal (PFEM), respectively. The damage identification capability of these two ANNs is compared. Results show that the PFEM using the first-order eigenvalue perturbation theory provides enough precision for detecting small structural damage and the computational requirement is greatly reduced. Typically, the eigensolution computational time for obtaining the train sample data using PFEM is only 1% of that using the traditional FEM [190].

The effectiveness of NN methods is determined by the completeness of original data library and the reliability of algorithms. The NN method may be effective for the on-line monitoring of large structures, such as cable-stayed bridges and suspension bridges.

8 EXAMPLES OF HEALTH MONITORING IMPLEMENTATION

In order for the technology to advance sufficiently to become an operational system for the maintenance and safety of civil infrastructures, it is of paramount importance that new analytical developments are ultimately verified with appropriate data obtained from monitoring systems, which have been implemented on civil infrastructures, such as bridges.

1. The Sunshine Skywey Bridge in Florida has been instrumented with more than 500 sensors to verify design assumptions, and monitor construction quality and the conditions in service [191].
2. A monitoring program has been initiated to study the dynamic properties of the 1543-m cable-stayed Tampico Bridge in Mexico. The main span is 360 m in length; 21 servo accelerometers have been installed and ambient and pull-back tests conducted. The resulting frequencies are in good agreement but the damping values are still being estimated [192].
3. Continuous monitoring of two steel bridges over the Conrail mainline tracks in Rochester, NY, is being done. These bridges were built in 1963. The monitoring system is included as part of rehabilitation contracts. Altogether 5 inclinometers, 22 accelerometers, and 5 strain gauges have been installed in these two bridges. All these were monitored to connect with circular to a remote host computer. Natural frequencies, mode shapes, damping ratios, MAC, etc., are then computed for use in condition monitoring and assessment [193, 194].
4. Structural monitoring system is designed and evaluated by solid-state sensors for installation in several bridges and buildings. It is reported this system is used in a project by installing fully automatic and telemetered strain sensors on 10 bridges in Georgia [195].
5. The feasibility of health monitoring of a 720-m span Hakucho Suspension Bridge in Japan is studied by ambient vibration measurement. An identification scheme that makes use of cancellation of randomness in data by shaking is employed to use the ambient vibration measurements with high accuracy [196].
6. The measurement and documentation of construction and service effects for a three-span continuous steel stringer bridge in Cincinnati, OH, is addressed. A total of 642 channels of sensor data are available for bridge monitoring. The measurements are used to check the design and the project is ongoing [197].

7. A long-term continuously operating health monitoring system has been designed and implemented for the Commodore Barry Bridge, with spans of $822 + 1644 + 822$ ft. Over 80 channels of different sensor types have been installed to collect data such as temperature, wind speed and direction, strains, acceleration, etc. Many types of sensors for health monitoring have also been installed in several long-span suspension bridges in China, such as Tsingma Birdge, Humen Birdge, and Jiangyin Yangzi Bridge [198].
8. The programs within European nations and European collaboration programs are introduced for SHM [199].
9. The research and development of SHM systems at the Bridge and Structural Lab of the University of Tokyo is introduced. The ambient vibration-based approaches for LDV and the applications in the long-span suspension bridges are also presented. The extraction of the measured data is extremely difficult because it is hard to separate changes in vibration signature due to damage from changes, normal usage, changes in boundary conditions, or the release of the connection joints [196].
10. There are more comprehensive examples for the following bridges mainly in United States [200].

The examples comprise the following:

1. Akashi Kaikyo (Japan).
2. Hong Kong Bridges (Hong Kong, China).
3. Woodrow Wilson Bridge (Virginia-Maryland, USA).
4. Benicia-Martinez Bridge (California, USA).
5. Commodore Barry Bridge (Pennsylvania, USA).
6. Colle D'Isarco Viaduct (Italy).
7. Hamilton Avenue Bridge (Ohio, USA).
8. Reading Road Bridge (Ohio, USA).
9. Sandusky Bridge (Ohio, USA).
10. Toledo Bridges (Ohio, USA).
11. Fleet Health Monitoring of T-Beam Bridges (Pennsylvania, USA).
12. A good review about the current state of SHM in Japan is reported [201].
13. State of the art for SHM in China covers some advanced methods [202].
14. Applications and researches in bridge health monitoring systems are reported [203].

New bridges offer opportunities for developing complete SHMs for bridge inspection and condition evaluation of the bridges from "cradle to grave".

Existing bridges provide challenges for applying state of the art in SHM technologies to determine the current conditions of the structural element, connections and systems, to formulate model for estimating the rate of degradation, and to predict the existing and the future capacities of the structural components and systems. Advanced health monitoring systems may lead to better understanding of structural behavior and significant improvements of design, as well as the reduction of the structural inspection requirements. Great benefits due to the introduction of SHM are being accepted by owners, managers, bridge engineers, etc.

9 RESEARCH AND DEVELOPMENT NEEDS

Most damage detection theories and practices are formulated based on the following assumption that failure or deterioration would primarily affect the stiffness and therefore affect the modal characteristics of the dynamic response of the structure. This is seldom true in practice, because of the following reasons:

1. Traditional modal parameters (natural frequency, damping ratio, mode shapes, etc.) are not sensitive enough to identify and locate damage. The estimation methods usually assume that structures are linear and proportional damping systems.
2. Most currently used damage indices depend on the severity of the damage, which is impractical in the field. Most civil engineering structures, such as highway bridges, have redundancy in design and are large in size with low natural frequencies. Any damage index should consider these factors.
3. Scaled modeling techniques are used in current bridge damage detection. A single beam/girder models cannot simulate the true behavior of a real bridge. Similitude laws for dynamic simulation and testing should be considered.

4. Many methods usually use the undamaged structural modal parameters as the baseline compared with the damaged information. This will result in the need of a large data storage capacity for complex structures. But in practice, there are majority of existing structures for which baseline modal responses are not available. Only one developed method, which tried to quantify damage without using a baseline, may be a solution to this difficulty [204]. There is a lot of research work to be carried out in this direction.
5. None of the methods has the ability to distinguish the type of damages on bridge structures.

It is not easy to establish the direct relationship between various damage patterns and the changes of vibrational signatures. Health monitoring requires clearly defined performance criteria, a set of corresponding condition indicators and global and local damage and deterioration indices, which should help diagnose reasons for changes in condition indicators. It is implausible to expect that damage can be reliably detected or tracked by using a single damage index. We note that many additional localized damage indices, which relate to highly localized properties of materials or the circumstances that may indicate a susceptibility of deterioration such as the presence of corrosive environments around reinforcing steel in concrete, should be also integrated into the health monitoring systems.

There is now a considerable research and development effort in academia, industry, and management department regarding global health monitoring for civil engineering structures.

Several commercial structural monitoring systems currently exist, but further development is needed in commercialization of the technology. We must realize that damage detection and health monitoring for bridge structures by means of vibration signature analysis is a very difficult task. It contains several necessary steps, including defining indicators on variations of structural physical condition, dynamic testing to extract such indication parameters, defining the type of damages and remaining capacity or life of the structure, and relating the parameters to the defined damage/aging. Unfortunately, to date, no one has accomplished the above steps. Many further studies are needed.

9.1 Where to go from here?

In order for the model-based damage detection methods to be adopted eventually for on-line health monitoring, the following should be addressed:

1. The accurate definition of damage and new sensitive damage indices should be developed. These indices could distinguish not only the place and the extent of damage but also the types of damage in a structure.
2. Fast algorithms for SI are needed, if possible, on a real-time basis. First, the identification of the basic characteristics of existing bridges must be accurate and reliable. This is the basis of the structural damage identification. Secondly, the objects of sensor arrangement must be clear, because there are large amounts of data to be treated and the noise should be filtrated. Furthermore, a method for localized structural identification is highly desirable so that not all of the sensor output is processed for on-line monitoring purposes. In this way, substructure identification method may be the direction.
3. There are still considerable uncertainties in the testing, analysis, and environment for the purpose of damage detection. Sometimes, it is very difficult to sort out the uncertainties and pinpoint whether the lack of reliable results from modal analysis was due to the damage or due to an error in the considerably complicated procedures of modal analysis. At this point, it is concluded that a controlled study of a physical model in the laboratory would be an excellent method to understand the sources of uncertainties and limits of confidence when modal analysis was used as a technology for condition assessment and damage identification. More research is needed on the analytical techniques for damage identification using available and realistic structural monitoring data, including the combination of static data and vibration testing information. This research should consider the uncertainties inherent in the materials and construction, the variability of structural properties due to environmental conditions, unknown modeling errors and assumption, etc.
4. Although we have not discussed any non-model-based damage detection methods, a

robust on-line health monitoring system would require a hybridization of both nonmodel and model-based methods. Studies are needed to develop sensible hybrid damage detection methods that are easy to implement and robust. According to the existing study, one of the realistic methods may be the stochastic subspace identification method by using the environmental excitation data.

5. Unfortunately, nearly all of the existing systems are not instrumented to get the responsible data. The data-acquisition systems with multichannel and signal-processing system are being developed for SHM. Economical sensor placement and data collection methodologies, both onsite and remote, are needed in order for on-line health monitoring technologies to have practical benefits for nation's existing infrastructure and transportation systems.
6. The reliability and durability of the entire SHM system should be studied. The interrelationship of structural behavior and the effect of all components of the monitoring system on the overall safety should be studied, including sensors and their optimal placements, communication, data acquisition, etc.
7. The evaluation of serviceability and load-carrying capacity for existing highway bridges based on the damage identification and reliability theory should be studied. It is very important for the load rating, condition assessment, and decision making of repair, strengthening, and rehabilitation of existing highway bridges.
8. Information techniques and imaginative systems are needed to integrate field, theoretical, and laboratory research for solving large SI and condition assessments problems.
9. New and innovative construction materials will enhance the strength and durability of the infrastructure system in the twenty-first century. Testing and evaluation methodologies need to be developed specifically for characterization of newer and high performance materials. Advanced condition monitoring technologies will enable detection of cracks, onset of failure, extent of degradation, and location of damaged zones in structural elements.
10. Standards and code for SHM, and how SHM can be better applied in practice—that is, Philosophies, cost, devices, efficiency. The health monitoring system of bridge will be included in the scope of bridge management system [205].

1 INTRODUCTION

The development of novel structures, continued existence of substandard ships, and the occurrence of structural damage at sea all demonstrate the importance and the need to implement an effective structural health monitoring (SHM) system for ship hull and local structures. These problems acknowledged in the early 1990s [1] have still to be solved or even fully addressed at the present time. There are significant differences between older, existing marine structures where limited data is available and newer structures where the design process is largely dependent upon numerical modeling. The inspection and monitoring needs and the required procedures and technologies of structural health diagnosis and prognosis are also greatly differing for commercial and military ships. Although general marine structural monitoring background is discussed as needed, this article will emphasize ship hull structure monitoring applications in US navy. An overview of marine SHM systems is presented in the introduction, followed by a description of typical ship structures and loads. The application of SHM systems throughout the vessel's lifetime is reviewed, and then health-monitoring systems and diagnostics are discussed. Finally, an example application of SHM systems to a current vessel is given.

A major objective of future US navy ship design is the development of high-performance and high-speed vessels. These designs will include many novel lightweight structural features, as well as possessing multimission adaptability and allowing for reduced levels of manning. For example, to reduce weight as much as possible to allow higher speeds and increased cargo capacity, high-speed vessels often employ novel and aggressive structural designs, using composite, aluminum alloys or high-strength steel, with innovative arrangements and fabrications to

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

maximize lightship weight reduction. These structural features and high-speed operating profiles may increase possible fatigue, buckling, and vibration problems as well as crew discomfort from increased wave slams and acceleration levels, and higher working stresses in the structure. To minimize the risk of operating such vessels in an unrestricted manner will require the ability to monitor operational loads, detect structural damage and performance degradation in the earliest possible stage, i.e., the ability to implement structural diagnosis in real time. This structural diagnostic information can then be used to predict the time to potential structural failure, and to provide strategies for corrective actions to support future navy operation and maintenance.

Despite great interest in the development of an SHM system in many industries, almost all damage detection methods currently in use are either visual or localized experimental methods, such as acoustic or ultrasonic nondestructive evaluation (NDE). These local detection methods are not only time consuming to perform, but they also require the general location of the damage to be known in advance and the structure to be taken out of service for inspection. In many cases, the visual or local inspection is impossible to perform owing to the inaccessibility of major portions of the structure. For example, it would be completely impractical on most naval vessels since the internal surfaces are almost entirely covered with insulation. This is true for both steel and aluminum ships. Long-term monitoring and early detection of damage via SHM systems would therefore present a significant benefit for the management of naval ship structures. In addition, inspections using visual or localized NDE methods do not attempt to provide a quantitative value for the remaining strength of the structure; in other words, these approaches do not intend to provide future progression of the damage and assessment of the residual performance capability of the structure.

As defined in [2], monitoring involves constant measuring or surveillance of ship structures to give actual time histories. The primary purpose is to be aware of what is happening to a structure, to:

- assess structural degradation at the time of inspection and in the future, and to manage the gradually degrading condition as it approaches a stage at which the level of risk or the degree of unreliability become unacceptable [3];
- verify design assumptions, in particular, for innovative structures where design loads and structural responses are based on advanced calculations and model tests, but where there is no experience available [4, 5];
- assess potential failures due to gross errors in the design, fabrication, and operation;
- assess the operational utilization of the structure.

These goals of a ship monitoring system define an integrated SHM process that combines structural diagnosis and prognosis components. The primary objective of a diagnostic task is to assess structural degradation by detecting, locating, and quantifying material or structural component damage using measured data (from past and present) and to establish state awareness through a diagnostic algorithm. Diagnosis covers sensing the current loading and condition of the structure. Although this information is useful on its own, load and structural response measurement system are just a subset of SHM and diagnosis functionality. Prognosis, on the other hand, aims to predict the future capability of structural systems using up-to-date diagnostic information and structural models in addition to estimating expected future loading. Prognostic information with some level of statistical confidence can be developed into decision-making tools to allow the authority to make intelligent deployment and maintenance decisions. This vision of model-based SHM approach is discussed recently in [6].

The development of monitoring, diagnostic and prognostic capabilities for marine structures, which is similar to other application areas, is uneven. Basic load and responses measurement systems are mature and used in applications today. Processing of these data into useful information to aid ship operations, such as providing feedback to the crew for the current loading on the vessel and for maintaining its proper speed to reduce slamming, is also fairly well advanced. However, damage detection capabilities and any prognosis capabilities are currently only developed to the basic science level.

To address the SHM technology in marine structural application, the remainder of this article provides a brief overview of typical ship structural configurations and a variety of loading sources at sea. It will also discuss the importance and the roles of an effective SHM system throughout the life cycle of a ship. Previous and current US navy SHM development efforts as well as required technologies for

health monitoring of ship structures will be reviewed and further discussed. To focus on getting information about the health state of ship structure on demand in real time, we address vibration-based damage assessment approaches and discuss the use of onboard sensors, advanced signal-processing methods to extract information from online data. In particular, examples of wave loadings at high speeds will be given and possible effects on local structures will be discussed. The choice of implementing appropriate technologies for ship SHM application is ultimately to address critical need in operation and maintenance, as well as a compromise between cost and benefit considerations.

2 OVERVIEW OF SHIP STRUCTURES AND SERVICE LOADING

2.1 Description of typical ship structures

A complete description of the wide variety of ship structures is beyond the scope of the current article; however, several established reference books contain extensive descriptions of structural configuration and analysis techniques [7–9]. For the purposes of this article, ship structures constructed out of metallic (steels and aluminum alloys) and composite material will be considered. Metallic ship structures are well developed and broadly similar over a wide variety of ship types and sizes [7, 8]. Steel metallic structures are used on all sizes of vessel, from small harbor craft to the largest naval combatants and cargo ships. The use of aluminum is typically restricted to higher-speed craft and to lengths less than roughly 140 m. Metallic structures typically consist of stiffened plate panels oriented with their long axis parallel to the vessel's keel. These panels are supported periodically by larger frames running transversely across the vessel to form larger grillages. Such grillages are in turn supported by a system of girders and pillars, or may be placed back-to-back to form a double-hull construction. These larger structures are shaped and combined to create the overall hull shape of the vessel. Typical structural configurations are shown in Figure 1. Connections between structural members are typically made by welding, although extrusions are commonly used for certain components in aluminum vessels. In weight-sensitive applications, plate-stiffener combinations may be replaced by a variety of cored panels assembled via welding for steel structures, or extruded in the case of aluminum.

Composite structures follow many of the same principles as metallic structures; however, the structural details differ to allow efficient construction with composite laminates. Composite construction has proven popular in smaller vessels, where reductions in

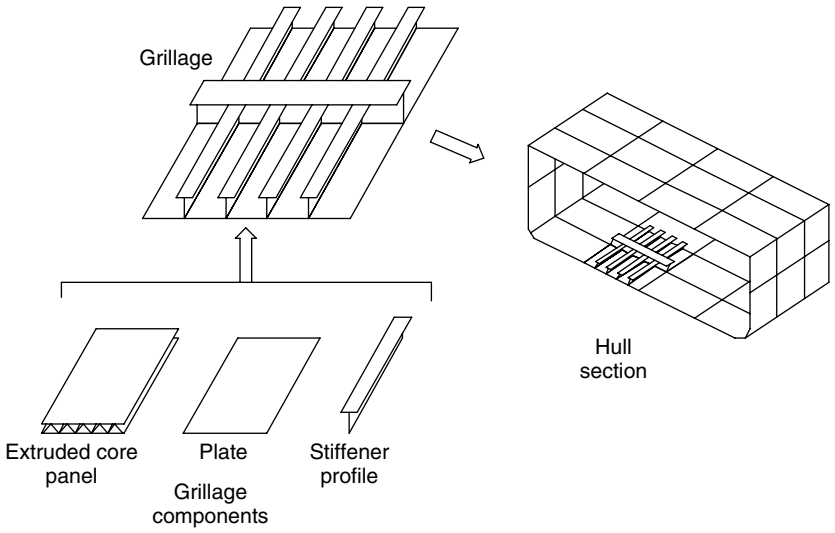

Figure 1. Typical metallic structural components.

weight, maintenance costs, and manufacturing costs for serial production are all achievable if composite construction is used in place of metallic structures. Composites may also be used for certain components of a larger metallic vessel, including deckhouses, masts, and independent tanks. Greene [9] gives a comprehensive overview of the uses of composites to date. In weight-sensitive applications, typically the outer skin of the vessel will be of cored construction, with two composite outer layers separated by a wood, honeycomb, or foam core. Such coring material is also used to build up stiffener and frame shapes. Major sections of the hull are joined by lap construction. A sample composite structure is shown in Figure 2.

2.2 Source of loading

When operating in a marine environment, a typical vessel structure is subjected to a wide variety of loads. Typically, these loads are classified into categories to facilitate load determination and analysis. A common breakdown is to use the time scale associated with the load application; this approach is taken in Principles of Naval Architecture [10], where four time scales are used. Some of the more common loads are summarized below, but this list is not exclusive and typically a vessel-specific list of loads would be generated for each design.

Static loads

- Local pressure and global bending moments, torsion, and shear forces from integration of calm-water buoyancy pressures and forces.

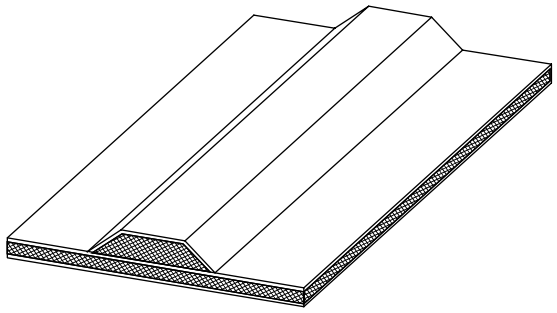

Figure 2. Example composite construction.

- Self-weight of the ship and its cargo.
- Thermal loads.
- Drydocking loads.

Low-frequency dynamic loads

- Hydrodynamic and global bending moments, torsion, and shear forces from integration of hull pressures from passing waves.
- Inertial cargo equipment and vessel self-weight reactions from ship's accelerations in waves.

High-frequency dynamic loads

- Main engine, waterjet or propeller vibratory loads.
- Hydro-elastic response of the overall hull girder.
- Hull girder whipping response from impact loads listed below.

Impact loads

- Slamming pressures from wave impacts.
- Green water impacts on deck.
- Internal tank sloshing impacts.
- Shock, blast, and other weapon effects.
- Aircraft and helo landings.

2.3 Degradation of marine structures

The marine environment is very demanding and all vessel structures suffer from age-related degradation that reduces their strength. A central goal of an SHM system is to monitor and identify such damage, and to quantify its effects on structural safety. Metallic structures suffer from three major categories of degradation [11]: corrosion wastage, fatigue cracking, and local denting and deformation of the structure. Corrosion is a central concern for steel vessels of all sizes, and significant effort is put into maintenance and inspections to minimize the danger of failure from reduced component thickness. While aluminum does not generally suffer wide-scale material loss from corrosion in the marine environment, certain alloys can be sensitive to intergranular and exfoliation corrosion. Fatigue cracking is a common occurrence in aging ship structures. A typical vessel can experience on the order of 10^8 wave loading cycles over its lifetime [8], leading to both fatigue-crack initiation and growth. This is further complicated by

the fact that a large vessel may have tens of thousands of structural connection details where fatigue cracks may initiate. Finally, cargo loading, docking and undocking, handling boats over the side, and a wide variety of impact loading discussed above can lead to local structural dents and deformations. Such local damage, and the associated out-of-plane deformations of the structure, can reduce the structure collapse strength. Additionally, the high local loading accompanying such deformations has the potential to cause yielding or cracking at welded connection details and other locations of high stress.

Composite structures are subject to the same types of loading; however, they suffer from different degradation mechanisms. Corrosion is generally not a concern for composites; however, water absorption can be an issue for certain types of composite construction. Fatigue failures of composites are complex, and may result in many different types of structural degradation, including debonding, delamination, cracking, or fiber breakage [9]. Impact loading may lead to a wide variety of local structural damages, especially in thin, cored construction, and thus, local denting and deformation is an important degradation mechanism in composites structures as well as metallic structures.

3 STRUCTURAL HEALTH MONITORING THROUGHOUT THE VESSEL'S LIFE CYCLE

The application of SHM systems to vessel structures is still an area of active development; however, it is possible to identify several common patterns in the application of SHM systems to date. Although the industry is still in the process of moving toward a complete through-life support of the vessel's structure with a comprehensive monitoring system, there is significant benefit in applying these systems in four main areas. The first area is design validation through sea trials. The second area is through-life load and usage monitoring, the third is damage detection and diagnostic systems, and the final area is prognosis, which has been mainly developed for fatigue life predictions to date. Each of these areas will be reviewed in turn.

3.1 Design validation through sea trials

Modern ship design involves a large amount of engineering modeling and idealization, especially in the areas of loading predictions and structural response. This is especially true for complex vessels or vessels whose design is at the edge of previous engineering experience. In these cases, it is useful to validate the engineering models used in design by testing the completed vessel in several sea conditions. Such an approach is especially valuable for lightweight high-speed vessels whose operation may be restricted to wave conditions below the limit threshold. In these cases, it is useful to validate that the vessel's responses are so modeled as to prevent enforcing needlessly restrictive sea condition limitations, as well as minimizing the probability of in-service damage from responses not anticipated during the design phase. Seakeeping trials may also be carried out after a significant conversion or change in the service environment of the vessel, or in response to a particular operational concern that has arisen in service. The process of conducting seakeeping sea trials to validate motions and loading is well established, especially for naval vessels [12]. The vessel is typically tested in several combinations of sea condition, vessel heading, and vessel speed. The sea conditions are captured as accurately as possible, often using monitoring components, such as deployed wave buoys, wave height meter (TSK) or a wave radar attached to the vessel.

In the most basic trials, the vessel's response may only be captured by accelerometers, which can then be used to estimate both motions and related global loads on the hull. However, more comprehensive trials will use strain gauges, local pressure transducers, and other additional monitoring components also to resolve more accurately the vessel's structural response. An example of a recently conducted seakeeping trial for HSV-2 Swift, a 98-m long, high-speed all-aluminum, wave-piercing catamaran built by Bollinger/Incat USA and delivered to the US navy in 2003, shown in Figure 3, will be discussed later in this article. Both global vibration modes and the stress state in selected local areas can be investigated. Thomas *et al.* [13] present an example of such a trial conducted during the delivery voyage of a high-speed ferry, whereas Pegg *et al.* [14] give an overview of

Figure 3. All aluminum high-speed vessel HSV-2, Swift.

conducting a sea trial and finite element model verification through natural frequency predictions of a SWATH vessel. Such design verification is a fairly routine practice today; however, both the sea condition and structural response monitoring equipment are typically removed or deactivated at the completion of a trial.

3.2 Continued load and usage monitoring

Although a typical sea-trial structural response measurement equipment is removed at the end of the trial period, there is growing interest in continuing to monitor motion and loads throughout the life of the vessel. High-speed ferries and other vessels that operate only in a restricted set of sea conditions are often fitted with permanent accelerometers to warn the crew as sea conditions and resulting accelerations approach the limiting value for the vessel. Such systems have also been extended to include pressure and strain monitoring equipment, as well as data processing and storage facilities so that the long-term loading on the vessel can be recorded for further structural analysis. Similar systems have been developed for the new generation of very large container ships, where limited visibility of the bow region from the bridge (ship navigation room) makes it difficult to accurately monitor bow slamming or shipping of green water on deck by purely visual means. For such vessels, monitoring systems can warn the bridge when large loads or structural responses are occurring. Such systems have also been developed by some vendors to include long-term load recording for fatigue life predictions and predictive modules that can anticipate likely change in motions and loads if the vessel changes heading or speed [15, 16]. Similar systems have also been developed to support transportation and installation of offshore structures, where real-time feedback on experience acceleration and loads is important to ensure that operational restrictions are observed. At the current time, some standards and guidance on developing such systems are starting to appear [17].

The experience with continued load and usage monitoring is currently growing, although most ships operate without any such system. Preventing damage to the ship structure by providing real-time feedback to the operating crew of the current structural loads and responses is one of the key advantages of fitting a continued load and usage monitoring system. Another key advantage of continued load and usage monitoring is that it provides real-time data for early damage identification and a real-world quantitative basis for fatigue life prediction. As reviewed previously, fatigue cracking is one of the primary degradation mechanisms for ship structures. The ability to correlate applied loading and service usage with fatigue damage found in the hull girder opens up the possibility of better planning fatigue inspections and estimating the remaining economic life of the structure, and also developing operational plans that minimize the exposure of the structure to the most damaging conditions.

Although the research and development communities of the navy envision this role of an SHM system application, especially for large high-speed vessels where quantitative measurements are needed to avoid unintentional damage, the continued load and usage monitoring has not been practiced for navy ship structures at the present time. However, there are some current and ongoing programs that will enable the continued load and usage monitoring technology for navy ships in service. This will be further discussed and an example will be given later in this article.

3.3 Structural damage detection and diagnostic systems

Early detection of structural damage via an SHM system would represent a major advance in marine

structure life-cycle management. As discussed in the introduction session of this article, most structural inspections for ship structures are conducted periodically by a trained surveyor, relying principally on visual inspection, backed up by local thickness measurements and NDE techniques in areas of interest. These local techniques are highly accurate but time consuming and can only be employed on a small subset of the structure. Visual inspection is able to detect corrosion and local deformations; however, for fatigue cracks, detection by visual inspection is typically assumed to become dependable only when the crack has grown to several inches in length [18]. Some vessels prone to structural damage may also have problem areas inspected more frequently by the crew using purely visual inspections. The current approaches are often time consuming, especially on vessels where much of the structure is normally covered by structural fire protection or other internal joiner work. Developing structural diagnosis capabilities that can supplement visual inspection is a key technical task for future marine SHM systems.

Various damage detection techniques and methodologies have been developed over the past several decades for aerospace, mechanical, civil, and marine structures. Numerous papers, books, and specialized conference proceedings have been published such as those in [19–23]. Damage detection and structural diagnosis will remain to be an area of active research. Some of these damage detection methods and diagnostic techniques have demonstrated feasibility in laboratory and controlled testing environments. However, we are still a long way from a shipboard SHM system that contains robust damage diagnosis capabilities. More detailed discussions and scientific and technological requirements for a comprehensive damage detection system for ship structures will be given in the next session.

3.4 Prognosis and fatigue life predictions

Along with structural damage detection, prognosis of the future state of the structure is an active area of research [24]. At the present time, most prognosis approaches in use are computationally quite simple. This is perhaps a reflection on the state of the art in structural damage detection, as limitations in knowledge of the structure's current state prevent the application of complex prognosis techniques. Fatigue life prognosis can be made in conjunction with continued load and usage monitoring. Typically, the fatigue life of a vessel's structure is estimated at the design stage by using the S–N fatigue approach and the Miner–Palmgren cumulative damage model [25]. Thus, the loading experienced and recorded by the SHM system in service can be converted into a Miner–Palmgren damage summation for various locations on the structure. This is often done via Rainflow cycle counting of recorded strains, with a suitable conversion to local fatigue stresses [26]. These service damage summations can be used to forecast when the fatigue life of the structure will be consumed. The S–N approach is typically used to predict fatigue-crack initiation and does not give any information on resulting crack growth or the risk of fracture. This limits such prognosis techniques to forecasting when fatigue cracking is expected to become prevalent on the vessel without directly determining quantitative measures of risk of structural collapse. Additionally, if the rate of recorded fatigue damage can be correlated to vessel speed, heading and sea conditions present when the recording was made, it is also possible to use this data to examine changing the vessel's operational restrictions in an effort to extend the fatigue life of the structure. The fatigue prognosis process has seen limited extension to remaining life assessments in the presence of a detected crack (e.g. [27, 28]). Such approaches could also be incorporated into an SHM system. As structural damage detection methods advance, creating more complex prognosis capabilities is likely to become more attractive to vessel owners and operators.

4 HEALTH MONITORING AND DIAGNOSIS

To reduce the risk of operating high-performance and high-speed vessels in an unrestricted manner will require the development and application of structural risk assessment and decision-making tools using innovative, time-efficient health-monitoring technologies. For example, applications of SHM system include long-term embedded sensors, wireless communications, *in situ* global and local damage detection methodologies, and software-based decision

tools. Many emerging technologies developed in the multidisciplinary field of SHM for a broad range of civil and aerospace structures can be utilized in marine structure applications. There are several components required for a general SHM capability, regardless of applications in a specific engineering system. For example, the three required components are

1. accurate knowledge of the structure's failure modes and related material's corrosion and fatigue properties;
2. diagnosis to know how the structure is actually being used via monitoring and detect damage to determine the actual current state of the structure;
3. a prognosis capability based on an engineering model capable of predicting the future condition of the structure based on the diagnosis data.

All three basic components require specific science and engineering knowledge of the system. This is the key for a successful implementation of an SHM system.

4.1 Marine structure monitoring considerations

The definition of marine structure failure modes that may affect each level of the structure is complicated by the continuous nature of the ship construction. Accounting for the interdependencies requires simplifying assumptions to allow a focus on one component or subsystem at a time, and its associated failure modes. Common-cause failures are failures of multiple components due to the same loading event. Each component may be subject to several failure modes that might combine to cause the component to fail depending on the form of the failure mechanism. Each failure mode for each component in the ship structure may have different levels of significance, or consequence of failure. The potential failure locations for a typical ship structure number in thousands. These facts are compounded by the uncertainty of loads that a typical ship experiences. As discussed previously, seaway load effects on the vessel hull are transformed by way of interaction with the vessel structure. Primary loads affect the entire hull, whereas secondary loads affect localized regions of the hull structure. Typically, numerically derived seaway loads are transformed into stresses similar to the manner in which strain gauge information is transformed into stress. The stress values are then input into failure mechanism models at the material and structural level. Prediction of realistic seaway loads is done using probabilistic models, and is a significant challenge for any surface vehicle, but particularly difficult for vessels that travel at high speed leading to great uncertainty as to the accuracy of the probabilistic predictions. In addition, the structural configuration is a challenge for modeling and simulation efforts as there are differences between the design and as-built, structural geometry and dimensions. Production methods for ships structures are not as controlled as other vehicle production such as for airframes. Misalignments, distortions, and residual stresses are introduced into the structure during the welding and fit-up, all of which are difficult to model accurately using a sophisticated numerical modeling and simulation process due to the scale of the structure and the lack of information at a sufficient level of detail. Introduction of new material, details and welding stresses into the structure requires an update to the structural model. It is important to be mindful of the basic engineering system characteristics as well as specific risk and economic concerns for marine structure health monitoring applications.

4.2 Effects of loading from random seaway and slamming

In addition to continued seaway load, one of the challenges facing ship hull structures is overloading that can occur during normal operations at high sea state (slamming) or when encountering an extreme event such as explosion or collisions. More importantly, the challenge is the ability to assess the adverse effects of the ship with accumulative loading demand throughout the service life, in other words, the effects of structural fatigue due to global and local load. An SHM system for ship structure applications needs to address both overloading and fatigue problems since each overloading incidence contributes to overall ship structural fatigue. At the present time, structural response due to local pressure created by slamming is not well understood. For example, HSV-2 encountered many slamming events during

rough water trial runs in winter/spring 2004 [29]. The hull response is measured by two groups' strain gauges that are identified by: global strain T1, stress concentrations related to local strain, T2. The global T1 strain gauge locations were chosen on the basis of a full-ship finite element model to capture primary load response. The local T2 strain gauge locations were chosen to indicate the level of structural response in known or suspected areas of high stress. Examples of T1 and T2 are shown in Figure 4.

Other measurements such as accelerometers are used to record wave impacts that can be used to correlate high strains at a given time. An example of recorded acceleration and global strain is shown in Figure 5.

An example of structural response due to wave slamming is shown in Figure 6. This figure displays

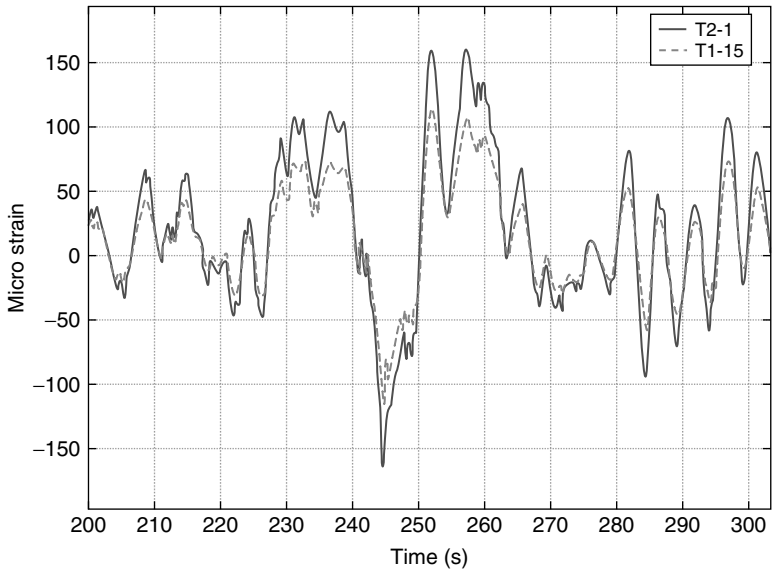

Figure 4. Global (dash line) and local (solid line) strains recorded in one of the seakeeping trial runs.

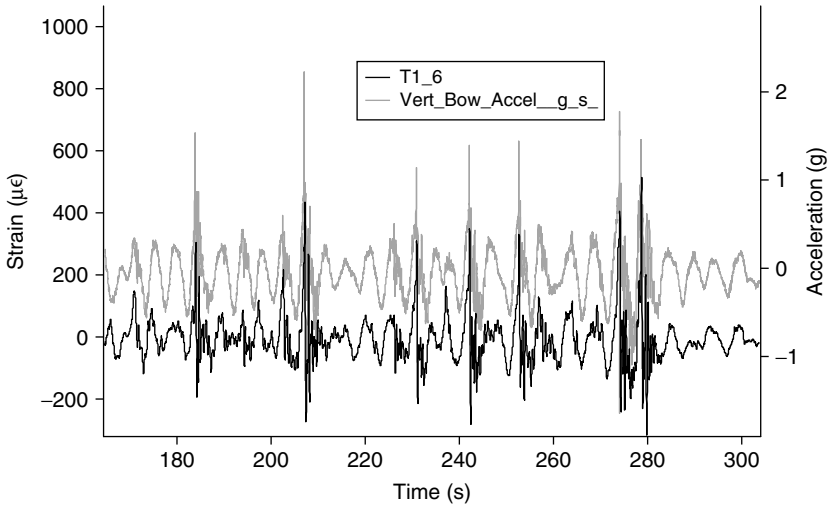

Figure 5. Recorded global strain and vertical acceleration in the bow area in one of the seakeeping trial runs.

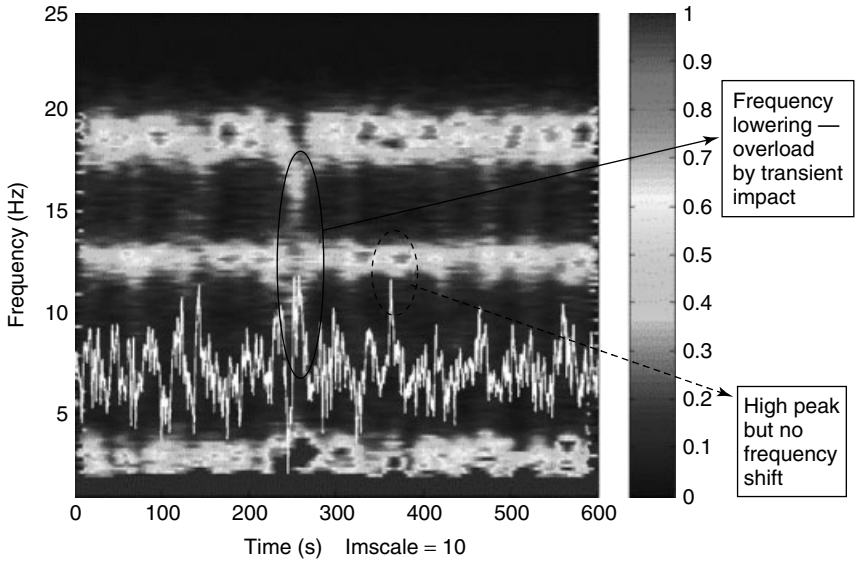

Figure 6. An example of time–frequency analysis of local strain.

the time–frequency analysis of measured strain time history using empirical mode decomposition and Hilbert–Huang transform [30]. The measured local strain T2 (solid white line) is at the deck-head on cross bracing near the side hull joint of the HSV-2 during one of the initial sea-trial runs. The peak-to-peak value of the data is approximately 400 microstrains displayed with the normalized time–frequency distributions.

At about 260 s, noticeable frequency downshift (indicating temporary stiffness loss) occurred for local responses at about 19 and 13 Hz. There are also high global structural responses between 2 and 4 Hz at the same-time window. This is likely due to significant overloading by the slamming event. On the other hand, about 120 s later, a similar peak strain is recorded from another wave slamming. Although the amplitude of the strain from this later slamming is similar to the first one, there is no frequency change observed. These results indicate that wave slamming magnitude and duration both play an important role on local structures.

The current methodologies to calculate accumulative fatigue due to wave impact do not take time durations and structural response differences into considerations. Lightweight ships will encounter more frequent slamming during high-speed operations, and therefore, it may be important to account for these local response differences to correctly assess the overall structural fatigue. This analysis result may lead to requirements such as more complex signal analysis that is capable of identifying time durations and determining the details of structural responses or other adjustments to the diagnosis component.

4.3 Real-time monitoring and damage detection

Global damage detection methods, also known as *vibration-based* (or *dynamic-based*) *methods*, are a promising technique for real-time shipboard SHM applications. This classification is based on the relative relationship of the signal wavelength with respect to the defect size, as well as to the overall structural dimensions. Typically, the local approach uses the wavelengths smaller than the size of damage to be detected and more sensitive to incipient damage, e.g., high-frequency guided wave, but the sensor and data handling cost can be overwhelming. In contrast to local NDE technologies and other local methods, global damage identification approach offers distinct advantages to damage detection of large and complex structures. For example, these methods require simultaneous measurements of much fewer locations to

provide global coverage of large area of the structure and they are capable of working at a "system level". It is not necessary that the sensors are located close to the damage site, which is an advantage that is significant for overall structural state assessment. Furthermore, they tend to be time effective and less expensive than most alternatives. The fundamental principal upon which vibration-based methods are founded is that small changes in a structure cause behavioral discrepancies in its vibration response [31, 32], and they can use the measured time traces and the traveling sequence of abnormality or sudden change in the time trace to locate damage. However, the dynamic-based approach may require more complex signal analysis and diagnostic algorithms that are capable of identifying pertinent features to infer the corresponding structural anomaly.

Many recent studies in global damage detection approach are stimulated by the new developments in advanced signal processing, as reported in [33]. To date, most damage detection methods use Fourier analysis as the primary signal-processing tool. From the resulting spectra, modal properties or damage-sensitive features are extracted to detect change in the signal properties. However, often the most important aspect of damage is in how these characteristics change in time as well as whether the system is nonlinear. Examination of the modal properties of a structure can neither typically identify a sudden change in system properties due to complete lack of time information nor can it provide information about whether a system is nonlinear. The nonstationary nature of measured signals produced by mechanical faults or structural damage suggests that time varying method of signal processing can be used to detect such faults as an alternative approach to the classical, Fourier-based methods. In particular, time-variant modeling and nonlinear signal feature extraction can offer a powerful solution to many nonlinear and nonstationary problems, especially when combined with time–frequency adaptive methods. (Some of these methods applied to SHM are discussed in greater detail in **Time–frequency Analysis**; **Wavelet Analysis**; **Damage Detection Using the Hilbert–Huang Transform**; **Nonlinear Features for SHM Applications**.) The development of real-time damage detection algorithm for large and complex structural systems such as ship structures will need to utilize these advanced signal process tools.

A robust damage detection system for ship structures includes capabilities to identify the presence of damage, to determine the location and extent of the damage, to establish the nature of damage, and to assess the cause of the damage. This is similar to four levels of damage assessment scale proposed in the civil engineering community about 15 years ago [34]. In addition, the system should be sensitive to critical damage mechanisms (e.g., impact and fatigue) and capable of characterizing the ensuing damage with an acceptable level of accuracy and reliability. In addition to the requirement of having to be sensitive to damage features, the advance signal-processing method also needs to be able to distinguish the vibrational characteristics change of a structure due to damage versus the change from other environmental and operational effects. To consistently identify these differences presents a technical challenge in the development of robust damage detection algorithms. Moreover, the most challenging fact is that damage is typically a local phenomenon and generally does not significantly modify the lower frequency response characteristics or global response of a given structure. In practical applications of real-time diagnosis, these dynamical response changes also need to be detected under normal operational conditions.

5 CURRENT HULL MONITORING SYSTEM AND REMAINING CHALLENGES OF MARINE STRUCTURE APPLICATIONS

5.1 An example of current hull monitoring system

The development of high-speed and high-performance vessels greatly accelerated the interest in equipping navy ships with an operational real-time monitoring system. Currently, there are several navy acquisition programs that contain ship and hull monitoring aspects. An example of such is a hull condition monitoring project for the Joint High Speed Vessel Program. This program develops a hull monitoring system that is composed of stand-alone commercially available software and hardware. It provides data

measurement, data collection and conditioning, data processing and evaluation, as well as results presentation and storage. An overview of the main contents of this hull monitoring system is shown in Figure 7.

The hardware system utilizes sensors and infrastructure such as accelerometers, resistance strain gauges, and wave measurements available from previous seakeeping trials [29]. These sensors, distributed throughout the hull structure, are tied back into a data recorder and acquisition systems.

It is important to note that there are many more practical issues that need to be addressed for continued shipboard data acquisition. Generally speaking, the available space and weight of a given vessel is very limited. Long-term load and usage monitoring system must efficiently utilize hardware size, weight, and space. If not addressed appropriately in the early system implementation, the whole system may be turned off or taken apart owing to other needs and priorities. The hardware system, such as computer, cable, and data acquisition, is significantly reduced in size and streamlined in design in the current hull monitoring system development effort compared with the measurement system used in seakeeping trials. Software developments include real-time indicators to alert the operators of structural overload and running fatigue damage estimates based on global wave impact. It can indicate the exposure of the ship by recording wave impact amplitude and nominal high stresses, and display a trend of the above indicators. These real-time display indicators for ship navigation and engineering spaces are intended to provide instantaneous information and knowledge for the operators. In addition, background processes that include statistical calculations, load, and fatigue damage accumulative estimation are periodically updated by running an "analysis engine" [35]. More details on the hull monitoring system development can be found in [36].

The hull monitoring system example discussed above is leveraging experiences gained from previous monitoring efforts on navy vessels as well as routine practice from design verification sea trials. Although it does not have structural diagnosis and prognosis capabilities, it delivers improved data recording, motion, load, and usage monitoring system. This project provides valuable experience toward the development of integrated SHM system that ultimately includes structural evaluation and diagnostic and prognostic capabilities. These capabilities will provide intelligent strategies and automated processes to effectively manage future naval ship structures.

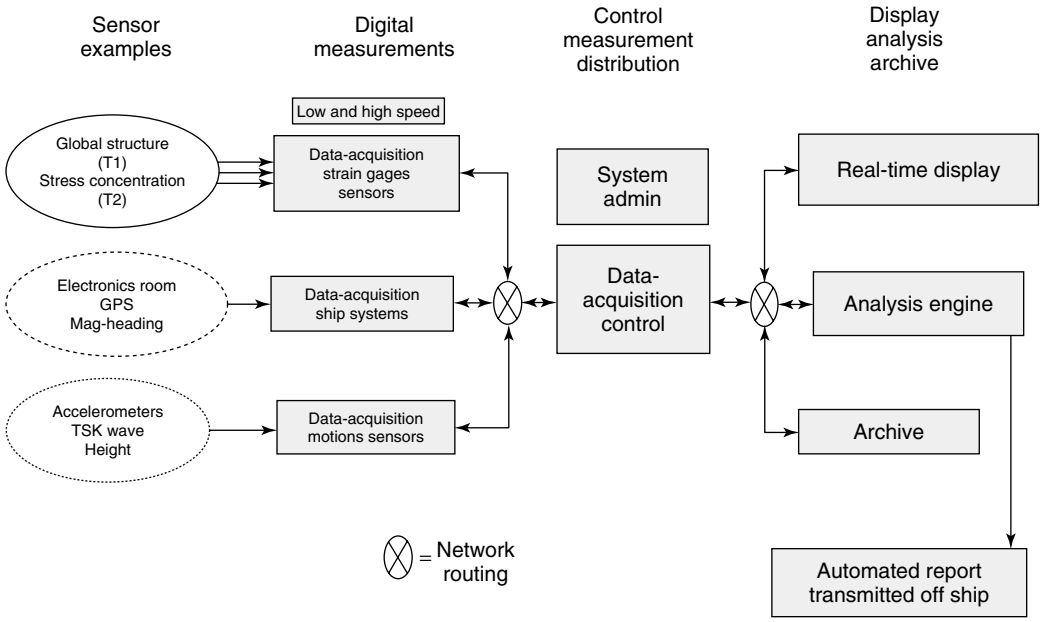

Figure 7. Overview of hull monitoring system for Joint High Speed Vessel Program.

5.2 Remaining challenges of implementing SHM systems for marine structures

As discussed previously in this article, SHM systems for marine applications are still largely developmental. Systems for sea-trial design validation have been widely used to date. Continued load and usage monitoring systems for fatigue prognosis exists on some commercial high-speed vessels and are being implemented on naval vessels in recent years. Real-time monitoring and reporting of vessel motions and structural responses are also increasingly common. Often these measurements are reported to the crew in comparison to predetermined threshold values, and used to warn the crew about dangerous loadings. Although these systems provide useful real-time feedback to the crew and are growing in complexity, most of them do not make any attempt to diagnose the current health of the structure or detect and localize early-stage damage such as fatigue-crack propagation. Likewise, prognosis applications of the current generation system tend to revolve around recording strain cycles and estimating the percentage of a predetermined fatigue budget that has been consumed to date.

Within the marine community, there is keen interest in more advanced diagnosis and prognosis capabilities that would allow for more targeted inspection and repair actions as well as support for handling accident situations, where the vessel has suffered damage from collision, grounding, or enemy actions in the case of naval vessels. However, several challenges still remain to be overcome to achieve such capabilities. In addition to the typical challenges related to sensor and signal processing common across many disciplines of SHM, marine structures suffer from a multitude of potential damage locations, i.e., "hot spots", including fatigue cracking and local structural collapse. At the current time, it is not economically feasible to monitor all of these locations. Prioritizing locations is also difficult as it is unheard of to test a full-scale prototype of a design for fatigue life as is common in the aircraft industry. Thus, ranking of hot spots must be done by analytical means and engineering judgment and the resulting system may miss some of the important damage locations. In addition to material, dimension, geometry, structural detail, and construction complexities of marine structures, difficulties of implementing SHM systems are also compounded by the uncertainty of seaway loads and their effects on the hull structure by way of local interactions as well as the scales of structure failure modes. Common-cause failures can be damages of multiple components due to the same loading event or several failure modes that might combine to cause the component to fail over time. Well-planed programs and collective efforts from many agencies and resources are needed to implement an effective and comprehensive SHM system for shipboard applications.

6 SUMMARY AND DISCUSSION

Ship structure and material, whether composite or metallic, degrade over time due to operational loads and the challenging ocean environmental conditions. Accounting for degradation, damage and repair in determining structural health is a significant challenge to ship operation and maintenance. The development of integrated SHM system with monitoring, diagnosis, and prognosis capabilities is critical for assessing the true performance and safety of the ship structural system. The current state-of-the-art marine SHM is not yet advanced enough to produce complete SHM system for shipboard field deployment. Both diagnosis and prognosis capabilities are still active research area with significant hurdles to overcome before practical systems are ready for widespread application. However, incremental development of continued load and usage monitoring aspects of SHM systems is actively being perused by both the US navy and the commercial marine industry. These ship hull monitoring systems can provide valuable experience toward the development of integrated SHM system that ultimately includes structural evaluation, diagnostic and prognostics capabilities.

It may be necessary to implement a diagnostic strategy in multiple stages for ship hull and local structural assessment. Initially, a real-time, onboard sensor network combined with dynamic-based damage detection algorithm is used to pinpoint possible problems and identify their locations. Then, further evaluations are justified using more localized techniques as well as incorporating sensor and inspection information into fracture-based fatigue models to evaluate details with known or suspected flaws to mitigate the risk of fracture and support

remaining life or time-to-repair prediction. This multiple stage approach can enhance the potential for finding damage early in the damage progression as well as perform the assessment for the entire ship to preventing catastrophic failure. As technologies become more sophisticated, such an approach could also provide feedback on how to operate the vessel for a given damage condition and provide the opportunity to greatly improve operability, maintenance, and repair strategies.

1 OFFSHORE TECHNOLOGY

The offshore industry uses some of the most advanced and extremely risk-laden technologies in the world. The basic industry structure is an oil rig, consisting of a high steel tower floating on large tanks, full of air. The tanks are underwater, making the oil rig mobile, and are called *submersible*. Sometimes, vessels are used for offshore technology and they are called *drillships*. When the sea is not very deep, rigs stand on tall legs on the sea bottom—modern types are called *guyed tower platform* (GTP). Sometimes, rigs stand permanently, but most often the legs retract and the platform moves from one position to another—these are known as *jack-up* oil rigs.

Oil rigs have a stainless steel screw capped by cemented carbide called a *drill*, which bores a narrow hole, 6–20 in. (0.1524–0.508 m). wide into the sea bottom. Then the machine pushes a strong, steel pipe into the borehole. If oil is near the surface of the sea bottom, it flows into the pipe at high pressure. The deeper the drilling required, the more advanced the technology that is needed.

The oil that comes from the borehole is generally a thick, sticky, dark brown liquid. It is a mixture of many kinds of hydrocarbons, both liquids like petrol and kerosene and gases such as propane, butane, etc. A refinery located in the tower separates oil into different kinds of liquids and gases. The oil is

carefully heated to a temperature higher than that of boiling water, so the petrol, which boils easily, turns into vapor. The kerosene, which boils at a higher temperature, remains liquid. The vapor of petrol is cooled, and the two liquids are stored separately. Gases are purified and pressured into a compressor, which carries them out into tanks. Sometimes, gases are carried out into pipes placed at the sea bottom, which connect the oil rig to the mainland [1].

2 THE OIL RIG-SPECIFIC MACHINES AND EQUIPMENT

The offshore industry is a combination of mechanical, electrical, and chemical technology. The harsh sea environment demands that all machines have to fulfill specific requirements. They cover the following aspects:

- marine classification certificates;
- fire resistance;
- reliability;
- EEx certificate;
- ISO requirements for all types of machines.

The main machines using diagnostic procedures in the production process on the oil rig are

- oil pumps with propulsion systems;
- gas compressors with propulsion systems;
- electric power station;
- propulsion systems of auxiliary vessels like tugs, tankers, etc.;
- automation of production processes.

An oil pump is a machine that carries out oil from the main pipe into separators; it is a basic constituent of the production chain. The pump, usually a centrifugal type, is capable of handling sand- and gravel-laden oil without undue clogging or wearing. Horizontal and vertical oil pumps are designed for heavy-duty applications such as offshore pipelines. A pump has a motor unit enclosed by clamshell housing sections or it stands free. It is powered by electric motors, diesel engines, or gas turbine engines (GTEs). The pump moves a working fluid through the housing to an outside load. Each section has intake walls defining a portion of an intake chamber and outlet walls defining a portion of an outlet chamber. Pumps work sometimes 24 h per day for 14 days.

A gas compressor is a mechanical device that increases the pressure of the mixture of gases coming from the separator by reducing its volume. Compression of the mixture of gases increases its temperature, so the cooling system is an important part of gas compressors. Reciprocating machines are mainly used as gas compressors on rigs. They are commonly powered by electric motors.

The electric power station is an important part of an oil rig. It supplies energy for technological processes, life support systems, and logistics. Electric generators are commonly propelled by gas turbines or diesel engines. Gas turbine propulsion units of electric power stations need gear boxes because of the high rotational speed of power turbines. At least one electric generator works 24 h per day, so reliability of the energy system is the main purpose of operational policy—oil rigs are not connected with the mainland's energy system.

The propulsion systems of an auxiliary vessel are subjected to specific sea loads due to wave and dynamic factors associated with the technical purpose of the vessel. Tugs and tankers play an important role in offshore technology. They ferry petroleum and kerosene, and supply food, hydroengineering materials, technical devices, and crew. Moreover, tugs support diving works and can be used as fire vessels, an important role due to the seriousness of fire and eruption alerts on the rigs.

3 HEALTH-MONITORING OIL RIG MACHINES—REQUIREMENTS

Currently, vibration procedures for diagnosing machines are very popular in offshore technology. They provide lots of information about the dynamic behavior of rotating machines and their structure [2]. The main disadvantages of the vibration method of diagnosing are the requirement for an *on-line* procedure and the need for knowledge of construction, materials, and forces reacting inside the machine. However, an *off-line* procedure is applied mainly in ISO standards' tests, which are sometimes quite useful. The off-line vibration method of diagnosing

needs statistical analysis of vibration signals to create operational characteristics.

Every monitoring system working on the rig has a declaration of conformity of *EEx* requirements (working in potentially explosive atmospheres) and ensures reliability of production. The principal requirements are:

- monitoring system—global or separated into subsystems;
- monitoring system should cover all strategic machines;
- guarantee redundant data transmission for a global system;
- guarantee shutdown of machines in fire and eruption alerts;
- recording all alerts to the memory, including operational parameters;
- connection to acoustic and visual signals alerts.

4 MECHANICAL VIBRATION MEASUREMENTS—PROCEDURES AND EQUIPMENT

Vibration monitoring systems demand specific, high-quality gauges (mainly accelerometers), cables, amplifiers, and analyzers. A typical, simplified configuration is presented in Figure 1.

There are three quantities that are of interest in vibration measurements: the displacement, D; the velocity, V; and the acceleration of vibration, A. Signals are analyzed as time waveforms, shocks, and spectra. Diagnosing systems can be made *on-line* (real-time monitoring systems) or *off-line* systems.

On-line monitoring systems are recommended for offshore technology, but *off-line* vibration measurements also perform an important role. Drillships often do not need a global monitoring system, since it can be very expensive and is only used rarely. They use *off-line* systems adapted to the specific operational requirements.

Simple periodic vibration may be analyzed as a time waveform, but unfortunately, it can be applied only to the very simple machines. The basic parameters of time waveform parameters are zero peak, peak-to-peak, root mean square values, etc. Because much more complicated machines usually work on rigs, this procedure is seldom used.

Monitoring systems generally perform spectral analysis, bandwidth filtration, and advanced statistical analysis of recorded signals. The following methods of vibration signals analysis are adapted:

1. FFT analysis without tracking;
2. analysis based on ordinary FFT spectrum analysis, where FFT spectra and slices, are shown as function of RPM measured by a tachometer;
3. order tracking, where the frequency range of the order analyzer changes in accordance with rational speed of the machines shaft—tracking;
4. autotracking, where Bayesian statistics is used for parameter estimation [3].

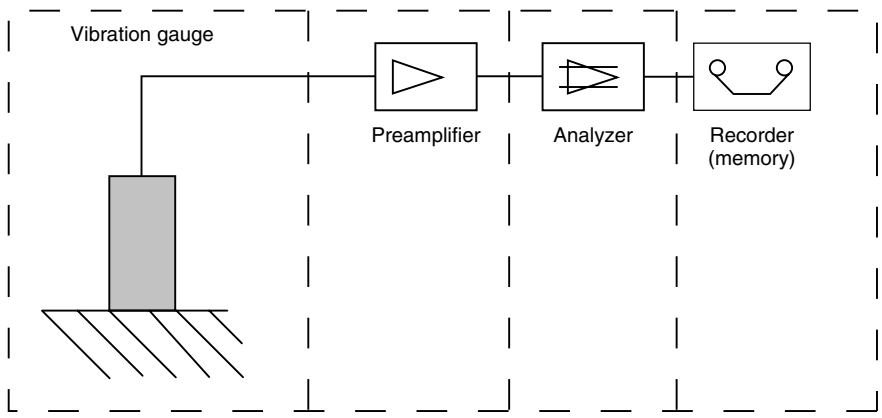

Figure 1. Typical vibration configuration.

Vibration and thermodynamic analysis requires the following transducer standardization (vibration and others):

- relative vibration, axial position, and keyphasor measurement;
- absolute vibration—accelerometers should be correctly suited to the type of machine;
- thermocouples or thermoresistor for temperature measurements;
- pressure transducer (static and dynamic measurements).

5 RECIPROCATING GAS COMPRESSORS— PRINCIPLE OF VIBRATION MONITORING SYSTEM

Reciprocating gas compressors are monitored by the manufacturer's system or an individually prepared system in accordance with ISO recommendations—ISO 10816-6:1995(E). Every manufacturer's monitoring system is a result of its experiences and knowledge, so the configurations of gauges and analysis types are specially declared for all types of machines [4, 5].

Sometimes, compressors do not have monitoring systems. *On-line* or *off-line* monitoring systems should fulfill the manufacturers' vibration parameter limits or the limiting values of overall vibration measured on the machine structure. This is determined by many parameters. Classification of compressors depends on their application, size, power, configuration, mounting, speed, etc. Limiting values of the vibration parameters (D, V, and A) are presented for a few classification numbers of machines.

Compressors with the same level of power reciprocation can be used in different machines. In this case, the limits of rigid vibration values can shut down a compressor that is in good technical condition. To avoid this situation, classifications that may be agreed upon between manufacturer and customers are made on the basis of experience or as a result of operations. Application of computer simulation for monitoring systems and finally diagnosing the technical state of gas compressors should be done during calculation and project process. This is a very useful tool for model analysis. There is a problem when the manufacturer does not include this kind of know-how in the technical specifications given to the customer. This situation occurs quite often for gas compressors used in offshore technology. The main problem is to assess the technical state of a machine and find the source of the problem. One of the potential solutions is to apply the vibration method for diagnosing the actual technical state [6, 7]. When the compressor is not identified as an object for *FE* (*final elements*) calculations, the situation requires application of another operational tool [8, 9]. The only way then is through periodical vibration research and tests accomplished through preferred standardization. Tests are accomplished according to ISO 18061-6, in three axes (Figure 2).

Research assumes periodic vibration tests as a function of crankshaft rotation and operational time. Accelerometers are mounted on the cylinder tie-bolt nut and to the bedplate in three axes. Every measured point is analyzed and each vibration spectra provides "fingerprints" of that particular machine. Every point of the spectra is stored in the data base and analyzed as a time function (Figure 3). Permanent measurement is defined for the *on-line* diagnosing system. A scheme of analyzing parameters is presented in Figure 4 and the measured point on the compressor cylinder is shown in Figure 5.

Off-line and portable diagnostic systems are inexpensive, but they have two major disadvantages:

- they fulfill only guarantee period requirements;
- all analyses are sustained.

On-line systems avoid these disadvantages and allow continuous monitoring. The main points are:

- the monitoring system makes managing the compressor's operation time much more rational, especially before maintenance;
- the vibration method is noninvasive and does not require taking the compressor out of service [10];
- the monitoring system leads to important economic benefits, especially in reliability improvement.

Finally, requirements for reciprocating compressors demand the following measurements (vibration and others):

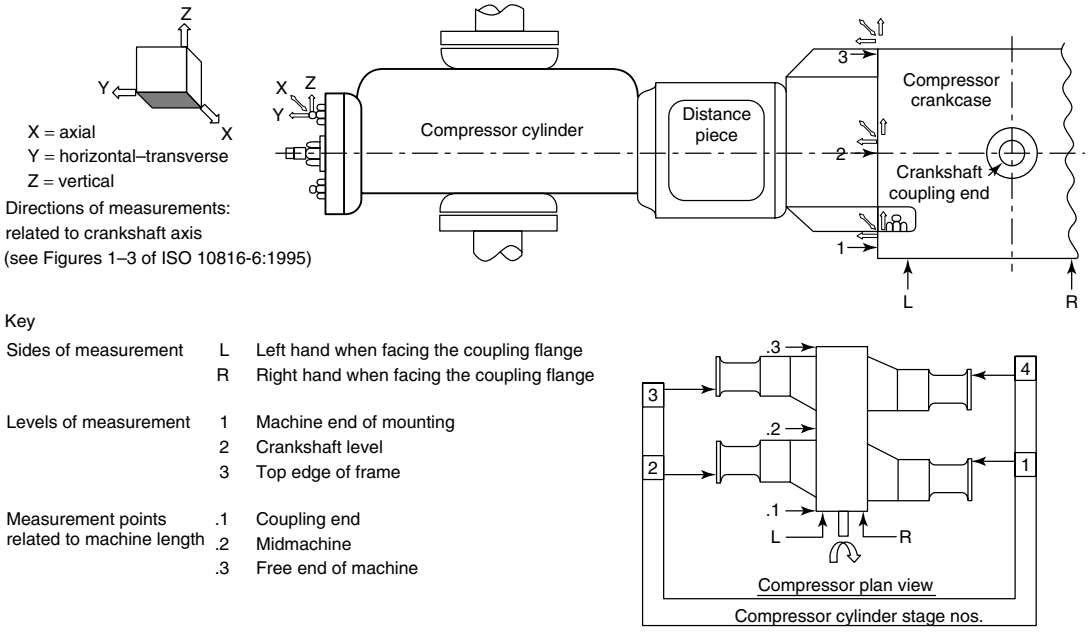

Figure 2. Location of measured points of a compressor.

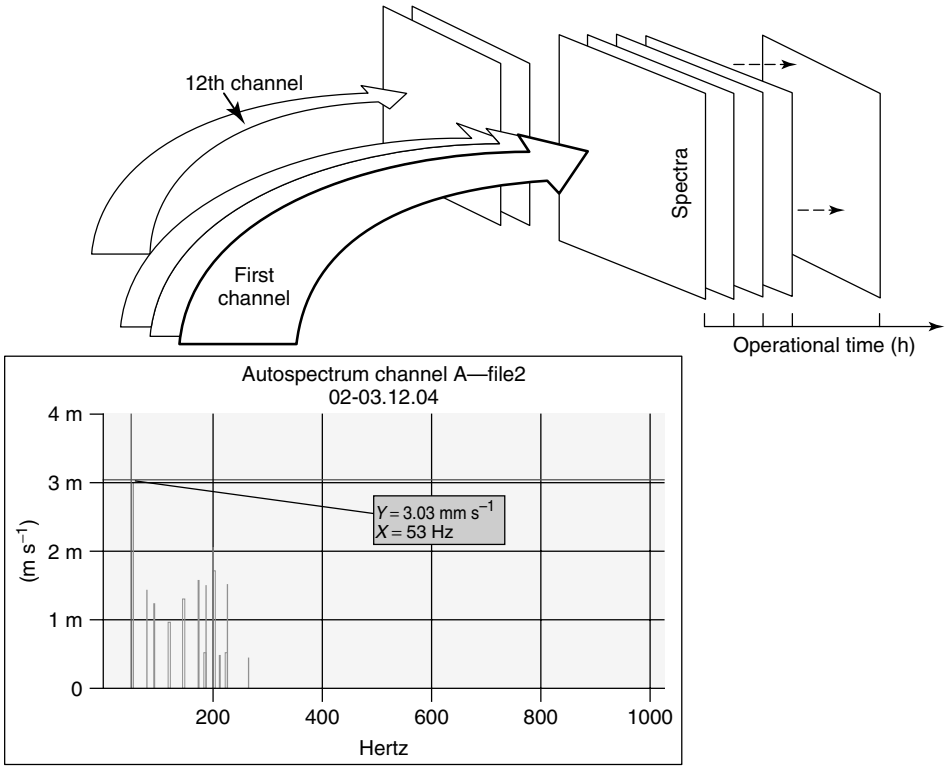

Figure 3. Structure of spectra data base.

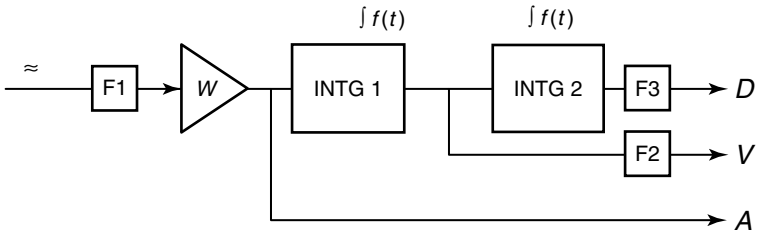

Figure 4. Scheme for measuring D, V, and A parameters.

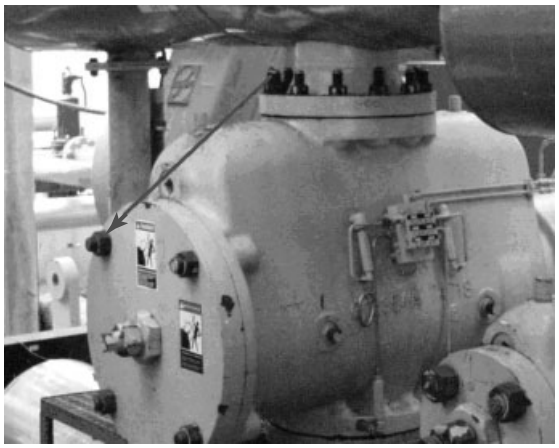

Figure 5. Measured point—cylinder tie-bolt nut.

- relative shaft vibration (two proximity probes on each slide bearing of the compressor and the driver machine);
- revolution of shaft;
- absolute vibration on each bearing housing of the electrical motor and the piston compressor;
- absolute vibration on the cylinder and the frame of the piston compressor;
- measurement of rod drop on each rod (two proximity probes in two directions—horizontal and vertical);
- temperature of the slide bearings (two redundant transducers mounted in the bearing sleeves);
- temperature of the windings (for electrical motor);
- temperature of suction and discharge valves;
- pressure measurement on each cylinder, damping device, and pipe [11];
- compressor suction and discharge pressure, and temperature measurement;
- lubricating oil pressure and temperature measurement;
- piston rod seal temperature measurement;
- piston rod seal leak—flow and pressure measurement;
- other important measurements: pressure, pulsation, temperature, power, etc., agreed upon between the vendor and the user of the machines.

6 PROPULSION SYSTEMS OF ELECTRIC POWER STATION AND OIL PUMPS—ON-LINE MONITORING SYSTEMS AND OFF-LINE MEASUREMENTS

Modern electric power stations that work on rigs are powered by GTEs and they are called *gas turbine generators* (GTGs; Figure 6). Application GTEs enable a fast start and the ability to take on a full load in a relatively short time interval (about 1 min). This is why GTEs can be adapted as the propulsion units for sand pumps and gas compressors

Figure 6. GTE enclosure on a rig.

on rigs [12]. Moreover, GTGs and GTEs consume one of the liquids produced—petrol [13]. Diesel engines are generally used for auxiliary generators.

Contemporary GTEs used for aircraft or shipboard propulsion have a wireless *on-line* monitoring system. The system operates time–frequency-based signal processing, probabilistic analysis, neural network classifiers, fuzzy logic decision support analysis, and Bayesian networks, just a few of the algorithmic approaches currently being implemented to provide for better awareness and prediction of equipment health state. The following mechanical faults should be recognized by the monitoring system:

- unbalance
- shaft interaction
- eccentricity
- squeeze film malfunction
- blade rub
- rotor instability
- oil in rotor
- flange/joint slip
- looseness
- misalignment
- swashed track.

To obtain reliable data on diagnostic parameters, monitoring of the gas turbines installed in electric power stations is carried out by means of the multi-symptom diagnostic model, a main feature of which is recording and analyzing vibration signals [14]. The measurements are mainly aimed at determination of permissible in-service imbalance and appropriate assembly of turbine rotors on the basis of selected vibration parameters, and, finally, determining their permissible operation time resources. Another task of monitoring vibration parameters is to shut down the engine in case vibrations parameters exceed their limits.

Another important problem is shaft misalignment between engines, reduction boxes, and generators (or pumps). Dynamic reactions, resulting from exceeding the allowable alignment deviations of the torque transmission elements, are liable to cause failure of the propulsion system in a relatively short time.

The dynamic problems of GTE and GTG are related to basic elements such as rotors, bearings, struts of bearings, engine body, type of substructure, hydro- and meteorological conditions (sea environment), and gas-flow parameters inside the engine. Dissipation of energy in rotating machines displays as a torque, revolutions, temperature, gas flow, and vibration. Vibrations are related to rotor unbalance, oversize of tolerated axis slope of shafts, abrade of blade tips with the inner roller, wear of axis and radial bearings, asymmetry of spring stiffness and damping characteristics of the rotor and their parts, and irregularity of gas-flow forces [15, 16]. Emission of vibration brings a lot of information including knowledge of the technical state. Measurements of vibrations, their identification, classification, and mathematical analysis, including trend function, bring information on the actual technical state and allow predicting the wear process in the future.

Every rigid body like the rotor has six degrees of freedom; however, a deformation body has unlimited degrees of freedom. Rotating machines like GTE have total degrees of freedom equal to the sum of all degrees of freedom of the engine's parts reduced by the number of rigid nodes connecting these elements of the engine. Each rotating part of the engine can be represented by physical characteristics obtained from vibration measurements or from modeling of geometry and material—a rigidly joined structure. The application of a specified model of a rigid body gives ordinary differential equations. The deformation body needs portative differential equations. The second assumption is much more complicated, but it can be closer to the real object, especially when it works over a wide range of rotary speed, like the sand pump propulsion system. This is the reason for choice of the second model for modeling. The scheme for a diagnostics model GTE is presented in Figure 7.

Residual imbalance occurs at each and every stage of the rotor. Two vectors of imbalance at both ends of the shaft can represent the imbalance effects. The vectors have different values and phase shifts. This FE individual and average model creates responses of unbalancing that can be compared with the reports of vibration measurements. The most sensitive imbalance response point at the GTE is the front frame over a vertical strut. It is an effect of minimal thermal expansion for radial and axis vibration at this point. The previous model can be linear, so it is clear that response is directly proportional to the amount of imbalance. It should be noted, that the real GTE response is unlikely to be linear over a wide range

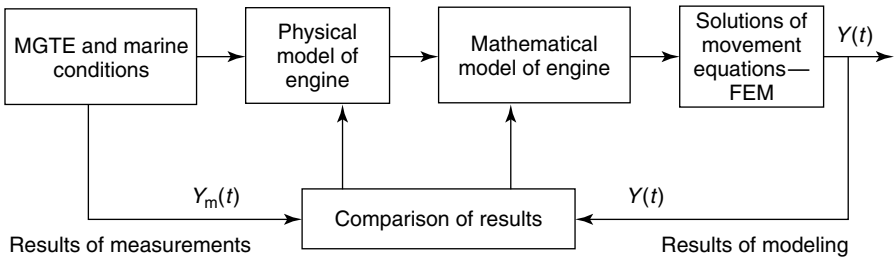

Figure 7. Scheme of diagnostics model GTE (FEM, finite element method).

(revolution of shaft). Furthermore, the result can be accepted only as a statistical approximation of the dynamic engine response.

The construction of a rotor has forces to consider. There is not only unbalancing or gas-flow forces but also vibration from cooperated machines like pumps, drills, enclosure modules, generators, and gearboxes as well. These forces form the focus during modeling and investigation of real systems. Losses of material also influence changes of moments of inertia of rotating parts. They cause the displacement of the main axis of inertia, which is not coincident to the axis of rotation. Finally, a main source of large vibration is low damping. Mathematical models are difficult because of assessments of damping and stiffness coefficients of struts and bearings. The shape of the axis deflection is defined as discrete sets:

- set of static deflections, $\mathbf{u}_s$;
- set of dynamic deflections, $\mathbf{u}_d$.

Both sets depend on the actual technical state of the rotor and the geometry, which are changed through cracks and wanes of engine parts.

$$\mathbf{u}(\omega t) = \mathbf{u}_s + \mathbf{u}_d(\omega t) \tag{1}$$

This equation is a discrete set of displacement value points of the axis of a rotor. Taking into account the damping and stiffness of a bearing's supports, it can be posited that they are functions of the temporary positions,

$$k_{ik} = f(u) \quad c_{ik} = f(u) \tag{2}$$

To simplify the problem, it can be assessed that for constant rotation these values are also constant. Using the FE method, the model presents a three-dimensional discrete model. Rotors of GTE, because of circular symmetry, have been described by one-dimensional, two hatches balk—rod symmetry FE, which have six degrees of freedom. All parts have geometrical and material characteristics. Movement parameters of a discrete model have been found by solving the following equation:

$$\mathbf{Ku} + \mathbf{C}\dot{\mathbf{u}} + \mathbf{M}\ddot{\mathbf{u}} = \mathbf{F}(t) \tag{3}$$

where $\mathbf{K}$ is the matrix of the structure's stiffness, $\mathbf{C}$ is the matrix of the structure's damping, $\mathbf{M}$ is the matrix of the structure's inertia, $\mathbf{F}$ is the vector of forces, and $\mathbf{u}, \dot{\mathbf{u}}, \ddot{\mathbf{u}}$ is the displacement and its derivatives (velocity and acceleration).

The issue can be solved as a linear problem, but in the GTE's rotor, one has to allow for changes of stiffness and damping, which are functions of the movement parameters. In this case, equation (3) can be expressed as

$$\mathbf{K}(\mathbf{u}, \dot{\mathbf{u}})\mathbf{u} + \mathbf{C}(\mathbf{u}, \dot{\mathbf{u}})\dot{\mathbf{u}} + \mathbf{M}\ddot{\mathbf{u}} = \mathbf{F}(t) \tag{4}$$

The main purpose is to find sensitive vibration symptoms representing residual imbalance of the rotors and forces from misalignment of shafts. FEA (finite element analysis) is used successfully for a wide range of problems and it may also be used for the modeling and analysis of a rotor system (Figures 8 and 9).

Currently, monitoring systems commonly use FE models and rotordynamics in conjunction with vibration analysis for detection and identification of unbalancing and misalignment of shafts. A linear model obeys the basic principle of linear superposition. Applied to a structure, this means that displacement resulting from a combination of structural loads is the sum of the displacements due to each individual load making up the combination.

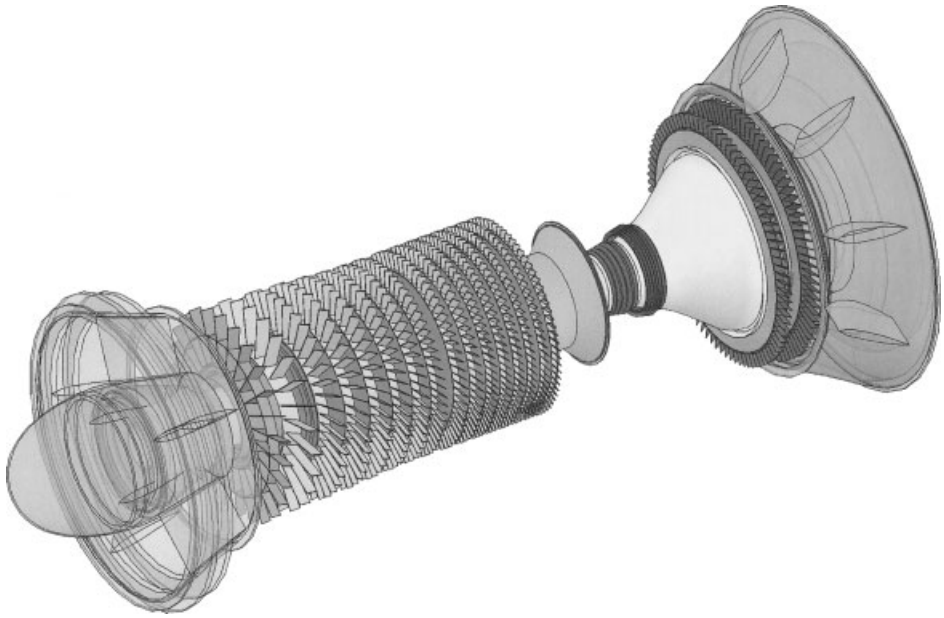

Figure 8. 3D model of a rotor system GTE.

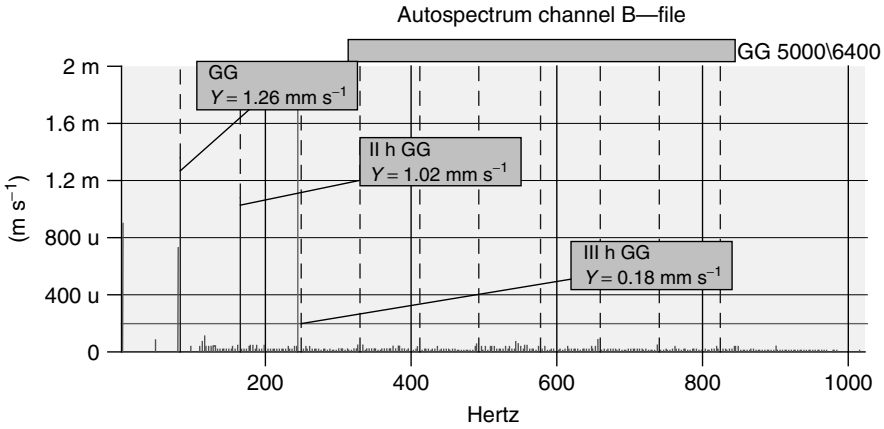

Figure 9. Example of a GTE spectrum.

Measuring transducers (generally accelerometers) are fixed to steel cantilevers located on the flange of the compressors and power turbines. The fixing accelerometers' cantilevers are characterized by a vibration natural resonance frequency value, sufficiently different from harmonic frequencies due to the rotation speed of the rotors and their harmonics. The measurements are taken perpendicular to the rotation axes of the rotors over the main bearings. Such a choice is made on the basis of theoretical consideration of excitations due to unbalanced shaft rotation [17]. As signals, usable for the "defect-symptom" relation, the following magnitudes are usually selected:

- the first harmonic rms value of vibration velocity (or displacement) amplitude related to the rotor of the compressor and the power turbine;

- the rms value of vibration velocity amplitude within the individual range of the bandwidth filter;
- the dimensionless parameters characterizing imbalance assessment of the turbine rotors:
  - S1—the ratio of the mean vibration velocity amplitude of a given rotor (first harmonic) and the velocity component relevant to the second harmonic excitation frequency of the rotor in question;
  - S2—the ratio of the mean vibration velocity amplitude of a given rotor (first harmonic) and the velocity component relevant to the third harmonic excitation frequency of the rotor in question.

Analyzing steady states of the compressor needs FFT analysis with tracking. Another problem is resonances, which require order tracking or autotracking analysis. Sometimes, changes in vibration symptoms are also subject to analysis of their trends as functions of the service time of the engines.

7 DIAGNOSING POWER PLANTS ON OFFSHORE TUGS AND TANKERS–CALL OF RELIABILITY

The propulsion systems of tugs and tankers are subjected to specific sea loads due to waving and dynamical impacts associated with the mission of a given vessel. Sea waving can be sufficiently exactly modeled by means of statistical methods. Many more problems arise from modeling impacts due to contact with floating objects, the hull of another vessel, or a rig's legs. In the operation of contemporary technical objects, including offshore vessels, greater and greater attention is paid to notions such as time of serviceability, repair time, maintenance, and diagnosing costs. Diagnosing process has now become a standard procedure performed during technical maintenance. Out of those mentioned above, the notions of time of serviceability and maintenance costs seem to be crucial for the diagnosing process of a vessel's power plant. Knowledge of a character of loading, which affects ship shaft line, engines, gear boxes, or propellers, can make it possible to identify potential failures by means of on-line vibration measuring systems [18]. This way, elimination of costly and time-consuming overhauls on dock leads to lowering operational costs and increasing vessel reliability.

Usual measurement methods of misalignment parameters of the propulsion system, like the laser method, require disassembling protection covers of shafting between engines and reduction gears. Measurement conditions make it necessary to suspend operation of the propulsion system for a few days and this is, of course, an intrusive method. A vibration method allows assessing permissible values of the alignment parameters without stopping operational use of the vessel.

Appropriate assembly of the main engines and the other torque transmission elements, inclusive of propellers, is practically determined by a set of tolerated dimension and geometrical location requirements, called the *geometrical dimension assembling chain*. Power plants are prone to coaxiality deviation from permissible values and, in consequence, to possible failure of one or more elements of the propulsion system. The excessive deviation can lead to the loads on bearings and gear teeth much higher than calculated and result in their premature failure [19]. The usual control methods of the coaxiality deviations do not always fulfill the user's expectations. Difficult access to flange connections, long control time, organizational difficulties, and lack of qualified personnel create hazards of taking measurements with errors exceeding allowable values. The vibration method, instead of the usual coaxiality control methods, is preferred on the basis of the result of an analysis of the earlier mentioned operational hazards.

The energy emitted as a result of a change of technical state of the flange connection is reflected in the recorded vibration signal—the second harmonic of the velocity. Archive charts of the investigation results of a typical offshore tug are exemplified in Figure 10. Application of the order tracking analysis in the power transmission system of offshore vessels for identification of resonances is an efficient method (Figure 11). Especially, in the case of an enclosed power pack, the autotracking method should be adapted as a preferable method.

In static calculation procedures of shaft lines, no analysis of dynamic excitations, except torsional vibrations, is taken into consideration. In certain circumstances, the adoption of static load criterion

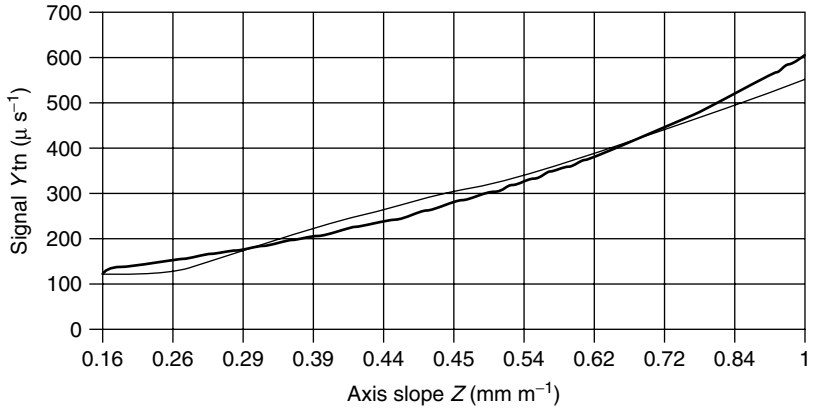

Figure 10. Regression functions of the change in vibration symptoms at different slope values.

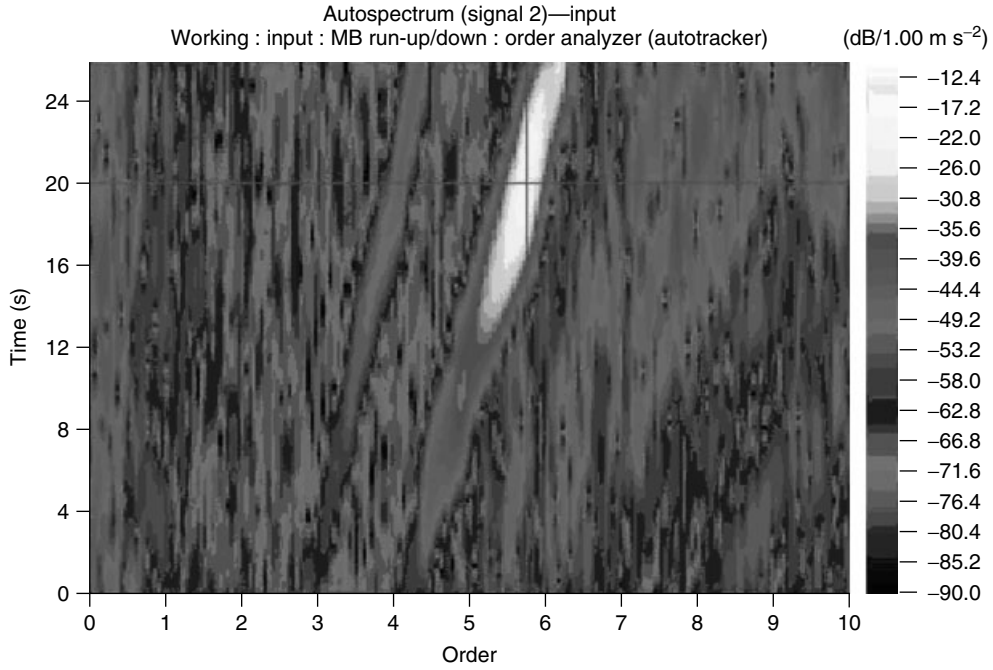

Figure 11. An example of identification of the resonance during the acceleration of shaft lines.

may be disastrous, especially in the case of resonance between natural vibration frequencies and those of external forces due to dynamic impacts. Theoretical analysis indicates that shaft bending deformation continuously accumulates as part of shaft torque. However, the quantity of torque nonuniformity is rather low since shaft-line eccentricity is low. It results from manufacturing tolerance, nonhomogeneity of material, propeller weight, and the permissible assembly clearances of bearing foundations. This condition makes it possible to predict that run-out of propeller shaft may also happen at rotational speeds other than the critical first kind calculated during the design process. For vessel propulsion systems, the torque pulsation expressed by means of the Fourier series is much more

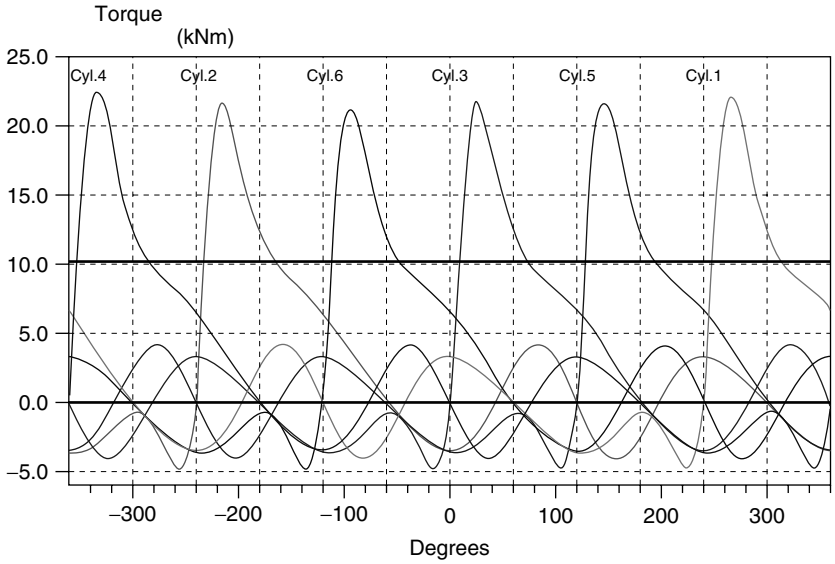

Figure 12. Time waveform of torque simulations for a six-cylinder four-stroke marine engine as a function of crankshaft rotation.

complex. It also contains components resulting from a number of propeller blades, kinematical features of reduction gear, as well as disturbances from the main engine and neighboring devices. In general, occurrence of only one harmonic case does not change reasoning logic. For a better understanding of the theoretical background, the virtual model of a propulsion system's excitation are presented in Figure 12.

Theoretical analysis of operational conditions of intermediate and propeller shafts indicates that static and dynamic loads appear. In a more detailed analysis of dynamic excitations of all kinds, the following factors should also be taken into consideration:

- disturbances coming from the ship's propellers (torsional, bending, and compressive stresses);
- disturbances from the propulsion engine (torsional and compressive stresses);
- disturbances from the reduction gear (torsional stresses);
- disturbances from other sources like a hull contact.

The wide range of stochastic dynamic loads acting on vessels during their lifetime mean that in the nearest future, the application of *on-line* diagnostic techniques to all types of offshore propulsion systems based on analyzing vibration signals will constitute an obvious economic and technical necessity.

8 CONCLUSIONS

Application of an *on-line* monitoring of vibration parameters of offshore machines and propulsion systems makes possible technical diagnostic tests of torque transmission systems, fluid and gas transportation, and identification of possible defects. In practice, vibration analyses are accomplished by two different procedures:

- *on-line* — in real time;
- *off-line* — periodic or single measurements.

Both procedures have their advantages and disadvantages. *On-line* systems give permanent control of vibration parameters in real time. They allow for monitoring vibration parameters, holding memory, and shutting down the machine in a critical state. The data preview of memory can activate the trend functions and it shows changes of frequency or time parameters of vibration as a function of operational time. The disadvantages of this system are linked with the cost of software and hardware, which are most often individually prepared.

The monitoring systems consist of few vibration and thermodynamical parameters. The main requirements are as follows:

- should be an autonomous system of modular structure, equipped with monitors for continuous measurements (*on-line* mode);
- should provide buffered signal outputs;
- should automatically store, archive, and analyze each monitored variable;
- should automatically perform basic vibration analysis like synchronous time–wave forms of vibration signals, spectrums, cepstrums, signal envelopes, orbits, shaft center line, waterfall spectrums, cascade spectrums, bode plots, polar plots, indicator plots (for reciprocating compressors), etc.;
- should register and archive measuring events and system events;
- should be equipped with an automatic self-control and self-diagnostic system for self-diagnosis of each of its own measuring loops;
- the cables should be specified by producers of machine monitoring systems;
- the cables should have minimum connections (without any additional junction boxes other than that on the skid);
- the cables should be situated away from any other power and supply cables;
- all equipment should be correctly grounded.

To summarize the difference between *on-line* and *off-line* systems, it should be noted that traditional *on-line* monitoring is either a simple safety switch system with no analysis or database functionality or a huge and multichannel stationary installation, featuring full capability described above. Such solutions can also be used for diagnostics; however, for less expensive machines it never brings an economic rationale that can be implemented. Also, monitoring systems provide a wide range of basic diagnostic tools, but are never flexible enough with regard to in-depth investigations of difficult and unique problems.

On the other hand, the typical *off-line* instrumentation is robust, handy, and portable, also featuring quite an acceptable cost of implementation. The instruments are compact analyzers and data loggers with usually one vibration channel (rarely, two) and some extra inputs for process parameters (like temperatures) and tachometers. They quite satisfactorily cover the periodic check procedures for less critical machines and can supplement big monitoring systems.

This classification naturally appears with some gray areas, which can be discovered by asking the question—then what about a multichannel, portable *off-line* and advanced analysis capability? Fortunately, recent developments bring such instruments, with multichannel capability, still portable and battery operated, featuring the recording functionality and performing standard, as well as very advanced analysis, both on site and as postprocessing. When combined with a 48-bit wide-input dynamic range, these become suitable for less-skilled operators.

1 INTRODUCTION

With increasing costs associated with fossil-based energy, there is large interest in deploying small and large wind turbines (WTs) for generating distributed power for residential and rural areas [1]. It is estimated that a small but significant part of the energy needs of the United States could be obtained through large-scale deployment of WTs [2]. WTs are deployed in rural areas where access to these structures is sometimes not feasible because of the elevated positions. Damage to the WT could cause large financial losses including loss of energy tapped during this outage; see Migliore *et al.* [1]. Structural health monitoring (SHM) of WTs is needed to ensure safety and to avoid overdesign of components. Overdesign will not allow maximum power from the wind to be captured. This article is a review of the current literature describing techniques for health monitoring of WTs. The main focus of the article is on monitoring the turbine blades, which may be the most critical component of

the turbine. Continuous health monitoring of the drive train (gearbox and bearings) and the wind turbine blade (WTB) will ensure proper performance of the WT. Bently Nevada Inc. has developed a commercially available module for continuous monitoring of the drive train [3] of WTs. Monitoring bearings and other components may be done using accelerometers. Since the frequencies of vibration and operation are low, the data-acquisition problem is simplified as a consequence of which allows a larger number of accelerometers or other sensors to be used. Similarly, continuous health monitoring of the WTB is needed. The design of the WTB is a critical factor in the performance (power production) and reliability of WT systems. The trend in blade design is toward improving the aerodynamic efficiency of the blade thus necessitating higher strength-to-weight-ratio materials such as carbon composites owing to their thinner airfoil profiles. A low-cost continuous health monitoring system could provide critical information about the location and propagation of damage in WTBs, and provide predictive maintenance information prior to a blade becoming unsafe. If a blade fails, the rotor can become unbalanced and cause the blade to impact the turbine tower, which can severely damage the turbine drive train. It is common for blades made of composites to have sudden audible acoustic emissions (AEs) during damage growth. AE is defined as the class of phenomena whereby transient elastic waves are generated by a rapid release of energy from a localized source or sources of damage; see Wells *et al.* [4]. Acoustic emission techniques (AETs) are often used to locate damage and to detect the growth of cracks during qualification testing of WTBs. Use of AE and other techniques for SHM of blades is discussed in this article.

Several researchers have attempted in the past to monitor WTBs for damage in a laboratory setting using various techniques. The simplest technique is to use strain gauges to detect high strains that could indicate damage. In general, too many strain gauges would be needed to have a high probability to detect small damage before failure could occur. Another approach is to use AE sensors. These are typically heavy barrel-type sensors that would be difficult to use in practice owing to the size and requirement that a large number of sensors and channels of high-rate analog-to-digital (A/D) data conversion would be needed to monitor the blade. Typically triangulation is used to locate damage similar to how the epicenter of an earthquake is located. Strain gauges and AE methods are passive methods wherein no artificial excitation of the structure is used, and the structure must be operating for damage to be detected. Active methods are another approach for damage detection. In active methods, a diagnostic waveform or some other form of artificial excitation is used to probe the structure for damage. Sundaresan *et al.* [5] used an actuator to pulse the WTB intermittently during quasi-static loading and store the received waveforms. The current data was compared with baseline data to identify damage. Migliore *et al.* [1], Dutton *et al.* [6], Joosse *et al.* [7], and other researchers performed testing on WTBs using AETs. AE "threshold-based" arrival systems can be used to approximately locate damage. An advantage of AE methods is that knowledge of the wave speed is not required to detect damage. Wave speed is a function of material properties and the geometry of the structure. WTBs consist of multiple anisotropic materials and have complex geometric features. An advantage of AE methods is that they can detect damage on complex anisotropic structures like the WTB shown in Figure 1. On the other hand, the following disadvantages are inherent in existing conventional AE-based systems: (i) each sensor requires an electrical circuit containing a preamplifier that increases the overall mass of the sensor; (ii) each sensor's output must be converted into a digital format using a high sampling rate A/D converter; (iii) a large amount of data is obtained, which requires rapid real-time data collection, storage, and processing; and (iv) the cost of the overall health monitoring system increases because of the above factors.

With the improvement in the field of microelectromechanical systems (MEMSs), the mass of the sensor and associated electronics can be mitigated. Recently, a structural neural system (SNS) has been developed to overcome some of the limitations of current AETs. The SNS is a signal-processing system that emulates how the human body processes signals from large numbers of highly distributed neurons and receptors (sensors). The SNS uses piezoelectric sensors bonded onto the blade. The surface-mounted sensors are easy to install, and can be repaired, retrofitted, or updated, and the sensor cannot degrade the integrity of the blade. These sensors are highly sensitive and can detect AE stress waves caused by

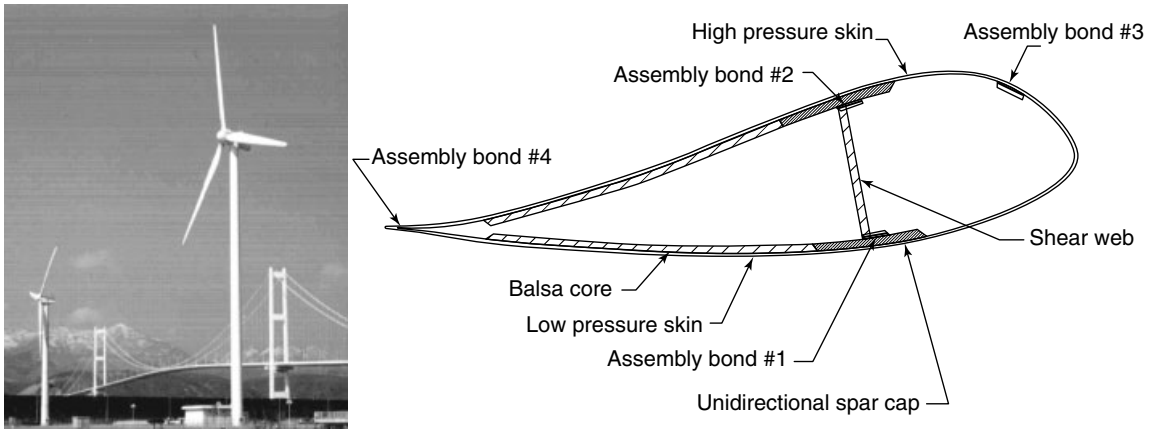

Figure 1. Wind turbines in action and cross section of a typical blade. [Reproduced from Ref. 8. © Derek Berry, 2004.].

small damage propagating in the blade, as shown by Joosse *et al.* [7]. The SNS is based on receiving AE signals and is a passive health monitoring method since no artificial means of exciting the structure is used. The frequency of the AE signal that is sensed is on the order of hundreds of kilohertz depending on the blade material and geometry. The SNS architecture was installed on a 9-m-long WTB that was tested to failure during quasi-static loading. Results of detecting and locating growing damage are summarized in this article. Information on testing of blades using conventional AE methods can be found at the US National Renewable Energy Laboratory (NREL) web site [2]. Information on testing different sensor types on WTBs for health monitoring and control is at present available through Sandia National Labs [8–11]. Nondestructive evaluation (NDE) and SHM of WTs is discussed in [9–36]. WT failures that have occurred over the past 30 years and safety concerns are briefly discussed next to help designers decide how practical SHM techniques should be developed.

1.1 Wind turbine failures and safety

To make WTs widely accepted, the public must be assured that WTs are reliable, safe, and benign [37–40]. This section provides an overview of WT failures to give designers an idea of how SHM systems might improve reliability and safety of WTs. WT failures are not well documented and data is not available for new designs. An unofficial and not comprehensive summary of WT accidents from 1975 to November 30, 2007 is given in [39]. The total number of accidents was 403. These resulted in 49 fatalities, of which about 35 involved wind industry workers. Fourteen accidents were public fatalities. The most common cause of fatalities was falls from turbines. Human injury occurred in a further 18 accidents. Blade failure is the most common failure mode on turbines. A total of 118 separate incidences of blade failure were reported in the study. Blade failure may result in whole blades or pieces of blade being thrown from the turbine. Fire is the second most common accident cause. Fire can arise from a number of sources including electrical malfunction and lightning strikes. Turbine fires cannot usually be stopped because of the turbine height, unless there is an onboard fire suppression system. Burning debris from a turbine may be scattered causing a wider-area fire risk. Structural failure is the third most common accident cause as per the data in [12]. Structural failure is assumed to be a major component failure usually owing to high wind gust exposure. Ice falling or throwing is another mode of danger. Transport accidents involve turbine sections falling from transporters including at sea. Driver distraction by turbines, thrown ice, and blade pieces landing on the road have also caused accidents. Some cases of environmental damage including bird and bat deaths have been reported. Other types of damage and accidents are owing to component malfunction, hail, and lightning strikes. Some of the possible indirect problems caused by WTs include interference with TV or

microwave reception, depreciating property values, WT noise, increased traffic, road damage, rotating shadows from the blades, aesthetics, concerns about electrical danger, and increased lightening strikes.

Failures of WT components [36] on a percent basis are electrical control 13%; gearbox 12%; yaw system 8%; entire turbine 7%; generator 5%; hydraulic 5%; grid 5%; blades 5%; brakes 3%; entire nacelle 1%; mechanical control 2%; air brake 2%; axle/bearing 1%; other components 30%; and the tower, foundation, hub and coupling <1%. Large WTs are equipped with a number of safety devices to ensure safe operation during their lifetime. Existing safety devices/approaches include vibration analysis, oil analysis, component temperature measurement, thermographics, shaft alignment, strain measurement, acoustic analysis, photo/thermo elastic analysis, electrical effects, overspeed protection, aerodynamic braking systems including tip brakes and mechanical braking systems, and visual and aural inspection. Difficulties that are to be overcome in order to install detailed SHM systems on WTs include the following: the requirement that they should last 30 years without causing false positives for failure, the cost to monitor data from the turbine, and the difficulty in servicing the SHM system. Research in SHM of WTs is being conducted in national labs [2, 11, 17, 33, 35–38], industry [3, 8, 36, 39], and universities [4, 7, 13, 21–28, 31, 34]. In particular, the Danish WT industry is a leader in commercialization. Twenty per cent of Danish domestic electricity production comes from wind. Based on the above data, SHM systems could be applied to the major areas where failures occur, such as blades and system components, to increase the safety and reliability of turbines. The SHM system would identify degraded parts in time for replacement to prevent failure, and this could prevent injuries that occur owing to failure of components or repair of failed turbines. Approaches for SHM of WTBs are discussed next.

2 METHODS FOR DAMAGE ASSESSMENT AND PROGNOSIS ON WIND TURBINES

This section discusses possible new methods of SHM of WTs [12, 13, 40]. Several different methods are needed to monitor the entire turbine because of the variety of mechanical components that are present in the turbine.

2.1 General methods for SHM of wind turbines

There are many methods of SHM being developed for a large number of applications. General characteristics of these methods are presented in order to help developers consider candidate techniques for specific WT applications. Monitoring the blades in a rotating system presents the problem of data transfer from the rotating frame to the fixed frame for all the methods discussed. A summary of the main methods is given in Table 1. It is anticipated that a medley of sensors and methods will be the best approach to monitor WTs. A fully integrated SHM system that can use different damage detection techniques and types of sensors would be the ultimate goal. Recent papers in the area of SHM (2002-up to the present) are published in *Structural Health Monitoring: An International Journal* [14]. This journal has a fairly comprehensive list of techniques for SHM. Other references on SHM are given in [9–11, 15–35] and can be found in [41–54].

Most of the SHM techniques and sensor types listed in Table 1 are discussed in other articles of this encyclopedia. However, there is not much information on application of these techniques to SHM of WTs. Several methods that have been applied to WT SHM include a scanning laser vibrometer [32], the fiber-optic method [33], vibration and other methods [34], and the impedance method [35]. The SNS, in particular, was developed for SHM of WTs and is not discussed elsewhere in the encyclopedia. Recent results are also available using the SNS to monitor damage on a WTB in a proof test. Thus, an overview of the SNS method and its testing are given in this article.

2.2 Introduction to the acoustic emission technique as an SHM tool

The AET has been used as a nondestructive testing (NDT) technique for several decades and is fairly well developed with commercially available instrumentation and standardized testing procedures [15].

Table 1. General methods for SHM

Method	Sensor/actuator type	Description of the method
Vibration	Accelerometer, piezo, or MEMS	The natural frequencies of the blade can be monitored for changes indicating damage. Small damage is difficult to detect
Strain	Foil strain gauge or fiber-optic cable	Strain can be monitored at critical points in the blade and other components. It is difficult to measure strain inside the composite and to have enough gauges to detect small damage. Fiber-optic Bragg gratings can provide a large number of low-bandwidth strain measurements. Passive method [33]
Ultrasonic wave propagation	Piezoelectric wafer	Good for monitoring uniform sections or hot spots. Need predamage reference data that may vary owing to environmental changes or sensor aging. Can detect damage when the blade is operating or not operating. Commercial systems are well along in development for several applications. Active method [12, 34]
Smart paint	Piezoelectric or fluorescent particles	Paint changes color when damaged. Visual technique that is low cost but not automated for remote applications. Passive method
Acoustic emission conventional	AE wideband barrel sensor	Can detect damage in complex structures. Fretting can cause false indications of damage and the turbine must be operating. Sensors are large and many are required. Fast multiplexing is simplifying the hardware requirements. MEMS AE sensors are reducing size and weight of the system. Passive method
Structural neural system (SNS)	Piezoelectric wafers or other sensor types	Overcomes problems of conventional AE by using piezoelectric wafer sensors and biomimetic highly distributed massively parallel signal processing. Multistate sensors (nanotube thread, pressure, temperature, etc.) can also be used. Passive method. Active SNS has also been tested and uses a simple method of neuron firing to detect damage in the passive and active systems [13]
Impedance	Piezoelectric wafer	High-frequency method that can detect local damage. Active method that uses an impedance analyzer and diagnostic signal; Inman [34]
Laser vibrometry	Scanning laser Doppler vibrometer	Difficult to measure the rotating blade which is also changing orientation, and the cost is high. Good for characterizing the blade in the lab. Active or passive
Impedance tomography	Carbon nanotube or other conductive filler	This method uses carbon nanotubes or other conductive particles to make the blade material electrically conductive. The impedance between arrays of electrodes is monitored to detect damage. The size of damage the method can detect depends on the size of the electrode patterns, and the method is passive and simple and does not require the structure to be operating.
Thermography	Infrared camera	This method uses an infrared camera to map the temperature of the structure. Damage can produce a local temperature rise owing to crack and delamination breathing. The method is expensive and difficult to use on a rotating system and it is difficult to detect interior damage
Laser ultrasound	Laser	A laser beam pulse excites the structure and also measures the response of the structure. Like the NDE ultrasound technique but noncontact. Difficult and expensive to use in the field and minor damage to the surface of a composite may occur by the laser excitation. Good for automated NDE of metals.

(*continued overleaf*)

Table 1. (*continued*)

Method	Sensor/actuator type	Description of the method
Nanosensors	Electronic particle	This future approach uses small particles embedded in the blade during the fabrication process. The sensors are transceivers that reflect an RF signal which changes owing to very local damage [13]. *See* **Nanoengineering of Sensory Materials** for further information
Nonlinear dyn., condition monitoring, etc.	Accelerometers, strain gauges, others	A wide variety of specialized methods for SHM are described in [14] by Todd, Adams, Zimmerman, Chang, Farrar, Pai, Peairs and Inman, and many others
Buckling health monitoring (BHM)	PZT patches	BHM has received little attention in the literature but is important for wind turbine blades and other structures such as radomes, civil infrastructure, and tower structures. Some work has been done by Frank Pai using the nonlinear finite element code Geometrically Exact Structural Analysis (GESA) and by Sundaresan using wave propagation

The AET relies on the dynamic release of elastic strain energy as damage grows within materials under stress. The released elastic energy propagates through the structure in the form of guided waves. AE sensors suitably located on the structure can detect these signals, as shown in Figure 2. The requirement of loading the structure and the need for the growth of damage for the AET to evaluate the structure separates this technique from other NDE or SHM techniques, which frequently do not need the damage to be propagating under load. This very same requirement also provides the AET the potential to directly quantify the damage severity possibly in terms of crack growth rate or the remaining fatigue life, and makes it suitable for health monitoring of structures in the field. However, one of the major shortcomings of the traditional AET is its susceptibility to false positives. False positives can be triggered by a large number of extraneous signals including mechanically induced noise signals such as friction of mating surfaces (fretting) and hydraulic noise, as well as radio frequency electrical noise. With the availability of new types of sensors including MEMS devices, miniaturized electronics, advanced signal-processing techniques, and pattern recognition, it is likely that false positives will be reduced significantly.

Health monitoring of WTBs is currently practiced only during laboratory tests and certification tests

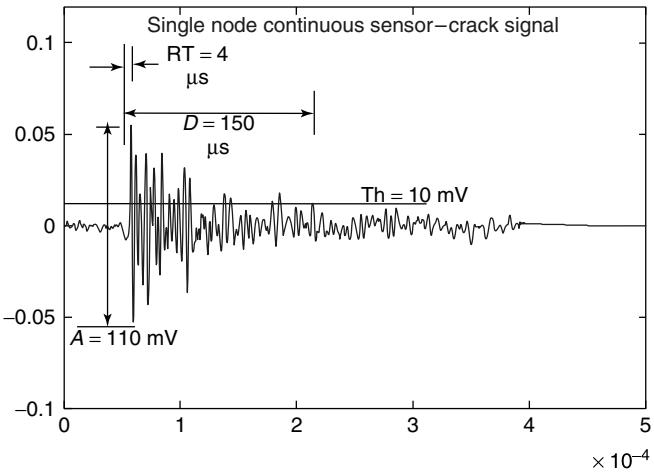

Figure 2. Conventional acoustic emission parameters extracted from a waveform.

[7, 16–18]. Such tests have been monitored using multichannel AE monitoring systems during repeated static loading to meet the certification requirements as well as during fatigue loading. Weak blades have been successfully identified by the AET during repeated ramp loading to the normal operational load of the blade, or a slightly higher level, followed by constant load hold periods and subsequent unloading. Composite materials that make up the wind turbine blades are known to be profuse sources of AE events and the difficulty of evaluating the blade lies in separating AE signals that are related to the critical damage events from the noncritical damage events. During these blade tests, it is assumed that good quality blades would emit AE signals during the load ramp-up and remain quiet during the hold period. When AE signals continue during the hold period, it is assumed to be a sign of active damage growth when none is expected and hence is an indication of a weak blade.

In addition to the AET, other techniques that have been considered for the SHM of WTBs include vibration monitoring using accelerometers and fiber-optic sensors [18]. Since the critical damage sizes in WTBs are relatively large and may introduce measurable changes in the frequency and mode shapes, accelerometers are considered a viable option. Microbend-type fiber-optic sensors are suggested for monitoring bond lines in WTBs. Remote monitoring of rotor blades in large offshore WTBs [18, 33] is considered to be both economical and technically feasible, and it is estimated that the cost of the additional expense related to the SHM instrumentation will be recouped within 3–8 years of the operation of the turbine. The large WTs (with capacities approaching 5 MW for a single turbine) that are being designed now are among the largest composite structures ever built. The initial investment and the reliability requirement of these blades are sufficiently high to justify the development and incorporation of SHM capability in these blades.

The transition of the techniques that have been used to monitor structural tests in the laboratory to actual SHM on operating turbines will require considerable effort. Embeddable sensors, instrumentation, and information transfer are needed. The design of the SHM system will have to consider the unique requirements of the current and next generation WTs including fabrication techniques (often on-site), material failure behavior [18, 34], the load spectrum, environmental conditions, and economics. Figure 3 shows a schematic of a WTB embedded with sensors and electronics that can potentially monitor AE signals, vibration characteristics, and blade deformation. Moreover, there is recent interest in using sensors on blades for control purposes. Thus, sensor systems on turbines may serve dual uses, for SHM and also for feedback control of the turbine.

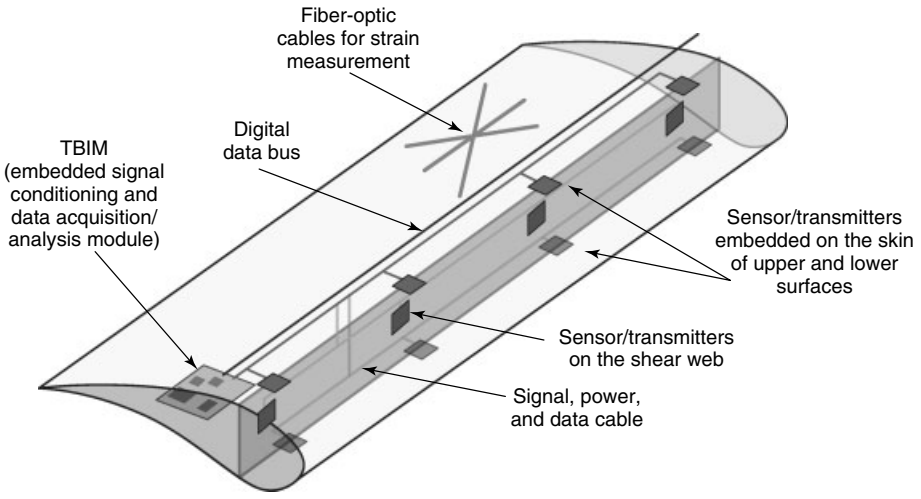

Figure 3. Schematic illustration of a blade with sensors for SHM under field conditions.

2.3 Damage assessment and prognosis using the AE method

Newer WTBs are made from several different materials and are tailored to harvest the maximum energy from the wind through bending-induced twist coupling and other means. Simultaneous achievement of good dynamic properties, light weight, and structural integrity is a challenge. Both gradual as well as sudden changes in the material properties are anticipated during the service life. Gradual reduction of properties could be owing to normal fatigue, ultraviolet (UV) radiation, hygrothermal effects, erosion, etc., while the sudden changes could be owing to lightning strike or gust loads. In addition, blade failure could result from local buckling, which is one of the most common modes of failure. An SHM technique should be able to recognize and address the interaction between these different causes of damage evolution. In addition, the sensors integrated into the blade could be utilized to assess the initial condition of the blade after the fabrication and establish the baseline responses useful for tracking the evolution of damage in the blade. A combination of sensors capable of addressing different aspects of damage evolution is likely to be successful. Embedded wireless resistance strain gauges and accelerometers will be inexpensive approaches to track the gradual degradation of elastic moduli and the blade's natural frequencies. Power harvesting from vibration of the blade is an approach to power the wireless sensors.

The AET offers a real-time SHM capability, which is particularly useful to identify sudden increases in the damage growth and hence is likely to be particularly useful in the prevention of catastrophic failure. AE-based SHM has the advantage of directly assessing the damage growth rate unlike other techniques that attempt to measure the damage size. Recently, bondable "continuous sensors" with individual nodes having wideband characteristics and sensitivities comparable to commercial resonant frequency AE sensors have been developed. This continuous sensor and the array sensor with multiple sensor nodes interconnected and with one signal output offer a means of simple and inexpensive monitoring of large WTBs with minimal hardware and signal processing.

The continuous sensors were shown to perform well in the fatigue life prediction of individual composite specimens and for their life extension. This approach of predicting the fatigue life of individual components has been tested on four different groups of specimens with different combinations of geometry, material properties, and loading conditions. Figure 4 shows a schematic representation of the service life of a structural component experiencing a spectrum loading, gradual aging, and encountering adverse events such as impact or lightning strike. While it is not possible to prevent damage to the blade owing to such unexpected events, it is possible to assess the combined effect of these factors and prevent further steep degradation in structural integrity by limiting the operational envelope of the turbine.

Figure 5 shows a portion of the life of the turbine simulated using laboratory specimens. A group of 30 woven fabric composite tensile specimens were subjected to varying levels of impact damage followed by simulated spectrum loading with load spikes. For these specimens, AE signals were collected only during the load increment. The specimens were subjected to fatigue load with peak stress

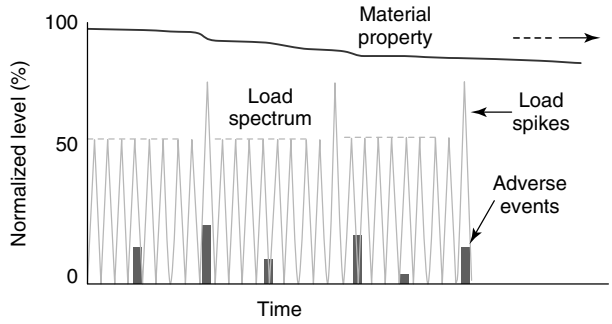

Figure 4. Schematic representation of load, adverse events, and aging of wind turbine blades.

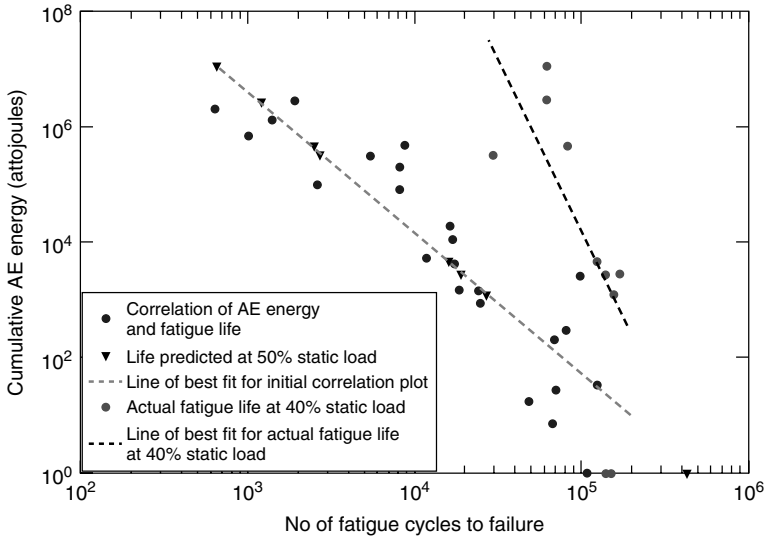

Figure 5. Correlation between AE prediction and actual fatigue life of woven fabric composite specimens subjected to impact load. The left dashed line represent the 50% static load case, the right dashed line represents the 40% static load case.

at 50% of the average static strength of these specimens. As indicated by the circles near the left dashed line in Figure 5, the cumulative AE energy during the incremental load correlated well with the subsequent fatigue durability of these specimens. A subset of this group was selected to verify if this prognosis could be used to identify and separate specimens that are bound to fail prematurely so that they could be used in less demanding services. The predicted lives of these specimens, at the load amplitude employed for the rest of the group, are shown as black triangles in Figure 5. To simulate a less demanding service life, the fatigue load was reduced from 50 to 40% of the average static strength. The distribution of fatigue lives at this reduced load amplitude is shown as circles near the right dashed line in Figure 5. The reasonable correlation between AE data and extended fatigue life for these specimens appears to support both the validity of AE-based prognosis and the opportunity for optimal utilization of available WTBs.

2.4 The structural neural system

Composite structures deteriorate gradually owing to operational effects and aging, and owing to unpredictable events such as impact and lightning strikes, and contamination from the environment. It is important to monitor the condition of large systems to prevent catastrophic failure owing to the combination of all the deterioration effects. Because multiple physical states exist in systems, the use of different types of sensors simultaneously may be a more accurate way to identify degradation, contamination, and damage before it reaches a critical size or level. From a practical standpoint, conventional methods of sensing and signal processing are often too expensive, heavy, and complex for comprehensive *in situ* monitoring of large systems, such as WTs, where degradation or chemical contamination (e.g., owing to rain erosion, acid rain, water ingestion, UV degradation, and volcanic ash in the air) can occur anywhere in the system.

Approaches for structural damage detection that use a large number of individually wired sensors, or storing large sets of predamage data, or using amplifiers to generate diagnostic waves, or performing complex signal processing may not be feasible for WTs. Future sensor architectures ideally would produce information based on ambient conditions, rather than using complex analytical models and predamage data to diagnose degradation and damage. To develop an efficient health monitoring system, we can gain inspiration from the human neural

system [19, 20]. The human body is composed of complex anisotropic heterogeneous materials. To monitor its health, millions of receptors and excitatory and inhibitory neurons are distributed throughout the body, which simultaneously process signals in an efficient hierarchical way. This section describes how the functional capability of the human neural system can be mimicked using electronic components. Continuous sensors attached to a signal processor form a neuron, which is analogous to the biological cell body or soma. The processor performs thresholding, firing, and inhibition to measure waves or strains that are caused by growing or breathing damage in a structure, or the change in impedance of a chemical sensor, or by measuring other physical states of the system. The receptor neurons can be designed to sense many types of physical response thus opening the door for many important applications on WTs and other structures.

2.4.1 Description of the SNS

The SNS is a biomimetic signal-processing system, which uses a multiple state continuous sensor network for health monitoring of large composite and metallic structures and other large systems. Passive sensing based on AE monitoring is used to detect damage such as fiber breaking and delamination in composites. Parallel signal processing inspired by the biological neural system is used to combine continuous sensors in a grid pattern into four channels of data acquisition to locate damage and capture the sensor signal. The SNS is a generic biomimetic signal-processing architecture designed to simplify health monitoring of large structures. In Figure 6(a), each vertical line indicates a column neuron and the horizontal line represents a row neuron. The neurons are not connected to each other. Figure 6(b) shows the general architecture of the SNS. The neurons are a continuous sensor connected to an analog processor at the end [21–28]. A continuous sensor also called a neuron is a series connection of many individual sensors with only one output signal per neuron. The output of the neurons is represented by V1 through V20 in Figure 6. V1–V10 are column neurons and V11–V20 are row neurons. Thus, a large sensor grid is formed wherein a reduction in the required number of channels of data acquisition is achieved by processing the outputs of only the neurons that produce anomalous signals, and keeping a track of which neurons are firing using the structural neural system analog processor (SNSAP). The output of the first 10 channels (column neurons V1–V10) is the input to the SNSAP 1, which reduces the required

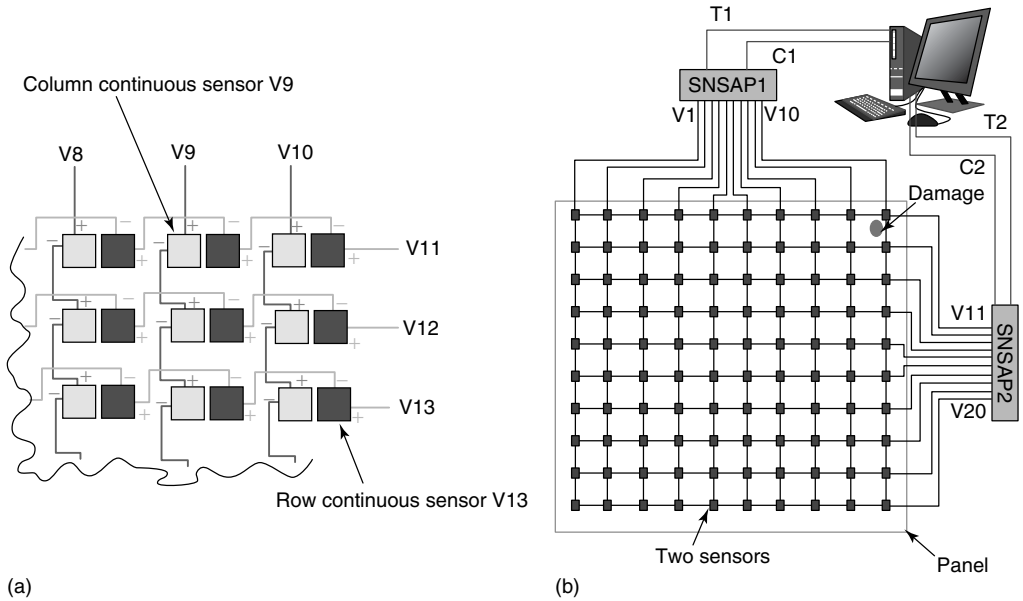

Figure 6. The SNS for WTBs: (a) detail of sensor connections and (b) sensor array.

number of data-acquisition channels to only two using firing of the neurons. One of the channels (C1) predicts the location of damage based on firing of the neurons. An algorithm is used to decode the firing signals and tell which neurons are firing. The other channel (T1) is the actual time response of the neuron and is used to qualitatively predict the severity of the damage. The same procedure follows for the row neurons (V11–V20) using the SNSAP 2 processor and the outputs C2 and T2. Thus, with an arbitrary number of sensor nodes, only four channels of data acquisition are required to predict the location and estimate the severity of the damage within a grid of sensors. Since each neuron can have 10 (or more) piezoelectric sensor nodes, and there are 20 neurons in this example, signals from 200 sensors are monitored using four channels of data acquisition.

The configuration of the electronic processor used to mimic the biological neural system is described in [21–26]. A brief explanation of how the neurons fire is as follows. When a neuron receives an AE signal, the signal is evaluated by the analog processor. If the signal meets set frequency and amplitude characteristics related to damage, the neuron "fires" a unique location signal and also passes the acoustic signal with those of any other neurons that are firing. A combined AE response analog signal and a second analog signal containing information on the locations of damages are sent to a central PC that performs A/D conversion and locates the damage and approximates the magnitude of the damage. Because of the high coverage of continuous sensors (neurons) on the structure, a neuron can be close to any damage site. This will allow the damage signal to be detected before it is attenuated and distorted and this makes signal processing and filtering easier when compared to using conventional AE sensor systems.

An important application of SHM is detecting crack initiation in areas of high feature density such as at joints. It is difficult to place strain gauges or to propagate waves to detect small damage in joints. The SNS is a simple onboard real-time NDE approach that listens for AE signals from damage in joints. There is no other sensor system that enables the simultaneous monitoring of tens or more long continuous sensors using as few as four channels of data acquisition. In comparison to other techniques, the SNS does not need an amplifier, diagnostic waves, or individual wires for large numbers of discrete sensors/actuators, and there is no need for storage of predamage data. The SNS provides *in situ* simultaneous sensing and intelligence at the sensor level that reduces hundreds of signals into easily interpretable damage information. The SNS is applicable for onboard real-time monitoring of any type of large sensor system in which anomalous events must be detected. The SNS is accurate, simple, miniaturized, lightweight, interior or exterior surface mounted, repairable, redundant, passive, requires low power, and is safe. This meets the objectives of reliable, accurate, and cost-effective operation. The SNS characterizes the severity of the damage right from damage initiation and tells if the damage is serious while the structure is operating.

2.4.2 Damage location algorithm

The neurons that are firing are used to locate damage. A combinatorial algorithm in MATLAB is used to decode which neurons are firing at any time. Because of the limited voltage range of the electronics and the limited number of unique combinations of voltages that can be decoded, this approach of identifying which neurons are firing is limited to about 10 neurons. Thus, a digital approach to locate the firing neurons is suggested for future work to allow up to hundreds of neurons to operate on a digital data bus. Four digital data buses and one power supply wire from a computer are expected to be able to transmit signals from hundreds of neurons in the SNS. This approach can make NDE using the AET practical and can allow monitoring of tens of row and column neurons and hundreds of miniature sensors on a large structure.

2.4.3 Developing the SNS

Initially a two-neuron first prototype of the SNS was designed and built. Results of testing the passive SNS two-neuron prototype are given in [24]. Subsequently, an SNSAP was designed with much faster electronic components and also with better electronic shielding. Also, to prove that the system is practical on a larger scale, the two-neuron prototype was extended to a four-neuron prototype. Results of testing the four-neuron prototype on a thin composite plate in a laboratory-controlled environment were reported by Kirikera *et al.* [25]. Kirikera *et al.* [26] implemented the SNS on a WTB for identifying

the location of propagating cracks during the quasi-static testing. Also, to understand the propagation of Lamb waves on a thin plate, a wave simulation algorithm was developed [25, 27]. The wave simulation algorithm was derived using the modal superposition method and is based on classical thin plate theory. The wave simulation algorithm was extended to excite a composite structure using an actuator at a specific frequency. Long continuous piezoelectric sensors were recently modeled in the wave simulation algorithm to study the ability of continuous sensors, which detect acoustic wave propagation [28]. Testing of the SNS is described in the next section.

3 MONITORING A WIND TURBINE BLADE DURING PROOF TESTING

The SNS was used to identify damage initiation and propagation on a 9-m-long WTB during a quasi-static proof test to failure at the NREL test facility in Golden, CO. The spar caps of the blade were constructed using a constant thickness variable width quasi-unidirectional unitary 3WEAVE carbon/Glass hybrid material [55, 56] developed by 3TEX Inc. The shear web is constructed from fiberglass and balsa wood. Balsa wood is also used in the leading and trailing edge and serves as a panel stiffener. A brief summary of identifying damage on the WTB is discussed in this section. For a detailed explanation the reader is referred to the article by Kirikera *et al.* [22, 26].

WTBs are composite structures with complex geometry and sections that are built of different materials. The 3D structure, large size, anisotropic material properties, and the potential for damage to occur anywhere on the blade make damage identification a significant challenge. During this test, 12 piezoelectric sensors were bonded onto the surface of the WTB and were connected to form four continuous sensors, which were used in the SNS to identify damage. Although 12 sensors monitored the WTB, the SNS produced only two output signals; the first signal identified and located damage and the second comprised combined AE waveforms. Figure 7(a) shows the top view of the outline of the blade with the locations of three load saddles. The load saddles are used for quasi-static testing. Figure 7(b) is an enlarged view of the sensor area

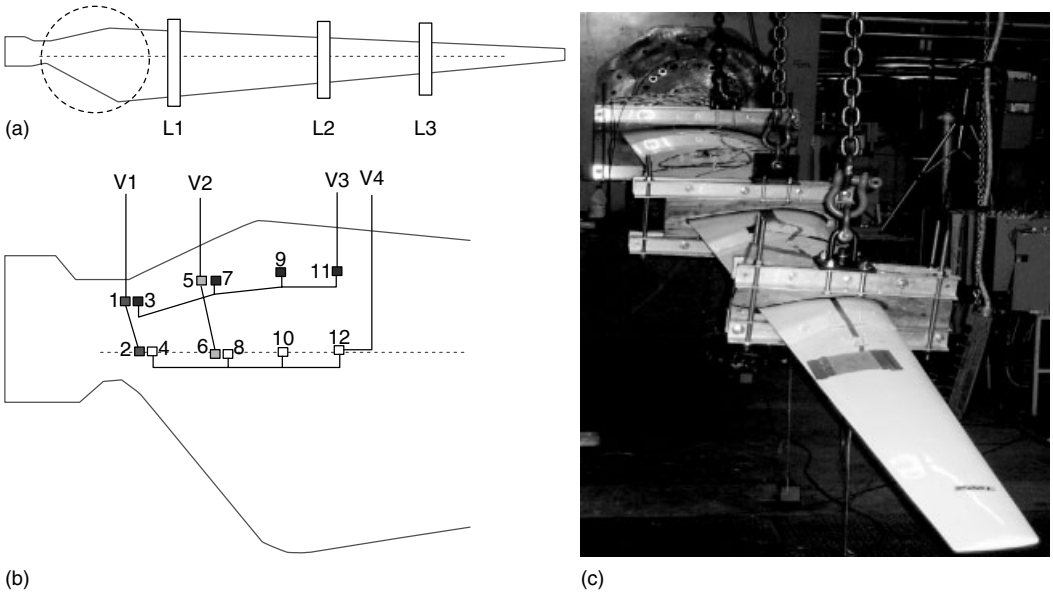

Figure 7. Experimental setup for the blade and SNS sensors: (a) geometry of the blade; (b) sensor locations on the blade; and (c) test setup with three load saddle. (Figure 7c is courtesy of 3TEX Inc. and the National Renewable Energy Laboratory).

on the blade, which is represented by a circle in Figure 7(a). The circled portion has surface-bonded continuous sensors (V1–V4). Twelve piezoelectric wafer sensors are connected in series to form four continuous sensors. Signals from these four continuous sensors are sent as analog inputs to the SNSAP. These signals are further reduced to two channels (T1 and C1). A load profile was applied to the blade using the saddles as shown in Figure 7(c). It is noted that this blade failed at a load above the design load.

Figure 8(a) shows the load profile applied to the WTB and also the response of SNSAP (the T1 and C1 channels in Figure 6). Each continuous sensor was assigned a unique voltage by the response of the C1 channel of SNSAP. A software was used to convert the unique voltages into corresponding neuron numbers, as shown on the ordinate of Figure 8(b). Figure 8(b) indicates the times at which each neuron received the AE signal.

Based on the neuron that receives the AE, multiple damage zones were manually mapped out as seen in Figure 9(a). At the end of the test, multiple damage zones were identified by the SNS (Figure 9a). After the predictions of the damage zones were made based on the SNS results, the blade was cut into sections by the NREL engineers to determine the actual locations of damage. The predicted damage zones were compared with three observed damage locations (Figure 9b) based on cutting the blade into sections. Zones 1A and 1B correspond to damage 1, zones 5, 1A, 1B, and 2 correspond to damage 3, and zones 3A and 3B correspond to damage 2. Zone 4 as predicted by the SNS was not identified in the visual analysis. On subsequent discussions with NREL engineers, it was concluded that damage indeed existed at zone 4 and was missed during visual postfailure observations.

Figure 10 shows the number of AE hits received from each zone. The number of zones is shown in Figure 9(a). On the basis of the number of AE hits, it is concluded that zone 1A has a large portion of the damage compared to zone 1B. Both zones 1A and 1B correspond to the same damage (damage 1 in Figure 9b). Similarly zone 3B has a larger damage than zone 3A as concluded from the visual postfailure analysis of Figure 9(b).

Damages 1 and 2 were visible on the surface of the WTB, damage 3 was not visible on the surface of the WTB. The blade was cut open to understand the cause of failure. The primary mode of failure was panel buckling [29]. The buckling could have started by either the leading edge of the WTB buckling inward or the trailing edge buckling outward leading to a rotation of the spar cap about its axis effectively peeling the spar cap off from the shear web section of the WTB. The rotation of the spar cap was likely a secondary mode of failure [29]. The out-of-plane movement of the panel led to catastrophic damage on the surface of the WTB, Figure 11. The separation of the spar cap from the shear web caused a bond line failure running from 700 to 1650 mm on the WTB, and is shown in Figure 12. Also, a dye penetrant was used to detect brittle gel coat cracks present on the surface of the WTB. The dye pattern did not correlate with the damage locations. The spar cap remained intact indicating that it had performed its

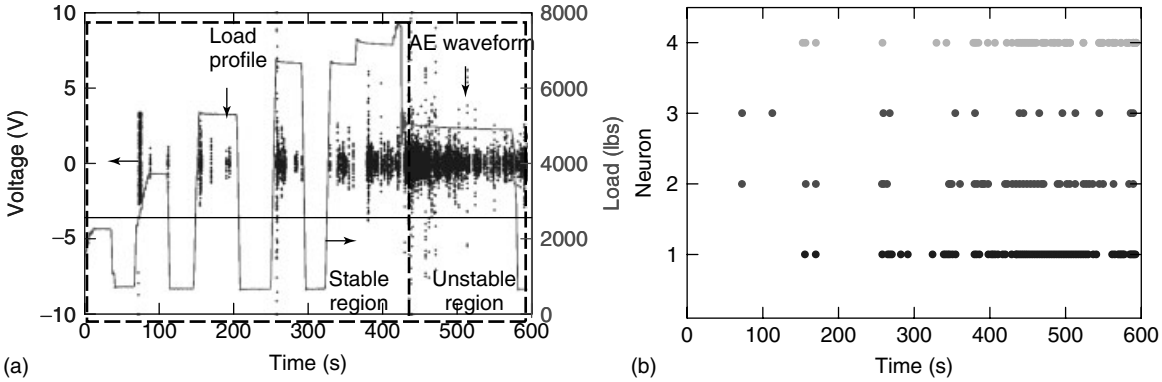

Figure 8. Test data from the SNSAP: (a) T1 channel of the SNSAP superimposed on the load profile and (b) response of the C1 channel of SNSAP used to locate the damages.

function of being the primary load carrying member, without sustaining catastrophic damage. Also, strain gauges were used on the WTB. The strain data did not indicate the damage progression, but detected the damage just at the onset of buckling failure. Strain gauge locations were not sufficiently close to the failure region to adequately capture the damage.

The SNS indicated the general area where the damage started and how the damage progressed, which is valuable information for verifying and improving the blade design and for verifying the manufacturing procedure. In the future, a grid pattern of sensors (neurons) could be attached inside the blade along the shear web to detect damage inside the blade with greater sensitivity. A major outcome of this testing was to provide confidence that SHM of large anisotropic composite structures that have complex geometry and multiple materials is practical using a simple, low-cost SNS. This test also showed that the SNS can detect cracking that precedes buckling and may be useful for buckling health monitoring (BHM) of large structures.

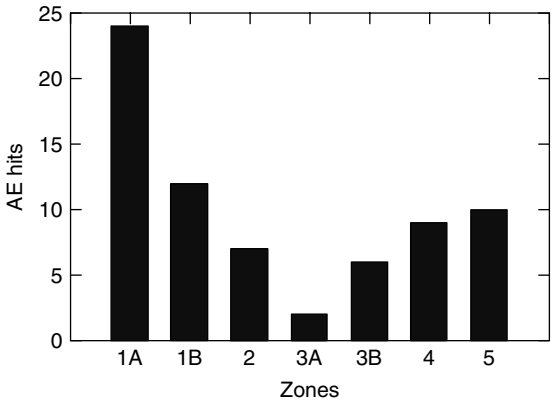

Figure 10. The number of AE hits produced from each zone.

4 BUCKLING HEALTH MONITORING TECHNIQUES

WTBs are hollow tubes designed to have bending twisting coupling and are prone to local buckling. Uncontrolled local buckling can lead to catastrophic failure of individual blades and subsequently the whole turbine. Since buckling initiates as an elastic deformation, the subsequent damage to the structure could be entirely prevented if this tendency is identified in real time and countermeasures are taken. Two different approaches have been examined for identifying the local buckling in WTBs.

The first approach is to propagate low-frequency Lamb waves across the region that has the tendency to undergo local buckling, regions A and B in Figure 13(a), as was used during static testing of a WTB [5]. During this test, a 5-kHz Lamb wave signal was able to indicate the initiation of buckling deformation at 40% length of the blade from the root

end. The blade failure at about 4500 lbs (2040.82 kg) load, Figure 13(b), was premature and was caused by this buckling. The initiation of buckling is indicated by the reduction in amplitude of the received Lamb wave signals around 4000 lbs (1814.34 kg) as shown in Figure 13(c).

The second approach is the monitoring of the natural frequency of the region that has a potential for buckling. This condition was simulated in a 4-in.-wide, 49-in.-long, and 0.125-in.-thick glass fiber epoxy composite strip. Finite element analysis of the vibration characteristics of this bar at various stages of buckling indicated that easily recognizable changes in frequency and mode shapes result even in the early stages of buckling. Experimental measurement of the frequency and mode shapes confirmed the feasibility of this approach. In this experiment, the bar was excited at the third natural frequency corresponding to the unbuckled configuration using a five-cycle windowed sine wave. The oscillation in the unbuckled bar lasted longer than 1 s. The duration of oscillation dropped significantly even in the early stages of buckling when the deformation was less than 0.25 in., providing a clear indication of the instability. Figure 14(a) shows the experimental configuration and Figure 14(b) shows the different time responses of the beam for different stages of prebuckling.

5 MULTISTATE CONTINUOUS SENSORS

This section describes recent advances in continuous sensor technology that allows different types of distributed sensors to be utilized inexpensively, reliably, and with low weight for monitoring complex structures such as WTs. The continuous sensor architecture is for use in an SNS described above. SNS is an electronic sensor network developed using highly

distributed interconnected continuous sensors coupled to a parallel signal-processing system to enable *in situ* real-time monitoring of WTBs. The generic SNS can use almost any type of passive sensor. Examples include piezoelectric ceramic wafers to monitor AEs due to crack propagation, and carbon nanotube (CNT) neurons (threads or film) to monitor strains, detect large cracks, and to detect electrolytes related to early stage corrosion and hygrothermal degradation. In structural applications, an SNS can detect damage such as composite fiber breaking and tell when impact damage is propagating. SNS is low cost and simple because no predamage data, actuation, or multiplexing is needed. Also, it is relatively insensitive to drift in properties of the sensors owing to environmental effects because reference data is not used. From an operational viewpoint, SNS is more than a monitoring system—it is an artificial central nervous system that monitors the condition of the structure without interruption and identifies when anomalous events and early degradation occur. It also defines the operational performance envelope and provides confidence in terms of safety and reliability of the system. In structures, degradation often occurs at complex built-up or joined sections where the load and acoustical paths are complex. SNS is excellent for use in these areas of high feature density where other monitoring techniques are impractical to use. Multistate continuous sensors extend the usefulness of SNS.

This section describes ongoing development of a suite of multistate continuous sensors, including MEMSs continuous accelerometers, CNT crack and corrosion sensors, pressure, temperature, and other types of sensors for use in an SNS. It reduces signals from many sensors to a small amount of essential information that can be equated to degradation of the system. Different types of sensors can be used with an SNS, but the design of the continuous sensor might differ for these different types of sensors. Moreover, the SNSAP parameters change depending on the type of continuous sensor. Details of filtering and thresholding also will, in general, be different for every sensor type. We are presently developing a suite of multistate continuous sensors for use in an SNS. The goal is to achieve integration of multiple sensor types into a single signal-processing architecture.

Dual use application of the SHM techniques for WT monitoring and other applications should be considered to reduce development cost and to take maximum advantage of technology. Besides mechanical applications such as monitoring WTBs, sensor networks are becoming increasingly important to safeguard the environment and homeland, and for medical applications. SNS has potential application in many types of sensor systems to simplify the hardware by reducing the number of wires and A/D convert boards. SNS is designed to sense anomalous values of a particular state variable over a large area using a continuous sensor. Figure 15 shows some of the individual sensors and sensor materials that can be used to form continuous sensors. The design of different multistate sensors for an SNS is discussed in the following text. It is also important to model the transfer function of the continuous sensor and SNS for new types of sensors. In particular, individual sensor nodes must be integrated properly to form continuous sensors—they cannot be arbitrarily connected. The rows overlap the column neurons and are electrically insulated. The size of the cells in the grid can be small to detect small damage. A description of the different sensor types is as follows.

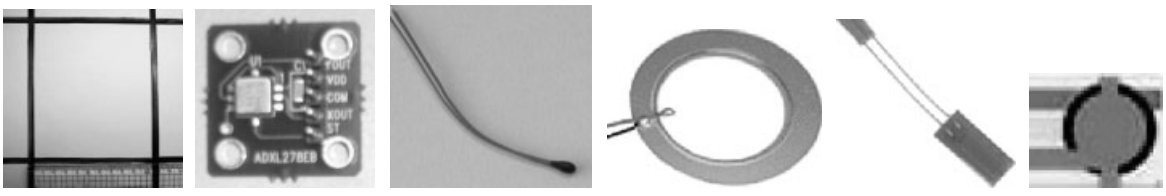

Figure 15. Sensor elements that can be used to form continuous sensors: (a) nanotube impedance film sensors to detect corrosion, cracking, and delamination for an SNS; (b) MEMS accelerometer on a circuit board; (c) thermistor that can from a continuous temperature sensor; (d) PZT commercial wafers with brass backing used to detect acoustic emissions; (e) strain gauge sensor; and (f) pressure mapping sensor.

1. Carbon nanotube continuous sensor

This sensor is to detect cracks, delamination, and corrosion damage based on electrical impedance. A prototype CNT-based sensor has been built and cracking and electrolyte representing corrosion have been detected based on the impedance of the sensor. CNT film sensors, highly distributed on the surface or embedded within a composite, are used to form a continuous sensor for crack and corrosion monitoring. An example of nanotube neurons on a simple panel is explained. A highly distributed network of nanotube continuous sensors, which sense along their entire length and have a biomimetic architecture, allows coverage of large structures. An example of the change in resistance as a crack passes through a single neuron is shown in Figure 16(a). There is a small change in resistance as the crack begins propagating through the neuron. The change becomes larger and approaches infinity as the crack passes through the neuron. An example of the change in capacitance as electrolyte is put on a single neuron is shown in Figure 16(b). Up to a factor of 50 increase in capacitance occurs because of the double layer supercapacitance property of nanotubes. The change in resistance owing to the electrolyte is only 6% as shown in Figure 16(b). Therefore, crack and corrosion sensing are mostly decoupled and can be measured using the same neuron. Signal processing using the nanotube neurons is greatly simplified because the electrical properties of the neurons, rather than structural waves, are used to characterize damage.

A prognostic method for damage modeling can be developed based on the changes in electrical parameters of the CNT neurons. The modeling of the neuron is based on the Randal Warburg circuit. The CNT is a strain sensor (piezoresistive effect) and a highly sensitive corrosion sensor (electrochemical impedance spectroscopy (EIS) effect). A model should be developed to predict the crack length based on the EIS spectra of the nanotube composite. An electrode configuration can also be used on a nanocomposite plate where the nanotubes are dispersed in the polymer matrix. Low-cost carbon nanofibers can replace high-cost CNT for large applications of an SNS.

An important application of the CNT neuron in WTB is health management of polymer matrix composites (PMCs). The CNT neuron can be developed for service life monitoring of PMCs used WTB structural applications. Two of the primary life-limiting mechanisms in polymer composites are hygrothermal degradation and oxidative degradation. Hygrothermal and oxidative degradation can lead to chemical changes in the resin system causing cracking and embrittlement in the surface layers of the composites. Within the oxidized layer of the composite, the tensile strength, strain to failure, flexural strength, density, and toughness decrease while the modulus increases. Surface cracks provide pathways for the transport of moisture and oxidants to the fiber/matrix interfaces that act as high-diffusion paths thereby increasing the degradation rate. The CNT neuron is a passive continuous sensor that

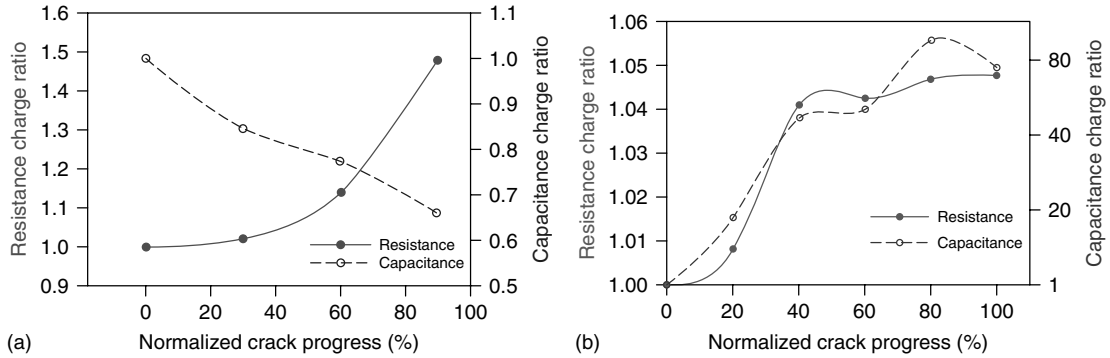

Figure 16. Change in capacitance and resistance of a carbon nanofiber neuron owing to simulated damage: (a) crack propagation damage, the resistance changed from 9.3 kΩ to infinity, the capacitance changed from 44 pF to zero; (b) electrolyte corrosion damage, the resistance changed from 117 to 123 kΩ, which is a 5% increase, the capacitance changed from 19.1 to 1109 pF, a 60 times increase.

can monitor the electrical impedance of composite materials to indicate degradation of PMCs used in WT structures. Future work should investigate the scientific, technical, and commercial feasibility of the CNT neuron for PMC health management including monitoring oxidative degradation for a neat resin aged in low temperature and oxidizing environments.

2. MEMS capacitive accelerometer
Accelerometer evaluation boards from Analog Devices Inc. were used to build a four-element continuous sensor. The accelerometers are two axis each and measure in-plane acceleration. The four accelerometers were used to form a continuous accelerometer with four inputs and one output in the x axis and a second continuous accelerometer with four inputs and one output in the y axis. These accelerometers work based on the capacitance of a MEMS cantilever. The accelerometers required a modified circuit to form the continuous sensor to sum and amplify signals and to prevent low-frequency signal feed-through. Initial testing was successful, opening up the use of MEMS continuous accelerometers for vibration measurement, impact detection, and condition monitoring of bearings, unbalance, and damage.

3. Thermistor continuous temperature sensor
This sensor is to monitor operating temperatures based on resistance of the sensor. Certain types of damage may cause an increase in temperature. The continuous temperature sensor may indicate hot spots in a structure.

4. Piezoelectric Lead Zirconium Titanate (PZT) wafers
These are being tested with a brass backing to sense AEs owing to cracks and delamination in metallic and composite structures. Prototypes were tested in the lab with good results. This sensor is more rugged than PZT wafers without a backing. Studies using the transfer function voltage output of the sensor divided by strain input (V_0/S) show that a large number of piezoelectric sensors will not reduce the quality of the data obtained for AE detection. Transfer functions must be determined for other sensor types in the project.

5. Continuous strain gauge
This sensor can be formed using miniature strain gauges in series or parallel. Equivalent electric circuits can be used to develop a transfer function. The strain gauge continuous sensor will be tested in the project to monitor large strain simultaneously at multiple gauges.

6. Continuous pressure sensor
This sensor can be built using a piezoresistive or capacitive film sensor typically with applications in biomechanics. The piezoresistive and capacitive pressure sensors are easy to incorporate as a continuous sensor. This sensor has many types of commercial applications.

Other sensor types include an inclinometer, humidity sensors, proximity sensor, magnetic sensor, flow sensor, and liquid level sensors. Another class of sensors is nanowire sensors. A nickel nanowire neuron continuous sensor is expected to be useful to detect cracks, delamination, and corrosion damage using electrical impedance or eddy current. The Ni nanowires are being produced at University of Cincinnati. Use of multiple sensor types and fusing data is possible using SNS and is an area of future work.

5.1 Manufacturing an SNS

Features of an SNS include the following: (i) it is a passive system; (ii) detects anomalous events; (iii) continuous sensors combine 10 or more sensor nodes into a one wire sensor; (iv) highly distributed continuous sensors called *neurons* can detect small damage on large structures with complex geometry and high feature density; (v) bioinspired parallel signal processing reduces the number of channels of data acquisition from tens or hundreds to four; (vi) sensor modules can be developed for different types of sensors (piezoelectric, piezoresistive, thermistor, strain, magnetic, etc.); (vii) multistate sensing is possible in one system architecture; (viii) sensing AEs to detect cracking is possible using high-bandwidth data-acquisition boards (up to 1 MHz); (ix) sensing vibration using accelerometers is possible using moderate-bandwidth data-acquisition boards (up to 50 kHz); and (x) sensing strain, pressure, temperature is possible using low-bandwidth data-acquisition boards (up to 1 kHz). Overall, SNS is

simple, low cost, redundant, and reliable. Other types of SHM systems may also have many of the attributes mentioned above. It is suggested that some type of SHM test bed be developed for WTBs to practically evaluate the different techniques for SHM.

A plan for manufacturing SNS should be developed such that the SNS is available for prototype testing on operating WTs. To a first-order approximation, the cost of an SNS can be quite reasonable (∼$20 000, including the analog electronics, computer, A/D boards, and sensors), and the system can be small and lightweight. Dual use commercialization of SNS should be possible. In military, the technology can be applied to aircraft for structural and engine applications, and for exhaust wash structures to monitor high-temperature PMCs. For commercial applications, the technology can be applied to civilian and military aircraft and nonaerospace applications such as bridges, buildings, rocket casings, and any structure with complex geometry that must be monitored for degradation in real time.

6 WIRELESS MEMS ACCELEROMETERS FOR SHM IN ROTATING SYSTEMS

Existing accelerometers and the data-acquisition systems used for structural analysis and monitoring studies are often cumbersome to use. Therefore, a wireless system using small MEMS accelerometers is being developed. The first stage of this development has been performed successfully at the University of Cincinnati. The accelerometer system was built by integrating commercial MEMS accelerometers (ADXL 278, Analog Devices Inc.) with wireless sensor technology from MicroStrain Inc. The wireless measurement system can be installed on a rotating WTB without being tethered to any external devices or computers. The current prototype system has eight MEMS accelerometers wired to an A/D converter and wireless transmitter (MicroStrain Inc.). The cost is about $3000. This battery-powered system (Figure 17) is in initial testing and continuously streams acceleration data wirelessly to a laptop computer with a bay station. This wireless system cannot store much data locally, but seems suitable for WT use. Battery life is a limitation and power harvesting from blade vibration may be used to charge the batteries. SNS could be adapted to the wireless system.

6.1 Damage detection and fatigue testing of complex joints

Detecting and locating cracks in WT structural components that have high feature densities is a very challenging problem and is not discussed much in the literature. In general, few SHM techniques have been applied to the monitoring of joints and complex structural geometries. However, reliable low-cost assessment of joints is crucial to maintain operational availability and productivity, reduce maintenance cost, and prevent catastrophic failure of WTs. SNS and other SHM systems should be deployed on components or sections of composite structures and tested together to understand the capabilities of the different approaches for SHM. SNS

Figure 17. Wireless data-acquisition system with eight MEMS accelerometers: (a) MEMS accelerometer/board, battery-powered wireless module, laptop computer with bay station and (b) one channel response due to a shock input. This system was assembled at the University of Cincinnati using commercial components. Continuous accelerometers can be used to allow 32 or more individual MEMS accelerometers to be used with this system.

could become a standard signal-processing architecture for general SHM systems, where reducing the number of data-acquisition channels and hardware is of critical importance.

6.2 Resources for SHM

An increasing number of publishers, companies, and research organizations are developing and providing information, sensors, and measurement systems that may be used for SHM including for WTs. A partial list of resources for SHM components and systems is given in [41–54].

7 SUMMARY AND CONCLUSIONS

Different techniques for monitoring wind turbines and particularly WTBs are discussed. Overall, we can say that monitoring degradation in WT structures is a complex problem that might be solved using multiple types of sensors and different damage detection techniques. New signal-processing architectures are also needed that simplify the hardware and reduce the cost of the overall health monitoring system. An SNS was developed as a simple approach for health monitoring of WTs. The neural system listens for AEs to detect damage in a WTB. The SNS was tested during proof testing of WTB and multiple damage zones were located. Subsequent postfailure sectioning of the failed blade showed close correlation between the predicted and actual damage locations. An SNS with multistate continuous sensors is also being developed to measure other variables such as pressure, acceleration, and electrical impedance to identify different types of damage. Power harvesting and wireless data transmission from the rotating blades to the fixed frame are other areas where research is needed. It is suggested that a test bed for WTBs be developed to practically evaluate the different techniques for SHM.

ACKNOWLEDGMENTS

The work related to the SNS was supported by the NREL under subcontract number XCX-2-31214-01. Mr Alan Laxson was the technical monitor of this project. Much of the help in making the prototype of the SNSAP was provided by engineers from Texas Instruments and Analog Devices. Also Mr Henry Westheider, Instrumentation specialist, and Mr Doug Hurd, Machinist, in the Department of Mechanical Engineering at the University of Cincinnati provided valuable help in building the SNS prototype. The static test of the 3-TEX-100 blade was performed at NREL test facility in Golden, CO. The LABVIEW expertise provided by Dr Vahan Gevorgian of NREL during the on-site testing of the SNSAP on the WTB is gratefully appreciated. Mr Derek Berry and Dr Mansour Mohamed are the principal technical leads from TPI Composites and 3 TEX, Inc., respectively. Mr Scott Hughes and Mr Jeroen van Dam are the NREL engineers who assisted during the WTB testing.

Chapter 148
Large Rotating Machines

Tomasz Gałka
Institute of Power Engineering, Warsaw, Poland

1 INTRODUCTION

The term *large rotating machines* refers mainly to turbine-generator units and high-capacity pumps, fans and compressors employed in power industry, process industry, mining, etc. "Large" means high power or, more precisely, high intensity of energy transformation processes. From the point of view of technical condition monitoring and assessment, they have four important features:

- complexity, which implies that such machines are characterized by a large number of technical condition parameters;
- individuality, which means that two machines of the same design often differ substantially from the point of view of condition assessment;
- critical nature, which means high cost, high reliability demand, and high risk involved in a failure (life hazard, damage, production loss, and environmental impact);
- long service life, usually with a number of major overhauls.

These features have a major influence on methods used for structural health monitoring, as well as on relevant measuring equipment and data processing techniques.

In general, monitoring large rotating machines has two principal aims:

- detection, identification, and assessment of failures (to maintain operational parameters, provide operational safety, and optimize overhauls);
- tracing condition degradation processes (to determine life consumption and/or residual life).

Both these aims are accomplished by using the same technical condition symptoms, but they differ in procedures and algorithms employed for this purpose.

Historically, the beginnings of structural health monitoring in large rotating machines can be related to the introduction of measurement of process parameters, which were later supplemented by vibration measurements. Apart from performance monitoring, they were initially employed for maintaining

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

operational safety. In the 1960s, the first generation of systems for continuous diagnostic monitoring was introduced. These systems were based on analog techniques and employed relatively simple data processing algorithms. The second-generation systems, which appeared in the 1970s, featured more advanced processing techniques, like fast Fourier transform (FFT). Third generation (expert systems), which saw widespread introduction in the 1990s, was based entirely on digital techniques and featured advanced software for data processing and presentation, as well as certain elements of diagnostic reasoning [1]. It seems justified to state that measurement techniques have reached a stage of maturity and certain patterns have been established. On the other hand, development in the field of data processing is very intensive; in particular, Artificial Intelligence (AI) methods are introduced to a growing extent.

2 CONDITION SYMPTOMS

Because of their complexity, large rotating machines are characterized by a number of technical condition parameters, which can be described by a vector $\mathbf{X}(\theta) = \{X_1(\theta), X_2(\theta), \ldots, X_m(\theta)\}$, where θ denotes machine lifetime.[a] Usually these parameters cannot be measured directly and the technical condition is determined on the basis of symptoms, i.e., measurable quantities covariable with the machine condition [2]. For a given machine, we can define a vector of symptoms $\mathbf{S} = \{S_1(\theta), S_2(\theta), \ldots, S_n(\theta)\}$. A fundamental relation is thus given by

$$\mathbf{S}(\theta) = \Phi[\mathbf{X}(\theta)] \tag{1}$$

where Φ denotes an operator. In some cases, for a symptom $S_i(\theta) \in \mathbf{S}$, we can assume a lack of cross relations, which means that

$$\vee_j \frac{\partial S_i}{\partial X_k} \approx 0 \text{ if } k \neq j \tag{2}$$

which implies that equation (1) can be reduced to the simplest possible form of a diagnostic relation

$$S_i(\theta) \approx \Phi[X_j(\theta)] \tag{3}$$

Such an approach sometimes yields analytical expressions, which can be directly employed in condition assessment procedures [3]. Their suitability is, however, limited to particular machine types or even individual examples. In practical applications, measurable symptoms depend not only on technical condition, but also on control parameters and interference, so that equation (1) has to be replaced by

$$\mathbf{S}(\theta) = \Phi[\mathbf{X}(\theta),\ \mathbf{R}(\theta),\ \mathbf{Z}(\theta)] \tag{4}$$

where $\mathbf{R}$ and $\mathbf{Z}$ denote control and random interference vectors, respectively.

Let us assume, for the time being, that influences of control and random interference can be either neglected or accounted for in some way (this issue shall be discussed later). Then, given long service life and overhauls performed at certain intervals, the time history of a symptom $S_i(\theta)$ can be considered as a combination of two functions. The first represents life consumption processes, inevitably resulting from normal operation. These processes can be described by monotonically increasing functions [4] with time constants of the order of machine service life. The second one represents the influence of overhauls and failures. Overhauls are represented by step changes. Failures manifest themselves as either very fast (almost step) changes or continuous evolution with a comparatively short time constant. This corresponds to the two principal aims of condition monitoring mentioned above.

2.1 Vibration-based symptoms

Because of high information content, vibration patterns are the most important source of diagnostic symptoms for condition monitoring of rotating machines. Various vibration characteristics provide information on machine condition [5, 6]; the most useful and commonly employed characteristics are

- absolute vibration spectra (bearings, casings, and foundations),
- relative vibration trajectories (orbits),
- vibration time histories or trends (evolution).

Large rotating machines produce broadband vibration spectra with many individual components. These components can be grouped in two categories. The first includes those resulting directly from rotary

motion, i.e., harmonics and subharmonics of the fundamental frequency f_0 that corresponds to the rotational speed. They are generally referred to as *harmonic components*. The second includes those generated by medium flow interaction with the fluid-flow system, sometimes called *blade components*. An example, for a steam turbine rotating at 3000 rpm, is given in Figure 1.

Subharmonic components are related to malfunctions like fluid-induced rotor instability (oil whirl and whip) and partial rub in journal bearings [7, 8]. Instability produces $n \times f_0$ components ($n < 1$), which often take the form of a broadband "hump" in the subharmonic range [7, 9]. Rub usually produces $(n/m) \times f_0$ components ($n/m < 1$, both n and m small integer values), which are clearly visible as peaks in narrowband spectra [7]. Shaft trajectory (orbit) analysis is usually conclusive.

Harmonic components are related to common malfunctions like unbalance, rotor bow, coupling misalignment, shaft crack, loose part, or debris accumulation. All these faults can result in the $1 \times f_0$ component increase, which usually provides the first warning. The $2 \times f_0$ component is usually related to misalignment [7, 10], but can also indicate a rotor crack. Higher harmonic components are more difficult to interpret; they sometimes result from faulty couplings, but can also be produced by fluid-flow system components [11]. In general, diagnostic relations for these symptoms are complex and cannot be reduced to simple and most convenient forms of the type given by equation (3). Diagnostic reasoning has to be augmented by other symptoms. Much can be deduced from how these components change with operational parameters and rotational speed (which can be determined during machine run-down) [7]. Correlation analysis (see below) can also yield conclusive results.

Blade components result from interaction between fluid-flow system components and medium flow. Frequencies of these components can be expressed by

$$f_w = l \cdot u \tag{5}$$

$$f_k = z \cdot u \tag{6}$$

$$f_{(k+w)/2} = (z + l) \cdot \frac{u}{2} \tag{7}$$

$$f_{(k-w)/2} = (z - l) \cdot \frac{u}{2} \tag{8}$$

where l and z denote number of blades in rotor stages and bladed diaphragms, respectively. Components with frequencies given by equations (7) and (8) result

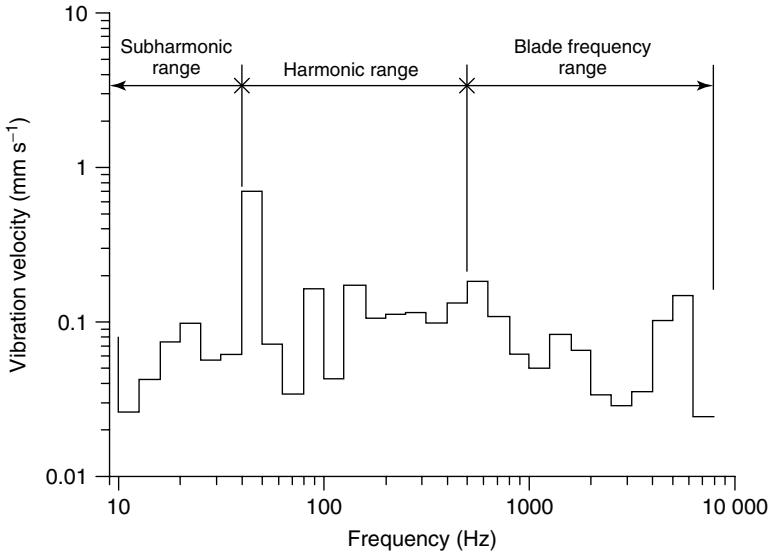

Figure 1. Example of a rotating machine with absolute vibration at the third octave (23% constant percentage bandwidth (CPB)) spectrum (200-MW steam turbine). A logarithmic horizontal scale is convenient because of the broad frequency range. Spectral analysis is dealt with in detail in **Statistical Time Series Methods for SHM**.

from interaction between adjacent stages and are in a way analogous to the treatment of nonlinear vibration without damping, with two harmonic components of exciting force [12]. Amplitudes of these components depend on the condition of fluid-flow system elements [10, 13] and can be employed as diagnostic symptoms.

Vibration trajectory or orbit represents a path of the shaft centerline in a plane perpendicular to the rotor [7]. In large rotating machines, relative vibrations of shafts in bearings are usually measured in two perpendicular directions (results are sometimes represented as vectors). For safety reasons, relative vibration amplitudes have to be kept within acceptable limits, determined by the machine manufacturer, in all operating conditions (including passing critical rotational speed or speeds during start-up). Vibration orbits are, however, much more useful as a diagnostic tool, as information is contained not only in amplitudes, but also orbit shape and direction of precession, as well as shaft centerline position as a function of operational parameters (rotational speed, load, temperature field, etc.). Normally, an orbit is elliptical with a single phase marker, which indicates domination of the f_0 component [7, 8].

Analysis of relative vibration orbits can yield conclusive results for malfunctions like rotor instability, rotor rub, excessive radial load, and misalignment. This is especially valuable for distinguishing malfunctions that produce similar absolute vibration patterns. In practice, analysis of absolute vibration is more convenient for determining amplitude–frequency characteristics. On the other hand, distorted orbits (banana-shaped, flattened, bent, or showing multiple loops) are indicative of certain malfunctions.

Information on machine condition is contained not only in absolute and relative vibration patterns, but also in vibration time histories (evolution). As mentioned above, slow monotonic increase is typical for normal life consumption in machines designed for long service life. Malfunctions result in "abnormal" evolution (Table 1) [5, 14]. Both evolution type and time constant (duration) provide information on malfunction type. It should be noted that in large rotating machines, time constants can vary from seconds to months or even years (Figure 2).

Trend analysis aimed at tracing life consumption processes can be performed only if available data cover a sufficiently long period. Such an approach can, however, be very useful if control and interference cannot be neglected (equation 4). In most cases, we can reasonably assume that components of **R** and **Z** vectors have no long-time trend; so for ith component we have

$$\frac{\Delta R_i}{\Delta\theta} = \frac{[R_i(\theta_0 + \Delta\theta) - R_i(\theta_0)]}{\Delta\theta} \to 0 \text{ if } \Delta\theta \to \infty \tag{9}$$

Table 1. Symptom assessment: example for absolute vibration evolution in a machine lifetime

No	Type of evolution	Duration (time constant)	Damage or malfunction
1	Simple, monotonic	1 day or more	Deformation of machine casing
		Several minutes to several hours	Shaft deformation, thermal unbalance
		A few seconds	Dry friction
2	Complex, approximately monotonic	Days to months	Deformations of casings and foundations
		Hours to days	Changes of natural frequencies
		Several minutes to hours	Thermal unbalance
3	Rapid, discontinuous	Below 2 s	Blade loss or damage, cracks of rotor elements
4	Exponential	Hours to weeks	Fatigue cracks
		10–20 min	Dry friction
5	Cyclic or diverging	Varying	Sliding friction (e.g., generator seals)
		A few seconds	Malfunction of gears
6	Cyclic, complex	Cyclic	Malfunctions of governing system
7	Rapid, random	Varying	Bearing instability, unstable medium flow

After [14], reproduced by permission of Queens University, Kingston.

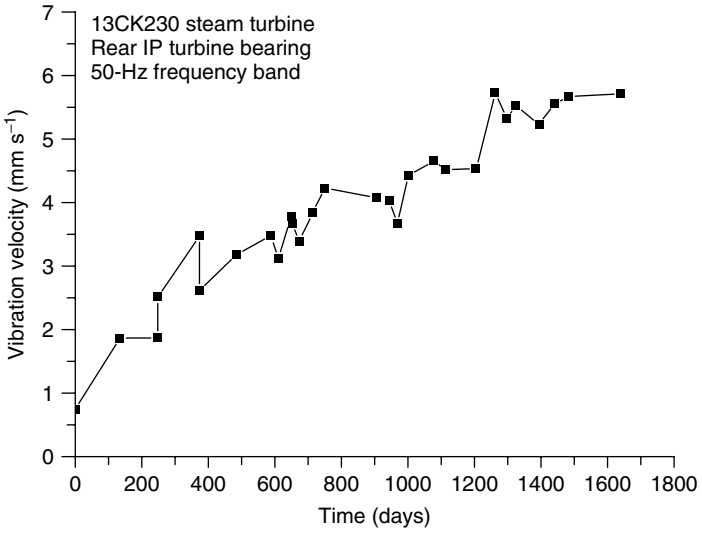

Figure 2. Example of a vibration trend analysis; slow increase of the $1 \times f_0$ component of absolute vertical vibration of a turbine bearing, caused by a slowly developing rotor bow.

$$\frac{\Delta Z_i}{\Delta\theta} = \frac{[Z_i(\theta_0 + \Delta\theta) - Z_i(\theta_0)]}{\Delta\theta} \to 0 \text{ if } \Delta\theta \to \infty \tag{10}$$

Thus, if we analyze an entire time history to extract a trend, we may neglect dependence of **S** on **R** and **Z**, provided that this time history covers a period ($\Delta\theta$) that is sufficiently long.

2.2 Other condition symptoms

Symptoms other than vibration-based ones are often provided by physical quantities that are monitored during machine operation, for either safety or performance control reasons. They are often useful in augmenting diagnostic reasoning. Their interpretation is in many cases quite straightforward.

2.2.1 Acoustic symptoms

Large rotating machines are usually operated in an environment characterized by high acoustic background level. This implies that interference (equation 4) markedly influences measured symptom values. Correlation between vibration-based and acoustic symptoms (sound intensity levels in individual frequency bands) in the harmonic frequency range is in many cases good [15], but the former are much more convenient from the point of view of measurement and interpretation. Acoustic symptoms have certain potential for detecting faults of control valves and labyrinth seals, but their application is in practice often limited to organoleptic noise level assessment, employing no measuring devices and based on individual experience.

2.2.2 Temperature

In thermal rotating machines (steam or gas turbines), the temperature at certain points is monitored continuously. This refers to bearings and casings. Increase of bearing temperature (and outlet oil temperature) is a symptom of excessive bearing load, usually caused by misalignment. Such malfunction results from faulty assembly, bearing pedestal displacement during start-up, or foundation distortion. Symptoms of this type can be useful if interpretation of vibration-based misalignment symptoms is unclear.

Monitoring casing temperatures is important, especially in steam turbines. High-pressure and intermediate-pressure casings are thick-walled elements and temperature gradients during transients (especially start-ups) must be kept within acceptable limits, to avoid excessive stresses. This limitation is imposed by both safety and life consumption reasons. Time histories of temperature in individual points and

temperature differences, especially between upper and lower casing parts, allow to detect water ingress into turbine, which results in intensive cooling of the lower part, large deformation, and usually, rotor jam. Interpretation of such symptoms is usually straightforward.

2.2.3 Displacement

During transient states (especially start-ups), axial displacement is monitored to keep clearances within acceptable limits. This is especially important in large steam turbines operating at high steam temperature, as thick-walled casings heat up much slower than rotors. Normally, displacements measured at individual points result directly from thermal expansion and/or axial forces imposed by medium flow. Substantial discrepancy is a symptom of expansion hindrance (e.g., due to slide block jam). Such symptoms are usually quite easy to interpret.

Radial (vertical and/or horizontal) displacement of machine elements may result in shaft line distortion that sometimes significantly influences dynamic behavior. This is particularly important in large machines with long shaft lines (in large steam turbines, even about 70 m). Excessive distortion usually leads to misalignment and problems with load distribution between bearings. This can be caused, e.g., by improper temperature field in foundation and support structure. Misalignment and load bearing problems can usually be identified with vibration-based symptoms [9]; however, to perform necessary readjustment of bearing positions, displacement measurements may be needed [16]. They are usually performed during start-ups and should cover the entire period from preliminary heating to steady-state operation, which in the largest machines can take several days. Figure 3 shows difference in the vertical displacements of two adjacent bearings in a turbine-generator unit, plotted against time [10]; in this case, the difference is rather large, but stabilization is achieved in a comparatively short time. Such measurements are sometimes time-consuming and tedious (especially if laser methods cannot be employed), but the interpretation of results is straightforward.

2.2.4 Electric parameters

Many large rotating machines include either electric motors (pumps, fans, and compressors) or generators (steam- or gas-turbine driven power generating units). Electric parameters, mainly voltage and current, are measured for both performance monitoring and operational safety reasons. They also provide input data for torsional vibration monitoring

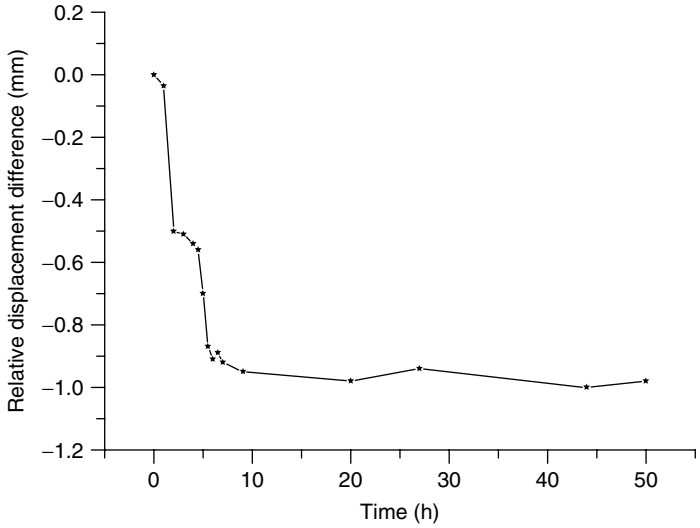

Figure 3. Relative difference in vertical displacements between rear turbine and front generator bearings plotted against time; developing misalignment is clearly visible [after [10], reproduced by permission of Polish Academy of Sciences].

systems in turbogenerators [17] and can be useful in identifying causes of failures resulting from accelerated fatigue.

In electric motors, failures like short-circuits or broken rotor bars produce uneven temperature distribution, which can lead to vibration patterns resembling unbalance [7]. In such cases, measurements of electric parameters may yield conclusive results.

2.2.5 Others

In steam and gas turbines, endoscopy is widely used for determining the condition of rotor blades [18]; state-of-the-art methods employ advanced image acquisition and processing techniques.

Large steam turbines are fitted with on-line or off-line systems for monitoring temperature, pressure, and steam flow. These quantities are necessary for energy conversion diagnostics, i.e., determining operational parameters like specific heat consumption and thermal efficiency [19]. They can also be used to monitor degradation of turbine fluid-flow system.

In compressors and pumps, pressure measurements are fundamental for performance monitoring. They are also important for operational safety (avoiding unstable operation conditions—stall or surge), which is particularly important with high flow rates and high-pressure ratios [20]. These quantities are of supplementary nature in condition assessment based on other symptoms.

Methods employing acoustic emission, widely employed in nondestructive testing, have not found widespread use in the monitoring of large rotating machines, despite their considerable potential [21].

3 DIAGNOSTIC RELATIONS

Development of structural health monitoring in large rotating machines has so far included four stages, namely,

1. symptom acquisition (measurement of physical quantities and data processing);
2. qualitative diagnosis (fault detection and identification);
3. quantitative diagnosis (fault extent or, more generally, life consumption determination);
4. prognosis (residual life determination).

Diagnostic relations can thus be either qualitative or quantitative.

In general, qualitative relations are of binary type: object condition is either "good" or "faulty"; symptom is either present or not present. For complex objects, like large rotating machines, such an approach is adequate only in few cases. Quantitative relations are provided by symptom value versus failure advance or life consumption, both members being continuous functions.

Diagnostic experiments of active type, involving large rotating machines are seldom possible; determination of diagnostic relations has therefore to be based on models. At first, these models were developed directly from an analysis of processes that are sources of diagnostic symptoms. Such an approach is exemplified by vibrodiagnostic models [3, 10, 22] that, in general, relate vibration components in individual frequency bands to elementary vibration sources. These models were initially of qualitative type. With the introduction of criteria values (see below), they were supplemented with a tool for quantitative condition assessment.

Because of complexity, interpretation of symptoms is often equivocal, i.e., the same symptom may result from different malfunctions or faults. $1 \times f_0$ component of absolute vibration is perhaps the most representative example (see Section 2.1). Thus, condition assessment on the basis of such models inevitably involves a measure of correct diagnosis probability. Only in some specific cases (e.g., detection of fluid-induced instability on the basis of subharmonic spectral components) can this probability be very high. Substantial improvement can be achieved if two or more symptoms appear simultaneously; in more general terms, this means employing correlation. A good example is provided by misalignment detection (three symptoms—increase of the $2 \times f_0$ component in absolute vertical vibration spectra, banana-shaped shaft orbit, and oil temperature change at the bearing outlet). Correlation of vibration time histories in various machine points can also be a useful symptom [11].

Much effort has been spent on modeling dynamic behavior of rotors and bearings [7, 8, 23, 24]. Finite elements method (FEM) is used to model the line of rotors. Various methods have been developed for modeling bearings and supporting structures (bearing pedestals, foundations, etc.). Even cursory description

of these complex issues is certainly beyond the scope of this article; from the point of view of condition assessment, this approach can be summed up as follows:

- the model is developed for a particular machine (rotor or line of rotors, bearings, supporting structure);
- certain imperfections that represent "real" malfunctions (like unbalance, misalignment, rotor or blade crack, bearing displacement, or skew) are introduced in the model;
- dynamic response of the model to these imperfection is determined (vibration spectra in individual measuring points, shaft orbits in bearings);
- results are validated in laboratory conditions.

Validation on full-scale rotors is seldom possible and scaled-down laboratory systems are used for this purpose [8].

Modal analysis provides a valuable tool for detecting failures that modify natural frequencies, in particular shaft cracks, which are among the most dangerous ones. It has been shown that transverse shaft cracks modify natural frequencies, but resulting changes are rather small, typically below 1% [25]. Experimental investigations [26] have pointed at a need for advanced measurement and signal-processing techniques to reveal corresponding spectral components. These methods have not yet found widespread applications, but they have a great potential; much work is currently under way. Modal vibration methods are dealt with in detail in **Modal–Vibration-based Damage Identification**.

3.1 Normalization of symptom values

In the above considerations, it has been assumed, more or less explicitly, that relation between symptoms and condition parameters given by equation (1) is valid. Usually, however, equation (4) is far more appropriate, which means that influences of control and interference have to be taken into account. In fact, this is the principal cause of difficulties in direct application of model-based simulation or laboratory-scale experiment results to real machines, operating in an industrial plant environment.

Normalization of the influence of interference vector components is, in general, not possible, as some of them are not measurable. Proper measurement procedures can alleviate the problem, but not solve it completely. Normalization of control parameters is usually a complex issue. Experimental investigations have shown that dependence of diagnostic symptom values on overall parameters, like machine load, cannot be neglected [27]; moreover, this dependence is strongly nonlinear. The problem is, in fact, even more complicated. Consider a given moment $\theta = \theta_0$. We have

$$P(\theta_0) = F_1[\mathbf{R}(\theta_0)] \tag{11}$$

where P is a parameter that describes "intensity" of operation (load, discharge, mass flow, etc.). At the same time, for a given symptom S_i, we have

$$S_i(\theta_0) = F_2[\mathbf{R}(\theta_0)] \tag{12}$$

Usually it is convenient to speak in terms of $S_i(P)$ relations, which are comparatively simple to determine experimentally [25]. However, the function given by equation (11) is usually unique, but not single, as various $\mathbf{R}$ vectors can yield the same value of P. Any normalizing function of the $S_i(P)$ type will thus be only an approximation. This complicates modeling, as many additional factors have to be accounted for.

Many faults produce significant changes of the symptom vector components, so qualitative diagnosis can be provided even despite these influences. Correlation analysis can also be very useful. In tracking long-time trends, related either to normal life consumption or slowly developing faults (Table 1), equations (9) and (10) are essential; usually there are considerable fluctuations, but "net" increase can be observed if a sufficiently long period is covered (Figure 4).

3.2 Symptom limit values

In practice, a decision has often to be made whether a machine can be further operated or not, and diagnostic procedures are expected to provide arguments. This is particularly important for critical machines. In a sense, this can be viewed as a return to the "binary approach" and thus some threshold symptom value has to be determined. This can be based on the analysis of energy transformation and dissipation processes, which leads to the energy processor

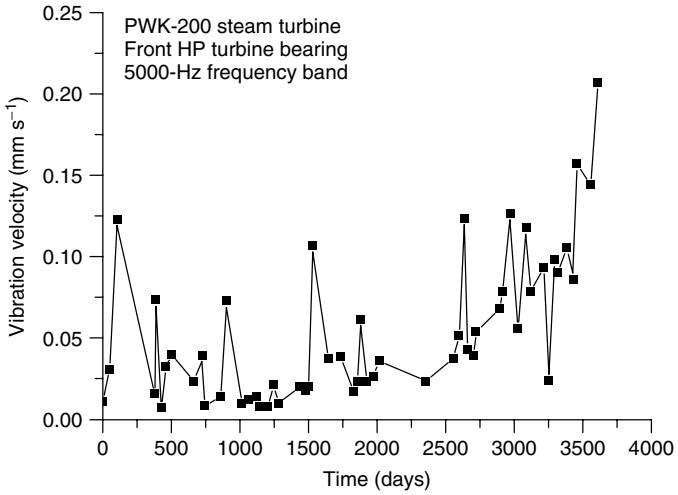

Figure 4. Example of a vibration trend; despite fluctuations, an increasing trend is clearly visible.

(EP) model [4, 28]. Application of the statistic decision theory and symptom reliability concept [4, 29] leads to so-called symptom limit value. Limit value (in some monitoring systems referred to as *alert value*) is defined as one corresponding to condition deterioration to a point beyond which the object cannot fulfill all requirements and should be considered faulty. This can be expressed as

$$S_i(\theta) < S_l \Rightarrow \text{GOOD condition}$$
$$S_i(\theta) \geq S_l \Rightarrow \text{FAULTY condition} \qquad (13)$$

where S_l denotes the limit value. At this point, the decision has to be made whether to operate the machine at reduced parameters (e.g., lower load or flow rate), reschedule overhauls, or perform a repair. Such an approach can be schematically illustrated by Figure 5.

The basic value represents a new object with no faults or malfunctions and, in theory, is the lowest possible value of the symptom under consideration. The admissible value is determined from safety considerations (usually by the machine manufacturer)

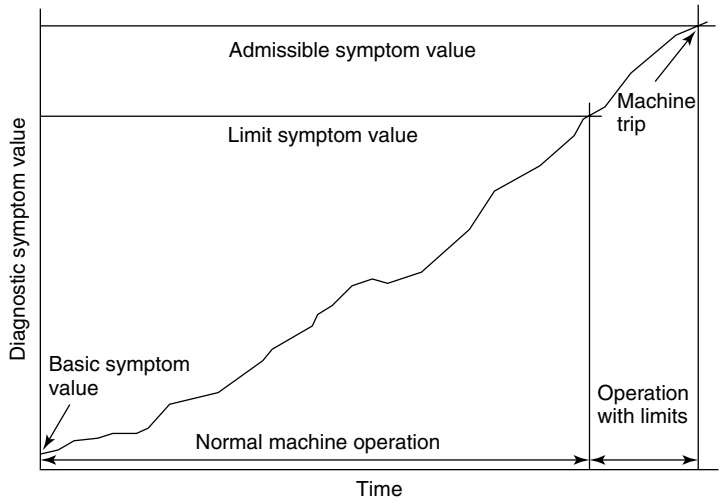

Figure 5. Machine condition assessment on the basis of criteria symptom values.

or imposed by relevant standards and basically is not related to condition assessment. This value should not be exceeded during steady-state operation; if this happens, the machine has to be tripped. In some monitoring systems, this value is referred to as a *danger* level.

In general, a limit value can be attributed to any diagnostic symptom, but in monitoring systems, such values are determined mainly for vibration-based symptoms [30]. For many large rotating machines, basic and limit values have to be determined individually, even for identical objects; steam turbines provide a good example [30].

4 MONITORING PHILOSOPHY

Typically, a large rotating machine will have a system for measuring parameters important for process control and operational safety. Some of these parameters also provide information important for technical condition assessment, but this task will usually be accomplished by a separate monitoring/diagnosing system. In general, two approaches can be distinguished: continuous (on-line) and periodic (off-line) monitoring. The choice will always be a compromise between demands and costs.

Since introduction in late 1960s, on-line monitoring of large rotating machines has evolved from comparatively simple systems for data acquisition, alarms generation, and protection to complex expert systems featuring leading-edge data processing techniques and AI methods. Several off-the-shelf systems from various manufacturers are available at the market, which facilitate various degrees of versatility and can be usually tailored to a specific application. Despite their trade names, in most cases, they feature only data acquisition, processing, and storage, with few diagnostic capabilities, if any. Exemplary layout of one such system is shown in Figure 6.

In many applications (e.g., in mining industry), several machines at various, often distant, locations have to be monitored simultaneously, which imposes high demands on data transmission. Owing

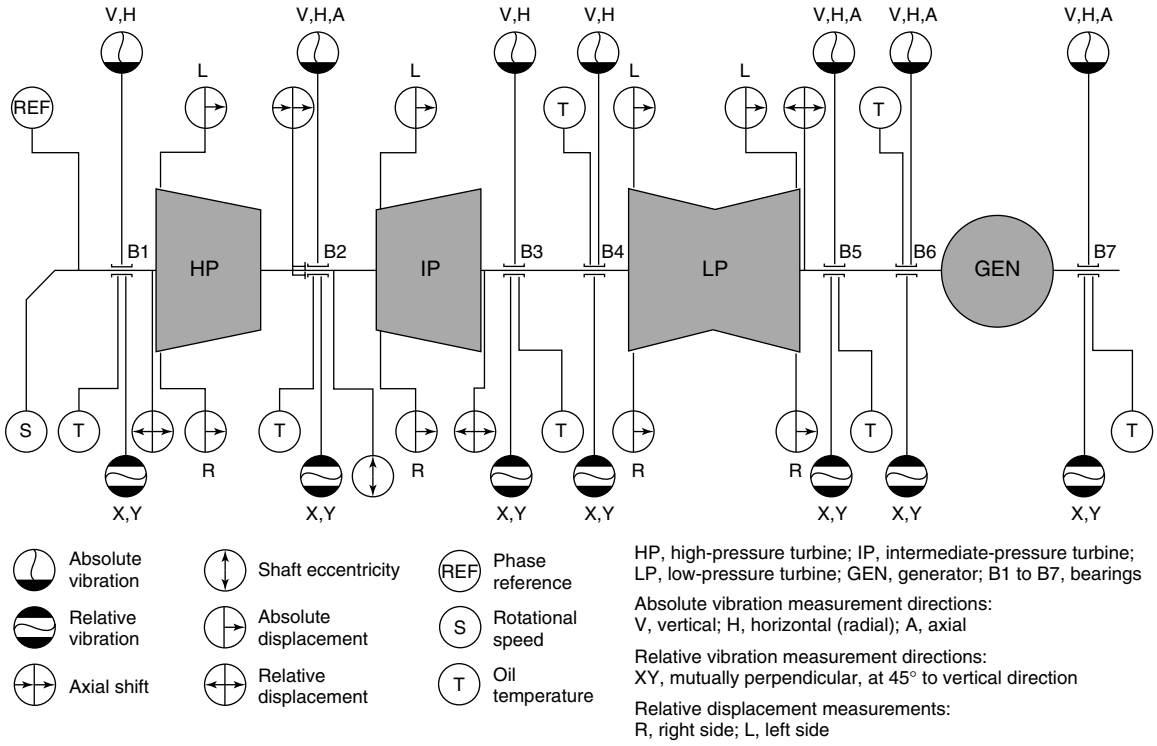

Figure 6. Example of a monitoring system layout for a 200-MW steam turbine.

to the large amount of data acquired from individual sensors, data compression can be of great importance. An example of such a distributed system is shown in Figure 7.

Advanced diagnostic systems, which incorporate expert systems, knowledge base, and database from both modeling and operational experience and employ AI methods are developed individually for particular machine types. The first systems of this kind were developed in the 1980s for large steam turbines in nuclear power plants. These systems are very costly, so their application is justified only for large machines with high reliability demand and extremely severe consequences of potential failure.

Much cheaper off-line systems are based on measurements performed at certain time intervals. They obviously cannot provide instantaneous reaction for a failure characterized by a very short "time constant" (Table 1), but have a number of advantages:

- array of measuring points and measurement settings can be adjusted to current machine status;
- there is some choice of transducers with characteristics usually superior to that of permanently installed ones (for example, vibration transducers permanently installed on rotating machines seldom exceed frequency range of 1 kHz, which excludes blade frequency range);
- measuring equipment and software can be easily upgraded as new versions become available.

Off-line monitoring/diagnosing systems use commercial (usually portable) equipment for data acquisition and various software packages for post-processing and supporting diagnostic reasoning. Such

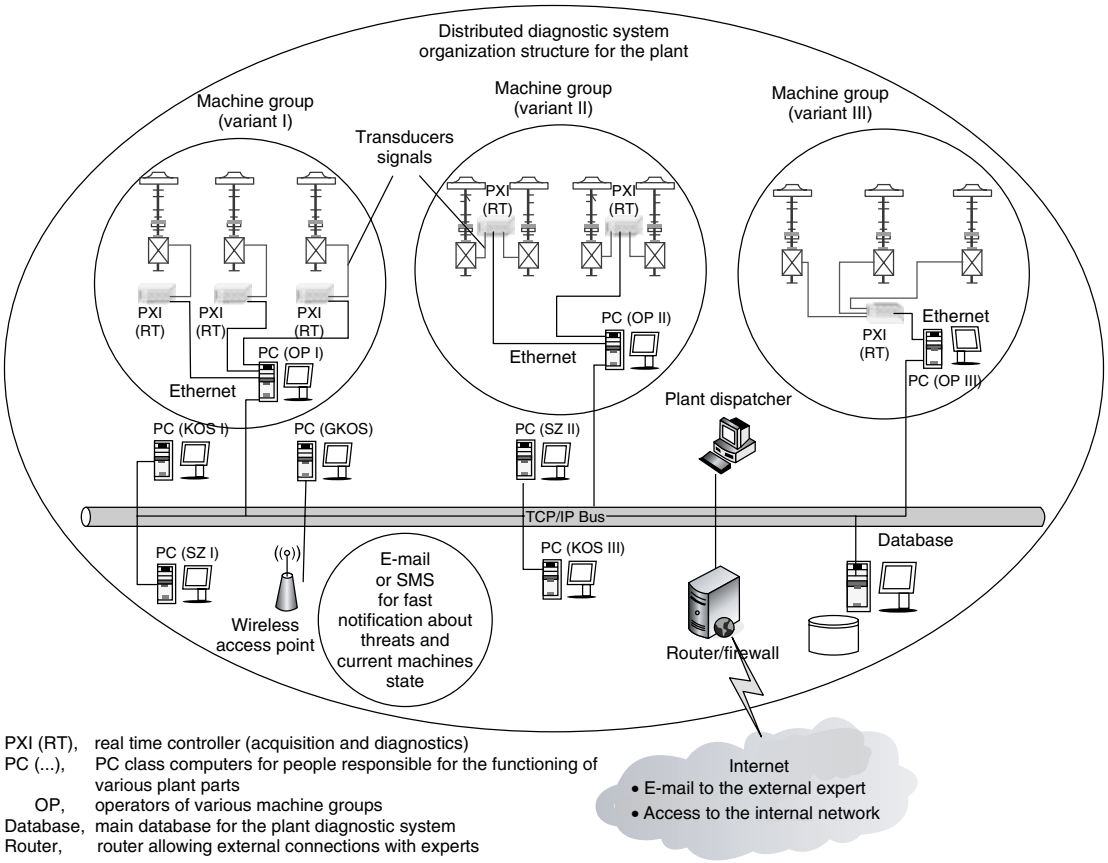

Figure 7. Exemplary structure of a plant distributed diagnostic system [after [31], reproduced by permission of Instituto de Telecomunicações, Coimbra].

an approach, combined with proper on-line operation monitoring, can be a good and cost-effective alternative to expensive on-line systems.

5 FUTURE DIRECTIONS

Structural health monitoring should be seen in the widest context of machine—or plant—maintenance improvement [32]. Certainly, the ultimate and ideal aim is to eliminate all unplanned maintenance [33]. In reality, there will always be a compromise between some acceptable level of failure risk on one hand and some acceptable percentage of unnecessary maintenance on the other, with all associated costs taken into account. This is exemplified by the Neyman–Pearson rule of risk assessment [4], which itself forms the basis for symptom limit value determination [30]. Improvement in this field calls for a system that is able to give a reliable prognosis or, more specifically, reliable residual life estimation. This means taking the next step in the development of condition monitoring (see Section 3).

State-of-the-art systems for structural health monitoring have reached an advanced stage of development as far as damage identification and quantitative assessment are concerned. On the other hand, still relatively few systems feature forecasting of technical condition evolution. Owing to the complexity of symptom–condition relations (see equation (4)), simple prediction methods are not adequate and much development is necessary. Given the demands imposed by the need for overall maintenance improvement, this will be an important, and probably the most important, trend in this field in the near future.

ACKNOWLEDGMENTS

I would like to express my deep gratitude to Professor Czesław Cempel for encouragement and discussion, which has helped me much in giving this text its final form.

END NOTES

[a.] Lifetime is here and in the following denoted by θ rather than t to avoid confusion with so-called dynamic time, which is used in equations of motion (*see* **Free and Forced Vibration Models**).

Chapter 150

Prognostics and Health Management of Electronics

Michael Pecht

Center for Advanced Life Cycle Engineering (CALCE), University of Maryland, College Park, MD, USA

1 INTRODUCTION TO THE PREDICTION OF RELIABILITY

The traditional reliability prediction methods for electronic products include Mil-HDBK-217 [1], 217-PLUS, Telcordia [2, 3], PRISM [2], and FIDES [4]. All these methods assume the components of the system have constant failure rates with "pi-factor" modifiers to account for various quality, operating, and environmental conditions. There are numerous problems with these types of modeling approaches, and these have been mentioned in hundreds of papers [5, 6]. The general consensus has been that these methods should never be used, because they are inaccurate for predicting actual field failure events, and they are highly misleading, and can result in poor designs [3].

In the Mil-HDBK-217A documentation published in 1965, there was only a single point failure rate for all monolithic integrated circuits, regardless of the stresses, the materials, or the architecture. Mil-HDBK-217B was published in 1973, with the RCA/Boeing models simplified by the Air Force to follow a exponential distribution. In 1979, Mil-HDBK-217C was published to "band-aid" the problems. To keep pace with the accelerating and ever changing technology base, Mil-HDBK-217C was updated to Mil-HDBK-217D in 1982 and to Mil-HDBK-217E in 1986. In 1991, Mil-HDBK-217F became a prescribed US military reliability prediction document [7]. In the meantime, IEEE 1413 standard provided guidance on the appropriate elements of a reliability prediction [8]. The IEEE 1413.1 guidebook provides a summary of the evaluation of the common methods of reliability prediction described in this document. That information should be utilized

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

for determining which reliability prediction method is appropriate in a particular application [9].

The physics-of-failure (PoF) approach and design-for-reliability (DfR) methods have been developed by the Center for Advanced Life Cycle Engineering (CALCE) at the University of Maryland with the support of industry, government, and other universities. PoF is an approach that utilizes knowledge of a product's life-cycle loading and failure mechanisms to perform reliability modeling, design, and assessment. The approach is based on the identification of potential failure modes, failure mechanisms, and failure sites for the product at a particular life-cycle loading condition. The stress at each failure site is obtained as a function of both the loading conditions and the product geometry and material properties. The use of PoF modeling approaches for electronic components and devices, like those used for mechanical systems, are a powerful tool in support of electronic prognostic capabilities. This is because the root cause of almost all electronic devices or component failures is often mechanical—something physically breaks at a subcomponent, solder joint, connection, layer, delamination, etc., level. Solder fatigue models are already under development and show promise [10, 11].

Prognostics and health management (PHM) is a method that permits the assessment of the reliability of a system under its actual application conditions. When combined with PoF models, it is thus possible to make continuously updated predictions based on the actual environmental and operational condition monitoring of each individual product.

Assessing the extent of deviation or degradation from an expected normal operating condition (i.e., health) for electronics provides data that can be used to meet several critical goals, which include (i) providing advance warning of failures; (ii) minimizing unscheduled maintenance, extending maintenance cycles, and maintaining effectiveness through timely repair actions; (iii) reducing the life-cycle cost of equipment by decreasing inspection costs, downtime, and inventory; and (iv) improving qualification and assisting in the design and logistical support of fielded and future systems [12, 13]. The importance of PHM has been explicitly stated in the US Department of Defense 5000.2 policy document on defense acquisition, which states that "program managers shall optimize operational readiness through affordable, integrated, embedded diagnostics and prognostics, embedded training and testing, serialized item management, automatic identification technology, and iterative technology refreshment" [14]. Thus, a prognostics capability has become a requirement for any system sold to the Department of Defense.

2 MODELING OF STRESS AND DAMAGE UTILIZING LIFE-CYCLE LOADS

Life-cycle loads of a product can arise from manufacturing, shipment, storage, handling, operating, and nonoperating conditions. The life-cycle loads (thermal, mechanical, chemical, electrical, and so on), either individually or in various combinations, may lead to performance or physical degradation of the product and reduce its service life. In the stress–damage prognostics approach, the extent and rate of product degradation depends upon the magnitude and duration of exposure to loads (usage rate, frequency, and severity). The life-cycle loads are monitored *in situ*, and used in conjunction with PoF-based damage models to assess the degradation due to cumulative load exposures.

In studies made by Ramakrishnan and Pecht [15] and Mishra *et al.* [16], the test vehicle consisted of an electronic component-board assembly placed under the hood of an automobile and subjected to normal driving conditions in the Washington, DC, area. The test board incorporated eight surface-mount leadless inductors soldered onto an FR-4 substrate using eutectic tin–lead solder. Solder joint fatigue was identified as the dominant failure mechanism. Temperature and vibrations were measured *in situ* on the board in the application environment. Using the monitored environmental data, stress and damage models were developed and used to estimate consumed life.

Shetty *et al.* [17] applied the PHM methodology for conducting a prognostic remaining-life assessment of the end effector electronics unit (EEEU) inside the robotic arm of the space shuttle remote manipulator system (SRMS). A life-cycle loading profile for thermal and vibration loads was developed for the EEEU boards. Damage assessment was conducted using physics-based mechanical and thermomechanical damage models. A prognostic estimate using

a combination of damage models, inspection, and accelerated testing showed that there was little degradation in the electronics and they could be expected to last another 20 years.

Mathew *et al.* [18, 19] applied the PHM methodology in conducting a prognostic remaining-life assessment of circuit cards inside a space shuttle solid rocket booster (SRB). Vibration time history recorded on the SRB from the prelaunch stage to splashdown was used in conjunction with physics-based models to assess the damage due to vibration and shock loads. Using the entire life-cycle loading profile of the SRBs, the remaining life of the components and structures on the circuit cards was predicted. It was determined that an electrical failure was not expected within another 40 missions.

Gu *et al.* [20] developed a methodology for monitoring, recording, and analyzing the life-cycle vibration loads for remaining-life prognostics of electronics. The responses of printed circuit boards (PCBs) to vibration loading in terms of bending curvature were monitored using strain gauges. The interconnect strain values were then calculated from the measured PCB response and used in a vibration failure fatigue model for damage assessment. Damage estimates were accumulated using Miner's rule after every mission and then used to predict the life consumed and remaining life. The methodology was demonstrated for remaining-life prognostics of a PCB. The result was also verified by the real time to failure of the components by checking the components' resistance data.

Simons and Shockey [21] performed a PoF-based prognostics methodology for failure of a gull-wing lead power supply chip on a DC/DC voltage converter PCB assembly. First, three-dimensional finite element analyses (FEA) were performed to determine strains in the solder joint due to thermal or mechanical cycling of the component. The strains could be due to lead bending resulting from the thermal mismatch of the board and chip and those resulting from local thermal mismatch between the lead and the solder, as well as between the board and the solder. Then the strains were used to set boundary conditions for an explicit model that could simulate initiation and growth of cracks in the microstructure of the solder joint. Finally, on the basis of the growth rate of the cracks in the solder joint, estimates were made of the cycles to failure for the electronic component.

Nasser and Curtin [22] applied PHM methodology to predict failure of the power supply. They subdivided the power supply into component elements based on specific material characteristics. Predicted degradation within any single or combination of component elements could be rolled up into an overall reliability prediction for the entire power supply system. Their PHM technique consisted of five steps: (i) acquiring the temperature profile using sensors; (ii) conducting FEA to perform stress analysis; (iii) conducting fatigue prediction of each solder joint; and (iv) predicting the probability of failure of the power supply system.

Searls *et al.* [23] undertook *in situ* environment loading, such as temperature measurements, in both notebook and desktop computers used in different parts of the world. In terms of the commercial applications of this approach, IBM has installed temperature sensors on hard drives (Drive–TIP) [24] to mitigate risks due to severe temperature conditions, such as thermal tilt of the disk stack and actuator arm, offtrack writing, data corruptions on adjacent cylinders, and outgassing of lubricants on the spindle motor.

Vichare *et al.* [25, 26] also conducted *in situ* health monitoring of notebook computers. The authors monitored and statistically analyzed the temperatures inside a notebook computer, including those experienced during usage, storage, and transportation, and discussed the need to collect such data both to improve the thermal design of the product and to monitor prognostic health. After the data was collected, it could be used to estimate the distributions of the load parameters. The usage history was used for damage accumulation and remaining-life prediction.

The European Union funded a project from September 2001 through February 2005 named *Environmental Life-cycle Information Management and Acquisition* (ELIMA) for consumer products, which aimed to develop ways of better managing the life cycles of products. It used technology to collect vital information during a product's life to lead to better and more sustainable products [27, 28]. The objective of this work was to provide a basic model for predicting the remaining lifetime of parts removed from products, based on the dynamic data collected by the ELIMA system. The ELIMA technology included sensors and memory built into the

product to record dynamic data such as operation time, temperature, and power consumption. This was added to static data about materials and manufacturing. As a case study, the member companies monitored the application conditions of a game console and a household refrigerator. The work concluded that for the remaining-lifetime prediction, in general, it was essential that the environments associated with all life intervals of the equipment be considered. These included not only the operational and maintenance environments but also the preoperational environments, when stresses imposed on the parts during manufacturing, assembly, inspection, testing, shipping, and installation might have a significant impact on the eventual reliability of the equipment. Stresses imposed during the preoperational phase were often overlooked.

Tuchband and Pecht [29] presented the use of prognostics for military line replaceable units (LRUs) based on their life-cycle loads. The study was part of an effort funded by the Office of the Secretary of Defense to develop an interactive supply chain system for the US military. The objective was to integrate prognostics, wireless communication, and databases through a web portal to enable cost-effective maintenance and replacement of electronics. This study showed that prognostics-based maintenance scheduling could be implemented into military electronic systems. The approach involves an integration of embedded sensors on the LRU, wireless communication for data transmission, a PoF-based algorithm for data simplification and damage estimation, and a method for uploading this information to the Internet. Finally, the use of prognostics for electronic military systems enabled failure avoidance, high availability, and reduction of life-cycle costs.

3 CANARY DEVICES APPROACH

Canary devices mounted on the actual product have been used to provide advance warning of failure due to specific wearout failure mechanisms. The word "canary" is derived from one of coal mining's earliest systems for warning of the presence of hazardous gas using the canary bird. Because the canary is more sensitive to hazardous gases than humans, the death or sickening of the canary was an indication to the miners to get out of the shaft. The same approach, using canaries, has been employed in PHM. Canary devices were integrated into a specific component, device, or system design and incorporated failure mechanisms that occur first in the embedded device. These embedded canary devices (also called *prognostics cell*) were noncritical elements of the overall design providing early incipient failure warnings before actual system or component failure [12].

Mishra and Pecht [30] studied the applicability of semiconductor level health monitors by using precalibrated cells (circuits) located on the same chip with the actual circuitry. The prognostics cell approach was commercialized by Ridgetop Group to provide an early warning sentinel for upcoming device failures [31]. The prognostic cells were available for 0.35, 0.25, and 0.18 μm CMOS processes. The time to failure of these prognostic cells could be precalibrated with respect to the time to failure of the actual product. The stresses that contributed to degradation of the circuit included voltage, current, temperature, humidity, and radiation. Since the operational stresses were the same, the damage rate was expected to be the same for both the circuits. However, the prognostic cell was designed to fail earlier owing to increased stress on the cell structure by means of scaling. For example, scaling could be achieved by controlled increase of the current density inside the cells. With the same amount of current passing through both circuits, if the cross-sectional area of the current-carrying paths in the cells was decreased, a higher current density was achieved. Both the structure and the loading could be scaled. Further control in current density could be achieved by increasing the voltage level applied to the cells. Higher current density led to higher internal heating, causing greater stress on the cells. When a current of higher density passed through the cells, they were expected to fail faster than the actual circuit [30]. Currently, prognostic cells are available for semiconductor failure mechanisms such as electrostatic discharge (ESD), hot carrier, metal migration, dielectric breakdown, and radiation effects.

The extension of this approach to board-level failures was proposed by Anderson and Wilcoxon [32], who created canary components (located on the same PCB) that include the same mechanisms that lead to failure in actual components. Anderson *et al.*, identified two prospective failure mechanisms: (i) low

cycle fatigue of solder joints, assessed by monitoring solder joints on and within the canary package; and (ii) corrosion monitoring using circuits that are susceptible to corrosion. The environmental degradation of these canaries was assessed using accelerated testing, and degradation levels were calibrated and correlated to actual failure levels of the main system.

Goodman *et al.* [33] used a prognostic cell to monitor time-dependent dielectric breakdown (TDDB) of the metal-oxide semiconductor field-effect transistor (MOSFET) on the integrated circuits. The prognostic cell was accelerated to failure under certain environmental conditions. Acceleration of the breakdown of an oxide could be achieved by applying a voltage higher than the supply voltage, to increase the electric field across the oxide. When the prognostics cell failed, a certain fraction of the circuit lifetime was used up. The fraction of consumed circuit life was dependent on the amount of overvoltage applied and could be estimated from the known distribution of failure times.

4 PoF-BASED PHM IMPLEMENTATION APPROACH

The general PHM methodology is summarized in CALCE and shown in Figure 1. It includes two main parts: virtual life assessment and real prognostics assessment. Design data, expected life cycle, failure modes, mechanisms, and effects analysis (FMMEA), and PoF models can be the input for the virtual life assessment to get a better reliability assessment based on the historical and current data. The next step is to get the *in situ* sensor data, bus monitor data, diagnostics data, and maintenance records for prognostics assessment in real product life cycles. Three methodologies for *in situ* prognostics assessment include (i) the use of expendable devices, such as "canaries" and fuses that fail earlier than the host product to provide advance warning of failure; (ii) the monitoring of parameters and the extraction of features that are precursors to impending failure [34]; and (iii) the use of stress and damage models that employ life-cycle loads (e.g., usage conditions, temperature, vibration, radiation). Approaches 1 and 3 are PoF related [16], so in this article, the focus is on detailed PoF-based prognostics, which is discussed in a later paragraph.

The PoF methodology is founded on the premise that failures result from fundamental mechanical, chemical, electrical, thermal, and radiation processes. The objective of the PoF methodology in the PHM process is to calculate the cumulative damage accumulation due to various failure mechanisms for a product in a given environment. The approach to implement PoF into PHM can be based on the FMMEA, which is shown in Figure 2. This approach

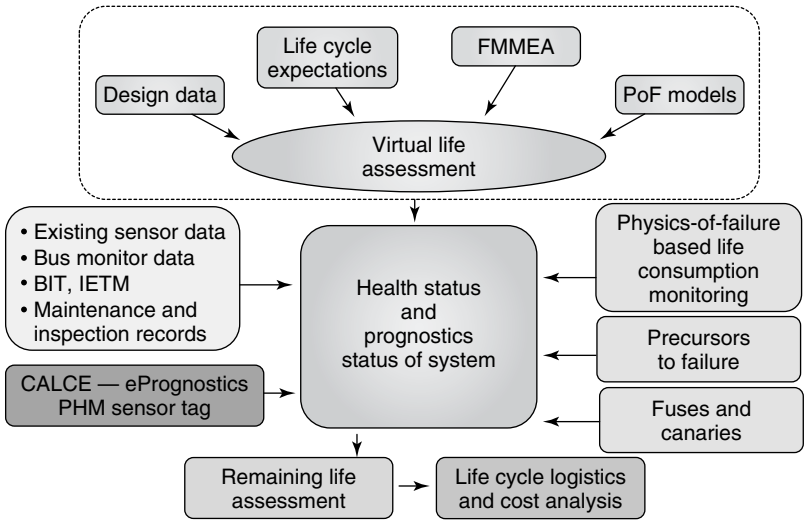

Figure 1. CALCE PHM methodology.

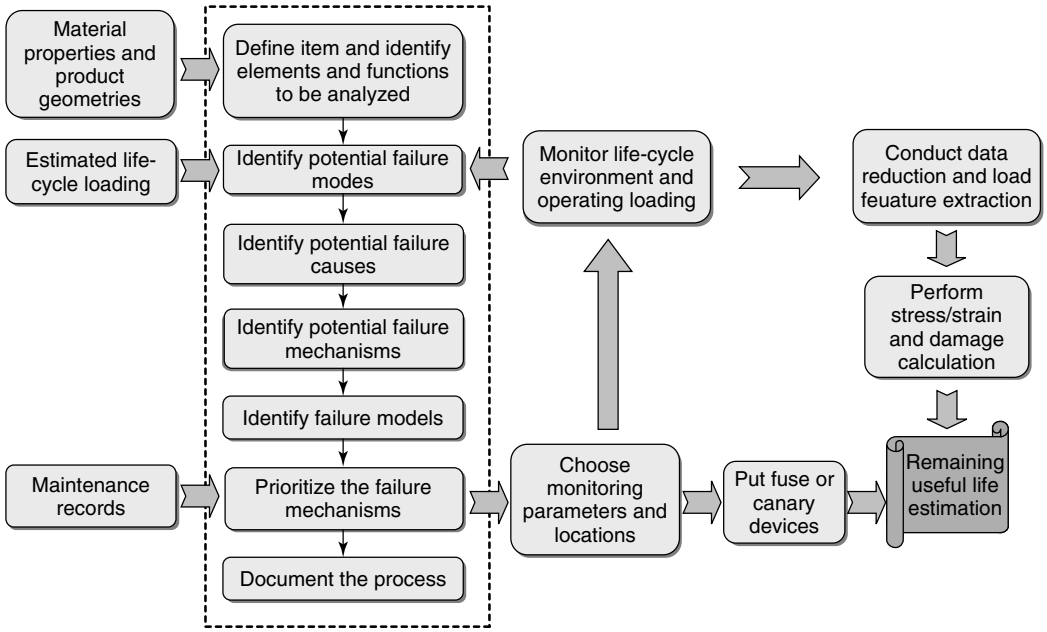

Figure 2. FMMEA-based PHM approach.

consists of design capture, identification of potential failure, and reliability assessment [15].

Design capture is the process of collecting structural (dimensional) and material information about a product to generate a model. This step involves characterizing the product at all levels, i.e., parts, systems, as well as physical interfaces. The potential failure identification step involves using the geometry and material properties of the product, together with the measured life-cycle loads acting on the product, to identify the potential failure modes, mechanisms, and failure sites in the product. This task is best performed through virtual qualification, which is a simulation-based methodology used to identify and rank the potential failure mechanisms. The reliability assessment step involves identification of appropriate PoF models for the identified failure mechanisms. A load–stress analysis is conducted using material properties, product geometry, and the life-cycle loads. With the computed stresses and the failure models, an analysis is conducted to determine the cycles to failure and then the accumulated damage is estimated using a damage model. Actually, the PoF methodology can provide a systematic approach to reliability assessment early in the design process.

4.1 Failure mode, mechanism, and effect analysis

A failure mode is the effect by which a failure is observed to occur [35]. It can also be defined as the way in which a component, subsystem, or system could fail to meet or deliver the intended function. All possible failure modes for each identified element should be listed. Potential failure modes may be identified using numerical stress analysis, accelerated tests to failure (e.g., HALT), past experience, and engineering judgment. The failure mode needs to be observable directly by methods such as visual inspection, electrical measurement, or other tests and measurements.

A failure cause is defined as the specific process, design, and/or environmental condition that initiated the failure, whose removal will eliminate the failure. Knowledge of potential failure causes can help identify the failure mechanisms driving the failure modes for a given element. One method of looking for causes is to review the life-cycle loads item by item to evaluate whether any of the loads there can cause the failure.

Failure mechanisms are the physical, chemical, thermodynamic, or other processes that result in

Table 1. Failure mechanisms, relevant loads, and models in electronics

Failure mechanisms	Failure sites	Relevant loads	Failure models
Fatigue	Die attach, wirebond/TAB, solder leads, bond pads, traces, vias/PTHs, interfaces	ΔT, T_{mean}, dT/dt, dwell time, ΔH, ΔV	Nonlinear power law (Coffin–Manson)
Corrosion	Metallizations	M, ΔV, T	Eyring (Howard)
Electromigration	Metallization	T, J	Eyring (Black)
Conductive filament formation	Between metallization	M, ∇V	Power law (Rudra)
Stress driven diffusion voiding	Metal traces	S, T	Eyring (Okabayashi)
Time-dependent dielectric breakdown	Dielectric layers	V, T	Arrhenius (Fowler–Nordheim)

Δ, cyclic range; V, voltage; T, temperature; S, stress; ∇, gradient; M, moisture; J, current density; H, humidity.

failure. Failure mechanisms are categorized as either overstress or wearout mechanisms. Overstress failure arises because of a single load (stress) condition, which exceeds a fundamental material strength. Wearout failure arises because of cumulative damage due to loads (stresses) applied over an extended time or number of cycles. Within current technology, PHM can only be applied in the wearout failure mechanisms. Typical wearout failure mechanisms for electronics have been summarized in Table 1 [36].

Failure models help quantify the failure through evaluation of time to failure or likelihood of a failure for a given geometry, material construction, environmental, and operational condition. For wearout mechanisms, failure models use both stress and damage analysis to quantify the damage accumulated in the product.

When using the canary devices PHM approach, the geometries or material properties of the prognostics cell can be scaled to accelerate the failure under user conditions, on the basis of potential failure mechanisms. When using the modeling of stress and damage approach, environmental and usage load profiles are captured using sensors. Sensor data is then converted into a format that can be used in the failure models.

In the life cycle of a product, several failure mechanisms may be activated by different environmental and operational parameters acting at various stress levels, but, in general, only a few operational and environmental parameters, and failure mechanisms, are responsible for most failures. High priority mechanisms are those with high combinations of occurrence and severity. Prioritization of the failure mechanisms provides an opportunity for effective utilization of resources.

4.2 Life-cycle loading monitoring

The life-cycle environment of a product consists of manufacturing, shipment, storage, handling, operating, and nonoperating conditions. The life-cycle loads (thermal, mechanical, chemical, electrical, and so on), either individually or in various combinations, may lead to performance or physical degradation of the product and may reduce its service life [1]. The extent and rate of product degradation depends on the magnitude and duration of exposure (usage rate, frequency, and severity) of such loads. If one can measure these loads *in situ*, the load profiles can be used in conjunction with damage models to assess the degradation due to cumulative load exposures. The typical life-cycle loads have been summarized in Table 2 [12].

4.3 Data reduction and load feature extraction

Experience has shown that even the simplest data collection systems can accumulate vast amounts of data quickly, requiring either a frequent download procedure or a large-capacity storage device [37].

Table 2. Life-cycle loads

Load	Load conditions
Thermal	Steady-state temperature, temperature ranges, temperature cycles, temperature gradients, ramp rates, heat dissipation
Mechanical	Pressure magnitude, pressure gradient, vibration, shock load, acoustic level, strain, stress
Chemical	Aggressive versus inert environment, humidity level, contamination, ozone, pollution, fuel spills
Physical	Radiation, electromagnetic interference, altitude
Electrical	Current, voltage, power

The main reasons for using data reduction in life-consumption monitoring are reduction of storage space; reduction in data-logger CPU load; and alignment with life-prediction models. The efficiency measures of data reduction methods should consider gains in computing speed and testing time; the ability to condense load histories without sacrificing important damage characteristics; and estimation of the error introduced by omitting data points.

The CALCE group has studied the accuracy associated with a number of data reduction methods such as ordered overall range (OOR), rainflow cycle counting, range-pair counting, peak counting, level crossing counting, fatigue meter counting and range counting.

Embedding the data reduction and load parameter extraction algorithms in to the sensor modules as suggested by Vichare *et al.* [25] can lead to a reduction in on-board storage space, lower power consumption, and uninterrupted data collection over longer durations. As shown in Figure 3, a time–load signal can be monitored *in situ* using sensors, and further processed to extract (in this case) cyclic range (Δs), cyclic mean load (S_{mean}), rate of change of load ($\mathrm{d}s/\mathrm{d}t$), and dwell time (t_{D}) using embedded load extraction algorithms. The extracted load parameters can be stored in appropriately binned histograms to achieve further data reduction. After the binned data is downloaded, it can be used to estimate the distributions of the load parameters. This type of output can be readily input into fatigue damage accumulation models.

In Vichare's study [26, 38], the temperature data was processed using two algorithms: (i) OOR to convert an irregular time–temperature history into peaks and valleys and also to remove noise due to small cycles and sensor variations and (ii) a three-parameter rainflow algorithm to process the OOR results to extract full and half cycles with cyclic range, mean, and ramp rates. The approach also involved optimally binning data in a manner that provides the best estimate of the underlying probability density

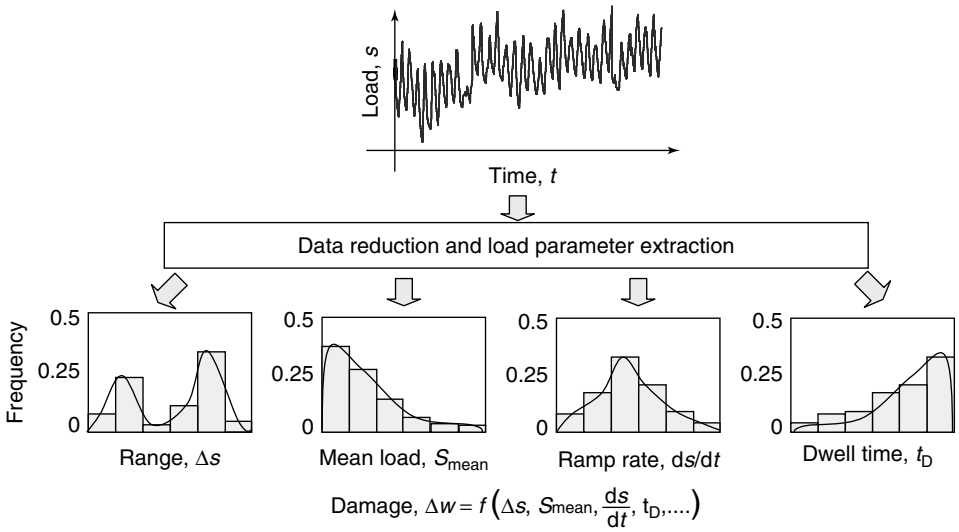

Figure 3. Load feature extraction.

function of the load parameter. The load distributions were developed using nonparametric histogram and kernel density estimation methods. The use of the proposed binning and density estimation techniques with a prognostic methodology was demonstrated on an electronic assembly.

4.4 Damage assessment and remaining-life calculation

Temperature and vibration are the most common causes of electronics failure [38]. The PoF models used to calculate the damage caused by temperature and vibration loadings are summarized in Figure 4. Damage caused by temperature can be calculated in time domain using Coffin–Manson's model. This approach has been demonstrated by Mishra *et al.* [16], Vichare *et al.* [39], and Cluff *et al.* [40]. Damage caused by vibration can be calculated in both time and frequency domains. The time domain, which has been demonstrated by Gu *et al.* [20], can use Basquin's model. The frequency domain, which has been demonstrated by Mishra *et al.* [16], can use first-order Steinberg's model [41].

4.5 Uncertainty implementation and assessment

The PoF model can be used to calculate the remaining useful life. However, it may still not be possible to make logistics decisions with certainty. Hence, it is necessary to identify the uncertainties in the prognostic approach and assess the impact of these uncertainties on the remaining-life distribution to make risk-informed decisions. Uncertainty analysis for prognostics implementations gives the prediction more meaning. With uncertainty analysis, a prediction can be expressed as a distribution rather than a single point. The prediction can be expressed as a failure probability.

Gu *et al.* [42] implemented the uncertainty analysis of prognostics for electronics under vibration loading. Gu identified the uncertainty sources and categorized them into four different types: measurement uncertainty, parameter uncertainty, failure criteria uncertainty, and future usage uncertainty. Then, the approach for implementing the uncertainty analysis was presented and shown in Figure 5 [42]. It utilized a sensitivity analysis to identify the dominant input variables that influence the model output. With information of input parameter variable distributions, a Monte Carlo simulation was used to provide a distribution of the accumulated damage. From the accumulated damage distributions, the remaining life was then predicted with confidence intervals. A case study was also presented, which used an experiment with an electronic board under vibration loading and a step by step demonstration of the uncertainty analysis implementation. The results showed that the experimentally measured failure time was within the bounds of the uncertainty analysis prediction.

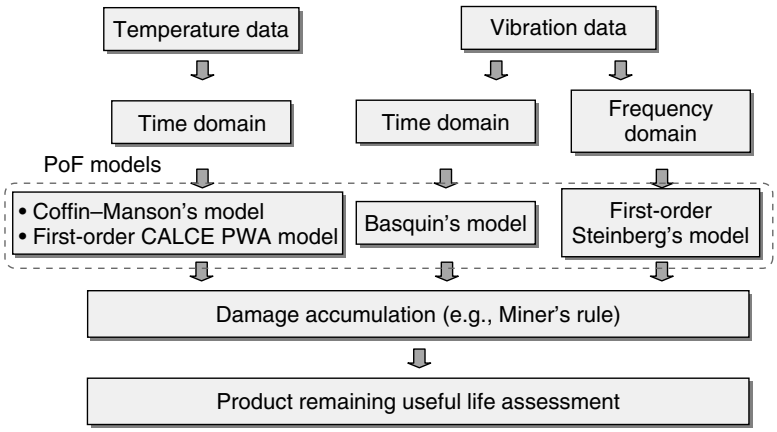

Figure 4. Damage calculation approach for temperature and vibration data.

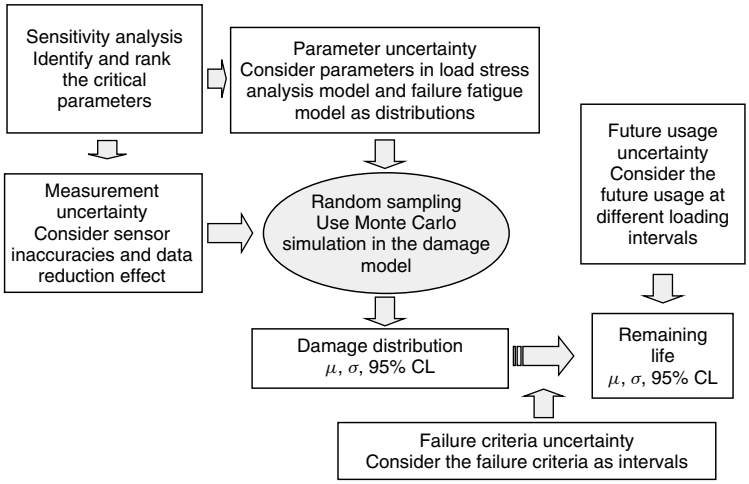

Figure 5. Uncertainty implementation for prognostics.

5 APPLICATION OF PoF IMPLEMENTATION FOR PHM

Prognostics based on the PoF model can be used in different areas, such as new products, legacy systems, and storage reliability prediction. Examples are discussed in the following paragraphs, along with a comparison of PoF-based PHM and data-driven-based PHM.

If the new product has not been manufactured, it is impossible to use the data-driven method since there will be no data available for training the algorithm. The PoF method normally only needs to change the material properties or geometries to model the new products, since most new products are not brand new and they have several previous versions or similar products can be referenced. Then it can save the time for performing prognostics for new products. On the other hand, the PoF approach makes it possible to give guidance for new product designs. The PoF approach incorporates reliability into the design process by establishing a scientific basis for evaluating new materials, structures, and electronics technologies. In addition, it can give feedback (such as failure site and failure mode) from life-cycle monitoring. Therefore PoF-based PHM is suitable for new products, and it reduces the design margin.

The legacy system continues to be used because of the prohibitive time and/or cost of replacing or redesigning it, though it is often less competitive and less compatible with modern equivalents [43]. Legacy systems can be found in both military and commercial sectors. PoF-based PHM to legacy systems can provide significant benefits. In the meantime, the data-driven approach lacks sufficient data to train the algorithm. Few legacy systems are in existence, and thus there are no extras for training purpose. The PoF-based PHM approach is based on an understanding of the life-cycle conditions of the legacy system and its failure modes and mechanisms. The first step is to use all available information (such as previous loading conditions, maintenance records, and so on) to assess the health status of the legacy system. The second step is to calibrate the health status using individual unit data so that an assessment of individual legacy systems' health can be derived. The third step involves the use of sensors and prognostic algorithms to update the health status on a continual basis to provide the most up-to-date prognosis of the system [44].

Improper storage is one factor that can precipitate failures in electronic products, especially in a hostile environment [45]. The temperature and humidity of storage areas are typically prime environmental factors. The extent and rate of product degradation depends upon the magnitude and duration of exposure (usage rate, frequency, and severity) to such loads. If one can measure these loads *in situ*, the load profiles can be used in conjunction with damage models to assess the degradation due to cumulative load exposures. Depending on the quality of the storage spaces,

environmental factors such as vibration, shock, fungi, sand and dust, and radiation might also come into the picture. Hence, the PoF-based PHM method is ready to be implemented. In the meantime, the limitation for the data-driven approach is that it can only detect failure when near the failure point. It is difficult to assess the remaining life from the beginning or middle of storage. The PoF approach will be more suitable since, for storage conditions, the loading will not change frequently, and dwell loading will become the dominant effect. On the basis of the PoF model, it is possible to assess the product reliability after a period of being stored, to indicate the remaining life, and to determine whether it can survive the next mission.

6 CONCLUSIONS

Traditional reliability predictions based on handbook methods are generally inaccurate and misleading. In this article, we have shown that PoF-based PHM is more suitable for reliability assessment. PHM can provide previously unknown information on life-cycle environmental and operational conditions, and previously unknown information on failure modes and mechanisms. It can also help prevent premature failures, and provide information on remaining life. In the future, owing to the increasing amount of electronics in the world and the competitive drive toward more reliable products, PoF-based PHM is being looked upon as a cost-effective solution to improve the reliability of electronic products and systems. Currently, more research should be focused on building physics-based damage models for electronics, obtaining the life-cycle data of product, and assessing uncertainty in remaining useful life prediction to make the PHM more realistic. Along with that, advance sensor technologies, communication technologies, decision making methods, and return of investment methods also need to be investigated.

1 INTRODUCTION

High-strength, multiwire steel strands are widely used in civil engineering such as prestressed concrete structures and cable-stayed or suspension bridges. Material degradation of the strands, usually consisting of indentations, corrosion, or even fractured wires, may result in a reduced load-carrying capacity of the structure that can lead to collapse. A survey involving the study of more than 100 stay-cable bridges [1] pessimistically reported that most of them were in danger mainly because of cable defects. Strand failures that caused bridge collapses are well documented [2–4]. Hence, it is of interest to develop structural health monitoring systems for strands that can detect defects as well as monitor applied loads to alert on any prestress loss.

Techniques proposed to detect defects (corrosion or wire fractures) in cables and strands include magnetic flux leakage [5], time-domain reflectometry [6, 7], and methods based on elastic waves, namely, acoustic emission testing [8–13] and ultrasonic testing [8, 14–22]. For the purpose of monitoring stress levels in the strands, methods of testing include fiber-optic strain sensors [23, 24], modal analysis based on the vibrating cord theory [25–27], magnetic permeability measurements [28–31], and wave-based ultrasonic testing [32–38].

The ultrasonic testing technique for strands is normally applied as guided-wave testing because it exploits the strand's waveguide geometry. The advantages of this technique over the others mentioned above include (i) the possibility of using

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

transducers permanently attached to the strand for continuous structural monitoring, (ii) the potential for providing simultaneous defect detection and stress monitoring capabilities for the strands with the same sensing system, and (iii) the possibility for detecting both active defects and preexisting defects toggling between the modes of "passive" acoustic emission testing and "active" ultrasonic testing within the same sensing system.

This article presents recent advances in the area of multiwire strand monitoring by guided ultrasonic waves (GUW), focusing on the "active" mode involving external generation and detection of waves. Wave propagation models are first presented to predict the complicated dispersive solutions of the strand waveguide in both free and embedded configurations. Experimental results are then presented with application to defect detection and stress monitoring in free strands. For defect detection purposes, the proposed system uses magnetostrictive transducers, wavelet-based signal processing, and statistical pattern recognition. For stress monitoring purposes, the proposed approach uses piezoelectric transducers, which monitor the ultrasonic "cross talk" between individual wires comprising the strand. The potential and difficulties of the field implementation of the technique are discussed in Section 5.

2 WAVE PROPAGATION MODELS FOR HELICAL AND AXIS-SYMMETRIC WAVEGUIDES

Proper modeling of guided waves propagating in the strands is important to identify modes, enhance sensitivity to detects, and select low-loss mode–frequency combinations.

The semianalytical finite element (SAFE) method is an effective tool to model waveguides of arbitrary cross section [39–41]. Here, the SAFE method is used to model the multimode and dispersive behavior of guided waves in a free, seven-wire strand (a pretwisted waveguide) and in a rod embedded in grout and concrete (an axis-symmetric multilayer waveguide).

The results presented here pertain to modal solutions of the defect-free structure. Therefore, they are of some use in the design of a guided-wave monitoring system. An improvement can consist of studying the interaction of waves with defects, which requires a different modeling strategy (e.g., a local–global approach).

2.1 Free strand (pretwisted waveguide)

The single strand can be represented as a pretwisted waveguide, for which the formulation proposed in [42] can be used. The equations of motion for this structural component can be written using a body coordinate system (ξ, η, ζ) that is related to the fixed Cartesian framework (x, y, z) through the relations (Figure 1):

$$\begin{aligned} \xi &= x\cos(\alpha z) + y\sin(\alpha z) \\ \eta &= -x\sin(\alpha z) + y\cos(\alpha z) \\ \zeta &= z \end{aligned} \tag{1}$$

where α is the uniform rate of pretwist in the axial direction. The displacement vector ($\mathbf{u}$), strain vector ($\boldsymbol{\varepsilon}$), and stress field ($\boldsymbol{\sigma}$) at a point with respect to the body coordinate system are as follows:

$$\begin{aligned} \mathbf{u} &= \begin{bmatrix} u_\xi & u_\eta & u_\zeta \end{bmatrix}^{\mathrm{T}} \\ \boldsymbol{\varepsilon} &= \begin{bmatrix} \varepsilon_{\xi\xi} & \varepsilon_{\eta\eta} & \varepsilon_{\zeta\zeta} & \varepsilon_{\eta\zeta} & \varepsilon_{\xi\zeta} & \varepsilon_{\xi\eta} \end{bmatrix}^{\mathrm{T}} \\ \boldsymbol{\sigma} &= \begin{bmatrix} \sigma_{\xi\xi} & \sigma_{\eta\eta} & \sigma_{\zeta\zeta} & \sigma_{\eta\zeta} & \sigma_{\xi\zeta} & \sigma_{\xi\eta} \end{bmatrix}^{\mathrm{T}} \end{aligned} \tag{2}$$

Linear strain compatibility relations and constitutive equations can be summarized as

$$\boldsymbol{\varepsilon} = \mathbf{L}_{\xi\eta}\mathbf{u} + \mathbf{L}_{\zeta}\mathbf{u} \quad \boldsymbol{\sigma} = \tilde{\mathbf{C}}\boldsymbol{\varepsilon} \tag{3}$$

where $\tilde{\mathbf{C}}$ is the complex constitutive matrix that describes the viscoelastic properties of the material [41] while $\mathbf{L}_{\xi\eta}$ and $\mathbf{L}_{\zeta}$ are differential operators as defined in [42]. The weak form of the governing balance equation for the given structure can be obtained via Hamilton's variational principle:

$$\begin{aligned} \delta \int_{t_1}^{t_2} \Bigg(\frac{1}{2} \int_{\zeta} \Bigg\{ \iint_{\Omega} \rho \dot{\mathbf{u}}^{\mathrm{T}} \dot{\mathbf{u}} \, \mathrm{d}\xi \, \mathrm{d}\eta \\ - \iint_{\Omega} \boldsymbol{\varepsilon}^{\mathrm{T}} \tilde{\mathbf{C}} \boldsymbol{\varepsilon} \, \mathrm{d}\xi \, \mathrm{d}\eta \Bigg\} \, \mathrm{d}\zeta \Bigg) \, \mathrm{d}t = 0 \end{aligned} \tag{4}$$

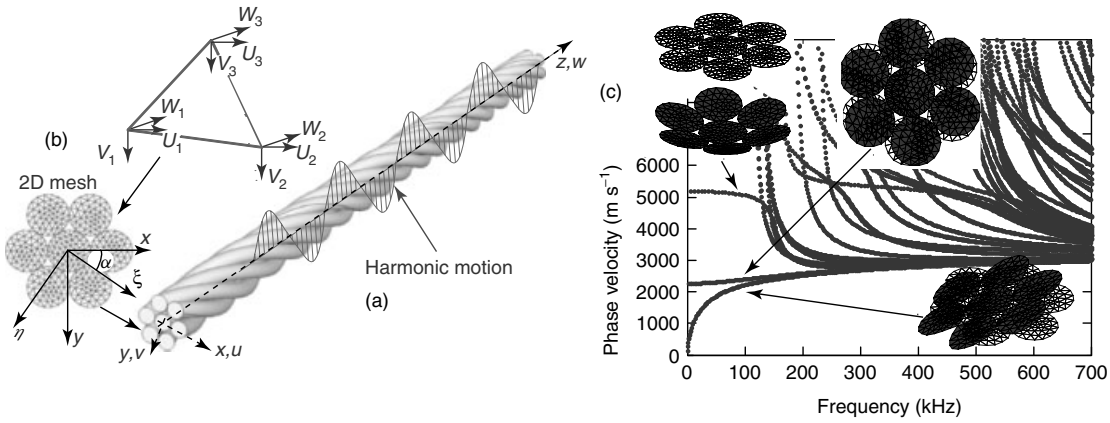

Figure 1. SAFE method. (a) Pretwisted waveguide representing a seven-wire strand, (b) generic element of the surface Ω, and (c) phase velocities and mode shapes for the strand at 100 kHz.

where a dot indicates derivative with respect to the time variable t, ρ is the mass density, and Ω is the area of the waveguide cross section. Assuming a harmonic motion along the propagation direction, $z \equiv \zeta$, and interpolating the displacement components over the cross section by standard finite element method, the approximated displacement field in the eth element takes the form

$$\mathbf{u}^{(e)} = \begin{bmatrix} \sum_{n=1}^{N} N_n(\xi,\eta) U_{\xi n} \\ \sum_{n=1}^{N} N_n(\xi,\eta) U_{\eta n} \\ \sum_{n=1}^{N} N_n(\xi,\eta) U_{\zeta n} \end{bmatrix}^{(e)} e^{\mathrm{i}(k\zeta - \omega t)} = \mathbf{N}(\xi,\eta)\mathbf{q}^{(e)} e^{\mathrm{i}(k\zeta-\omega t)} \tag{5}$$

where k is the guided-wave wavenumber and ω is the circular frequency.

Equation (5) is the core of the SAFE method where i represents the imaginary unit, $\mathbf{q}^{(e)}$ is the displacement vector of the eth element with nodal displacement components $U_n = U_{\xi n}$, $V_n = U_{\eta n}$, $W_n = U_{\zeta n}$, and $\mathbf{N}$ is the shape function matrix. Substitution of the last expression in the Hamilton's principle and subsequent standard finite element assembling result in the following wave equation:

$$\left[k^2\mathbf{K}_1 + \mathrm{i}k\mathbf{K}_2 + \mathbf{K}_3 - \omega^2\mathbf{M}\right]_M \mathbf{Q} = \mathbf{0} \tag{6}$$

with M as the number of total degrees of freedom of the cross-sectional mesh. For the sake of brevity, expressions of the stiffness matrices $\mathbf{K}_1$, $\mathbf{K}_2$, $\mathbf{K}_3$, and mass matrix $\mathbf{M}$ are not shown here but can be found, for example, in [42]. The eigenvalue problem in equation (6) is a two-parameter $(k-\omega)$ eigensystem. If material damping is neglected and only propagative modes are of interest, the wavenumber can be assigned as a real number and ω is adopted as eigenvalue parameter. Thus, for each wavenumber k in input, M eigenfrequencies ω_m and M eigenvectors $\mathbf{Q}_m$ are obtained, corresponding to propagating waves. Once ω_m is known, the dispersion curves can be easily computed. The phase velocity for the mth mode can be evaluated by the expression $c_{\mathrm{ph}} = \omega_m / k$. $\mathbf{Q}_m$ describe the cross-sectional mode shapes of the mth mode.

This formulation was adopted to study the dispersion properties of the structural component shown in Figure 1(a). The waveguide is a 15.24-mm-diameter (0.6-in.), high-strength steel grade 270, seven-wire strand. The pitch of the helical wire is equal to $p = 17 \times$ diameter and the material has the following nominal properties: bulk longitudinal velocity $c_{\mathrm{L}} = 5960\,\mathrm{m\,s^{-1}}$, bulk shear velocity $c_{\mathrm{T}} = 3260\,\mathrm{m\,s^{-1}}$, and density $\rho = 7700\,\mathrm{kg\,m^{-3}}$. The

mesh, shown in Figure 1(b) and generated by Matlab's "pdetool", consists of 323 nodes and 512 triangular elements with linear interpolation displacement functions. The phase velocity dispersion curves are shown in Figure 1(c) up to a frequency of 700 kHz. Notice the complexity of the modes. Mode shapes computed by SAFE for the three fundamental modes (longitudinal, torsional, and flexural) are shown in the same plot. These results are important to select suitable modes in experimental tests, as well as to identify the modes being measured from their arrival times.

2.2 Rod embedded in grout and concrete (axis-symmetric waveguide)

The SAFE method can be used to study the case of a strand embedded in grout and concrete. In the case of embedded member, it is important to model the ultrasonic energy leakage into the surrounding medium. The objective is to identify mode–frequency combinations, which propagate within the strand with minimum attenuation losses. The strand is approximated here by a straight rod, since the focus is on the interlayer energy leakage. The attenuation dispersion curves can be obtained using complex stiffness matrices in the SAFE formulation as described in [41].

The embedded rod can be treated as an axis-symmetric multilayer waveguide. For axis-symmetric geometries, it is convenient to develop the wave equations by using a cylindrical reference system, with the cross section lying in the $r-\theta$ plane and the z axis being parallel to the longitudinal direction of the waveguide (Figure 2a). The displacement, strain, and stress vectors variables at a point of coordinates (r, θ, z) and time t are, in this case, defined as follows:

$$\begin{aligned} \mathbf{u}(r,\theta,z,t) &= \left[u_r u_\theta u_z\right]^{\mathrm{T}} \\ \boldsymbol{\varepsilon} &= \left[\varepsilon_{rr}\ \varepsilon_{\theta\theta}\ \varepsilon_{zz}\ \varepsilon_{\theta z}\ \varepsilon_{zr}\ \varepsilon_{r\theta}\right]^{\mathrm{T}} \\ \boldsymbol{\sigma} &= \left[\sigma_{rr}\ \sigma_{\theta\theta}\ \sigma_{zz}\ \sigma_{\theta z}\ \sigma_{zr}\ \sigma_{r\theta}\right]^{\mathrm{T}} \end{aligned} \tag{7}$$

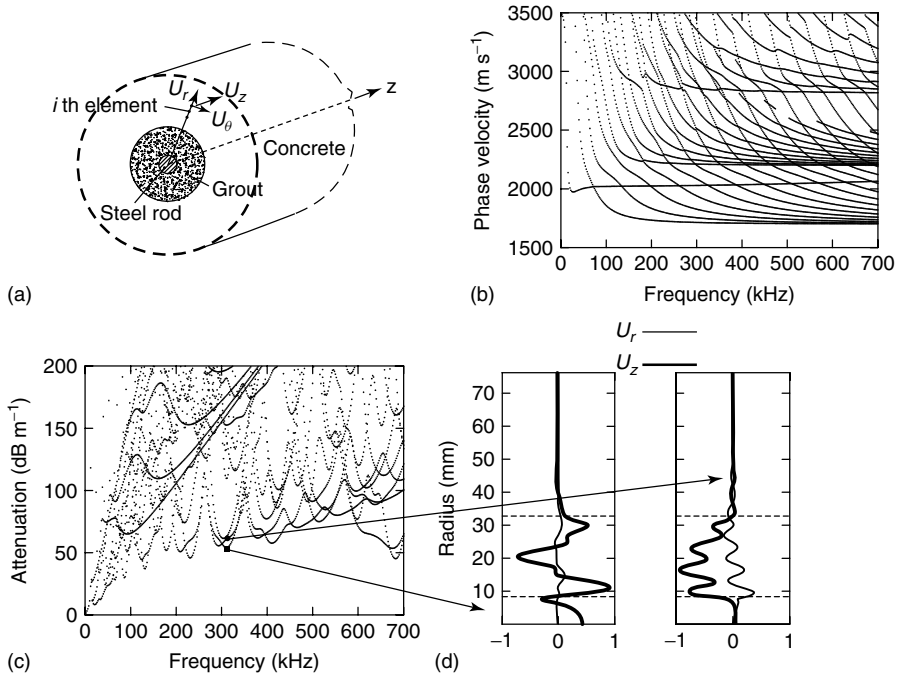

Figure 2. SAFE solutions for a 15.24-mm steel rod embedded in a 63.5-mm grout layer and a 152.4-mm concrete layer (axis-symmetric modes). (a) System modeled, (b) phase velocity curves, (c) attenuation curves, and (d) displacement mode shapes of two modes at low-loss points.

The mechanical variables in this equation are related by the compatibility and constitutive equations written in the cylindrical coordinate system

$$\boldsymbol{\varepsilon} = \mathbf{L}\mathbf{u} \quad \boldsymbol{\sigma} = \tilde{\mathbf{C}}\boldsymbol{\varepsilon} \tag{8}$$

where $\mathbf{L}$ is the compatibility matrix.

Subdividing the cross section into finite elements, the approximate displacement field in the element is

$$\mathbf{u}^{(e)} = \begin{bmatrix} \sum_{n=1}^{N} N_n(r) U_{rn} \\ \sum_{n=1}^{N} N_n(r) U_{\theta n} \\ \sum_{n=1}^{N} N_n(r) U_{zn} \end{bmatrix} e^{\mathrm{i}(n\theta + kz - \omega t)} = \mathbf{N}(r)\mathbf{q}^{(e)} e^{\mathrm{i}(n\theta + kz - \omega t)} \tag{9}$$

where n is the circumferential order of the mode, $\mathbf{N}(r)$ is the matrix of the shape functions, and $\mathbf{q}^{(e)}$ is the element's nodal displacement vector. The discretization is performed here only along the radial direction (r) using monodimensional elements owing to symmetry. Hamilton's principle can be used to generate the governing equations of motion:

$$\int_{t_1}^{t_2} \left\{ \int_z \int_0^{2\pi} \int_{R_\mathrm{i}}^{R_\mathrm{o}} \left[\delta\boldsymbol{\varepsilon}^{\mathrm{T}} \tilde{\mathbf{C}} \boldsymbol{\varepsilon} + \delta \mathbf{u}^{\mathrm{T}} (\rho \ddot{\mathbf{u}}) \right] r \, \mathrm{d}r \, \mathrm{d}\theta \, \mathrm{d}z \right\} \times \mathrm{d}t = 0 \tag{10}$$

where R_i and R_o are the waveguide inner and outer radius, respectively. The finite element procedure reduces equation (10) to a problem similar to the one in equation (6) [43]:

$$\left[k^2 \mathbf{K}_1 + kn\mathbf{K}_2 + ik\mathbf{K}_3 + n^2 \mathbf{K}_4 + in\mathbf{K}_5 + \mathbf{K}_6 - \omega^2 \mathbf{M} \right]_M \times \mathbf{Q} = \mathbf{0} \tag{11}$$

Nontrivial solutions of equation (11) can be obtained by solving a three-parameter ($n - k - \omega$) eigensystem. Herein, n is assigned to obtain the nth order axial symmetric modes and k is adopted as the eigenvalue parameter for a given frequency ω. The M-dimensional second-order eigenproblem for k can be solved by recasting equation (11) into a $2M$ first-order form as follows:

$$[\mathbf{A}(n, \omega) - k\mathbf{B}(n, \omega)]_{2M} \quad \mathbf{U} = \mathbf{0} \tag{12}$$

For details on the complex matrices $\mathbf{A}$ and $\mathbf{B}$ see, for example, [41]. For each frequency ω, $2M$ complex eigenvalues k_m and $2M$ complex eigenvectors $\mathbf{Q}_m$ are obtained, corresponding to right-propagating and left-propagating waves. The first M components of $\mathbf{Q}_m$ describe the cross-sectional mode shapes of the mth mode. In this case, the phase velocity for the mth mode can be evaluated as $c_{\mathrm{ph}} = \omega/\mathrm{Real}(k_m)$, where $\mathrm{Real}(k_m)$ is the real part of the wavenumber. The imaginary part of the wavenumber is the attenuation, $att = \mathrm{Imag}(k)$, in nepers per meter (8.686 dB).

Figure 2 shows the SAFE results for a 15.24-mm-diameter (0.6-in.) steel rod embedded in a 63.5-mm (2.5-in.) outer diameter layer of grout and a 152.4-mm (6-in.) outer diameter layer of concrete. By simply discretizing a radius of the multilayer waveguide, the SAFE routine efficiently computed phase velocity (Figure 2b), attenuation (Figure 2c), and cross-sectional mode shapes (Figure 2d). Material properties assumed in the simulation are summarized in Table 1. Only axis-symmetric modes ($n = 0$) are shown. Twenty-five quadratic elements were used to discretize each of the three layers. The particular displacement mode shapes plotted correspond to small attenuation losses of two modes at 310 kHz. It can be seen that no energy is present in the outer concrete layer at both of these low-loss points.

Table 1. Material properties used in the SAFE model of the steel rod embedded in grout and concrete

	Longitude velocity, c_L ($\mathrm{m\,s^{-1}}$)	Shear velocity, c_T ($\mathrm{m\,s^{-1}}$)	Density, ρ ($\mathrm{kg\,m^{-3}}$)	Longitude attenuation, κ_L (Np/wavelength)	Shear attenuation, κ_T (Np/wavelength)
Steel rod	5960	3260	7700	0.003	0.008
Grout layer	2810	1700	1600	0.043	0.100
Concrete layer	3758	2090	2152	0.186	0.229

However, one of the two modes generates substantial displacements within the steel rod. This kind of analysis can help in designing a structural monitoring system that concentrates the ultrasonic energy within the rod and maximizes the inspection range.

3 DEFECT DETECTION IN STRANDS

3.1 Experimental setup and procedure

Defect detection results will be presented for the grade 270, seven-wire twisted strand with a diameter of 15.24 mm (0.6 in.). A notch was machined, perpendicular to the strand axis, in one of the six peripheral wires by saw-cutting with depths increasing by 0.5-mm steps to a maximum depth of 3 mm (Figure 3). A final cut resulted in the complete fracture of the helical wire (broken wire (bw)), which was the largest defect examined corresponding to a depth of 5 mm. The smallest notch depth of 0.5 mm corresponded to a 0.7% reduction in the strand's cross-sectional area. The largest notch depth of broken wire corresponded to a 15.6% reduction in the strand's cross-sectional area.

The strand was subjected to a 120-kN tensile load, corresponding to 45% of the material's ultimate tensile strength (UTS). Magnetostrictive transducers resonant at 320 kHz were used to excite and detect longitudinal guided waves in the strand (Figure 3). This frequency was chosen since it is known to propagate with little losses in loaded, free strands [36]. The distance between the transmitting and the receiving transducers, d_1 in Figure 3, was fixed at 203 mm (8 in.) in all tests. By sliding the transmitter/receiver pair along the strand, tests were conducted at the five different notch-receiver distances, d in Figure 3, of 203 mm (8 in.), 406 mm (16 in.), 812 mm (32 in.), 1016 mm (40 in.), and 1118 mm (44 in.). The latter was the largest distance allowed by the rigid frame of the hydraulic loading. Five-cycle tonebursts centered at 320 kHz, modulated with a triangular window, were used as generation signals. Signals were acquired at a sampling rate equal to 33 MHz and stored after different number of digital averages, namely, 500, 50, 10, 5, 2, and 1 (single generation).

Two time windows were selected for the direct signal and the defect reflection measured by the receiver. The gated waveforms were then processed through the discrete wavelet transform (DWT) using the Daubechies of order 40 (db40) mother wavelet. For a 33-MHz sampling frequency, the 320-kHz frequency of interest was contained in the sixth level of DWT decomposition, according to

$$f_j = \Delta \times \frac{F}{2^j} \tag{13}$$

relating the reconstructed frequency f_j at level j to the center frequency F of the mother wavelet, the scale 2^j, and the signal sampling frequency Δ. Thus, the sixth level was the only one considered in the further analysis (pruning). Representative results of the pruning process are shown in Figure 4, presenting the signals reconstructed from the first six DWT detail decomposition levels ($D_1 - D_6$). The original signal was taken without any averages. The D_6 reconstruction correctly identifies (at around 140 μs) the reflection from a 2.5-mm-deep notch in the helical wire. Since levels 1–5 will merely reconstruct noise, they were eliminated in the DWT analysis process.

Subsequent to pruning, the sixth decomposition level was subjected to the thresholding process. The

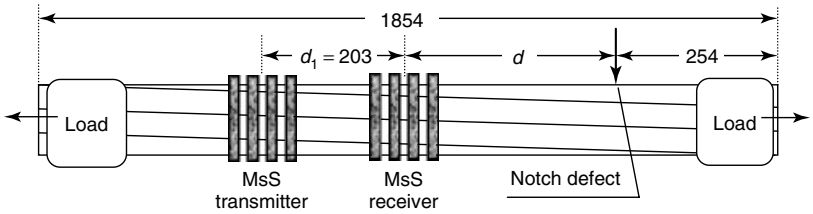

Figure 3. Experimental setup for defect detection in a strand using reflections of guided waves excited and detected by magnetostrictive transducers (dimensions in millimeter).

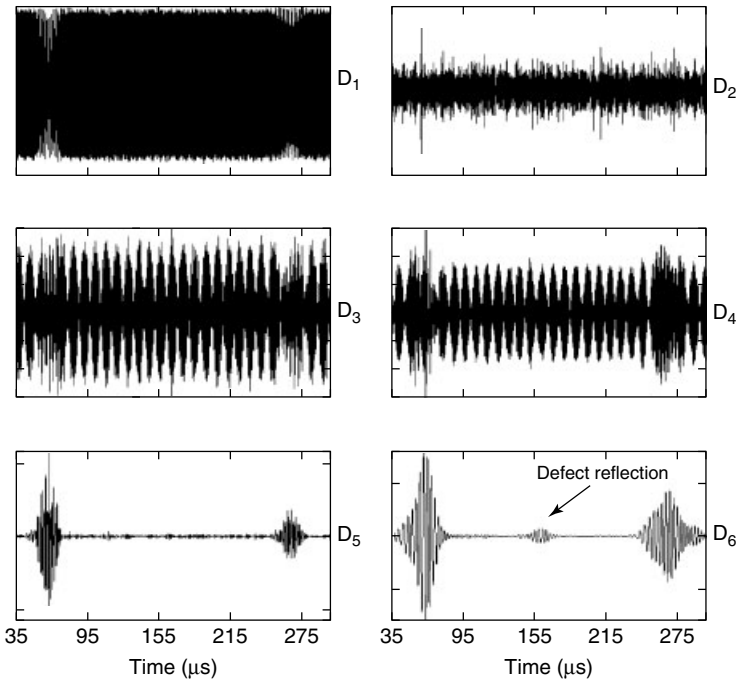

Figure 4. Signals reconstructed after pruning the DWT coefficients at the first six decomposition levels.

threshold chosen to select the relevant wavelet coefficients is an important variable that affects the sensitivity of the defect sizing. An optimum threshold combination for the direct signal and the defect reflection was searched on the basis of obtaining the largest sensitivity to defect size through a variance-based reflection coefficient. It was found that the larger sensitivities were obtained when setting more severe thresholds on the defect-reflected signals, with little effect of the thresholds imposed on the direct signal. On the basis of the findings in [20], optimum thresholds were fixed at 20% of the maximum wavelet coefficient amplitude for the direct signal, and at 70% of the same quantity for the defect reflection.

A "reflection" damage index (**DI**) vector was constructed from the ratios between certain features of the reflected signal, $F_{\text{reflection}}$, and the same features of the direct signal, F_{direct}:

$$\mathbf{DI} = \left[\frac{F_{\text{reflection},\, i}}{F_{\text{direct},\, i}} \right] \tag{14}$$

After parametric studies, the following four features were used to compute a four-dimensional **DI**: variance, root mean square, peak amplitude, and peak-to-peak amplitude of the thresholded wavelet coefficients at level six. All **DI** components showed a quite linear dependence in a semilogarithmic scale on the notch depth, and a relatively negligible dependence on the defect position for notches between 1.5 and 3 mm in depth. The experimental data for two of these components are shown in Figure 5. The results for very small notches, below 1 mm in depth, were less stable against varying distances owing to the poorer SNRs of the defect reflections. The results for the broken wire case (5-mm-deep notch) also showed an increased dependence on the notch-receiver distance, with **DI** components generally increasing for defects located further away from the receiver. This trend is opposite to what would be expected considering wave attenuation effects, and its origin is probably associated with the interference of multiple propagating modes that is distance dependent. It was also found that the **DI** component based on the variance of the wavelet coefficient vector (Figure 5) had the largest sensitivity to notch depth compared to all other components.

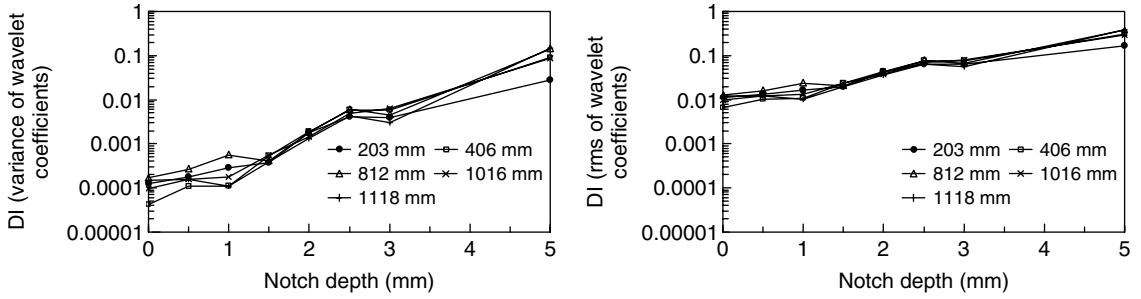

Figure 5. Components of the damage index vector measured from the variance and from the root mean square of the thresholded wavelet coefficients at the sixth decomposition level.

3.2 Statistical defect classification

A multivariate statistical analysis was performed to discriminate the defect indications from random noise, which may be present in the measurements. The Mahalanobis squared distance (MSD), D_ζ, was used as the discordancy test according to [44]:

$$D_\zeta = (\mathbf{x}_\zeta - \bar{\mathbf{x}})^{\mathrm{T}} \mathbf{K}^{-1} (\mathbf{x}_\zeta - \bar{\mathbf{x}}) \qquad (15)$$

where $\mathbf{x}_\zeta$ is the potential outlier vector, $\bar{\mathbf{x}}$ is the mean vector of the baseline, $\mathbf{K}$ is the covariance matrix of the baseline, and T represents a transpose matrix. In the present study, since the potential outliers were always known *a priori*, D_ζ was calculated exclusively without contaminating the statistics of the baseline data.

The baseline distribution was obtained from the ultrasonic signals stored after averaging over 10 acquisitions and corrupted by two different levels of white Gaussian noise. The noise signals were created by the MATLAB *randn* function. The random noise increased the sample population and simulated possible variations in SNR of the measurements that can be originated, in practice, by a number of factors including changing sensor/structure ultrasonic transduction efficiency, and changing environmental temperature affecting ultrasonic damping losses. The *randn* function generates arrays of random numbers whose elements are normally distributed with zero mean and standard deviation equal to 1. The function was premultiplied by a factor that determines the noise level. Factors equal to 0.01 and 0.1 were considered as "low noise" and "high noise", respectively. For each noise level, 300 baseline samples were created.

The same approach was taken to generate a large number of data for the damaged conditions. Six of the seven total notch sizes discussed in the previous section were considered. The 10 average signals acquired for each of the six defects were corrupted by the low noise level and the high noise level, generating a total of 300 samples for each damage size. These samples represented the testing data of the algorithm. A total of 2100 samples data were thus collected for each noise level. The added noise can be quantified in terms of SNR by the following expression:

$$SNR(\mathrm{dB}) = 10\ \mathrm{Log} \left[\frac{\sum_{i=1}^{N} s_i^2 \Big/ N}{\sum_{i=1}^{N} u_i^2 \Big/ N} \right] \qquad (16)$$

where s_i and u_i are the amplitudes of the ultrasonic signal and the noise signal, respectively, and N is the number of points. The SNR between the direct signal and the two 0.01 and 0.1 noise levels was about 43 and 23 dB, respectively. The SNR between the reflection from the 3-mm-deep notch and the two 0.01 and 0.1 noise levels was about 32 and 12 dB, respectively. Clearly, the latter two values decreased with decreasing notch depth.

3.3 Defect detection results—"low" noise

The MSD computed from the four-dimensional **DI** of all samples, including the baseline data and the damage data, calculated for the low noise level of

0.01 are summarized in Figure 6(a). The mean vector and the covariance matrix were determined from the 300 **DI** vectors associated with the undamaged condition of the strand. The horizontal line in this figure represents the 99.73% confidence threshold value of 21.579. Eight baseline samples are outliers, and thus false positive indications. Clear steps can be seen for increasing levels of damage. All damaged conditions were properly classified as outliers and thus there were no false negative indications. The MSD values showed good discrimination between all defect sizes, including the smallest notch depths, confirming that it is advantageous to combine multiple GUW features to provide a large sensitivity to the defects. Nevertheless, compared to previous multivariate outlier analyses in structural monitoring applications, the dimension of the **DI** was still kept at a very low value by selecting only four features of the DWT-processed wave signals.

3.4 Defect detection results—"high" noise

The MSD results of the **DI** corrupted with the high noise level of 0.1 are shown in Figure 6(b). The 99.73% confidence threshold was now computed as 18.137. Compared to the low noise results of Figure 6(a), it is clear that the heavier noise corruption compromises the ability to detect the notch depths below 2.0 mm, corresponding to a 5% reduction in strand's cross-sectional area. The ratios of correctly classified outliers below 5% area reduction were only 12/300, 7/300, and 1/300 for notch depths of 0.5, 1.0, and 1.5 mm, respectively. Above the 5% area reduction, the sensitivity to defect detection was also degraded with the increasing noise level; for example, the MSD values for the 2-mm-notch depth in Figure 6(b) are 4 orders of magnitude smaller than the corresponding values in Figure 6(a). The reduced

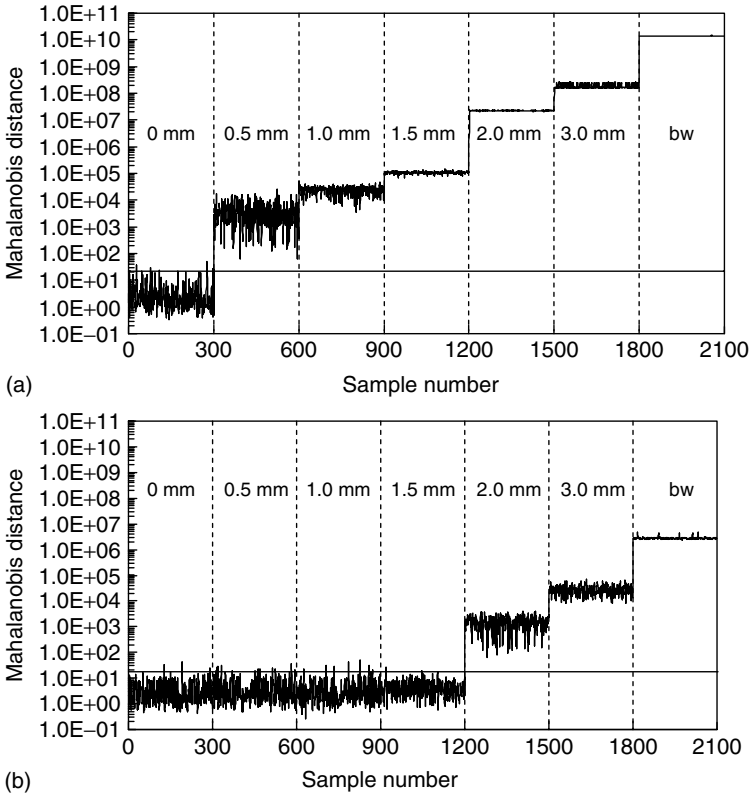

Figure 6. Mahalanobis squared distance for the baseline (undamaged) and damaged strand data corrupted with the low-level noise (a) and the high-level noise (b).

Table 2. Results of defect detection from outlier analysis: number of outliers $n/300$ for the various damage sizes and two levels of noise

Noise level	Damage size (notch depth, mm)						
	0	1.5	1	1.5	2	3	5.0 (bw)
0.01	8/300	300/300	300/300	300/300	300/300	300/300	300/300
0.1	3/300	12/300	7/300	1/300	300/300	300/300	300/300

number of false positive indications (three against eight) is the only improvement over the low noise level.

Table 2 summarizes the number of outliers detected in the multivariate analyses for both levels of noise considered; the outliers are false positive indications for the baseline data (damage size 0) and, instead, correct indications of anomalies for the defect data.

4 STRESS MONITORING IN STRANDS

It is known that the application of an axial load to a multiwire strand generates radial forces between the individual wires comprising the strand [45]. After extensive studies of wave propagation in loaded seven-wire strands, it was determined that the most effective strategy for stress measurement is one which monitors the ultrasonic "cross talk" between the peripheral and the central wires as a function of applied axial load. For this purpose, ultrasonic transmitters and receivers must be small enough to probe the individual wires. Two ultrasonic features, which are presented in the following sections, were found suitable for monitoring applied stress in free, seven-wire strands. These are the interwire energy leakage and the interwire frequency shift.

4.1 Experimental setup and procedure

Tests were performed at UCSD's Powell Labs on a SATEC M600XWHVL, 600 kips capacity, pneumatic test apparatus configured for tensile loading. A single specimen, again the grade 270 seven-wire strand ($UTS = 1.86$ GPa), was tested at a length of 1.82 m (72 in.). Figure 7(a) shows a picture of the strand on the testing machine.

A variety of ultrasonic transducers were installed on the specimen as shown in Figure 7(b). The focus here is on the piezoelectric (PZT) transmitter installed on a peripheral wire, PZT 3 in Figure 7(b), and on the two piezoelectric sensors installed at the strand's bottom end, PICO(C) and PICO(P) in Figure 7(b). Pictures of these transducers are also shown in Figure 7(c). PZT 3 was a 10 mm $\times$ 3 mm, rectangular piezoelectric plate, which excited waves in the peripheral wire. The waves were detected at the strand's end by both sensor PICO(C) (Physical Acoustics Corporation), installed on the central wire, and sensor PICO(P) installed on the same peripheral wire as PZT 3.

Load–unload cycles were performed with 11 load steps in each cycle. The steps were based on 70% of ultimate load or 182.4 kN (41 kips), consisting of a 0%, 20% (8.2 kips), 40% (16.4 kips), 60% (24.6 kips), 80% (32.8 kips), 100% (41.0 kips), and down to 80, 60, 40, 20, and 0%.

At each load step, the excitation frequency to PZT 3 was swept in the ranges 50–700 kHz and 700 kHz–2 MHz with a ~300-V peak-to-peak, 3-cycle Hanning-modulated toneburst. The signals measured by PICO(C) and PICO(P) were acquired and analyzed using a National Instruments data-acquisition unit.

4.2 Stress monitoring results—interwire energy leakage feature

The amount of ultrasonic energy leaking from the peripheral wire to the central wire was expected to increase with increasing load applied to the strand as a result of the increasing interwire contact. The "interwire energy leakage" feature was calculated as the ratio between the root mean square (rms) of the central wire signal from PICO(C) and the root mean square of the peripheral wire signal from

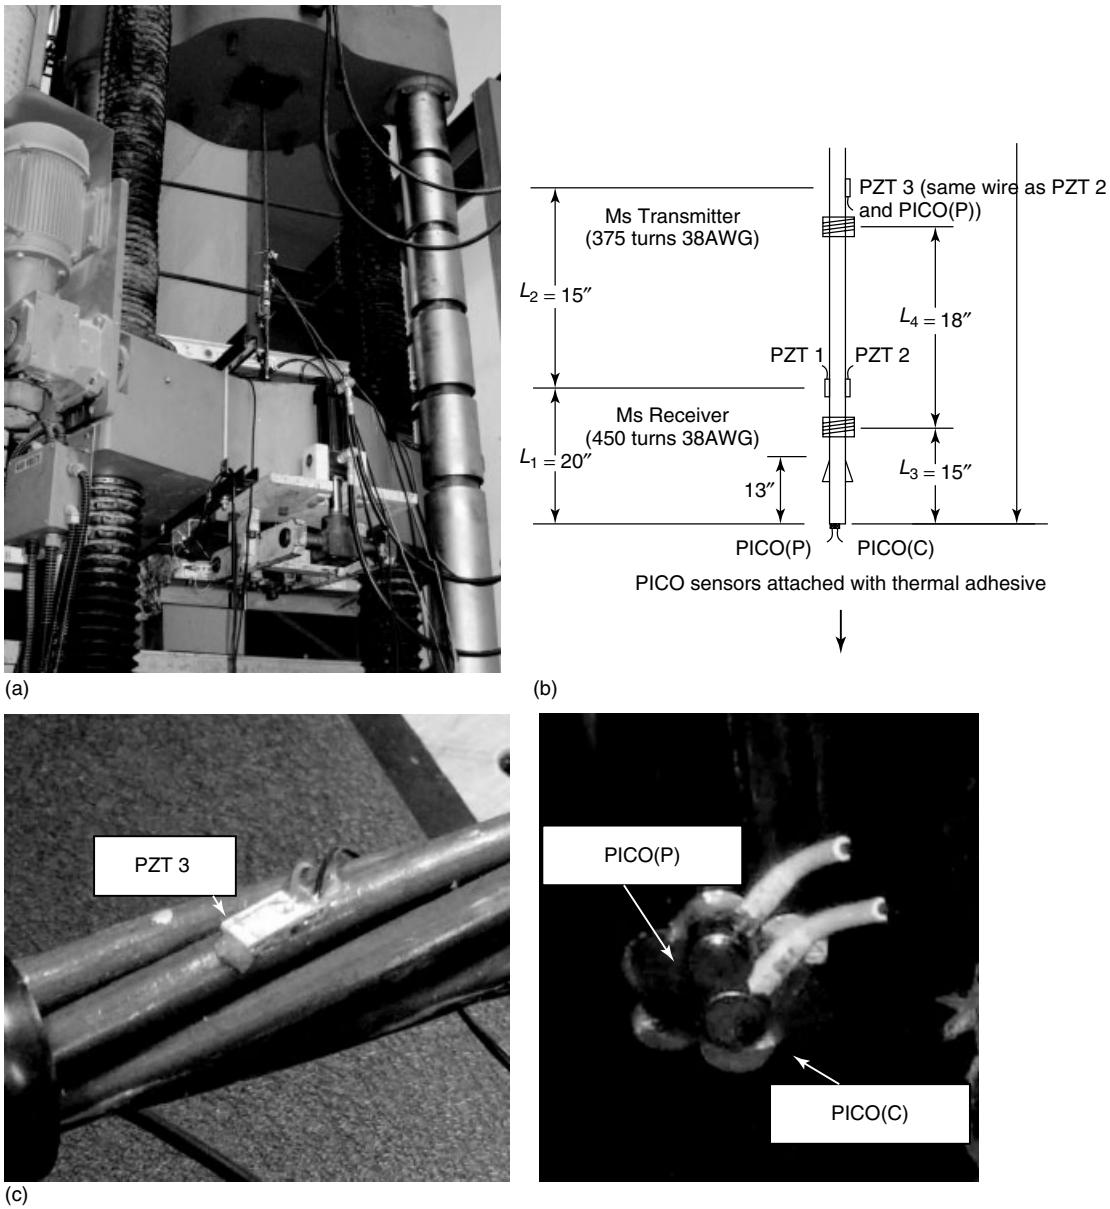

Figure 7. (a) The 1.82-m, seven-wire strand installed in the SATEC testing machine for stress monitoring tests; (b) ultrasonic sensor layout; and (c) pictures of the piezoelectric transmitter (PZT 3) on the peripheral wire and the two piezoelectric receivers on the strand's bottom end probing the central wire, PICO(C), and the peripheral wire, PICO(P).

PICO(P). This feature was calculated on the first arrival. The normalization makes the feature independent of generation power and thus eliminates the need for a baseline measurement, once the distance of the transmitter from the strand's end is fixed.

Figure 8 shows the normalized energy leakage measured in the low-frequency range of 300–700 kHz in a load–unload cycle. It can be seen that the interwire leakage increases with increasing load as expected. The behavior is consistent between load

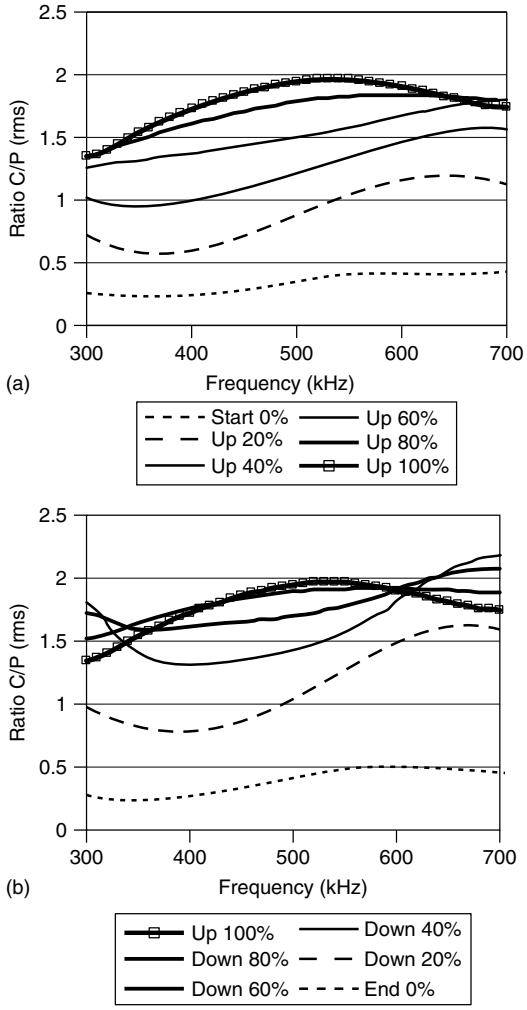

Figure 8. Normalized energy leakage between peripheral wire and central wire as a function of load applied to the strand, in the range 300–700 kHz. PZT 3 transmitting, PICOs (C) and (P) receiving. (a) Load ramp and (b) unload ramp. 100% load = 70% ultimate load (U.T.L.) or 182.4 kN.

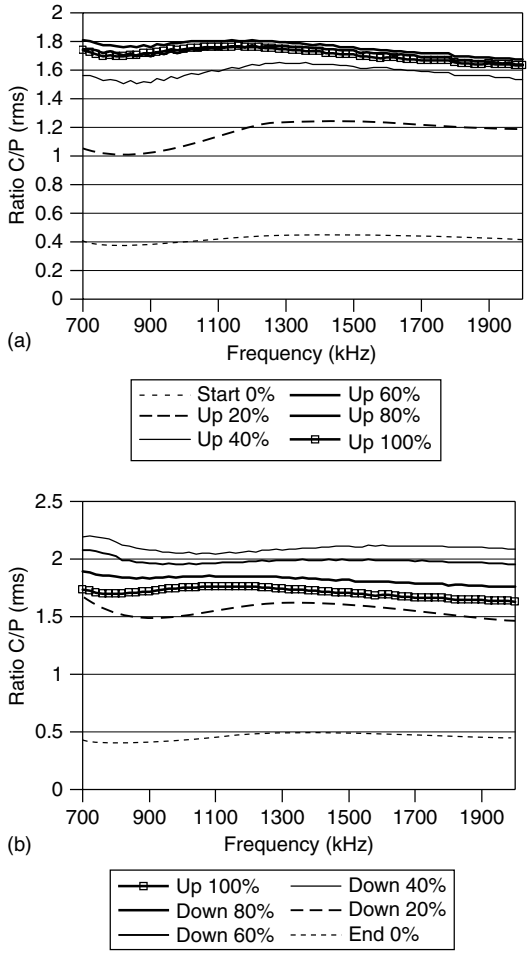

Figure 9. Normalized energy leakage between peripheral wire and central wire as a function of load applied to the strand, in the range 700 kHz–2 MHz. PZT 3 transmitting, PICOs (C) and (P) receiving. (a) Load ramp and (b) unload ramp. 100% load = 70% U.T.L. or 182.4 kN.

and unloading ramps. Also, the trend is such that individual load levels can be well discriminated, in addition to allowing a clear distinction between loaded and fully unloaded strand. Maximum sensitivity to load levels is observed between 400 and 500 kHz.

The same energy leakage feature was monitored in the high-frequency range of 700 kHz to 2 MHz. The results are shown in Figure 9 for a load–unload cycle. The results confirm the trend of increasing interwire leakage with increasing load level. However, compared to the low-frequency range of Figure 8, there is less discrimination among load levels, although the ability to distinguish between loaded and fully unloaded strand is maintained. Also, discrepancies exist in Figure 9 between load and unload ramps. These discrepancies appear owing to interwire contact stresses, which are not released at once during unloading until the load is completely removed. This apparent hysteretic behavior of the strand is only seen in the higher frequency range where the waves are more sensitive to

localized stress/strain fields. For these reasons, the low-frequency range of Figure 8 remains better suited than the high-frequency range for load level monitoring.

4.3 Stress monitoring results—interwire frequency shift feature

The frequency shift feature is also attractive because of its robustness against transducer structure contact and baseline-free characteristics.

The frequency feature is better discussed in light of Figure 10, which shows the peripheral-to-central wire transmissibility in terms of rms of the PICO(C) signal under the PZT 3 excitation, again calculated on the first arrival. Two distinct peaks of maximum transmission are seen in the ranges of 50–130 kHz and 130–250 kHz, respectively. The two peaks have opposite trends with increasing load, with the first one shifting toward higher frequencies and the second one shifting toward lower frequencies, and hence the need for examining the two peaks independently. Comparing load and unload ramps, it can also be seen that the hysteretic behavior of the strand only appears in the higher frequency range where the waves are sensitive to the residual, localized interwire stresses.

The shift in peak frequency relative to the unloaded peak frequency is shown in Figure 11 for the low-frequency range of 50–130 kHz during a load–unload cycle. The plot shows the expected increase in peak transmission frequency with increasing load level, which is consistent with the vibrating cord theory. This behavior is expected since the low frequencies capture the vibrational behavior of the strand as a whole. The shift is as high as 50% between fully loaded and fully unloaded strand. It is also possible to discriminate among different load levels. The trend is consistent between load and unload ramps. These results demonstrate that frequency shift in the range of 50–130 kHz is another promising feature for load level monitoring in the strand.

Figure 12 shows the relative frequency shift for the high-frequency range of 130–250 kHz in the same load–unload cycle. It can be seen that the frequency decreases with increasing load. This result is due to the fact that higher frequencies capture the vibrational behavior of the individual wires rather than that of the entire strand. The difference between load and unload ramps also confirms the sensitivity to residual interwire stresses. The high-frequency range of Figure 12 does not offer the same load discriminating capability as the low-frequency range of Figure 11. However, it still allows to distinguish between a loaded and a fully unloaded strand.

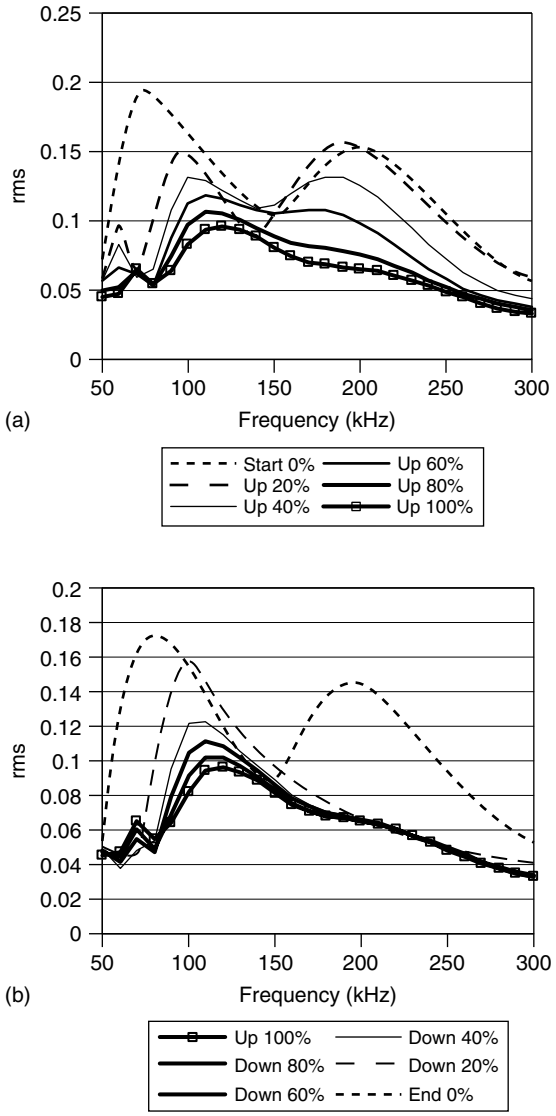

Figure 10. Energy leakage between peripheral wire and central wire as a function of load applied to the strand, in the range 50–300 kHz. PZT 3 transmitting, PICO(C) receiving. (a) Load ramp and (b) unload ramp. 100% load = 70% U.T.L or 182.4 kN.

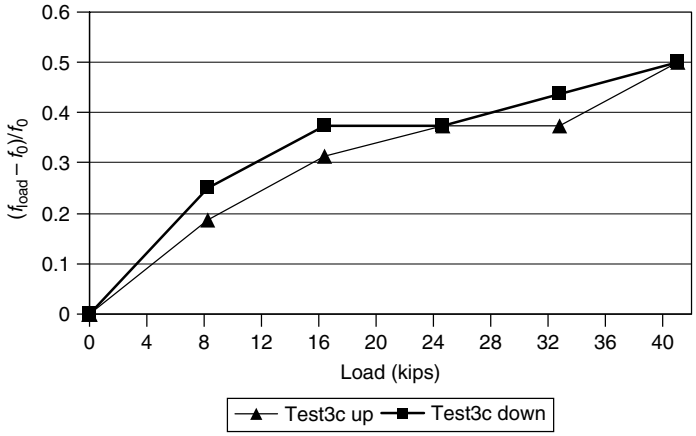

Figure 11. Shift in peak transmission frequency between peripheral and central wire as a function of load applied to the strand, in the range 50–130 kHz. PZT 3 transmitting and PICO(C) receiving. Maximum load 41 kips = 70% U.T.L.

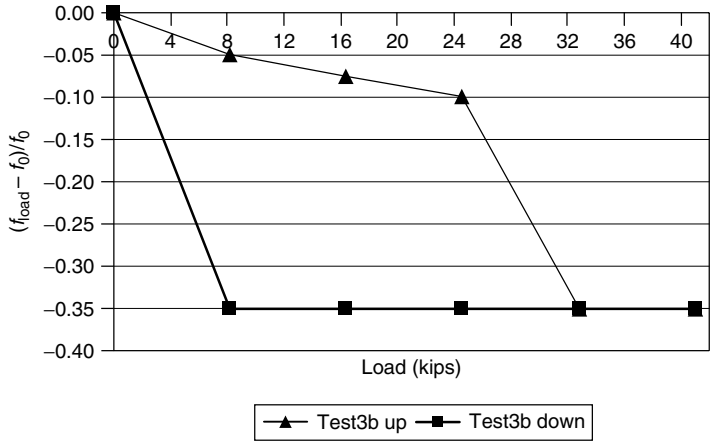

Figure 12. Shift in peak transmission frequency between peripheral and central wire as a function of load applied to the strand, in the range 130–250 kHz. PZT 3 transmitting and PICO(C) receiving. Maximum load 41 kips = 70% U.T.L.

5 DISCUSSION AND CONCLUSIONS

This article presents a technique based on ultrasonic guided waves to monitor the structural condition of multiwire strands used in prestressed concrete structures and cable-stayed or suspension bridges. The ultrasonic technique has the potential for providing both defect detection and stress monitoring in the strands.

The SAFE method was used to model the multimode and dispersive behavior in a free, seven-wire strand (a pretwisted waveguide) and in a rod embedded in grout and concrete (an axis-symmetric multilayer waveguide). In the second case, ultrasonic leakage from the rod into the surrounding media was modeled to identify mode-frequency combinations, which propagate within the rod with minimum attenuation losses for long-range monitoring.

For defect detection purposes, an array of magnetostrictive transducers probing the strand as a whole is proposed. Proof-of-principle results for the detection of notch-like defects were shown on the basis of a reflection damage index vector containing four components. A multivariate statistical analysis based on an outlier analysis showed the ability to distinguish the notches, which were located as far away as

1100 mm from the transducers, from simulated digital noise. The algorithm was able to properly flag notches as small as 0.5 mm (0.7% strand's area reduction) for SNRs on the order of 32 dB. For higher noise level, corresponding to SNRs on the order of 12 dB, the properly flagged notches were as small as 2 mm (5% strand's area reduction).

For stress monitoring purposes, piezoelectric transducers probing the individual wires near the strand's end are proposed. The best transducer layout was found when ultrasound excitation is performed on a peripheral wire and ultrasound detection is performed on the central wire and the peripheral wire at the strand's end. Two features proved suitable for stress monitoring. The first feature, the interwire leakage between the peripheral and the central wire, does not require a baseline once normalized, and in the range of 400–500 kHz it appears effective not only to detect a complete loss of stress but also to quantify the level of applied stress. The second feature was the shift in peak frequency of the peripheral-to-central wire transmissibility spectrum. The frequency shift proved most sensitive in the range of 50–130 kHz; it does not require a baseline and it can detect both a complete loss of stress and the level of applied stress.

The experimental results presented were obtained in the case of free strands. For embedded strands, the sensitive frequency ranges may change as a result of the different waveguide problem. However, the general trends of ultrasonic features as a function of defects and applied stress are expected to be similar to those found for the free waveguide case.

In an actual posttensioned structure, the stress monitoring technique simply requires access to a peripheral wire of the strand (at a location ∼1 m into the embedded portion) to install the PZT transmitter, and access to the strand's free end to install the piezoelectric sensors. If these access points are granted, existing structures can be instrumented. For new structures, the strands would clearly be instrumented before prestressing. Because of their geometry, the installation of the magnetostrictive transducers for defect detection requires access to the entire strand surface; hence, the defect detection method is more applicable to new structures where the strands are instrumented before installation. Clearly, the technique remains to be proven in the field.

ACKNOWLEDGMENTS

The strand monitoring project was funded at UCSD by the US National Science Foundation under grant # 0221707 (Dr S-C. Liu, Program Manager), and by the California Department of Transportation under contract # 59A0538 (Dr C. Sikorsky, Program Manager). Funding was also provided by the Italian Ministry for University and Scientific & Technological Research MURI (40%). The topic of research is part of the research thrusts of the Center of Study and Research for the Identification of Materials and Structures (CIMEST) at the University of Bologna.

Chapter 154
Landfills

Kai Münnich, Jan Bauer and Klaus Fricke
Leichtweiss-Institute, Department of Waste and Resource Management, Technical University of Braunschweig, Braunschweig, Germany

1 INTRODUCTION

Sanitary landfills are still most commonly used in the global scheme of things to dispose of municipal solid waste (MSW). The disposal of waste is always the origin of unwanted emissions, which might have a negative impact on the environment at large and the human health in particular. As a result of the industrial and economical improvement of the last decades, which is often very closely related to an uninhibited growth of the cities especially in the developing and low–income countries, problems with uncontrolled waste disposal have become more and more serious. One reason is that landfills, which were built in former times at the periphery of the cities, are now very often directly surrounded by residential quarters, so the residents are often directly affected by the waste disposal. From the multitude of different impacts [1] due to the imminent danger and long-term hazards, the focus is set here on

- fluid emissions and
- mechanical failure.

These different kinds of risks are interlaced; only a separate consideration of specific failure mechanism allows insight into a part of the *in situ* situation. Owing to the mechanical failure of the landfill, for example, caused by nonuniform settlements, changes occur in the microbial and chemical conditions inside the landfill body. Rainfall and oxygen permeate into the disposed waste and cause renewed aerobic conversion of biodegradable organic substances. The gas thus produced leads to direct emissions and, because of the rise of gaseous pressure, to interferences with the mechanical stability of the landfill body. The same effect on stability occurs when only rainfall infiltrates the waste and the percolation of the water is hindered by impermeable layers (e.g., plastic foils or daily soil cover).

The large landfill catastrophes of the last years (Table 1) with the collapse of large parts of the landfill body were among others caused by a combination

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

Table 1. Landfill catastrophes of the last years

Year	Location	Cause of failure	Volume displaced
1997	Bogota, Colombia	Pore pressure caused by leachate recirculation	800×10^3 m^3
1997	Durban, South Africa	Pore pressure caused by codisposal of liquid waste	160×10^3 m^3
2000	Manila, Philippines	Shear failure following heavy rainfall	$13–16 \times 10^3$ m^3
2005	Bandung, Indonesia	Mechanical failure caused by fire and heavy rainfall	2700×10^3 m^3

This list is not exhaustive. The table was drawn from a number of sources, which appear in the reference list [2–6].

(a) (b)

Figure 1. (a) Payatas landfill slope failure [Reproduced from Ref. 5. © Kavazanjian *et al.*, 2005] and (b) Leuwigajah valley after the landfill failure—downhill view. [Reproduced from Ref. 6. © Koelsch *et al.*, 2005.]

of inappropriate waste disposal (poor compaction) and high water saturation of the waste (heavy rainfall, no drainage system at all or not functioning). In developing countries residential developments are very often located close to landfills, which results in accidents with many fatalities and destruction of these structures (Figure 1).

Over the last few years, the knowledge of the potential long-term risk of landfills has resulted in the intensification of a couple of regulations concerning the construction and controlling of landfill bodies. In all countries having directives concerning the waste disposal on landfills, it is therefore regulated by law that landfills must be built as a capsulate construction with a base and surface sealing. These very complex engineering structures are—unlike most other structures such as bridges or roads—intended to last forever or at least as long as the wastes represent a potential danger. Another important aspect of landfills is on one hand their dimension (e.g., the Fresh Kills Landfill of New York City has an area of 1.5 km^2 and a volume of about 750 million m^3) and on the other hand the inhomogeneity of the waste, whose chemical and physical properties are strongly changing with time.

It is, therefore, necessary to monitor the functioning of the installed equipment in and around the landfill as well as the mechanical behavior of the landfill body in all phases of the lifespan of the landfill. The different phases (operation, closure, and aftercare) may last for centuries depending on the volume of the landfill and the disposed waste [7, 8]. The main focus in the legal requirements regarding the monitoring of landfills is set on the measurement of settlement of the landfill surface, the quantity and quality of polluted water leaving the landfill, and the groundwater quality in the surroundings of the landfill.

However, it remains unclear if these parameters are sufficient and significant to make a reliable statement about the status of the landfill body and its hazard potential. As the monitoring program might become

very expensive, it is necessary to reduce the measurements to the required minimum, because the costs for the monitoring, even in the closure and aftercare phase, have to be received during operation. So, from the point of view of the landfill operator, monitoring is often only an imposition, which, on the one hand, has to be done because of the requirements made by the supervisory authority and on the other hand when data registration is necessary for technical processes (i.e., leachate or gas treatment).

2 MONITORING OF LEACHATE EMISSIONS IN LANDFILL DRAINAGE SYSTEMS

In the phase of waste disposal, precipitation freely infiltrates the waste and slowly percolates downward to the landfill base. During this transport process the liquid reacts with the waste material to produce leachate, which is thereby often characterized by high concentrations of contaminants. A generation of leachate can be observed at nearly each landfill, even under arid conditions, in the case of the disposal of high volumes of organic material or sludges. The quantity of leachate depends on the local climatic conditions, the water content in the waste, and the daily amount of disposed waste and its compaction, among others. To avoid a backwatering of leachate in the waste and the affiliated problems of stability, a drainage system has to be installed at the base of the landfill. The functioning of this system, made of a gravel filter in combination with drainage pipes (concrete or high density polyethylene (HDPE)-material), has to be controlled by establishing a water balance for the site [9]. If possible, a camera inspection of the drainage pipes has to be made at regular intervals to identify local damage spots and settlement measurements have to be made in view of controlling the minimum slope of the pipe for a free outflow of leachate [10]. For water balance or the modeling of the long-term leachate discharge and its quality, the specific discharge per unit area is often assumed to be constant for the landfill. Although this assumption is made because of the inhomogeneity of the disposed waste, the distribution of the biological activity, problems with incrustation processes in the drainage layers, and the partial accumulation of leachate, a nonuniform discharge might be expected to be more realistic.

At present, very often the emission of leachate from landfills can be classified according to quantity and quality only at the input of the purification plant, which means an integration of the whole landfill with its different phases of activity. When measuring at the outlet of a single drainage pipe, the catchment area is reduced from several hectares for the whole landfill to a maximum of about 12 000 m^2 for a single pipe (according to German regulations, maximum length is 400 m and maximum distance between two pipes is 30 m). This catchment area might even be too large, because the mass of waste disposed on the area might be very high (e.g., about 500 000 t at a landfill height of 40 m) and besides the MSW shows a large variability in its physical and biochemical properties.

In order to fine-tune the network of discharge measurements, the optimum would be to measure the discharge at any place at the landfill base sealing. For existing landfills, which have priority in this article, a manipulation of the landfill, for example, the installation of discharge-measuring gauges across the base sealing, is not possible. Therefore, the existing landfill facilities have to be used. Hence, a measuring system to determine the discharge in unreachable pipes has been developed, which allows the leachate discharge volume to be assessed at various points within the leachate collection pipes.

The measuring device to be developed had to fulfill various requirements, to achieve the greatest possible measured lengths in order to include the entire landfill surface, where possible. Simultaneously, it must be reliable and easy to operate as well as fulfilling the usual safety requirements for work at landfills, as, for example, the explosion protection requirements. Furthermore, it should be possible to integrate other measuring systems for the classification of leachate quality.

From these requirements, a commercially available camera system, which is commonly used for the inspection of drainage pipes, was used and adapted to the special purposes. A spillway weir was installed on the camera head, which can be moved in all directions (Figure 2). The placement of the weir and the required temporary sealing of the leachate flow in the pipe can be controlled over the movement of the camera head. A supplementary data transfer cable was not necessary because almost the entire

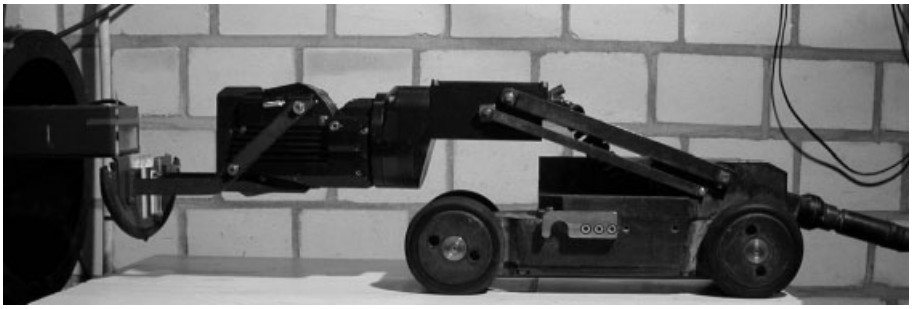

Figure 2. Camera lafette with elevated weir (on the left side).

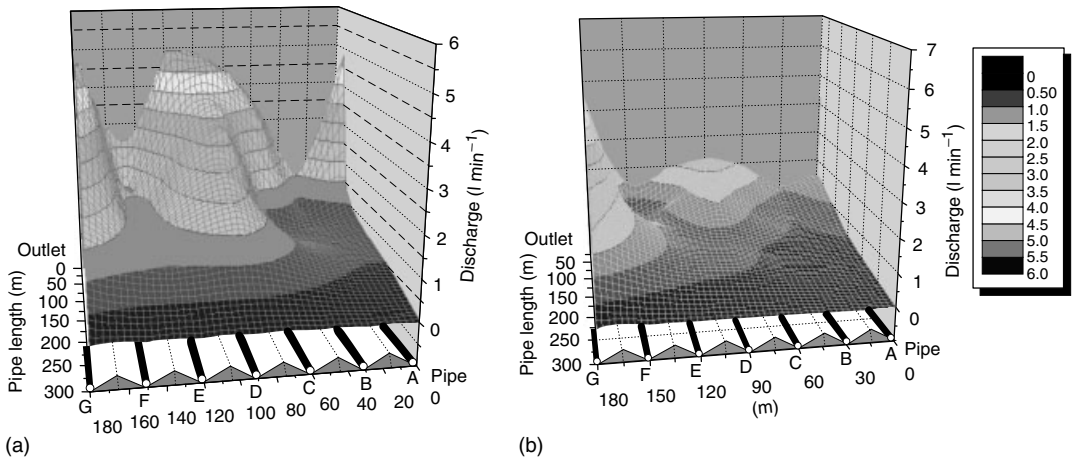

Figure 3. Discharge volume at the base of a landfill in (a) winter and (b) summer.

spillway weir is visible through the camera. The height of the impounded water is measured over a storage tube with millimeter scale, which is readable through the camera. In addition, a sensor for electrical conductivity and temperature is installed on the weir to identify changes in the quality of the leachate. The efficiency of the camera carriage is reduced by the installation of the spillway weir only very minimally.

A typical result of the monitoring of the leachate discharge into drainage pipes is shown in Figure 3. As expected, the discharge at the beginning of the pipe is small and increases with the length of the pipe and reaches the maximum value at the outlet. Not expected were the large differences in the discharge volume in-between the single pipes, although the interspace is only 30 m. The high discharge volume in drains D and E is caused by a recirculation of leachate in the landfill on the surface. Repetitions of the measurements at different dates show that the maximum discharge volume and the pipes, where it can be observed, are changing depending upon climatic and operation conditions.

Starting from the measured results and the known geometry of the landfill base, a surface-specific calculation of discharge can be made. The total length of the drainage pipe can be divided into parts of different lengths by changing the measuring point distances. Thus, the specific collection area can be adapted to the conditions present at the landfill. An example is shown in Figure 4. During the first measurements in April 2000, the distances between the measuring points were 50 m, and these grid distances were reduced for the following measurements. As the landfill segment was already surface covered at the time of the measurements, it was possible to make references to irregularities during waste deposit or surface installment through the measurements. Inspections made in this regard showed a faulty area in the surface

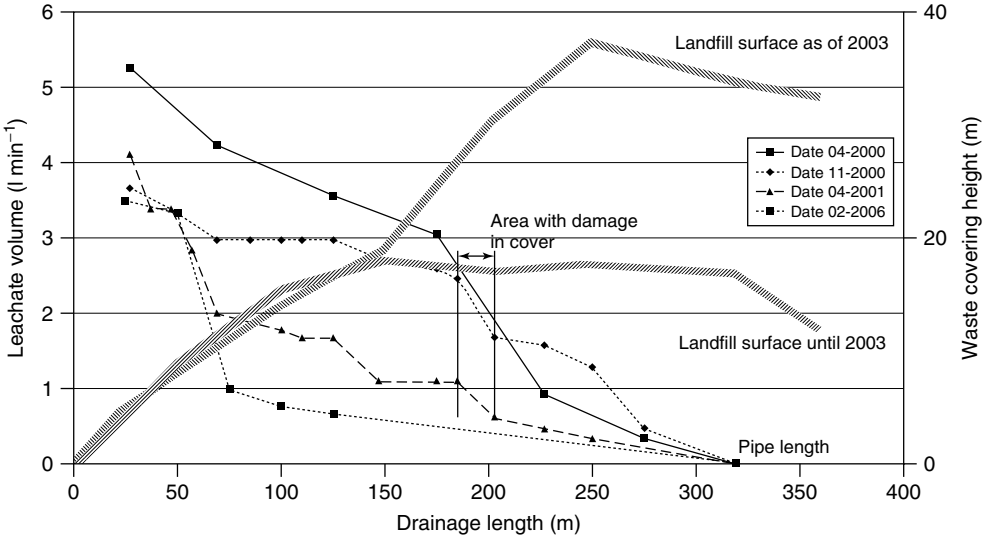

Figure 4. Leachate discharge of one particular drainage pipe.

covering. After the repairing, the volume coming into the collector is reduced significantly.

The distribution over the drainage length also shows that the volume discharged on the first, approximately, 75 m of the pipe increases with time. This might be caused by the partial deformation of the pipes so that the leachate flows beside the pipe in the gravel layer and is collected only at the outlet of the pipe because of the sealing system in the landfill slope. This assumption is supported by the observations made while driving into the pipe. In all pipes where the measurements have been made a backwater in the drainage system, could be observed over a distance of more than 15–20 m starting from the outlet of the pipe. This would mean that a part of the landfill is saturated at the base, which would have an important influence on the slope stability of the landfill in these areas. A supplementary measurement of the slope of the installed drainage pipes shows that, in parts, settlement of the liner system give result to partial backwater of leachate.

Since measurement within the pipes can only be conducted at relatively long time intervals, information regarding the variability of the leachate discharge in time cannot be gathered. For this reason another measuring apparatus was constructed, which can continuously record the outflow volume and the quality of leachate at single outlets of drainage pipes. Here also, the principle of measurement is a spillway weir, but the reading tube was replaced with a pressure sensor connected to a data log. In arbitrary time intervals, the backwater height and the electrical conductivity are recorded.

The results of monitoring over several years show that during waste disposal the discharge fluctuates over short periods, but that this fluctuation approximately balances itself out over a longer period. Furthermore, the discharge increase after a period of rain is recognizable, practically nearly without time delay. Also, the changes in landfill operation, e.g., the removal of the surface cover and the disposal of new waste in certain areas, can be tracked (Figure 5). As a consequence, the discharge increases with a certain time delay. Also, the above-mentioned bad spot in the sealing system was recorded as an increase in the discharge volume of the leachate. After the repair, the discharge decreases very fast to values as before. The placement of the final surface cover leads to a slow decrease in the leachate volume collected. With these data, the storage capacity and the degree of saturation of the waste can be evaluated.

3 MONITORING OF THE DEFORMATION OF LANDFILLS

Waste is a very compressible material, which is piled up in landfills to heights of 50–60 m or even more. As

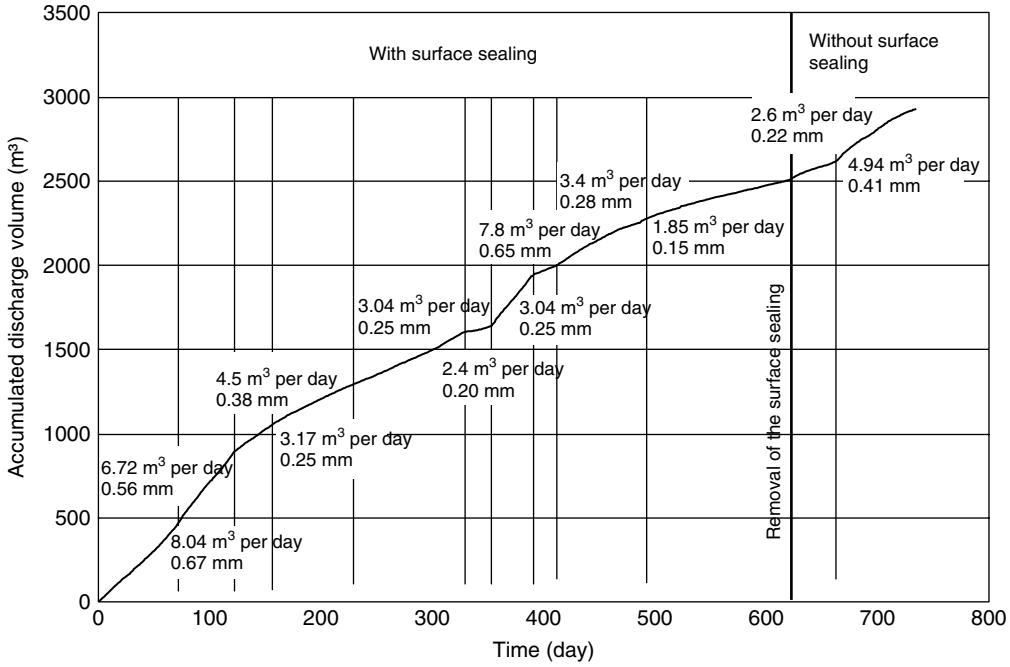

Figure 5. Results of continuous discharge measurement.

a consequence of the self-weight of the waste and the degradation of parts of the waste, nonuniform settlement of the surface occurs. A magnitude of up to 40% of the initial height of the landfill settlements represents a serious threat to the structures installed in the landfill (e.g., top cover system and gas drainage). In general, deformation measurements of landfill bodies are only conducted on the surface and in drainage pipes at the landfill base. The measurements at the landfill base are made to control the geomechanical properties of the underlying liner system and subsoil. In the past, some landfill collapses were caused by the breakdown of the subsurface soil under the high load of the waste. In most of these cases the plane consists of soft soil (e.g., [11]).

The monitoring of the surface is commonly made with conventional geodetic techniques as triangulation and distance measurement, with electronic tacheometers, or with a global positioning system (GPS). In some cases, internal instruments like inclinometers, extensometers, or buried plates/plates are installed [12]. The measured movements of the internal instruments must not be identical to those of the surrounding waste, as the instruments have different physical properties compared to waste (weight, stiffness, etc.).

In Figure 6, the settlement behavior of two different areas of one landfill are shown. Area 1 was filled with waste from 1967 to 1980 and then covered with a soil material. The measurement bolts were installed in 1993. Area 2 was filled from 1980 to 1990 and the bolts were installed in April 1997. The curves make it clear that even 25 years after finishing, the waste disposal settlement occurs. For both cases, it must be taken into account that the measurement started some years after the last disposal of waste, which means that the major settlement has not yet been recorded.

All these measurements are very precise, but only punctual, so the areal resolution to detect stability problems of landfills is not sufficient. A solution to this problem might be the ground-based 3D laser scanning technology, which is in use for more than 10 years in civil engineering for monitoring dams, landslides, etc [13]. Until now, 3D laser measurements were only made within research works on different landfills [14, 15]. The main advantages of this technology, the point density and the ease of implementation, may result in a more frequent

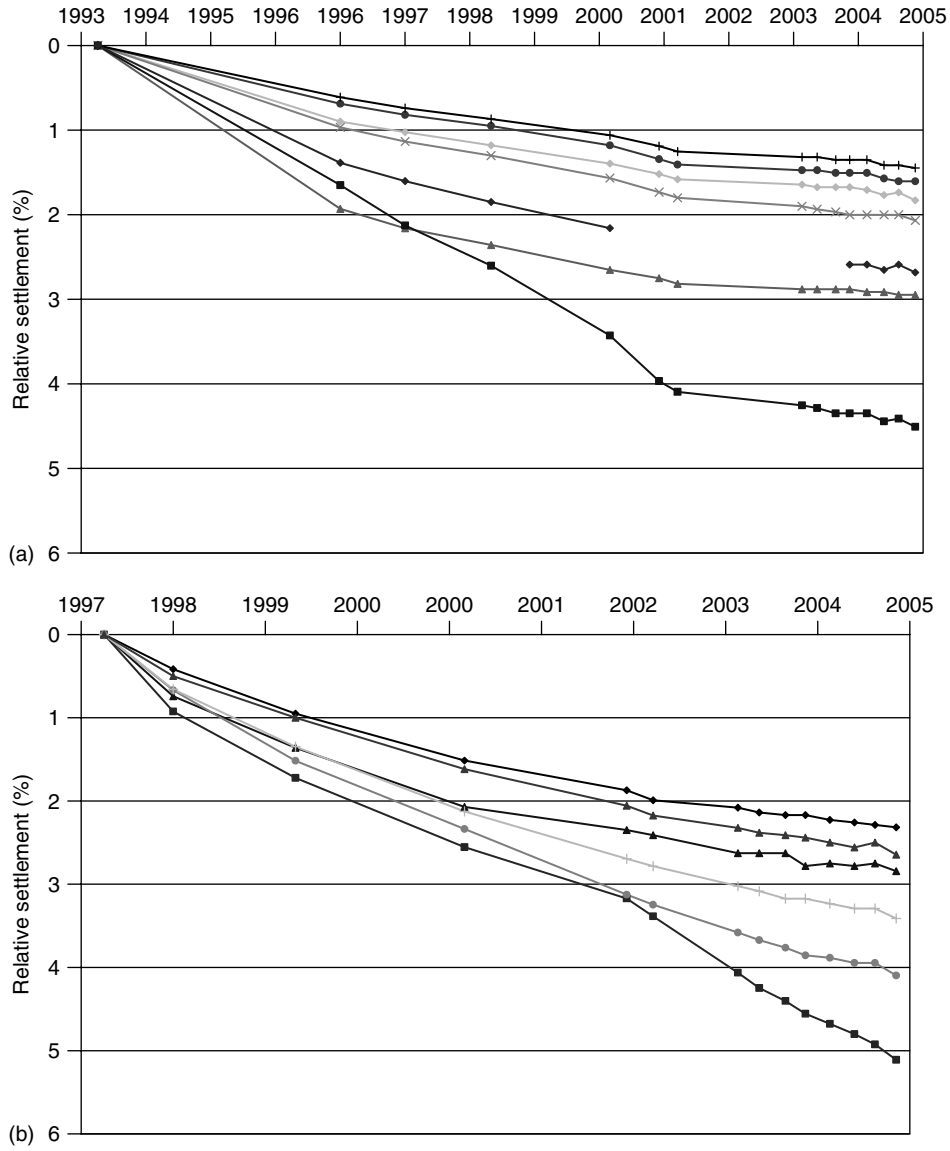

Figure 6. Surface settlement at different points of an older (a) and newer (b) area of a landfill.

measurement so that a more continuous representation of the landfill is enabled. A better understanding of the hydrobiophysical and mechanical interactions between waste and structures is possible.

These surface measurements are not always sufficient to describe a possible failure of the landfill slope, because the horizontal movement of the waste inside the landfill is often larger than that on the surface. The effect can be observed on the surface, where gas or leachate shafts have a strong inclination very often. To get an idea of the three-dimensional movement, an approximately 10-m-high and 10-m-wide ditch was dug for research purposes into the slope of an older landfill. The ditch is equipped with several measuring bolts on the slope surface to detect the three-dimensional deformation by tacheometry and differential global positioning system (DGPS) measurements. Also, eight measuring pipes at four

levels were installed into the slope of the ditch and in a range of up to 5 m into the landfill body. One of their purposes was to measure the vertical deformation inside the landfill body. The open walls were covered with foil, in order to prevent the penetration of oxygen into the landfill body and to avoid an influence on stability during heavy rainfall. During the excavation work waste samples were taken, in order to classify the waste and determine the density. The waste was weighed and the waste volume was calculated by laser scanning. The hydrostatic profile measurement of the measuring pipes confirms the order of magnitude of the settlement of the ditch wall. Regarding the settlement velocity over time, the pipes for the settlement investigation show seasonal settlement behavior with larger settlements after rain events. Furthermore, the results show a settlement that is not constant over the length of the pipe, without a significant deformation of the initial pipe length profile, but the more the pipe reaches inside the waste body, the settlement rate grows. A comparison between the beginning of the pipe on the back wall of the ditch and the end of the pipe inside the landfill body shows a 40% increase in the settlement, on an average, inside the landfill body. The difference between the beginning and end of the pipe increases from the head of the slope to the bottom.

Horizontal deformations occur in a magnitude of up to 14 cm in the three-year survey period. The horizontal movements, on an average, are approximately 75% of the settlement values. There is no significant correlation between horizontal deformations and settlement, and the results of the measurements do not show that they are influenced by each other (Figure 7). In this case, the horizontal deformations depend on the geometry of the slope excavation and the landfill topography. The main horizontal movements occur in the range of the slope foot because of the shear load of the whole landfill body. Even the horizontal movement exceeds the settlement values in the lower level of the back wall. Remarkable is the overall low horizontal movement of the two vertical

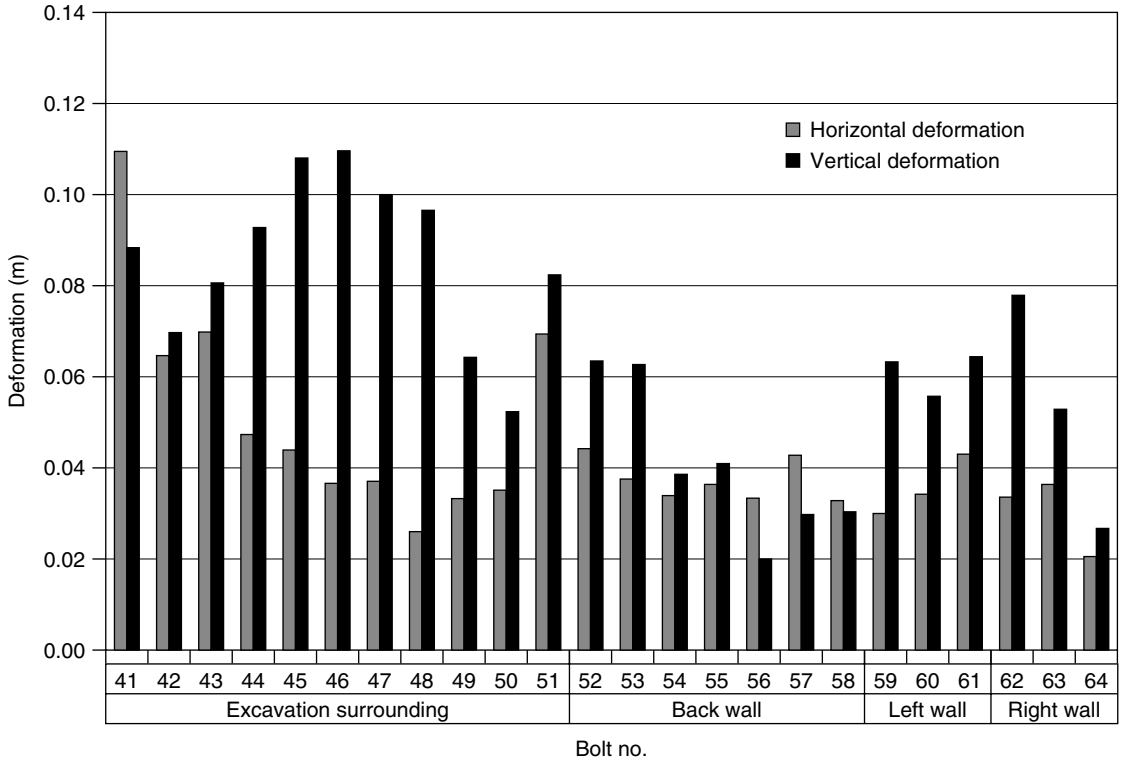

Figure 7. Deformation of surface points in a 2.5-year survey period.

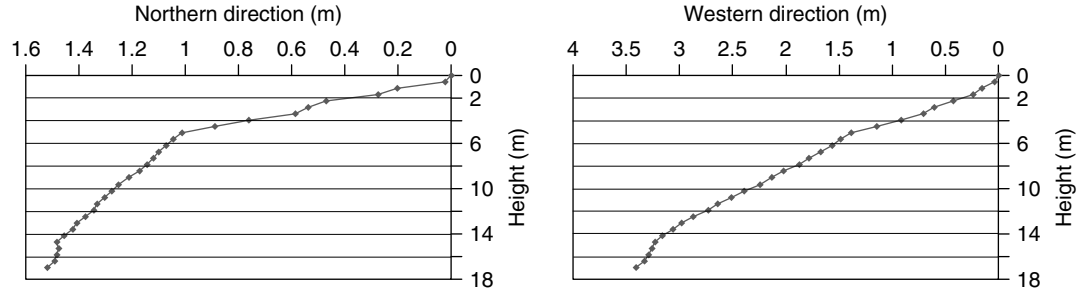

Figure 8. Horizontal deformation of a gas shaft.

side walls and the nearly vertical back wall of the excavation, which was not to be expected and is an indication of the stability properties of MSW.

To determine the horizontal displacement inside landfill bodies, inclinometers are sometimes installed in the existing shafts or special shafts are drilled in the waste. These inclinometers are used since a long time in the survey of buildings, dams, etc. The accuracy of these instruments is very high, but the disadvantage is that because of their construction, strong local deformations cannot be determined as the guiding tubing is ruptured. New inclinometers have been developed, which allows the use of existing gas shafts for the measurement [16]. This allows measurements to be conducted without destroying the surface cap, and it reduces the costs of measurements, since new pipes need not be installed. Furthermore, it is possible to measure pipes that have already been deformed over time, giving more information about landfill movement. For measurements, the probe is lowered into the shaft on a steel cable with the aid of a winch. After initial measurements at the shaft base, the probe is pulled in portions that correspond to the length of the probe. In each portion, the inclination of the pipe, the pivoting of the probe, and the exact time of measurement are recorded. Exact positioning in millimeters of height is achieved through the use of a highly accurate cable length counter. Centering at the beginning of every measurement is performed by the pressure-controlled centering device of the probe. The horizontal turn of the probe is determined by a rotation rate sensor. The electronic gyroscope determines the deviation from a direction independent of the earth's magnetic field so that the piping of the well or other iron items do not influence the measurement.

The first measurements made in an old landfill show that the horizontal deformations are high as expected compared with values measured in geotechnical engineering. A horizontal displacement of about 3.5 m of the bottom of a 17-m-long shaft could be observed (Figure 8).

The horizontal deformations were so high that the serviceability of the vertical gas wells was impaired. In spite of these deformations, no mechanical failure of the waste, which leads to cracks on the landfill surface or on slopes, could be detected.

4 SUMMARY

At present, knowledge about the physical behavior of landfill bodies is still insufficient. More precisely, no information is as of yet available on the connection between the mechanical strength and the hydraulic behavior, which is why precise conclusions concerning the deformation behavior cannot be drawn. Such data are important for the serviceability of the technical equipment installed in landfill sites and to avoid the worst case scenario of slope failures.

Monitoring techniques commonly used in structural and civil engineering, which allow a registration of data with high accuracy, are often not suitable for landfills. The cause of it may be seen in the large values of movements/displacements in waste, which may not result in the failure of the structure. Furthermore, as landfills are dynamic systems, which change their physical behavior with the ongoing process of biodegradation of the waste material, the critical points for monitoring are not always obvious and they are changing with time.

The latest landfill adapted technologies to monitor the leachate emissions and mechanical behavior of landfills are presented. Monitoring with these tools allows a better spatial resolution of important data

such as leachate generation, leachate quality, and horizontal and vertical movement of the waste body. The *in situ* measurements on leachate discharge and vertical and horizontal deformation should be completed by laboratory tests for the physical fundamentals.

The collected data and the data from the literature emphasize the need for monitoring the behavior of landfills at different stages of the lifespan of the landfill. Although these actions are often costly and their need is not always evident at first sight, it is essential to start monitoring during the disposal of waste and not to stop when the landfill capacity has been reached. Only a long-term monitoring of the relevant parameters enables the landfill owner and operator to get a better understanding of landfill behavior as a response on the specific conditions of the site (climate, waste composition, volume of waste, etc.).

1 INTRODUCTION

Significant parts of industrial piping systems are partly or totally inaccessible for traditional nondestructive inspections, e.g., by being insulated or by being located at extreme positions. Therefore, it is not possible to detect damages without acceptable time and effort. For these kinds of problems, reliable monitoring techniques are needed. These techniques have to account for the fact that damages in piping systems manifest themselves on different scales ranging from global vibrational changes due to damaged support elements up to local changes caused by cracklike defects. Therefore, the corresponding monitoring system should have two "observing eyes", a *global* one for the overall condition and a *local* one for crucial error-prone parts of the structure. This dualism can be ideally realized by a structural health monitoring (SHM) system based on guided elastic waves and vibrations. The implementation of such a system including hardware and software development, decision support system (DSS), and subsequent

lifetime management of industrial piping systems is one of the main goals of the ongoing European SAFE PIPES project. Intermediate results of this work are presented in the following.

2 THE SHM "GLOBAL EYE": MODEL-BASED MODAL ANALYSIS

2.1 Preface

The global eye of the SHM system is represented by model-based vibration analysis. Its main objective is the detection of changes of boundary conditions that influence the life cycle of a piping system. The method is based on the fact that changes in system stiffness and boundary conditions are reflected in significant changes of experimentally detectable and numerically computable natural frequencies and related mode shapes. Besides the piping system with rigid supports this means, above all, changes in the stiffness of supporting constructions, e.g., loss of load-bearing capacity of aged spring hangers, increase of hysteresis with spring and constant hangers, load rearrangement due to heating and cooling processes of piping systems with constant hangers and the failure of pipe clamps due to fatigued bolts. In view of the fact that this method detects actual changes in the system, it can be used at any point of the life cycle of a system. The finite element method (FEM) modeling of a partly fatigued pipe, however, is highly problematic. For this, it is desirable to simulate and measure the undamaged zero state of a system. The individual steps in the context of model-based modal analysis are described as follows.

2.1.1 FEM simulation as a basis

In the first step, the design state of the piping system is transferred to a FEM model for static and dynamic analysis. The mechanical system of the pipe has to be modeled with appropriate accuracy, whereas first discrepancies may already occur between the idealized model and the real pipe since structural modifications can sometimes be decided only on site. Possible deviations can be discovered in the zero state, e.g., by walkdowns, and the model then must be updated accordingly. However, if a pipe that is already damaged or aged has to be simulated, it is hardly possible to determine the complete life-cycle consumption and other changes experienced by a pipe during operation and to describe such changes in a FEM model with sufficient accuracy.

2.1.2 Measurements

Kinematic quantities, e.g., accelerations, vibration velocities, and deflections are measured together with strains at appropriate points at anchoring elements and at the pipe itself. Forced vibrations of the system with excitations from plant operation as well as vibrations initiated by artificial or ambient excitation are measured. For operational vibrations and ambient vibrations, the determination of the excitation by measurement is often impossible. For measurement of free vibrations, initiated by artificial excitations, it is necessary to choose an excitation that is suitable to excite an industrial piping system, due to its frequency content and excitation energy, without the danger of damage to the structure. For measurement of modal quantities (experimental modal analysis, EMA) ambient vibrations (wind, soil tremor, and general plant operation) or artificial impacts (impulse hammer, shaker, and snap back) can be used as excitation. The resulting modal parameters serve as basis for updating the FEM models.

2.1.3 Experimental and operational modal analysis

An EMA provides natural frequencies, mode shapes, and modal damping values of the system, however, additionally requiring the determination of the excitation force of the structure. Since it is hardly possible to measure the excitation of operational vibrations and ambient vibrations, the operational modal analysis (OMA) has been currently developed. Within the OMA framework, explicit knowledge or control of the input excitation is no longer necessary.

Related to natural frequencies and mode shapes, the results of EMA or OMA correspond to those of FEM simulations. However, with the last-named simulation method besides modal quantities, displacements and stresses can be simulated and presented for the entire structure.

2.1.4 Model updating

By comparison of measurement and analysis results that can be carried out individually or by software-based model update, the model can be verified. With a close matching of results, the FEM model verified by measurement presents a safe basis for prognostic statements concerning planned modifications of the piping system, e.g., of the anchoring concept. In the case of modifications of the pipe during operation, the comparison of the measuring data with the unchanged simulation model vice versa allows the drawing of conclusions concerning the damage state. For example, a change in stiffness due to corrosion or due to a locked spring hanger may lead to a shift of natural frequency or a change of mode shape [1, 2]. For that purpose, in the FEM model, regions where damage is expected must be identified. These "unsafe regions" allow a *local* adaptation of physical parameters such as stiffness and mass. These parameters are modified in the unsafe regions until the deviations between the identified (measured) natural frequencies and mode shapes and the simulated data are minimized.

As long as measurement and simulation results match, the structure does not show any damage that influences the stiffness. If deviations emerge from the comparison of natural frequencies determined by measurements and those determined by FEM simulation, a damage of the pipe must be assumed. The model update results in a modified simulation model, which again correlates with the modified measuring data and thus iteratively describes the modifications or damage of the pipe, respectively. However, comprehensive research work is still necessary in the updating of the damping.

2.1.5 Reassessment of the pipe

One of the simulation results of the model, subject to modification through model update, consists in the new stress distribution as a consequence of the modified load-bearing behavior. By comparison with relevant codes, the stresses in the piping system can be reassessed and statements concerning the exploitation of the system are possible. The analysis of the updated stress distribution and the load history of the system (heating, cooling, vibration cycles, and singular events) provide information on the life-cycle consumption or the remaining lifetime, respectively.

2.2 Example A: modal analysis based on shaker excitation

The following test carried out at a mock-up of a piping system gives an insight into the procedure of the modal analysis method. A piping system equipped with instruments was excited in its first natural frequency until a failure of the welded seam between base plate and pipe was produced (Figures 1 and 2). This damaging could be traced. The failure of the welded seam could be implemented in the FEM model of the pipe by model updating.

At the bottom of the upward branch, the piping system was welded on a base plate (Figures 1a and 2a); on the right side it was held vertically. Directly following the descending branch, the excitation was applied by means of a shaker (Figure 1c). Within the scope of a FEM analysis, the first vertical natural frequency was determined to be 5.09 Hz. An attempt was made to excite the pipe in this resonance frequency continuously [3]. By this directed excitation, a failure of the welded seam at both sides of the base point (Figure 2) could be produced after approximately 30 000 load cycles. Despite continuing excitation, the amplitudes at all measuring points of the mock-up decreased significantly (Figure 3a). By this damage—representing a considerable loss of stiffness at the clamping—the natural frequencies of the system were shifted downward. For instance, the first natural frequency at 5.09 Hz was shifted to 3.59 Hz. The shift of natural frequencies can clearly be seen in the waterfall diagram shown in Figure 3(b).

This measurement data then served as input for the model update. At the hot spots (high-stressed areas) of the pipe where the damage was expected, unsafe model regions were defined. The restraints as well as the elbows were used for this purpose. If the stiffness of an element changes due to a flaw, this also influences the stiffness and, therefore, the natural frequencies and modal matrix. Thus, the software must be capable to identify the flaw and its location. At the destruction of the clamping, a decrease from 5.09 to 3.59 Hz (30%) of the first vertical natural frequency was observed in that system. After approximately 18 iterations within the model updating program, the natural frequencies of the *measured* data and the changed *analytical* model matched, meaning that the model is successfully updated.

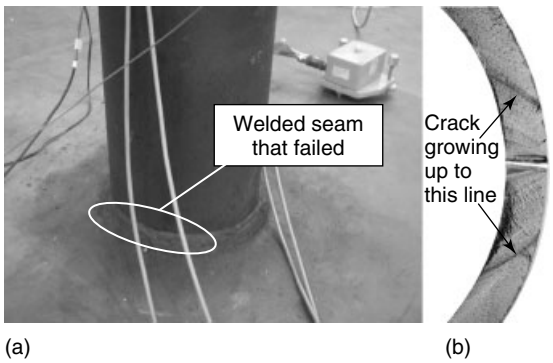

Figure 2. (a) Failure of the welded seam caused by shaker excitation. (b) The remaining load-carrying cross section at the end of the test.

2.3 Example B: modal analysis based on ambient vibrations

In this case, no artificial excitation of the system is necessary, but the stochastic excitation by operational oscillations and oscillations of the environment—so-called ambient vibrations—is sufficient to excite the system even during revision of the facility. For this purpose, highly sensitive seismic velocity sensors are used. This analysis method is safer than conventional methods where artificial excitation, e.g., by shakers or impulses, might damage the investigated structure. In special cases, measurements can be taken directly on

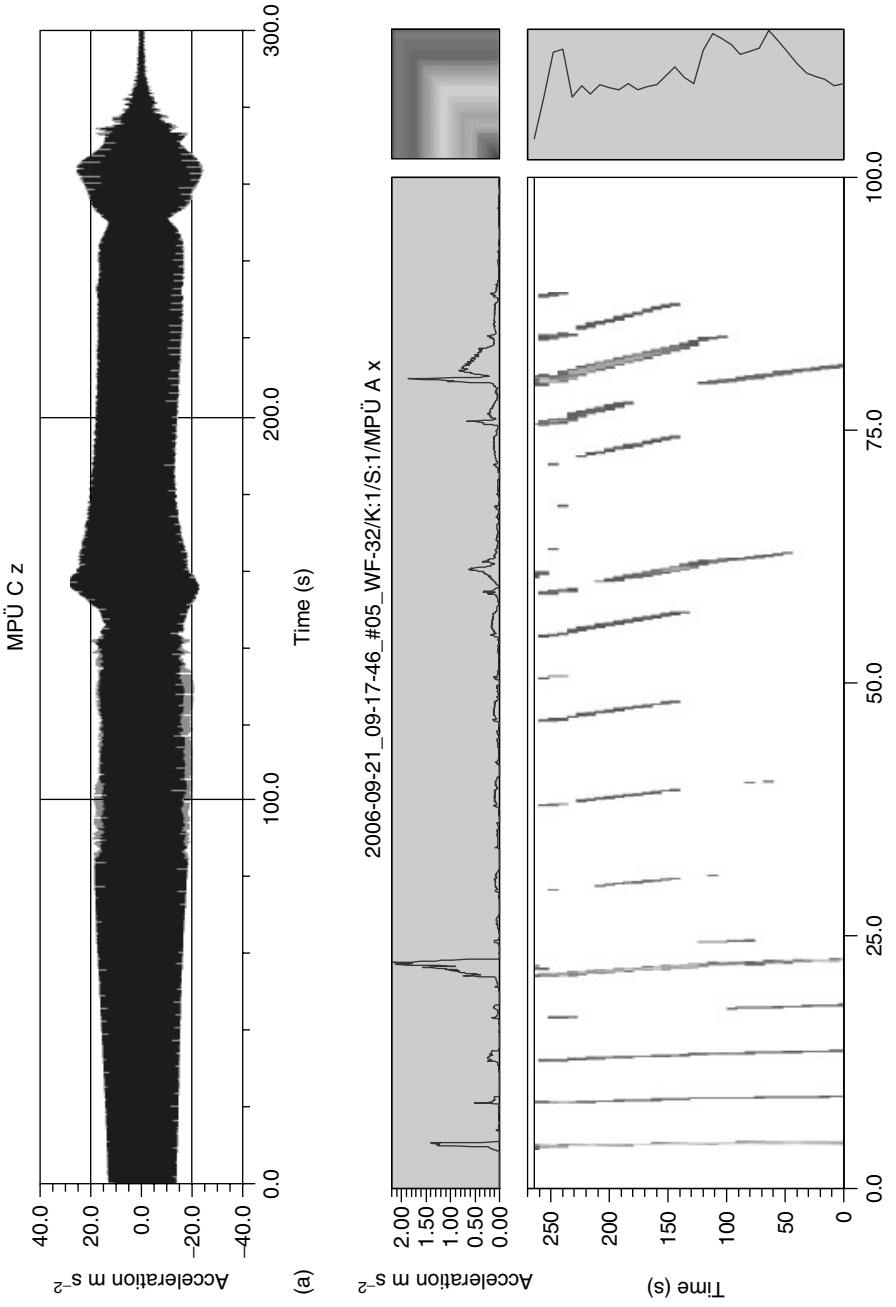

Figure 3. Modal analysis results at the pipe mock-up. (a) Reduction of accelerations at measuring point C. During this process, the natural frequencies decreased with progressing crack propagation. Higher frequencies are more sensitive to changes in the stiffness (b).

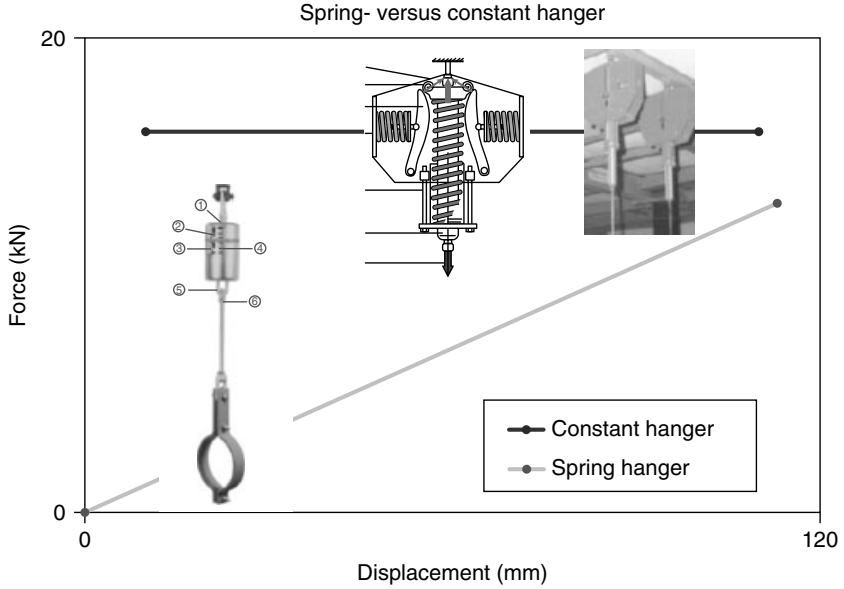

Figure 4. Load-bearing behavior (load-displacement curve) of typical piping supports such as spring hangers and constant hangers.

the insulation of a pipe. As no artificial excitation is necessary, the expenditure is limited. With this excitation mechanism no "force inputs" are necessary, only "outputs" coupled by a reference signal are used [4, 5]. This technique is very well known and is established as "OMA method" (see Section 2.1.3). The number of the usually expensive transducers can also be limited by this method. Groups of measuring points are recorded by only a few transducers, then shifted with respect to time and later on coupled by a reference signal.

Within the scope of a national research project [6], the potential of the method for identifying current conditions of piping systems was demonstrated especially regarding the state of spring hangers and constant hangers. The hangers are supports of the piping to bear the loads (dead loads, loads due to thermal expansion, earthquake loads, etc.). They are situated between piping and building. A spring hanger consists of a mechanical spring with a linear force-displacement behavior. The constant hanger consists of a mechanism, which transfers only constant loads between piping and building within a defined range independent from the displacements between piping and building. This is often meaningful because of large piping movements due to elongations caused by rare temperature differences (Figure 4). The analysis of these tests revealed the following:

- The results of the FFT analysis (fast Fourier transform) yield definite spectral densities of the measured velocities at all measuring points.
- Changes in systems with spring hangers could be recorded with high accuracy. Measurements and calculations coincide.
- The simulated locking of a spring hanger leads to a change in the mode shapes.
- An amplitude dependency of some mechanical hanger-parameters complicates the updating of the calculated model to the experimental modal results.
- The locking of a constant hanger leads only to a small change of the natural frequency of the investigated system; however, the resulting nodal point generates a characteristic mode shape.

Another task during an application to a piping system with nominal diameters DN 350/DN 250 in a nuclear power plant in Germany (Figure 5) was to prove whether the calculated frequencies and related modes are actually present at the real structure, especially the mode shapes in the range of 10 Hz. Precalculations led to the result that at this frequency

level the switch-off of the high-pressure pump of the emergency core cooling system induces resonance effects and, therefore, a comparison of measurement and calculation was of great interest.

The area of measuring points is marked in Figure 6(a). The support of the piping system consists of the quasi-fixpoints (FP) at the reactor pressure vessel (RPV) and at the two penetrations through the containment, of a slide bearing at measuring point 14, and of struts and spring hangers. The piping system was partly insulated between the tee and the RPV. By FFT analysis of the single signals the natural frequencies can be obtained. From the transfer functions between these signals and a reference point signal, the mode shapes can be determined. For this purpose, a 3-D-transducer was installed at measuring point 8 as a reference point during all measurements.

The natural frequencies were derived from the spectral densities of the velocity signals. The corresponding experimentally determined first mode shape is shown in Figure 6(b). The list of all measured frequencies is documented in the first row of Table 1. The first comparison between measurement and design calculation did not show a satisfactory agreement (Table 1, columns 1 and 2). A view on the measured mode shapes leads to the conclusion that at the low-excitation level applied, sliding at the single slide bearing did not occur. A modification of the calculation model (Table 1, column 3) also did not lead to the desired coincidence. Some frequencies coincide, but not the first one. Only the mode shapes of the first two frequencies look similar.

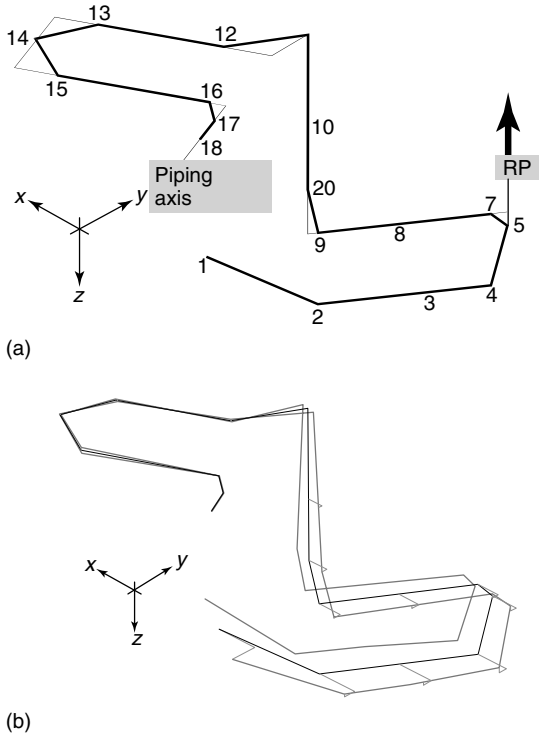

Figure 6. Location of measurement points at the emergency cooling piping (a) and experimentally determined vibration mode at 2.5 Hz (b).

Table 1. Comparison of measured frequencies at a nuclear power plant with those of different FEM calculations

1	2	3	4
Measurement (Hz)	Design calculation (Hz)	Model—modification slide bearing → fix point (Hz)	New FEM calculation (Hz)
2.5	1.43	1.48	2.4
	2.33	2.51	
	2.75		
3.8	3.26	3.19	3.6
	4.18		
5.2	5.35	5.24	6.1
	6.16	6.26	
6.8	6.56	6.44	6.9
8.1	7.71	7.76	7.5/8.3
9.1	9.49	9.51	8.8
10.0	9.96	10.12	9.7/11.9

These large differences are due to the typical construction of a hanger support as shown in Figure 7. From this picture, it becomes clear that the support with two struts with two single-edge-connected hinges has not only vertical direction stiffness values as assumed in the design calculation but also stiffness values in other directions (horizontal translation and rotation around the pipe axis). This implies overall that the pipe is supported stiffer than assumed in the design calculation. For this reason, a parameter study based on a finite element calculation with the code ABAQUS was carried out with a more detailed model in which such constructions were modeled with more suppressed degrees of freedom according to present construction drawings. This led to an increase in the frequency of the first mode compared to the model of the design calculation. One result is shown in Table 1, column 4. Also, the number of the calculated natural frequencies, therefore, declines in the frequency range of 0–10 Hz, and now the mode shapes agree with the measurements quite well. Further experiences with OMA were gained during the European project SafePipes [7].

3 THE SHM "LOCAL EYE": GUIDED ELASTIC WAVE MONITORING

For crucial error-prone parts of a structure, vibration monitoring can be efficiently supplemented by using elastic waves in the kilohertz frequency range. These ultrasonic waves have a shorter range but are more sensitive to smaller defects and thus can serve as an early warning system raising an alarm long before critical damage occurs. If the wavelengths are comparable with or larger than typical dimensions of the structure (e.g., thickness), the waves are called *guided waves*. In this case, geometrical dispersion cannot be neglected in general (see e.g., [8]).

When using elastic waves for SHM purposes, two different approaches are possible, a passive and an active approach. In the passive SHM system, only sensors are needed and "natural" sources like acoustic emissions (AEs) caused by crack generation and growth are detected. In the active SHM

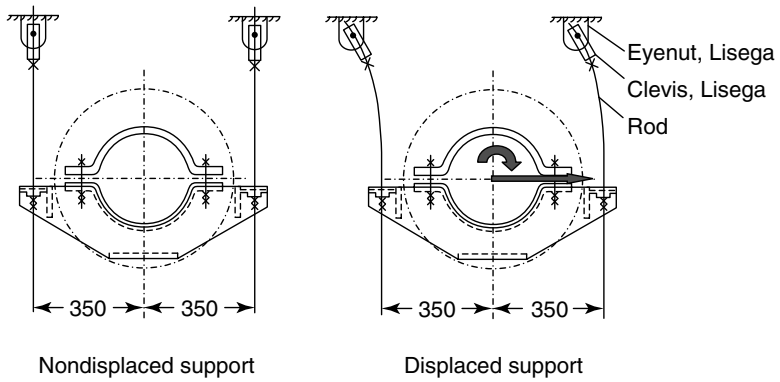

Figure 7. Typical construction of a hanger of the investigated piping system with two struts. The deflection picture on the right shows that additional acting stiffness is present.

system, the transducers are acting as both, sensors and actuators. By using pulse echo or acoustic signature techniques, scattered waves from inside the structure or the changes in acoustic signature response can be detected and used as damage indicator.

In order to implement a monitoring system based on guided waves, the theoretical fundamentals of guided-wave propagation in various materials and structures and their interaction with potential defects have to be investigated first. This can be done via numerical simulation (Figure 8) or by laser detection of elastic wave fields at the surface of the structure.

The simplest case of guided waves can be found in platelike structures where the so-called plate waves or Lamb waves exist. In general, symmetric and antisymmetric wave modes are being distinguished. They are dispersive in general. In most cases, SHM techniques work in the frequency range between 50 and 500 kHz and only the zeroth-order Lamb waves are of particular interest for monitoring applications. In addition to the Lamb waves, horizontally polarized shear waves (SH waves) can also be used. In contrast to the Lamb waves, the zeroth-order SH wave is nondispersive. Numerical and experimental investigations show that each wave mode mentioned earlier shows different sensitivity to specific kinds of damage. The SH0 mode is well suited for crack detection and for any application where a surrounding fluid limits the range of the other modes. The antisymmetric A0 Lamb mode is best suited for determination of delaminations in composites and local changes in wall thickness. The symmetric S0 mode is also suited for crack detection. Since it often represents the fastest wave mode in the structure, it is typically used in cases where first-arrival time picking together with a clear identification of the incoming wave is necessary.

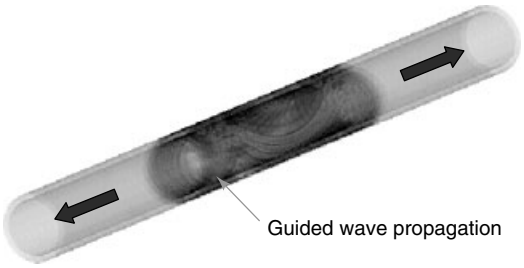

Figure 8. Guided elastic wave propagation in a steel pipe generated by a mechanical radial force point impact on the outer surface of the pipe. The wave front picture was calculated by using the 3-D cylindrical elastodynamic finite integration technique (CEFIT, [9]) and show the helical nature of the elastic wave field. Further interesting numerical and analytical investigations of guided waves in free pipes can be found in [10, 11]. [Reproduced from Ref. 9. © Elsevier, 2004.]

The main difference between a pipe and a plate is the curvature of the pipe producing additional dispersion effects. In guided-wave theory of cylindrical shells, the following naming convention for the different wave modes is commonly used:

1. *Longitudinal* modes are named $L(0, m)$ with $n = 0$ indicating an *axisymmetric* mode and $m = 1, 2, \ldots$ indicating modes of order 1, 2, etc.
2. *Torsional* modes are named $T(0, m)$ with $n = 0$ indicating an *axisymmetric* mode and $m = 1, 2, \ldots$ indicating modes of order 1, 2, etc.
3. *Flexural* modes are named $F(n, m)$ indicating non-axisymmetric modes with $n, m = 1, 2$, etc.

Up to a certain frequency threshold only three wave modes are present, $L(0,1)$, $L(0,2)$, and $T(0,1)$. Their flexural counterparts are $F(1,1)$, $F(1,3)$, and $F(1,2)$. These basic pipe modes can be associated with the fundamental plate modes, i.e., the fast symmetric and weakly dispersive S0 mode ($\cong L(0,2)$), the slow antisymmetric and dispersive A0 mode ($\cong L(0,1)$), and the nondispersive SH wave ($\cong T(0,1)$). Above the frequency threshold mentioned above, higher order modes arise ($T(0,2)$ and $L(0,3)$ in this case), similar to plate diagrams. For the sake of simplicity and clarity, we call these modes "pipe-S0", "pipe-A0", and "pipe-SH" or shorter, P-S0, P-A0, and P-SH in the following, although this procedure is not quite correct formally.

Another peculiarity of wave propagation in a pipe is that waves generated by pointlike sources are propagating along a helical curve around the longitudinal axis. This is shown in Figure 8, where the transient wave field due to a point impact on the outer pipe surface was calculated by using the numerical 3-D CEFIT technique [9]. As a consequence of helical-wave propagation, one and the same wave mode can be detected several times at a certain sensor position since different travel paths from the source to the sensor exist.

In order to demonstrate the existence of different wave modes, various measurements were performed

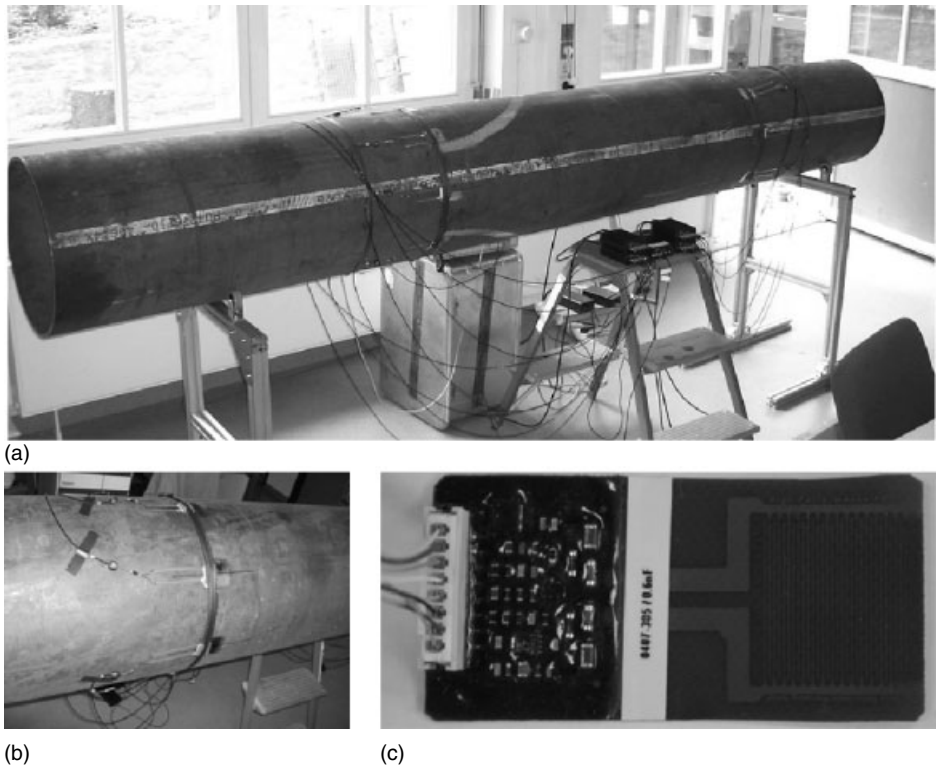

Figure 9. (a) Steel pipe as used for the laboratory measurements (length = 3 m, diameter = 406 mm, wall thickness = 9 mm). (b) In the present case, PZT fiber transducers are glued to the outer pipe surface (b and c). These transducers are characterized by a preferential directivity along the pipe axis and can be used for low-temperature applications up to 100 °C and for frequencies up to 600 kHz. (c) The picture shows a variant where PZT part and preamplifier are combined within one single transducer patch.

using the laboratory setup shown in Figure 9(a). For this low-temperature application, specifically adapted lead–zirconate–titanate (PZT) fiber transducer patches (Figure 9b and c) have been used to excite Ricker wavelets [12] with center frequencies of 70, 126, 240, and 370 kHz, respectively. The detected waveforms at a sensor position lying 150 cm away from the source are given in Figure 10. It should be noted that the time axis is given with a constant offset of +68 μs, i.e., the arrival times have to be corrected for that value before calculating the corresponding wave speeds.

In Figure 10, the first arrival is due to the fastest wave mode present, i.e., the P-S0 mode (or $F(1,3)$). The second elementary wave mode in the first two rows of Figure 10 can be associated with the P-A0 mode (or $F(1,1)$). If the center frequency of the input pulse is increased to 240 kHz, a new wave mode suddenly occurs. It is strongly dispersive and—due to its group velocity—can be identified as the first higher order symmetric mode P-S1 (or $F(1,5)$).

Besides these primary wave modes; secondary wave modes also appear. At 460 μs (−68 μs offset) a wave mode appears at 70 and 126 kHz that is in line with the first-order helical P-S0 mode whose travel distance between the source and receiver is approximately 2 m instead of 1.5 m for the direct wave. The same effect can be observed for the P-A0 mode whose first-order helical counterpart arrives at approximately 700 μs (−68 μs offset). In both cases, the signal shape of direct and helical wave is similar but the amplitude of the helical wave is smaller due to the larger geometrical spreading along the longer propagation path.

Another interesting echo can be found at 665 μs (−68 μs offset). Since the distance between each

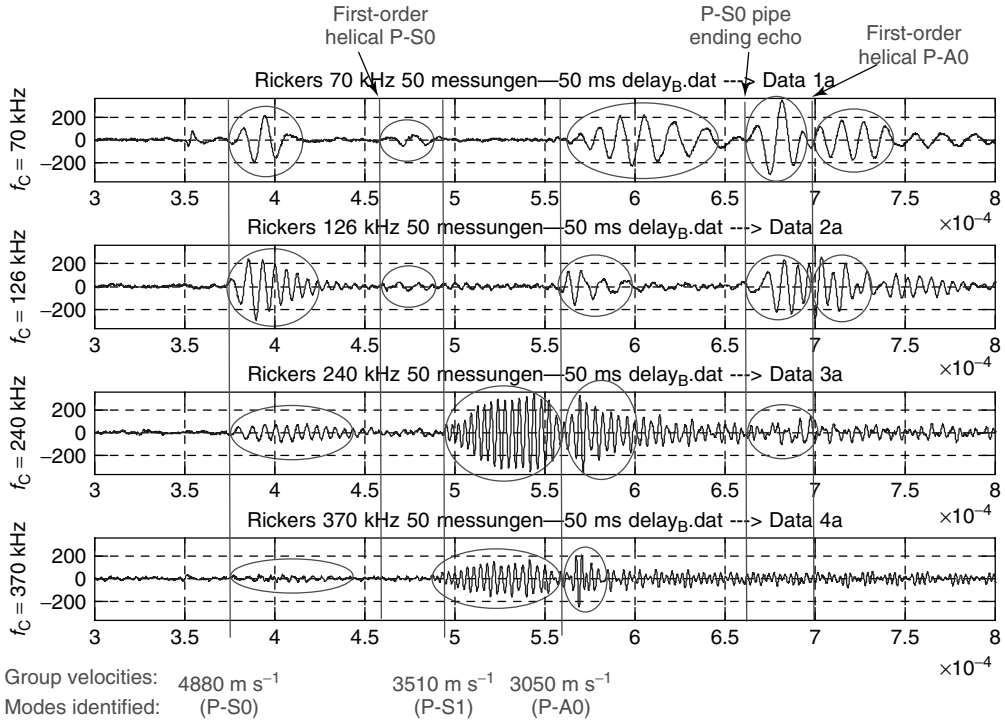

Figure 10. Measured time-domain signals along the steel pipe for four different center frequencies of the input pulse. All elementary wave modes as predicted by theoretical and numerical investigations (including helical modes) could be identified.

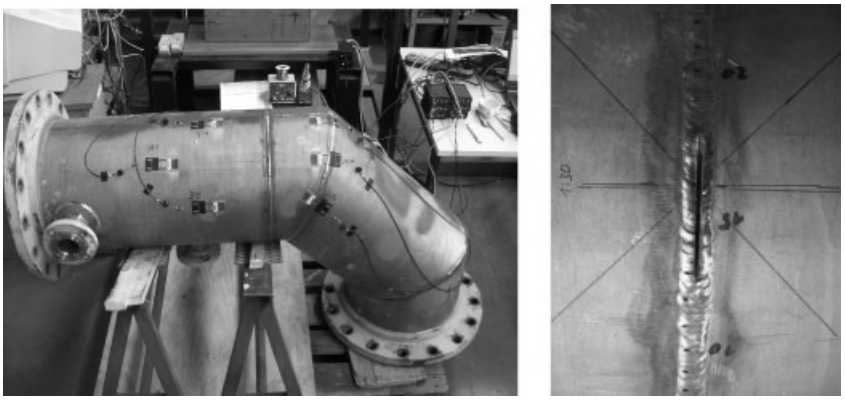
of the two transducers to the nearest pipe ending was 75 cm, a wave reflected at the pipe endings reaches the sensor after a propagation path of 3 m. Thus, the wave described above can be identified as the P-S0 echo of the pipe ending. Owing to reflection at the free end and the fact that two different propagation paths with identical length contribute to the signal ("actuator → right pipe ending → sensor" and "actuator → left pipe ending → sensor"), the amplitude of the echo is larger than the amplitude of the primary wave.

3.1 Interaction of guided waves with defects

The interaction of elastic waves with structure-relevant defects represents the most important aspect of guided-wave-based monitoring systems. In general, one can summarise that the higher the frequency the better the spatial and temporal resolution of the monitoring system and the better the sensitivity to small defects. However, for high frequencies, the number of existing wave modes is increased and strong dispersion leads to a complex situation and a severely limited range. The lower the frequency, the smaller the number of wave modes and the larger the obtainable range. However, these advantages are cancelled by a significantly lower sensitivity to small defects. Therefore, to choose a specific frequency for the input pulse always means to make a compromise between flaw sensitivity, on one hand, and obtainable range and dispersion of the corresponding wave modes on the other hand. By using traditional ultrasonic NDE systems working in the megahertz frequency range, very small cracks in the micrometer range can be found but the structural information is usually limited to a small area of the pipe. In order to test the entire pipe, an appropriate scanning device is necessary.

In guided-wave-based SHM, a larger part of the pipe can be examined within one measurement cycle.



(a) (b)

Figure 11. (a) Titanium elbow (wall thickness = 6 mm) (b) with notches artificially introduced into a weld seam. The notch depth was varied between 1 mm (first step) and 5.3 mm (last step). Owing to the sawing, the initial notch length of approximately 12 mm was also increased stepwise.

Owing to the fact that monitoring can be performed in nearly arbitrary time intervals of a few seconds up to a few days, the critical size of defects that have to be found can be increased compared to traditional NDE, which is usually applied in periodic intervals of months or years. Statements from industrial partners revealed that in a typical pipe, cracklike defects, not larger than three times of the wall thickness and not deeper than One-third of the wall thickness, have to be found by an SHM system. For a steel pipe as described earlier (wall thickness = 9 mm), this means that the monitoring system must be able to find cracks not larger than 27 mm and not deeper than 3 mm. As a rough rule of thumb, a defect becomes detectable if its lateral size is at least comparable to the wavelength of the specific wave mode used for the measurements and if its depth is larger than 10–15% of the wall thickness. According to this rule, guided waves in the frequency range between 100 and 200 kHz with wavelengths between 20 and 50 mm as described earlier should be able to meet the requirements of defect sensitivity, on one hand, and sufficiently large range on the other hand.

The main idea of the underlying SHM system is the comparison of the actual state of the pipe with a certain reference state ("baseline approach"). This reference state can either be the pipe without any defects or, alternatively, a state with smaller defect size. For the present investigation at a titanium elbow as shown in Figure 11(a), a reference measurement without any defects was performed first. After that the measurements including the defects were done and compared to the reference state.

In one of the weld seams of the elbow, artificial notches were inserted by sawing (Figure 11b). The depth of the notch was increased from 1 to 5.3 mm in discrete steps. Owing to the sawing, the length of the notch was also increased simultaneously from approximately 12 to 35 mm. For each state, the system response of the elbow due to pulse excitation was determined for different actuator/sensor combinations and was compared with a reference state without defects.

Figure 12(a) shows a typical time-domain signal obtained by using one PZT transducer as actuator and another one as sensor. The center frequency of the input pulse was $f = 150$ kHz in this case. For a 1-mm-deep notch (results not shown here), the difference to the reference measurement without notch is rather small and thus, the linear correlation coefficient between both curves is nearly equal to one. For the 3.5-mm notch as shown in Figure 12 the difference between the curves is significantly larger and, therefore, the correlation coefficient drops to approximately 0.97. For calculation of the correlation coefficients, we used the Hilbert envelope of the signals instead of the signals themselves due to higher robustness.

The measurements were repeated for different notch depths and various center frequencies of the

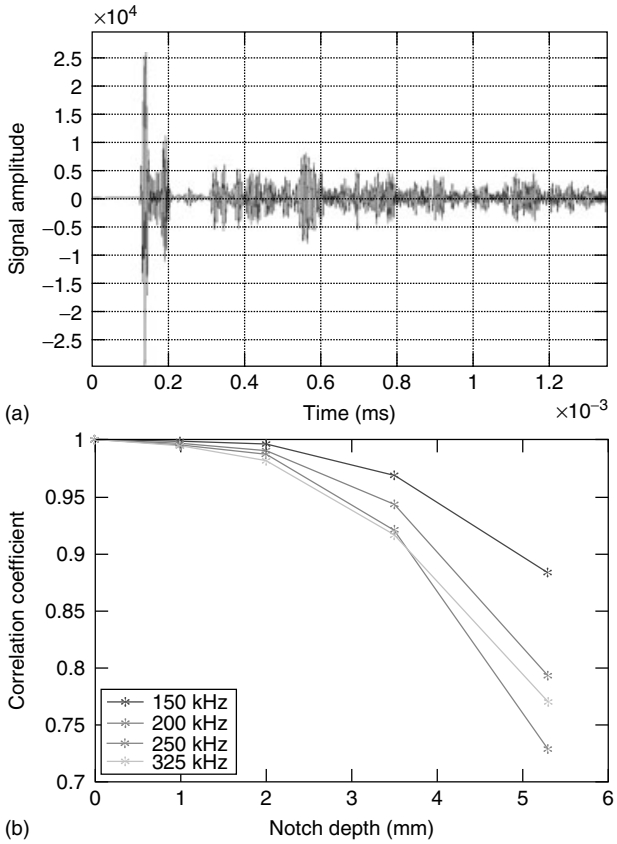


Figure 12. Data evaluation with baseline approach. (a) Typical guided-wave system response of the titanium elbow for a 3.5-mm-deep notch together with the reference signal of the system without notch (the two curves are only discriminable in the colored online version of the Figure). (b) Typical correlation coefficients as a function of notch depth (horizontal axis) and center frequency of the input pulse (different curves), obtained by comparing the particular Hilbert envelopes of the time-domain response with the reference measurements without notch. As a general trend, the correlation coefficient decreases with increasing notch depth and increasing frequency and thus serves as a sensitive damage indicator.

input pulse as well as for different (short and long) propagation paths. In Figure 12(b), the results of the correlation analysis for the short propagation path are displayed for notch depths of 1, 2, 3.5, and 5.3 mm, and for frequencies of 150, 200, 250, and 325 kHz, respectively.

As a general trend, we find that the correlation coefficient decreases with increasing notch depth and also with increasing frequency. These results are physically plausible since in both cases the interaction between guided waves and the defect is enlarged. For the short propagation path, the correlation coefficient drops to values between 0.88 and 0.73. For a longer path (curves not shown here), the correlation coefficient drops to values between 0.931 and 0.937, which is clearly smaller but still significant, even for the lowest frequency.

The results revealed that under laboratory conditions, cracklike defects having a depth of only One/fifth of the wall thickness can be detected by such a monitoring system even in complex geometries with flanges, weld seams, and curvatures, and in cases where the wavelengths are not significantly larger than the lateral size of the defect and where the distance to the source and receiver is rather large. In field tests, a worse signal-to-noise ratio can be expected due to background noise and other disturbances. However, owing to the fact that the coupling

conditions remain constant and the excitation is reproducible, the measurements can be repeated many times in order to increase the signal-to-noise ratio until it reaches an acceptable level.

4 HARDWARE AND GENERAL CONCEPTION OF THE SHM SYSTEM

In order to combine global and local condition monitoring as described in Sections 2 and 3 within a joint SHM system, multichannel network nodes have been designed and developed (Figure 13). Each single node represents a four-channel monitoring system, which is able to manage different kinds of actuators and/or sensors (for low- and high-temperature applications and for low- and high-frequency monitoring). Two different types of nodes are available, one for high-frequency guided-wave monitoring (the local eye) and another type for low-frequency vibration monitoring (the global eye). Each single node can be combined with several others (local or global) resulting in a multichannel monitoring system.

One node consists of four analog input channels per module having a bandwidth of 10 mHz to 10 kHz for the global eye and 20–1000 kHz for the local eye. In the latter case, the sampling is up to 18 Megasamples per second. A 32-bit fix point digital signal processor (DSP), an arbitrary waveform generator, a power amplifier as well as a hardware trigger with synchronization are included. A CAN-Bus interface is normally used but wireless Bluetooth, ZigBee, and nanoNET interfaces are under development. The power supply is 24 V dc. The measured data can be stored on movable memory cards or can be transferred online via USB-Ports.

As explained earlier, the key concept of the new SHM system is the combination of low- and high-frequency monitoring as demonstrated in Figure 14. While the passive low-frequency nodes with acceleration and strain sensors are responsible for global vibration monitoring of the structure (providing information on basic boundary conditions caused by supports and dampers) the active high-frequency guided-wave nodes are used to monitor local crucial and error-prone parts of the piping system. Both levels, i.e., local and global ones, will be combined adaptively dependent on the actual state of the piping system.

The monitoring results from both types of nodes finally merge in a joint decision support system (DSS), which should contribute to the following points in its final version:

1. identification of defects: raise an alarm if a defect is present;
2. localization of defects: if a defect is present, determine its (approximate) position;
3. relevance of defects: determine the kind of defect and state if the defect is relevant for the structural integrity of the pipe; and

Figure 13. Four-channel sensor/actuator nodes for SHM of piping systems. The nodes can be combined to a multichannel measuring system that can be used for both active and passive monitoring. The present nodes are based on a CAN–Bus interface but wireless interfaces are also under development. Details of the hardware implementation can be found in Section 4 and in [13]. [Reproduced with permission from Ref. 13. © SPIE, 2007.]

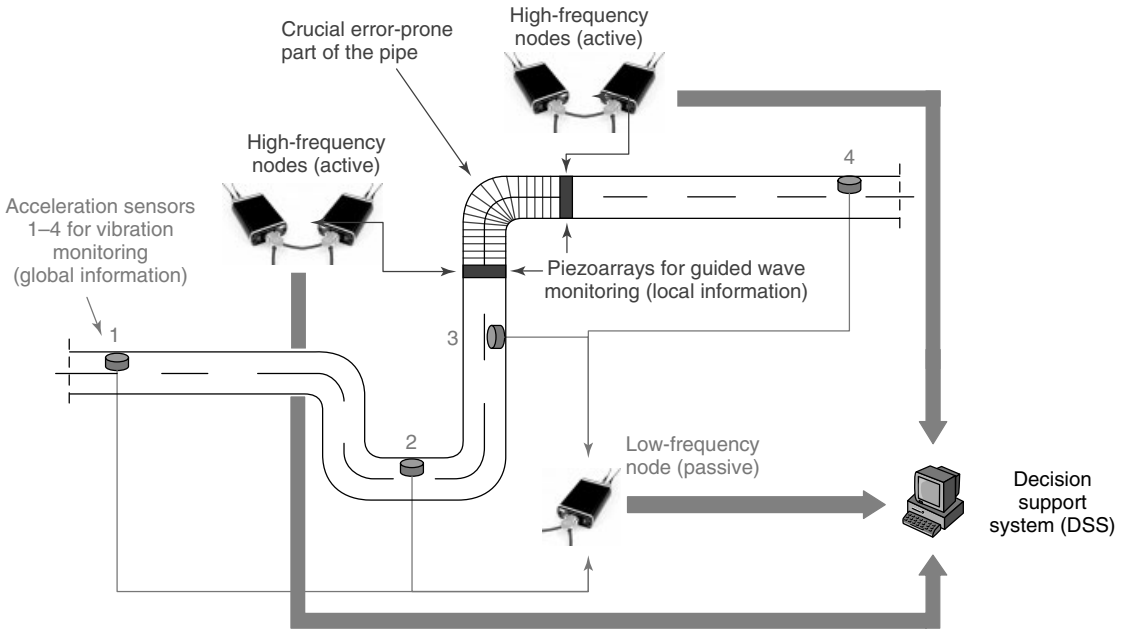

Figure 14. Combination of low- and high-frequency monitoring. While the passive low-frequency nodes with acceleration and strain sensors are responsible for global vibration monitoring of the structure (providing information on basic boundary conditions caused by supports and dampers) the active high-frequency guided-wave nodes are used to monitor local crucial and error-prone parts of the piping system.

4. residual lifetime: try to estimate the remaining lifetime of the structure.

The last two points in the preceding list are embedded in an overall lifetime management of the whole structure and should, therefore, be closely connected with former experience and databases of the plant operator. For this purpose, the DSS will be based on a case-based reasoning approach in order to allow for a close interaction between operator and monitoring system.

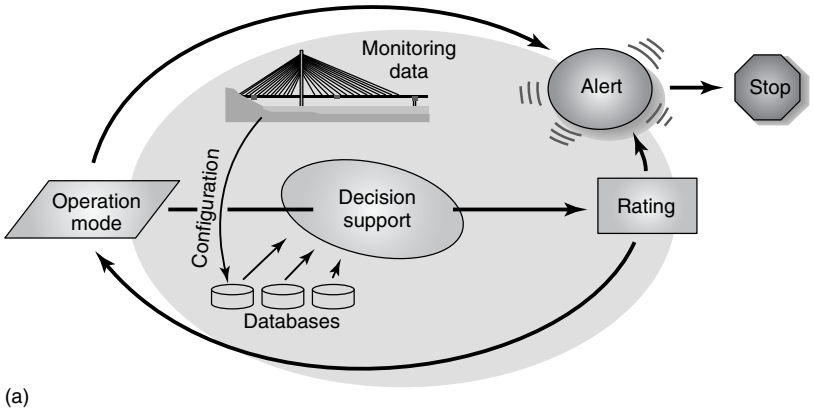
5 DECISION SUPPORT SYSTEM

During the SAFE PIPES project, a DSS called *VCDECIS* has been developed for the assessment of industrial piping systems (Figure 15a). VCDECIS combines previous knowledge with actual measurements (e.g., of ambient vibrations [14]) and offers a variety of options for assessment and damage-detection procedures. It provides all the necessary tools for decision making when monitoring data are available. It allows a combination of various methodologies and provides options for the compensation of environmental influences like temperature, external loading, or radiation from sunshine.

The system consists of five modules which are as follows:

- the operation module (operators tool)
- the databases
- the decision support module
- the alert system
- the output module (takes action if appropriate).

Here, we only focus on the decision support and the alert system. The DSS is defined by rules, which allow an assessment on finding facts and indicators in the available data. Some of the methodologies are complementary and it is intended to conduct parallel processing and comparison of the results. The building of a mean also might make sense in several cases. The rules are the core of the assessment system. They consist of methodologies developed in order to get the maximum information out of the data. The set of rules is permanently updated and enlarged.



(a)

Risk level	Why	What to do
Low	Info	Regular operation
Moderate	Info	Long-term action
Considerable	Show development	Mid-term action
High	Demonstrate risk	Immediate action
Extreme	Show default	Automatic alert, action

(b)

Figure 15. (a) System architecture of the decision support system VCDECIS and (b) the implemented risk levels with cause and consequence. The coloring follows the international practice, i.e risk level Low = green, Moderate = yellow, Considerable = orange, High = red, Extreme = framed blazing red. The colors are only displayed in the coloured online version of the Figure.

The system is started through a configuration file, where the user is asked which methodologies shall be applied and which combinations are desired. A default menu is available that directs the user to a standard evaluation. Each assessment step provides results, which are then stored in the knowledge database for statistical use.

There is an option to go with the process through a neural network that has been trained by the previous applications. Nevertheless, this step is not fully developed, yet owing to insufficient training possibilities for the network and ongoing development work, it is anticipated that support can be provided in the future for the user by this system.

Information on the risk level is also provided to the user. The system has been chosen in connection to alert systems used for natural hazards. Landslide or avalanche alert systems know five distinct risk levels, which are shown in Figure 15(b). When risk level 4 is reached, a consultation with an expert is proposed. The alarm is provided to the operator, who is asked to consult an expert on the observed phenomena. After that the risk level can be up or downgraded. This is the only active interference option.

When risk level 5 is reached, automatic action by the system can be triggered. This could be eventually a red traffic light at the approach to a pipe monitored. The other risk levels provide information for the operator and also ask for his input. As explained in the operation mode, the operator has the opportunity to interfere with the system here and to add his subjective impression to the process. The actions to be performed at each level will have to be defined from case to case. It has to be coordinated with the standard procedure of the plant owners.

6 LIFETIME MANAGEMENT

Lifetime management (Figure 16a) stands for the integration of aging management and economic planning for systems, structures and components (SSC) and, therefore, also for piping systems in power

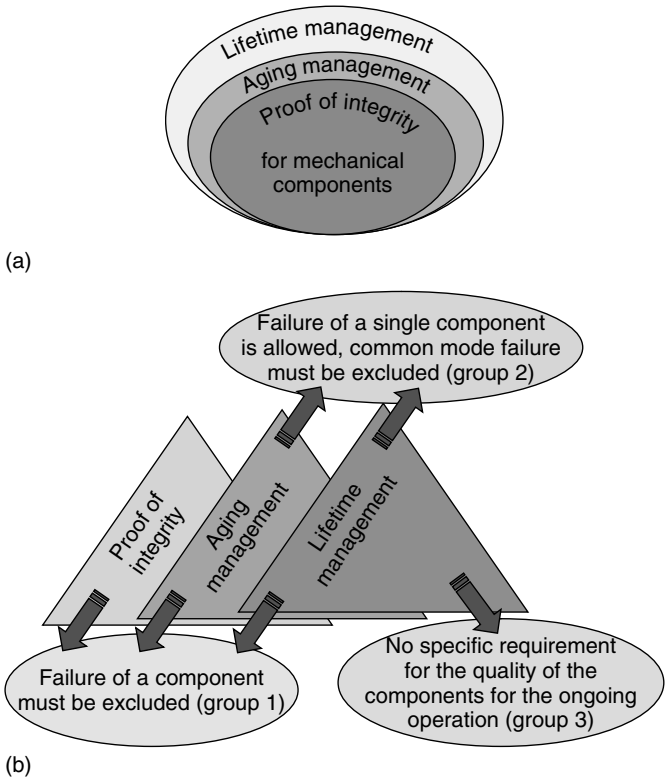


Figure 16. Concept of lifetime management of industrial piping systems. (a) Correlation between lifetime management, aging management, and proof of integrity for systems, structures, and components (SSC); and (b) application of lifetime management, aging management, and proof of integrity for SSC of groups 1, 2, and 3.

plants. The main goals of lifetime management are to optimize the operation, the maintenance and the lifetime of the plants, to maintain an accepted level of safety and performance, and to maximize return on investment over the lifetime of the plant.

Lifetime management has very strong and clear definitions in the field of nuclear power plant, which is shown as follows and reported in [15–19], for example. Various engineering measures are required depending on the safety relevance of the SSC or for reasons of preventive maintenance. Consequently, the SSC have to be divided into three groups (Figure 16b).

The first step within the scope of lifetime management of mechanical components is to select and arrange the SSC and to assign these to group 1, 2, or 3. The classification is according to the requirements of the nuclear codes and standards and if necessary according to plant-specific and safety-related factors. The plant operator is responsible for the classification and an expert has to check it on the basis of the current codes, standards, and the state of the art.

- **Group 1**

Failure of the SSC shall be excluded to avoid subsequent damage, e.g., main coolant lines (MCL). The required quality shall be guaranteed for subsequent operation. The causes of possible in-service damage mechanisms shall be monitored and controlled (proof of integrity). Implementing this "proactive approach" prevents damage.

- **Group 2**

For redundant SSC, the failure of a single part is allowable from a safety relevant point of view. However, common mode failure shall be excluded.

The present quality shall be maintained for subsequent operation. The consequences of possible in-service damage mechanisms shall be monitored (preventive maintenance, time or condition based).

- **Group 3**

There are no defined standards for the quality of the SSC concerning subsequent operation (failure-oriented maintenance).

These guidelines, codes, and standards concern safe operation during the total lifetime (lifetime management), safety against aging phenomena (aging management) as well as proof of integrity (e.g., break exclusion or avoidance of fracture). Within this field, the aging management is a key element. Depending on the safety relevance of the SSC under observation including preventive maintenance, various tasks are required, in particular, to clarify the mechanisms that contribute system-specifically to the damage of the components and systems and to define their controlling parameters, which have to be monitored and checked. Appropriate continuous or discontinuous measures are to be considered in this connection.

7 CONCLUSIONS AND OUTLOOK

In this article, only a short extract of the results obtained within the SAFE PIPES project could be given. The whole results obtained so far revealed that both global vibration monitoring and local guided-wave monitoring of industrial piping systems provide complementary information about the structure under investigation. While vibration monitoring is able to characterize the global condition of the structure due to supports and dampers, the guided-wave module is able to find small cracklike defects and corrosive material degradation in crucial error-prone parts of the components. It can, therefore, be expected that a combination of the "global" and "local eye" will lead to a monitoring system with significantly increased performance and reliability. The development of a joint DSS that evaluates both low- and high-frequency data and that is embedded in an overall lifetime management of industrial piping systems still needs to be completed and is therefore the subject of ongoing work within the SAFE PIPES project.

ACKNOWLEDGMENTS

The present work has been supported by the Commission of the European Communities in the framework of the specific targeted research project SAFE PIPES (Safety Assessment and Lifetime Management of Industrial Piping Systems) under the sixth framework program (NMP2-CT-2005-013898) as well as by the German Bundesministerium für Bildung und Forschung (BMBF) and the Bundesministerium für Wirtschaft und Technologie (BMWI), respectively. This support is gratefully acknowledged. We also thank all our partners in the SAFE PIPES consortium, especially NMW Würzburg for providing us with the PZT fiber transducers and DOW Stade for supply of the titanium elbow.

Chapter 81
Microelectromechanical Systems (MEMS)

Jonas Meyer, Reinhard Bischoff and Glauco Feltrin

Structural Engineering Research Laboratory, Empa, Swiss Federal Laboratories for Materials Testing and Research, Dübendorf, Switzerland

1 INTRODUCTION

Microelectromechanical systems (MEMS) are integrated devices or systems of devices that combine electrical and mechanical components and that have a size, which ranges from the submicrometer to the millimeter level. Miniature mechanical elements such as beams, diaphragms, and springs are fabricated by micromachining techniques from silicon wafers and are combined with microelectronic components and circuits to form microsensors, microactuators, and microengines. The microfabrication technology allows for fabrication of large systems of MEMS devices, which individually perform simple tasks, but in combination can accomplish complicated functions. MEMS allow sensing, controlling, and activating physical and chemical processes on the micro and, by a suitable combination of clusters of MEMS devices, also on the macro scale.

Typical examples of MEMS devices are accelerometers, gyroscopes, strain gauges, pressure and flow sensors, miniature robots, fluid pumps, microvalves, and micromirrors. The term *MEMS* was coined in 1987, long after the first micromachined devices, in particular, microsensors, were commercially available. Equivalent terms for MEMS are microsystems and micromachines.

The term micromachining designates the fabrication of micromechanical parts (such as diaphragms or beams). These parts were fabricated by etching away selected areas of the silicon substrate to obtain the desired micromechanical components. Since the early 1960s, various etching techniques were developed to improve the fabrication of micromechanical components and these techniques form the basis of the so-called bulk micromachining processing techniques. The need for higher design flexibility and better performance, however, gave rise to surface micromachining techniques, in which the so-called sacrificial layers are deposited between structural

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

layers for mechanical separation and isolation. These sacrificial layers are then removed by etching to free the structural layers and to enable mechanical components to move relative to the substrate. Surface micromachining enables the fabrication of complex multicomponent integrated micromechanical structures that would not be possible with traditional bulk micromachining. Details on MEMS and their fabrication technologies can be found in [1–3].

2 MECHANICAL MEMS SENSORS

MEMS devices for sensing mechanical quantities are the most important class of microsensors. The first fabrication of silicon-based MEMS devices started in the late 1950s with the development of pressure microsensors. In 1974, National Semiconductor launched the first high-volume pressure sensor in the market. Silicon pressure sensors are at present the commercially most important microsensor type with a billion-dollar market and large-scale technical applications in different industries like the automotive and aeronautical industry.

The discovery of the piezoresistive effect in silicon and germanium in 1954 enabled the development of silicon-based micromachined strain gauges with a gauge factor 10–20 times greater than those based on metal films. Micromachined piezoresistive strain gauges are now a standard component in accelerometers and pressure sensors.

2.1 Accelerometers

Accelerometers are the commercially second most important type of mechanical microsensors. The design principle of MEMS accelerometers is the same as traditional accelerometers: an inertial mass suspended by a linear elastic mechanical component (micromachined cantilever beam, bridge, or membrane). Accelerations cause inertial forces, which deflect the suspended mass from its zero position. This deflection is converted by a pickup to an electrical signal, which, after a suitable signal conditioning by an internal integrated circuit, appears at the sensor output. The two most prevalent pickup types of MEMS accelerometers are: capacitive and piezoresistive pickup of the seismic mass movement, where capacitive polysilicon surface-micromachined and single-crystal micromachined devices are the most important types.

The amplitude range of capacitive MEMS accelerometers varies between a few g up to $50g$ for applications in air bag systems. Currently, several low-g MEMS accelerometers are commercially available. Table 1 displays a selection of these accelerometers, which have the characteristics to be applicable in structural health monitoring (SHM).

2.2 Application aspects

MEMS sensors have several advantages compared to conventional sensors. They are small, generally low power, highly integrated, and, usually, cheap. These

qualities enable the deployment of SHM systems with a large number of small sensors, partly integrated into the structure, at affordable costs. When deploying a large number of sensors, the cabling of all sensors with data logging units becomes so labor and cost intensive that it cancels all the advantages of applying MEMS sensors. Therefore, to overcome the limitations of cabling, MEMS sensors are often used in combination with wireless communication technologies. In this area, wireless sensor networks (WSNs) are an emerging technology that heavily bases its sensing capability on small, low-power, and cheap sensors. A WSN is a network of many small intercommunicating computers that are equipped with one or several sensors (*see* **Wireless Sensor Network Platforms**). Since WSNs rely completely on batteries, the application of low-power sensors is a key requirement, and minimizing power consumption is fundamental for extending the operation lifetime of the network. WSNs are being investigated for use in a variety of military, environmental, home, health, and SHM applications. SHM systems based on MEMS devices have been developed and tested in aerospace [4] and automotive [5] engineering. A review of WSNs for SHM is found in [6] and in-depth information about architectures and protocols for WSNs in [7].

3 MEMS-BASED STRUCTURAL HEALTH MONITORING SYSTEM

An application that illustrates very well the potentiality of an MEMS-based WSN is cable tension force monitoring of stay cable bridges. Cable stay forces can be monitored by means of natural frequency estimations based on vibration measurements. By using an appropriate cable model, the relation between the natural frequencies and the tensile cable force can be described.

3.1 Sensor node hardware

A typical network node is composed of one or more sensors, a signal conditioning unit, an analog to digital converter, a data processing unit with memory, a radio transceiver, and a power supply. These components are integrated into an enclosure, which protects the hardware components from mechanical, chemical, and environmental impacts. Figure 1 shows the open rugged and waterproof enclosure, which is designed for applications in harsh conditions. The enclosure contains the hardware components and the power supply, which consists of two 1.5-V batteries with 16 500 mA-h each. External status light emitting diodes (LEDs), switches and connectors allow supervising, interacting, and connecting external sensors, which have to be mounted directly to the structure (e.g., strain gauges).

Many hardware platforms are commercially available that are optimized in terms of power consumption. The prototype network presented in this article is based on the Tmote Sky platform [8]. It features a 6-channel ADC with a resolution of 12 bit, a 16-bit processor with 10-kB RAM and 48-kB program flash memory, and a radio transceiver operating in the 2.4-GHz ISM band with a raw data rate of 250 kbps.

The signal conditioning unit enables to interface various sensing elements. A Sensirion humidity sensor SHT11 [9] is mounted into an opening in the enclosure and allows for temperature and humidity measurements outside of the box. For vibration measurements, the MEMS accelerometer LSI2L06 of ST Microelectronics [10] has been applied because of its good noise performance, low-power consumption, and low costs. The accelerometer and the signal conditioning circuitry, consisting of an amplifier and a low-pass filter, are mounted on a dedicated board (Figure 2).

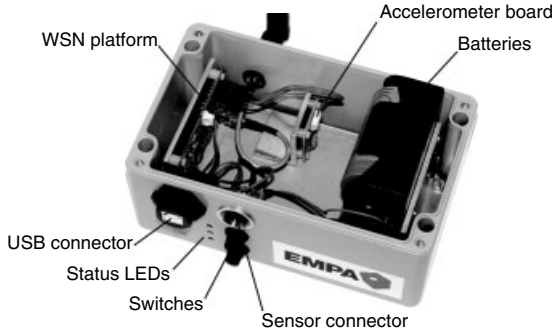

Figure 1. View of a physical sensor node with rugged and waterproof enclosure.

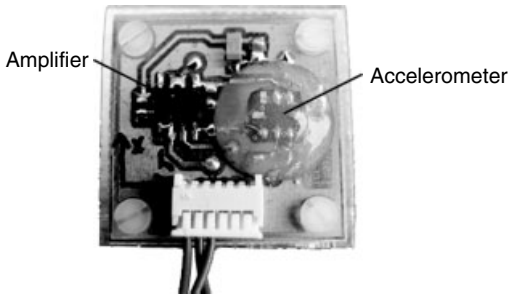

Figure 2. MEMS accelerometer board with amplification and filtering circuitry.

3.2 Sensor node software

The software running on each sensor node sets up the communication links between the sensor nodes, organizes the network topology, synchronizes the nodes, acquires measurements, and performs the data processing. The software is implemented as TinyOS components [11]. TinyOS is a component-based software framework designed for sensor networks and tailored to fit the memory constraints of the sensor nodes. It provides a concurrency model and mechanisms for structuring, naming, and linking software components to form a robust network embedded system.

The basic network functionality is provided by low-level network management components that operate independently from the actual monitoring applications. They are responsible for establishing the wireless links between adjacent nodes, for building the routing tree and for network-wide time synchronization. The monitoring application, which is built on top of these modules, uses this functionality to send and receive data and to have access to global time information. This allows for flexible exchange of the communication and time synchronization components.

A scheduler component forms the core of the actual monitoring application. It manages the data acquisition performed by the sensor node. Its clock is synchronized to the global time. The scheduler configures the measurement and data processing parameters like sampling rates, filter coefficients, thresholds, etc.; it triggers the data acquisition at the scheduled time. In addition to temperature, humidity, and acceleration measurements, information about the internal state of each sensor node (battery voltage) as well as communication parameters of the sensor network (e.g., routing tree) are monitored.

3.3 Data processing

The limited energy resources on each sensor node present the most restricting factor in designing and implementing WSN-based SHM systems. In terms of power consumption, wireless data transmission is much more expensive than data processing. In order to extend the system lifetime, it is therefore preferable to process the raw sensor readings in each sensor node with the aim to significantly reduce the data items that need to be transmitted to the data sink. This strategy is particularly recommended when monitoring vibration-based processes, which produce large amounts of raw data. There are several methods to reduce the size of raw data:

- Data compression encodes the data in a new representation that uses fewer bits than the original, not encoded data. This data reduction is done by using specific encoding schemes, which can either be lossless or lossy [12, 13].
- Data transformation transforms the raw data into a new kind of information that requires less space in terms of bits. Examples of simple data reductions can be maxima, minima, mean values, rms (root mean square), or statistical probability distributions of a physical quantity.
- Data analysis on the sensor node level reduces the amount of data transferred to the network. It differs from the methods described above because the raw data is subjected to an evaluation. The data is analyzed according to given criteria and a decision is taken if the data is relevant or not. Irrelevant data can already be discarded at the sensor node level.

Hence, long-term monitoring with WSN implies decentralized data processing and analysis. However, this is by far not possible for every analysis method. The limited energy resources restrict the complexity of the computational hardware of the sensor node, basically the memory size and computing speed of the hardware, and consequently affect the achievable analysis complexity.

In conventional monitoring systems, natural frequencies can be determined by identifying the

peaks in a frequency spectrum that are computed via averaged spectrogram based on fast Fourier transform (FFT). An efficient in-place FFT computation of 1024 data samples of 16-bit length requires approximately 2 kB. This is a quite large amount of memory usage for low-power microcontrollers, with typical memory sizes of 2–10 kB, since the programs for data processing, task scheduling, time synchronization, and networking must be stored in the very same memory. Therefore, a much less memory demanding method for computing natural frequencies is needed.

Parametric methods of spectral analysis fit this requirement. The natural frequencies are estimated by computing the poles of a spectral model based on a rational function. If the natural frequencies are well separated in the frequency spectrum, a requirement that cable stays usually fulfill quite well, the vibration components associated to a vibration mode can be isolated by filtering the recorded data with a band pass filter. The use of a very simple two-parameter discrete time autoregressive (AR) model is then sufficient to estimate the natural frequency. An algorithm that enables a data reduction by a factor of 500 performs the following steps:

1. The analog signals of the accelerometer are digitalized and stored in a buffer.
2. The offset in the recorded data produced by the earth's gravity is removed by subtracting the average of the recorded data.
3. The recorded data is filtered with a band pass filter to isolate the frequency components close to one of the natural frequencies.
4. A data block is extracted from the filtered data. The size of the data block should contain at least one period of the natural frequency that will be estimated.
5. Using the data block, the parameters of the AR model are fitted. With these parameters, the natural frequency and the damping ratio of the AR model are estimated.
6. The quality of the natural frequency is tested using the estimated damping ratio, since a low damping ratio correlates with a nearly pure harmonic. If the damping ratio is greater than a given threshold, the estimated natural frequency is rejected and step 7 is skipped.
7. The natural frequency estimations that passed the quality test are stored in an array.
8. A new data block is extracted from the filtered data and the steps 5, 6, and 7 are repeated until all data blocks have been processed.
9. The mean value of the natural frequency estimations stored in the array is computed. This represents the estimated natural frequency that is transmitted to the network.

A detailed description of the implemented algorithm can be found in Feltrin *et al.* [14].

4 FIELD TESTS WITH THE MEMS-BASED SHM SYSTEM

The field tests were performed on the Stork Bridge, a two-span cable stayed road bridge with a total length of 124 m. The monitoring was performed on 6 of the 24 cables. Before deploying the monitoring system, a preliminary investigation with standard data-acquisition equipment was performed with the goal to determine the natural frequencies of the six cables and identify the vibration modes with the highest vibration level. This information was used to select the natural frequencies to be tracked by the WSN and to design the band pass filters.

4.1 Overall SHM system

The logical structure of the WSN monitoring system that has been deployed on the bridge is displayed in Figure 3. It is composed of three subsystems. The first subsystem is the WSN that consists of seven sensor nodes: six sensor nodes mounted on the cables, labeled as C21–C26, and the root node, labeled as C0, which is situated under the bridge deck at the abutment (Figure 4). The root node is connected via USB to the base station, which was placed inside the abutment. The base station is powered via the mains supply. The second subsystem is the remote control center that collects all data generated by the WSN and is responsible for the long-term storage of the data. It implements the data visualization and representation tools. Furthermore, this subsystem provides an interface to the operator to observe, control, and configure the WSN remotely. This subsystem was located at the EMPA site in Duebendorf, at a distance of 16 km from the Stork Bridge. The third subsystem forms

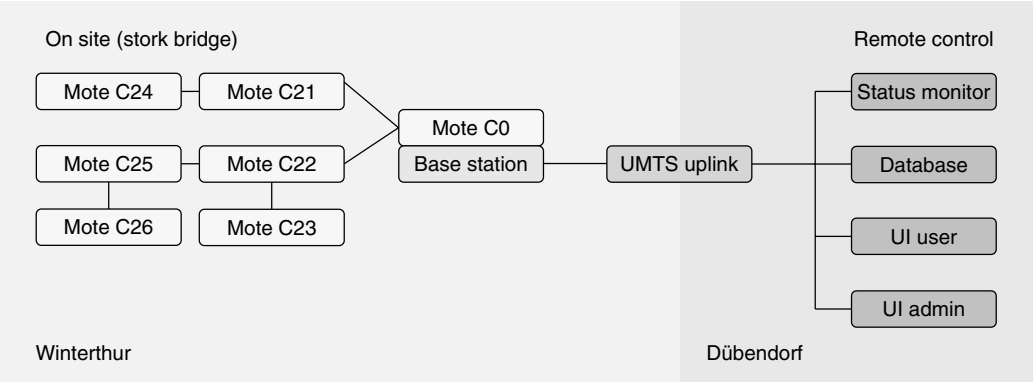

Figure 3. Logical structure of the structural health monitoring system.

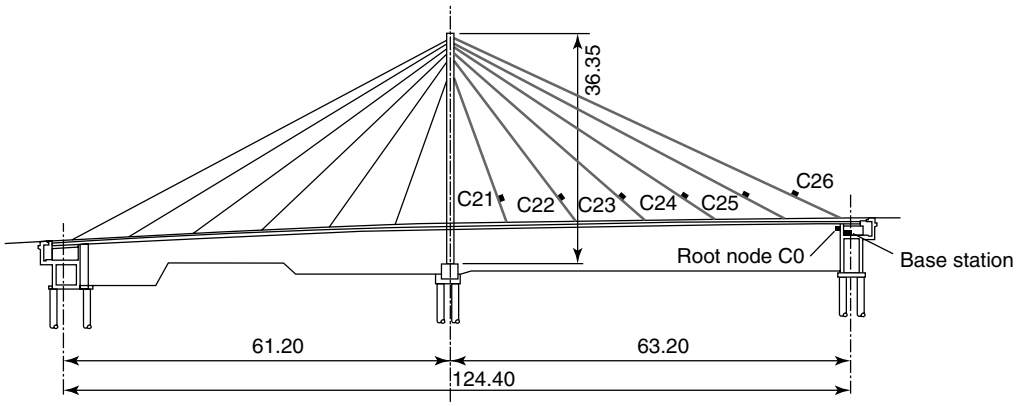

Figure 4. Elevation of the Stork Bridge with structural health monitoring setup.

the communication link between the WSN deployed on the bridge and the remote control center. This link is established via the base station using a standard wireless Universal Mobile Telecommunications System (UMTS) connection. A view to a network node mounted on a cable and to the root node below the bridge is shown in Figure 5.

The most challenging issue was to achieve overall system stability. A major source of instability was data processing. The computation of natural frequencies in one shot occupied the CPU for a long period and spoiled the execution of processes that guarantees the basic network functionality producing frequent system break downs. To overcome this problem, the algorithm was split up into tiny threaded code sections that required limited CPU time and that permitted an execution of basic network processes between two sequential threaded code sections. Furthermore, the integration of data acquisition, data processing, time synchronization, process scheduling, etc. into one software system turned out to be very sensitive to many tiny details regulating their interrelations. A change of duty cycle, for example, could destabilize the system producing system breakdowns within a short time. The modest CPU and RAM resources of the Tmote Sky platform significantly accentuated these problems.

5 RESULTS

Figure 6 displays a typical time history of the accelerations that were captured on the longest cable (C26) with the MEMS accelerometer LSI2L06 at a sampling rate of 100 Hz. The magnitude of the ambient cable vibration is very low. With respect to the 12-bit AD

Figure 5. Views of a sensor node mounted on a cable and the root node in the bridge abutment below the bridge deck.

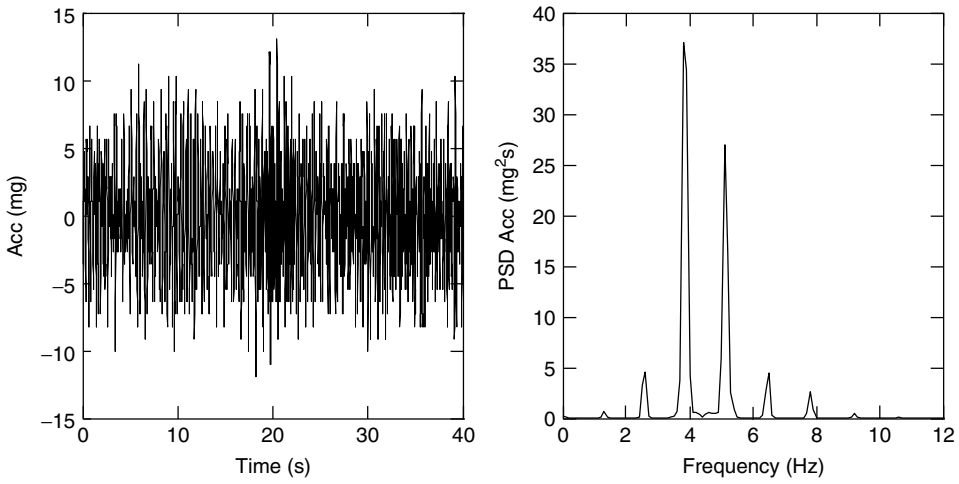

Figure 6. Time history of the accelerations sensed with the MEMS accelerometer LSI2L06 and its power density spectrum.

converter, which maps 1 mg approximately to 1 bit, the maximum of 13 mg is equivalent to 4 bits. Nevertheless, the natural frequencies can still be extracted from the time history as is demonstrated by the power density spectrum shown in Figure 6.

Figure 7 displays the natural frequencies of the cables C24, C25, and C26 of the Stork Bridge during a period of 60 days. The natural frequencies were estimated every minute from ambient vibration data using the algorithm described in this article. The typical rms magnitude of the ambient vibration data was 4–20 mg. The computation of the natural frequency lasts approximately 8 s. The algorithm was implemented in a series of threaded code sections to enable concurrent processes (e.g., time synchronization) to access the CPU. The three bands displayed in Figure 7; demonstrate that the algorithm generates estimations with a significant scattering. The accuracy of individual frequency estimations is within 5–10%, which is a direct consequence of the low level of accelerations and the short data blocks used for estimating the natural frequency (blocks of 50 samples, which correspond to 2–2.5 cycles).

A more accurate estimation of the natural frequency is obtained by using a moving average filter with a span of 200 samples (black curves inside the bands). Relatively small variations of natural frequencies are still detectable. This data processing step was done at the off-site control center with data retrieved from the data base. For monitoring

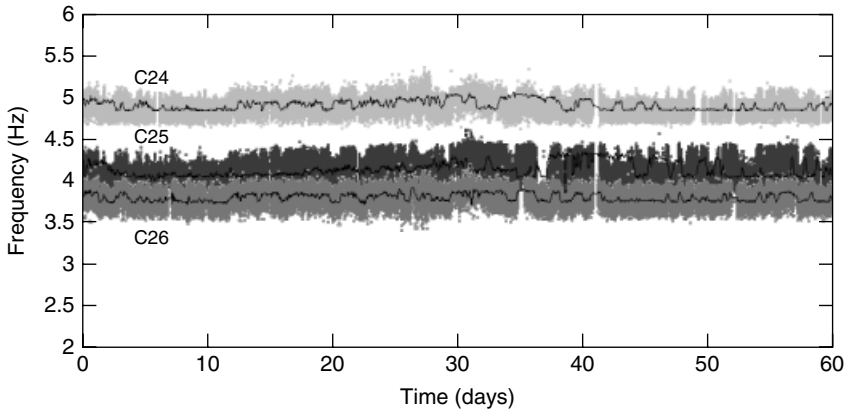

Figure 7. Time history of the natural frequencies of the cables C24, C25, and C26.

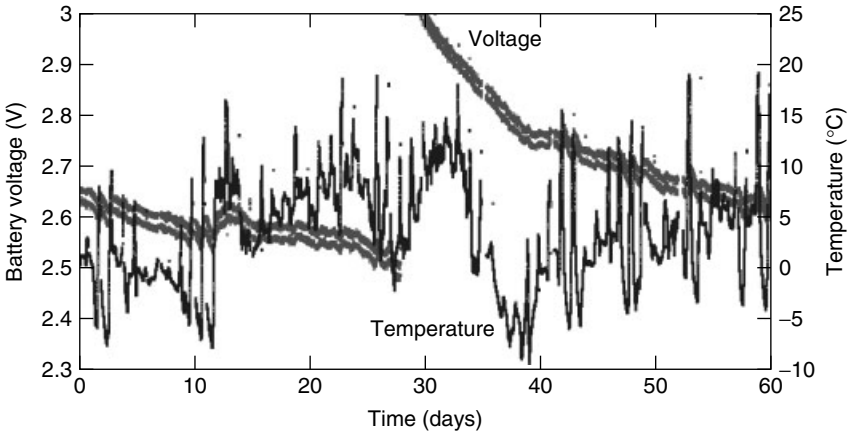

Figure 8. Time history of the battery voltage of the sensor node and the temperature measured on the cable C26.

of cable tension, the accuracy is good enough, since only significant changes are of concern for ensuring structural safety of a bridge.

Figure 8 shows the decay of battery voltage and the temperature on sensor node C26 over a 60-day period. It clearly depicts the dependency of battery capacity on temperature. The voltage graph consists of two lines. This effect is due to the fact that the battery voltage drops about 100 mV when the radio chip is turned on. Since voltage measurements are not synchronized to this switching, some measurements are taken when the radio is on and some when it is off. The voltage drop within 30 days is approximately 0.2 V. The theoretical lifetime of the WSN is approximately three months. This lifetime can be easily extended by a factor of 2 or 3 by extending the time between natural frequency estimations or by decreasing the duty cycle (the ratio of the system on time in a given period of time to the period of time), which was 40% during this test period. The voltage jump at day 29 is due to the replacement of batteries.

The graphs shown in Figures 7 and 8 reveal data losses during some periods of time. The causes of these losses are manifold: data from the sensor nodes is lost during the transport to the base station, stability issues in the communication software on the sensor nodes which lead to communication link breakdown, bugs in the software that render the base station irresponsive and block the reception of the data packets from the sensor nodes, and UMTS link breakdown caused by the telecommunication provider. The tests

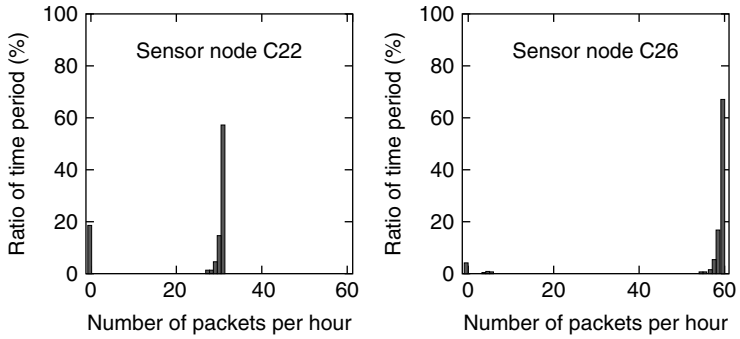

Figure 9. Frequency distribution of the number of valid data packets acquired within an hour of the cables C26 and C22.

demonstrate that data loss is intrinsically linked to the WSN since a lossless communication protocol would be too energy-consuming for field applications. Figure 9 displays the frequency distribution of the number of valid data packets within an hour of the cables C22 and C26 that were recorded at the remote control center during the 60-day period. For cable C26, which is closest to the root node, most of the time (67%), 60 packets out of 60 arrived at the control center. In 5.1% of the time no data was recorded. The same figures of the cable C22, which is farther away from the root node, are 57% with 30 packets out of 30 and 18.7% of the time with no data records. For the nodes C22, the natural frequency estimations occurred every 2 min. The mean data packet arrival rate over the 60 days was 24 out of 30 for C22 and 55 out of 60 for C26. As expected, the data loss increases with increasing distance to the base station. Moreover, the frequency distributions demonstrate that the wireless network is either up with a high reception rate (greater than 90%) or totally down. The case of an intermediate reception rate occurs very infrequently.

6 CONCLUSIONS

The field test on the Stork Bridge demonstrates that long-term monitoring with a low-power WSN is feasible. The feasibility is mainly based on the application of low-cost and low-power MEMS sensing technology and on a significant reduction of raw data that is achieved by decentralized data processing. The test demonstrates that the current technology does not provide the same reliability of mature wired monitoring systems in terms of stability, accuracy, and data loss. This outcome is not surprising since research and application of WSN technology in monitoring is still at a very early stage. The most critical issue is the handling of data processing and basic network functionality on a single CPU with very limited computational and memory resources. However, in the near future, these problems will be less critical since WSN platforms will be available that significantly provide more resources. Furthermore, to avoid conflicts between data processing and basic network functionality, the two tasks can be allocated to two separate low-power CPUs. Energy efficiency of hardware and software components will continue to play a central role. However, the progress in low-power microelectronics, which is driven by the huge market of portable electronic devices, and the application of energy harvesting technologies will mitigate the current limitations regarding power consumption. Nevertheless, the experience on the Stork Bridge demonstrates that with a well-balanced resource distribution between data processing and basic network functionality, a stable system can be achieved with existing low-power WSN platforms that provides useful information with an accuracy that is compliant to the monitoring objectives.

Chapter 155
Reliable Use of Fiber-optic Sensors

Wolfgang R. Habel
Division VIII. 1 Measurement and Testing Technology: Sensors, BAM Federal Institute for Materials Research and Testing, Berlin, Germany

1 INTRODUCTION

When users want to get a measurement task solved, they expect optimum performance from available sensor systems. Preferably, a complete measurement solution consisting of the sensing element, supply and recording device(s), and some accessories is required. Moreover, the users certainly expect that an appropriate application methodology is available. In contrast to this, some users prefer to design the sensor system by themselves; they purchase components, like resistive strain gauges, and, in some cases, rent the measuring equipment. This can become complicated if the components of the measurement system are not fully compatible with the specifications of the measurement task. For a better selection of monitoring components, and to be sure to have created a reliable measurement system, confirmed information about the component's characteristics, reproducibility, long-term stability, expected drifts and creep, parameter limits, and eventually, information about the expected uncertainty of the results measured, is needed.

The design work for a sensor system and the choice of a specific application procedure on site must follow specific demands according to the measurement task. Engineers have to find optimum answers with regard to all components of a sensor system, which also includes the selection of an appropriate sensing method out of a multitude of possibilities. Customers, consulting engineers, and suppliers need a well-founded overview on fiber-optic sensor technologies, available components, and recording systems. They have to analyze the measurement task and the influencing operational and environmental conditions. Depending on these prerequisites, the appropriate sensing system consisting of the

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

optical source, optical fiber with a specific coating, sensing element itself (extrinsic or intrinsic type), some components like connectors, beam splitters, and finally a recording device with appropriate specifications can be selected. To find all this information summarized, an encyclopedia like this one or standards and guidelines would be helpful. Unfortunately, there is a lack of clear guidelines that summarize all necessary information for design and operation of specific optical sensor systems. Hence the most appropriate sensor system is sometimes not selected, or the expected measurement uncertainty is not achieved, and the customers are disappointed with the results measured. Guidelines and standards are therefore increasingly requested by different groups such as the following:

- **Customers**

They want basic (not really scientific) information about functional principles and basic specifications of the alternative measurement method to "fiber-optic sensors". They are often interested in quite fairly cheap solutions; however, they are mostly willing to pay an appropriate price if the new technology has advantages over the conventional one. To give them confidence in any discussion with fiber-optic sensor experts or consultants, customers should be able to follow a checklist containing all important aspects.

- **Engineering consultants**

They need, first, an overview about available sensing methods and corresponding components to design fiber-optic sensor systems. Customers would be well advised, if they do not receive one offer only for a measurement system, or an offer from only one company. The engineers should be able to compare different offers to find out the most effective sensor technology (sensor system). High-quality systems e.g., for long-term measurements, require high-performance components and facilities; measurement tasks with low-resolution requirements or for only short-term measurements (e.g., without disconnecting cables) need quality systems with lower system performance. Consulting engineers have to estimate and recommend the system which is the most effective one for the user.

- **Innovative companies, skilled personnel**

They have to deal with clear performance specifications for fiber-optic sensor systems as well as their components. This requires a correct use of the expression of performance determining quantities, static, and dynamic specifications. This must be done in accordance with international standards and must use appropriate vocabulary for describing general terms in the measurement techniques (including the use of SI units). The correct terminology ensures that the interdisciplinary community of e.g., physicists, fiber-optic experts, and mechanical and civil engineers understand each other [1].

- **Manufacturers**

Companies that produce and deliver sensors or sensor components have to provide validated products. This means that they have to confirm by examination and prove that the objectives of the particular requirements for a specific intended use are fulfilled. Validation of products as well as measurement methods can be carried out according to standard ISO/IEC 17025/2000 of the International Standardization Organization (ISO) [2]. Then, for a specific intended use, the sensor or the measurement system works as reliably as has been requested.

Using standards and guidelines, the confidence of the user community in fiber-optic sensor technology will increase. Standards generally facilitate the use of technology. As a competent summary of valuable technical recommendations, they contain all details for the use of a sensor system. There are four major types of standards:

- fundamental standards that define terminology, signs, symbols, and basic conventions;
- test methods as well as data-analysis standards that define measurement characteristics (temperature, pressure, physical, and chemical measurands);
- organization standards that describe company-related procedures such as quality management system, maintenance procedures, product or logistic management; and finally
- specification standards, which in the current fiber-optic sensor development stage is the most relevant standard type, since it comprises the particular characteristics of a product, its performance threshold such as functional parameters (measurement accuracy, stability), interface

and interchangeability, measures enabling cost reduction, environmental protection, and overall health and safety.

Guidelines to help the design and selection of a sensor system must consider all aspects such as the following characteristic features, characteristic features of sensor components, characteristic features of interrogation systems, and application and service aspects. Standards also define validation procedures, which deliver the largest contribution to the user's confidence in fiber-optic sensing systems. Steps necessary for a validation of fiber-optic sensor systems are described below.

2 INTERNATIONAL ACTIVITIES TO DEVELOP FIBER-OPTIC SENSOR GUIDELINES

ISIS Canada Research Network (*I*ntelligent *S*ensing for *I*nnovative *S*tructures) is actively developing guidelines for implementing structural health monitoring (SHM) methods in civil engineering such as fiber-reinforced polymers (FRP) containing integrated fiber-optic sensors. The first manual that gives a brief introduction to select fiber-optic sensor technologies was published in 2001 [3]. It provides a number of specifications and instructions on handling and installation, and considers application-related aspects for fiber-optic sensor systems. However, these recommendations cannot be used as guidelines or technical standards for fiber-optic sensors. Nevertheless, this manual is an important step toward developing guidelines for handling of fiber-optic sensors on site.

Research groups in the US standardization organization National Institute of Standards and Technology (NIST) in Boulder, Colorado, USA, have been involved in research into the behavior of fiber Bragg grating (FBG) sensors and associated devices. The basic metrology considerations developed by them provide valuable input for the definition of system component specifications [4]. Preliminary specifications have been developed for FBG sensors, FBG interrogators, and interferometric sensing systems (*see* **Fiber Bragg Grating Sensors**). These activities were mainly driven by companies that offer devices and systems or those that want to use fiber-optic sensor technology. The US Optoelectronics Industry Development Association (OIDA) provides an effective platform to overcome the barriers to generate a robust fiber-sensor market environment. This objective includes the development of standards and guidelines.

NASA utilizes fiber-optic components for the space flight sensor system, and is therefore obliged to validate the components of the sensor system. They use test procedures for materials validation as well as special test programs developed by the American Society for Testing and Materials (ASTM international) to validate sensor functions under specific space-typical requirements [5]. In this case of a very specific application area, the testing parameters must be adjusted for each component to simulate the environmental conditions or the worst case to be expected. Although there is no document cited comparable to a standard for the validation of fiber-optic sensors, the described test program can be considered as a discussion basis along the way to fiber-optic sensor guidelines.

Under the aegis of the "International Union of Laboratories and Experts in Construction Materials, Systems, and Structures" (RILEM), a new Technical Committee "Fiber-Optic Sensors" (TC-OFS) has been established. This committee specifically aims at developing guidelines and standards for fiber-optic sensor technologies in civil engineering. The general objective of the new RILEM TC-OFS is to promote the proper use of fiber-optic sensors in civil engineering applications such that their advantages can be fully exploited. A state-of-the-art report is under development. On this basis, application guidelines for fiber-optic sensors in civil engineering will provide expertise on the most important questions concerning reliability and stability of such sensor systems. Details can be found on the website of the TC-OFS [6]. The activities of this Technical Committee are—according to the general intentions of the RILEM organization—limited to sensing needs that are of direct relevance to civil engineering. However, it is expected that these guideline activities will serve as a model for other application areas, e.g., composite materials monitoring, monitoring of industrial plants with specific risks, and evaluation of new materials.

Activities related to the development of guidelines and standards have been observed in some

European countries. Investigations concerning reliability and long-term stability of components of fiber-optic sensor systems have been carried out at the Swiss Federal Laboratories for Materials Testing and Research (*EMPA*) in Duebendorf, Switzerland [7]. These investigations were subject to characterization of fiber-optic sensor components under the influence of typical environmental and loading conditions, and for the estimation of their lifetime. These investigations provide fundamental knowledge for guidelines, specifications, and standards.

Specific company-related guidelines have been developed by SMARTEC SA, Switzerland, for validation of SOFO system components [8]. SMARTEC developed their own validation program to check the performance of their sensor products. Such activities reveal the interest of innovative companies to offer validated products, and thus to promote confidence in new technical solutions.

In Germany, activities related to the development of guidelines and standards for fiber-optic sensors have been going on for years in Berlin, at the Federal Institute for Materials Research and Testing (BAM) and in the German Association of Engineers (VDI). VDI provides the platform for the Working Group AK17 on "Fiber Optic Measuring Methods" within the German "Society for Experimental Stress Analysis" (GESA), where a guideline for FBG strain sensors is being developed [9]. VDI guidelines, such as Guideline VDI/VDE/GESA 2635 "Experimental Structure Analysis; metallic bonded resistance strain gauges" [10], are generally regarded as competent recommendations. Such guidelines find an interested community and are considered as generally recognized engineering standards. The VDI core group for development of the FBG strain sensor guidelines consists of experts from companies and research institutes with a number of years of special experience.

"FIDES" (Optical Fibres for New Challenges Facing the Information Society) [11] is another European activity on the development of fiber-optic sensor guidelines established by the European COST Action 299. The Working Group (WG 4) "New Challenges in Fiber Optic Sensors" under this activity addresses the development of guidelines and standards for preferably long gauge length sensors. This working group promotes fruitful discussion and interaction with other groups acting in international standardization groups.

Although few companies have been developing test programs for validation of their products in accordance to their own rules, and research institutions like EMPA or BAM have established validation laboratories, generally binding standards or guidelines for fiber-optic sensors are not yet available.

3 DESIGN OF A FIBER-OPTIC SENSOR SYSTEM—RELIABILITY/STABILITY-RELATED ASPECTS

This section and the ones that follow describe important aspects that have to be considered (in standards and/or guidelines) when a measurement system is designed, sensors are applied onto or in measurement objects, and the measuring system is in service over a number of years. Because FBG strain sensors are very often used for SHM purposes (*see* **Fiber Bragg Grating Sensors**), important aspects of fiber-optic sensor applications are exemplified for FBG sensors. All these aspects can certainly be transferred to other sensor types and systems.

To solve a measurement task by using a fiber-optic sensor, first, the appropriate sensor type with specific performance features has to be selected from the different types that are available (*see* **Fiber-optic Sensor Principles**; **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**; **Fiber Bragg Grating Sensors**). The optimum design of the fiber-optic sensor systems comprises a number of components that have to work reliably together under on-site conditions. Figure 1 shows the general hardware structure of a fiber-optic sensor system.

Behind these physical components, numerous parameters that influence the performance (reliability) of the sensor signal and the stability of the system components are hidden. Most of the commercially available fiber-optic components (connectors, connecting cables, FBG elements, reading devices) are validated according to standard test procedures developed for data-communication purposes, or according to the individual manufacturer's own rules. At least functional tests are carried out. However, the optical measurement equipment is sensitive to ambient temperature and pressure variations. For example, an optical spectrum analyzer (OSA) occasionally used

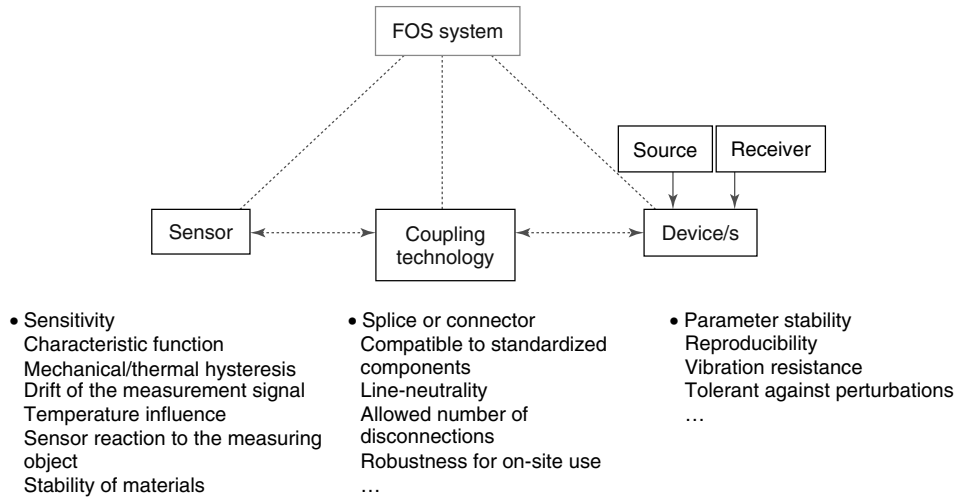

Figure 1. Main components of a fiber-optic sensor system.

for recording the FBG signal can have a temperature sensitivity K_T of about $10\,\mathrm{pm\,K^{-1}}$, which means it corresponds to the same temperature sensitivity of an FBG. If such a read-out device is used to record a signal from an FBG sensor on site, the measurement uncertainty could exceed the acceptable level. On the other hand, the calibration curve for the sensing element and/or the completed sensor sample must be available. If the equipment has to be replaced later by another one with different temperature sensitivity, the measured strain or temperature signal does not represent the previous sensor behavior.

Besides the influence of temperature on all system components, the effect of overall climatic conditions on all the specifications should also be considered. Primarily, the component's behavior under reference climate conditions must be understood. The following list provides an example of some of the important technical features and characteristic quantities that have to be proven for deformation sensors at reference climate:

1. optical characteristics (i.e., attenuation, reflection coefficient, and pulse characteristics, e.g., for FBG);
2. deformation sensitivity;
3. transverse (lateral) sensitivity;
4. ultimate deformability (axial strain, pressure, bending) of fiber sensing area;
5. mechanical hysteresis;
6. fatigue behavior;
7. influence of thermal and mechanical changes along the leading fiber on a sensor signal;
8. ultimate acceptable optical power at reference climate, as well as in general terms;
9. temperature resistance of the whole system;
10. temperature characteristics of sensor material $[\alpha_{\mathrm{Sensor}}(T),\ \alpha_{\mathrm{Sensor}}(T) - \alpha_{\mathrm{Material}}(T)]$;
11. temperature characteristics of optical signal $[\partial n/\partial T]$;
12. influence of local temperature changes on sensor signal;
13. temperature characteristics of sensitivity of deformation $[\partial S_n/\partial T]$; thermal hysteresis.

If sensor systems have to work under very different environmental conditions, performance should also be proven for the limits of intended use. The IEC 61757 standard for fiber-optic sensors [12] and specific sector standards propose few more parameters and test procedures. Some special aspects for the main components of an FBG strain sensor system are described in the following.

3.1 Optical source, detector, modulation, and demodulation

It can be certainly assumed that the optical source delivers a signal with sufficiently stable spectral and intensity characteristics as is needed for the respective

modulation technique. Depending on the sensor signal resolution requirements, devices with different interrogation methods are used. For example, a spectroscopic method using a charged coupled device (CCD) spectrometer provides a simple method with quite a good resolution. In contrast to this, devices that use interrogation methods on the basis of tunable filters, fiber interferometers, or planar integrated optical chips enable very high signal resolution. Stability and reproducibility of the wavelength measurement on FBG sensors decisively determine the uncertainty of the sensor system. This problem can be understood by considering two aspects. The first aspect concerns parameters of the FBG that define the Bragg wavelength. To measure strain or temperature, it is necessary to know the setup wavelength of the grating. The key question is which part of the spectrum should be used for the center wavelength calculation. Figure 2 highlights this problem. Using the definition that the width of a grating peak is defined by the distance between the two minimum points in the peak, this calculated Bragg wavelength λ_B differs from another estimation of the wavelength that is based on the -3-dB level definition. In those cases where the main peak has another side peak, e.g., due to birefringence effects, or has split into asymmetric peaks, the spectral shape has an enormous influence on the λ_B value, and the -3-dB definition must be modified. Unfortunately, there are no recommendations yet in the existing standards or guidelines as to which peak form is recommended or which method for calculating the peak wavelength should be used. To get a good signal-to-noise ratio, a broad spectrum is desired. To achieve a good peak identification, however, a narrow reflection spectrum with a sharp peak is recommended. In any case, peaks with flat or nonuniform tops, asymmetric peaks, and large side lobes must be avoided. Thus, the precision in estimation of the grating wavelength strongly depends on the grating characteristics (mainly strength, uniformity) [13].

The second problem concerns the wavelength stability of the measurement device. Measurement devices for highly precise wavelength reading use standard commercially available etalons similar to gas cells, or at least wavelength-stabilized FBG sensors. It is obvious that only such devices can be recommended for measurements under full climatic and temperature conditions. If customers are only able to fund low-cost devices for a specific task, the relatively high uncertainty in measurement results must be addressed and must be acceptable to the users. Generally, it cannot be expected that customers know or understand all these aspects. Following the allowable uncertainty—and considering the achievable real system-inherent uncertainty—engineering consultants can seriously recommend the measuring method and device that fulfills the customer requirements best.

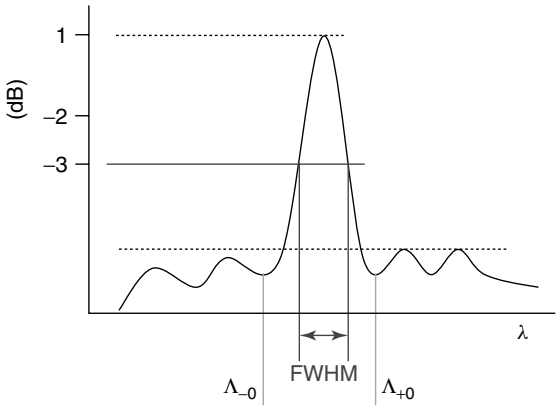

Figure 2. Calculation of the peak wavelength from the spectral characteristics. FWHM (full width at half-maximum) describes the difference between the two independent pulse values (here: wavelength) at which the dependent variable is equal to half (-3 dB) of its maximum.

3.2 Fibers, cables, connectors, and other components

There are an almost unmanageable number of standards for optical fibers, cables, connectors, and other components. All these components are also used in telecommunication and data-communication systems. International standards can therefore be found in the International Standard Classification (ISC), nr. 33.180. To enhance the reliability of components, some investigations were made within COST 270 [14]. For example, the connector group defined a reliability qualification test that resulted in the IEC standard 62005-9-2. In any case, when components developed for telecommunication purposes are used

in sensor systems, their behavior under specific environmental conditions have to be verified.

3.3 Sensing element

From the measurement reliability point of view, the most challenging part of a fiber-optic sensor system is the signal from the sensing element itself. In case of strain sensors, the question is how much of strain is durably transferred from the structure to be evaluated into the sensing element. Depending on the method of sensor application (embedded, clamped, surface-glued, and welded) and type of sensor (sensor fibers, e.g., with gratings inside, sensor patches, or rods), the interaction between the measurand and the sensing element is influenced by numerous factors. From the author's point of view, the appropriate application of FBG strain sensors is very complex and quite difficult. Hence, some sensor aspects related to the reliability of the measurement result will mainly be considered for FBG strain sensors in the following sections.

Almost every expert team uses a different method of attachment or embedment of FBG sensors. Coatings and adhesives with different specifications even for similar measurement tasks are used. This very complex part of the measurement system brings the largest uncertainty—actually, this could even be considered a skills-based uncertainty. In comparison with the large number of commercially offered system components mentioned above, it must be realized that there is still a lack of well-validated methods for the application of FBG sensors. Moreover, only few companies offer application expertise that includes a warranty claim. For example, the embedment of FBG strain sensors in rotor blades of helicopters or wind turbines is, at present, mainly carried out by research institutions or research departments of companies according to their best knowledge because generally accepted technical rules are not yet available. However, the user community interested in fiber-optic sensors promotes and supports more and more research and development (R&D) activities in this area to close the gap in the expert's knowledge and to push the development or completion of corresponding guidelines and standards.

4 VALIDATION—THE METHOD TO ENSURE RELIABLE SENSOR USE

If users want to be sure that they get an appropriate sensor system, they have to ensure that a validated fiber-optic measurement system is used. Users benefit from validation because they get assured information about the performance and limitations of the sensor system. According to the definition in standard ISO/IEC 17025/2000 [2] of the International Standardization Organization (ISO), validation is the confirmation by examination and the provision of objective evidence that the particular requirements for a specific intended use are fulfilled. It means that validated systems enable consulting engineers, suppliers, and users to evaluate suitability and reliability of the measurement system for the specific use. The key questions of accuracy, long-term stability, and reliable function under environmental influences to be proven by validation depend on the client's needs. Validation is always a balance between cost, risks, and technical possibilities.

Validation should be carried out by institutions that fulfill the requirements for technical competence in the field of fiber-optic sensor technology. The testing institution should preferably be recognized by accreditation bodies. Validation can also be carried out by third-party laboratories (unbiased institutions) that are able to bring in expertise and have the special equipment meet the requirements concerning uncertainty of measurement and traceability to etalons or national standards.

Procedures for validation of the sensor system components comprise

- sensor-related characteristics (measurement range, resolution, sensitivity are the most important);
- measurement uncertainty, repeatability, and reproducibility of data from components of the measurement system;
- proof of stability of the system components characteristics.

Apart from the stability of the sensor system or the reliability of the measurement method, the uncertainty estimation of the measurement results has particular significance. Validation enables getting data that are important for the evaluation of the measurement

uncertainty. Basically, this information can only be achieved under certain conditions:

- all equipment used for tests and or calibrations (including equipment for subsidiary measurements, such as environmental conditions) shall be calibrated before being put into service;
- equipment shall be operated by personnel with sufficient competence in the field of fiber-optic sensors;
- the calibration procedure has to ensure that all measurements are traceable to the International Systems of Unit (SI); the link to SI units may be achieved by reference to measurement standards and high-quality measurement instruments. A calibration laboratory or an unbiased competence center establishes traceability to the SI by means of an unbroken chain of calibrations or comparisons linking the available standards to relevant primary standards of the ISO units of measurement (e.g., national measurement standards). A short remark concerning traceability seems to be necessary (compare it also with EN ISO/IEC 17025 [2, Chapter 5.6] and ISO 10012 [15, Chapter 4.15]): it is clear that the resolution of measurement results achievable with relevant measurement standards (including its repeatability) must approximately be one order better that those of the measurement systems to be evaluated.

However, it is extremely difficult to get validated data for surface-applied or embedded sensors because it is not possible to discriminate between the sensor's behavior and sensor signal influences coming from application (as already pointed out previously). This basic problem leads to a certain amount of uncertainty, which cannot be estimated. In any case, recommendations for application procedures based on fully established expertise will minimize uncertainty.

Not only users but also manufacturers and sales agencies benefit from validation and corresponding guidelines because damage can then be prevented during the production stage. Performance gaps in the measurement system can be displayed and removed by systematic optimization. In case of damage or if measurement results are not accepted by the user, the supplier is able to prove that he has complied with his obligation to exercise due care (product liability).

5 GUIDELINES FOR APPLICATION AND OPERATION OF SENSOR SYSTEMS

Generally, a distinction has to be made between the sensor signal coming from the sensing element (FBG, Fabry–Perot interferometer, distributed fiber-optic sensor) itself and the sensor signal recorded by the applied sensor. The characteristics of the unapplied sensor can more or less differ from the attached one. Moreover, it must be aimed to distinguish between measurement signal-relevant information that comes from the sensor, including surrounding effects, and the contribution from the structure to be evaluated. In almost all cases, it is not possible to discriminate between creep of the structure (measuring object) and creep of the adhesive, e.g., used for bonding of the FBG sensor so that the customer is only able to record the behavior of the structure from the measurement result with a certain sensor-related uncertainty. The largest challenge for fiber-optic sensor experts is to reduce application-related influences.

Whatever type of mechanical sensor is used, enduring reliable strain transfer from the measurement object into the sensing element must be ensured over the complete period of operation. Irrespective of the mode of sensor fixation, the sensor fiber and/or the fiber-optic sensing element has always to be bonded to a support component or to a fixing element, and finally to the measuring object. A number of aspects for consideration arise such as the following:

- characteristic mechanical behavior of fixing components (substrate, adhesives, protective layers/coating), materials combination sensing element/measuring object, and covering must be known and characterized for the total environmental range;
- proof of sensor position accuracy;
- thermally induced stress loading of the sensing element during application;
- sensitivity of all components (sensing element, leading fiber, connectors and splices, optoelectronic components) to mechanical and thermal influences;
- attacks from aggressive media;
- chemical and physical interactions of materials close to the sensor;

- methods to test and evaluate the bonding behavior (creep) of applied sensors over long periods of operation.

Specific aspects have to be considered especially when FBG sensors are used, e.g., possible influences of unwanted mechanical perturbations like transverse pressure or bending of the sensing element. Transverse pressure into the fiber at the location of the grating, or any mechanically induced deformation of the fiber core might change the spectral characteristics of the FBG element. This spectral change can lead to faulty measurement results if the appropriate interrogation system is not used. The possibility of appearance of transverse influence must be estimated, especially when the FBG sensors are embedded in nonhomogeneous materials like reinforced composites or rough materials such as concrete and are subjected to thermally induced material contraction.

Other points concern hydrogen-loaded FBG sensors. A decay of the reflectance can be caused over time by out-diffusion of hydrogen; or applied and permanently strained fibers can be subjected to stress relaxation effects, which lead to a wavelength shift. Finally, decay of the refractive index modulation could occur over time. All these characteristic features have to be considered with regard to long-term measurements. Guidelines will help here to avoid underestimation of these effects.

If strain sensors are to measure not only tensile but also compressive strain, they have to be pretensioned. This procedure is not trivial during application under field conditions because the pre-tension must be held as long as the curing or hardening process is incomplete. Figure 3 shows a methodology on how to introduce strain in FBG arrays during manufacturing of large composite components in a factory. Prefabricated sensor patches could be used alternatively, however, the patches must hold the pre-tension of the sensing element during manufacturing of the patch and later on during potential heat treatment (tempering). In this case, the patch or the adhesive could shrink and the pre-tension of the fixed grating is reduced or lost. The appropriate methodology for application of continuously fixed FBG sensor depends on technological conditions. It must be considered that surface-glued fiber gratings produce an unsymmetrical interface structure, and a reliable and reproducible bonding of the fiber is not easy to reach [16]. Hence, embedment of FBG sensors seems to be less problematic.

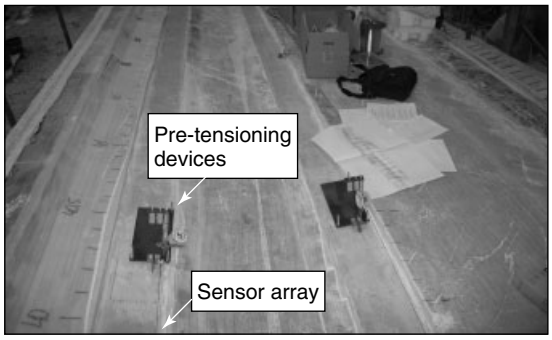

Figure 3. Embedment of FBG arrays into reinforced composite structures using a special device to pre-tension the sensor fibers under defined conditions (here by 0.34%) during the lamination procedure, Photo: BAM.

Embedment of FBG arrays into reinforced composite structures using a special device to pre-tension the sensor fibers under defined conditions (here by 0.34%) during the lamination procedure (Photo: BAM).

Apart from FBG sensor application procedures, arrangement of the wiring of the sensors must not be underestimated. Under harsh mechanical or environmental conditions, splices inside the material to be assessed and ingress/egress points are critical zones. Splices should also be embedded just like the fibers. This is usually possible in huge composite structures with sufficient thickness. However, in steel structures or very narrow tubes, other methods have to be developed. Figure 4 shows a reliable solution to protect the splice joints by storing them in a very small box inside a steel anchor tube. Figure 5 shows the fiber-optic cable at the ingress/egress point, which has to be protected for the process when the anchor is introduced into the bore hole.

On the basis of the manifold experiences of fiber-optic sensor experts in creating ruggedized packaging, guidelines have to list and propose for the user community all technical aspects that are intrinsically tied to application and installation of sensing components on site. This comprises

- preparation of the area where the sensor is to be installed;
- connecting fiber ends and protecting splice areas very close to the measuring object (under field condition);

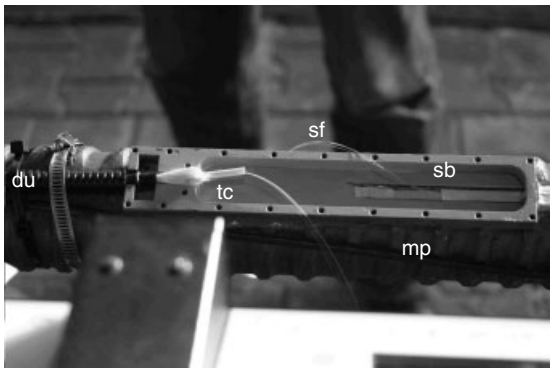

Figure 4. Attachment of FBG arrays onto heavy steel anchors for use in geotechnical engineering (sf, sensor fiber; sb, splice box; mp, micropile/anchor steel; du, duct; tc, transmission cable). Photo: BAM.

Figure 5. Critical points are splice joints (left) and cable egress points (right) in heavy steel anchors (mp, micropile/anchor steel; du, duct; tc, transmission cable). Photo: BAM.

- supervisory procedure to check the appropriateness of the sensor installation;
- protection of sensing area;
- robustness—aging of, e.g., connectors when they are frequently opened;
- mechanical and thermal hysteresis of embedded or applied sensor fibers, e.g., containing FBG sensors;
- identification of zero-point changes when devices have to be disconnected or leading cables have to be cut and exchanged;
- packaging and protection of the ingress/egress areas to make sure that embedded or attached fiber-optic sensors are fully protected over the whole service life of the structure without jeopardizing data integrity;
- sensor reaction to mechanical or thermal impacts (shocks) during operation;
- sensor behavior/aging under repeated vibration;
- sensor behavior (including cabling) under harsh climate conditions;
- durability of sensor-related materials under thermal, chemical, and mechanical conditions.

Additionally, recommendations and advice for repair of applied components of the sensors system should be given in the guidelines. The demand on exchangeability of sensors or components clearly determines the choice of the measurement and application method. Guidelines should also give recommendations for some other critical aspects that can affect reliability and/or stability.

6 TEST METHOD TO CHARACTERIZE MEASUREMENT RELIABILITY

The most critical influence on the reliability of mechanical sensors comes from the stress/strain conditions in the interface area between the sensing element and the material or structure to be measured or monitored. There are at least two boundary layers: (i) the interface between the structural material and the fiber coating and (ii) the interface between the optical fiber and its coating. Because deformation of the structural material must be transferred into the fiber-optic sensor, the mechanical and physicochemical properties of selected and/or existing materials at the interface determine the performance of the sensor. A debonded interface of a continuously attached sensor fiber (Figure 6b) or changes in the interface's behavior due to aging of the involved materials would detrimentally affect the transfer of the measurand to the FBG, and result in erroneous readings. For example, fatigue tests with acrylate-coated FBG embedded in composite samples of wind turbine rotor blades revealed a continuously increasing aging effect in the FBG signal (150 $\mu\varepsilon$ loss after 1 600 000 cycles) for exactly the same deformation values. Some more results are described in [17].

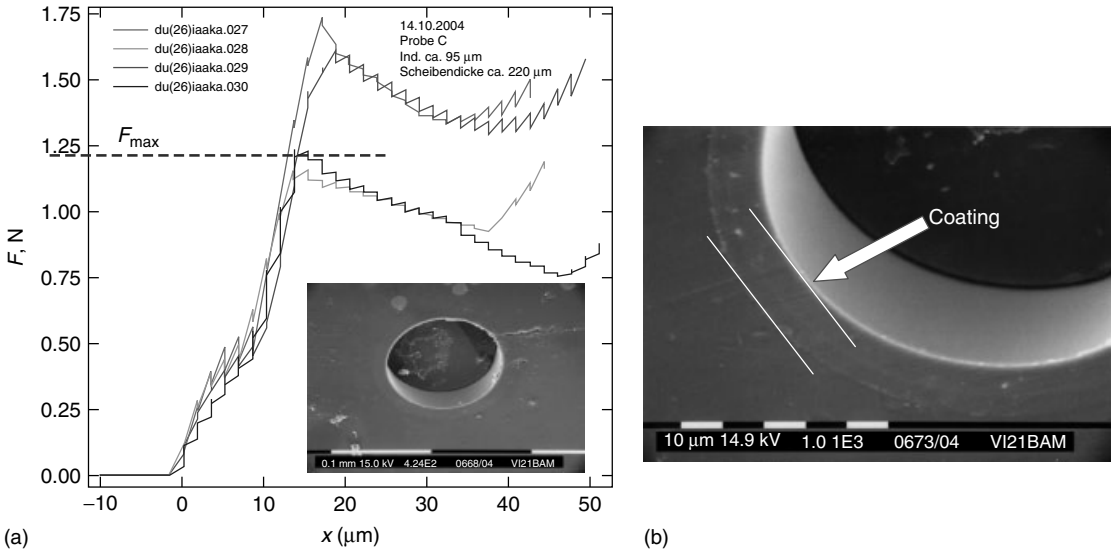

Figure 6. (a) Strain transfer characteristic of PI-coated optical fibers in typical epoxy resin used for composite material (abscissa: displacement of the indenter, ordinate: force at the indenter). (b) Debonding of the coating from the optical fiber beyond the reliable operating range of the sensor [17].

Another systematic influence on the measurement signal of continuously attached fiber-optic sensors comes from the viscoelastic properties of the coating. Coating thickness and Young's modulus have an influence on both the static and dynamic responses of the sensor. In every application (embedment or surface application), the interfacial mechanics has to be well understood. Unfortunately, as of now, there is no complete description of all the correlating effects because test methods to validate the strain transfer behavior have not yet been fully developed. However, standard testing approaches from the field of composite materials research can be used to characterize the interface bonding behavior of embedded or attached fiber-optic deformation sensors. Figure 7 shows such a testing facility to evaluate the bonding behavior of fiber-reinforced materials; this is also used at BAM for characterization of embedded optical sensor fibers [18]. The microindentation testing machine consists of a very stiff beam, which is one-point supported at the middle of the beam. At one end of the beam, a high-precision stepping motor is positioned, which drives the beam in the vertical direction (upward). At its other end, the indenter is fixed at the beam, which introduces the force into the test sample. A microscope is available to position the sample exactly below the indenter needle. The testing procedure is computer controlled; and the force introduced into the fiber as well as the displacement of the end face of the fiber due to the pushing force are automatically measured and recorded. This method is primarily used to determine the appropriate sensor coating for a specific measurement task. Apart from the experimental proof, or at least estimation, of bond strength of the coating at the fiber surface, this test method delivers characteristic behavior of the shear stress development in the border zone coating/structure. Research is needed to correlate these test procedures with other interfacial parameters such as coefficient of friction, thermal residual radial stress, and coating stiffness.

7 OUTLOOK

Significant steps have already been taken toward formulating a set of guidelines and standards for fiber-optic sensors. Few companies and institutions have developed or are developing validation programs to make guideline-like documents available. There is some basic knowledge about materials properties,

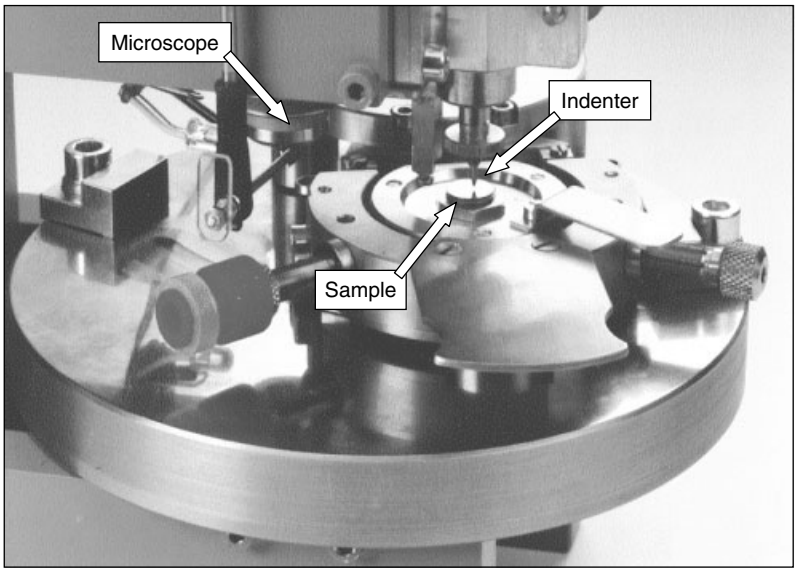

Figure 7. Microindentation test facility for evaluation of the fiber-bonding behavior (Photo: BAM).

interaction of specific sensor materials with environment, and characterization of the sensor behavior under specific operational conditions that are necessary for developing standards and corresponding recommendations.

Few national and also international expert groups, mainly established in the civil engineering and SHM field, have been established and have started work to promote the development of guidelines. There are already some documents that might have the model character for establishing competent international fiber-optic sensor guidelines. With more activities in international expert groups coming to address open questions concerning reliability, reproducibility, stability, and technical rules, confidence in the use of fiber-optic sensors will grow in the user community. Among other fiber-optic sensor technologies, FBG sensor technology is most commonly used in SHM. A set of guidelines will therefore be developed for this sensor type in the near future. Scientists and interested engineers with hands-on expertise are also aiming to establish well-researched guidelines and recommendations on how to handle and install the sensor system outside the laboratory or manufacturing environment, the type of adhesion or bonding material to be chosen, and finally, which influences resulting from application might perturb or possibly damage the sensor signal.

1 INTRODUCTION

The origins of structural health monitoring (SHM) in commercial aviation are possibly difficult to track. One of the major impacts triggering SHM, which was of course not called SHM at the time, was the comet accidents in the early 1950s. These accidents alerted a variety of parties in aviation, initially more from the military aviation side, to look into loads monitoring for the assessment of structural performance. Associated with this was damage monitoring, where the different methods emerging in nondestructive testing (NDT) were considered. Acoustic emission (AE) methods (*see also* **Applications of Acoustic Emission for SHM: A Review**) were among those first SHM technologies investigated for application to commercial airframe structures. In this method, when a load is applied to a solid structure (e.g., by internal pressure or by external mechanical means), it begins to deform elastically. Associated with this elastic deformation are changes in the structure's stress distribution and storage of elastic strain energy. As the load increases further, some permanent deformation and cracking may occur, which is accompanied by a release of stored energy, partly in the form of propagating elastic waves termed *AEs*. If these emissions are above a certain threshold level, they can be detected and converted to voltage signals by sensitive piezoelectric transducers mounted on the structure's surface. During the 1970s and early 1980s, the Canadian Department of National Defense supported efforts [1–3] to flight test and demonstrate the use of AE methods for detecting the growth of fatigue cracks in airframe structures during flight. The flight testing was performed primarily on military aircraft such as the Canadian CC-130, CF-5, CF-100 and British Tornado. Although these investigations were able to demonstrate the feasibility of utilizing AE methods for the detection of crack growth in aircraft

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

structures during flight, several issues precluded implementation by commercial aircraft operators and original equipment manufacturers (OEMs). Some of the issues are summarized as follows:

- size and weight of equipment required for data acquisition and extensive data storage requirements;
- detailed calibration of the structure was required for the unambiguous detection of crack growth;
- no reliable methods available to distinguish and properly identify AE signals from crack growth versus other high-frequency noise sources such as crack face rubbing, electromagnetic interference (EMI), and airframe structural noise due to in-flight loads;
- reliability of sensors subjected to extreme environments and high loading conditions; and
- lack of quantitative data on crack size, location, and probability of detection (POD).

Recently, owing to the high labor costs for performing detailed structural inspections, commercial aircraft operators and OEMs have developed a renewed interest in SHM methods as a means of conveniently inspecting the locations of airframe structures that are hard to access. In the late 1990s, both Boeing and Airbus made efforts to evaluate several SHM technologies for potential application to their commercial transport aircraft. These efforts are described below.

2 AIRCRAFT OEM AND OPERATOR DEVELOPMENTAL EFFORTS

Although not being implemented today, both the commercial aircraft manufacturers, Airbus and Boeing, have made remarkable progress in the implementation of SHM.

Boeing's ideas of implementing SHM go back to the early concepts proposed by Hickman *et al.* in the early 1990s [4]. After a period of wider exploration, the Boeing Commercial Airplane Company began a collaboration with Delta Airlines to evaluate and flight test several SHM technologies in 1998. The technologies of interest were primarily for the monitoring of corrosion, corrosion by-products, moisture, and strain to determine actual aircraft environments, flight loads, and usage [5, 6]. The Boeing Phantom Works organization had developed an autonomous structural integrity monitoring system (ASIMS), which was a small rugged, battery-powered data-acquisition system that could be placed onboard an aircraft and operated independent of any aircraft system. The ASIMS was capable of interfacing with a variety of environmental and structural sensors and recording both digital and analog sensor data. It was designed to interface with other data-acquisition units and a variety of sensor types including fiber-optic and microelectromechanical system (MEMS) devices, and could be placed in remote, hard-to-access areas of flight vehicles, ships, and ground vehicles to monitor the health of structural components. A ground-based reasoner (GBR) consisting of software running on an off-board computer provided the means for studying, managing, and assessing the data. Delta Airlines provided an in-service Boeing 767-300ER aircraft for the flight testing and data gathering, and the maintenance personnel to install the equipment and periodically download the data from the ASIMS. The data was then sent to Boeing for evaluation.

A variety of sensor systems were placed onto the Delta Airlines 767-300ER aircraft for flight testing and data gathering. The SHM sensor systems included a linear polarization resistance (LPR) corrosion environment sensor and two separate fiber-optic sensor systems. The LPR sensor system developed by Analatom, Inc. is basically an MEMS device that incorporates a galvanic sensor that measures the change in resistance of a host material, which corrodes away. The first fiber-optic system to be included was developed by Blue Road Research, Inc. It utilized sensors consisting of polyimide-coated fiber Bragg gratings (FBGs) to monitor changes in relative humidity (RH). The second system was developed by Luna Innovations, Inc. and used long-period grating (LPG) moisture and humidity sensors along with extrinsic Fabry–Perot interferometric (EFPI) pressure and temperature sensors to monitor environmental conditions conducive to corrosion in aluminum aircraft structures. Figure 1 shows the Boeing ASIMS data-acquisition system (lower left corner) and battery (upper left) integrated with the Luna fiber-optic sensor signal conditioning system. An example of the Analatom LPR/MEMS sensor system is shown in Figure 2. Figure 3 shows the installation of the sensor systems in the forward cargo

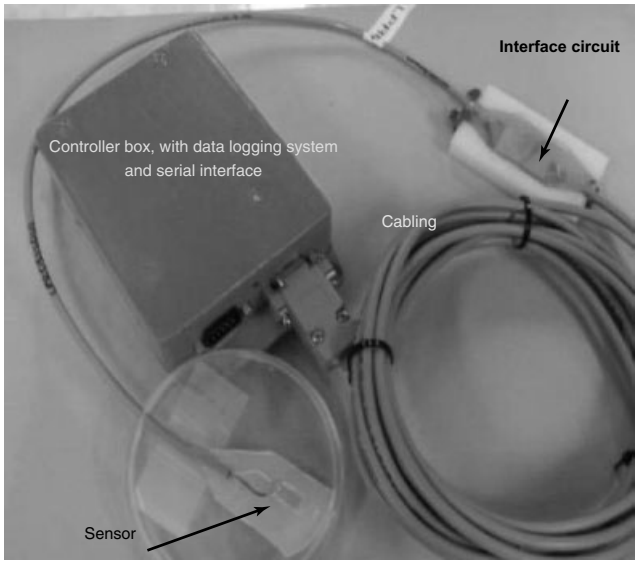

Figure 2. Analatom's microelectromechanical systems (MEMSs) LPR corrosion sensor system.

bay of the 767 flight test aircraft. The sensors were installed beneath the cargo bay flooring in locations that were suspected to be "hot spots" for corrosion. These areas were also chosen for ease of correlating sensor data to actual inspection data that would be provided by Delta maintenance personnel.

Data from the ASIMS and sensors installed in the 767 were downloaded and evaluated for a period of more than two years. Unfortunately, after the airline industry experienced a severe downturn following the terrorist attack of the World Trade Center on September 11, 2001, the effort was discontinued in

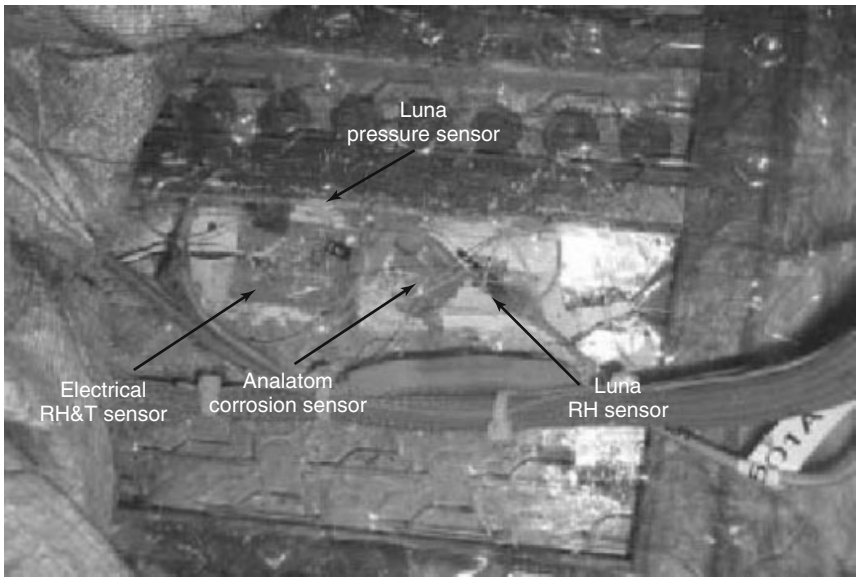

Figure 3. Example ASIMS 767-300ER forward cargo bay installation.

2002 when the airlines began to experience extreme financial difficulties. The effort, however, provided valuable information on the benefits and procedures for installing SHM onto commercial transport aircraft, and the training of airline maintenance personnel for SHM system installation, and data downloading and evaluation.

Another collaborative effort by Boeing, Northwest Airlines, and Structural Monitoring Systems, Ltd (SMS) was started in 2000 to test and evaluate comparative vacuum monitoring (CVM) (*see also* **Comparative Vacuum Monitoring (CVM™)**) systems for monitoring the presence and growth of fatigue cracks in commercial aircraft structures [7]. The basic principle of CVM sensor is that a small volume under a steady-state vacuum is extremely sensitive to leakage, and the resulting change in vacuum level due to air ingress is measurable. The sensors are manufactured from a flexible polymer with channels molded into the applied surface (Figure 4). The sensor is manufactured with a pressure-sensitive adhesive on the applied face and is installed in much the same way as a self-adhesive label. When the sensors have been adhered to the structure under test, these fine channels, and the structure itself, form a manifold of galleries alternately at low vacuum and atmospheric pressure (Figure 5). When a crack develops, it forms a leakage path between the atmospheric and vacuum galleries, producing a measurable change in the vacuum level. The channels should be oriented perpendicular to the expected crack growth direction. The spacing of the channels on the sensor defines the crack size detection limit.

Initial testing was conducted by SMS, with further laboratory validation testing performed at Boeing in Seattle. Testing was conducted on dog-bone-type specimens that had been cut at the centerline. A notch was cut at one of the four bolt holes and a CVM sensor installed on both sides of the plate. Doublers were added and a single line of four bolts along the longitudinal centerline was used to attach the doubler plates to the dog-bone-type specimen. In this way, a high load transfer situation existed between the two halves of the dog-bone specimen and the doubler plates. The CVM sensors were slightly over 0.004″ (0.1 mm) in thickness and were installed directly upon the faying surface of the dog-bone specimen. The standard laboratory equipment offered by SMS was used for crack detection (Figure 6).

After the CVM sensors were tested in a laboratory, they were flight tested on three commercial aircraft beginning in April 2005. A two-year flight test validation program was conducted by the Sandia Corporation in cooperation with the Federal Aviation

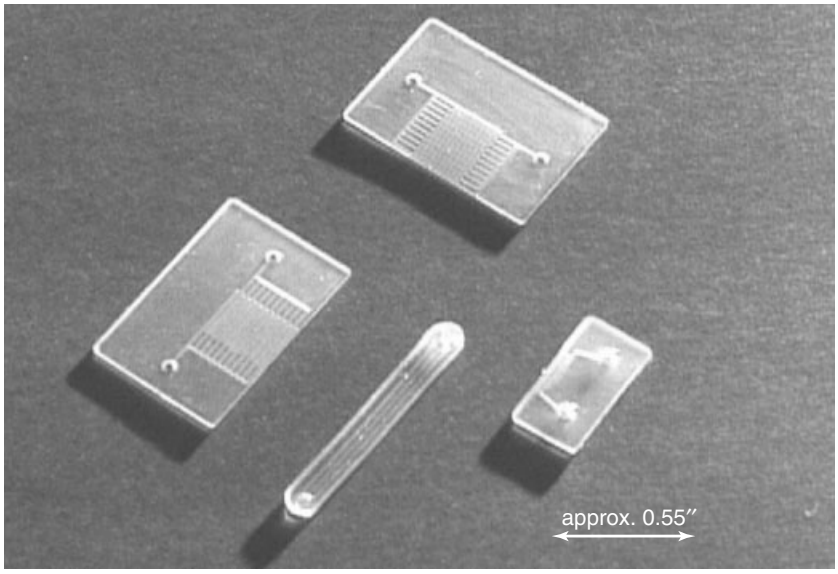

Figure 4. Typical CVM sensors.

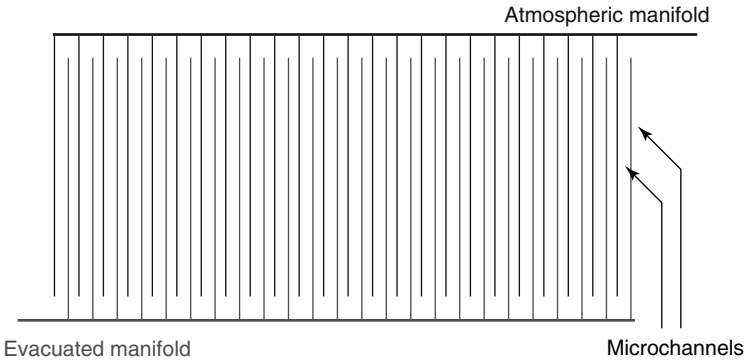

Figure 5. CVM sensor manifolds.

Administration (FAA), Boeing, SMS, a number of US airlines, and the University of Arizona [8]. The program successfully culminated in the FAA certification of the CVM system for a particular nondestructive inspection (NDI) application on a Boeing commercial aircraft, and Boeing's inclusion of CVM technology in its common NDI Manual. This was an aviation industry first for an SHM technology.

Many of the SHM activities of Boeing mentioned above and even more have been summarized in a white paper in 2003 [9]. Here, for the first time, ideas have been presented in a holistic approach including how SHM information would have to be integrated into the aircraft and fleet management process. It is in this paper that possibly for the first time Boeing addressed the concept of a hard landing monitoring system using a neural network-based system.

Although not called SHM at that time, the approach of Airbus toward SHM can be tracked back to the late 1980s when an operational loads monitoring system was developed following the method adopted for military aircraft [10]. The system was configured to be used on the Airbus A320 for monitoring loads specifically in terms of hard landings and limit load exceedances. Although a prototype was realized in hardware, it was hardly flown on a test aircraft

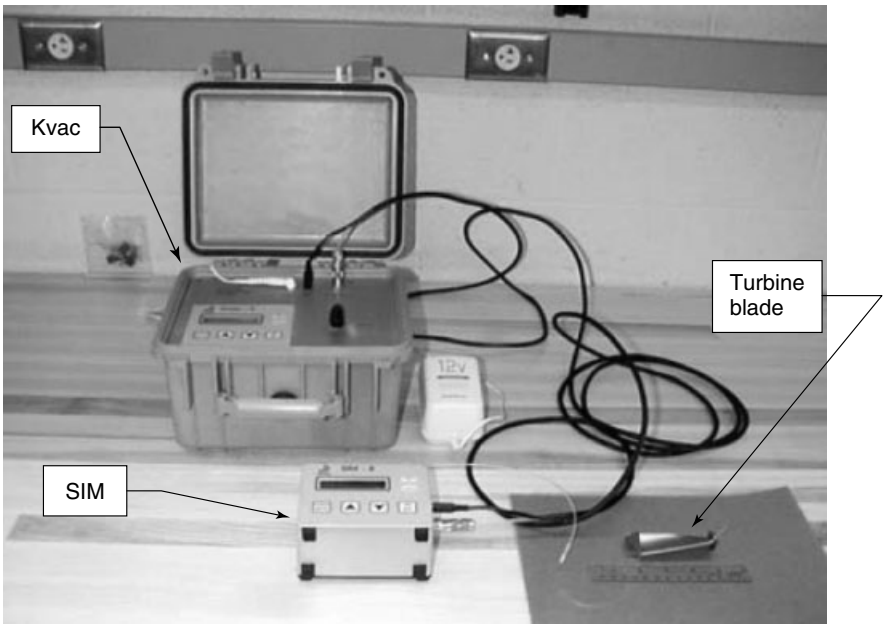

Figure 6. SMS/CVM vacuum-based crack monitoring system (details in **Comparative Vacuum Monitoring (CVM™)**).

officially because economic benefits could not be demonstrated. However, the loads recorded need to be sufficiently precise such that a follow-on residual structural life assessment can be made. This has been a continuous critical point of discussion since the past and becomes even more important once loads monitoring and in-service fatigue assessment become an integral part of an aircraft and fleet management system. Solutions for this are more laborious than anticipated at that time and have resulted in major European research initiatives such as within the EU-funded integrated project *TATEM* that started in 2004 [11].

The initiatives of Airbus toward damage monitoring and SHM, in general, were triggered by the different initiatives in the different countries that were part of the Airbus consortium. A major step in that direction was possibly the MONITOR project, the results of which have been summarized in [12]. It was then that British Aerospace (now BAE Systems) brought in the idea of using acoustic emission and optical FBG sensors for loads monitoring followed by the German side, where Daimler–Benz's corporate research centers, which were also in charge of aerospace technology at that time, brought in the idea of acousto-ultrasonics and optical FBG sensors as well. However, one of the most pioneering publications came from Hofer at MBB Lemwerder (now part of EADS) in 1986 [13] who proposed a transmission-based fiber-optic nervous system (FONS) to be integrated into a composite material, which he had successfully demonstrated in some laboratory experiments. About a decade later a joint test had been done on a multi-riveted lap joint using acousto-ultrasonics [14], which set on further initiatives from Airbus Germany. A remarkable effort was also done by integrating FBG sensors into the rear pressure bulkhead of an Airbus A340 as described in further detail in [15]. The FBG sensors are kept in the aircraft and are subject to further testing with regard to endurance of the sensor system. Activities devoted to CVM were initiated out of Airbus Germany directly as well with initial work starting in the late 1990s, with the first results being reported in [16]. In Spain, work on SHM was initiated at the beginning of the millennium and mainly included monitoring of composite structures either along the Resin Transfer Moulding (RTM) process or within components such as frames, fan cowls or horizontal tail planes [17]. All these activities were finally merged in the EU-funded project called *SMIST*. Details of this as well as the strategic approach of Airbus have been expressed in [18].

A further contribution from civil aviation and Airbus specifically, which set another true milestone, has been H.-J. Schmidt's idea of using SHM for the enhancement of the damage tolerance principle and hence reduced structural weight [19]. This idea has been further pursued and analyzed. It is currently seen that SHM allows for weight reductions of around 20% in the respective components being considered (*see* **Design Benefits in Aeronautics Resulting from SHM**).

According to [18], Airbus has targeted a potential entry into service (EIS) of several competitive SHM technologies for the year 2008. Unlike the early Boeing work, which looked at the development of SHM technologies for enhanced NDI applications for existing aircraft, Airbus envisioned the use of SHM systems permitting new approaches both in the design and the maintenance of new aircraft airframe structures, with the following specific advantages:

- SHM will contribute to reduced structural weight by changing design principles;
- SHM will benefit future designs for composites and metals, maintenance costs will be reduced, and aircraft availability can be increased; and
- SHM will enable new maintenance concepts.

In the late 1990s, Airbus began an evaluation of several SHM technologies [18]. In particular, the following SHM technologies were investigated (i.e. **Acoustic Emission**; **Applications of Acoustic Emission for SHM: A Review**; **Ultrasonic Methods**; **Guided-wave Array Methods**; **Eddy-current Methods**; **Stanford Multiactuator–Receiver Transduction (SMART) Layer Technology and Its Applications**; **Comparative Vacuum Monitoring (CVM™)**, etc.):

- CVM—see above for a detailed description of the SMS CVM system.
- FBG—see above for a detailed description of the system.
- Acousto-ultrasonics—acoustic waves are sent through the material and received by specific transducers. A change in the local behavior of the material (and hence any structural damage) can be picked up and localized by an array of such transducers.
- Microwave antenna—microwaves are sent and received in a pitch–catch mode inside the material and provide a picture of the water content, which can be used to detect the ingress of water to structures.
- Acoustic emission (see above).
- Eddy-current foil sensors—Eddy currents are generated in the structure. Their pattern and frequency distribution vary according to the presence of cracks or other damages.

Extensive evaluation and testing of the CVM system developed by SMS (*see* **Comparative Vacuum Monitoring (CVM™)**) and an acousto-ultrasonics system developed by Acellent Technologies, Inc (*see* **Stanford Multiactuator–Receiver Transduction (SMART) Layer Technology and Its Applications**) were performed by Airbus. The evaluation of the CVM system by Airbus concluded that it offered a quick and easy way to monitor "hot-spot" areas and thus improve the operational efficiency of an aircraft.

The Acellent acousto-ultrasonics system is based on the use of a network of distributed piezoelectric transducers (sensors/actuators) embedded on a thin dielectric carrier film called the *SMART Layer*, to query, monitor, and evaluate the condition of a structure (*see* **Stanford Multiactuator–Receiver Transduction (SMART) Layer Technology and Its Applications**). Acellent's SHM system includes not only the SMART Layers but also all the hardware and software needed to do the signal transmission, data acquisition, signal processing, and diagnostics. Figure 7 shows an application of this principle to meet the requirements of an aircraft manufacturer. Further applications have been considered such as for monitoring crack growth under composite-bonded repair patches. Figure 8 shows Acellent's SMART Layer applied to a repair patch coupon and the test results displayed as crack growth images and crack length as a function of the number of loading cycles.

The evaluation performed by Airbus included testing of multiriveted aluminum panels under uniaxial constant-amplitude fatigue loading to detect crack initiation at the different rivets as well as the ensuing crack growth [14]. The results of the testing and evaluation performed by Airbus concluded that with a technology like the Acellent SMART Layer, a product was on the way that could be easily bonded on the surface of a structure at relatively low cost. It could be used to automate a troublesome

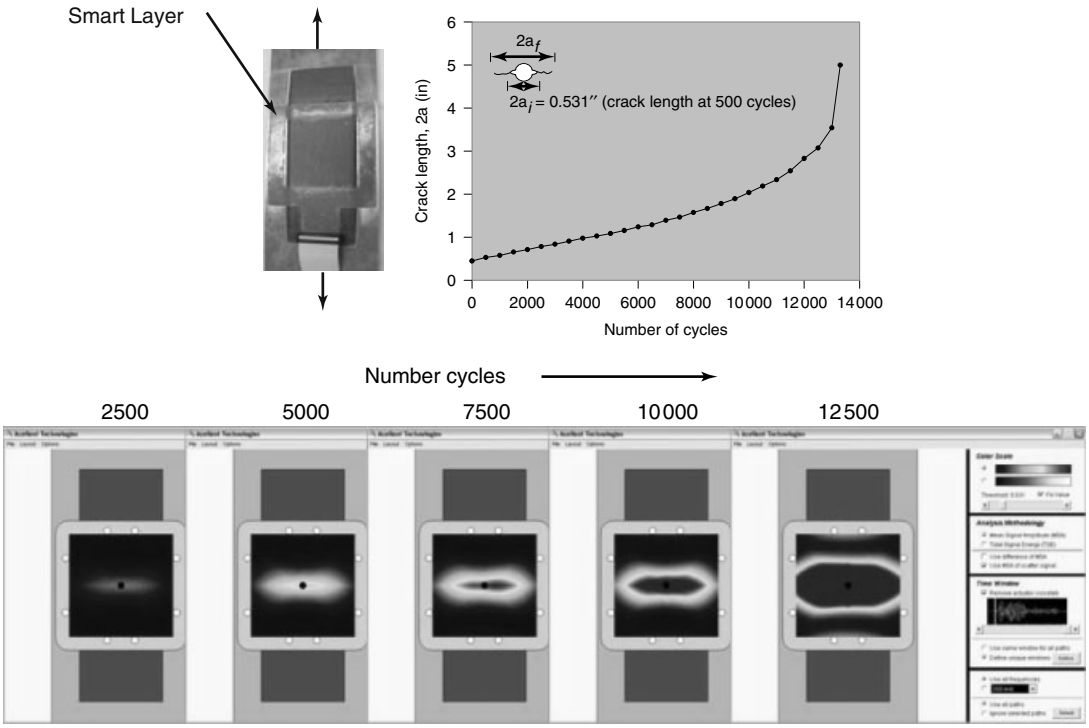

Figure 8. Acellent's SHM system applied to composite-bonded repair patches to monitor crack growth and debonding.

inspection process by avoiding dismantling of complex structural assemblies on an aircraft, and could help make a damage-tolerant design philosophy even more attractive than it is already today.

The meandering winding magnetometer (MWM) sensing principle proposed by Jentek Sensors Inc. is similar to the SMART Layer (*see* **Eddy-current *in situ* Sensors for SHM**). These sensors are shaped field sensors designed as conductive metallic windings, which are placed on a carrier such as Kaptone using microfabrication techniques. A magnetic field is generated from one of these windings, which is then recorded by the other windings. This allows crack propagation in metallic structures to be monitored. The system can also be extended to a high-resolution eddy-current imaging system by introducing a single spatial wavelength or periodic, square-wave inductive drive winding with a linear array of inductive sensing elements. Further to this, the wavelength of the magnetic wave can be varied, which allows to detect cracks, inclusions, and corrosion even in thicker metallic components. The system has been proven to work on cracked aluminum panels, around rivet holes of an aging Boeing 727, and on a C-130 flight deck chine plate. In the 1990s and later, several programs were run by Jentek in cooperation with OEMs and under US government funding including several full-scale tests (such as the Lockheed Martin P-3 test [20]) and numerous coupon tests. For Example, Figure 9(a) provides recent coupon test results performed by the Israeli Air Force (IAF) with support from JENTEK, Figure 9(b) shows a landing

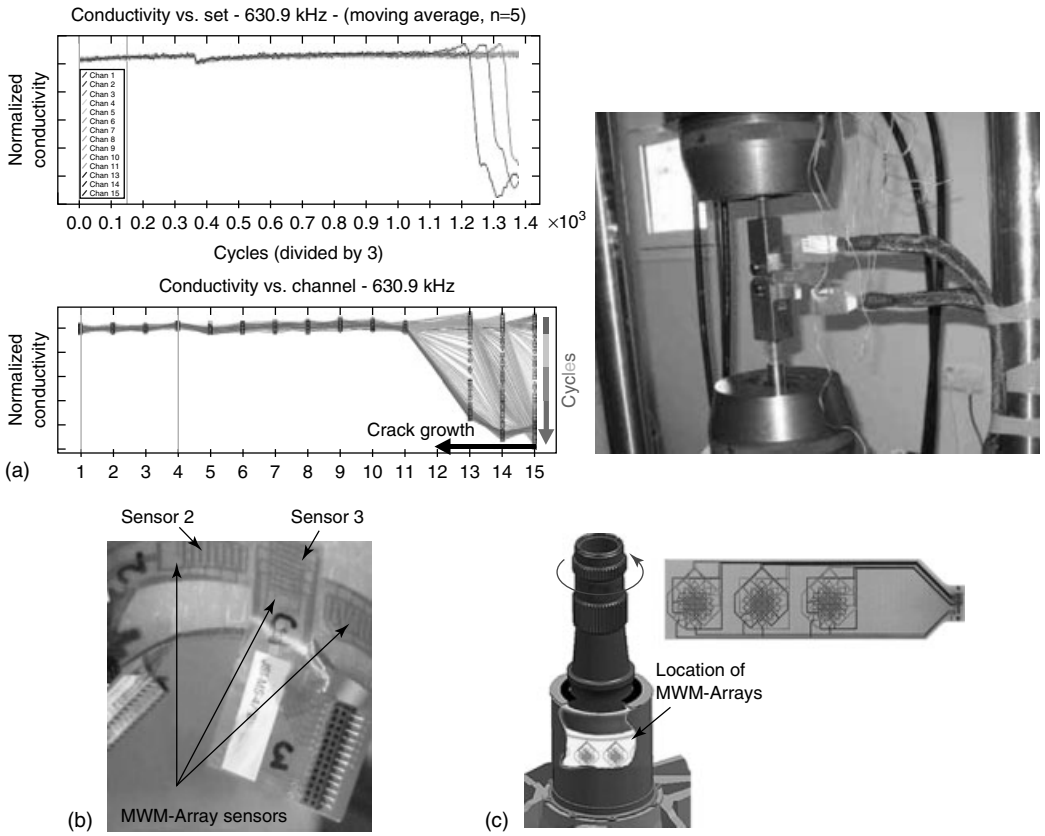

Figure 9. (a) Recent coupon test results performed by the Israeli Air Force with support from JENTEK Sensors; (b) photograph of landing gear component with MWM-Arrays mounted on a critical surface as part of an OEM test; and (c) illustration of an MWM multidirectional stress test recently performed at Boeing Philadelphia. [Figures courtesy of Jentek Sensors Inc.]

gear overload test illustrating MWM stress measurement [21], and Figure 9(c) illustrates an MWM multidirectional stress test recently performed at Boeing Philadelphia [22, 23]. Flight testing of these sensors is now beginning with the IAF and US Air Force. The MWM-Array technology is also used for conventional NDT applications [24].

The Brazilian aircraft manufacturer Embraer is said to place increased emphasis on SHM although not too much has been reported so far [25]. Manufacturers in Japan may be gradually involved into SHM, as can be seen from work being done in large SHM aircraft demonstrators looking at the integration of sophisticated FBG sensors into aircraft composite fuselage structures [26].

3 ROTORCRAFT SHM CERTIFICATION EFFORTS

Over the past three years, commercial aviation regulatory agencies such as the FAA have been increasingly interested in the development of procedures for the certification of SHM technologies for specific aircraft applications. It was previously noted that the FAA was an active participant in the certification of the CVM system for application as an alternative NDI method for a Boeing commercial aircraft. In 2005, the FAA Rotorcraft Directorate initiated a comprehensive program to develop and validate procedures for the certification of health and usage monitoring systems (HUMSs) for commercial rotorcraft [27] and **Experience with Health and Usage Monitoring Systems in Helicopters**. A part of that effort was the development of procedures for the certification of an SHM system for commercial rotorcraft structures [28]. The SHM system would be an integral component of an end-to-end rotorcraft HUMS. As a part of this effort, Acellent Technologies, Inc. is developing a smart patch system (SPS) for rotorcraft structures that will be able to (i) detect fatigue cracks and damages before critical threshold is exceeded or incipient failure occurs and (ii) quantitatively characterize fatigue cracks and damages. This is a five-year project due to be completed in 2010. A prototype

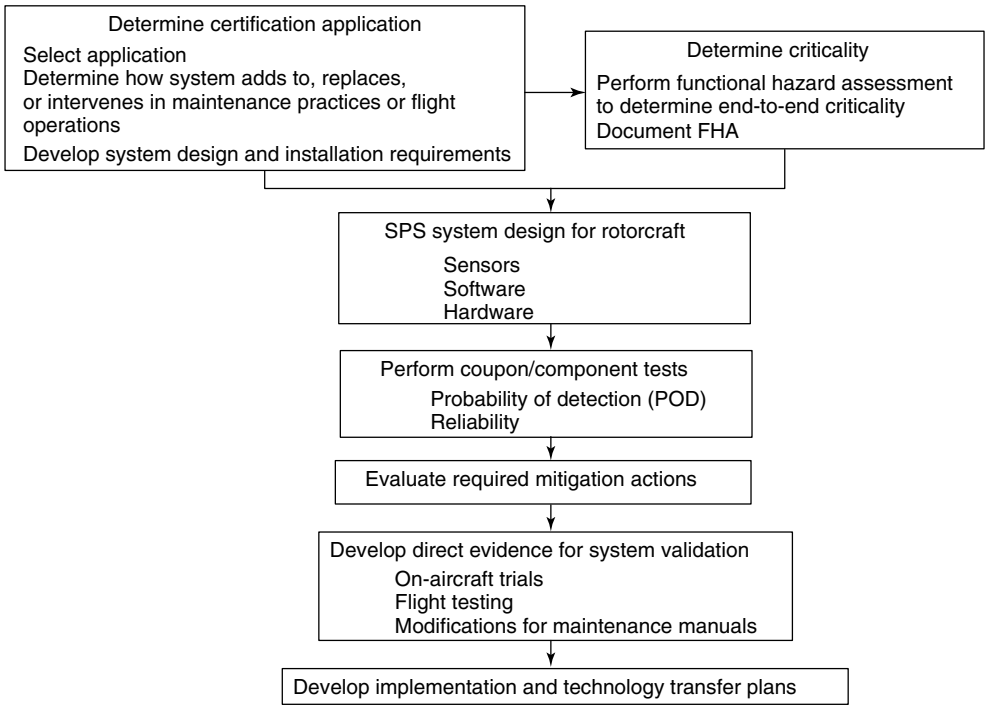

Figure 10. Procedure for the certification of SHM system for commercial rotorcraft applications.

SPS with advanced software, algorithms, and methodologies is being developed, validated, and demonstrated on rotorcraft airframe structures and dynamic components. The basic certification procedure developed to comply with the FAA HUMS certification Advisory Circular (AC) is shown in Figure 10. It addresses the three basic aspects for HUMS certification as described in the HUMS AC, i.e., installation, credit validation, and instructions for continued airworthiness.

4 SUMMARY

Past efforts by commercial aircraft OEMs, airlines, and SHM equipment manufacturers have resulted in the development, demonstration, validation, and certification of a number of SHM technologies that are ready for implementation on commercial transport aircraft. Even though SHM is a relatively new concept to the commercial aircraft industry, the benefits for reducing airframe inspection and repair costs have captured the interest of commercial aircraft operators and the regulatory agencies. Additionally, the commercial aircraft OEMs are now looking at ways to integrate SHM into airframe structural design practices and maintenance concepts for their new aircraft. Although mainly initiated by Airbus and Boeing in commercial aviation, there is hardly any commercial aircraft OEM these days that is not considering SHM to be implemented into its aircraft.

Chapter 97

Fatigue Monitoring in Military Fixed-wing Aircraft

Matthias Buderath

Product Support, EADS Military Air Systems, Ottobrunn, Germany

1 INTRODUCTION

The general aim of a fatigue monitoring system is the prediction of the remaining fatigue life of each individual aircraft of a fleet. Since military aircraft especially are exposed to a wide range of loads, structural health is one of the substantially limiting factors for their in-service time. Generally, different levels of effort can be applied to realize fatigue monitoring. Low effort on fatigue monitoring results in low costs regarding the monitoring effort but in a high loss of fatigue life. In this case, high safety factors have to be applied or high in-service loads have to be assumed so that structural failure can be excluded.

Increasing investments in the development and production of a new weapon system such as a military aircraft have promoted the tendency to extend the in-service time of existing weapon systems. The initially planned in-service time is ensured by the results of a fatigue test, which is initiated in the design phase. When extending the in-service time, the experience of operational usage, which might differ from the assumptions made in the design phase, becomes more and more important. Changing boundary conditions, such as modified parameters of operational usage and modifications of the weapon system itself, require high accuracy in evaluating individual operational loads.

2 PRINCIPLES OF FATIGUE MONITORING SYSTEMS

Fatigue monitoring has become an essential consideration in regard to the longevity of military fighter and transport airframe structures. Airborne fatigue monitoring systems have been widely discussed in recent decades. Following [1] these systems typically collect

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

operational data for the calculation of the safe life or the inspection interval of the airframe.

The fatigue management of an aircraft is configured in the design process as a result of either the safe life or damage tolerant design principle applied, the load spectrum an aircraft structure is exposed to, the material being used and the shape of the structure itself. All of this results in an aircraft structure's life estimation. This estimate is then certified through a structural fatigue test, following which the aircraft operator collects service load data and puts together a management policy. The process of collecting service load data is termed *fatigue monitoring*, and airworthiness regulations like MIL-A-87221 and Def Stan 00–970 require all military aircraft to be fitted with an onboard fatigue monitoring system. Figure 1 provides an approach as to where results achieved from a fatigue test such as the major airframe fatigue test (MAFT) are taken to identify fatigue critical areas (FCAs) that will then require specific care over the operational life. Another tracking is ongoing for in-service aircraft (and thus in flight), which will allow potential FCAs occurring only in service to be identified and treated accordingly. This latter procedure is specifically important with regard to modifications to be made on an aircraft, which are unavoidable over an aircraft fleet's operational life. All data being generated and collected have a feedback loop into other different blocks of fatigue data generation, which can easily result in a substantial database for fatigue life monitoring [2–5].

2.1 Purposes of structural health and usage monitoring systems

As described more extensively in [1] the only means of managing the fleet in the early days of fatigue management of aircraft was through documenting the number of flight hours or landing cycles. Once the certified number of flight cycles had been reached the aircraft was retired irrespective of its true degree of damage. Later cycle counting methods were developed which allowed some further differentiation in terms of the flight spectra being applied. Subsequently this was further enhanced by the introduction of a peak count method which resulted in so-called fatigue meters (g-counting and fatigue meter formula) and later on, with increased digital storing and processing capability, the recording and utilization of flight parameters and/or strain gauges became a fatigue monitoring standard level. However, the purposes of fatigue monitoring systems remain unchanged. As

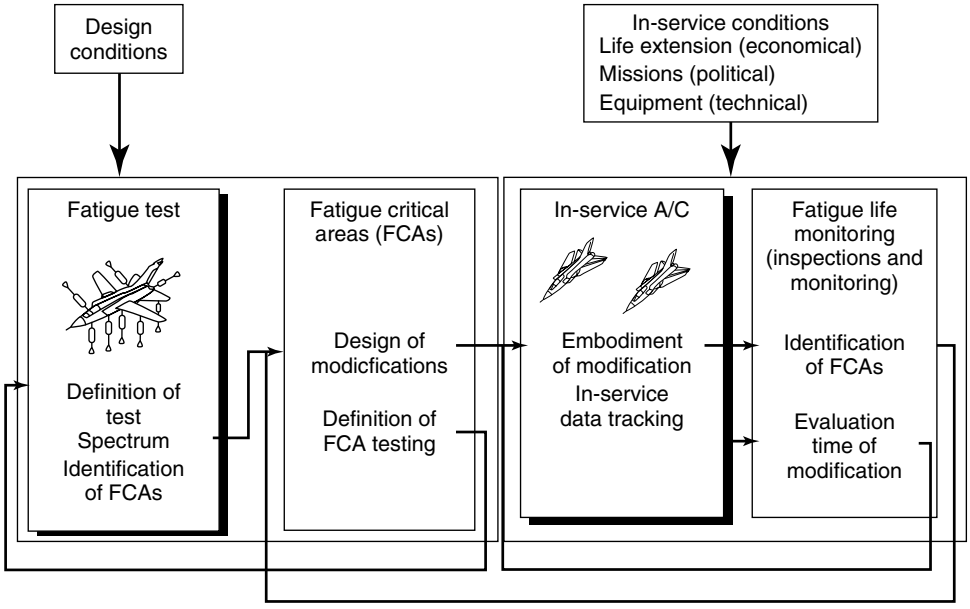

Figure 1. Structural integrity data generation and assessment process during design and operation of military aircraft.

mainly also stated in [1] and **Agile Military Aircraft**, the main purposes are to:

- Fulfill airworthiness requirements to ensure that aircraft are not operated beyond an acceptable level of risk.
- Determine the fatigue life status of a fleet of aircraft throughout its life based on an operational spectrum.
- Determine the actual service load history (many operators in the military aviation sector, and here specifically with fighters, have found that operational usage of an aircraft is significantly more severe than the design spectrum) and to ensure that aircraft are not operated beyond the fatigue damage accumulation threshold for various components as demonstrated through the MAFT (full-scale testing).
- Provide life data that allow the justification and modification of the structural inspection program to be made.
- Improve/optimize the structural integrity management of the fleet (condition-based maintenance (CBM), when done in conjunction with program-based tracking of each aircraft in the fleet). The assertion here is that the utilization of each aircraft is different and that using an average value of aircraft usage is inaccurate when monitoring the whole fleet.
- Detect occurrences (events and load exceedances) of structural overloads in a timely fashion, thus enhancing the fleet safety.
- Assist in the definition of a flight load spectrum for new aircraft of the same type.

Figure 2 summarizes experience gained [6–10] and provides an overview as to when different types of maintenance can only be applied. It becomes obvious that the type of maintenance to be applied is defined during the design stage and that existing aircraft have to stay with basic monitoring system principles in case their type of maintenance cannot be redesigned.

$$UI = \text{usage indicy} \quad \frac{\text{utilization as is}}{\text{utilization as qualified}} \tag{1}$$

$$FI = \text{fatigue indicy} \quad \frac{\text{stress spectrum as is}}{\text{stress spectrum as qualified}} \tag{2}$$

2.2 Functionalities of a fatigue monitoring system

As mentioned above, the process of collecting service load data and combining those with fatigue damage estimation and resulting residual fatigue life estimation is termed *fatigue monitoring*. These service load data generally consist of flight parameters taken from sensors already inherent to the aircraft, which are then converted to the respective operational loads. This approach has the advantage of not requiring any sensors to be added to the aircraft. However, there may be customer requirements or structural necessities that will need the strain (and thus load) sequence to be measured directly in which case a strain gauge (or other sensor) will have to be attached to well-selected locations. Some monitoring systems collect only raw data (time domain data of the respective sensor), while others process the data onboard the aircraft. Besides the question of where the flight data should be processed effectively, the main functionality of an onboard fatigue monitoring system is the recording of all in-service/operational data necessary regarding the fatigue usage of an individual aircraft.

However, the accurate recording of raw data (regarding number of flight parameters/strain gauges, appropriate sample rate, etc.) is only one side of the coin. The other real function of an aircraft fatigue monitoring system lies in the detailed offboard postprocessing and extraction of fatigue-relevant information.

However—and this is the difficulty which is specifically stated in [1] and **Agile Military Aircraft**—military aircraft operators do not follow one standard method of fatigue management as no detailed specifications exist. Design philosophies that feed into fatigue management programs are varied, fatigue test results are interpreted in different ways, and different scatter factors are applied to the fatigue test spectra and fatigue test result. Nevertheless, the necessary growth potential of the basic and enhanced functionalities to cover possible national customer requirements can be summarized for the different categories of onboard and offboard data processing as follows.

2.2.1 Onboard processing

- Recording of an appropriate number of flight-parameter/sensor time histories under consideration of individual sample rates.
- Storage of data on a flight-by-flight basis.
- Upload of user-definable monitoring configuration data without changing the onboard software.
- Load exceedance monitoring including time flag of structural event.
- User-definable allowable loads envelope for load exceedance monitoring.
- Recording span of time around load exceedances.
- Growth potential to add additional parameters and/or sensors.
- Data checking routines; system failure analysis.

2.2.2 On-ground processing

- Download and check of the recorded data regarding completeness and integrity.
- Load exceedance warning, tools for evaluation, and maintenance actions.
- Data processing to calculate/generate fatigue spectra.
- Calculation of usage indices (UIs) and fatigue indices (FIs) based on design assumptions, results of full-scale fatigue tests, etc.
- Growth potential to generate life metrics to support CBM and maintenance optimization.
- Growth potential to generate life metrics for fleet management.
- Growth potential for special technical investigations, e.g., for unexpected in-service problems.
- Database for reevaluation of fatigue-sensitive components.
- Database for unmonitored flight substitution (Sortie Code versus Fatigue Index, etc.).
- Modification of operations to stabilize the rate of fatigue life consumption.

Figure 3 shows the data information flow of onboard data throughout the on-ground fatigue monitoring system. Owing to the complexity of information being presented in terms of decision support and

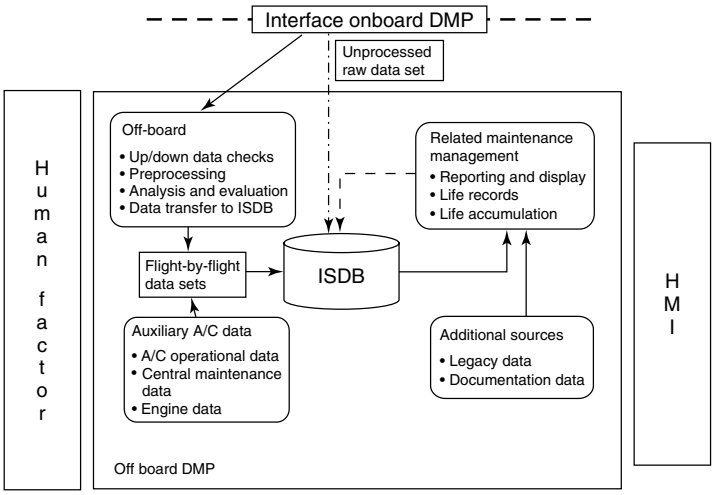

Figure 3. Schematic overview of how to create and how to deal with life consumption.

advisory generation, human factor issues have to be considered as well.

3 FATIGUE MONITORING METHODS

3.1 Flight parameter–based monitoring

The early concepts of aircraft usage monitoring systems were based on flight parameters such as flight hours, mission types, configuration at takeoff, landing weight, and latterly, control surface positions, speed and height among others. With the development of sophisticated acquisition systems, it is now possible to record all necessary parameters as time histories for major load carrying members and subsequently to calculate loads using regression techniques.

These loads can be converted to stresses and strains at fatigue critical locations using transfer functions either derived analytically or by numeric approaches such as finite element modeling. Loading conditions may be separated in terms of tensile, compressive and possibly even multiaxial loads, symmetric or asymmetric flight conditions, different stores configurations, or sub- and supersonic flight.

In summary, it can be stated that flight parameters alone can be used to estimate the dominant load affecting fatigue-sensitive components and, coupled with the use of transfer functions, can be related to stresses at critical locations. Although reasonable levels of accuracy can be achieved, "parameter-only" based approaches for fighter aircraft (using standard flight parameters) can neither account for abrupt maneuvers and gust loads nor directly measure buffet loading. which, for certain components, may contribute significant fatigue damage. For heavy military transport aircraft, these shortfalls may not be relevant.

3.2 Strain gauge–based load monitoring

The sensitive location of the strain gauges can account for aircraft weight and store effects (such as different weapon systems attached to the aircraft), and the variation of principal loads such as the wing root bending moment. Furthermore, strain gauges are sensitive enough to measure abrupt maneuvers and dynamic loading like gusts and buffeting. Thus, the strain gauges must be placed at locations where the fatigue critical loads are representative so that the damge being accumulated can be determined accurately. To achieve this benefit, the location of the strain gauges must be carefully chosen. Following [1], **Agile Military Aircraft**, and others [11–13] care must be taken in particular to ensure that the location of the sensor:

- can be calibrated to the damage-inducing load;
- is dominated by the principal load and insensitive to other loading actions;

- is in an area with a low stress gradient;
- can be directly related to the stress at fatigue-relevant locations;
- is accessible for sensor replacement;
- is replicated on the fatigue test article so that direct comparison can be made; and
- is not dependent on load path variations due to multiple load paths.

3.3 Hot spot monitoring

As stated in reference [14], an alternative philosophy to the strain gauge–based load monitoring is intended to place strain gauges such that they directly monitor the strain/stress at the damage critical locations ("hot spots"). However, there are several problems that can arise:

- The sensor may not be dominated by the principal damage-inducing load and, in particular, it may be difficult to calibrate the sensor response.
- The hot spot may have a high stress gradient.
- There is no guarantee that the maximum strain is monitored.
- If a new hot spot arises, and the gauge does not respond predominantly to the load affecting this new location, then there will be no data available for assessment.
- The hot spot may not be readily accessible.
- Hot spots are not known before finishing the full-scale fatigue test.

3.4 Parameter- and strain gauge–based monitoring

A look at the various fatigue monitoring systems for modern military aircraft being used worldwide reveals that the most popular method is the combination of both flight-parameter and strain gauge–based systems within a fleet. Within this approach, the monitoring methods complement each other. A set of typical parameters being recorded and generated for the different systems is summarized below:

3.4.1 Flight parameter–based system

- Generation of UIs for global overview.
- Parameter/load transfer functions for the generation of load fatigue spectra.
- Parameter/strain transfer function for the generation of "virtual strain gauges" fatigue spectra (based on flight measurements).
- Calculation of FIs based on load/stress fatigue spectra.
- In-flight calibration of strain gauges.

3.4.2 Strain gauge–based system

In addition to the above, this system includes the following:

- load path and hot spot measurements where flight parameters are insufficient and
- support to virtual strain gauge generation (only on dedicated aircraft).

3.5 Processing of collected data

As mentioned before, it makes no sense to record time flight parameters and/or strain gauge responses without subsequent analysis and calculation of UIs, FIs, etc. The purpose of any fatigue monitoring system is therefore the determination of the fatigue life status of an aircraft based on its operational usage.

Independent from the type of in-flight recorder, the amount of collected flight parameters and, if used, the position of the strain gauges, there is still much processing to be conducted before the in-flight data can be used for an assessment of the fatigue usage of an aircraft.

As stated in reference [14], generally, a code is required to format an aircraft's unique data so that it can be processed. It should provide the capability to identify the aircraft (tail number), flight number, aircraft configuration, and mission type. Processing of data recorded is organized in a set of modules in the different actions mentioned below are included.

3.5.1 Data checking and preprocessing module

- Validation of recorded data regarding data integrity (completeness, corrupt data, etc.).
- Determine failed sensors (including sensor information from the flight control system (FCS)).
- Extract number of load exceedances including all information necessary for evaluation and maintenance activities.

- Extract recorded data to time histories.
- Extract number of cycles, e.g., undercarriage cycles and cargo door cycles.
- Extract number and type of landings, e.g., touch and go (TAG), roller, and full stop landings including landing mass, sink rate, bank angle, and drift angle at the moment of touch down.
- Data preprocessing via transfer functions, cross correlations, etc. to get, e.g., aircraft center of gravity (CG), aircraft weight, major loads, and strains/stresses.

3.5.2 Sequence counting module

This module may include a rainflow cycle counting analysis required to generate fatigue spectra for the subsequent calculation of fatigue and thus UIs.

3.5.3 Fatigue module

After generation of the in-service fatigue spectra, fatigue calculations are calibrated against the appropriate fatigue tests having been performed in terms of:

- Global view of the aircraft
  - G spectrum
  - product of N_z *weight spectrum
  - number of, e.g., landings and cargo door cycles
  - product of landing mass × sink rate
  - differential pressure spectrum, etc.
- Major component view
  - wing root bending moment
  - forward and rear fuselage bending
  - fin root bending, etc.
- Local view
  - damage critical areas (hot spots) within the aircraft.

This module generates the life metrics for major components (or even all serialized components) necessary for an advanced maintenance and fleet management concept.

3.5.4 Postprocessing module

This module, whose logic is shown in Figure 4, is the brain of the whole fatigue monitoring system. It is configured as the data management platform (DMP) and updates the database file (in-service database (ISDB)) for each aircraft and, if the accumulated damages equal target values, a warning is given. Furthermore, based on the ISDB maintenance optimization, mission optimization, trend analysis, and fleet management tasks can be performed. The human factor plays an important role on one side, which is the way in which the human being influences the system as such, and the human machine interface (HMI) on the other side, which is the way the communication between the human and the monitoring system is established.

4 AIRFRAME FATIGUE LIFE MONITORING CONCEPTS BASED ON TORNADO AIRCRAFT

The Tornado weapon system was introduced in 1980. Right from the beginning of its in-service time, Tornado was equipped with fatigue monitoring devices to control the remaining fatigue life of critical areas detected during the fatigue test.

Since that time, the concept of fatigue monitoring has been modified, going along with in-service experience and technical innovations. Considering the fact that, for the Tornado weapon system, an extension of the originally scheduled maximum flight hours in the German Air Force is also under discussion, the importance of a reliable fatigue monitoring concept becomes evident. The fatigue monitoring concept applied consists of three major tasks. These are

- in-service measurement;
- mathematical modeling/evaluation of damage calculation; and
- maintenance planning.

The technical innovations led to the fatigue monitoring concepts with increasing accuracy in predicting the remaining fatigue life. As a result of decreasing costs and weight of data-storage capacity, the amount of measured data to represent in-service flight conditions could be enhanced. The corresponding data-evaluation algorithms have gained increased accuracy. This has resulted in a

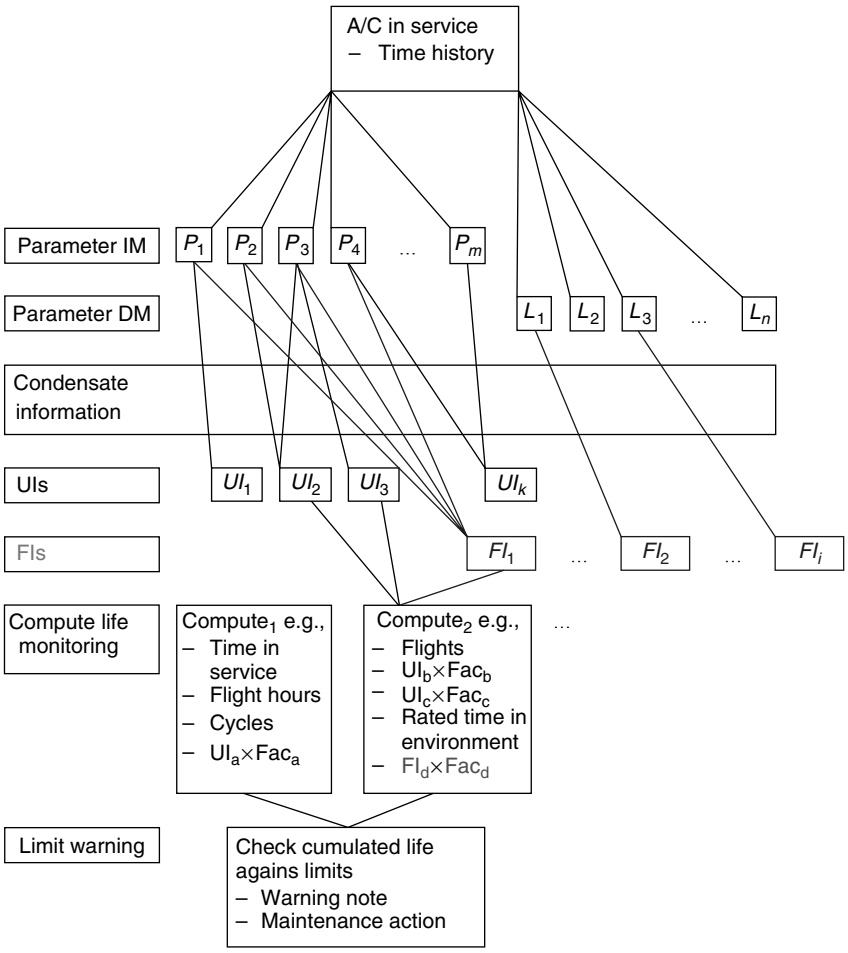

Figure 4. Generic architecture of an on-ground fatigue monitoring system.

subsequent improvement of maintenance planning or, in other words, in maintenance planning that goes along with the actually occurring stresses of individual FCAs [15].

4.1 In-service fatigue monitoring

The "in-service measurement" task for the Tornado weapon system shown in Figure 5 can be described as an integrated concept, consisting of three interrelated components. These are

- individual aircraft tracking (IAT);
- temporary aircraft tracking (TAT); and
- selected aircraft tracking (SAT).

All three components are essentially based on the acquisition of flight parameters, representative of external loads. The components differ with respect to the extent of the measured data.

4.1.1 Individual aircraft tracking (IAT)

The IAT covers a measurement concept, which is applied to all aircraft. A so-called pilot parameter set (PPS) is measured continuously and stored during operational usage. The PPS consists of the parameters N_z, weight, wing sweep angle, and stores. The IAT contributes the data-basis for the calculation of the individual damage index of the FCA.

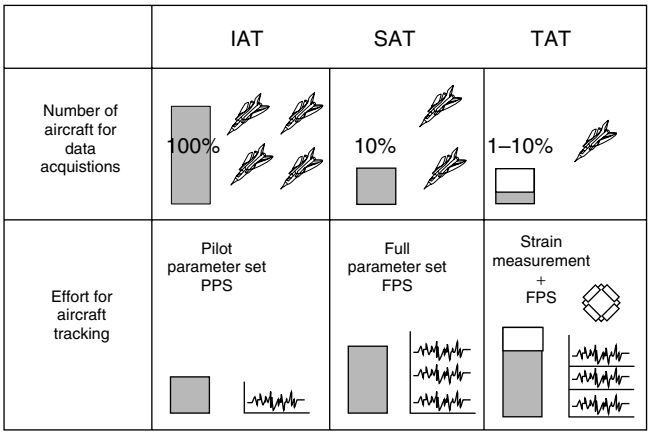

Figure 5. Integrated concept of fatigue monitoring.

4.1.2 Temporary aircraft tracking (TAT)

The TAT is applied to selected aircraft. The measured data set is the most comprehensive one compared with the data sets of the other components. It covers the measurement of the so-called full parameter set (FPS) and the pilot parameter set, which is an inherent part of the FPS. In addition to the flight-parameter sets FPS/PPS, in the scope of TAT, strain is also measured. Strain gauges can be placed at various FCAs. The flight parameters and the simultaneously measured strain allow the adjustment of the coefficients of a flight-parameter-dependent mathematical setup by matching with the actually measured strain.

4.1.3 Selected aircraft tracking (SAT)

The SAT is also applied to selected aircraft. It covers the measurement of FPS and PPS. The SAT is the connecting link between IAT and TAT. The PPS is measured for all aircraft. Starting from a relatively small parameter set, the calculated strain is comparatively inaccurate. The FPS supplies more accurate results regarding the strain, but it is measured only for selected aircraft. To transfer the benefit of a higher accuracy of FPS-based calculated strain, a so-called transfer function is created. It arises from the comparison of the FPS-based calculated strain with the PPS-based calculated strain, which is carried out with the data obtained from the SAT.

Each aircraft of the fleet is thus at least subjected to IAT. Selected aircraft are additionally subjected to TAT or SAT. The general idea behind the concept in data acquisition is that the aircraft that belong to the restricted data-acquisition component (IAT) benefit from the higher accuracy of the limited number of SAT and TAT components. This is an approach that is cost-efficient and simultaneously achieves an overall high accuracy. The flight recorders used with SAT and TAT are distributed on a statistically representative basis throughout the individual squadrons. The simultaneously performed strain/flight-parameter measurements of TAT are cyclically repeated for the same FCA on several aircraft.

4.2 Mathematical modeling

As shown in Figure 6, the precedence of mathematical modeling is coordinated with the concept of in-service data tracking. Results obtained from TAT- and SAT-derived data sets drop into the evaluation of the restricted parameter set of IAT. Because all aircraft are at least subjected to the basic data tracking, this is the basis for the fleet-embracing calculation of the damage factors and, therefore, also the basis for the maintenance planning.

The mathematical model in general should supply the occurring stresses and strains of each aircraft at each FCA by evaluating the incoming flight parameters. The concept of the mathematical modeling has to be adapted to the "physical reality" by considering the system's inherent characteristics and boundary conditions.

Since the comprehensive recording, which is more accurate with respect to the "physical reality", is

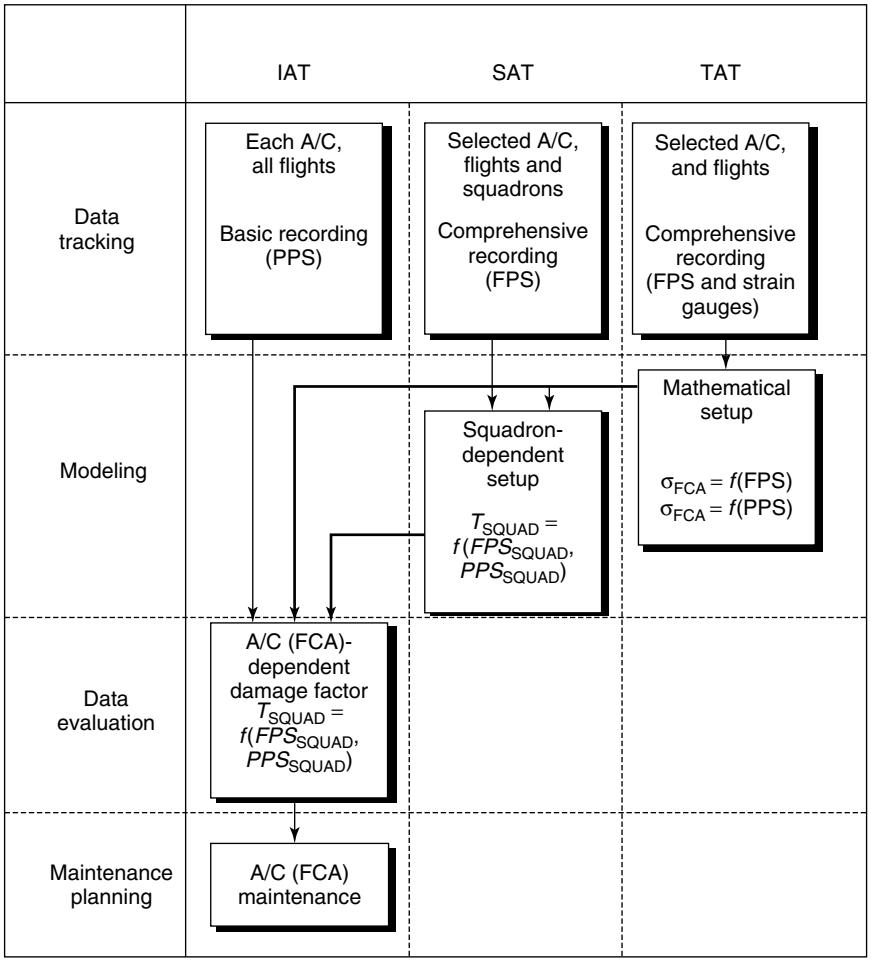

Figure 6. Link of mathematical model with fatigue monitoring.

restricted only to selected aircraft, the concept of modeling also incorporates statistical evaluation methods.

The data obtained from TAT serve for the derivation of the functional relation between the measured flight parameters and the strain at individual FCAs. To choose an appropriate functional setup, first the "physical reality" has to be considered. The strains' respective stresses at particular FCAs depend on the deformation of the aircraft structure. The deformation has to be discussed considering the following two main aspects.

- The external forces and forces resulting from the inertia of masses are the origin of the occurring deformations. The forces can have various points of application depending on the particular maneuver the aircraft is performing. Besides, there are forces that have a deterministic origin as well as forces that occur stochastically, e.g., forces resulting from TAG are induced by pilot action and are therefore of a deterministic origin, whereas forces resulting from gusts have a stochastic origin. Different "classes" of forces might have various influences on functional relations of the strain at a particular FCA.
- The second aspect is that the aircraft itself is not a fixed mechanical setup. Especially, Tornado is a weapon system, which can have various

mechanical setups. The most conspicuous fact in this situation is that the Tornado weapon system makes use of wing sweep technology. Another aspect regarding the mechanical setup of Tornado is the variable mass distribution. Tornado can operate carrying various external loads at different stations. Thus, Tornado might carry the MW1 weapon, weighing more than 2040 kg, under its fuselage or—during another mission—external tanks, weighing 1530 kg maximum each, at the wings. It is obvious that various mechanical setups will have an influence on the strain occurring at particular FCAs.

When setting up a mathematical model to describe strain as a function of flight parameters (Figure 6), the question arises as to how to implement the existence of different aircraft mechanical setups or different classes of external loads resulting from clearly distinguishable sequences of operational aircraft usage. In the concept of the mathematical modeling, this is done by classification. This means that various classes of operational usage are introduced and for each class a set of functions

$$\sigma_{\mathrm{FCA}} = f(FPS) \tag{3}$$

$$\sigma_{\mathrm{FCA}} = f(PPS) \tag{4}$$

has to be derived. In the ideal case both functions should be the same if the PPS parameters are the ones characterizing the loads and thus stresses and strains. However, if this is not the case, then preference will have to be given to the data generated on the basis of FPS.

Figure 7 shows a selection of how classes regarding the mechanical setup of the Tornado weapon system are defined and shows the significant variations a fighter airplane can have in terms of its different configurations.

The next step in formulating the TAT-related mathematical model is to find a mathematical relationship to adjust coefficients by performing a regression analysis. The accuracy of the relationship can be proven by deriving the correlation coefficients between the measured and calculated strain values.

The dependency of strain on a flight parameter can be evaluated by performing correlation analysis. The vertical acceleration N_z is the most influencing flight parameter regarding the strain of an A/C structure. This is the reason why N_z in combination with the

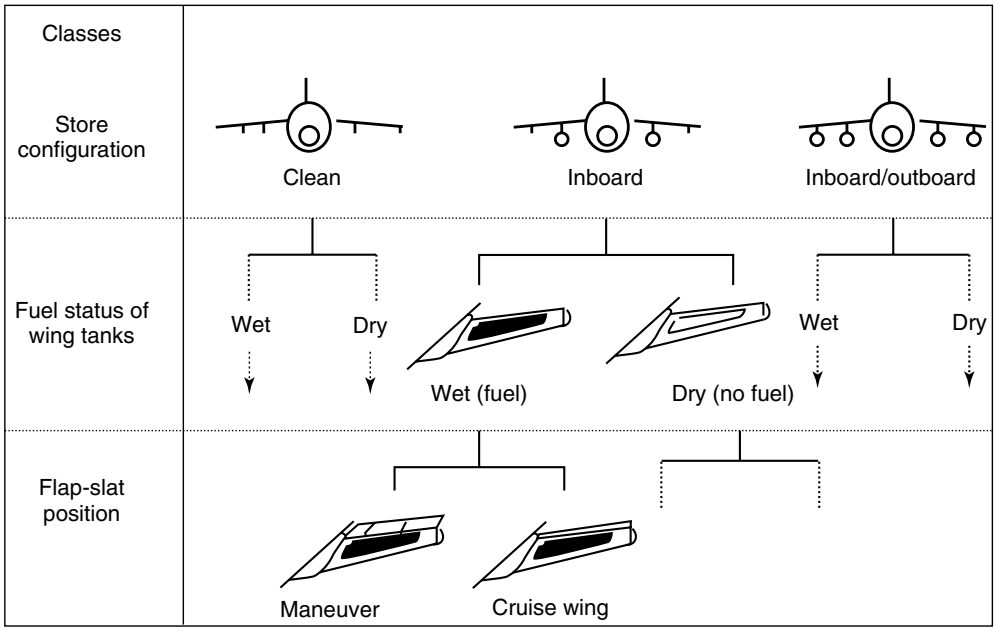

Figure 7. Defined classes.

aircraft weight is the essential flight parameter of the PPS.

Other flight parameters also correlate with strain. The extent of influence depends on the particular flight parameter as well as the location of the FCA. A mathematical setup, which considers various flight parameters, is based on a selection of flight parameters of the FPS obtained with TAT.

4.2.1 SAT-based mathematical modeling

The mathematical modeling in the range of SAT is based on the functional setups obtained from TAT and explained above. These functional setups that rely on the FPS are of a relatively high accuracy, whereas the other setups based on PPS do not fully comprise the influences of maneuvers that are or are not substantially N_z $^*W$-determined. These maneuvers are not considered in the results of the PPS-based function but they are considered in the FPS-based function. Therefore, the PPS-based results always differ from the FPS-based results depending on the occurrence of non-N_z $^*W$-determined.

The structural health monitoring system (SHMS) of Tornado assumes that particular maneuvers are statistically linked to specific tasks of different squadrons. Therefore, the deflection of the FPS-based results to the PPS-based results should be typical of a particular squadron. To benefit from the higher accuracy of a FPS-based result, a squadron-specific transfer function is derived so that less accurate results of a PPS data set can be transformed to a higher accuracy considering the characteristics of squadron-specific operation usage. The target of SAT is to derive squadron-specific transfer functions that determine the relation of FPS-based results to PPS-based results. SAT- and TAT-based mathematical modeling supplies functions that allow the derivation of strain at particular FCAs proceeding from the PPS data. TAT contributes the general functional setup, whereas SAT contributes the squadron-specific influences of the non-N_z $^*W$-determined maneuvers.

4.2.2 Maintenance planning

First experiences regarding FCAs were obtained from the MAFT. For the design of this test, a common load spectrum was defined, which covered the most stringent requirements of the nations participating in the Tornado program. The results of the fatigue test provided the basis for fatigue life assessment in service. The test program revealed the maximum number of safe-life test hours of various FCAs.

Design improvements to modify the FCAs had been derived from the fatigue test results and—as far as feasible—implemented during the manufacturing of the aircraft. Owing to the overlap of fatigue testing and aircraft manufacturing, this was not always possible. Besides, it had to be understood that not all FCAs could be identified by ground testing. Consequently, some retrofit modifications had to be embodied during in-service time for the extension of the fatigue life.

The time of implementing a structural modification is identified by fatigue life monitoring. In case of the FCAs, identified by the fatigue test, the fatigue consumption depends on the usage spectrum of the individual aircraft. Test hours of the fatigue test do not follow a simple correlation with the flight hours of the fatigue test. Therefore, it is necessary to convert the fatigue damage into individual flight hours for the derivation of the point of embodiment for the modification.

Figure 8 schematically shows the major structural modification packages applicable to the German Air Force Tornado fleet and the standardized time of embodiment related to the design life limit. The design life limit (flight hours) represents the number of admissible test hours of the fatigue test.

The respective flight hours are represented by the bars of the chart, e.g., the modification of the center fuselage has to be embodied, when its fatigue life, which corresponds with 100% of the fatigue life according to the design life limit, is consumed. As it is seen, a higher number of flight hours compared with the test hours can be obtained before modification becomes necessary. This means the consumption of fatigue life during operational usage is not as high as the fatigue consumption during testing. The hatched area of the bar indicates the difference between the aircraft with the hardest and the aircraft with the softest operational spectrum of the fleet.

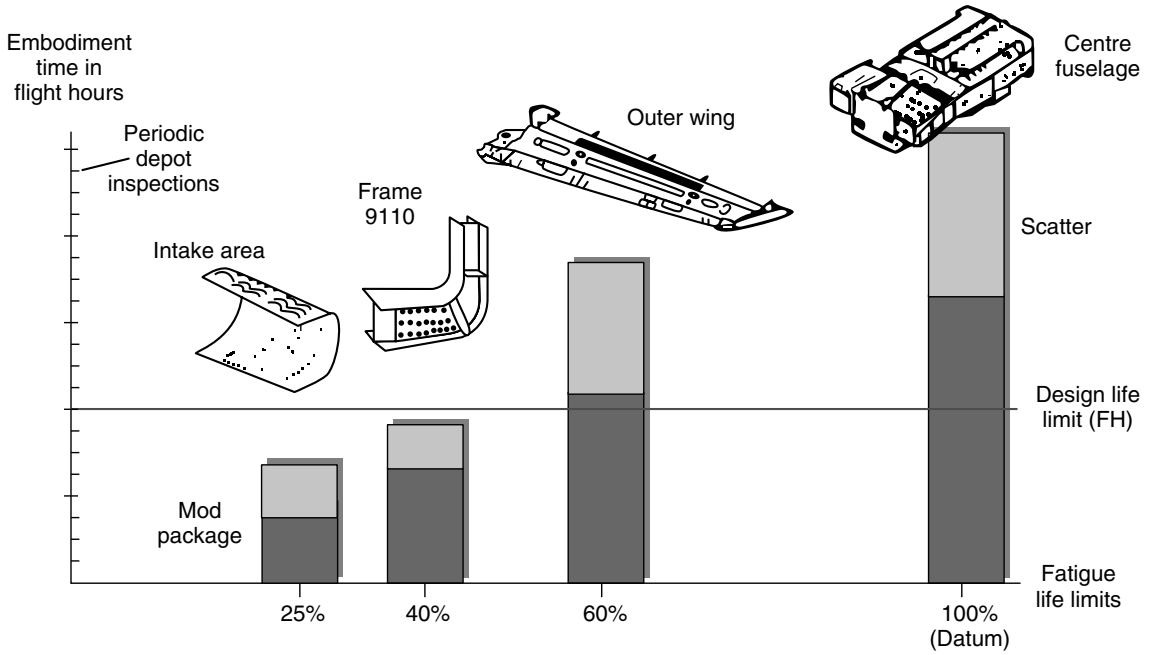

Figure 8. Usage-based maintenance planning.

5 INNOVATION IN FATIGUE LIFE MONITORING

The dynamism in sensor development, loads' modeling and fatigue monitoring techniques these days, which, among others, can be observed in terms of miniaturization, performance, and price, combined with the remarkable progress achieved in sensor signal processing through mushrooming computational power and advanced algorithms, has brought in a new wave of structural technology development that can be entitled "structural health monitoring" (SHM). New and further sensors will allow the monitoring of operational loads at various locations on the aircraft in much more detail, which will further allow the calculation of consumed operational life to be done much more in accordance to the real usage. This will be supported by high detailed loads and finite element models, which allow an accurate calculation of loads based on standard flight parameters. Further to this, there are now more and more sensors emerging that allow the monitoring of damage linking to the traditional usage monitoring of the airframe structure. It can also be observed that the fatigue monitoring, and in the future hopefully also damage monitoring, is becoming an integral part of an aircraft maintenance information system. This article provides a brief overview of the innovation in the field of fatigue monitoring and uses examples from the Tornado Eurofighter and A400M aircraft.

5.1 TORNADO aircraft

The early German Air Force Tornados were equipped with the so-called fatigue meter, which records the cumulative N_z classes within three different wing sweep ranges. As outlined in the previous section, this "basic" classification meets the requirement of a subdivided evaluation for various "mechanical setups" of the Tornado.

Since the Tornado is a weapon system with a wide spectrum of operational usage, the refined concept of fatigue monitoring also considered additional parameters concerning the mass distribution among the aircraft structure as well as various aerodynamic configurations. Thus, the concept using the fatigue meter was replaced by the so-called OLMOS

(onboard life monitoring system) concept. OLMOS and its attached technical devices are still involved in the present evaluations. The data for IAT are stored in the data-acquisition unit (DAU). The device stores the cumulative $N_z{}^*W$ classes depending on the different aircraft setups. These "setup classes" consider the wing sweep angle, the flap and slat position, the external store configuration, and the fuel level in the wing tanks.

Within the scope of TAT, a comprehensive recording of flight parameters is performed. Data are stored by a special device, the maintenance recorder (MR). The data-storage capacity is sufficient to store time sequences of various flight parameters.

The most recent development in data evaluation aims at a comprehensive data recording for each aircraft. The new data-storage device, the flight data recorder (FDR), was introduced to the first aircraft in the German Air Force in 1999 and substitutes the MR. Since the FDR will be installed in each aircraft, this opens new prospects for further development of the data-evaluation algorithms and, hence, for managing the life cycle of the aircraft more efficiently. Figure 9 summarizes the evolution of the different operational load monitoring systems on the German Air Force fleet of Tornados.

5.2 Eurofighter aircraft

Two SHM versions called the *Baseline Fit* and *National Fit* respectively have been developed and are described in further detail below. These reflect the customer requirements for either a parametric-based or strain gauge–based fatigue monitoring system. Both versions are validated by comparison with flight test data correlated to fatigue test results. Figure 10 shows a general overview of the SHM system. The SHM system calculates fatigue life consumed at specified locations on the airframe. The software fitted to the aircraft provides the operator with the option to define the facility via data uploaded by support personnel, whether the location is monitored either flight parameter- or strain gauge–based system.

The SHM system performs real-time fatigue calculations and determines the fatigue life consumed by

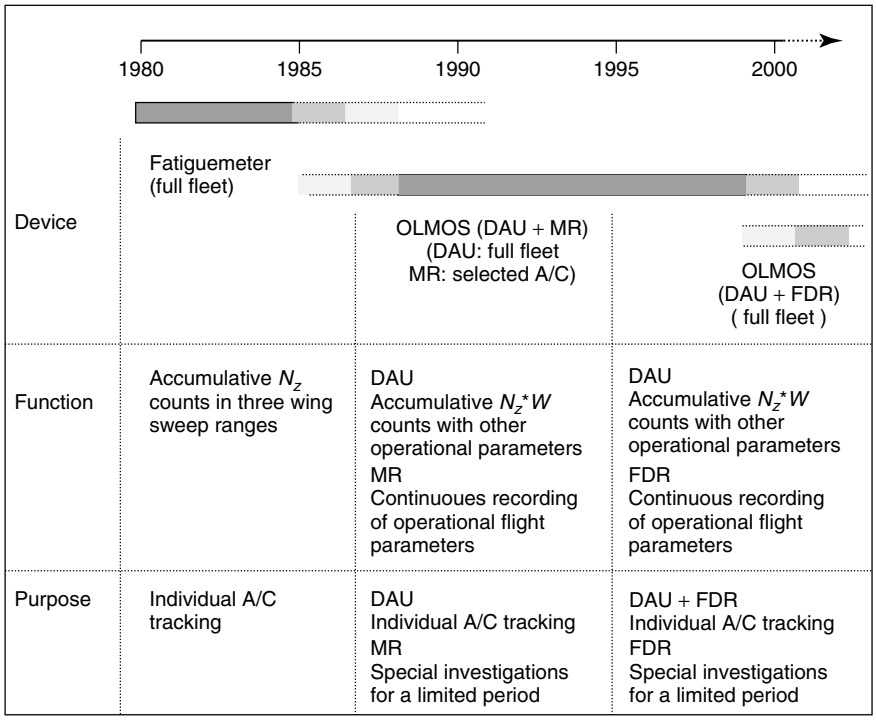

Figure 9. New generation of the Tornado fatigue monitoring system.

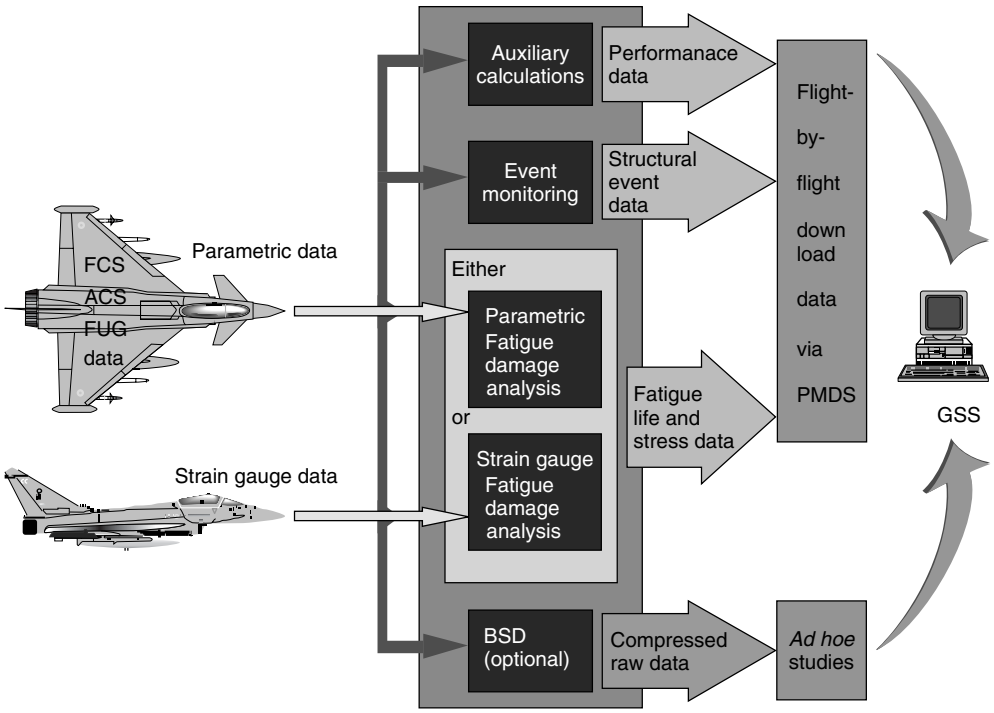

Figure 10. General view of the Eurofighter SHM system.

the airframe with significant structural events and flight performance parameters being also monitored. A facility exists to record parameter and strain gauge time histories, if requested by the operator, for *ad hoc* studies.

5.2.1 Parametric system—Baseline

An overview of the main fatigue calculation processes for the Baseline Fit is shown in Figure 10. Real-time data are captured from the FCS, aircraft control system (ACS), and the fuel gauging system (FUG). The FCS provides aircraft altitude, velocities, and accelerations, the ACS provides information on the aircraft weapons configuration, and the FUG provides fuel mass information. These data are fed into the on-aircraft stress functions, which calculate the stress and hence the damage at each monitored location by comparison with approximately 18 500 templates held in internal memory. Each template, derived from finite element analysis and the results of ground-based airframe fatigue tests, corresponds to a particular aircraft configuration and set of flight parameters. The above process is iterated to generate a history of stress for each location. The stress history is subjected to a real-time range-mean-pairs cycle counting analysis to calculate stress spectra and fatigue damage. The baseline SHM system is based on monitoring 10 locations, with growth potential for monitoring a further 10 locations accommodated by a software change. The system is designed to start operating once the engines have been started and the FCS is active, and it ceases to operate at engine shut down.

5.2.2 National Fit system—strain gauge inputs

An overview of the main fatigue calculation processes for the National Fit system is shown in Figure 11. The National Fit system can record up to 20 analog channels of sensor data. These require sampling and digitizing at rates that are dependent upon the particular monitoring location. A digitizer is required to convert the 20 analog channels to digitized format with a combined sampling rate of at

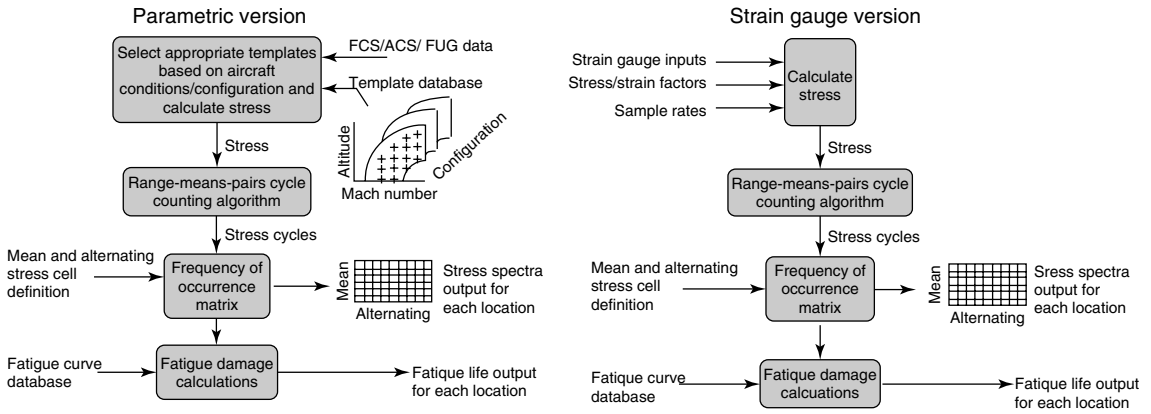

Figure 11. Baseline- and strain gauge–based fatigue calculation.

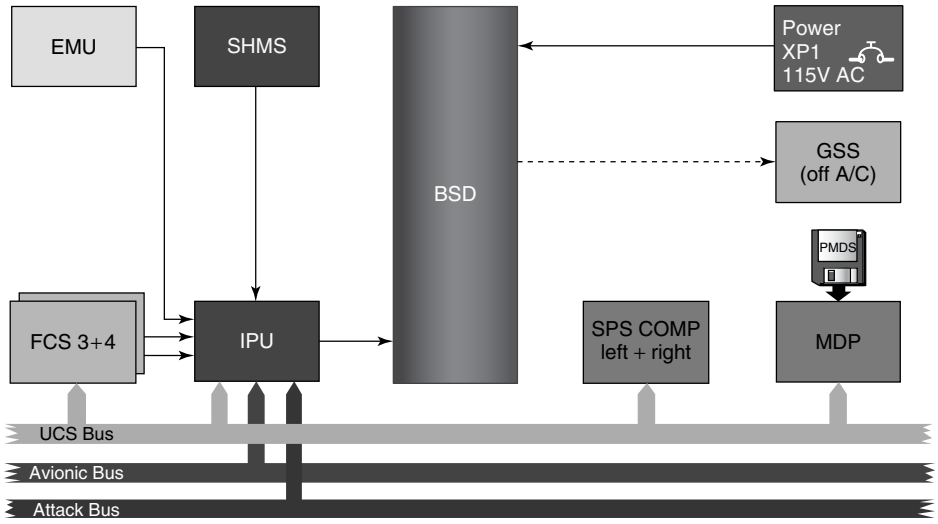

Figure 12. SHM and integral part of the integrated monitoring and recording system Eurofighter. EMU, engine monitoring unit; IPU, integrated processing unit; BSD, bulk storage device.

least 2048 samples per second and a maximum rate of 256 samples per second for any one channel. The sampling rate for each of the 16 monitored channels is set by means of the application software. The digitized data from the 20 channels are placed into memory prior to onward processing. The National Fit system is delivered with 16 sensor channel transducers installed for onboard fatigue damage calculations. The sensor sampling rates and strain-to-stress conversion factors per monitored location are all user-definable via the portable maintenance data store (PMDS).

5.2.3 Integrated Monitoring and Recording System

The SHM algorithms form part of the integrated monitoring and recording system (IMRS) software fitted to each Eurofighter (see Figure 12). The IMRS forms an integral part of the avionics suite on Eurofighter. Its main features are facilities related to the following:

- structural health monitoring
- mission data loading

- video voice recording
- mission data recording
- crash recording
- maintenance data loading
- limited configuration checking
- maintenance data recording
- special study recording
- warning handling
- build in test handling
- recording of consumables information and
- erasure of secure data.

5.2.4 Maintenance Data Panel

The maintenance data panel (MDP) is a fixed on-aircraft piece of equipment that displays information to the support personnel, allowing them to query on-aircraft systems data. SHM details available on the MDP show the total life consumed by each SHM-monitored location and information on SHM event messages that may have occurred on the previous sortie.

5.2.5 Portable Maintenance Data Store

The PMDS is a solid-state memory device approximately the same size as a cigarette packet ($\sim 100 \times 60 \times 25$ mm). The PMDS is used to transfer SHM engine and maintenance data to and from the aircraft as described for various cases in [16–19].

5.3 A400M aircraft

Monitoring systems onboard the aircraft may supplement or even replace periodic inspections that are part of the scheduled maintenance program. Automatic monitoring of the aircraft allows the replacement of certain tasks at predetermined intervals by on-condition maintenance, thereby extending the service life of some items by avoiding premature replacement. An assessment of aircraft status and the need for maintenance action in such cases will be determined by monitoring dedicated parameters to identify the need for maintenance action before an anticipated failure occurs, and monitoring performance or systems configuration degradation to enable maintenance to be undertaken before a critical loss of function occurs.

Degradation of a mission-critical system, otherwise imperceptible to the crew, is detected by the monitoring system, which predicts a schedule interval during which a maintenance action will be required. For the duration of this interval, maintenance action may be deferred to the most convenient time, and aircraft operation may continue with a high degree of confidence that a mission loss or further degradation will be avoided. Despite the fact that this might lead to the removal of a component that still has some potential, it allows the corrective maintenance activity to be performed when the aircraft is on standby or preferably during a scheduled inspection, thereby avoiding mission loss or removal of the aircraft from the flight line. The scheduled interval can be defined based on parameter or configuration requirements, as shown in the example of Figure 13, which should be self-explanatory.

On-condition maintenance, used for a long time on Airbus aircraft, is being systematically applied to all the systems and the structure of the A400M when flight safety allows it. For that purpose, the

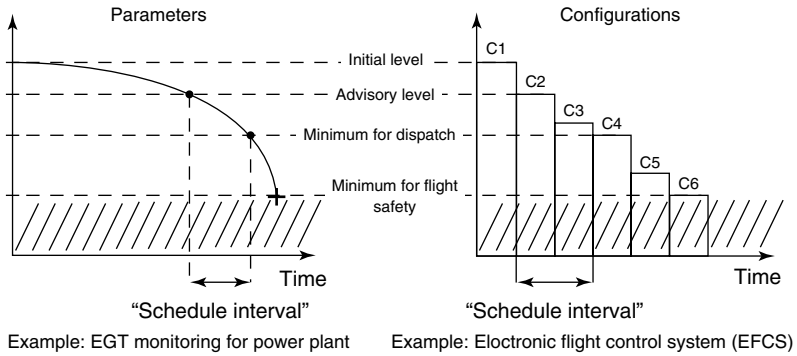

Figure 13. On-condition maintenance—examples of schedule interval definition.

integrated avionics of the A400M is equipped with an aircraft integrated monitoring and diagnostic system (AIMDS) that centralizes the control of the built-in test equipment (BITE) of all systems on each aircraft, detects system faults and provides failure messages in plain English, and collects and records engine, Auxiliary Power Unit (APU) and critical systems data. This data can then be analyzed using the maintenance data system (MDS), which is explained in more detail below, to enable prognostics, trend analysis, maintenance planning, and health and usage monitoring.

In addition, the extensive use of integrated modular avionics (IMA) and redundant architecture makes the continuation of operations with degraded configurations easier. The dramatic reduction of hard-time inspections and overhauls brought about by on-condition maintenance on modern aircraft and on the A400M is one key to reducing the operation and support cost of the A400M aircraft and to ensuring a high operational availability rate.

5.3.1 A400M Aircraft Integrated Monitoring and Diagnostic System (AIMDS)

In addition to an efficient system installation, which reduces the duration of components' replacement, maintenance time can be reduced by improving the diagnostic capabilities of the aircraft. As mentioned before, the AIMDS of the A400M is used to centralize the control of BITE, detect system faults, and provide failure messages in plain English, and collect and record engine, APU and critical systems data, thereby enabling trend analysis and maintenance planning.

This data can be analyzed either onboard the aircraft or more deeply on the flight line by using a portable multipurpose access terminal (PMAT) that allows ground crews to interrogate the AIMDS via plug-in points inside and outside the aircraft to facilitate a more in-depth analysis of failures. In addition, the PMAT will provide access to the Interactive Electronic Technical Publication (IETP) of the aircraft for troubleshooting and corrective actions.

In addition, the aircraft is equipped with a lifetime monitoring system (LTMS), to perform direct measurements via strain gauges to detail information of the usage and fatigue life consumption of the monitored components. This system will record aircraft structural loads, including overloads, hard landings, and total cycles accumulated, enabling operators to track aircraft utilization and associated fatigue. This will allow the operators not only to plan their on-condition maintenance more efficiently but

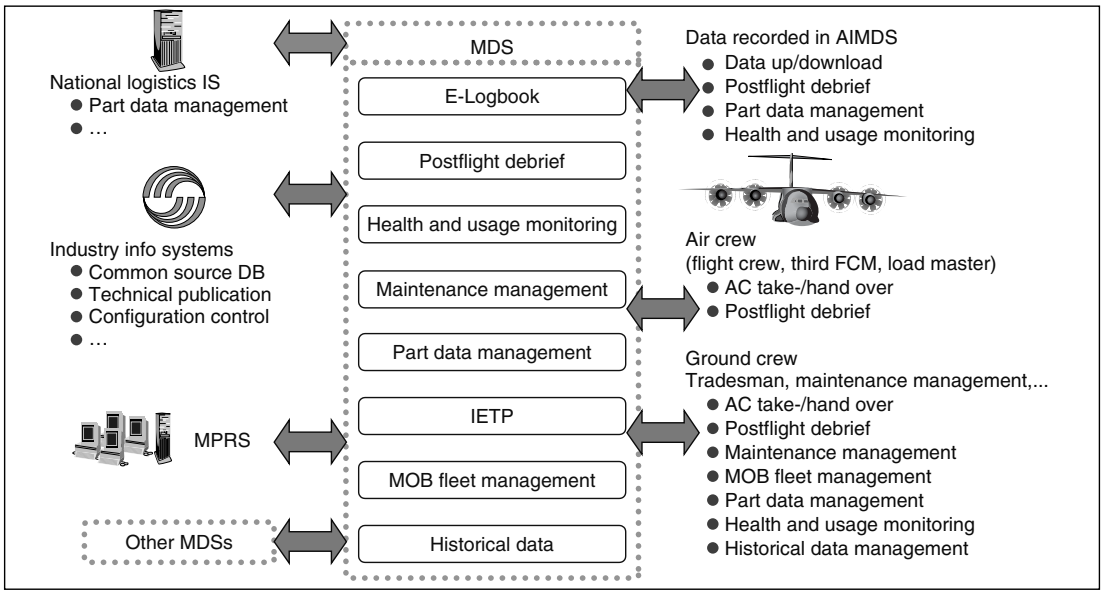

Figure 14. A400M MDS external interfaces and main functions.

also to review the scheduled maintenance program if required. The LTMS will work on the same principles as described in this article.

A schematic representation of the functionalities of the A400M MDS, showing its external interfaces and main functions, can be found in Figure 14.

The PMAT can download the AIMDS data and upload it into a ground support system (GSS) that includes both a mission planning and restitution system (MPRS) and a MDS. These systems allow the storage of the data in a database, manage the performance, fatigue and corrective actions on the aircraft, and schedule the preventive maintenance tasks. It presents the aircraft status in real time and performs other functions such as SHM. In addition, studies are being conducted to allow the transmission of maintenance data from the aircraft in flight to the ground via a data link, which would allow more efficient management of maintenance activities on the flight line and increase operational availability. Such methods are already in use by some civil airlines and military transporters [20].

6 CONCLUSIONS

The article shows the principles currently applied in the development and implementation of structural health and usage monitoring systems for military aircraft. The article also links the fatigue monitoring principles to a real application, e.g., Tornado aircraft fatigue monitoring and management.

The innovations in that field are exemplary, illustrated by the Eurofighter and A400M programs. The principles of fatigue and usage monitoring are more or less the same but many improvements in the information fusion, integration, processing, and information management technologies can be seen. These are considered as key enablers to manage structural integrity, aircraft/fleet availability, and the reduction of operation and support costs. In particular, operational availability cannot be dissociated from the related costs going along with corrective and scheduled maintenance actions. Significant operation and support reductions can only be achieved at aircraft level by having a comprehensive view about the aircraft system and structural performance. The more the information can be integrated into a maintenance information system, the more operational and cost benefits become obvious. This is a common requirement seen in the military air forces.

The next generation of military aircraft will hopefully have a usage and damage monitoring system implemented.

Chapter 102

Health and Usage Monitoring Systems (HUM Systems) for Helicopters: Architecture and Performance

Kenneth Pipe
Humaware, Petersfield, UK

1 INTRODUCTION

The first work attempt to use condition monitoring techniques for helicopters was a research program undertaken by the UK ministry of defense (MoD) in the late 1970s. The technical breakthroughs in the technology were made by a UK R&D company—Stewart Hughes Ltd—by pioneering the use of pattern matching and model reference techniques. This technology became the foundation of what is now known as a HUM system (*health and usage monitoring system*), which is described in this article. The acronym HUM was coined by Westland Helicopters to describe a range of technologies, which, when taken together became an integrated system that could be fitted to a helicopter to provide a defect forecasting capability. The first implementation was on the Westland WG 30 helicopter. Other manufacturers—Sikorsky with their mechanical components diagnostics system (MCDS) and MDDS programs, Eurocopter with the Euro-ARMS program, and Bell Helicopter with their BUCS program—also developed a capability during the 1980s.

The first HUM system was certified in November 1991 for operation in the North Sea. The system was one of two competing designs developed for meeting the oil companies' requirements for a HUM system following the HARP (helicopter airworthiness review panel) review of helicopter airworthiness. Both systems were designed to meet the

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

same requirements, but each operated with significantly different functionality and operator interfaces. In the 10 years that followed, HUM systems for civil helicopters have appeared from Eurocopter and latterly from Bell, again ostensibly designed to meet the same North Sea requirements, but they are also distinctly different systems. Lately, in the military arena Intellegent Automation Inc (IAC), General Electric (GE) Aerospace, and Goodrich have produced HUM systems, which represent yet further variations in design.

There is guidance on what constitutes a HUM system published by the UK CAA (Civil Aviation Authority) Helicopter Health Monitoring Advisory Group [1], but this guidance has not led to the emergence of a consistent systems' design philosophy nor has it established criteria for the measurement of a HUM system's performance.

This article aims to explore how the performance of these systems of differing designs can be established and provides a comparison of their relative attributes.

The purpose of a HUM system is to provide a timely indication of the deterioration of the continued airworthiness of a component in order that maintenance can intervene and rectify the defect. It is a supplementary method to the various prescribed inspections and preventative maintenance actions contained in the helicopter's maintenance handbook to ensure the helicopter's continued airworthiness and thus enhance the margin of safety of helicopter operations. To achieve this improvement, HUM systems monitor (i) the usage of the lifed components, (ii) any exceedances from the operational envelope, and (iii) the health of the power train components. The health monitoring of components provides a goal keeper function, guarding against any failure of the maintenance procedures to preserve the airworthiness of the helicopter. The most important health monitoring feature is the vibration monitoring function, which utilizes techniques of varying degrees of sophistication to identify defects developing in the power train components.

There are secondary functions in HUM systems, which relate to obtaining maintenance credits (*see* **Experience with Health and Usage Monitoring Systems in Helicopters**). Principal amongst these is the balancing of shafts and rotors without employing specialized maintenance test equipment and in the case of the main rotor, eliminating the need for maintenance test flights following the rotor adjustments.

It is, though, the primary requirement of a HUM system to enhance airworthiness, which requires that the contribution of a HUM system to a helicopter's airworthiness can be measured.

2 MEASURING AIRWORTHINESS

Airworthiness can be defined as the risk to an aircraft of a catastrophic incident posed by its design or operation. The design criterion set in the Federal Aviation Authority's (FAA) JAR 29.547(b) and 917(b) is that for any failure mode in the dynamic train, the risk of it causing a catastrophic failure of a helicopter must be less than 1 catastrophic failure in 10^6 flight hours, which is a probabilistic measurement of a very rare event. The only practical estimates of this probability are from large fleets of aircraft operated over many years. Relating a helicopter's overall risk of failure to the performance of a particular HUM system function is not possible unless statistics from many billions of flight hours more than the fleet will fly can be gathered.

The Regulatory Authorities and the accident investigation bodies do look at the contribution, or otherwise, of a HUM system in the case of a catastrophic failure. Design assessments for certification of new helicopter design can assess the contribution of a HUM system to overall aircraft airworthiness. Neither of the above processes has produced criteria around which HUM system performance standards can be determined.

The Heinrich Principle states that accidents have incidents as their precursors. Analysis of the causes of the much more frequent occurrence of incidents can be used to provide data that would allow measures of risk to be made. This allows performance measures to be established that will by inference ensure the much less frequent accident rate is impacted in the desired direction.

The Regulatory Authorities maintain records of mandatory occurrence reports and the CAA, which is the only Regulatory Authority to mandate a HUM system [2], does record its contribution to reported events. Therefore, there is an experience base of HUM system operation that can provide some actuarial evidence of performance. The CAA has

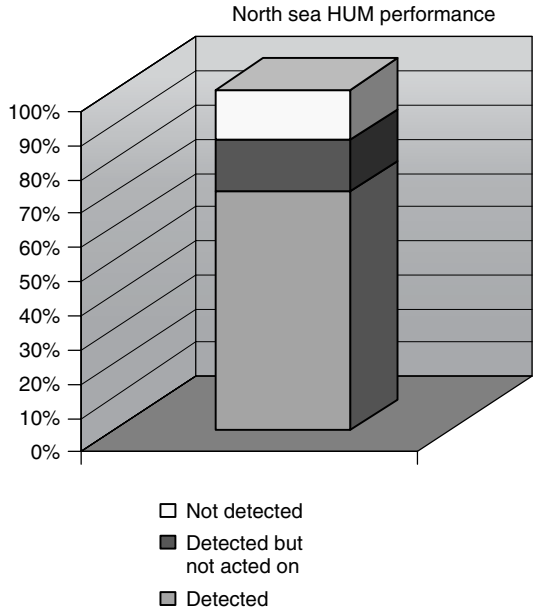

Figure 1. Success Rate of HUMS in North Sea.

published data on HUM system performance in the North Sea [3] as summarized in Figure 1. This data was informally updated in 2002 and the success rate was basically the same [4]. This North Sea experience documented by the CAA shows a 70% success rate in detecting defects. This can be used as a performance measure for the contribution of HUM systems to airworthiness.

The distribution of faults detected by North Sea HUM system is shown in Figure 2. This diagram shows that, with the exception of the planetary gear system, there is no justification for applying different performance standards for individual components of the dynamic train. Clearly, components where the technology has not been shown to be effective should be excluded from the performance measure, or a measure more applicable than the North Sea standard should be employed.

This actuarial measurement of performance is only viable for large fleets generating a large number of hours and where there is independent verification of the statistics. This is possible in aviation because of the monitoring of operations imposed by the Regulatory Authorities. It is unlikely that any vendor would accept such a performance criterion unless he is offering a mature system with a track record of success. This overall performance criterion does represent a differentiator for separating the wheat from the chaff in the market place.

The corollary to the success rate is the false alarm rate. Specifying a demanding target for the success rate could always be met in principle, but with a high cost in nugatory maintenance activity. Fear of this potential problem with HUM systems has been a major impediment to helicopter manufacturers

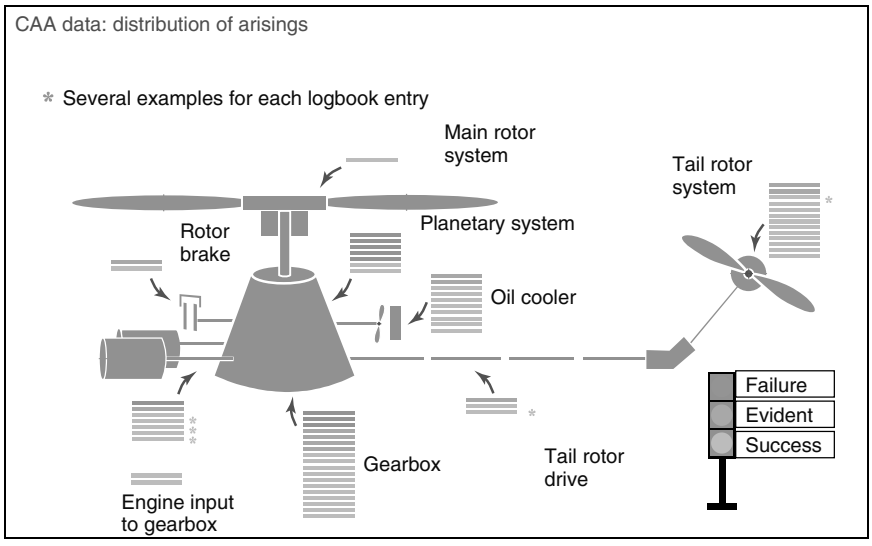

Figure 2. Drive Train Defect Coverage. [Reproduced with the permission of the UK Civil Aviation Authority].

incorporating HUM technology into their maintenance practices.

An acceptable definition of false alarm in the HUM system context is contentious. For much of the industry, any single alarm generated by a HUM system not shown to result in a defect being found is judged to be a false alarm, even though the alarm did not lead to any nugatory maintenance. This is a very demanding definition, particularly for alarms being set on random data such as those generated by vibration. It is usually found that setting of alarm levels with sufficient sensitivity to fault conditions leads to the generation of spurious alarms. If these are shown to be spurious and dealt with without incurring unnecessary maintenance actions, such as inspections, then this should be treated as part of the alarm processing, albeit processing by the engineer rather than the system. A better definition of a false alarm is an alarm that has caused nugatory maintenance action. Dealing with spurious alarms in a HUM system environment can be regarded as an operating overhead. This overhead cost should be measured and the system should have features that ensure that it is kept to a minimum. The time spent at the ground station and skill levels for alarm processing needs to be specified by the vendor.

The inverse of the successes are the missed faults, which is also an important measure for controlling the performance of the system. Determining the reason for a HUM system failing to detect a fault is necessary for quality control of the HUM system and for ensuring that any gaps in performance that are within the scope of the technology are closed.

These actuarial measures of HUM system performance can be monitored by any operator operating under the CAA's CAP 693 guidelines [5].

Any actuarial measurement of performance relies on ample evidence being available to generate the statistical measures at an acceptable confidence level. For a new HUM technology or a new helicopter design, these data are not going to be available and other approaches have to be taken.

3 BUILDING BLOCKS OF A HUM SYSTEM

The approach to a new system has to be to identify the components of a HUM system and establish the performance criteria for these components such that an estimate of the expected overall performance can be made. Figure 3 shows the processes that have to be performed for an alarm to be produced by a HUM system.

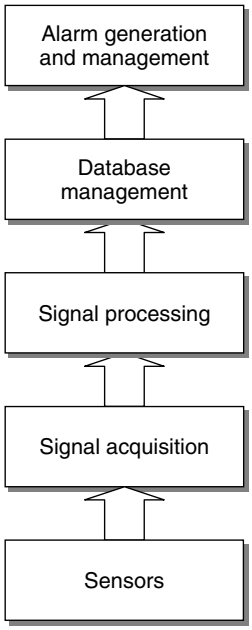

Figure 3. HUMS Architecture.

Sensors with the correct characteristics have to be fitted; the signals are then acquired and processed to produce variables that are stored in a database. There may be more than one database that has to store the variables without loss; and these variables are then processed to produce alarms, which have to be managed until either a defect or a false alarm is determined.

For the monitoring of data such as airspeed, the HUM system has to emulate the processing used for acquiring and displaying the data in the cockpit, with application of the same performance measurement criteria. There can be difficulties here in that usually the HUM system's signal acquisition and processing is not identical to the cockpit instrumentation and can produce results of differing accuracy and resolution. Establishing what the tolerable difference between the HUM system's data and the cockpit data, which is usually less accurate and of a lower resolution, can be a more strenuous exercise than first envisaged.

This problem can be further compounded when data is used in calculations such as those used to compute power assurance. These differences are often small but can cost the credibility of the system unless they are understood and accepted by pilots and engineers.

There are sensors and processing used in HUM systems for different purposes than those for which they are used in the aircraft. Tachometers are typical of these. These Tachometers are usually pulse devises, integrated to produce shaft speed, for HUM system, and they are also often used as a phase reference for vibration processing, so that the performance of the sensor in terms of producing a regular and well-defined pulse shape is more precisely specified. In most HUM systems, the processing of vibration data is highly dependent on reliable tachometer data, requiring that the performance and integrity of this system component is very thoroughly engineered.

Then there are the specialized sensors and processing that are peculiar to HUM system; these are principally the vibration processing for health monitoring of the shafts, gears, and bearings, and also the blade tracking systems combined with the vibration processing used for rotor track and balance. Vibration processing adds a great deal of cost and complexity to a HUM system and needs to perform well to justify the burden it imposes.

4 VIBRATION PROCESSING IN HUM

Vibration has been shown to be a very powerful tool in faultfinding in the helicopter's dynamic train [6]. Any deformation of a rotor or shaft produces an increase in its vibration. Faults in gearing actions, cracks in splines, and spalls in bearings all produce discernable changes in the vibration characteristics of the helicopter.

Shaft-induced vibration has been shown to be relatively straightforward to deal with reliably by HUM system and it produces a high probability of success at an acceptable false alarm rate. This is not so for the more complex analysis techniques where a more variable performance has been experienced in the field.

The difficulty with vibration monitoring is that one sensor integrates a large number of vibration signals from the components of the machinery it is monitoring. A typical vibration signature for a component on a helicopter transmission is shown in Figure 4.

The vibration spectrum for a helicopter can be divided into six regions. The lowest frequencies are quite discrete and are primarily due to the helicopter's rotors and their harmonics. As the frequency increases, the transmission shafts, engine shafts, and meshing frequencies come into play. All of these machinery-generated vibrations cause the structure to

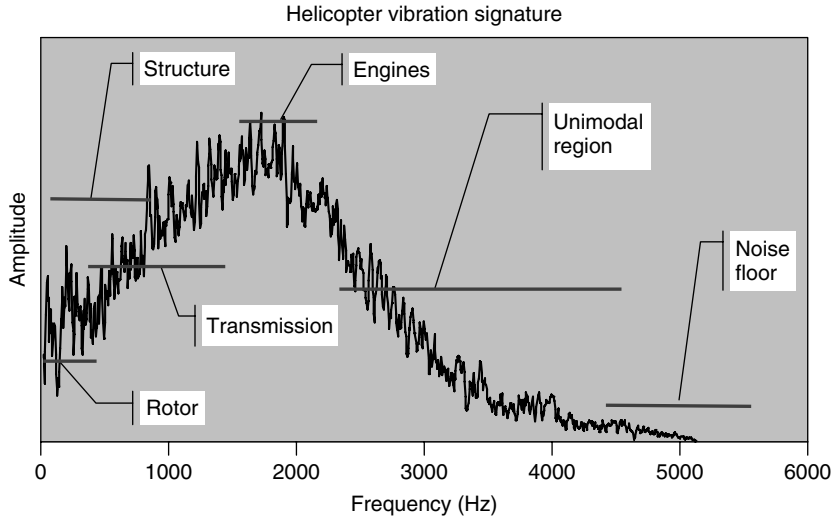

Figure 4. Helicopter Vibration Signature.

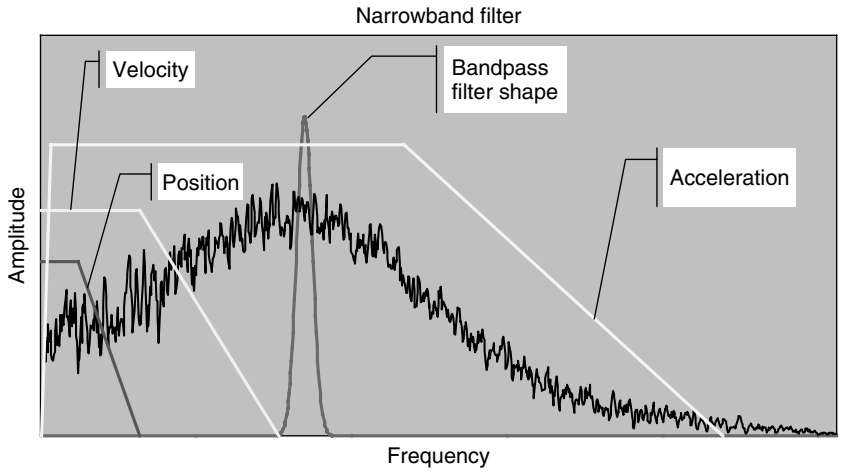

Figure 5. Narrow Band Filter.

vibrate, and as the sensors are mounted on the structure, the structural resonances or modes generate a range of tones throughout the vibration signature. All of these vibrations produce harmonics and the energy in the increasingly complex signature builds up into the characteristic bell shape as shown in the diagram, with the frequency discrimination increasingly becoming less distinct. After the primary shaft orders and major structural resonances frequencies have passed, the spectrum is then made up of only the higher harmonics, the energy in the spectrum then falls off, and any frequency discrimination disappears altogether. The lack of frequency discrimination leads to the term *unimodal* to describe this region. Finally, no spectral energy is discernable and the energy levels off, this is the noise floor of the sensor and processing.

Each of these regions makes different demands on the vibration processing and different technologies have been produced to provide useful analysis of the data. This has impacts on the sensors as well as on the processing capability of HUM system. These will now be considered in turn.

5 SENSORS

Performance of the sensors is clearly critical to the performance of the vibration processing in a HUM system. Vibration sensors originally measured position and were very restrictive in frequency range or bandwidth. The technology then progressed to velocity sensors, which offered higher bandwidths and tracking filters, as shown in Figure 5; these could be used to analyze higher frequencies such as engine spool vibration. It was the development of the accelerometer that brought sufficient bandwidth to cope with the whole of the useful spectrum.

Accelerometers do have a problem of roll-off at dc as well as at high frequencies. Specifying an accelerometer that can measure the low-frequency rotor orders as well as the higher frequency harmonics of the mesh tones can prove to be a demanding requirement. Often accelerometers with different sensitivities and bandwidths have to be used on the helicopter: one for structural vibration monitoring giving the required performance at lower rotor and structural resonant frequencies, and another type for the transmission and engine frequencies. Environmental conditions also play an important role in accelerometer specification.

At the start of the HUM system development, accelerometers were largely laboratory devices but great strides have been made in their design and constriction to make them suitable for use in the aviation environment.

The positioning and installation of an accelerometer is as critical as its bandwidth, range, and sensitivity for determining its performance. If the sensor is acquiring the lower frequency rotor and structural vibration, then the sensor positioning is less critical

as these vibrations can be sensed almost anywhere in the helicopter. For the higher frequencies, or for when the shaft frequency is the same, sensor positioning is more critical to produce the necessary discrimination between components. The sensor has to be installed as close as possible to the component so that its vibration dominates the spectrum.

Great care has to be taken over the installation of sensors to ensure that the sensor orientation is appropriate for the vibration that is being measured and that the installation bracket does not introduce structural responses that either swamp the signal or interfere with it.

Adequacy of the sensor positioning can only be demonstrated by the production of spectra that show that the characteristics of the monitored component's vibration signal is clearly discriminated in its normal operation such as the once per rev vibration and harmonics from the shaft and the mesh tones in the gearing.

The problem comes in determining whether components that do not produce a characteristic vibration in normal operation can be monitored. Bearings and splines fall into the class of components that only produce vibration when there is a fault present. The only practical method to determine if the component can be discriminated is by trials using seeded "marker" faults in the component. Only the helicopter manufacturer has the resources to perform this exercise, but it is expensive and is probably only practical to carry out during the development program's rig tests of components.

In the absence of this evidence, what can be done to establish performance? For external bearings, such as tail rotor drive bearings, placing the sensor on the bearing housing and checking the signature for the lack of other vibrations apart from the supporting shaft is a reasonable approach. It is important that where evidence of the component's characteristic vibration being discerned cannot be produced, then alternate techniques should be available in the HUM system to monitor the component.

The best evidence that the sensors have been selected, positioned, and installed correctly can be produced by performing trials to establish that the vibration signals can unambiguously discriminate the features required to substantiate the claims made for the defect monitoring. One sensor type is unlikely to meet all monitoring requirements. Specifying the characteristics of the sensor independent of its installation is not sufficient. Positioning and installation of the sensor are much more critical to a HUM system's overall performance and this aspect of the sensor's performance cannot be determined from the drawings.

6 SIGNAL ACQUISITION

Unlike process variables such as pressure and temperature, vibration does not have a single mode of operation to model to develop its performance criteria. Signal acquisition techniques for vibration again follow the development of the technology from RMS measurements of the overall signal energy, through tracking filters and finally the modern digital signal-processing techniques. In terms of technology, the digital acquisition of signals represents a complete break from the past, and using digital techniques to emulate the older RMS and tracking filter techniques is not generally possible.

Current processor technology and very low cost memory means that signal processing is now entirely software driven and signal acquisition is a matter of anti-aliasing filtering, analog to digital (A/D) conversion at a high frequency to a resolution of 16 bits or higher and then piping the data into memory (*see* **Data Preprocessing for Damage Detection**). This approach can have performance consequences downstream. For example, if a spectral resolution of 2 Hz is required to discriminate the rotor frequencies and a maximum frequency of 50 KHz is required to acquire the higher frequencies and if there are 16 sensors acquiring data once every 20 min, then the amount of data accumulated per flight hour is in excess of 150 MB. It is now not a problem to store or process this data, but it could take some time to download it from the aircraft.

If HUM system data is going to be useful for identifying meaningful trends, then most data needs to be gathered in steady-state conditions or in specific regimes. For a reasonable acquisition rate to be achieved, then specifying the regime recognition parameters that match the regimes the helicopter actually flies is important. This is a more difficult issue than it appears as there is always a conflict between reducing the range of the regime to minimize the variation in the data and increasing the range so that

it does not restrict the time for data acquisition and hence the number of acquisitions.

The number of acquisitions that are required per flight hour is the key parameter to specify for data acquisition, and not the number of channels. The acquisition rate needs to be sufficient to allow for the time the helicopter spends in maneuver. A single channel of acquisition can mean that for the number of sensors fitted in HUM system applications, the number of acquisitions per flight hour may not be sufficient to generate meaningful trends.

Quality and quantity of data are the features that drive the data-acquisition requirements in HUM system, and these are the items that need to be specified with clear performance criteria that relate to trending and other uses of the data.

7 SIGNAL PROCESSING

There is no single signal processing technology that is effective for all types of vibration analysis. The fast Fourier transform (FFT)-based spectrum analysis techniques that are effective at low frequencies where resonances are pronounced are ineffective in the midfrequencies where the spectral energy is dense and complex in structure and they are totally ineffective in the unimodal region where there is no tonal energy at all. In these cases, more sophisticated types of processing have to be employed. Key to the performance of a HUM system is that appropriate vibration analysis techniques are employed for the range of fault detection capabilities claimed.

All processing is now digital using the FFT in varying degrees of sophistication on the data piped to memory from the acquisition process. There is a problem in FFT processing of matching frequency resolution with frequency range as shown in Figure 6. It shows the number of spectral lines in each decade of frequency range for an analysis with a minimum frequency of 5 Hz and a maximum of 10 KHz, plotted on a logarithmic scale. In the lower frequencies, which contain most of the spectral data, there are the least number of lines, 2 in the 1–10 Hz range and 18 in the 10–100 Hz range. In the unimodal region where there is no spectral information, there are 1800 lines. FFT processing covering a wide frequency range will not produce the frequency resolution where it is required. There are "zoom" FFT processors that can locally increase resolution in the frequency band and this processing is essential if spectrum analysis is going to be used over a wide frequency range.

The most powerful technique developed for frequency analysis in the complex environment of the helicopter is synchronous signal, or time domain averaging (*see* **Statistical Time Series Methods for SHM**). This produces spectra where the resolution is a multiple of the period of one cycle of revolution of the shaft, and the frequencies are a function of the shaft speed. This separates the contributions of each shaft to the overall signal and automatically controls the FFT processing's resolution and bandwidth conflict. HUM system vibration processing

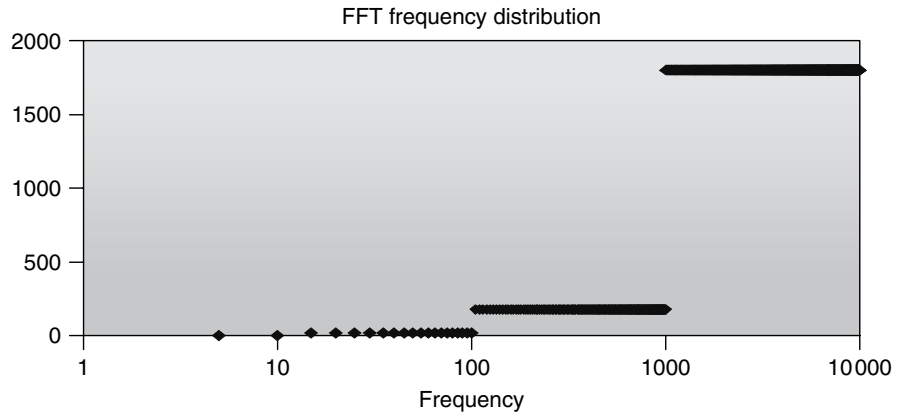

Figure 6. FFT Frequency Distribution.

without signal averaging is unlikely to be effective for the complex signals generated by the main transmission. This processing is more complex than asynchronous spectrum analysis and a system has to be specifically designed to accommodate it. It cannot be implemented postacquisition without utilizing very sophisticated signal processing techniques. Signal averaging represents a cost driver in HUM system design, but it is an essential feature of the system if gear box analysis is to be attempted.

The highest frequencies of the spectrum contain the vibration that relates to fatigue cracking and to pitting or seizing of bearings. To analyze this component of the signal, the lower frequency information has to be removed. This is normally achieved by band-pass filtering as shown in Figure 7. The filter removes both the lower frequency vibration and the noise floor. The energy of the resulting signal is measured or it is subjected to statistical techniques such as Kutorisis estimation to identify the impulsive characteristics of the signal that are related to faults. These techniques are sufficient where a single component's vibration dominates the signal. There is a number of proprietary techniques [6] utilizing pattern recognition (*see* **Statistical Pattern Recognition**) that are necessary in the more complex areas of the transmission.

It is essential to clearly establish the functionality of the vibration processing in order to establish its performance, and too many vendors try to hide behind inadequate descriptors such as "advanced" or "state of the art". The standard performance criteria for vibration processing of bandwidth, frequency, and amplitude resolution are meaningful for the basic spectral measurements of low-frequency features, but are not meaningful for the more complex analysis techniques frequently used in HUM system. The criteria for acceptable performance of the vibration processing are that the resulting spectra and other indicators clearly demonstrate that each of the shafts can be discerned from the background signal. For gearboxes, where signal averaging is implemented, the shaft frequency and mesh tone (dual mesh tone for epicyclics) should be clearly discerned. For systems claiming bearing fatigue and similar defects, the signal in the unimodal range should be free of tones and well above the noise floor. It is also important to demonstrate insensitivity of the data to the normal small variations in shaft speed, weight, and center of gravity that can be experienced during and between flights.

It should then be possible for any HUM system to establish a matrix of which components are monitored and for what type of fault, clearly delineating the signal processing techniques employed to accomplish the task as a basis for establishing performance criteria for the processing.

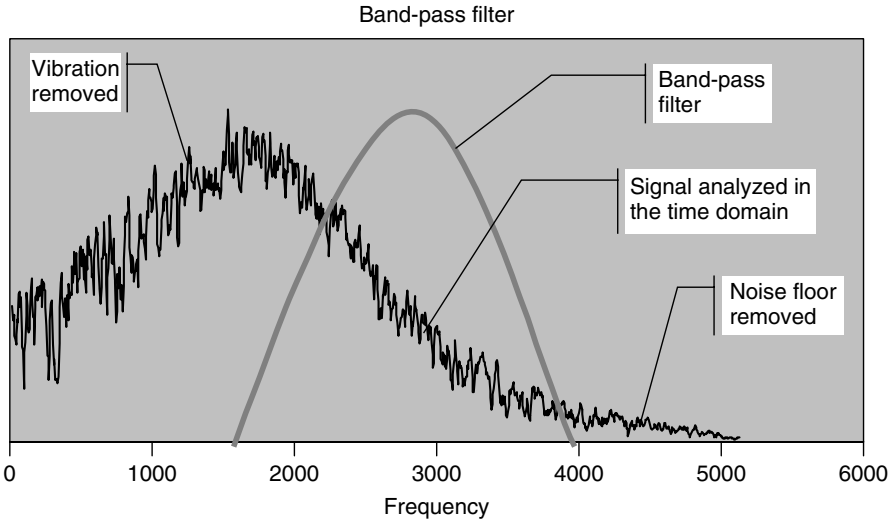

Figure 7. Band Pass Filter.

8 DATABASE MANAGEMENT

HUM systems have to store large amounts of data per flight, which over time build up into huge amounts of data. Very little of the data is ever reviewed. Avoiding data corruption and maintaining reasonable access times is not a straightforward design issue. The problems are compounded if the data is to be accessed by a number of users over a network.

The first process in managing the data is the postflight downloading of the data from the aircraft and in some cases preflight uploading of the configuration data. Clearly, performing these tasks should not interfere with the normal operation of the helicopter. Specifying the routine download times and pilot/engineer interaction with the system is critical. Nothing is more fatal to the acceptance of HUM system in the field than the system being perceived as obstructing the normal efficiency of flight operations.

At the ground station, there is a similar issue of the acceptable latency in transferring the data from the download device and the subsequent updating of the database. If care is not taken in the design, then after a few hundred flight hours of operation these latencies can become excessive. It is essential that the download times and latency in updating the database have limits specified. Data from a number of aircraft being downloaded simultaneously and nonsequentially can cause chaos. Difficulty in extracting data from aircraft is a real problem in HUM system ground station operation. Flexibility of download modes is as important as latency if the system is to gain acceptance at the flight line. Latency in retrieving data, in particular data for postflight pilot review, also needs to be specified. It is important that these latencies are specified for mature databases containing hundreds, not tens, of flights for a representative number of aircraft being supported by the ground station.

Failure to put practical hard limits on these issues has resulted in HUM system being designated as unusable. Software engineers tend to concentrate on functionality and make light of these performance issues. They must have performance standards to achieve if setting to work and operating a HUM system is to be a tolerable experience for the operator.

Database integrity is a difficult feature to specify, but if the data is to be trusted then integrity is essential. Error detection and correction features need to be included in the specifications, particularly for databases that are moved with the aircraft. Data loss needs to be very rare if confidence is to be achieved in the data and if its eventual application is to provide usage or maintenance credits (*see* **Experience with Health and Usage Monitoring Systems in Helicopters**).

9 ALARM GENERATION AND MANAGEMENT

Most HUM systems use a threshold method to generate alarms. In setting a threshold level, there is always the pressure to set the thresholds conservatively to reduce false alarms resulting in the threshold being set too high to be sensitive to a developing fault as shown in Figure 8. As the occurrence of faults is very rare, there is a lack of a counterpressure to balance the pressure from engineers to minimize the false alarm rate.

To guard against this, a target acceptable false alarm rate could be set across the fleet. If the observed rate is less than this target, then the thresholds should be reviewed to ensure that fault sensitivity is not being sacrificed. If it is more than the target, then the suitability as a HUM system indicator of the parameter needs to be reviewed and, if possible, an alternate more stable parameter used.

Vibration signals and noise on other signal types always produce “wild” points in the data. No system can maintain sensible threshold levels without an appropriate form of wild-point rejection in the processing. All of the wild points in Figure 8 exceeding the lower more sensitive threshold level would be removed by this processing and detection of the trend would remain unaffected.

The use of fleet statistics to set alarm levels can also have an impact on performance. In general, the higher the frequency of analysis is, the less likely that a group threshold is going to be valid. In the group of helicopters if the differences in the statistical means and variances of the data monitored are small, then the group threshold level is likely to perform well for all. If the means are well separated or one data trend has a dominant variance as shown in Figure 9, then a threshold set by the group statistics is only going to be valid for either the data with the highest mean or largest variance.

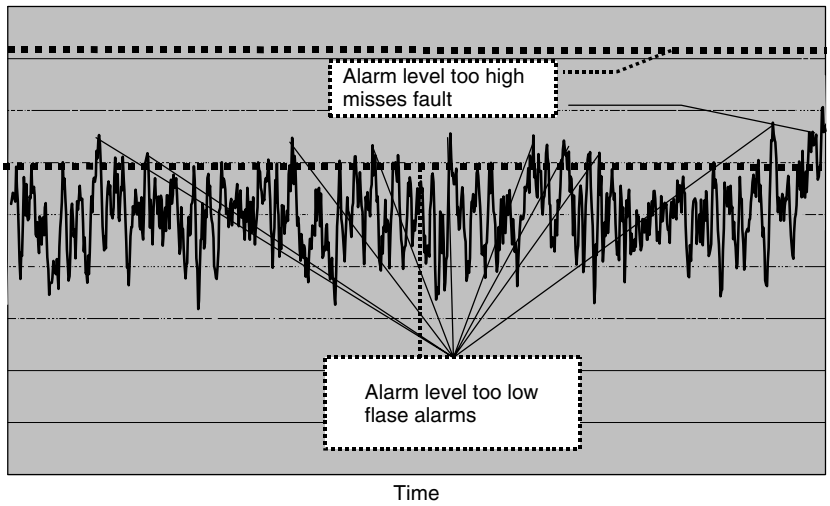

Figure 8. Classical Threshold Setting.

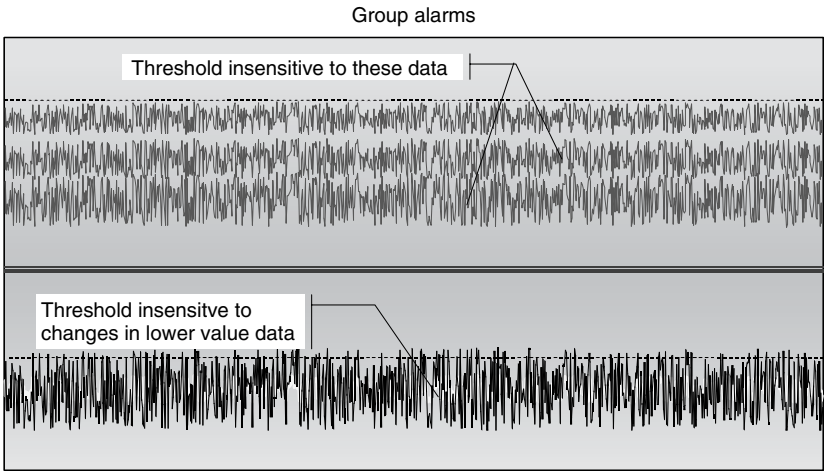

Figure 9. Group Threshold Setting.

Facilities to corroborate data are also essential to assist in determining whether an alarm is a result of a faulty sensor or just noise. It is rare in vibration that a shaft vibrating abnormally will be discerned on just one sensor.

Sensitivity to faults can only be determined if the HUM system has actually identified any. Establishing the range that is known to be sensitive to detecting a fault is important for assurance that the threshold is set appropriately. These data are only likely to be available for mature systems with sufficient flight hours behind them to have developed a track record of success.

Alarm management in HUM system as a proactive task goes beyond the process of checking and following through on any actions caused by an alarm being transgressed. To keep the system adequately sensitive, the alarm levels need to be subject to management scrutiny. Changes in weather, pilot, weight, and center of gravity of the helicopter all

change the characteristics of the HUM system data and can compromise some of the thresholds levels. Monitoring the performance of the alarms to determine the validity of all of the thresholds being applied is critical to maximizing the overall performance of the system.

The key performance measure for managing the threshold setting is the false alarm rate. In case of too few alarms, there is a problem with fault detection sensitivity, and in case of too many alarms, there is a problem with suitability of the data. Also, the probability of success is only maintained if the arisings that are identified by other means are investigated to determine if the fault was present in the HUM system data and why the alarm threshold was not triggered.

10 MAINTENANCE MONITORING

Vibration levels on shafts and performance monitoring of the engines are common maintenance functions where a HUM system replaces the existing maintenance test equipment. It needs to be ascertained that the HUM system really does replace the test equipment. For vibration, some test equipment utilizes older analog vibration measurements such as RMS or swept band filtering. It is not possible, without a great deal of effort, to reproduce these data with the digital signal processing techniques found in HUM system. Establishing the correspondence between handbook vibration limits and HUM system data is a key performance attribute for a system and this correspondence can usually only be established by the design authority.

The ability of HUM system to routinely monitor the rotor and produce recommendations for adjustment that keep the rotor in smoothest possible condition is an important function. Rotor track and balance systems usually contain proprietary software for determining the rotor adjustments. Specifying performance is not possible without the disclosure of the processing. Accuracy of sensors is not a guide to the overall performance of a rotor smoothing system. For rotor smoothing, the only effective check is to maladjust a smooth rotor well within its safety limits, and to check that the track and balance system predicts the correct adjustment to make the rotor return to the smooth condition. A correctly performing system should not confuse a weight adjustment with a track rod or a tab adjustment.

The key performance features here are (i) the average vibration level achieved and (ii) the reduction of effort required to tune the rotor. It is not unreasonable to require that the rotor vibration in all axes and flight conditions is maintained to be less than a specified percentage of the handbook limits for 95% of the time. This has to be on the condition that the adjustment recommendations produced by the HUM system are implemented. Also, this measure should exclude the adjustments following blade removal where a specification should be to bring the system to below the target vibration level in less than two test flights.

11 EQUIPMENT STANDARDS

HUM systems are peculiar in three respects when compared to other avionics: (i) the system's complexity, (ii) the split of functionality between airborne equipment and ground equipment, and (iii) the interaction of the system with the helicopter's design and operation.

If the equipment is specified as part of the helicopter's minimum equipment list (MEL), then many, but not all, of the large number of sensors that make up a HUM system greatly reduces its overall reliability. A long mean time between failure (MTBF) is essential for individual equipments in order that the overall system MTBF is reasonable, or the MTTRs are very short and adequate spares are provisioned so that the MEL requirements can be met.

The split of monitoring functions between the airborne and ground components of the system can cause difficulty in certifying the system even if the certification standard is no hazard/no benefit. The FAA's HUM system advisory circular (AC) [7] requires different software standards to be met for the ground station than those for the airborne because of the use of commercial off the shelf (COTS) software in most ground station applications. For a HUM system, other than no hazard/no benefit, the ground station software has to be of a higher software standard than that of the airborne component, or independence of the HUM system processing to the COTS software has to be demonstrated. Some further hurdles have to be cleared for credits to be possible,

such as the independent verification of data and the mitigation of the credit to ensure that airworthiness is enhanced. This level of functionality is beyond the scope of current HUM system design.

Where maintenance credits are to be sought, it usually requires that the design authority approves the changes to procedures. Only the design authority has the necessary knowledge to determine if an anomaly detected by a HUM system is damaging to the extent of risking the airworthiness of the helicopter. This requires that the helicopter manufacturer acknowledges and supports the data analysis produced by HUM system. Design authority approval, or at the very least the HUM system having no objection status, is an essential attribute of any HUM system.

12 CONCLUSIONS

Divining performance measures that relate directly to the purpose of HUM system requires the assessment of the contribution of the technology to helicopter airworthiness. The nearest approximation to this is achieved by building up a statistical knowledge of more frequent events such as maintenance arisings and other events reported to the Regulatory Authorities. The monitoring performed by the CAA shows that, generally, a 70% success rate of defect detection is achievable, and would provide an overall performance standard for HUM system.

Measuring the performance of the HUM system in service is most easily achieved by monitoring the false alarm rate. This should be randomly distributed amongst the components of the dynamic train and within a range that is acceptable to the operator. It is not the case for HUM system that no news is good news.

For a new HUM system type or a system that is to be fitted to a new aircraft design, the actuarial data for determining the performance of a HUM system does not exist. The performance of the individual building blocks of the system has to be specified such that confidence in the overall system performance will be adequate. For flight data, then, the normal system engineering practices of modeling the process so that the required performance of each component of the system can be determined, will suffice. But the major component of a HUM system is the vibration processing and it cannot be dealt with in such a straightforward manner.

Measuring the performance of a modern vibration analysis system based on digital signal processing is essentially a process of the vendor demonstrating that the features used for monitoring purposes can be clearly discerned in the measured spectra of the normal operation of the helicopter, or at the very least the data contains no phenomena that prevent the monitoring function from being effective. The features that count, if the performance of the system is to be unequivocally determined, are (i) a clear statement of the components that are to be monitored from the sensors, (ii) the techniques to be used for the monitoring, (iii) the acquisition rate, and (iv) the positioning of the sensors (viz., accelerometers).

The suitability of sensors and processing in terms of resolution, range, and bandwidth needs to match the monitoring techniques used. A clear statement of these attributes and their specific purpose in terms of the fault modes monitored in the helicopter's dynamic train components should be produced with evidence that the processing can discern the relevant attributes. Without this, any attempt to substantiate the efficacy of the processing cannot be made in any quantitative way.

Measurement and processing are not sufficient in themselves to determine the likely performance of a HUM system. The alarm processing and management functions of the system need to be flexible enough that the thresholds can be tuned to achieve the desired false alarm rate and maximize the system's sensitivity to faults. The features that count in the alarm system are the availability of management functions for setting and assessing the threshold levels so that the sensitivity to faults is optimized with respect to the acceptable false alarm rate and the cost of managing the spurious alarms by the engineer. A system for removing singleton alarms is essential if viable threshold levels are going to be set.

A HUM system is not a "fit and forget" system; management of the alarm threshold system is essential if the expected improvement in the safety margin is to be achieved. For convenience, it is all too easy for alarms levels to be too conservatively set, making the system insensitive to faults. The other performance check to determine that the thresholds are sensitive to faults is to investigate arisings that are not indicated by the HUM system and to identify whether the threshold is set at a suitable level or on the most appropriate data.

The system's operation has to be acceptable to both pilots and line engineers, and their management. Latency and integrity of the operation of ground station and its databases are the key features here. These need to be unambiguously specified and performance should be measured on mature databases.

Finally, care needs to be taken that the system can support the MEL requirements and that the software and HUM system AC requirements are met if maintenance credits are to be sought.

In short, do not take anything for granted, and ensure that the system is adequately and clearly specified, that acceptance testing includes performance measures that relate directly to the purpose of the HUM system, and that the operation of HUM system does not interfere with operational efficiency. Besides, for a specification that stipulates meaningful performance measures, the contract has to be sufficiently robust to ensure that these specifications are met and maintained.

Chapter 101
Unmanned Aerial Vehicles

Matthias Buderath
Product Support, EADS Military Air Systems, Ottobrunn, Germany

1 INTRODUCTION

With the newly emerging interest in unmanned aerial vehicles (UAVs), such as those used for surveillance missions, like Global Hawk or Predator, the new trend in military aeronautics is to clarify whether the UAVs' technology can be used not only for surveillance but also for combat missions.

The main difference between a cruise missile and an UAV is that the UAV will be recovered after its mission, while the cruise missile will not. This distinction is clearly made in the definition of UAVs in the Joint Publication l-02 of the Department of Defence (DoD) dictionary [1]:

> *A powered aerial vehicle that does not carry a human operator uses aerodynamic forces to provide vehicle lift, can fly autonomously or be piloted remotely, can be expendable or recoverable and can carry a lethal or nonlethal payload. Ballistic or semiballistic vehicles, cruise missiles and artillery projectiles are not considered to be UAVs.*

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

UCAVs (unmanned combat air vehicles) are supposed to be the next generation of military aircraft. The DoD of the United States and many other countries claim that the combat aircraft of the future will be unmanned and that the last manned combat aircraft will be the Joint Strike Fighter. The main characteristics of a UCAV are as follows:

- It is capable of autonomous flight but can be remotely piloted, if necessary.
- It can be recovered after completion of mission or can even be expended with.
- Its operation is not dependent on or limited to human restrictions such as G force, mission and relaxation time, and combat readiness.
- It is predestined for hazardous missions and enemy region penetration.

The main characteristic of this weapon system is that the pilot is located outside the air vehicle, probably in a ground control station (GCS).

The idea is that the UCAV can fly autonomously but with a man in the loop, who can take over at any time. It is important that the communications cannot be jammed, so a high encryption will be needed to

ensure that the weapon system cannot be controlled by any unauthorized person.

UAVs will fully utilize the emerging information revolution. They are expected to take advantage of multiple, real-time data sources and secure communication networks to plan for, and respond to, the dynamically changing battlefield.

But why this interest in UAVs? UAVs are supposed to fulfill the most hazardous missions, where manned aircraft pilots have to risk their lives to accomplish their mission. One of these hazardous missions could be the suppression of enemy air defenses (SEAD).

So, not having a pilot onboard would permit the air vehicle to take on greater risks than a manned aircraft would.

A further motivating factor is that UAVs are supposed to be less expensive in their life-cycle cost than the average manned aircraft. UAVs are considered as items that can be stored and only brought out for service during times of conflict or that can be operated for 24 h and more. A limited number of UAVs are operated because of expected high mission capability, no need for training in peacetime and new maintenance concepts, e.g., maintenance-free operation periods. UAVs are expected to achieve savings in operation and support costs of 30% compared to traditionally 60% of the entire life-cycle cost.

2 OPERATIONAL REQUIREMENTS

Three key elements have been identified, which justify the development, integration, and use of a health management system for UAVs; these are

- improved decision support for autonomous mission execution;
- reduction of mission, operation, and support cost; and
- contribution to the certification process of the UAVs.

As already mentioned, to derive the functional and design requirements of a health management system that includes structural health management (SHM), it is essential to understand the mission and operational support requirements. Therefore, this article discusses, to some extent, the operational requirements that can serve as a guideline for the potential SHM technology provider.

Figure 1 describes the dependencies and trade-offs between the concepts of operation and operational support. The better one optimizes and consolidates the needs and performance of both concepts, the more easily one can achieve the following goals:

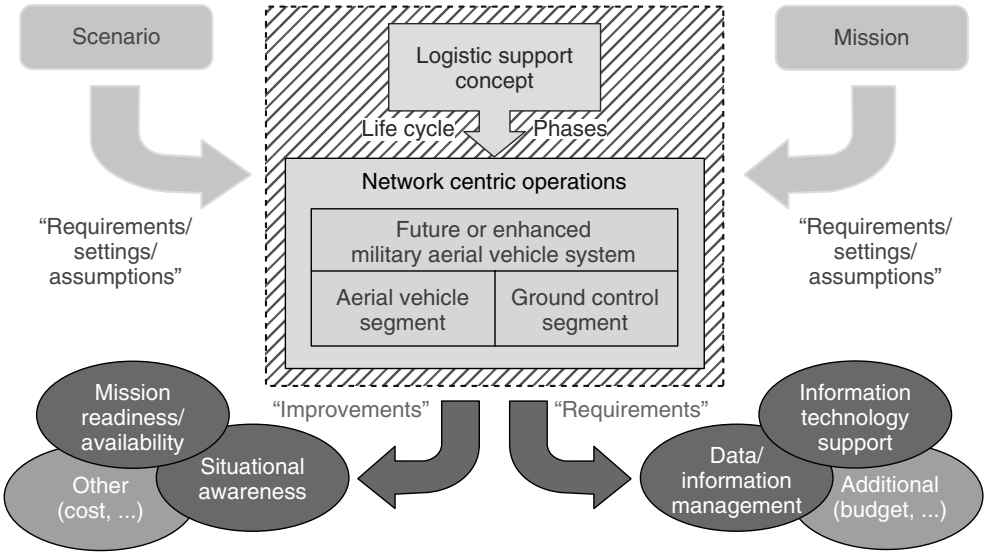

Figure 1. Operational support scenario.

- reliable autonomous mission execution;
- improved aircraft operability, which also means a control of mission and operational support cost;
- mission effectiveness/capability (the hours a fleet is available to perform missions versus the hours a fleet is possessed by a flying unit); and
- compliance with certification requirements.

An overview of the mission and thus operational effectiveness is provided in Figure 2.

2.1 Autonomous mission execution

There are different operational and thus autonomous mission approaches, but one common challenge to be met is the proper understanding of operational and operation support requirements of UAVs to ensure safe and reliable autonomous mission executions. Besides the top level requirement (TLR) of a high probability of detection through inspection, the integration of an SHM system into the avionics suite is mandatory. Integration into the avionics suite makes sense, since most of the SHM system is anyhow electronics-based and avionics *per se* is already well associated with built-in test equipment (BITE). Furthermore, health management for an UAV is a crucial requirement, and, as such, SHM will thus become a part of it. The expression of "health management" implicitly includes SHM throughout this article.

It is recognized that a vital goal for autonomous missions is to enable intelligent decision support. An operational risk assessment (ORA) in close relation to the mission plan has to be part of the decision support algorithm. A very important aspect of OR is determined by the health status or anticipated health status of the aircraft.

Two possible levels of integrating SHM with mission management are considered. The levels of integration are determined by the levels of autonomy that are intended to be achieved by the UAVs.

In the technical literature, six levels of autonomy are defined, ranging from level 0 (remotely piloting the vehicle) to level 5 (aircraft flies by itself; an operator may, however, interrupt what it is doing). In this article, levels 3 and 4 are considered. Level 3 is when the UAVs indicates its status and an operator decides on the basis of this information to command the vehicle to take a certain action. Level 4 is when the vehicle itself decides to take action based on its status. The operator may, however, command it to do otherwise.

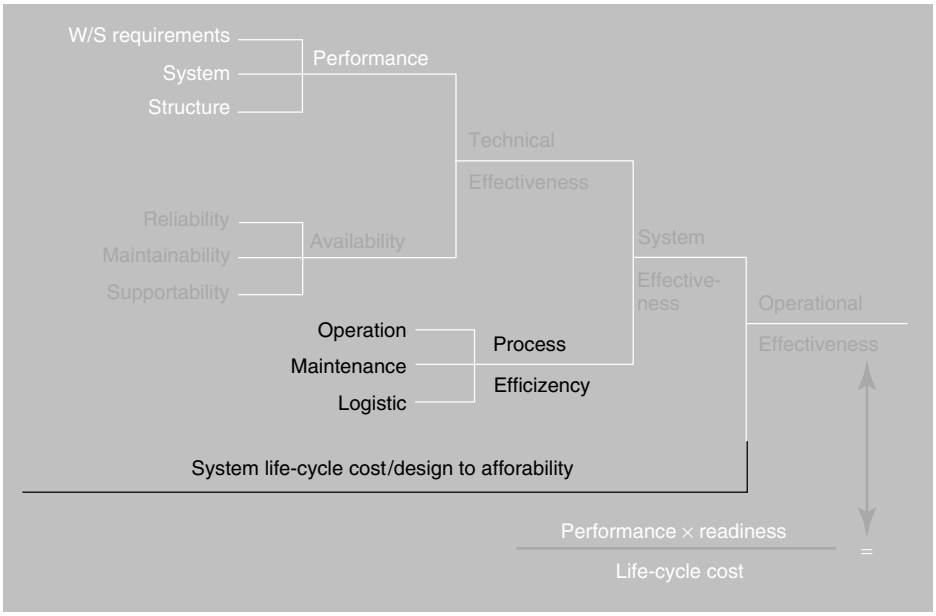

Figure 2. Definition of operational effectiveness.

2.2 UAVs with autonomy level 3: accept advice authorize action

In this case, the health management system provides the status/anticipated status to the operator and hence this must be available at the GCS. The operator then commands the aircraft to take a particular action. In keeping with goals, the information is provided as an ORA. The emphasis is on providing the prognosis of health, with risk level and consequences as a basis for the operator's decision. This drives the architecture as follows: no interaction between the health management system and the onboard mission management system (MMS) is necessary. The health management could have minimal functionality onboard and the prognostic functions could reside on the GCS. A possible approach could be to develop and integrate the functionality on the ground and then later migrate the functionality to onboard the aircraft in anticipation of achieving the next level of autonomy, described below.

2.3 UAVs with autonomy level 4: action unless revoked

In this case, the health management system provides the status/anticipated status to the onboard MMS. The MMS makes the decision of what action has to be taken, but it must first provide information to the operator, in order to give him/her a chance to revoke the action. The aircraft initiates its own action based on preloaded rules or decision algorithms. This drives the architecture as follows: a substantial interface is required between the health management system and the MMS: functions need to reside onboard. If anything, the interface to the GCS is minimal, as the operator is monitoring and only intervenes when it is felt necessary.

It is assumed that software will need to be developed, but that it can be integrated into the existing/newly provided hardware.

2.4 Aircraft operability, including control of mission and operational support costs

Since UAVs are operated in a network of systems in which mission effectiveness is dependent on mission capability of all platforms involved, the term *availability* or *operability* adds another dimension to mission cost.

Some governments, like that of the United States, have introduced in their acquisition regulations, directives such as the DOD 5000.2-R, "Mandatory Procedures for Major Defense Acquisition" [2], in which one of the major themes addressed is that "The acquisition process must consider both performance requirements and fiscal constraints. Accordingly, cost must also be an independent variable in programmatic decisions, with responsible cost objectives set for each Program Phase".

In this context, the translation of the top-level mission operational support requirements means we have to provide excellent health monitoring and management performance without increasing acquisition and support costs. In order to meet these, performance requirements, a health monitoring system should provide the capabilities and features listed below:

- a high probability of damage detection while determining the condition of the monitored component;
- integration of sensors into the structure that will provide more efficient information than is available today;
- consideration of low cost but reliable sensors that can be integrated into the structures and be more than sufficient;
- provision of power supply to the acquisition system without compromising weight and structural-system performance;
- processing of the high quantity of information generated at component/system level;
- health management within the health management architecture hosted in the onboard and on-ground data management platform;
- prognosis (link usage/load monitoring to damage monitoring) within the health management architecture hosted in the onboard and on-ground data management platform; and
- decision support (including replacement of the pilot detection and assessment capability in case of specific in-flight events) within the health management architecture hosted in the onboard and on-ground data management platform.

2.5 Certification

So far, SHM systems have been considered for monitoring the theoretical fatigue life consumption as a basis for fleet management and for scheduling of inspections and modifications. Owing to the used safety factors and scatter factors, the implication for the day-to-day airworthiness was a secondary factor.

With the development of high-performance aircraft, the issue of airworthiness has become more significant in postflight assessment with regard to an intact structural strength capability.

Nevertheless, the identification, assessment, and decision making in case of an in-flight event like a bird strike, lightning strike, battle damage, or damage during taxiing or landing caused by foreign object damage (FOD) always rests with the pilot. To allow for cases in which the pilot is not in a position to make a decision, additional advanced in-flight capabilities for data acquisition, state detection, health assessment, and decision support need to be provided.

Future requirements therefore include a reduction of UAV mishap rates and an integration of UAVs into national/international aerospace outside restricted areas. This will also raise issues of establishing rules and guidelines for UAV certification. These two items emphasize the necessity for an onboard real-time loads monitoring and damage detection system with a subsequent diagnosis and health assessment functionality to check the structural strength capability and structural performance after an in-flight event.

This will lead to increased demands for the use and integration of health management systems for which sufficient evidence and qualification must be provided to demonstrate their maturity level and the readiness for operation.

Figure 3 shows the top-level process and related requirements on an in-flight SHM event-monitoring function.

3 CONCEPTUAL APPROACH

Two different types of monitoring systems are currently under evaluation with conventional aircraft [3, 4] (*see* **Principles of Structural Degradation Monitoring**; **Usage Management of Military Aircraft Structures**; **Development of an Active Smart Patch for Aircraft Repair**.):

1. load/usage monitoring and
2. damage monitoring.

The aim of the load/usage monitoring system is the measurement of the loads (deflections, temperature, strains, and subsequent loads) during operation (*see* **Loads Monitoring in Aerospace Structures**; **History of SHM for Commercial Transport Aircraft**; **Fatigue Monitoring in Military Fixed-wing Aircraft**; **Agile Military Aircraft**; **Operational Loads Monitoring in Military Transport Aircraft and Military Derivatives of Civil Aircraft**). Such monitoring systems serve as a database for real loads acting on the component to be monitored during operation and reduce the uncertainties of the operation scenario models. Still, accurate models for the prediction of the onset

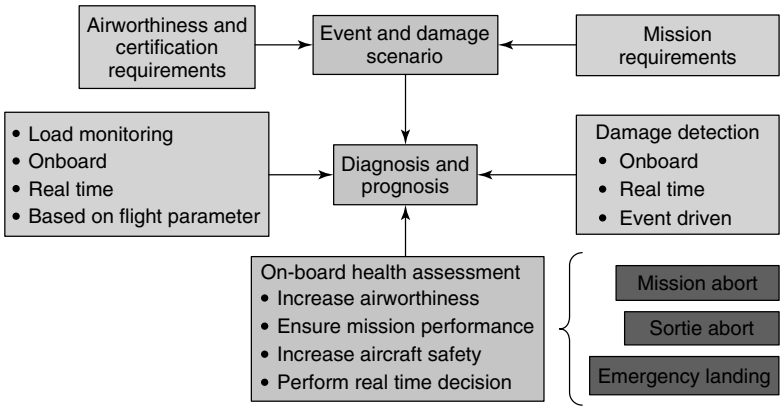

Figure 3. Design requirements and process.

and growth of damage and the remaining life of components are required (*see* **Modeling for Detection of Degraded Zones in Metallic and Composite Structures**). Especially in cases of composite structures, these models have a lot of uncertainties due to a large number of influencing factors, like production and handling procedures, calling for a number of safety measures. The aim of the damage-monitoring system is to determine the type of damage (e.g., fatigue crack growth in metals or impact delaminations in composites, location, and size) during operation (*see* **Military Aircraft**; **Use of Leave-in-place Sensors and SHM Methods to Improve Assessments of Aging Structures**; **History of SHM for Commercial Transport Aircraft**; **Flight Demonstration of a SHM System on a USAF Fighter Airplane**; **Comparative Vacuum Monitoring (CVM™)**; **Development of an Active Smart Patch for Aircraft Repair**; **Aerospace Applications of SMART Layer Technology**).

By combining both systems, together with a reliable materials model, the real load history and the actual damage distribution as input data, should, subsequent to the optimization of the decision support algorithm, result in more accurate predictions of the remaining life of the component. Therefore, the technology of SHM systems forms the basis for the realization of autonomous missions and contributes to implementing new maintenance strategies for UAVs, e.g., in the change from "time-based" to "condition-based" maintenance. Also, SHM systems for sensing and characterization of the structural condition of specific components have to meet the certification requirements (aircraft accident prevention). For example, NASA performed a study in 2002 [5] in which the requirements for such SHM systems, the characterization of a prototype structural sensor system, the development of sensor interpretation algorithms, and the demonstration of the sensor systems on operationally realistic test articles were addressed, in all of which the sensor data served as inputs to ARINC's Aircraft Condition Analysis and Management System (ACAMS) [6].

Usage monitoring systems serve as a database for real loads acting on the component to be monitored during operation and reduce the uncertainties of the operation scenario models. To guarantee availability and operability, the operator needs condition awareness to make decisions throughout the whole life-cycle process. Related to the monitoring of the structural strength capability of the aircraft, the load monitoring will provide the relevant details, for example, by comparison of the expected load against the measured loads, as a basis for the real-time assessment of the aircraft condition. In addition to the fatigue life monitoring, accurate models for the prediction of the onset and growth of damage and the remaining life of the components are required. Especially in cases of composite structures, these models have a lot of uncertainties due to the large number of influencing factors, such as those resulting from production and handling procedures, which require that high safety measures be imposed. An SHM system for UAVs should therefore cover a process, which is shown in Figure 4.

3.1 Operational requirements/operational parameters

The basic process to fix a problem is to step from an unknown condition of a component to a known condition, which may then require a dedicated maintenance action. To do this, operational parameters need to be evaluated as part of the condition state assessment and the health assessment. Today, the most common operational parameters are time, i.e., the number of flights, and results from visual inspections, such as cracks, corrosion, wear, and dust. To improve the diagnostic, prognostic, and decision support capabilities, more information is likely needed on what is the load impact that occurs and when (i.e., the real load sequence), the damage characteristics and location, etc. This requires a careful selection of sensing technologies that support the above-listed features (*see* **Principles of Structural Degradation Monitoring**; **Commercial Fixed-wing Aircraft**). Figure 5 gives an overview of operational parameters that are taken into account for monitoring followed by a subsequent assessment.

Since design principles in engineering are well established, and monitoring is just a consequence, the central question with regard to monitoring is as follows: what are the parameters that are lacking, which we need to assume, in regard to a cost-effective design with improved operability?

All structural design is based on loads (static, as well as cyclic) that we have to assume prior to configuring the structure. These loads do not

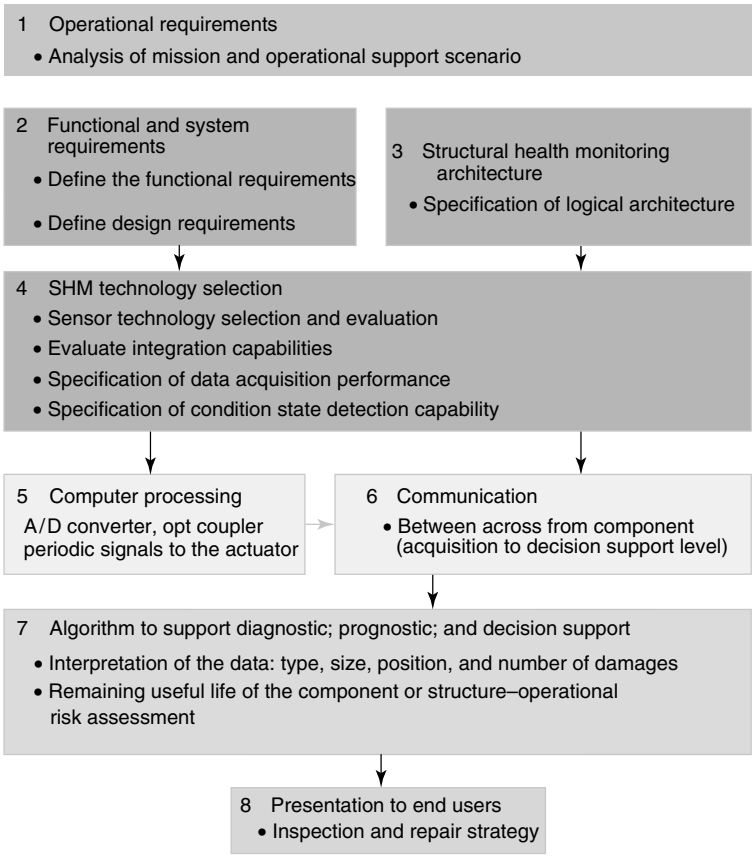

Figure 4. Elements of an SHM development and integration process.

have to be limited to mechanical loads only. They can also include other environmental loads, such as temperature, humidity, chemical corrosives, etc (*see also* **Environmental Monitoring of Aircraft** and **Aircraft Structural Diagnostic and Prognostic Health Monitoring for Corrosion Prevention and Control**). To improve the diagnostic, prognostic, and decision support capabilities, we require more information on when each load occurs (i.e., the real load sequence), the damage characteristics, location, etc. This would allow us to manage operational risk and availability of resources more efficiently, without compromising safety.

The other factor that needs to be monitored and which is a consequence of aircraft design and usage is damage. The assessment of whether a structural condition is acceptable or not for aircraft operation is largely covered by design limits. Design limitations are different in nature, especially for different types of materials and structural concepts.

Whatever these limitations are and no matter how they are characterized, it is basically assumed that, for safe aircraft operation, the condition is allowed to change within certain allowable bandwidths, given by the design.

If the actual structural condition remains within the given design bandwidth, it can be assumed safe: "assumed actual condition safe". If the actual structural condition exceeds the given design bandwidth, it has to be assumed unsafe: "assumed actual condition unsafe".

The definition of "safe" is fundamental to the design process. Typically, it follows that the probability of extreme failure (and consequential loss of lives) must be very small. The overall aircraft system (including operational processes) must be designed

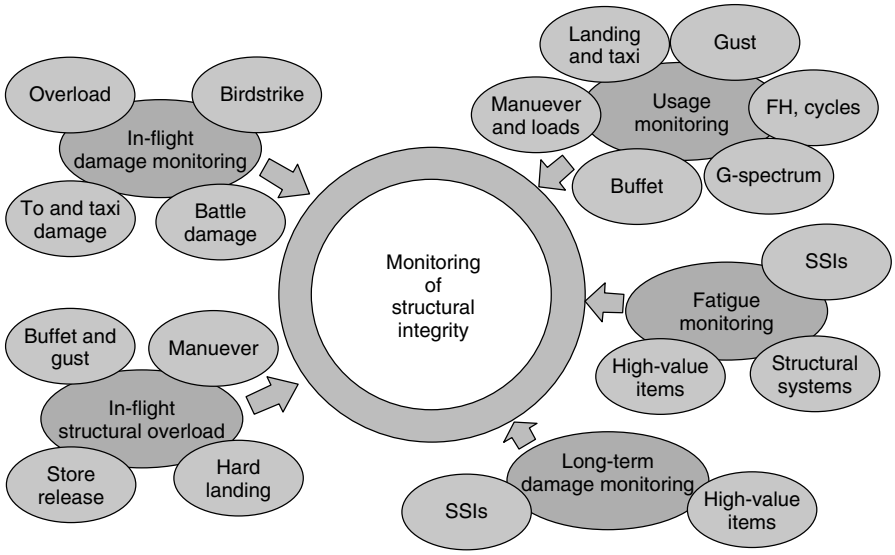

Figure 5. Operational parameters.

so as to ensure safety at all times. Whatever the operational optimization goal of the operator is and whatever infrastructure the operator has available in terms of maintenance alternatives, design limits have to be obeyed at all times.

Figure 6 schematically shows the complete bandwidth of degrading structural condition along which safety is not compromised. The left part includes the region where the actual condition cannot be measured due to limitations in knowledge and monitoring techniques while the right hand part includes the region where the condition is measurable and tolerable from the point of view of structural integrity and which is worth exploiting.

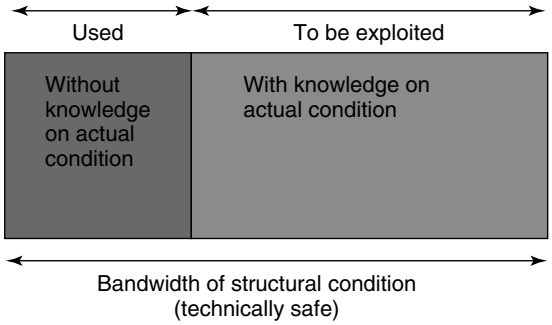

Figure 6. Illustration of achievable bandwidth of structural condition without compromising safety.

To exploit the available bandwidth, it is necessary to know with sufficient accuracy that the structural condition remains within the allowed bandwidth under operation at all times. This is the reason why structural condition monitoring and thus SHM for modern aircraft is of interest.

Structural condition monitoring is the continuous process of determining the condition of a structure. The primary objective of structural condition monitoring is to ascertain that the structural condition remains within the allowed bandwidth under operation. Of course, this requires greater accuracy the closer that it approaches the design limits.

A potential improvement on condition monitoring is the process of "condition-based planning" (see Figure 7). Therefore, the benefits of condition monitoring can be summarized as follows:

- **Full health exploitation**

Statistically, the individual damage-free period of a part is significantly (related to a "scatter factor") higher than is assumed during design and subsequently cleared for operation. Condition monitoring in combination with a detectable damage being below the critical damage in damage tolerance terms would be sufficient to exploit the available structural health without compromising safety or the need for unacceptable short-scheduled maintenance.

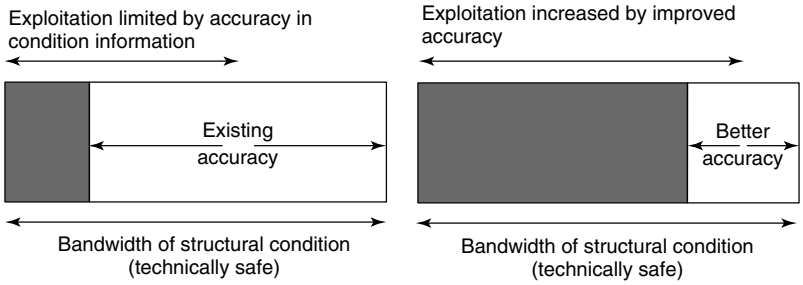

Figure 7. Illustration of limitation of exploitable bandwidth of structural condition due to available accuracy.

- **Improved risk reduction**

Improved condition monitoring continuously gives information about the actual condition of a structural item, because the frequency of monitoring can be significantly increased without increasing the inspection effort.

- **Condition-based planning**

The more accurate the structural condition monitoring is, the more reliably the operator can plan the necessary maintenance actions to avoid unscheduled actions or unnecessary originally scheduled actions.

- **Improved operational margin**

Improved condition monitoring increases the available time for planning maintenance alternatives and selecting the optimum. It helps to reduce unscheduled maintenance.

3.2 Functional and system requirements

The functional requirements needs to be derived from the functional view of the required health monitoring and management capabilities. Here, the diagnostic, prognostic, and decision support capabilities should be defined for individual component and aircraft levels. Figure 8 shows a typical overall functional view in which each function is specified in detail, e.g., to derive the input and output data for the models and the algorithm to determine the CPU requirements, etc. The logic provided here is strongly based on the Open Systems Architecture for Condition-Based Maintenance (OSA-CBM), which is explained in more detail in **Open Systems Architecture for Condition-based Maintenance**. The approach shown in Figure 8 is a structured monitoring data management approach that consists of the following seven layers:

- presentation (Pres)
- display selection (DS)
- prognostics (Prog)
- health assessment (HA)
- state detection (SD)
- data manipulation (DM) and
- data acquisition (DA).

In the functional view, the end-user requirements, like types of damage, critical damage size, and level of importance of the structural components to be monitored, include the layout, interaction, and redundancy depending on the level of reliability of the components of the SHM system. Depending on the application, different types of methods for optimized sensor placement, like "improved genetic algorithms", finite element model (FEM) methods or spectral finite element method have been used (*see also* **Optimization Techniques for Damage Detection**; **Modeling for Detection of Degraded Zones in Metallic and Composite Structures**; **Sensor Placement Optimization**). This includes the decision between on-line (real-time) or off-line (discontinuous) operation and the density of sensors versus damage resolution.

3.3 SHM architecture

The modern avionics system combined with remote interface unit (RIU) technologies have tackled the major challenges like

- **Weight**

The RIU, Aircraft Mission Computer (AMC), and bus architecture have eliminated the excessive wiring that would otherwise be required with multiple individual systems. This allows the SHM software and

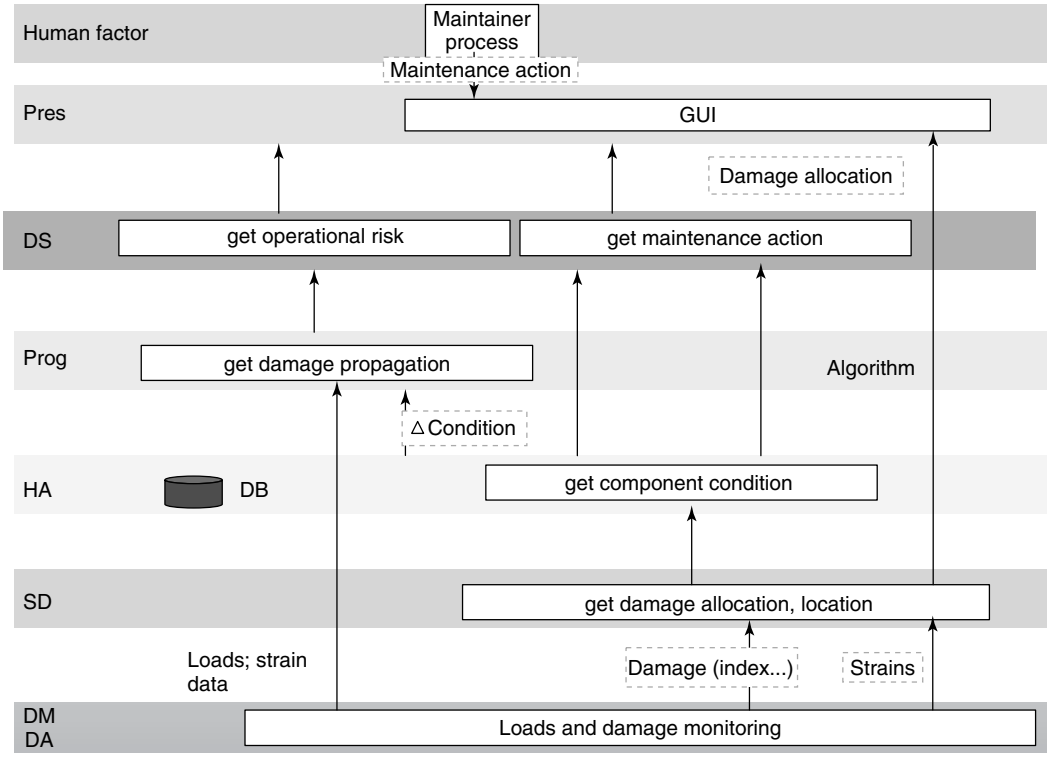

Figure 8. Functional view.

algorithms to be run alongside the other airborne software, avoiding the need for extended SHM hardware, even extending as far as utilizing the aircraft's normal communication methods.

- **Cost**

By utilizing the existing aircraft hardware in terms of both processing and network capability, the cost of installation now becomes one of the sensors, something that modern "virtual sensing" techniques are tackling, and software that can be installed without significant aircraft downtime.

- **Complexity**

By transmitting all the data over common buses and to a common core, the complexity is greatly reduced and this has been tackled even further by developments such as the OSA-CBM initiative (*see* **Open Systems Architecture for Condition-based Maintenance**). The maintenance technician can now expect one coherent interface to the entire maintenance system. Current research is looking at taking this even further to provide a "process-oriented" structure to the data displayed at the point of need.

In addition to this, it has also placed all of the data in one place, which has opened up the possibility to see the bigger picture of how the aircraft is performing; this truly is a case of "the whole is greater than the sum of the parts".

However, to realize a workable system still requires an open software architecture in which airframers, equipment suppliers, and specialist prognostic health management (PHM) companies can provide the tools to turn these data into information, knowledge and, finally, actions. This is where developments such as OSA-CBM are allowing the further realization of these systems.

The goal of OSA-CBM as shown in Figure 9 is "to facilitate the integration of PHM components from a variety of sources. OSA-CBM is striving to build a *de facto* standard that encompasses the entire range of functions from data collection through the recommendation of specific maintenance actions".

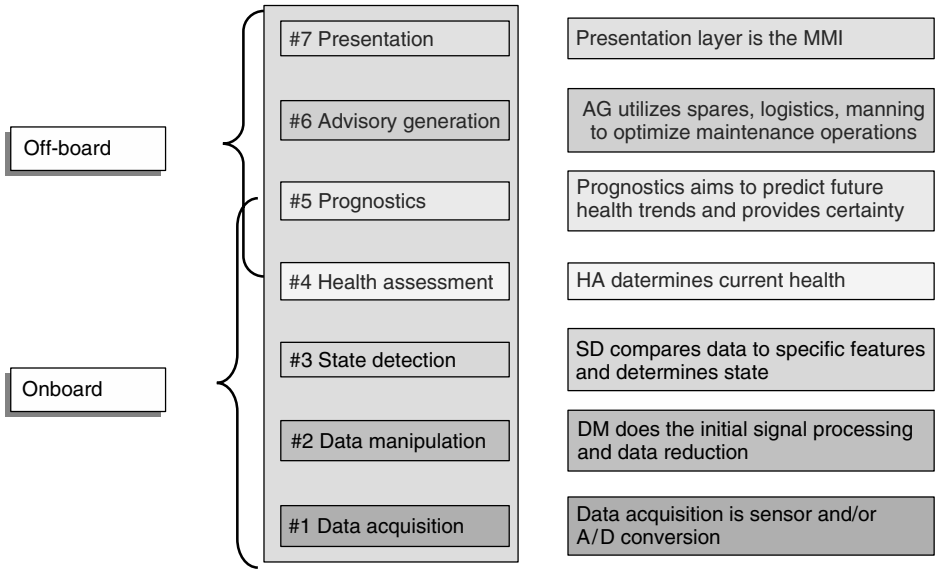

Figure 9. OSA-CBM.

3.4 SHM technology selection

Sensors meeting respective needs will allow monitoring of operational loads at various locations on the aircraft in much more detail, which will further allow calculation of consumed operational life more according to the real usage. This will be supported by loads determined at a higher degree of detailing and finite element models, which allow a more accurate calculation of loads being based on standard flight parameters. Further to this, there are now more and more sensors emerging that allow the monitoring of damage to structures *in situ*. This offers potential to help to meet the operational requirements.

The most important component within the SHM process is the identification of the relevant kind of damage depending on the material and load and its impact on the performance of the component. With metallic structures, designers and operators are mostly concerned with fatigue cracks and corrosion, while for composite materials, delamination and impact damage are more of a concern. In that regard, appropriate sensors have to be selected, for which a variety are described in Part 5 of this encyclopedia.

Selecting the appropriate SHM technology for a specific application can be a rather tedious process. Under the Techniques and Technologies for nEw Maintenance concepts (TATEM) project, the technology selection matrix shown in Figure 10 has been developed and used for the technology selection process under real conditions. This assessment of SHM technology is based on a cascading set of requirements. Starting from simulating future maintenance scenarios, TLRs have been defined, further followed by specific SHM system requirements. All of these requirements have then been summarized. It is the purpose of the procedure to work out and check a framework that allows prioritization and selection of new sensor systems and SHM technologies for air vehicles such as an UAVs, i.e., to determine those systems that allow the information recorded and processed to step from an unknown to a known condition of the item to be monitored. Figure 10 gives an overview on how to assess an SHM technology. The procedure starts by setting up the list of requirements, which can either be the TLRs *per se*, SHM system requirements or a combination of both. These requirements are then correlated with technology criteria that are described in further detail below. Finally these technology criteria are then used for correlation with the respective sensing (SHM) technology considered, resulting in a technology assessment matrix that allows different technologies to be prioritized on a numerical basis.

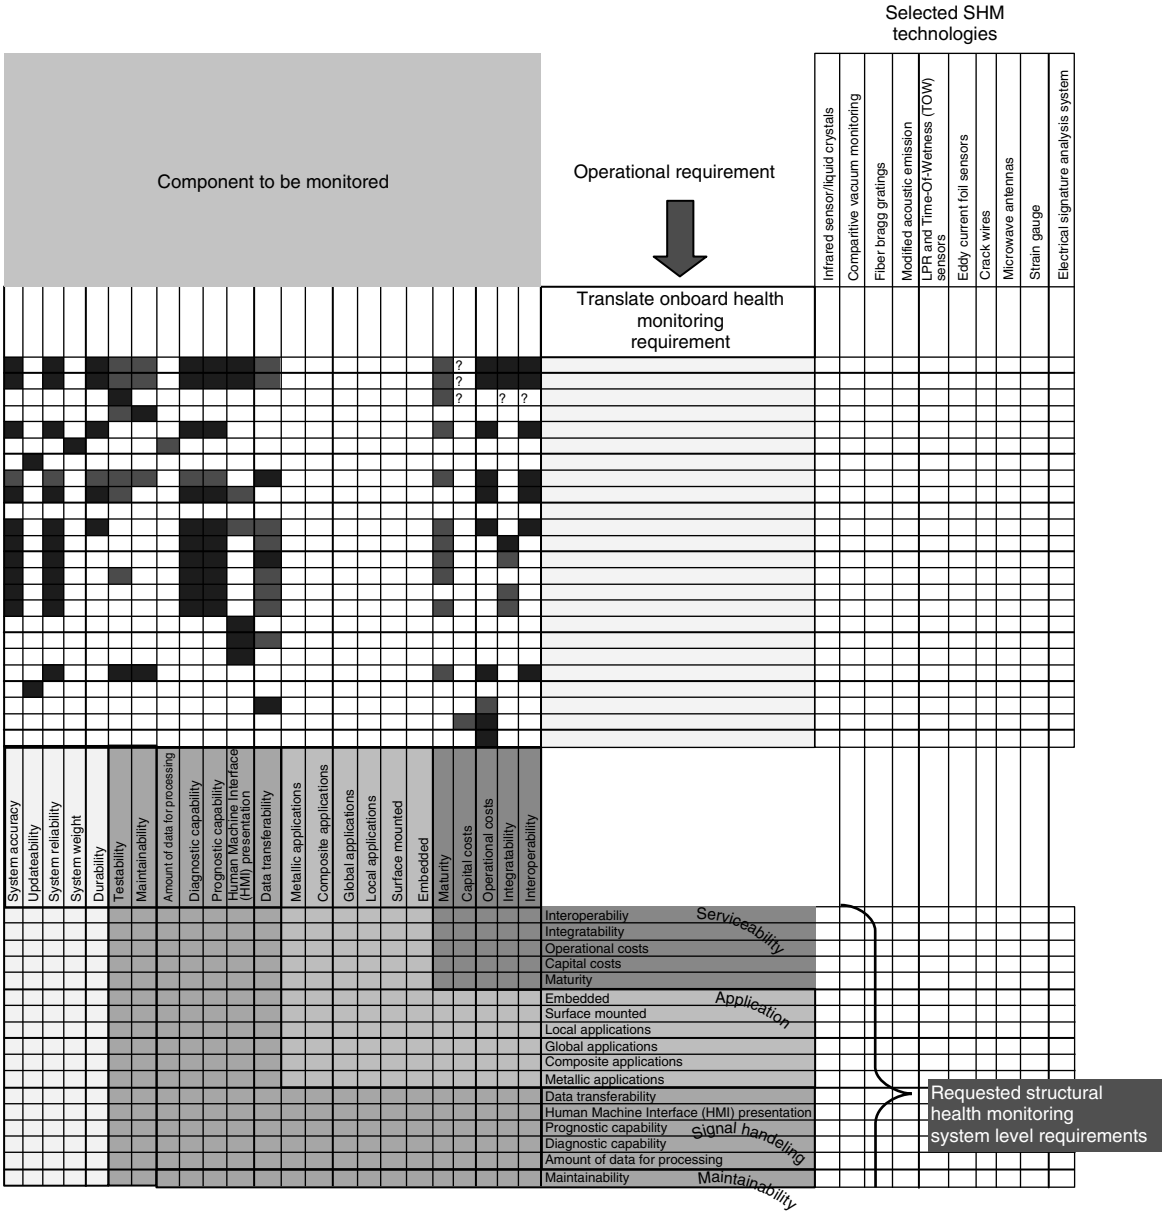

Figure 10. Technology selection matrix.

Technology criteria (also considered as operational handling requirements) in TATEM were derived from a broad variety of operational parameters that mainly looked at metals and composites, the two main classes of structural materials used in aerospace, and at the damage resulting on them. Technology criteria were split into five areas that include

- performance
- maintainability

- signal handling
- maintainability and
- performance.

The procedure was applied to identify promising SHM technologies to be applied for monitoring horizontal tailplane (stabilator) of an F/A 18 fighter airplane, composed of carbon/epoxy skins on an aluminum honeycomb core with an internal metal structure at the stabilator root and a longitudinal riveted aluminum joint of an Airbus A340 front fuselage. Similar applications could therefore be sought for UAVs.

3.5 Sensor signal processing

Several processing units are necessary to operate an SHM system. On the local level, a processor must interface with the sensors to acquire the data and convert the raw analog signals to digital ones. If it is an active system, such as with Lamb-wave methods, the processor must send instructions or waveforms to the actuator periodically. High data rates would be necessary for a set of either Lamb-wave or acoustic-emission sensors collecting data. It can easily be seen that data manipulation and data fusion in the sense OSA-CBM must be provided by the SHM system at the component level. As a result, a damage index or equivalent data is sent via the data bus to a host such as the AMC, which hosts the health assessment applications. Part 3 of this Encyclopedia describes several signal processing techniques. An overview of the health management architecture is provided in Figure 11.

3.6 Communication

A variety of communication models exist for communication between a network of components, which include: multicast, broadcast, and client–server. In the multicast model, the information supplier publishes his information to the network, addressed to a known list of recipients; this is considered to be an asynchronous approach. In the broadcast model, the information supplier publishes his information to all network listeners and the listeners must decide if they are interested in the content of the message. Finally, the client–server model pairs a client (who initiates communication) with a server (who is designed to respond to certain requests). The server implements interfaces that may be used by a client to request a service. A client can only request services available at the server's public interfaces. Data passing may be implemented by means of a single synchronous message, or through a pair of asynchronous messages.

Most of the components mentioned above require power to function. Piezoactuators, for example, operating at 15 kHz with 5-V peak to peak would draw

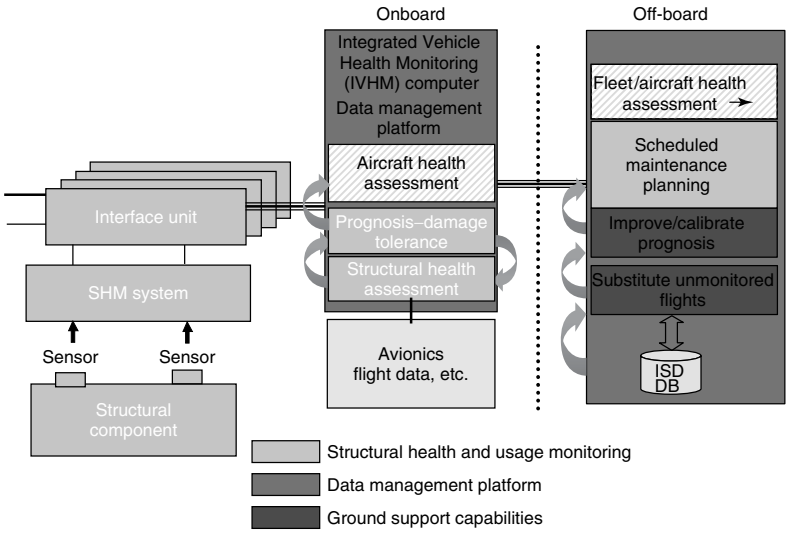

Figure 11. Proposed health management architecture.

24 mW each. A low power microcomputer to process the data would likely draw about 10 mW, and a short-range wireless device would require about 5 mW to function. Although the individual component power demands are low, this becomes challenging when there are many components distributed throughout the surface of the structure, some of which can even be embedded within the skin. The power supply should be provided via the vehicle power management. This does not answer the question of how the connection to the electrical data bus can be realized. There is a wide range of discussions from structure-integrated electronics to poor surface applications. Independent of what one can finally achieve, the power supply is the key enabler and requires efficient integration.

Comparison between the detectable damage size of one single sensor on a 1 m × 1 m composite panel as a function of sensor size, coverage area, and the required power for different SHM technologies has been provided by Kessler in [7].

3.7 Provision of an algorithm to support diagnostic, prognostic, and decision support

3.7.1 Algorithms

Algorithms are probably the most essential elements to an SHM system. They are necessary to decipher and interpret the collected data, and require an understanding of the operational environments and material thresholds. Examples of algorithms that have been used in this research include codes that perform modal analysis and wavelet decomposition. Other algorithms that could be embedded into an SHM system include codes that interpret the sensor data to specify the damage size and location, codes that calculate the residual strength or stiffness of the structure, or codes that predict failure based upon the measured damage.

Health monitoring and management encompasses the set of activities that are performed in order to identify, mitigate, and resolve faults and damages on the aircraft [8]. The activities can be grouped into the four phases, illustrated in Figure 12 and described below.

3.7.2 Condition state detection

There is a need to monitor the systems, equipment, and components that have the greatest impact on mission effectiveness, maintenance, and operation cost.

3.7.3 Health assessment and prognosis

The detection of failures or damage and isolation of the corresponding causes ("what is wrong with the component/structure") and the assessment of the actual aircraft status given any detected failures, damage, and actual degradation ("the overall fitness—i.e., nothing may be broken but the condition is still not 100%") and the prediction of the future

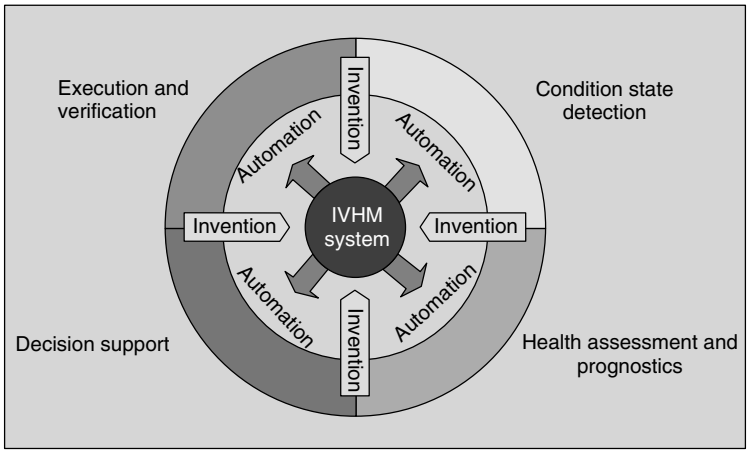

Figure 12. Modified health management activity model (proposed by Aaseng 2001).

condition of the monitored system subsystem or component to provide a remaining usable life (RUL) ("how much longer will the structure/component last").

3.7.4 Decision support

This provides advice for the maintenance engineer and planners to perform their jobs better in face of time pressure, complex scenarios, etc. ("What is the best course of action—monitor, repair, replace—and then how to go about it?").

3.7.5 Execution

This involves performing activities to replace or repair the failed or damaged components, to ensure that the repairs and inspections were performed correctly, and that the system has been returned to full operational status.

The development of the diagnostic, prognostic, and decision support capabilities as part of the aircraft health monitoring consists of the following steps:

- definition phase
- design phase
- development and qualification phase and
- usage phase.

The main parameters that have to be taken into account for diagnosis are as follows:

- Aircraft type
- Modeling of operational scenario
- Mission variability and area
- Usage parameters (environmental parameters)
  - event monitoring
  - damage monitoring
  - load monitoring (including dynamic loads)
  - usage monitoring
  - fatigue life monitoring and
- Critical areas
- Damage index or condition state
  - failure model
  - material properties
  - threshold parameter
  - aircraft and component qualification
  - etc.

A snapshot of the operational scenario modeling is provided in Figure 13. The scenario is divided into operational scenarios such as intelligence, surveillance, and reconnaissance (ISR), strike and suppression of enemy and electronic attack and combat, shown as the horizontal lines. Each of these scenarios is the result of different loading and damaging conditions, which need to be covered by the SHM system.

	In-flight damage monitoring and assessment	In-flight structural overload monitoring	Usage monitoring (UM) and fatigue life monitoring (FLM)	Long-term damage monitoring
ISR Long distance, high altitude	Birdstrike	G-monitoring Hard landing monitoring	Usage monitoring Gust, FH, cycles	Single cases
ISR Short distance, medium to low altitude	Birdstrike Battle damage	G-monitoring Hard landing	Usage monitoring G-spectrum, Gust, FH, cycles	Single cases
Strike/ suppression of enemy defense	Birdstrike Battle damage	G-monitoring Hard landing Store release	Extended UM Dedicated FLM	Dedicated areas Manuever loads Low-cycle fatigue
Electronic attack and combat	Birdstrike Battle damage Structural overload damage	Manuever Hard landing Store release Buffet	Extended UM Dedicated FLM	Dedicated areas Manuever loads Low-cycle fatigue

Figure 13. Snapshot of operational scenario modeling.

4 HEALTH ASSESSMENT

This new decision support process to be covered within the "operational support" will add a proactive function to the decision support algorithm, where a GO or NO–GO decision will be assisted by the health assessment function of the integrated vehicle health management of an aircraft. The "operational risk assessment" concept appears here—an extended function of the operational support that will be supported on the structural health information to develop predictions of the future maintenance-relevant events (e.g., component degradation–driven repair or replacement events) and their impact on the operational planning of the aircraft/fleet. On the basis of the ORA, short-term scheduled maintenance activities should be proactively defined and the long-term scheduled maintenance planning should be adapted. It is recommended that the ORA be carried out according to OSA-CBM architecture in the onboard data management platform.

As part of the health assessment, it is essential to generate a conditional view function that is responsible for providing the RUL prediction with associated confidence level at real operation with respect to the expected usage of the aircraft. This conditional view will provide a basis for operational risk estimation, together with other sources of information, such as operational constraints, economic/safety information, etc.

4.1 Prognosis

There are basically three types of information that may be the basis of the RUL prediction in prognostic approaches. At one end are the models based on statistics (reliability or failure data). Here, knowledge is based just on failure probabilities that can also be coupled with expert judgments. The "confidence" that may be associated with the estimation provided in this way is the lowest, although the applicability of this method within the aircraft is widest. At the higher end of reliability should be located those estimation approaches that are built on top of physical or mathematical models, usually validated physically at component or major airframe fatigue test level. Here, once the main input parameters are known, it is possible to estimate the system condition with great accuracy. Information for the prediction may be based on condition of usage monitoring that allows incomplete models of the degradation of monitored components to be derived, normally on the basis of identification of partial information within the model (trends, limits). In this case of model-based information, the RUL output can usually be interpreted as degradation information, whereas when only statistical or reliability information is available, the RUL estimation referred to is a perceived probability of failure (with no relation of the internal degradation of the piece).

In Figure 14, a possible approach to performing reliable diagnostic measurements and prognostics is shown, which has been derived from a concept initially proposed by Boeing [9] (*see also* **Commercial Fixed-wing Aircraft**) and adapted to the needs of UAVs. The basic idea is to link usage, damage, and damage monitoring of monitored components. This approach requires the development of a database including a wide set of data, e.g., damage index or condition state of all flights, failure model, material properties, threshold parameters, aircraft and component qualification, configuration, etc. A further prerequisite is synchronization, e.g., regarding time of usage and damage monitoring. This is not considered as critical in the case where damage monitoring is linked to the data bus. By means of the operational parameters and the accurate condition state determination, reliable diagnosis and prognosis appears to be feasible.

4.2 Decision support

The ORA in the scope of aircraft operational support calculates a set of discrete probabilities of operational interruptions over an assigned set of missions. The calculation is made under the terms of improved operational effectiveness optimization. The ORA in this context describes the calculation of probabilities of operational interruptions caused by unscheduled maintenance events.

The processing of ORA starts with the estimation of the survival rate for each monitored system or component, as well as for the complete aircraft for an assigned mission.

The estimation of managed components and aircraft-level survival rate uses an implementation

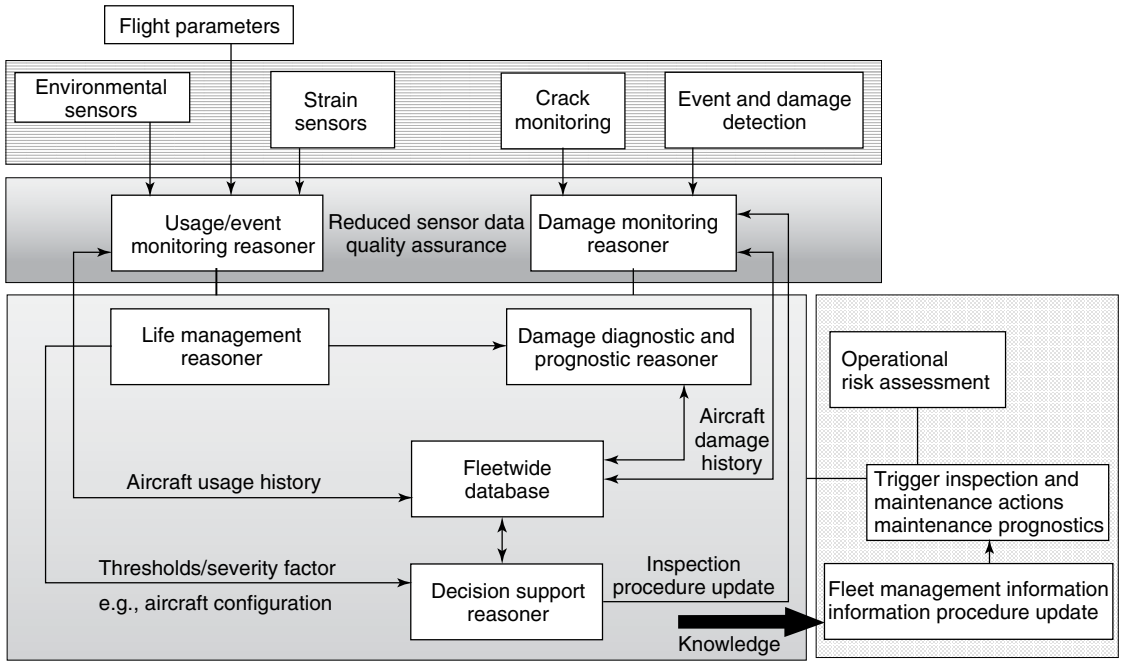

Figure 14. Conceptual approach to performing diagnosis and prognosis at aircraft level as part of an embedded health management system.

of the maintenance-free operating period (MFOP) approach. It allows the reliability assessment of complex technical systems. The primary goal is the calculation of the survival probability for a discrete time period to a given level of risk for availability of the technical system.

The parameter to be calculated in this assessment is the maintenance-free operating period survivability (MFOPS), the probability of survival for a lapse of time t_{mf} time units. t_{mf} is, in this context, the concrete MFOP cycle and defines the lapse of time in which the system will be able to perform its function accordingly.

5 CONCLUSIONS

The variety of activities mentioned in this article with regard to designing, monitoring, and integrating SHM systems into UAVs to support new maintenance strategies and support autonomous missions form a challenge. Significant activities have to be performed until SHM systems become part of the future design process, mainly due to the fact that the interface between fatigue monitoring systems, the subsequent management of aircraft life limitations and repair limits is still missing. Broader thinking in terms of life-cycle cost has become highly important.

Advanced sensing, materials, and data-processing technology are possibly the biggest challenges in revolutionizing the inspection process and in automating the procedure leading to the most common information of "no failure found". In case this automation can be achieved, then further, and possibly a much larger potential can be seen in the integration into the decision support algorithms for autonomous missions. Further pursuing this method will allow new maintenance concepts and strategies for UAVs and repair techniques that can be more easily certified and more efficiently applied. There is, therefore, much potential still waiting to be explored.

Chapter 116
Monitoring of Solid Rocket Motors

Gregory A. Ruderman
Air Force Research Laboratory, AFRL/RZSB, Edwards AFB, CA, USA

1 INTRODUCTION

Missiles are typically considered to be "wooden rounds", in that they are deployed in the field as all-up, ready to go devices, which require no maintenance and will function correctly when required, even if that time is many years in the future. During this time, the missile may be subjected to a wide range of inputs. Depending on the environment, these can include mechanical and vibrational loads from transportation and operational use as well as a broad range of thermal environments, which may occur in rapid cycles due to deployment on aircraft. In addition, motors are also subject to chemical attack, which may occur entirely internally to the motor, or could involve the external environment, often from moist or saline environments. The structure of the rocket motor itself contains a number of bondlines, which are often the location of structural flaws, and these may affect the integrity of the system. The energetic materials and binders in different regions may attack other materials, changing the local properties. And the entire system is enclosed in a pressure vessel, which must resist high thermal and structural loads from both internal and external environments during operational use.

Despite these challenges, solid rocket motors (SRMs) typically not only have extremely high reliabilities and mission success rates, which is a tribute to the design process and the design engineers, but they also often incorporate large factors of safety to ensure reliability. As budgets decrease, however, more is often requested from systems, whether it is improved performance or extended service life, which eats into that margin and requires both development of improved modeling techniques and sensor technologies, which will be able to accurately assess the condition of missiles.

2 FUNDAMENTALS OF SOLID ROCKET MOTORS

SRMs are generally simple devices, particularly from a structural point of view [1]. The propellant grain, a composite of energetic materials and a polymeric

 ISBN: 978-0-470-05822-0.

binder, is enclosed by a case, which serves as a pressure vessel. As the propellant burns, hot gases are generated and the thermal and pressure energy is converted into kinetic energy by a nozzle. Each of these components has their own structural issues, individually and with respect to the entire missile system that are discussed below. Figure 1 presents an idealized SRM for reference. This motor was developed by ATK Launch Systems, Brigham City, Utah, under the Air Force Research Laboratory's "Critical Defect Assessment" program [2]. While it does not correspond to any operational system, it possesses many of the aspects, which create difficulty for analysts and motor designers, including a segmented grain and a complex geometry composed of a combination of the central cylindrical bore and six radial fins, making it an ideal validation case for sensors and computational models.

SRMs come in a variety of shapes, sizes, and thrust levels, depending on the mission requirements. For the purpose of this article, they can broadly be divided into three classes: tactical, strategic, and boost/space launch, each with unique missions and issues relating to structural requirements and monitoring.

Tactical missiles are often small, ranging from 70 mm (2.75 in.) diameter, typically deployed on missile pods of helicopters, to 127 mm (5 in.) Sidewinder, 178 mm (7 in.) AMRAAM, and 254 mm (10 in.) Patriot missiles. These missiles are used all over the world and are, as such, exposed to a variety of environments from Arctic to desert to oceanic, and in the particular case of air-launched missiles, the missiles are often rapidly cycled between these environments, as an aircraft takes off, climbs to the cold upper atmosphere, and then is subjected to high heating at supersonic speeds.

Strategic missiles, broadly, are significantly larger (e.g., 211 cm (83 in.) for the Minuteman III and 234 cm (92 in.) for the Trident D-5) and are used to deliver long-range payloads such as nuclear devices. Unlike many tactical missiles, strategic missiles are deployed to a single location such as a silo or submarine and left in place, generally reducing the variability and severity of the environments they are likely to face.

Space launch motors can be considered as a separate category generally in the way they are treated. While many are of similar size to strategic motors, they are designed and manufactured specifically for launching payloads to space, and are generally treated very carefully and not allowed to age significantly before use. Common solid motors for this application are the Space Shuttle Reusable Solid Rocket Motor (RSRM) and the Atlas V Solid Rocket Booster. Upper stage motors are often also solids, but are significantly smaller and come in many shapes and sizes (e.g., the

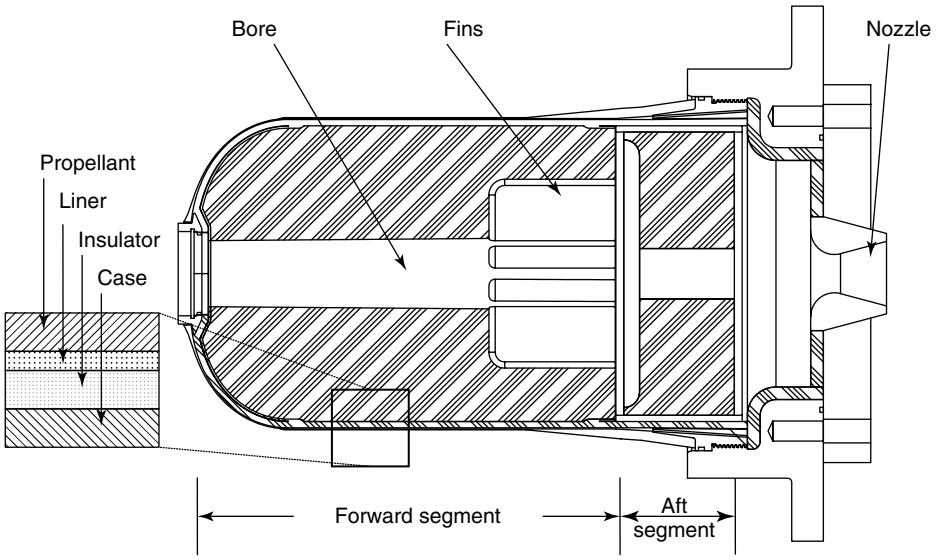

Figure 1. Schematic of an idealized solid rocket motor.

Orbus or Star motor series). A notable exception to the idea that these motors are of recent pedigree is the Orbital Sciences Corporation Taurus, Minotaur I, and proposed Minotaur IV, which will use decommissioned strategic missile stages.

3 MOTOR COMPONENTS

In the next section, individual components of the SRM are examined in greater detail, emphasizing the challenges and opportunities for structural health monitoring for each.

3.1 Cases

The case of an SRM is a pressure vessel, maintaining the integrity of the motor at high pressures during operation. Cases are typically made from materials such as D6AC steel, 6Al-4V titanium, or various fiber composites such as Kevlar, glass, or carbon fiber. Generally, the cases for larger motors have a greater potential to be composite, although this is driven by mission requirements rather than the size itself. For example, tactical missiles tend to have metal cases because of the need for longitudinal stiffness during maneuvering, while the space shuttle RSRM boosters are steel simply so they can be reused on future missions.

The use of composite materials, as in many other applications, is strongly driven by the high specific strength of these materials. Reduction in the inert weight of a system directly enables improved capability for the missile, usually in terms of increased payload, but the use of these materials also entails new risks. Unlike metal cases, composites can be fairly easily damaged by impact, and can be damaged severely that a catastrophic motor failure can result while still not being detectable to the naked eye. Composites, at least in comparison to the metal cases they replace, can allow diffusion of water into the motor, particularly if the matrix has been damaged by handling. In addition, due to the natural anisotropy of the wound bottles and complexity of design, fidelity analysis of composite pressure vessels is not as mature as that for metals. Composite cases are regularly overdesigned in the dome region to ensure failure in the cylinder, where predictive models are more accurate.

3.2 Propellant–liner–insulator (PLI) system

Working inward from the case, the first material encountered is the insulation, typically a rubber material such as ethylene propylene diene monomer (EPDM), which protects the case from the extreme thermal environment in the motor and maintains the integrity of the case as the burning surface of the propellant approaches the case wall. Often, the insulation is reinforced with Kevlar or other fibers to protect the case wall from mechanical erosion caused by the burning fuel particles. The insulator is adhesively bound to the case wall, but often has sections in the head or aft end (or both) where it is not bound. These "flaps" reduce the stress and strain on the propellant during motor operation by freeing the propellant from stretching as much as the case does under pressure. The next layer is the liner, a polymeric material, the main purpose of which is to bond the propellant to the insulator, although in many systems, this includes a "barrier coat" designed to prevent the diffusion of chemical components from the insulator into the propellant (or vice versa). The importance of these types of chemical processes to the structural aspects of SRMs is discussed in greater detail.

The next layer is then the propellant itself. The most common type of propellant, particularly for use in Air Force ballistic missile and space launch applications, is composite propellant. Typical composite propellants are composed of a crystalline oxidizer, often ammonium perchlorate (AP), ground to a nominal particle size of typically 200 μm, although many propellants have bi- and trimodal distributions of sizes to improve mixing properties and tailor burn rates. Aluminum powder is added to the mix as a fuel and both are held together by a polymeric binder. Commonly used binders include hydroxyl-terminated polybutadiene (HTPB) or polybutadiene acrilonitrile (PBAN). These materials are mixed, along with appropriate curatives and other chemicals such as burn-rate modifiers, cast into the motor and cured. Some tactical motors reduce or omit the aluminum fuel, as it generates a highly visible white smoke trail, which can easily be used to track back to the source of the missile. Many Army tactical and Navy strategic motors use a propellant type known as *double base*, composed of nitrocellulose and nitroglycerine, sometimes with aluminum and/or

nitramines (HMX or RDX added). Regardless of the type, rocket propellants are generally chemically and mechanically complex, nonlinear, viscoelastic, prone to damage, debonding of particles from the binder, and often nonuniform in properties due to material flow and particle segregation during the manufacturing process.

There are multiple different effects that make structural analysis and health monitoring challenging for SRMs. These include material property variation (spatial nonuniformity), defects (voids and inclusions), and material aging (chemical–mechanical link). Each of these is discussed in the following sections.

3.2.1 Material property variation

To understand the variability inherent in the mechanical properties of an SRM, it is necessary to examine the process by which the propellant is made and the motor cast. The propellant is manufactured in a large mixing bowl and then cast directly into the case. For motors with a bore or fins, a casting tool of the appropriate configuration is placed inside the case and the propellant flows around it. The uncured propellant has a similar consistency to thick cake batter and tends to flow nonuniformly as it fills the case. Larger motors can require multiple separate mixes of propellant (the largest mixer in common use in the rocket industry is 6800 liters), which may cause knit lines to form between the different portions of the cast. During the casting process, the particles in the propellant often segregate by size, with smaller particles remaining closer to the bore and larger particles comparatively richer in the bulk. This is a known effect that is most often seen in unexpected changes in the burning rate of the propellant often called the *burn anomaly rate factor* (BARF), but can also be seen in the resulting differences in propellant properties in those regions as well. The fully loaded motor is then placed into an oven, where the propellant is cured at elevated temperatures, for multiple days in the case of large motors. While care is taken, nonuniform oven temperatures can also occur, which may affect the cure process in different locations within the motor.

3.2.2 Material aging

Aging of motor materials is one of the greatest concerns for the long-term viability of a motor. Aging generally falls into three categories, which are generically, and somewhat inaccurately, called *aging*. In the first instance, the materials themselves may simply change chemically (and therefore mechanically) over time. For example, the binder material is generally lightly cross-linked and, as a result, is prone to oxidative cross-linking at exposed surface (e.g., at the bore), which generally results in propellant hardening. A second type of aging involves the influence of adjacent materials on each other, typically involving chemical diffusion at the various bondlines between the propellant, liner, insulator, and case. These chemical constituents can migrate between materials, driven by chemical gradients and accelerated by temperature. In some instances, the curative of one material has unexpectedly turned out to be antagonistic to the bonds in another material, eventually resulting in a bondline of zero strength and a motor exploding soon after ignition as the entire grain attempted to be extruded through the nozzle. The third type of aging is typically called *mechanical aging* or *mechanical damage* in the SRM community. This involves direct mechanical changes in the properties of the materials, typically as a result of thermal cycling, vibrational loads, or physical insult, which can result in the weakening of bonds, either between the particle and binder, or within the binder itself, which can lead to weak spots, fractures, or increased porosity.

3.2.3 Defects

Despite the best efforts of manufacturers, rocket motors often have unexpected features. Voids in propellant often occur as a result of insufficient settling of the propellant during the casting process. Trapped air bubbles are not fully eliminated and a small area is formed, which contains no propellant. If small enough, these are not typically of great concern, although if they are proximate to an interface or other high stress or strain region can contribute to the formation of cracks. Inclusions are objects that end up in the propellant, which should not be present. These can be large pieces of propellant ingredients or other

motor materials, but also include anomalous objects. Notable inclusions that have historically occurred in motors include lead shot and a crumpled paper cup. Regardless of the source, these objects are often poorly bonded to the propellant and cause perturbations to the stress/strain field of the motor in a similar fashion as voids. If the item is large enough or not fully consumed, then damage may result on the inside of the case and to the nozzle causing a major concern. Depending on the material in the inclusion, the combustion process in the region can be significantly changed. In some cases, this has been intentionally used to advantage, such as placing fine metal wires in the propellant to increase the burning rate by increasing thermal conduction and providing a path along which the flame travels more easily.

Cracks can occur throughout the motor, although they are often seen in the bore, particularly in motors that have undergone thermal cycling. When a crack occurs, there are two scenarios. In the first case, when the combustion surface reaches the crack, the flame speed exceeds the crack propagation velocity. In this situation, the crack tip is blunted by the burning and does not propagate, so the concern is simply the increase in pressure of the motor due to additional burning surface area. If the crack area is small compared to the surface area of the motor, the pressure will not be significantly increased and this will not be a major issue. In the case that the crack propagation speed is greater than that of the flame, the crack will propagate. In this situation, the burning surface is exposed deeper in the motor before it is expected. Since the insulation thickness is determined during the design process by the calculated time of exposure to the hot gases (with an appropriate factor of safety), early exposure can overwhelm the insulation, heating the case and creating an opportunity for failure. Cracks also occur in the propellant near the propellant–liner interface. This compounds the problem, as there is hot gas near the wall, and if the crack propagates, the motor grain is detached from the bonding surface.

Debonds are similar to the cracks described earlier, but result from insufficient or incomplete bonding between two of the propellant–liner–insulator materials. As with cracks, the concerns are augmented burning near the case wall and the structural impact of the decreased bonding.

4 CURRENT STATE OF THE ART FOR SOLID ROCKET HEALTH MONITORING

The air force is interested in developing health management technology for SRMs to reduce system life-cycle costs while improving safety and reliability. The ultimate goal is to be able to tell which assets have aged out or otherwise need to be replaced and which assets are still viable. Currently, a typical missile aging program takes a small number of motors, fires some, and dissects others for verification. This is performed periodically, and as long as the verification firings and dissection data are nominal, the entire lot is considered viable. Otherwise, following further investigation, the entire lot of missiles may be condemned and destroyed. While attempts are made to choose motors that are expected to be "bad", i.e., which have seen more time in service or excessive thermal cycling, often the precise history of any given motor is not well known, making such attempts problematic. Since a statistically meaningful quantity of verification motors are not used, there is a strong probability that viable motors will be destroyed and have to be replaced at a significant cost to the government, or that despite "successful" verification of the system, failures will occur, potentially causing mission failure, destruction of government property, or loss of life.

Changing to a condition-based paradigm has potentially enormous payoffs. Consider the following notional example (numbers are used for illustrative purposes and do not relate to any current policy or system): Assume a missile fleet of some size X. The fleet is considered nonviable at 17 years, at which time 2.5% (0.025X) will not successfully complete the mission due to age-out of a structural material. Currently, the entire fleet would be retired and replacements procured, rather than culling and replacing the bad missiles and leaving the rest. As those original missiles age, more will need to be retired more rapidly, but never as many as replacing an entire fleet in a short period to maintain readiness. Simple analysis assuming this 17-year service life and motors aging out in a Gaussian distribution means we have built approximately 2X missiles at the end of year 51. However, following the current paradigm, we will have built the original fleet and replaced it entirely three times (total of 4X missiles).

While this is a very simple example, it reveals some of the enormous benefits that could be realized.

4.1 Current use of IVHM for strategic systems

The major health monitoring activity for current strategic motors is the automated nondestructive evaluation system (ANDES 2) at Hill Air Force Base, Utah [3, 4]. ANDES 2 is the second generation of an non-destructive evaluation (NDE) data analysis system currently examining computed tomography (CT) data and capable of inspecting all three stages of a strategic system, detecting voids, inclusions, debonds, or other flaws as small as 0.25 mm (10 mils). One of the benefits of this second generation of ANDES is the capability to be "trained" on any type of NDE data, be it digitized film X ray, CT, or ultrasound. Any identified flaws are reported to the user and a recommendation is provided as to whether these meet the motor specification. These data are maintained by Hill air force base (AFB) and provide a zero-time assessment of motor structural state. The ANDES system has historically been used for inspection of the current Minuteman III fleet. Unfortunately, due to cost and logistical difficulties, these inspections are not performed regularly, but only when the system needs to be brought back to the depot for other maintenance.

Marks measured and evaluated by ANDES are converted into faceted surfaces, which can be transferred directly to the Air Force's Structural/Ballistic Analysis System (SBAS II). SBAS is an analysis code that solves coupled fluid-structural-thermal-ballistic problems [5]. Of particular interest to structural analysis, SBAS reads the marks detected by ANDES and can take a baseline motor mesh and automatically integrate the flaws, remeshing the model as necessary without user intervention. As the analysis proceeds, if integrated continuum failure or fracture propagation models determine that a crack will form or propagate, this too is performed automatically, significantly reducing the time required for an analysis.

Other nondestructive techniques are rarely used on deployed systems. Eddy current or ultrasound are sometimes used for quality control by the motor manufacturers during the manufacturing process, but are not typically used once a motor has been fielded. Embedded sensors have been frequently used in demonstrations on subscale articles, but are not used on deployed systems. Chemical sensors are currently being developed, but remain at a low technology readiness level (TRL). All chemical data used in aging models is acquired in a destructive fashion, usually by dissection of the motor, after which the desired properties (e.g., cross-link density, sol–gel, and chemical concentrations as a function of position) can be determined in laboratory experiments. Chemical aging models have been significantly improved in the last decade, allowing not only a high reliability prediction of the current chemical state of the propellant–liner–insulator (PLI) system but also a prediction of the mechanical state of the motor as a function of the chemical state. This type of modeling is critical to the prediction of motor service life, but is currently limited in functionality as the motor of interest is always destroyed in the process of acquiring the necessary data [6, 7].

4.2 Current state of the art in laboratory demonstrations

In the past decade, the various Department of Defense laboratories have demonstrated new sensors and data-acquisition systems, usually in conjunction with rocket motor manufacturers such as Aerojet and ATK Launch Systems in an effort to raise the TRL to the point where the technology can be transitioned to a program office for use on a new system.

So far, the embedded (bondline) sensor, which has shown the greatest promise, is the Micron Instruments dual bond stress temperature (DBST) sensor, a small steel stress sensor 7.6 mm in diameter and 2.0-mm thick. DBSTs have been used in laboratory demonstration assets such as the motor shown in the first section. They have been flown in tactical configurations and have been used in motors, which have been fired on test stands. Currently, the Air Force Research Laboratory possesses two motors with embedded sensors, including DBSTs, which have been set aside for long-term storage and examination to ensure reliability and stability [7]. The other area that has shown some promise in the laboratory environment is sensor networks to detect and quantify damage to

composite cases. These have taken various forms, including a network of embedded multiaxial fiber-optic Bragg gratings (*see* **Fiber Bragg Grating Sensors**) wound into the composite case performed by Blue Road Research [8], and a network of piezoelectric sensor/transmitters (*see* **Piezoelectric Wafer Active Sensors**; **Hybrid PZT/FBG Sensor System**) attached to the surface of the case, which has been demonstrated by Acellent Technologies [9]. In both cases, the idea is to provide a system which, when interrogated, can detect the invisible or barely visible impact damage, which could result in the complete loss of structural integrity of the composite case without needing the data and logistics overhead required by an accelerometer that is always on.

5 CURRENT CHALLENGES FACING SRM IVHM

Despite the research, which has been performed by Department of Defense (DoD) laboratories and many contractor organizations, no current SRM system in operation possesses an onboard health management system. In part, this is due to practical reasons. New systems are not developed often, and the best time to insert health monitoring is during the design process. Once a system has been designed, even if modifications are required (for example, due to material obsolescence issues), those changes are kept to the absolute minimum to reduce requalification costs and any potential issues that might crop up due to design changes. In essence, while the philosophy has generally been that any kind of health monitoring needs to "buy its way onboard", i.e., have a quantifiable payoff that (far) exceeds the challenges of implementation, the buy-in has the potential to be even higher for the existing systems.

Of course, this argument assumes that the TRL of the system and associated technologies is sufficiently high. Unfortunately, while this is the case for some individual sensors or systems, overall, we are not quite there. Following are some of the outstanding issues that need to be further addressed before use of this technology can be seriously considered.

5.1 Data acquisition, storage, and analysis

One of the greatest challenges in the implementation of a practical integrated vehicle health monitoring (IVHM) system is the sheer quantity of data that can be collected. This is made even more difficult if one considers the example of a tactical rocket motor. As previously described, these items may be shipped to various locations across the globe and experience extremes of thermal, chemical, shock, and vibration loading. Depending on the rate of data acquisition, even for just a single asset, this could very easily overwhelm any amount of storage available. Clearly, despite the relatively low (and rapidly shrinking) cost of data storage, simply acquiring raw data at a high rate would not be practical, except in rare situations.

The obvious solution to this issue lies in significant improvement in constitutive modeling for any life-limiting component of the rocket motor. An accurate model of the behavior of the propellant–liner–insulator system would enable both detailed simulation of the rocket under various loading conditions and a fundamental understanding of the limits of loads, which could be applied without causing permanent damage and reducing functionality. Models of this type have been pursued for many years with varying degrees of success. Phenomenological models have historically been used to describe material behavior, but due to the complexity of the materials have been of little predictive utility, ultimately resulting in the large factors of safety and margins mentioned in Section 1. For example, propellants are typically considered to be nonlinear viscoelastic materials with an associated damage function in which the damage may or may not be reversible to some degree. Integration of the aging process into these models has been problematic as well. More recently, mechanistic models, which describe the material behavior in terms of the interaction of the constituents, have been developed and are coming into use [2, 5]. However, these models are extremely computationally intensive and significantly require more expertise to develop and use correctly.

The current approach is twofold. The phenomenological models are continuing to be developed with more advanced capabilities, including chemical aging models, multiaxiality, and new failure theories. Likewise, the mechanistic models will also continue

being developed, taking advantage of increasing processing power, computational efficiency measures, and the like. Ultimately, some combination of the two approaches will likely be employed. A fast model embedded in the asset could make an initial, rough assessment, and if it calls into question the asset's reliability or capability, a much more detailed analysis could be performed at the depot or other location when time permits.

5.2 System longevity and reliability

Another challenge to implementation has to do with the long-term stability of the sensor system itself, and the effect it might have on the rocket motor. In general, the sensors that have been demonstrated on Air Force Research Laboratory programs have been made of inert materials (glass for fiber-optic sensors, ceramics for piezoelectrics, and steel or titanium for stress sensors), which have shown no chemical effect on the motor in accelerated aging tests. In addition, because of concerns that the placement of the sensors within bondlines could actually generate the flaws that we are attempting to avoid or detect, a large number of bondline test articles with different sensors have been tested. In every case, the articles failed away from the sensor, suggesting that the effect of the sensors is smaller than that of the natural nonuniformities in the material. Of course, this assumes that the placement of the sensors is performed correctly by not placing them in a region that would be very sensitive to small flaws or variations.

Long-term reliability and stability of the sensors themselves then becomes the problem. Assuming that the sensors survive the manufacturing process, the immediate concern is whether the sensors are still correctly calibrated, and if so, for how long will they remain so. So far, this remains an open question. While some embedded bondline sensors have shown excellent long-term stability, maintaining accurate readings in a laboratory environment for many months, others have shown a tendency to drift from their calibration. Without a reliable method for *in situ* recalibration and validation of the sensor data, the data will always have some level of question surrounding it.

In the very long term, for example, over an expected 35-year service life of a new strategic missile, we have no data on how any sensor system will survive. It is possible to make an excellent argument, however, that as long as the sensor fails gracefully, it does not really matter how long the sensor lasts. Even though motors continue to evolve over their entire lives, most of the aging changes (as opposed to the changes driven by external boundary conditions) occur in the first few months. *In situ* data in this time period would significantly improve any models and allow the operators to understand the pedigree of individual assets, which, in turn, will improve predictions of future behavior.

5.3 Lack of service life sensors

One of the more interesting issues in using health monitoring to determine service life of SRMs is that the sensors currently available, and the majority of those in the current development, cannot directly measure the phenomena of interest that would correlate directly to service life-limiting phenomena. For example, sensors that have been embedded in the propellant–liner–insulator interfaces measure stress or strain, but ultimately what is desired is a way of measuring the material moduli, as those are the intrinsic properties that change with time and environment. Complex sensors that can locally determine the modulus have been proposed, but are generally in very early stages of development.

With the development of mechanistic material models, sensors that can measure primitive variables in those models are greatly desired. For example, any method that could directly determine the cross-link density of the polymer (which is directly related to the modulus) would be of great value. Similarly, the idea of chemical sensors that can directly measure either the chemicals that diffuse from different regions of the motor or that are by-products of chemical aging processes has been frequently discussed, but has not been greatly successful. Fiber-optic Raman spectroscopy probes have been explored, but have a tendency to heat the propellant locally, influencing the process (and in the case of one experiment, nearly igniting the propellant) [6]. Other chemical sensors such as fiber optics with coatings that respond to the presence of certain chemicals have also been discussed, but concerns about whether the sensors themselves would act as chemical sinks and influence

the local behavior, or would become saturated and rapidly stop working has limited development.

5.4 Business case

While not a technical issue, the successful development of a legitimate business argument for the implementation of IVHM systems is probably the largest hurdle to overcome [10]. Such an argument must address the concerns of all the stakeholders, from the policy makers, to the program offices, to the end users, and explain why taking a relatively simple and generally reliable system can be improved by adding complexity.

The simplistic example previously provided begins the discussion, but does not address the details necessary to allay concerns. The addition of IVHM will increase the complexity of the manufacturing process, add to the logistics tail of the system by requiring personnel to acquire, store, and analyze the data, add to inert weight, and cost more. This must be balanced against the potential payoffs in terms of reliability, safety, and availability. The argument will have to be made on a system-by-system basis and involve all the stakeholders from the beginning of the process. Otherwise, the IVHM system, as is often the case, may be the first thing to go when a program has cost overruns or exceeds the planned weight.

6 CONCLUSION: A WAY FORWARD

Despite all the challenges, the expected payoffs of an IVHM system are great and will continue to be pursued. In the short term, a minimally invasive approach will likely be the most successful in being adopted by the user community. In tactical motors, this most likely means a compact environmental (temperature, humidity, and vibration/acceleration) datalogger, which can be stored in the missile's transport case. Analysts will have access to high fidelity information on the motor environment for the first time and will be able to use that data to both make predictions and improve the predictive models with real-world experience.

In larger motors, a similar concept with sensors integrated into the weather seal may be possible. Integrating the environmental monitoring system, potentially with gaseous chemical sensors in the bore, should be a necessary first step in any new system, and could even be easily integrated into existing systems without costly design changes.

In the longer term, embedded sensor systems need to be considered as part of the design process, along with external monitoring such as the case of damage-detection systems or future generations of the ANDES system. Continued development of physically based models is critical to the process, as are the advances expected due to the advancements in computational and storage technology. The long-term ideal would be a fully instrumented asset that can assess its own status and, if necessary, make adjustments or inform the users that it needs to be replaced or taken back to the depot for a more detailed inspection. While we are currently far from that kind of system now, the demonstrated success of such systems on commercial automobiles and other complex vehicles suggests that we are not as far off as we might think.

Chapter 106

Comparative Vacuum Monitoring (CVM™)

Duncan P. Barton

Structural Monitoring Systems Ltd., Perth, WA, Australia

1 CVM™—A SHORT HISTORY

Comparative Vacuum Monitoring or CVM™, was invented by Ken Davey in the early 1990s. Ken had been a commercial pilot during the 1960s and had been on a Vickers Viscount the flight before its wing fell off on descent into Port Hedland New Year's Eve 1968, killing all onboard. The main wing spar had failed owing to a fatigue crack initiating from an incorrectly installed rivet. Ken knew the crew of the ill-fated aircraft and vowed to find a better way to monitor the structure of an aircraft.

Several years later, Ken eventually stopped flying due to health reasons and after trying a few different jobs, he eventually founded a company for repairing the picture tubes in televisions. The final step in the repair process requires the glass tube to be placed under a vacuum. Ken observed that if there were any small cracks in the glass the vacuum was quickly lost. Ken combined the earlier tragedy with this observation and in 1994 patented "the Davey System", the basis of what is now known as *Comparative Vacuum Monitoring* or *CVM*™.

Ken successfully demonstrated a prototype of the system to the Australian Defence Science and Technology Organisation (DSTO) during a series of laboratory trials in the late 1990s [1]. On the basis of these promising early results a company, Structural Monitoring Systems Ltd., was formed to develop the system for use in the aerospace industry. As the technology has continued to be developed, it has been used in numerous programs including the certification of Glare® for the A380 with Airbus and flight trials with Airbus, Boeing, and several Air Forces. The technology is now also finding uses in other industries, including automotive testing and monitoring of infrastructure.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

2 THE CVM™ TECHNOLOGY EXPLAINED

2.1 The basic principle

The principle behind CVM™ is uniquely simple; a vacuum contained in a small volume is extremely sensitive to any leakages [2]. The CVM™ principle relies on placing a sensor onto the surface of a component where damage is expected to occur (see Figure 1). The sensor contains a manifold of fine channels that are open to the surface. Once the sensor has been installed on the surface, the channels form closed "galleries" to which a vacuum can be applied. It is important to note that the surface of the component forms part of the sensor system, with the crack itself providing the leakage path for air into the vacuum galleries.

The sensor is connected to a vacuum source through an accurate flowmeter. Figures 2 and 3 show a schematic of the equipment used in laboratory trials, which allows continuous monitoring of a sensor, or several sensors connected in series or parallel (not shown). If there is no damage on the component, then the vacuum in the sensor will be approximately the same as the vacuum source (Figure 2). If, however, a crack develops, a leakage path will exist and the vacuum level will be reduced in the sensor manifold (Figure 3).

2.2 The sensors

A variety of sensors have been manufactured from a number of materials, for a range of applications. The various sensor types are described below.

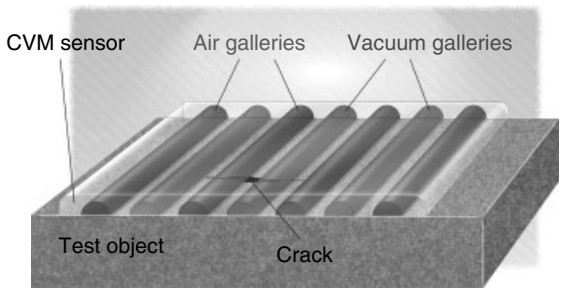

Figure 1. A schematic of a simple CVM™ sensor.

2.2.1 Sensors for metallic structures

The original sensors were manufactured using silicone with silicone or acrylic pressure-sensitive adhesive. The pressure-sensitive adhesive allows the sensor to be removed from the storage box and installed directly onto the surface of the component in much the same way as a postage stamp or tape. The silicone allows the sensors to conform to complex geometries with minimal internal residual stresses (Figure 4). Sensors are also manufactured from polymers such as polyimide and FEP for applications with different environmental and geometrical requirements. Polymer sensors can be manufactured to longer lengths, but are only able to conform to simple component geometries.

It is important to note that the sensors are the same whether used in a laboratory or an in-service component. This allows the response of the sensor configuration to be characterized in the laboratory for a specific component and then for these results to be transferred directly to an in-service application.

2.2.2 Sensors for composite structures

Sensors for composite structures are able to monitor barely visible impact damage (BVID) using standard sensors Figure 5a installed on the back face of an impacted structure and disbond using through-the-thickness or TTT sensors Figure 5b. By placing standard surface sensors, with detection galleries widely spaced on the back face of an impacted structure BVID can be reliably detected [3, 4]. The impact on the structure causes microcracks in the resin matrix, which can be detected using the CVM™ system.

The second form of composite sensor being developed is a TTT sensor. The sensor involves creating a small (diameter <1 mm) blind hole through the bonded structure and into the adhesive layer, which is then connected to a flow meter and vacuum source. If the adhesive layer fails, the damage forms a leakage path for air that is then detected by the flow meter. The size of the detectable damage is determined by the spacing of the holes in the structure. The sensors have been used to detect poor manufacturing processes and damage due to impact on the whole structure, with results confirmed using standard C-scans and thermography.

Figure 2. CVM™ system installed on an intact component.

2.3 The instrumentation

The CVM™ instrumentation consists of various derivations of vacuum source and a flow meter [5]. The laboratory variant allows users to gain experience with the new technology and understand its advantages and limitations. A periodic, off-board system allows the minimum level of instrumentation to be installed on an aircraft; essentially just the sensors, vacuum tubing, and a pneumatic connector. This system has enabled a history of robustness and durability data to be accumulated for the sensors. A cheap and simple CVM™ switch has been developed to meet the needs of the automotive testing industry and a fully integrated airborne monitoring system is currently in an advanced stage of design.

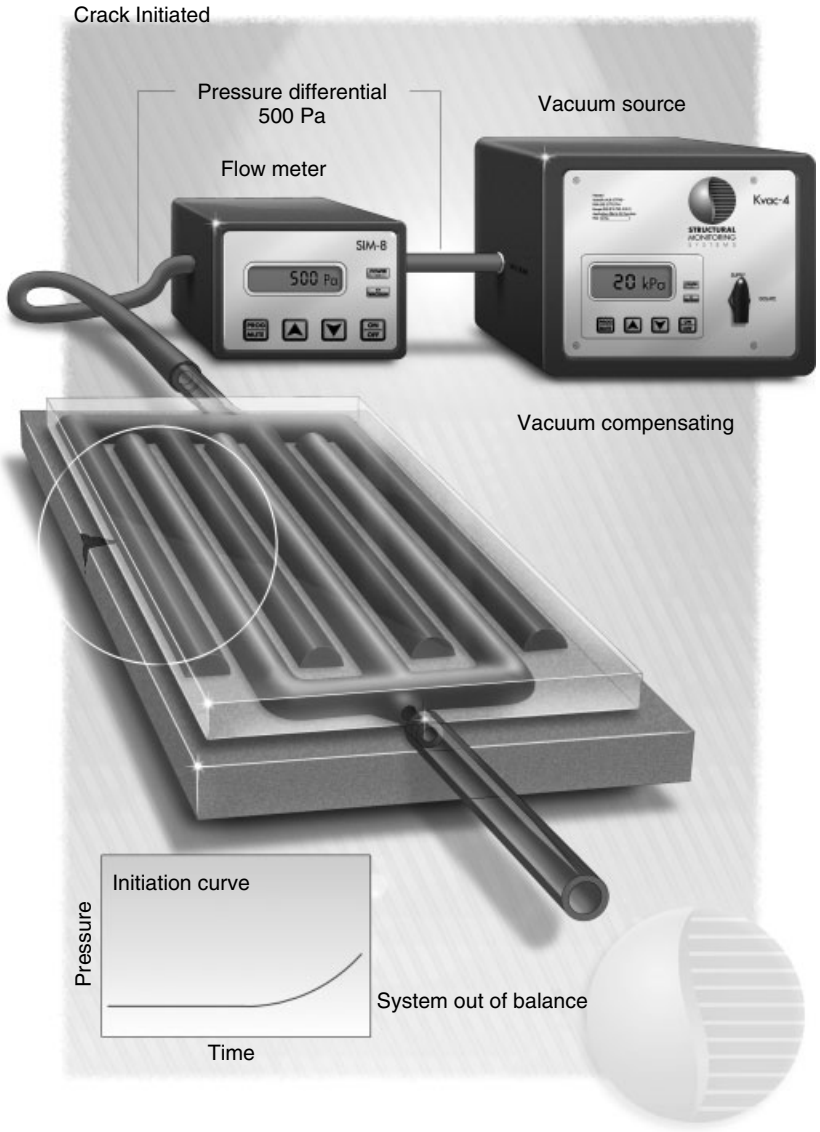

Figure 3. CVM™ system installed on a damaged component.

2.3.1 The laboratory kit

The CVM™ instrumentation was initially designed as laboratory equipment as shown schematically in Figures 2 and 3. The laboratory equipment continues to be used extensively in test programs from coupon level tests utilizing single sensors to full-scale fatigue test programs with several hundred sensors throughout the test structure and many tests in between.

The laboratory kit consists of a vacuum source, which can be reticulated to a number of flow meters, which can in turn be connected to a number of sensors. The whole system can be connected to a single computer to allow the data to be collected and stored in a standard database format. The system also includes standard analog and digital control output options to allow the instrumentation to turn off fatigue machines as soon as a crack has been detected. This

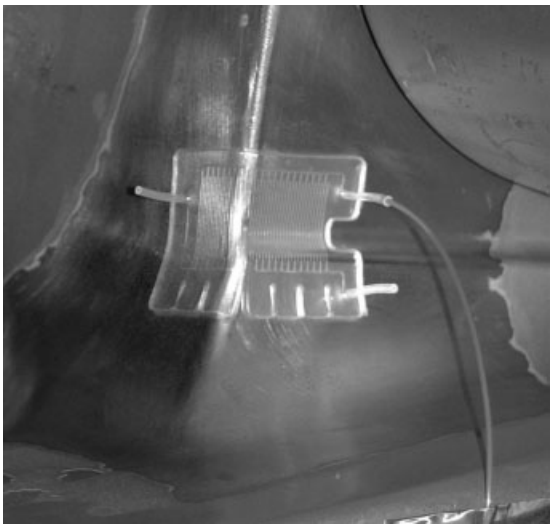

Figure 4. A silicone sensor used to detect crack initiation on a complex geometry.

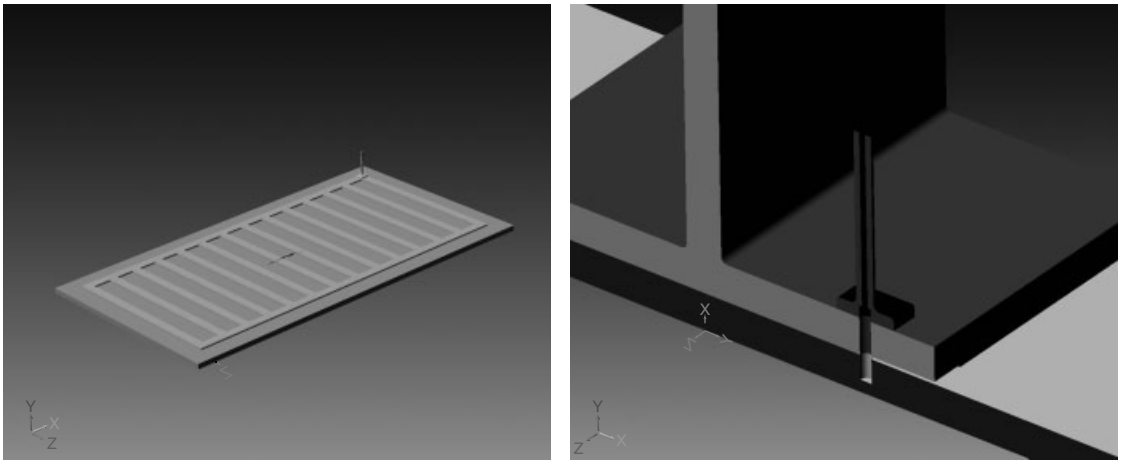
option, coupled with the fact that a sensor failure will also produce a signal to turn off the system (a large inflow of air on the rare occasion a sensor were to disbond), has allowed the system to be used to improve the productivity of a number of test laboratories that now rely on the CVM™ laboratory kit to turn off experiments left unattended during overnight testing.

2.3.2 The periodic monitor

In order to have sensors placed on aircraft quickly, an off-board periodic system of measurements was defined. Essentially, a very sensitive piece of ground equipment allows sensors permanently mounted on an aircraft to be monitored from a connector placed at a convenient inspection point. The system includes active noise dampening to remove many of the changes that can occur in a pneumatic system due to thermal and permeability changes of the air inside the tubes and of the tubes themselves and measures the conductivity (the inverse of impedance) of the sensor system in units of $m^3\,s^{-1}$.

The periodic system functionality is outlined in Figures 6–8. The sensor and connector are permanently installed on the aircraft, the sensor over a region where damage is likely to occur and the connector in a location with convenient access. The connector contains a passive microchip that is only activated when the instrumentation is connected to it. The microchip contains a serial number, and metadata including the aircraft (or other vehicle's) tail number, the sensor location, and a number of baselines required for the measurement.

When the instrumentation is plugged into the onboard connector, it automatically determines that it has been connected, downloads the data contained in the microchip, and begins the test procedure. In essence, the inspector simply needs to be able to turn



(a) (b)

Figure 5. Surface sensors for detecting BVID on composite structures (a) and a TTT sensor hole for detecting disbond in bonded composite structures (b).

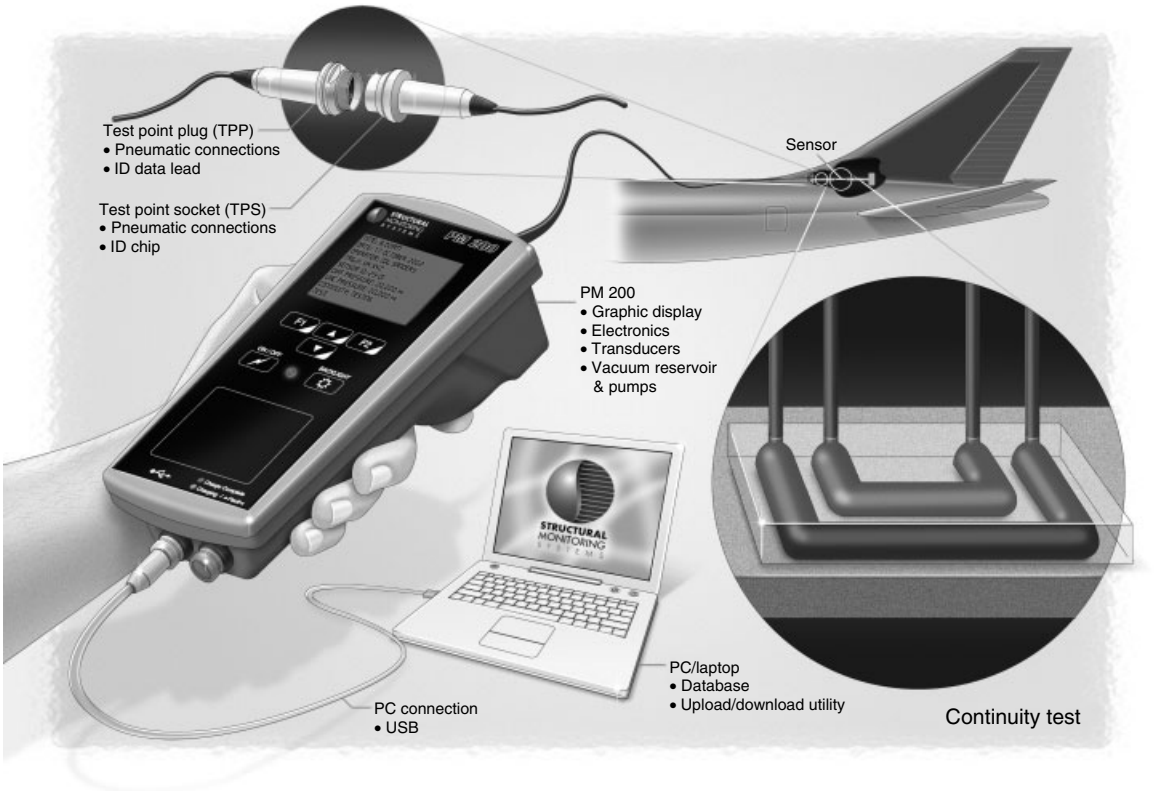


Figure 6. Continuity check of the periodic system—ensuring the sensors are not blocked.

on the instrument, select their name (pin protected), and be able to plug the system in; the instrument is otherwise fully automated.

The first test that the system performs is a "continuity" check; the vacuum is applied to one end of the sensor system and the other end is left open to atmosphere. If there is no blockage in the sensor system, air will flow through the system at a measurable rate. The actual rate is dependent on the impedance to flow of air by the sensor galleries and connecting tubing, the electrical equivalent being a number of resistors in series. The baseline value is determined at installation and a change in this value is indicative of potential system issue.

The second measurement closes the sensor system at the previously open atmosphere end, providing a sealed vacuum system (Figure 7). If the component is intact, the vacuum level will fall to the reference vacuum level obtained at installation, with a small flow of air through the system due to the permeability of the materials used.

The system is able to detect very small changes in the baseline conductivity value, which was determined at installation to allow very small cracks to be reliably detected (Figure 8). This has the required active noise dampening to remove changes in the conductivity measurement due to thermal noise (ideal gas law: $PV = nRT$ where P is the pressure (Pa), V is the volume in which the gas (air) is contained (m^3), n is the number of moles of the gas contained within the volume, R is the gas constant ($8.31441\,J\,mol^{-1}\,K^{-1}$), and T is the temperature (K)), and changes in permeability of the materials due to changes in environmental conditions. The instrumentation is able to discriminate real signals from the noise sources without operator involvement once the baselines have been determined as part of the installation process.

Figure 7. CVM™ check of the periodic system on an intact surface.

The requirement for such a high sensitivity is driven by the issue of crack closure in metallic structures. Small cracks can be closed to even the smallest flow of air due to residual stresses within the plastic zone and/or corrosion by-products if the crack is not being held open due to tensile loads in the structure. Crack closure delays the ability of the system to detect the crack, which has lead to the determination of $a_{90/95}$ probability of detection (POD) curves for the system for a number of metals (for example, see [6]). An $a_{90/95}$ POD curve is a measure of an inspection technique indicating the size of defect that will give at least 90% POD in 95 of 100 POD experiments under nominally identical conditions. The crack closure issue has not been observed in composite components; once the resin matrix has been damaged, the damage remains open with relatively large flow rates.

The instrumentation stores all the data from each measurement onboard. These data are able to be downloaded to a PC using an USB cable at the end of the shift into the system's data management software, or directly into an existing maintenance management database.

2.3.3 The CVM™ switch

The CVM™ Switch, shown in Figure 9, is the simplest of the instruments developed so far, and was originally designed to meet the requirements of the automotive test industry. The principle of the switch is identical to the rest of the CVM™ family of instruments, but the functionality has been kept to a bare minimum. The switch simply provides a factory preset alarm when a crack is detected. The alarm triggers a relay (which can operate in a latched or unlatched mode) to allow a fatigue machine to be turned off automatically and/or the time of detection to be recorded using an external data capture. The

Figure 8. CVM™ check of the periodic system on a cracked surface.

Figure 9. The CVM™ switch.

system has been designed to detect relatively large cracks (>5 mm).

A self-contained system with a CVM™ switch(es), small vacuum pump, general packet radio service (GPRS) transponder, and power supply has been adapted for monitoring the health of bridges and other major infrastructure.

2.3.4 Fully integrated CVM™ airborne monitoring system

SMS is currently working with a number of aircraft original equipment manufacturers (OEMs) to design a CVM™ system that can be fully integrated into their aircraft. The system is essentially a miniaturized laboratory system, with a regulated vacuum provided to measurement modules located close to the sensors. The closer the measurement modules can be to the sensor, the greater the amount of miniaturization

that can occur as the total volume to be monitored decreases proportionally.

The advantage of monitoring the airframe in real time, or at predetermined times during flight, is that the sensors can be monitored under ideal loading conditions, reducing or removing the effects of crack closure on metallic structures. The development program for the CVM™ airborne monitoring system will include the certification requirements for an aircraft system.

3 LABORATORY-BASED PROGRAMS

The CVM™ system has been proven in laboratory programs dating to the late 1990s [1]. The laboratory equipment has been designed for ease of use, to allow CVM™ sensors to be monitored in real time from basic coupon level tests to complex full-scale fatigue programs with Airbus and Embraer. The laboratory programs fall into three basic categories:

1. programs utilizing CVM™ to find damage in specific coupons or components;
2. programs to determine the functionality of the CVM™ system; and
3. programs to determine the robustness and durability of the CVM™ system.

3.1 Programs utilizing CVM™ systems

As CVM™ has gained acceptance as a technology, it has been utilized to detect cracks, delamination, disbond, or changes in base material properties in coupons and components in a variety of tests. Initially, many of these tests were also to determine the functionality of the system and its ability to withstand severe test conditions such as high vibration loadings.

The CVM™ sensors have been used to detect crack initiation in aircraft turbine blades [7], to detect crack initiation in Glare® lap joints [8] (Figure 10), and to monitor locations of interest in full-scale fatigue tests for both Airbus and Embraer, to name a few. The system has been used in laboratories in Australia, Europe, and United States and has allowed increases in productivity as the system can be safely allowed to run overnight; a sensor failure will switch the fatigue test off, as a disbond will cause a large amount of air to enter the system, triggering the alarm.

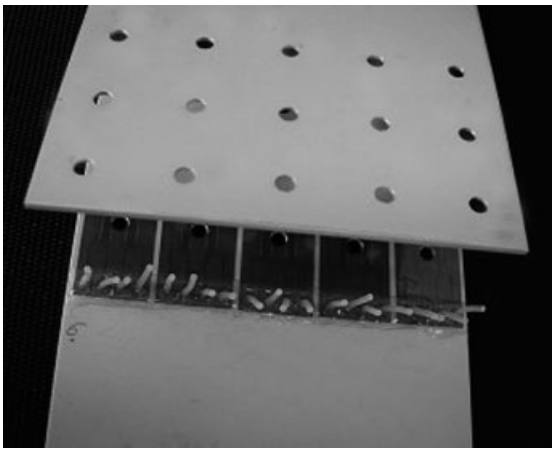

Figure 10. CVM™ integral sensors for detecting crack initiation within a Glare lap joint. [Reproduced from Ref. 8. © Airbus SAS, 2004.]

Sensors capable of being installed within lap joints to detect crack initiation from the bolt or rivet hole have also been developed [8]. The sensors were designed to detect sub-2-mm cracks required for the certification of the Glare® glass-fiber/aluminum laminate material used in the upper fuselage of the A380 aircraft (Figure 11). Standard inspection methods such as eddy-current and ultrasonic methods are not suited to such materials due to the number of reflection boundaries caused by the multiple aluminum layers. After a significant research and development program, sensors able to withstand the crushing forces below the titanium rivets used in the lap joints were developed and are now in regular use at Airbus in their test laboratories. Comprehensive testing by Airbus has shown that the sensors do not affect the shear strength, other mechanical properties or fatigue properties of the structures under test.

The CVM™ system has also been installed in programs to monitor full-scale fatigue tests (Figure 12), with large numbers of individual sensors (>100) being monitored in real time by a network of flow meters connected to a single computer.

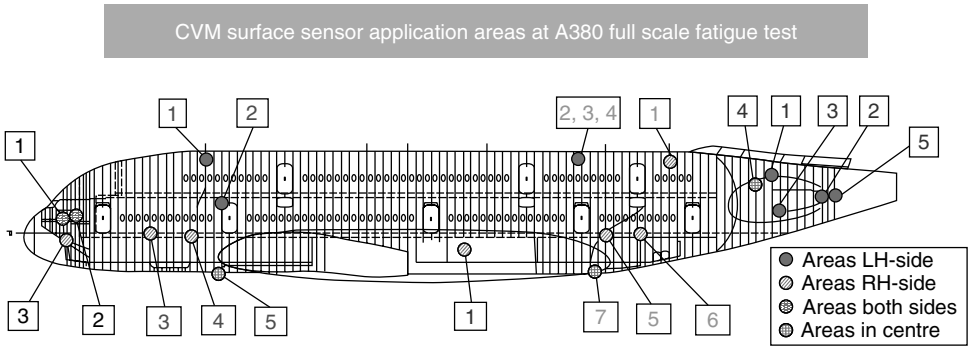

Figure 12. CVM™ sensor locations on the A380 full-scale fatigue test in Dresden, Germany. [Reproduced with permission from Ref. 8. *copyright* Airbus SAS, 2004.]

3.2 Programs to determine the functionality of the CVM™ system

A number of programs have been initiated to quantify the functionality of the CVM™ system. The real-time systems such as the laboratory equipment, the CVM™ switch and the airborne monitoring system do not suffer from the effects of crack closure in metallic structures. Many of the trials using these instruments have utilized the continuous monitoring characteristics to detect cracks in components under load and have continually demonstrated the repeatability of the system. Most of the programs remain proprietary; however [7–9] provide some useful examples.

The majority of recent functionality programs have focused on the development of a standard $a_{90/95}$ confidence curve for the CVM™ system when it is used in a periodic configuration. Crack closure will delay the detection of cracks under conditions of zero load or a compressive load. The effects are variable depending on the alloy used and the thickness of the component, but will result in the crack tip passing a small distance past the detection gallery before sufficient air can be drawn through the crack to measure the airflow with the instrumentation. Several studies have been undertaken at DSTO in Australia for the Australian Defence Force, Sandia National Laboratories for the Federal Aviation Administration (FAA) [6] and by Airbus to characterize the phenomena in a way that is easily recognizable within the aviation community.

Several test programs have also confirmed the ability of the CVM™ sensors to detect cracks in metals beneath a layer of paint. These programs have concluded that the CVM™ results are not affected if they are installed on bare metal, standard primer, and single layers of top coat. Hood and Nguyen [10] showed that thicker layers of top coat ($>60\,\mu$m) will cause a delay in the detection of the crack tip, but the measured value was less than 1.0 mm for a sensor installed on a 110-μm-thick paint system.

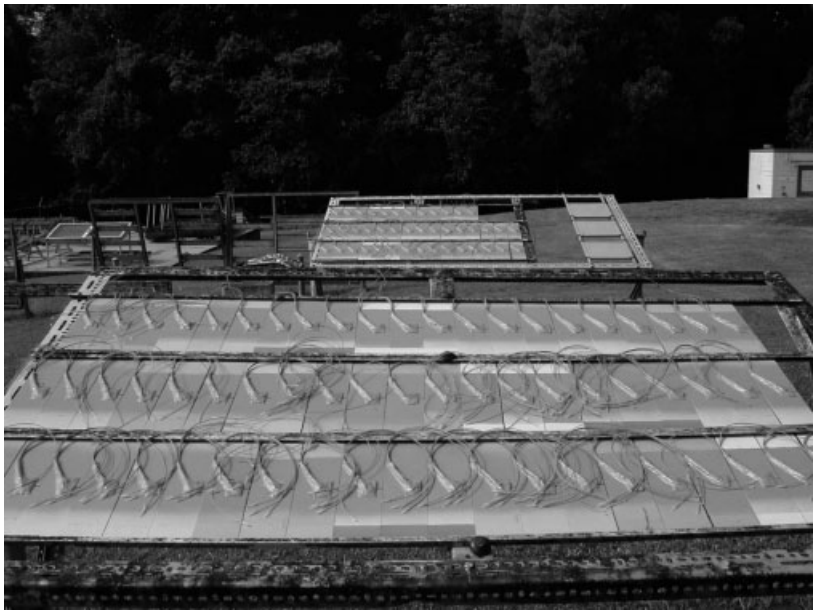

Figure 13. Test coupons experiencing hot/wet tropical conditions. [Courtesy of DSTO].

The measured delay was shorter if the paint system had aged.

The ability of CVM™ sensors to detect BVID, disbond, and delamination in composite structures has recently been explored through the SMIST and TATEM European Union Framework FP7 programs, and in projects in cooperation with the Cooperative Research Center for Advanced Composite Research (CRC-ACS) based in Melbourne, Australia [3, 11].

3.3 Programs to determine the robustness and durability of the CVM™ system

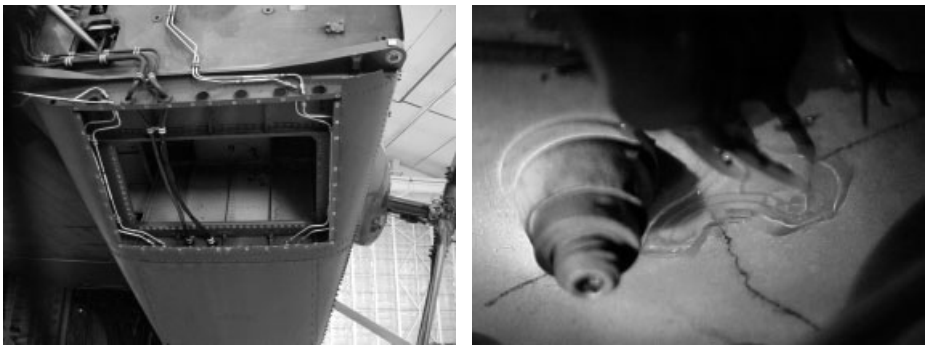
In order to ensure that CVM™ sensors were safe to be installed on aircraft and to meet future certification requirements, a number of laboratory programs have been undertaken to confirm that the CVM™ sensors meet the stringent requirements set by the aerospace community. These have usually included an in-service trial as well, which is discussed in the following section.

The first such trial program to determine if the sensors could remain functioning after exposure to aerospace conditions was conducted by the Australian DSTO [12]. Almost 250 sensors were put through a three-year program including cycling between -55 and $+100\,^{\circ}$C, immersion in hydraulic fluid and salt water, and exposure to high UV and humidity (tropical hot/wet) at a coastal environment (See Figure 13). All the coupons have been subjected to tensile loading to develop cracks detected by the sensors, to ensure full functionality of the CVM™ system at the conclusion of the exposure period.

Certification requirements have been developed through consultation with OEMs and regulatory authorities (military and civilian); the requirements for structural health monitoring (SHM) technologies to meet the requirements of the DO-160E [13] standard for environmental durability and robustness have become more evident. The various components of the CVM™ system have either undergone, or are undergoing, testing to show that they meet the various facets of the robustness and durability requirements as set out in the DO-160E standard.

4 AIRCRAFT PROGRAMS

CVM™ sensors were first installed on a US Navy H-53 helicopter in February 2002 as part of a trial program (Figure 14). The sensors were installed



(a) (b)

Figure 14. Crack location in the tail boom of the US Navy H53, with sensor installed.

in front of an existing crack in a location that required approximately 4 h to disassemble, inspect, and reassemble. This inspection was required every 25 flight hours on a large and heavily used fleet, but was reduced to approximately 5 min with the CVM™ system without any requirement to disassemble the aircraft. The system successfully detected crack growth on three separate occasions.

To date, only the periodic system has been installed on flying aircraft. The certification requirements for placing instrumentation related to the CVM™ system onto a flying aircraft are extensive, whereas only placing sensors and a small connector onto the aircraft and monitoring the system with ground equipment significantly reduces the requirements. This approach has allowed a large body of knowledge with regard to the sensor system to be developed through a number of military and civilian trial programs.

The CVM™ sensors have been installed and monitored on a number of military aircraft as indicated in Table 1.

Table 1. CVM™ military in-service trials

Country	Operator	Aircraft	Install date	Notes
US	Navy	H-53 Helicopter	February 2002	Successfully detected crack growth. One aircraft
Australia	RAAF	P3 Orion	September 2003	No cracks detected (or present) Functioned correctly for entire trial Three aircraft
Singapore	RSAF	A4	2004	One sensor installed in wheel well Functioned correctly for entire trial One aircraft
Singapore	RSAF	S-211	2004	Forty-two sensors installed throughout the aircraft Continues to function correctly One aircraft
Australia	Army	Blackhawk	April 2005	Two sensors installed per aircraft One-year trial completed successfully Three aircraft
UK	Navy	Sea King	June 2005	Eight sensors installed per aircraft Two-year trial completed successfully Three aircraft
UK	Air force	Nimrod	August 2005	Nine sensors installed on one aircraft Stress corrosion cracking detected if the fuselage is pressurized to 21 kPa (3 psi).

Table 2. CVM™ civilian in-service trials

Country	Operator	Aircraft	Install date	Notes
US	NWA	DC-9	2003	Six sensors installed in the fuel tank, and unpressurized empennage of the aircraft Trial ongoing
US	NWA	A320	2003	One aircraft
Germany	Airbus	A320	December 2006	Three sensors installed in wheel well One aircraft

As the civil aircraft OEMs have increased their interest in using the CVM™ system as a maintenance tool and, in the longer term, to potentially reduce the weight of their aircraft [14], their programs started to include installations on selected aircraft to gain experience on what is required to install the CVM™ sensors. Even on a trial basis, the paperwork to install the CVM™ sensor system can take several months and requires many of the tests outlined in DO-160E to be completed and documented. Table 2 shows a list of civilian in-service CVM™ sensor trials.

5 CERTIFICATION ISSUES

The case for SHM technologies in the aviation field has been well documented over the last decade or more and there now exist biannual SHM conferences in the United States, Europe, and Australasia. Airbus [14], Boeing [15], EADS [16], and the US Air Force [17] have all recently documented their broad requirements for SHM systems and the perceived advantages for maintenance of new and existing aircraft (*see* **Military Aircraft**; **Use of Leave-in-place Sensors and SHM Methods to Improve Assessments of Aging Structures**), as well as the possibility of introducing significant weight savings if SHM technologies can be implemented to improve structural efficiency (*see* **Design Principles for Aerospace Structures**; **Design Benefits in Aeronautics Resulting from SHM**; [14]). The primary driver in the short term appears to have improved maintenance regimes for both retrofit and new aircraft, with the goal of weight saving a medium to long-term benefit. An overview of the benefits for the use of SHM technologies in aerospace composite structures was well summarized by Scott *et al.* [18].

Although the need for SHM technologies has been demonstrated, the specific regulatory requirements for an SHM system remain vague and poorly defined. There does not currently exist a definitive list of requirements for certificating an SHM system or the organization that manufactures, installs, or supports it. The SHM system directly relates to the safety of the aircraft and as a result will need to comply with the most stringent regulatory requirements. An aerospace industry steering group (AISG-SHM) has been recently formed to address these needs and to define the requirements for SHM systems.

Prior to commencing any certification program, the airworthiness regulator must be closely involved. SHM technology maturity has, to date, been developmental; hence, regulatory involvement has been mostly by observation and professional interest. SMS is now moving from the developmental stage and has directly engaged with the Civil Aviation Safety Authority (CASA) to formally define the exact certification requirements for CVM™. There is a degree of interaction required on both the SHM-OEMs and the regulator, to ensure that both sides understand each other's requirements and a consistent certification plan is developed—one that supports the twin objectives of a business proposition on the part of the SHM-OEMs and safety on the part of the regulator. The earlier this relationship between the SHM-OEMs and the regulator is commenced, the more focused and hence more successful will be the development and execution of SHM technology.

5.1 Certification requirements

The fundamental principle of aviation certification is ensuring that aircraft and aircraft systems have

a uniformly acceptable level of safety. For civilian aircraft this level of safety is legislatively mandated around the world against a uniform worldwide standard. Military safety requirements are often either sourced directly, or closely aligned, with civilian practice. Safety, or inversely risk, is built around a total system philosophy not only controlling design requirements for aircraft and its components but also the human elements such as design, manufacture, operation, and maintenance. Consequently, to enter into the aviation industry, a new entrant must show the local aviation regulator that

1. the equipment being used is certified as meeting the appropriate airworthiness standards and
2. the entrant is certified as meeting the appropriate airworthiness standards for the types of operations being conducted.

It is only recently that papers have appeared considering the regulatory requirements for installing SHM systems on civilian and military aircraft. The papers have generally only considered the robustness and durability requirements of the system [19] using existing standards such as DO-160E. However, the certification of an SHM system requires the technology and its manufacturer to meet regulatory requirements in three distinct areas:

1. Functionality of the SHM technology
This is where it is shown that the intended purpose of the system does not adversely impact the inherent risk in the host aircraft's design over the period of installation (e.g., the SHM's crack-detection capability is acceptable to the aircraft's damage-tolerant design philosophy).

2. Fitment of the SHM technology to the aircraft structure
This is where it is shown that the presence of the system does not adversely impact the inherent level of risk in the host aircraft's design over the period of installation (e.g., the fitment of the system does not adversely affect the aircraft's weight and balance).

3. Certification of the organization
This is where it is shown that the SHM system designers, manufacturers, users, and maintainers can and do produce and maintain a product to an assured level of quality commensurate with the intended use over the period of installation. In the aviation arena, this is generally the ability of the SHM organization to design, manufacture, and support the SHM system to the level required by the airworthiness regulations.

Evidence would suggest that most SHM technology manufacturers have, to date, focused on part of the functionality of their systems without considering the equally important and necessary requirements outlined in points 2 and 3 above.

5.2 Certification of the equipment

5.2.1 Functionality of the SHM system—general requirements

In general, the certification path for any SHM system is built from a staged program consisting of three distinct steps. These steps are as follows:

1. Proving that the system works in detecting the intended target problems. This usually involves such activities as laboratory "POD" testing on simple test pieces.
2. Proving that the system works in detecting the intended target problems in the intended operating environment. This usually involves testing against environmental standards such as DO-160E [13] or MIL-STD-810F [20], "on wing" trials, and the like.
3. Proving that the system works in detecting the intended target problems in the intended operating environment for the life of installation. This involves reliability testing, system safety studies, and other similar activities.

It is proving the functionality of SHM that the understanding of the SHM concept of operations comes to the fore. An SHM system intended for use on a section of aircraft primary structure as a direct replacement for a mandated conventional nondestructive testing (NDT) technique, such as high-frequency eddy-current (HFEC) inspection, will have a much different functionality certification requirement set to an SHM system monitoring secondary structure or providing long-term research information on structural deterioration.

The relationship of SHM to standard "damage tolerance" or "safe-life" philosophies needs to be well

understood to ensure that the capability satisfies all the requirements of the different design philosophies. An interesting article by Easton (FAA) and Swift (CASA) [21], provides the most recent discussion by two regulators on how SHM technologies may fit into design and maintenance philosophies from a regulator's perspective. SHM systems are invariably compared to standard NDT techniques. This leads to a need to define their ability to detect cracks in terms of an $a_{90/95}$ POD. This may extend to requiring trials on varying thicknesses and geometries of these materials. Roach and Rackow [6] provide a summary of such a POD program evaluating three SHM techniques on a specific test coupon by Sandia Laboratory.

Combined with the (usual) SHM requirement for long term, no maintenance installation of SHM components, the random nature of system challenge (i.e., when a defect actually manifests relative to when inspections actually start), and SHM being used to support structural reliability requirements like FAR 25.1309 [22]; reliability determination is probably one of the most difficult certification challenges faced by any SHM system.

SMS is working toward certification of the CVM™ technology and the organization with the guidance of CASA. This decision was taken due to proximity of the Australian regulators to SMS' headquarters, CASA's familiarity with CVM™, and the existence of bilateral agreements between CASA, the FAA, European Aviation Safety Agency (EASA), and other regulatory agencies worldwide.

SMS has found the process of understanding and scoping the effort required to receive such organizational certifications especially enlightening. SMS has specifically employed engineers experienced in the aviation industry, who are used to operating within the aerospace organization and with relevant processes, because to outsiders its requirements can seem daunting, overly bureaucratic and complex.

6 OTHER (NONAEROSPACE) APPLICATIONS OF CVM™

CVM™ is not limited to the aerospace industry. Its sensors can be easily adapted to other industries where detection of surface-breaking flaws and damages is required. The CVM™ switch was specifically designed to meet the need of automotive testing and was launched in conjunction with a manufacturer of brake calipers to provide a significant improvement of efficiency in their quality assurance/quality control (QA/QC) test procedures. Figure 15 shows a fully instrumented caliper that is subjected to a battery of tests.

The CVM™ system is being used by a major automotive firm for track testing of their cars, providing real-time monitoring of crack initiation and growth

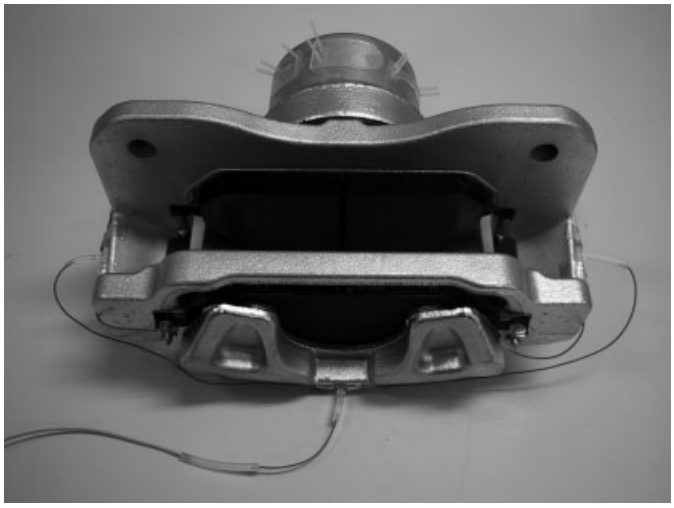


Figure 15. An instrumented brake caliper for improved QA/QC testing using CVM™.

previously unavailable to its test department. The system has been used to monitor failures of punched rivets in rail cars and could feasibly be adapted to remotely monitor structures such as bridges and ships once a business case has been identified.

7 CONCLUSION

This article provides an overview of CVM™, the vacuum-based monitoring technology originally invented by Ken Davey in 1994. The technology has been developed to monitor metallic and composite structures in the aviation industry. It has been used extensively in laboratory and full-scale fatigue programs by both military operators and civilian OEMs and has been flown in a number of in-service trial programs since 2002. The technology is close to meeting the certification requirements to allow it to be used in civil aircraft after an extensive test program including robustness and durability, functionality, and audit of the manufacturing process and facilities.

Chapter 107

Development of an Active Smart Patch for Aircraft Repair

Nik Rajic

Defence Science and Technology Organisation (DSTO), Fisherman's Bend, VIC, Australia

1 INTRODUCTION

The strong imperative for weight reduction in aircraft design typically leads to highly optimized structures that often have an increased vulnerability to fatigue failure. The risk of in-flight failure, while real, is kept acceptably low through a structural management philosophy that is prescriptive, rigorous, and expensive. For aging aircraft especially, these costs are substantial and factor significantly in the decision to retire an aircraft. The ongoing costs associated with nondestructive inspection and preventative maintenance, in particular, have fueled strong interest recently in *in situ* structural health monitoring (SHM) technology and its potential to foster a more cost-efficient, condition-based approach to aircraft structural management.

Of the many sensor technologies that have emerged with potential for application in structural health monitoring, ultrasonic approaches (*see* **Ultrasonic Methods**) using piezoelectric materials (*see* **Piezoelectricity Principles and Materials** and/or **Integrated Sensor Durability and Reliability**) have arguably received the most widespread interest. Most of these are adaptations of standard inspection strategies used routinely in medical and structural ultrasound, and differ primarily in the use of ultrasonic source and receiver elements that are permanently attached to the structure. With appropriate powering and communication functionality, a network of such elements offers a potentially powerful and inexpensive basis for continuous autonomous monitoring of structural condition.

Compared to conventional ultrasonic inspection practice strategies employing a known, stable, and fixed source of ultrasound offer important diagnostic advantages. One such strategy is acousto-ultrasonics

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 Commonwealth of Australia. ISBN: 978-0-470-05822-0.

(AU), which is described in [1] as an inspection technique where ultrasound produced by a fixed source reminiscent of a spontaneous structurally sourced acoustic emission is sensed at a separate receiving location and used to identify material anomalies within the wave path. The term has since broadened from this early definition to encompass almost any technique involving the use of elastic waves in the ultrasonic regime transduced by elements fixed to or embedded in a host. The advantage of a stable ultrasonic source is twofold. It eliminates probe-coupling variations that can produce spurious response signals. But more fundamentally, it allows for the assessment of the acoustic response on a relative rather than an absolute basis. That is, a permanently attached source/sensor pair with stable transduction characteristics allows for the response to be compared to a baseline measurement corresponding to a structurally sound state (*see* **Signal Processing for Damage Detection**). The noise mitigation advantages of a differential measurement are well known.

Interest in this form of structural health monitoring strategy has grown rapidly in recent years, both within the scientific community, and amongst fleet operators. While key underpinning technologies are yet to reach commercial readiness, there is increasing confidence that this will occur. Indeed, major aircraft manufacturers like Boeing and Airbus have expressed the intention of incorporating SHM systems in next-generation commercial aircraft. Importantly, work has recently begun on the in-flight evaluation of prototype acoustic-based systems with technology demonstrations underway on both civilian [2] and military [3] platforms.

This article describes the application of *in situ* AU technology to an aircraft repair. Repairs are an important class of problem for SHM technology for two key reasons: (i) the technology provides a basis for assessing the performance of the repair system and in the case of bonded repairs can potentially address long-standing structural certification issues; and (ii) repairs are an ideal application to foster the transition of SHM technology into the field. The latter point is worth expanding. Aircraft repairs typically present a well-defined structural problem where the parameters required for the design and development of an SHM system are known. These include the failure mechanisms to be assessed by the diagnostic regime, the mechanical loading and environmental conditions experienced in service, and the target zones of diagnostic interest, which are often localized. Information of this type is critical to a systematic development and to the demonstration of a compelling business case for the technology.

The application considered here involves a composite bonded repair developed for a critical wing structure in the F-111C aircraft [4]. The development of an SHM *in situ* structural health monitoring capability for this repair is yet to be completed, but is sufficiently advanced to underscore both the inherent promise of the technology and the broader engineering and scientific challenges that still need to be resolved.

2 ACTIVE SMART PATCH REPAIR FOR THE F-111 LOWER WING SKIN

The F-111C is a high-performance strike reconnaissance aircraft that has been flown by the Royal Australian Air Force (RAAF) since 1973. With the help of the Australian Defence Science and Technology Organisation (DSTO), the RAAF has always maintained a high degree of self-reliance in airframe support, which has led to the development of several novel and cost-effective mitigation strategies for structural problems in the aircraft. One of the more serious cases involves fatigue cracking in a critical region of the lower wing skin (LWS). The cracking initiates at a stiffener depression (Figure 1),

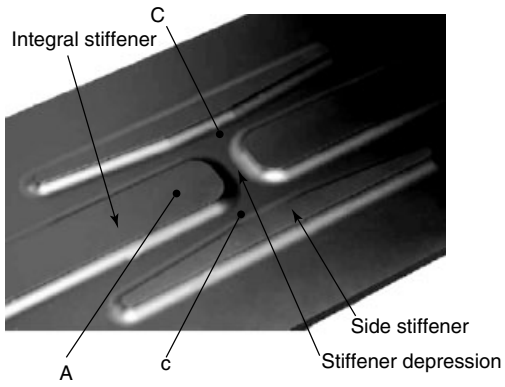

Figure 1. Structural detail in the FAS281.28 region of the F-111C lower wing skin (interior). Cracking initiates in the stiffener depression. Locations of interest labeled for reference.

conceived at the design stage to facilitate fuel flow and drainage between adjacent bays of the wing-box fuel tank. High local tensile-stresses were found to cause premature crack initiation and accelerated crack growth. If a repair could not be made, the only alternative would be to replace the wing—a very costly step.

A strong economic case made the development of a composite bonded repair for the damaged wing attractive. It was, however, an ambitious application since it involved a critical flaw in a primary or flight critical structure. Structural certification of the repair was consequently a key issue. Eventually, its compliance to strict airworthiness requirements was demonstrated through a stringent substantiation testing program [5]. However, the process proved costly and time-consuming, emphasizing that certification requirements would, in general, pose a serious impediment to the broader application of composite bonded repair (CBR) technology. This concern remains despite the long record of success of CBR technology in the field.

The certification issue led eventually to the concept of a "smart" composite repair. This envisioned a composite patch with an integrated network of diagnostic elements capable of furnishing a useful measure of the structural health and performance of the patch. Its development took several years, and, in 2006, culminated in a pioneering flight trial [6] on an aileron hinge in a RAAF F/A-18 aircraft. Structural health was inferred from strain relaxation measured in the patch using integrated strain sensors. Although effective in this application, where the patch was relatively small, the technology was understood to be generally useful only in circumstances where the location of deterioration was *a priori* known, since the strain sensors could then be placed accurately to ensure adequate coverage of the critical areas. This limitation led to the investigation of a more advanced form of smart repair called the *active smart patch* (ASP) which achieves broad-field coverage through the use of elastic waves produced by integrated piezoelectric elements.

Two diagnostic roles were envisioned for the piezoelectric network in the ASP: (i) to furnish information on the structural integrity of the bondline—the key issue for certification of composite bonded repairs, and (ii) to monitor crack growth in the parent structure. Although the first aim targets the certification issue directly, initial development of the ASP focused only on the cracking problem for two reasons. Firstly, it was thought to be a technically simpler problem partly because of the smaller area to be inspected. Secondly, despite its effect in profoundly reducing rates of crack growth, the patch does not alleviate the requirement for nondestructive inspection (NDI) of the damaged region, and indeed makes the inspection problem more difficult. Removing this requirement would both eradicate a large ongoing support cost and potentially improve the probability of crack detection by allowing a comparative basis for and removing human factors in the inspection process, important objectives in their own right. Diagnostic coverage for bondline degradation would be added as the next step in the development of the ASP.

This staged approach to the development of diagnostic functionality in the patch was deemed essential, given the limited resources available, as effort could then be made on concurrently addressing key engineering issues vital to a useful diagnostic capability, such as

- the mechanical and environmental durability of transducers;
- the structural impact of sensor embedment on the host;
- network powering and communication; and
- hardware reliability and robustness.

The ensuing discussion addresses these and other factors in relation to the development of the ASP for the F-111 LWS application.

2.1 Transducer development

One of the critical requirements of an ultrasonic transducer is that it should exert sufficient actuation authority to generate a measurable wavefield in the host. Piezoceramic materials are attractive in this respect, as is a relatively stiff mechanical coupling between the transducer and structure. This raises at least two structural implications. One is the impact of a stiff inclusion on the structural integrity of the host. Studies on laminates (see [7, 8]) have found that embedded sensors are largely benign to the host. Composite bonded repairs, however, are a separate class of problem as the elements may be embedded within the adhesive bondline, as in the particular example considered here. In general, it is

thought that the structural impact of an inclusion could be managed by ensuring that elements are placed within zones of damage tolerance and that the element dimensions are kept below a threshold size. The second point relates to the mechanical durability of a piezoceramic transducer under typical service loading. Since little, if any, scope will exist for replacing failed transducers embedded within a structure, transducer performance will, in general, need to be assured for the life of the platform. This is likely to mandate an extremely strict certification basis for the system.

Tensile strains at candidate transducer locations in the repair zone of the wing skin approach 2200 $\mu\varepsilon$ at the design limit load (DLL) [9]. At strain levels of this order, the fatigue resistance of piezoceramic materials is open to question. For example, Ref. 10 reports a deterioration in piezoelectric performance for elements embedded in a carbon–epoxy laminate loaded cyclically at a strain amplitude of 2000 $\mu\varepsilon$. Part of the deterioration in that study was attributed to failure of the adhesive bond between the piezoceramic element and the electrical interconnect, which is arguably the most vulnerable part of a wired piezoceramic transducer.

Notwithstanding concerns about the fatigue resistance of piezoceramic materials at high strain levels, which is a matter for further investigation, effort in developing a piezoceramic transducer for the ASP application focused chiefly on the creation of a robust electrical interconnect. A discourse on the development of the transducer is beyond the scope of this article. It suffices here to summarize the basic construction, which consists of a hard piezoceramic (Pz27) disc attached to an electrical interconnect layer comprising a polyimide film with conductive tracks.

Mechanical durability tests completed thus far have shown encouraging results. These tests involved bonding elements to a metal coupon that was loaded cyclically at constant strain amplitude. Electrical impedance spectra were measured prior to commencing the test to establish a baseline for the transducers, and then at periodic intervals during the test. Figure 2 shows the evolution of the impedance spectrum for a single typical element. It reveals largely stable behavior across the 25 million loading cycles despite strain amplitudes reaching 3000 $\mu\varepsilon$.

Closer inspection of the figure reveals some perturbation in the spectrum at around 20 million cycles. The precise nature of this change is clarified in Figure 3 which compares impedance spectra measured after 14 and 25 million load cycles to the baseline data. The main difference is a slight variation around the fundamental lateral and longitudinal resonances, at approximately 500 kHz and 3.5 MHz, respectively. However, the chief electromechanical indicators of failure in a piezoceramic material are a change in capacitive reactance and/or a frequency shift in the resonances, which are not represented in the data. The observed increase in strength of the lateral resonance suggests, instead, a possible

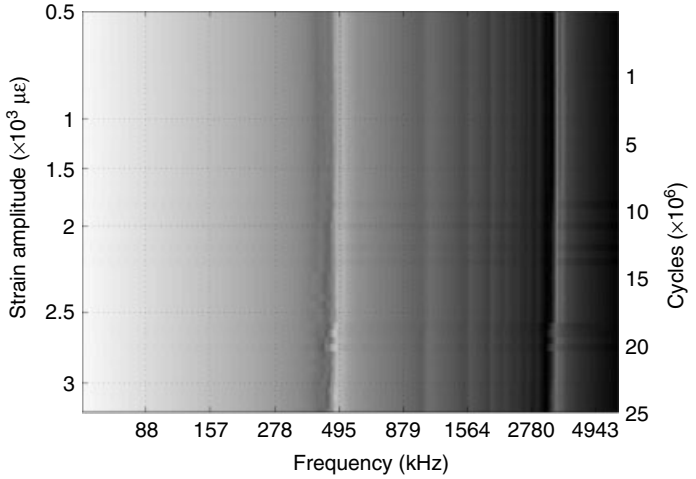

Figure 2. Evolution of the electrical impedance magnitude spectrum as a function of load exposure.

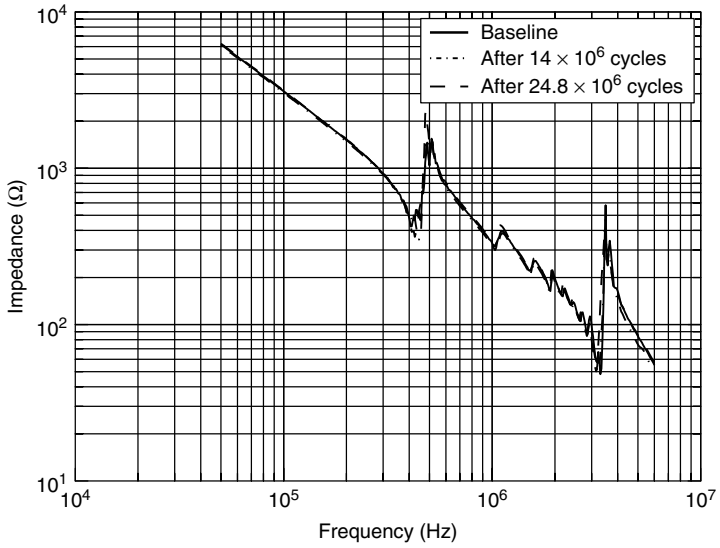

Figure 3. Electrical impedance magnitude spectrum.

deterioration of the bond between the element and the host; allowing the element to resonate more freely. Although a stable spectrum is a good result, it is important to stress that the electrical impedance spectrum provides only an indirect measure of the ultrasonic performance of a piezoceramic element. An in-depth study of fatigue resistance is currently underway that aims to measure directly the ultrasonic transduction efficiency of the elements as a function of exposure to cyclic loading.

Previous work [11, 12] has shown that factors like the transducer geometry and the properties of the adhesive bond can have an important bearing on the performance of structurally integrated piezoelectric elements. It was considered instructive therefore to examine the influence on transduction efficiency of the compliant electrical interconnect layer used in the transducer construction. To do this, an experiment was conducted, in which the strength of the elastic wavefield produced by the packaged transducer was compared to that produced by the bare constituent piezoceramic element. The elements were disc shaped, 10 mm in diameter, and were adhesively bonded to a 1-mm-thick sheet of aluminum alloy. The transfer efficiency was evaluated from the ratio of the amplitudes of the drive voltage and the out-of-plane plate velocity, measured 150 mm from the source using a laser vibrometer. The ratio is shown in Figure 4 as a function of drive frequency. With one exception, the transfer efficiency is lower for the layered element. Although undesirable, the decline is considered an acceptable trade off for the engineering benefit of a compliant and durable electrical interconnect.

2.2 Hardware

From a purely functional viewpoint, conventional laboratory instrumentation provides an adequate hardware platform for most AU inspection tasks and would do so for the current application as well. However, such arrangements are only partially effective in demonstrating the true practical potential of SHM technology. A set of ambitious but realistic design specifications were laid out for an ideal dedicated AU hardware platform, including performance, cost, and size objectives. A survey revealed that no off-the-shelf technology was available that could meet the specification, necessitating the manufacture of custom hardware. Local industry was engaged in a DSTO-led effort to develop a suitable system. The outcome was a novel device called the *AUSAM* (acousto-ultrasonic structural health monitoring array module), shown in Figure 5. The module contains two output and four input channels but is designed to operate synchronously with other units and so can accommodate larger transducer networks.

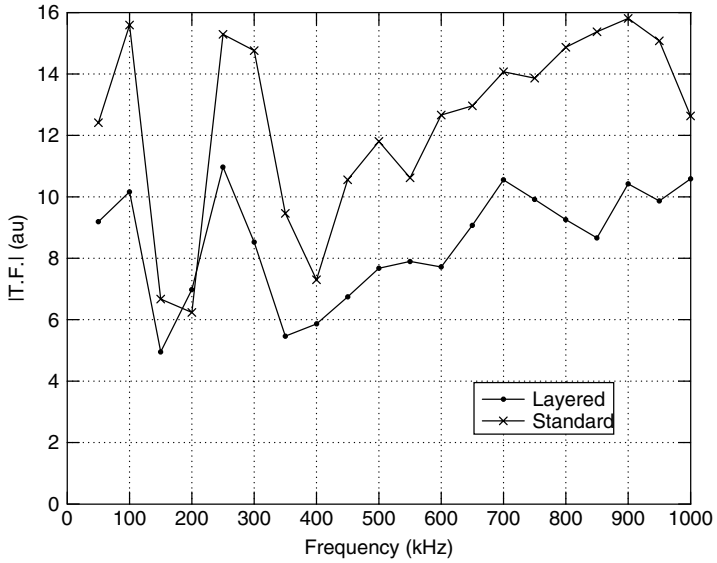

Figure 4. Measured electromechanical transfer function for a layered and bare piezoceramic disc of 10 mm diameter.

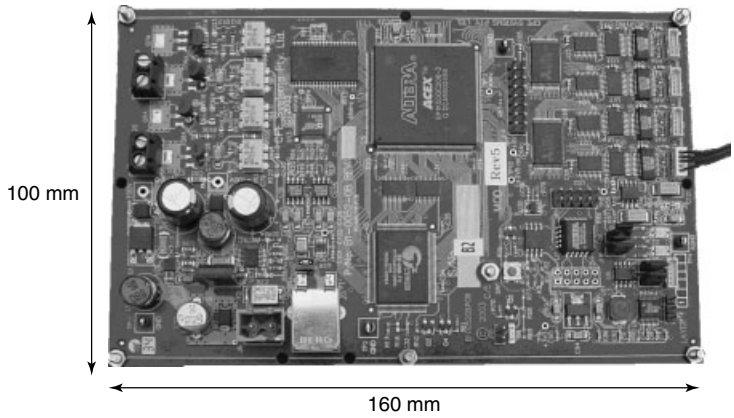

Figure 5. AUSAM device.

It links to a host (notebook or PC) through a USB connection, which also supplies all electrical power required by the device. The output channels produce a narrowband drive signal at frequencies up to 2 MHz. The drive amplitude varies with load capacitance, but is typically of the order of 100 V for a disc element 20 mm in diameter and 0.5 mm thick.

Proprietary software written for the AUSAM device allows for the autonomous control of drive and sense functions, with acoustic response data supplied periodically to the host through the USB. The transferred data is processed on line with real-time display of information.

3 FEASIBILITY TESTING OF A PROTOTYPE ASP

To address the initial diagnostic objective laid out for the ASP concept, a prototype patch was developed to investigate the feasibility of detecting simulated crack growth in a reinforced metallic coupon. The coupon comprised a 400 mm length of 6060-T5 aluminum

alloy bar stock 32 mm wide and 6.2 mm thick. The patch was produced from carbon-fiber prepreg in the layup $[+45, 0, -45, 90]_{2s}$, yielding a quasi-isotropic laminate approximately 2-mm thick. Transducers were bonded to the precured patch in depressions formed by dummy elements installed during the cure process. These were located symmetrically about the midpoint of the specimen, 170 mm apart.

The primary impetus for the development of wireless technology for sensors [13] comes from the practical challenges posed by wired installations. Problems include a susceptibility to electromagnetic interference (EMI), vulnerability to environmental and mechanical degradation, and the addition of structural mass (*see* **Energy Harvesting and Wireless Energy Transmission for SHM Sensor Nodes**). Notwithstanding the obvious benefits of a wireless approach, funding and time constraints dictated the use of conventional copper wiring in the current version of the ASP.

A key step in the design of a wired system is to identify an optimal path for the wiring through the patch. Two options were examined in this work: (i) along the bondline with an egress at the patch edge and (ii) through the patch with an egress from the top surface, avoiding the bondline entirely. While the through-ply access required for the latter option could potentially provide an ingress point for moisture, it was considered the better alternative as it would allow the entire transducer system to be contained within the damage-tolerant zone of the patch. Also, the shorter conductor length was considered beneficial in reducing vulnerability to EMI. Small holes were made in the precured patch to accommodate egress of the lead wires. Figure 6 shows an example of this wiring arrangement for an ASP installed on an aluminum coupon. In this case, the lead wires are fixed to a solder tab to allow for easy connection to instrumentation. Obviously, a less conspicuous and more robust termination would be required for in-flight applications.

The growth of a crack in the coupon was approximated by a notch, formed using an abrasive disc cutter 1 mm wide and 20 mm in diameter. Figure 7 compares, for a 600 kHz tone-burst excitation, the baseline receiver response to the response measured for a 2-mm notch depth. The pulse centered at $t = 0$ is EMI from the drive signal and provides a reference marker for the elastic waves, the first of which

Figure 6. Photograph showing egress of lead wires from a piezoelectric transducer embedded in the ASP. Wires are shown connected to a solder tab.

appears after a delay of about 35 μs, indicating a velocity of just under 5000 m s^{-1}. Reflections from the ends of the coupon are expected to arrive at the receiver after 80 μs, and were excluded from analysis by windowing the signal. The time period 60–80 μs was particularly instructive on the influence of the notch. The peak signal power deduced from a wavelet transform showed an increase of approximately 60% after the introduction of the notch. For comparison, the system noise floor accounts for a variation of about 2%. Figure 8 traces the evolution of signal power across the full range of notch depths. The growth in signal at short notch depths and the overall nonmonotonic trend are nonintuitive features that underscore the complex nature of wave–defect interaction. In light of this behavior, the development of a robust quantitative diagnostic assessment capability will require either a thorough understanding of the relevant wave dynamics or a careful calibration of the system. Both approaches involve some challenging problems. The case also highlights the value of a continuous monitoring regime in catering for system complexity. For instance, the behavior shown in Figure 8 would pose a difficult uniqueness problem under a conventional noncontinuous inspection strategy.

4 STRUCTURALLY DETAILED SPECIMEN

Compared to the idealized coupon in the previous example, the FASS281 structure constitutes a far

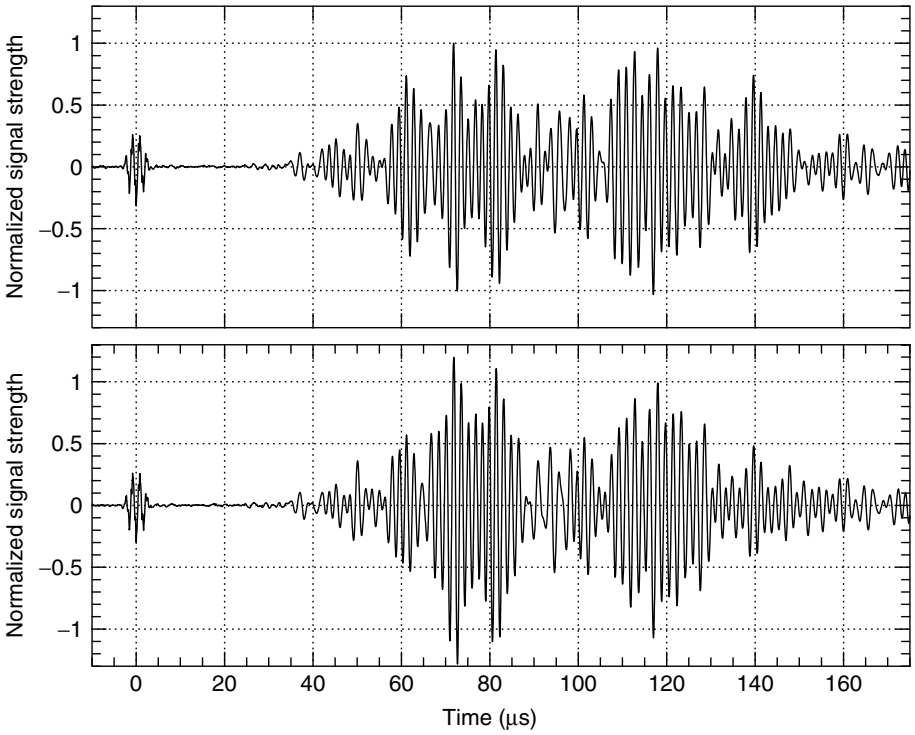

Figure 7. Receiver signal for a 600-kHz excitation. Upper trace shows the baseline response, while below is the response to a notch 2 mm deep.

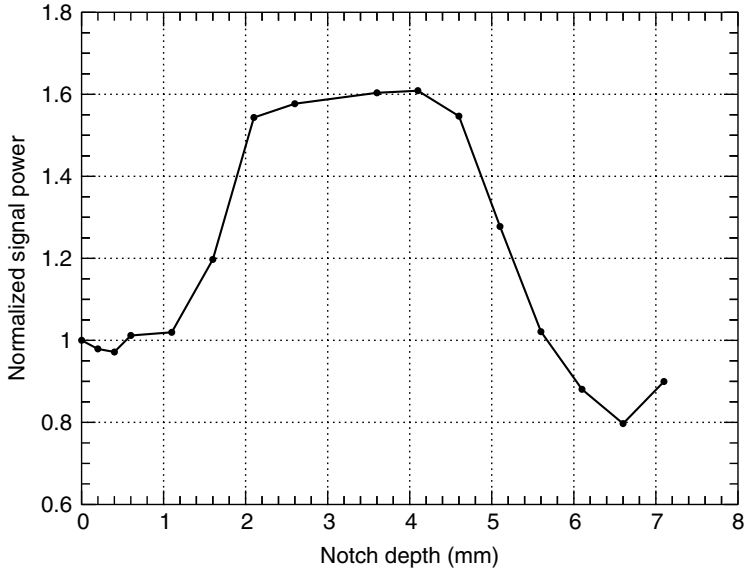

Figure 8. Variation in signal power as a function of notch depth for a 600-kHz drive frequency.

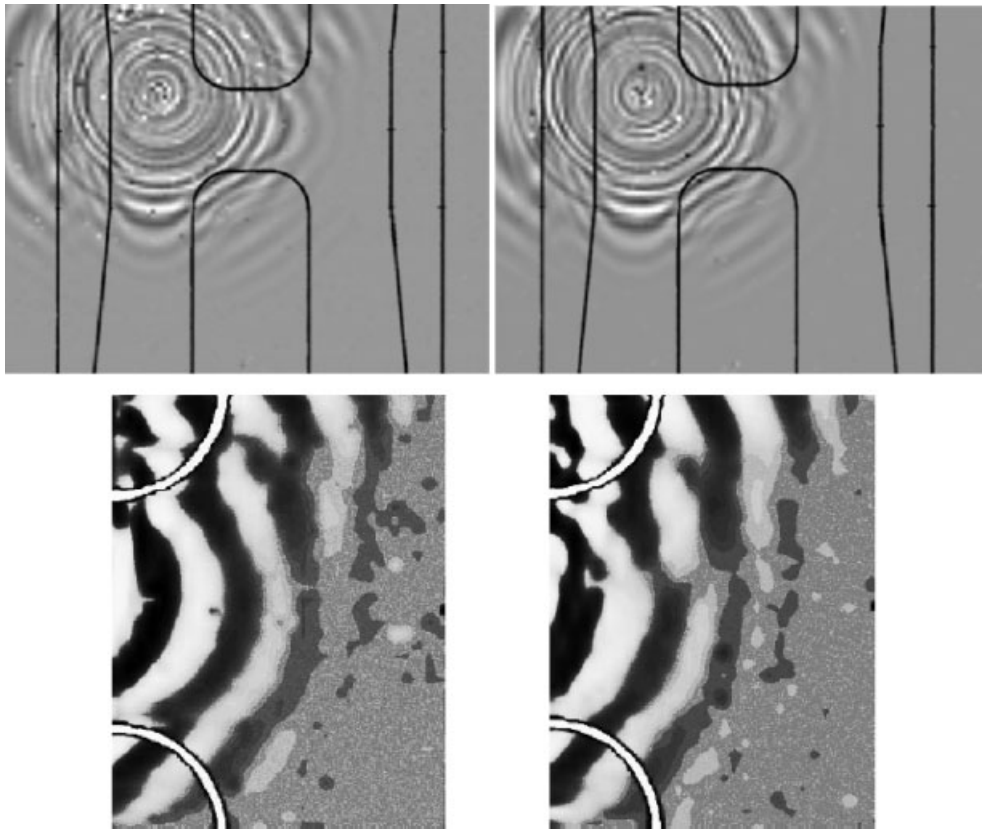

Figure 9. Velocity wavefield (a) in the absence of a notch and (b) with a notch. The bottom frames show zoomed and contrast-enhanced views of the region adjacent to the notch. The ultrasonic source frequency is 1.1 MHz.

more challenging problem, involving not only a far more complex geometry but other factors like crack closure and fuel ingress.

To help develop an understanding of the elastic wave dynamics in the LWS structure, laser- scanning vibrometry was applied to the outer (flat) surface of a structurally detailed sample for two candidate ultrasonic source locations: (i) on the main stiffener and (ii) adjacent to the depression where the panel thickness is approximately half that at the stiffener. These are respectively marked **A** and **C** in Figure 1. The panel was scanned twice, once in a baseline undamaged state and again after cutting a small notch in the depression to simulate the presence of a fatigue crack. The notch was semielliptical in profile, 2 mm deep, 1 mm wide, and with a length of 20 mm.

Of the two source locations, position **C** produced the stronger wavefield in the stiffener depression. The scan shown in Figure 9 corresponds to this source location where the excitation comprised a five-cycle narrowband tone-burst signal at a frequency of 1.1 MHz. The stiffeners produce strong scattering of the wavefield, which is fostered in part by the relatively high excitation frequency. The impact of the notch is not pronounced, but some scattering is evident in the enlarged and contrast-enhanced view of the region adjacent to the notch (Figure 9). An example of the perturbation in velocity response at an arbitrary point within this zone of scattering is given in Figure 10. The reduction in signal strength caused by the notch is more than 40%. Interestingly, the same analysis applied for the case of a 750-kHz drive frequency yields an increase in signal of about 30%. This marked difference in behavior reinforces the remarks made earlier about the complexity of the interaction of elastic waves with real structural

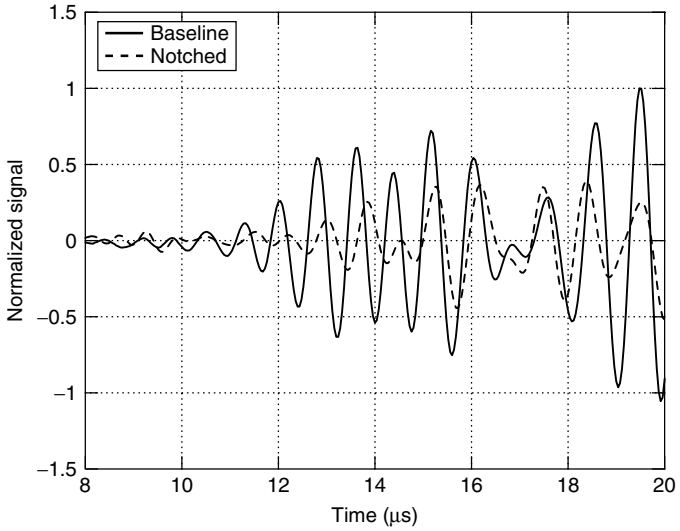

Figure 10. Perturbation in velocity response caused by the notch in the region of scattering shown in Figure 9.

features, and highlights the importance of sensor location for optimal sensitivity to crack growth.

Vibrometry scans are a useful resource for investigating candidate locations for sensor placement. In general, an optimal location will correspond to where the scattering of waves by a defect is at a maximum. The scattered field is obtained by subtracting from the measured field a baseline corresponding to the reference structural condition, which can be expressed as

$$\delta_p(i, j) = \frac{1}{\Delta} \sum_{k=k_a}^{k_b} (v^n_{i,j,k} - v^u_{i,j,k})^2 \qquad (1)$$

where v^n and v^u are the measured plate velocities for the notched and baseline conditions respectively, k is a time index, and the subscripts a and b relate to the time gate which has a width of $\Delta = (k_b - k_a)\,\mathrm{d}t$, where $\mathrm{d}t$ is the temporal sampling interval. An example of a scattered field calculated from measurements taken for a 1.1-MHz source frequency is shown in Figure 11. Three regions of apparent strong scattering are revealed; however, the two located in the left half of the image are artefacts caused by poor surface reflectivity, for example, at the coordinates (74 mm, 70 mm), where the piezoelectric source is attached. Genuine scattering is observed in the shadow zone of the notch. The elongated pattern is broadly intuitive, but is relatively narrow. Optimal placement of a sensor, in this case, would prove difficult without the guidance of a scattering map such as this. The distribution and strength of the scattered field varies significantly with the source frequency as this influences both the modal composition of and the dominant wavelengths in the elastic wavefield. Consequently, an optimal sensor location for one drive frequency is unlikely to be optimal for another. The scattering pattern will also vary with flaw geometry, further qualifying the optimality of any one sensor location.

By ignoring the presence of a repair patch on the studied panel, the analysis is only approximate. Since the wavefield in the repaired structure is expected to exhibit strong coupling between the adherends, the scattering in an unrepaired damaged panel is likely to be different from that in an equivalent patched panel. Consequently, measurement of the wavefield in the patch may not furnish a useful description of scattering from a flaw in the parent structure.

This technical limitation, as well as the laborious nature of the empirical approach provide a strong impetus for the development of a predictive elastic wave modeling facility that could provide guidance on optimal transducer placement. If modeling can account accurately for wave scattering caused by representative defects and other structural detail like thickness variations, adhesive layers, and composite reinforcements, the design process for integrated AU

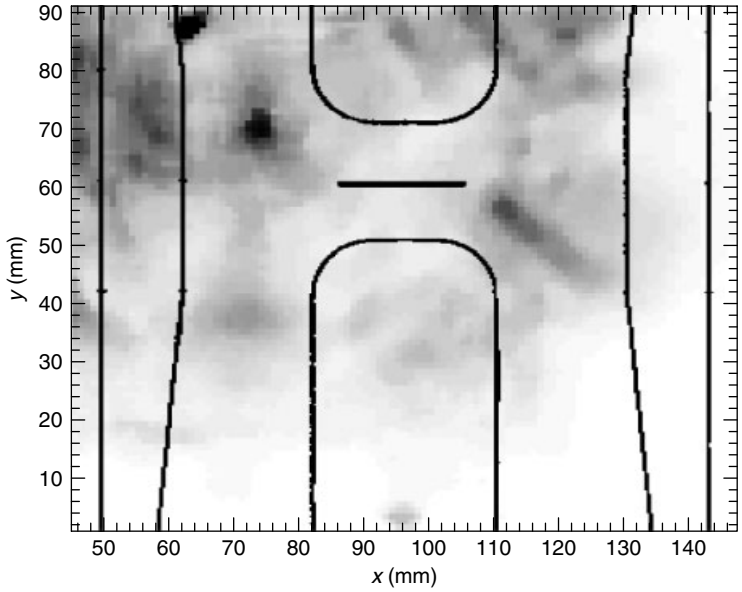

Figure 11. Scattered wavefield in LWS structure for a 1.1-MHz drive frequency.

inspection systems could be made far more efficient and would result in improved performance. With this aim in mind, finite element models of the LWS structure have been developed [14] and tested against experimental observations. The findings indicate that reconciling wavefield predictions with experimental data is difficult, and that more work on validation is needed. An example of an elastic wavefield prediction obtained from a finite element model of the LWS structure is shown in Figure 12.

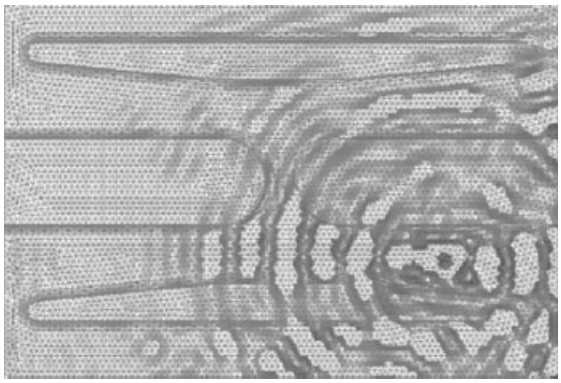

Figure 12. Finite element simulation of the displacement wavefield in the LWS structure for a circular source of ultrasound (200 kHz narrowband pulse).

5 SUMMARY AND FURTHER WORK

The development of the ASP for the F-111 wing skin application has brought into focus a range of challenging technical problems. One of these, and, arguably, the key impediment to the commercial acceptance of systems like the ASP, is transducer durability. The F-111 application is an ideal test case in this respect since it involves a realistic loading spectrum. A program is underway at the DSTO to systematically evaluate the performance of transducers developed for the ASP application under F-111 spectrum loading. Part of this effort involves an evaluation of load-mitigation strategies like the introduction of residual compressive stresses in the transducer.

Another important consideration is the potential impact of the embedded elements on the structural performance of the patch itself. While it was remarked earlier that restricting embedment to the damage-tolerant zones of the patch would likely minimize any deleterious influence, experimental work is needed to properly assess the impact of these inclusions.

One of the advantages of transducer embedment in the context of an in-flight application is the

protection it affords from the harsh environmental conditions encountered during flight, which include exposure to temperature extremes, moisture, and erosion. However, a system that interfaces with external instrumentation through a physical connection still has a point of vulnerability. Efforts are now underway to replace the wired interface of the ASP with a capacitively coupled configuration that eliminates the need for a connector. The approach is facilitated by the use of boron, an electrically nonconducting material, in the manufacture of the F-111 patch however, the approach is also adaptable to conductive materials like carbon–epoxy. Another obvious benefit of the approach is that it leaves the surface of the patch aerodynamically clean.

6 CONCLUSION

This article has given a short account of the application of AU to the development of an "ASP" repair for the F-111C, a high-performance strike reconnaissance aircraft flown by the RAAF. Laboratory testing has established that the approach is likely to yield sufficient diagnostic capability to resolve damage in the wing skin, and, in this sense, the program has produced a good outcome. However, a successful flight demonstration will require operation under both a relatively severe loading spectrum and harsh environmental conditions, issues that apply to almost all aircraft SHM systems. If the ASP can be shown to perform satisfactorily under these conditions, the scope of potential application for the technology is broad.

ACKNOWLEDGMENTS

The author acknowledges Mr Ian Powlesland for his instrumental role in creating the AUSAM device, Dr Sami Weinberg for developing the software interface, Dr Cedric Rosalie and Dr Kelly Tsoi for contributions to experimental work and data analysis, and Dr W. K. Chiu for his input to the numerical modeling.

Chapter 109
Fiber-optic Sensors

Peter Foote
BAE Systems, Advanced Technology Centre, Bristol, UK

1 INTRODUCTION

The rationale for structural health monitoring (SHM) of civil and military aircraft structures is being closely examined by aircraft manufacturers and those operators or owners who shoulder the life-cycle liabilities of these vehicles. Consensus is emerging that SHM offers potential advantages [1–3], but the choices and trade-offs involved in realizing those advantages are a subject of hot debate. Clear understanding of the "value proposition" of SHM must be achieved for individual manufacturers and operators before wide-scale adoption of the technology happens.

The trades inherent in this process range from high-level commercial and operational considerations down to choices in individual technologies and equipment. At the front end of SHM technology is the sensor or sensing principle that allows structures to be monitored in the manner required. The big ideas in SHM are that the structure can "self-inspect" and also record how it has been used and what environment it has been exposed to. The challenges for the sensor specialists, therefore, is to come up with devices that can detect accidental damage as it occurs and track its progress; detect environmental damage such as corrosion and ingress of moisture; monitor the stresses and strains during use as well as record the exposure to potentially harmful (e.g., corrosive) environments.

In this article, the role of optical fiber sensors for SHM is described. An overview of the main principles involved is provided followed by a comparison with other, nonoptical techniques highlighting respective advantages and disadvantages. Some examples of recent trials of fiber-optic sensing for SHM in aerospace are presented with an emphasis on actual aircraft installations. Finally, an opinion regarding future trends and needs for fiber-optic sensors is offered.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

2 WHAT ARE FIBER-OPTIC SENSORS?

Optical fibers were first developed in the 1970s, especially by Corning Inc., as a means of transmitting data over long distances without the need for electrical wires. Most readers will be familiar with fiber-optic cable installations in offices or as part of the spread of cable networks to homes for entertainment, Internet broadband, and phone links. However, almost as soon as optical fibers arrived, their exploitation as sensors had begun [4]. These sensors work by making use of the influence of light on the fiber by the surrounding conditions. The passage of light along the fiber can be affected by many factors such as temperature, strain, vibration, and chemical influences. The "pain" of the telecommunications technologist who would strive to avoid these is the "gain" of the sensors practitioner.

From a physicist's point of view, there are only really two properties in the fiber that can be changed by external influences, viz., optical path length and optical absorption. Nevertheless, a multitude of sensor techniques, which are relevant to most engineering disciplines and even medical applications, have emerged in the last three decades. Detailed descriptions of the operations and qualities of many of these techniques can be found elsewhere in this encyclopedia (*see* **Fiber-optic Sensor Principles**; **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**; **Fiber Bragg Grating Sensors**; **Novel Fiber-optic Sensors**).

3 AEROSPACE STRUCTURAL MONITORING

For aerospace structural monitoring applications, the requirements for sensors are driven by the same factors, irrespective of the sensors technology (i.e., electrical or optical); however, the optical approach offers some unique advantages as described in the next section.

For structural monitoring, there are three main categories of threat to structures that the sensor systems must address: fatigue, accidental damage, and environmental damage.

3.1 Fatigue

The measurement of strain at key points in an airframe allows the usage (or abuse) of the aircraft to be monitored [5] (*see also* **Loads Monitoring in Aerospace Structures**; **Fatigue Monitoring in Military Fixed-wing Aircraft**; **Agile Military Aircraft**; **Operational Loads Monitoring in Military Transport Aircraft and Military Derivatives of Civil Aircraft**). Stress levels can be calculated from strain and on this basis, it can be determined how much "life" remains in the structure before it is in danger of developing fatigue damage (cracks). Aircraft in military service have used this approach for some years, using electrical strain gauges (*see* [6], **Agile Military Aircraft**; **Operational Loads Monitoring in Military Transport Aircraft and Military Derivatives of Civil Aircraft**). Fiber-optic sensors could also perform the task.

Unexpected changes in strain across a structure can also give warning that damage has taken place. For example, if a strut or stiffener has broken away, the load will be taken up by other parts of the structure leading to a change in the distribution of strain.

3.2 Accidental damage

Aircraft can be damaged through operational misuse (overload) but more commonly by accidental collision with objects such as birds and hail when airborne, and vehicles (such as baggage trucks) when on the ground. *Hangar rash*, a term used to describe damage while the aircraft is being moved, stored, or maintained on the ground, is also common. A major thrust in SHM is the development of damage-detection methods that perform the equivalent function of detailed inspection currently undertaken manually.

Sensing methods based on the interaction of sound with structural defects such as cracks in metals and delaminations in composite materials have been intensively studied (*see* **Ultrasonic Methods**; **Guided-wave Array Methods** for more details). Fiber-optic sensors can be made sensitive to ultrasound by acting as tiny microphones. Their susceptibility to sound is simply an extension of their susceptibility to pressure and strain. Acting in combination with a source of ultrasound [7], the optical fiber can pick up sound waves traveling in the structure. If

a crack occurs, the sound waves are scattered and this change can be detected by the sensors (*see* **Stanford Multiactuator–Receiver Transduction (SMART) Layer Technology and Its Applications**; **Hybrid PZT/FBG Sensor System**; **Development of an Active Smart Patch for Aircraft Repair**).

Since the fibers can act as microphones, they are also able to "listen" to the structure. When metal or composite material cracks, it sends out pulses of sound called *acoustic emissions*. These may also be detected by the sensors [8] (*see also* **Acoustic Emission**; **Applications of Acoustic Emission for SHM: A Review**). Besides cracks, impacts caused by birds striking wing leading edges or engine cowlings, or baggage trucks colliding with cargo door surrounds could also be picked up [9].

3.3 Environmental damage

Corrosion is probably the biggest problem with aging aircraft structures. In the US Air Force alone, corrosion has been estimated to cost nearly $1.5 billion annually [10]. Although the aluminum alloy from which most airframes are constructed is carefully treated during manufacture, any corrosion prevention eventually breaks down. Sensors can be used to sniff the environment to judge how much exposure to corrosive conditions a structural item has seen (*see* **Environmental Monitoring of Aircraft**; **Aircraft Structural Diagnostic and Prognostic Health Monitoring for Corrosion Prevention and Control**). Then, by using an understanding of the chemical and the physical processes of corrosion, an assessment can be made of the likely level of damage in the monitored area. Alternatively, the sensors themselves can be constructed to experience the same degree of corrosion as the surrounding structure by making them from similar materials [11]. As these sacrificial sensors rot away, their characteristics change in a precalibrated way, hence indicating the likely condition of the surrounding structure (*see* **Aircraft Structural Diagnostic and Prognostic Health Monitoring for Corrosion Prevention and Control**).

Optical sensors can be designed both as environmental monitors [12] detecting parameters such as moisture and acidity/alkalinity (pH), and as sacrificial devices [13]. The sensor proposed in [13] works by encasing the sensor in a prestrained alloy package. As the package disintegrates through corrosion, the strain on the optical fiber is relieved, hence changing its light-transmission properties.

Composite materials using carbon or glass reinforcing fibers can also be affected by moisture, which can work its way into the material's layers through surface damage or manufacturing defects. As with environment sensors, optical fiber can be designed to sense moisture by using special coatings that react to moisture, in turn, affecting the light transmission of the fiber.

4 WHY USE OPTICAL FIBERS INSTEAD OF ELECTRICAL SENSORS?

Electrical sensors have been providing measurements for engineers since the nineteenth century. A wealth of experience and a bewildering array of devices and methods have built up during the 100 plus years since the birth of electrical engineering. Why is there a need to change to optics?

In many cases, no change is needed. Electronic sensors are constantly evolving (*see* **Nanoengineering of Sensory Materials**; **Miniaturized Sensors Employing Micro- and Nanotechnologies**) and many SHM methods push these sensors to the limits (e.g., acoustic emission detection sensors, *see* **Acoustic Emission**). However, the special features of fiber optics may prove irresistible in cases where they can clearly offer advantages of cost, weight, and measurement ability. In the highly safety conscious world of aerospace engineering, change is a costly and time-consuming business. So one can be sure that fiber-optic sensors will never be chosen in preference to tried and trusted electrical sensors unless they can offer at least one (or more likely all) of these advantages.

Here are some of the features that make fiber-optic sensors special (*see also* **Fiber-optic Sensor Principles**):

- **Immunity to electromagnetic interference**

Optical fibers are made from glass, a nonconductive dielectric material. It conducts no electrical current and is unaffected by radio or microwaves from nature (e.g., electrical storms and solar activity)

or from manmade sources. Light can travel along the fiber in electromagnetically "dirty" environments and be completely unaffected. Many aerospace environments, especially in the military, are saturated with radar and lower frequency electromagnetic interference. Electrical systems have to be carefully designed and shielded before they can function. This usually means added weight, cost, and complexity. Some environments are so bad that no electronic sensors can be used (e.g., power transformers and high-voltage switchgear systems). Fiber-optic sensors can clearly offer an advantage over electrical sensors in these conditions.

- **Low ignition hazard**

Having no electrical current flow, fiber-optic sensors present little or no hazard in combustible or highly inflammable zones such as fuel tanks and associated systems. Stringent standards for intrinsic safety must be met by electrical devices operating in such environments. Again, this adds to weight, cost, and complexity, which could be avoided if fiber-optic sensors are chosen for the job.

- **Light weight**

A typical optical fiber weighs about $30\,\mathrm{mg\,m^{-1}}$. A 1-mm-diameter copper conductor weighs nearly 80 times as much. Even when packaged, similar differences in weight between fiber optics and electrical cables are prevalent. Electrical cable often needs shielding from electromagnetic interference, which adds still further to weight. Fiber-optic cables and sensors need no such shielding. The advantages, especially for highly weight sensitive applications, such as aerospace, are obvious.

- **Small size**

The typical optical fiber is $125\,\mu\mathrm{m}$ in diameter, similar to a human hair. Many electrical sensors used for structural monitoring are bulkier than this. For example, the humble strain gauges used in current load monitoring systems aboard military jets, although based on thin film tens of microns thick, have surface areas of a few square millimeters. The vanishingly small size of optical fibers has led to their incorporation within the body of composite materials such as glass- and carbon-reinforced plastics [14]. In these cases, the optical sensor becomes part of the structure itself, realizing a "smart structure".

- **Multiple sensor capability**

This is sometimes known as *multiplexing capability*. This means that many sensors can be arranged along just a single strand of optical fiber. The most extreme examples of this are the so-called distributed sensors [15], where the entire length of a fiber-optic cable acts as an ensemble of thousands of sensor points. Temperature and strain can be measured at any point along a fiber that may stretch for thousands of meters around a structure. The measurement location along the fiber can be judged by accurate time measurement of the reflections from short light pulses as they travel along the fiber.

- **Reliability**

Optical fiber sensors, especially Bragg gratings are extremely resilient to fatigue. The silica from which they are made is a supercooled liquid and, provided it is adequately protected, does not fatigue readily. Electrical sensors are metallic and prone to fatigue just like the metal structures they are used to monitor. Sensors such as Bragg gratings also encode strain information as wavelength changes. This means that if the fiber is damaged or a connector degrades, provided there is still some light transmitted, a measurement can be made. This robust format is akin to digital signals in electronic systems. Electrical sensors such as strain gauges can give false readings if circuit voltages vary for any reason other than strain change.

Figure 1 illustrates the multisensor capability of fiber-optic Bragg grating strain sensors contrasted with electrical strain gauges.

If fiber-optic sensors are so good, why are they not being used more widely for SHM? Inevitably, they have their "downside". In addition to the natural conservatism found in safety-critical industries like aerospace, the optical sensor systems are often much more expensive than their electrical counterparts. The balance in cost per measurement point only tips in favor of fiber optics when large numbers of sensors are needed per system.

Connecting fiber optics together in dirty and dusty conditions is also a challenge. Alignment between fiber cores to a precision of less than $1\,\mu\mathrm{m}$ is called

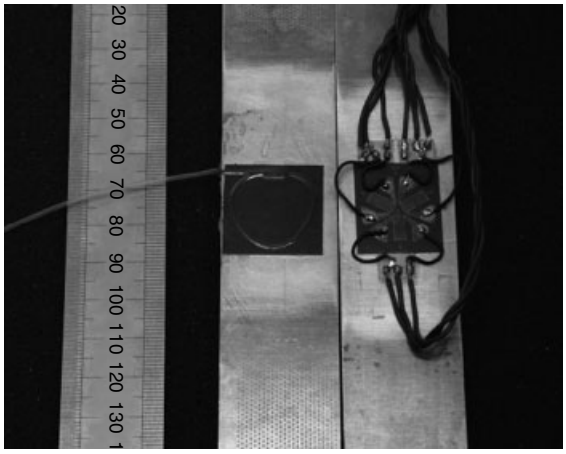

Figure 1. Comparison of a 3-axis, optical fiber strain gauge rosette (left) with an equivalent electrical strain gauge (right). Of note, the optical fiber device makes three independent strain measurements plus a temperature measurement using a single fiber connection. The electrical device requires nine connections and has no temperature measurement.

for and joining and repairing optical fibers needs specialist skills.

Much of the supporting hardware for optical sensor systems is in the form of specialized kits comprising semiconductor, laser light sources, and relatively delicate optoelectronic components. As yet, there are no industry standards or norms by which different suppliers' solutions can be compared. A discussion of specification standards and testing and application guidelines for optical fiber sensor systems is given in **Reliable Use of Fiber-optic Sensors**. The technology is still emerging, so the supplier base is patchy and typically consists of small start-up companies, often spun out of universities. This does not encourage long-term users/supplier partnerships.

However, the prospects for availability and cost of equipment are good, since most fiber-optic sensor technology draws heavily from the telecommunications business. The insatiable demand for bandwidth is encouraging the capacity of fiber networks to expand at a rate faster than Moore's law. The cost and availability of fiber-optic components has reduced by orders of magnitude over the last decade and the trend shows no sign of slowing. The commercial forces at work in the telecommunications industry will inevitably benefit the fiber-optic sensors industry.

5 SOME EXAMPLES OF FIBER-OPTIC SENSORS FOR STRUCTURAL HEALTH MONITORING

5.1 Strain sensing for operational loads and fatigue monitoring

Optical fiber strain sensors have been at the focus of many demonstrations and proposals for SHM. The hairlike nature of fibers has been exploited in trials of "smart structures" in which sensors are embedded into composite materials [14]. Behind this lies the desire to monitor loads in aerospace structures during operation to enable predictions of aircraft fatigue-life consumption.

Aircraft programs, especially in the military, are increasingly dependent on some form of operational loads monitoring to enable fleets to be managed in the most efficient way [5] (*see also* **Loads Monitoring in Aerospace Structures**; **Fatigue Monitoring in Military Fixed-wing Aircraft**; **Agile Military Aircraft**; **Operational Loads Monitoring in Military Transport Aircraft and Military Derivatives of Civil Aircraft**). The usage of individual aircraft can be monitored allowing them to be deployed around fleets so as to even out airframe fatigue-life consumption and thereby maximize the usable life of the aircraft.

Two types of fiber-optic sensors have emerged as having the most potential for this use. They are extrinsic Fabry–Perot interferometer (EFPI) and fiber Bragg grating (FBG) sensors. The EFPI sensor is essentially an optical fiber that has been cut. The cut ends are then rejoined within a sleeve, leaving a small gap between them. The gap acts as an optical interferometer. A full description of these devices is given in **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**. FBGs are modified regions [16] (typically a few millimeters long) in an otherwise standard optical fiber. The regions are exposed to ultraviolet radiation patterns to form the FBG diffraction gratings. These reflect

light of different wavelengths depending on the state of strain or temperature in the fiber at their location. A full account of these is given in **Fiber Bragg Grating Sensors**.

5.2 Relative merits of fiber Bragg gratings (FBGs) and extrinsic Fabry—Perot interferometric (EFPI) sensors

FBG sensors are an intrinsic part of the optical fiber. They require no other components to form the sensor. Methods for producing them have advanced to the point that they can be created cheaply using premade fiber without disrupting the fiber in any way [17]. This means that the fiber retains all its intrinsic strength. The EFPI devices, on the other hand, need either some form of additional components such as a housing to contain the gap between fiber faces or they require the fiber to be cut and rejoined. These processes reduce their overall strength when compared with FBGs.

Many FBGs can be multiplexed in the same fiber [18]. The only limitation in this respect is the available spectral bandwidth of the light sources used to interrogate them and the wavelength range of the fiber. EFPI sensors are more difficult to multiplex since they are not inherently wavelength selective, at least in the manner that allows them to be easily distinguished from one another. Multiplexing can be achieved but with more complex methods [19].

Both types of sensors are susceptible to temperature changes as well as strain changes. Each can be used as temperature sensors in their own right, adding to the range of structural monitoring applications. More often though, temperature susceptibility is a problem [20]. Methods can be used to overcome this in strain measurement systems by mechanically isolating sensors within an installation, so that they experience temperature change but not strain. When combined with readings from nearby sensors subject to both temperature and strain, the temperature effects can be calibrated out. EFPI sensors that have evacuated or air-filled gaps are less sensitive to temperature than FBGs.

FBGs emerge as winners in comparison with most of the other interferometer style sensors. For this reason, there is a burgeoning market for sensor systems that use them and a growing number of applications of these in engineering.

5.3 Damage detection sensors

One early use of fiber optics for damage detection in composite materials relied on the fracture of the fiber when the structure was subjected to impact. The (visible) light in the fiber would bleed from the damaged fiber and could be seen at the point of impact through the translucent glass/resin of the structure [21, 22].

While limited in practical applications, these early demonstrations fired the interest in fiber sensors for SHM for aerospace applications.

Two major categories of fiber sensors for damage detection are those based on strain changes caused by damage and those used as acoustic sensors.

5.4 Strain-based damage detection

These methods rely on the redistribution of loads in a structure that occur when it is damaged. “Far-field” strain in a structure is usually only changed by large-scale damage. Damage detection requires measurement very near the area of damage. For this reason, methods using fiber-optic strain sensors are best suited to structural “hotspots” where high stresses are expected. Bonded or fastened joints are such regions where there are high local concentrations of stress. The linear nature of these structural features also suits the long-gauge measurement features of optical fibers very well.

In one such use of Bragg gratings, a fiber containing a series of gratings has been attached to a structure along a bonded stiffener made of carbon fiber composite material [23]. As the bond between the stiffener and skin breaks, the local stresses around the gratings distort. In this case, as the break reaches each grating, its reflection wavelength is blurred or distorted in a measurable way. This indicates that the crack face has reached that particular sensor and hence the onset and progress of damage can be tracked.

A similar technique uses the effect of transverse pressure on an optical fiber in which the polarization of light in the fiber is changed by that pressure [24].

As with the Bragg grating example given above, the sensor fiber is laid into a composite structure. When permanent deformation is induced in the structure by impact damage, the forces acting on the fiber change and locally affect the polarization of light in the fiber. Using a type of interferometer to analyze the light transmitted by the fiber, the location of this disruption along the length of the fiber and hence the position of the damage can be determined.

5.5 Acoustic sensors for damage detection

As mentioned earlier, damage in structures can be detected by using acoustic sensors either to "listen" for cracks or as receivers of ultrasound in conjunction with a suitable sound source. Optical fibers react to sound pressure fields in much the same way as they react to strain; only the effects are much smaller. Acoustic fields induce much smaller and higher frequency changes in the phase or intensity of light passing along the fibers. Sound pressure levels associated with damage-detection methods such as ultrasound and acoustic emission result in equivalent strain amplitudes in optical fiber of the order of picostrain (millionths of a microstrain). The techniques for strain measurement already described are not generally appropriate for such small effects, nevertheless, a range of optical methods have been developed for acoustic detection.

The changes in optical transmission in optical fibers caused by phase changes can be enhanced simply by increasing the length of the fiber in the sensor. By coiling optical fiber around spools, many meters of fiber can be contained in a small package. During the 1980s, there was much development of hydrophones using optical fibers designed to detect extremely faint, ocean-borne sounds. These devices were exceedingly sensitive and could detect sounds at great distances [25]. Hydrophones are designed for sound detection in the low-kilohertz frequencies. SHM sensors based on acoustic methods often operate at ultrasound frequencies (100 kHz to a few megahertz), nevertheless, they can use principles similar to those used in the hydrophone devices.

Ultrasound systems using sound generators are usually based on piezoelectric transducers and fiber-optic "microphones". For these systems, the fiber-optic sensors are often simply lengths of plain fiber, which form one arm of an interferometer [26]. Since the ultrasound signals are well-defined tone bursts of fixed frequency, the signals from the interferometer are easy to distinguish from background noise.

Acoustic emission requires greater sensitivity since the emissions from, for example, cracks in metals are generally broadband and of lower energy than the signals used in ultrasound systems, however, optical sensors that are capable of detecting these signals are under development [8]. Although more difficult to detect, acoustic emissions require no accompanying artificial source of ultrasound, which generally requires electrical power to function. Damage-detection methods using just acoustic emission can be performed using optical sensors alone.

6 TRIALS OF FIBER-OPTIC SENSORS FOR SHM IN AEROSPACE APPLICATIONS

6.1 Beginnings

As yet (at least to this author's knowledge), there are no SHM systems in service that use fiber-optic sensors either in civil or military aircraft. To date, the trials that have taken place have been experimental systems to evaluate performance in ground-based tests or in the flying environment. However, the abundance of research literature, including that of leading aerospace manufacturers, portrays a consistent and growing interest in the topic. Ironically, as the interest intensifies, less may be heard in public as the work becomes more proprietary and commercially sensitive.

The ease with which fiber-optic sensors can be embedded in composite materials and attached to structures captured the imagination of sensor researchers and aerospace engineers alike in the late 1980s. Large arrays of sensors using fibers weighing just a few milligrams can be achieved. This led to the notion of "smart structures" where sensors are embedded in structural materials such as glass and carbon-reinforced plastic at the point of manufacture and act as artificial nervous systems (see Figure 2 as an illustration of the smart structure concept). As long ago as 1989, Measures [22] provided early demonstration of how simple optical fibers could be

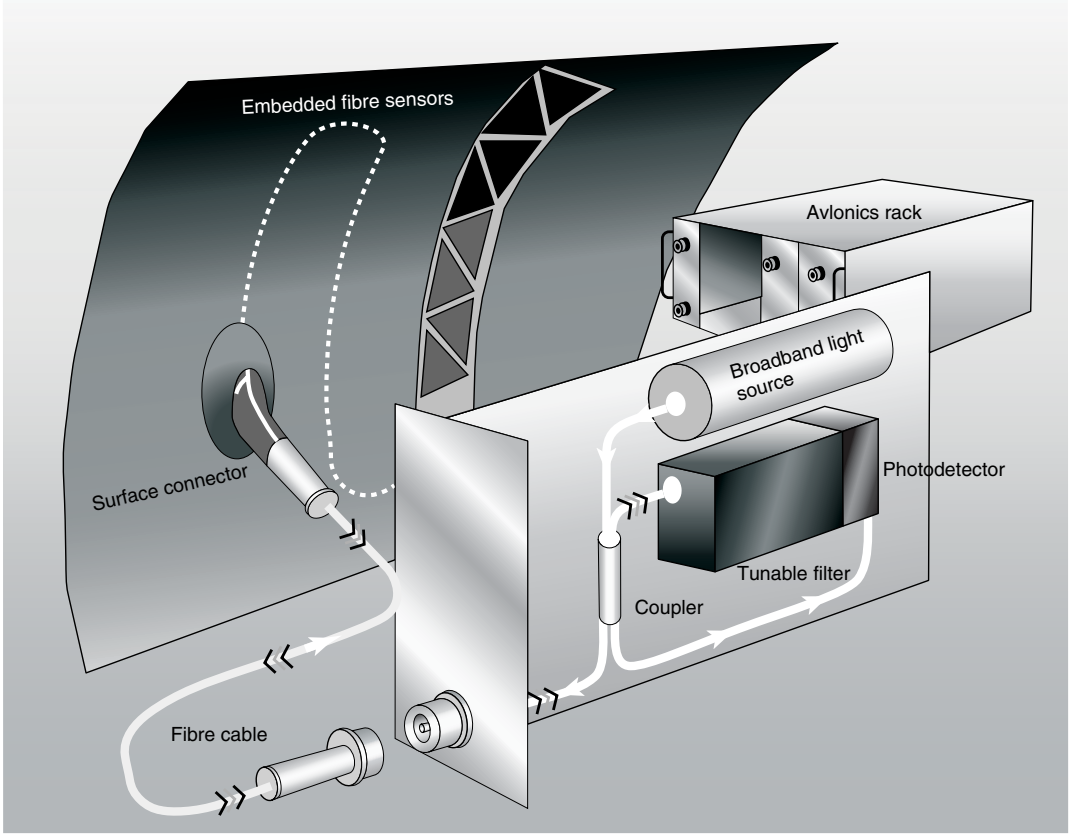

Figure 2. Smart structure concept for aerospace using structurally integrated, embedded optical fiber sensors.

used to detect the occurrence of damaging impacts in laminated glass fiber material of the sort used in aircraft construction. The sensors were modified optical fibers, buried within the material. When there were impacts of sufficient strength to damage the structure, the fiber fractured, spilling red laser light that could be seen through the translucent material in the region of damage. This was a very graphic illustration of structural damage detection using optical sensors and did much to spur on further development.

Udd [27] was also an early exponent of the smart-structure concept who, among others, proposed extending the structural monitoring principle to process control during the manufacturing stage. After the fiber was embedded, the optical sensors could detect the temperature, strain, and pressure conditions within composite materials during their manufacture and cure. This would invest such structures with "cradle-to-grave" self-monitoring capability.

Fürstenau *et al.* [28] claimed the first flight trials of fiber-optic strain gauges using a light aircraft as a flying test bed. A carbon fiber composite plate, on which optical fiber interferometric sensors were bonded, was attached to a Cessna C207A main wing spar. The strains in the plate were monitored during a series of test flights entailing varying flight maneuvers. The optical sensor performance was compared with electrical strain gauge data, thus demonstrating the ability of such sensors to operate in flight.

Slightly earlier, Murphy *et al.* [29] reported the installation and operation of a pair of EFPI optical strain gauges on a F-15, full airframe fatigue test. In this ground-based test, the sensors were bonded to the underside of the aircraft's wing, approximately 1 m from the root. The F-15's wings were deflected under static load to simulate up to 7g-loading during maneuver. Again, the optical sensor performance was

compared with conventional electrical strain gauges demonstrating the viability of the methods.

Demonstration and validation of new technology in the aerospace industry is costly, since even simple flight test equipment must still meet minimum certification and qualification requirements. The majority of aerospace trials with fiber-optic sensors are therefore ground based, but may still involve actual aircraft structures under varying conditions of flight simulation.

6.2 Developments from the 1990s to the present

Research and development activity on sensors for aerospace has slowly but consistently increased during the last two decades with active groups across the United States, Europe, Japan, and Australia. Many experiments report combined efforts from industrial and collaborative partners, which aids dissemination of results and also makes costs more manageable.

Significant development and demonstration of fiber-optic structural monitoring occurred during the NASA space plane studies for X-33 and X-38. Actual flight tests of fiber-optic strain sensing systems comprising both sensors and instrument units have been reported during the last decade. In one example [30], a combination of SHM technologies were flown aboard the NASA Systems Research F-18 aircraft. A number of Bragg grating sensor arrays were attached to this aircraft; these were positioned along the wing, including leading edge locations. Sensors were also placed in a purpose-built flight test structure attached to the underside of the aircraft. The system underwent a series of flight trials, which were part of the technology development for the X-33 reusable space plane project.

Ecke *et al.* [31] reported extensive development and testing of rugged FBG sensor installations and instrumentation for the NASA X-38 space plane program. The X-38 was NASA's prototype emergency crew return vehicle for the International Space Station. The vehicle was intended as a life-boat enabling crew to return to earth in the event of an emergency. The sensors would be required to withstand the harsh environment of space and the high loads, vibrations, and temperatures during reentry. A rugged instrument unit based on wavelength multiplexed FBG sensors was developed and partially qualified. A technique of packaging the sensors in a specially adapted organoceramic coating suitable for exposure in space environments was also developed.

Froggat *et al.* [18] demonstrated aerospace structural monitoring using FBGs in extraordinarily large numbers. Four optical fibers, each containing 500 FBG sensors were deployed on a large composite wing test. The researchers used FBG sensors with very low reflectivities and hence were able to multiplex them in large numbers along a single fiber. Each sensor could be interrogated by use of an optical frequency-domain method similar in principle to an electrical signal technique used to locate faults in long cables. Sensors of 5-mm length placed every 10 mm along the fiber were created and deployed on the test structure by bonding along structural features in the composite wing such as cutouts. A detailed map of strain distributions was achieved while the structure underwent static loading.

In Japan, extensive research into the use of optical fiber sensors in the aerospace industry is underway. Takeda [9] reports efforts in Japanese industry to advance composite structural damage detection and strain monitoring using FBG technology with small diameter optical fibers. The smaller, 40-μm-diameter fibers are more suited to embedment in composites, since they constitute a smaller inclusion than the standard 125-μm fibers and result in no loss of material strength due to their presence. Dense meshes of sensors have been implanted in composite specimens forming grids for damage detection and location. The close proximity of sensors in this arrangement allows the detection of damage by measurement of localized strain deformation. The same University of Tokyo team have also participated in flight tests of a reusable, vertical takeoff, and landing rocket vehicle. FBGs were attached to the liquid hydrogen tank and were monitored during ground test firings and also in flight. The flight test also included wireless sensor data telemetry.

Besides detection of damage and fatigue monitoring in aero structures, optical sensors can also play a role in structural repair monitoring. Metal-skinned aircraft are routinely repaired by blending out corrosion or drilling crack arrestor holes, for example. More complex repairs can involve building and fitting patches that are secured by fasteners. An alternative is to repair the damage by using

bonded patches. Qualification of this type of remedy presents problems because bonds may deteriorate, hence weakening the repair. This often restricts their use to secondary structure, hence limiting their usefulness. Repeated inspection is one way to overcome this difficulty, but this is labor and time intensive, especially if the repair is not easily accessible. Optical sensors can be used to monitor strain and hence load paths either within the body of a bonded repair patch or within the bond layer. In either case, if the bond between repair and structure fails, the load carried through the patch and its bond line will change and should be detectable using strain sensors. Davies [32] reports advances in low-cost monitoring techniques for such patches using FBG sensors. The technique uses a reference sensor bonded close to the patch but on the structure itself (Figure 3). The monitoring sensor is carefully matched (in terms of reflection wavelength) and bonded to the patch. When the repaired structure is put under load, a simple intensity-based optical system is able to detect relative changes in the strains between reference and sensor FBGs, hence indicating any deterioration in bond quality.

A challenging obstacle to the realization of fiber-optic smart structures is any standardized design and engineering guidelines for the fiber embedment processes. One aspect of sensor embedment frequently overlooked is the provision of appropriate connector technology. The point of egress, where the buried fiber emerges to the surface or edge of a composite panel leaves the fiber extremely vulnerable during the material fabrication process and during subsequent handling. Commercial fiber connectors, although very well developed for the telecommunications industry are not suited to the high temperatures, pressures, and contaminants encountered during composite manufacture. Specific component development is needed to meet these demands. Read [33] reported the development and testing of single mode, fiber-optic connectors designed to be compatible with the manufacture of aerospace grade, autoclave cured, and carbon fiber composite material. The connectors were preassembled with attached fibers and laid into the composite layers during manufacture. The components and tooling could be used by nonspecialist fabricators. Two styles of connector were trialled: a surface-emitting connector that allows fiber to be connected anywhere on a surface and side-emitting connectors that are accessed from panel edges (Figure 4).

The major commercial aircraft manufacturers, Boeing and Airbus, periodically report activities involving the use of fiber-optic sensors for SHM.

Airbus [34] have reported installation of FBG on aircraft wing and fuselage structures. An A340/600 test aircraft has been fitted with a loop of sensors around the rear fuselage, which has undergone loading during ground tests. The authors report that eight strain sensors and six temperature sensors (strain-isolated FBGs) were used. The optical sensors

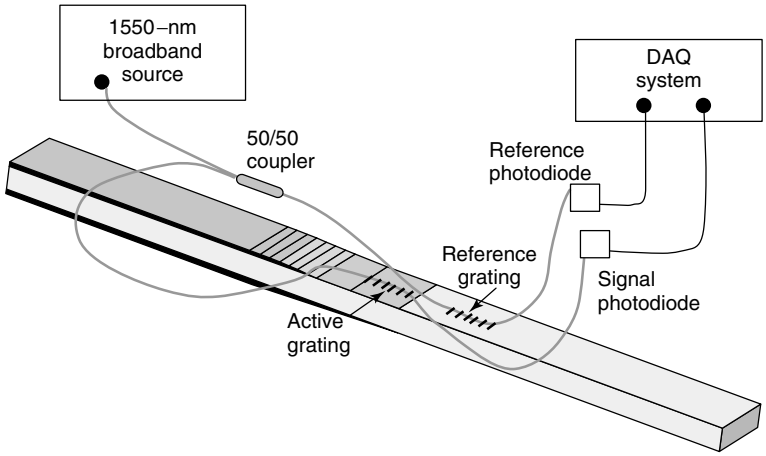

Figure 3. Composite-bonded repair patch concept using fiber Bragg grating sensors. [Reproduced from Ref. 33. © Stanford University, 2005.].

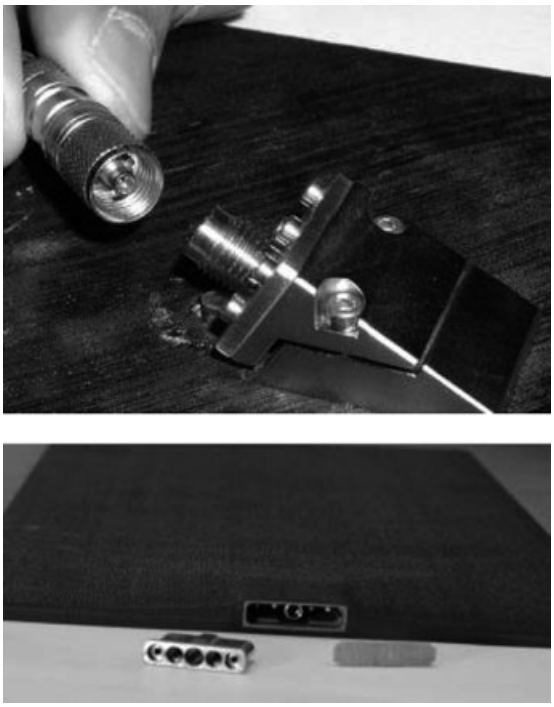

Figure 4. Optical connectors designed for fiber sensors embedded in high-performance composite material.

were bonded to the aircraft structure and the measurements produced compared with electrical strain gauge readings from comparable locations.

Boeing has reported aircraft installation of fiber-optic sensors for the detection of environmental damage in aging aircraft [12]. The fiber-optic sensors were designed to measure humidity, pressure, and temperature and were operated from a self-contained, battery-operated instrument unit. The installation was on board an aging Delta 767-300ER jet. The sensors were a mix of FBG-based devices and EFPI sensors, but the instrument unit was designed to operate with any sensor functioning on a spectral modulation principle (this includes most types of interferometric sensor as well as FBGs).

FBGs have also been evaluated in an A340/600 engine fan cowl test structure manufactured from carbon fiber reinforced plastic [23]. The sensors were embedded at the interface between the skin and a stiffener. When the structure was damaged, the gratings could be used to monitor the progression of disbond of a stringer from the main structure.

In similar trials, FBGs were attached to a large test structure comprising a fuselage barrel section based on the design of the Airbus A321 [35]. The section was made from carbon fiber composite material for the European Framework Project TANGO (Technology Application to the Near-term business Goals and Objectives of the aerospace industry). The test structure underwent static, fatigue, impact, and pressurization loading. The sensors were configured to detect impact on the structure and also to monitor any residual strain created by the impact event and thereby detect damage.

FBG strain sensors have been used to validate stress models on military aircraft airframe components within the Australian defense industry. An F/A-18 stabilator spindle (a component of one of the aircraft's control surfaces) was instrumented with both optical sensors and electrical stain gauges. The component was tested *in situ*, in ground-based airframe load tests [36].

Other flight trails were performed on a BAE Systems Jetstream 31 aircraft [37] in which patches containing FBG strain and temperature sensors were bonded to the aircraft's wing at a location on the lower leading edge. The sensors measured strain and temperature during a series of flight trials. More recently, a fiber-optic sensor system has also been flown in trials onboard a BAE Systems Hawk Jet in a flight test pod containing a range of SHM technologies (Figure 5).

A composite damage-detection system has been demonstrated for helicopter applications, this time using polarization effects in birefringent optical fiber [38]. This demonstration used polarization-maintaining fiber and a ground-based interferometer to check for permanent deformation in sandwich composite structure caused by impact damage. The optical fiber sensors were embedded in a rear deck cowling inspection door of the NH90 helicopter.

For damage detection using acoustic emission, highly sensitive transducers are needed (*see* **Acoustic Emission**). Currently, the best devices are piezoelectrical. If similar performance could be extracted from optical devices, then all of the advantages described earlier could apply to acoustic sensors as well. In an attempt to realize this performance, sensors have been built [39] and evaluated using an EFPI design. The sensor is probed

Figure 5. Recent flight tests of optical sensors aboard a Hawk military jet. A group of SHM systems, including fiber-optic strain gauges were contained in an underwing pod during flights.

by two lasers operating at differing wavelengths allowing the interferometric measurement to be decoupled from the effects of quasi-static strain. The technique is also immune to changes in temperature, since thermal effects occur on timescales much slower than the perturbation caused by ultrasound. The sensors were used to detect emissions from a barrel section structure made from aerospace carbon fiber composite after it had been damaged by an impact. After impact, when the structure was loaded in compression, the sensors detected acoustic emission from the damaged region. Similar optical sensors have also been reported [40], which use a specially made tapered and fused fiber coupler as the sensor element. Some development of techniques is still necessary to match the sensitivities of electrical sensors using these approaches.

Besides the NASA F/A-18 flight tests, a number of other programs aimed at future space vehicles have taken place. The European Space Agency Future Launcher Preparatory Program has evaluated the use of multifunctional FBG sensors to measure strain, temperature, and the presence of hydrogen [41].

EFPI sensors have also been evaluated in a program [42] targeting high-temperature measurement for reusable space-vehicle applications. The sensors were used to measure temperature and strain at up to 500 $^{\circ}$F (260 $^{\circ}$C) and were chosen because of their lower sensitivity to thermal effects and hence lower cross talk between temperature and strain.

7 CONCLUSIONS—FUTURE PROSPECTS FOR FIBER-OPTIC SENSORS FOR SHM IN AEROSPACE

The current picture of fiber-optic sensors for aerospace applications is one of unrealized potentials. Many of the unique attributes of optical fiber sensors (e.g., weight, size, and nonelectrical nature) described in this article are well suited to aerospace environments and yet they are still not in routine use. Part of the reason is the safety criticality and the ever-increasing cost sensitivity of the business. These factors often create hurdles to the introduction of new technologies such as SHM. Even though SHM has already been established in military applications, the more traditional electrical gauge devices are a first choice since they are the familiar technology.

For fiber-optic sensors to break through in this market, they must buy the manufacturer or operators a clear advantage in cost and performance. Inevitably, a "Catch-22" situation exists in which emerging business (typically small companies) will not invest in the expensive process of airworthiness certification

for their technologies until they can see a market large enough to provide a return on investment. Likewise, aircraft manufacturers will not select technology that has no proven track record or suitably qualified equipment from multiple sources. This implies a leap of faith or circumstances where the benefits of optical sensors are so compelling that manufacturers have no option but to commit.

The positive signs are that fiber-optic sensors companies are establishing markets in industries such as oil and gas, civil engineering, and wind power. This is leading to rapid maturation of the technology and consequent reduction in equipment costs, which will lower the hurdle to insertion in the aerospace business.

1 INTRODUCTION

One application where the science of fatigue prediction reaches fruition is in the management of airframe structural fatigue. Fatigue management is now critical in aircraft operations, owing to the increased production costs of many newer models exerting pressure on operators to extract as much life out of their aircraft as possible. Furthermore, inspections, modifications, repair, and aircraft replacements are all expensive activities that are often a direct result of fatigue problems. Consequently, there is much incentive for operators to have efficient structural health monitoring (SHM) systems as part of structural integrity management programs in place. The primary component of the SHM system is the individual aircraft fatigue monitoring program (*see* **Fatigue Monitoring in Military Fixed-wing Aircraft**).

The fatigue management of an aircraft starts in the design process with the application of a design philosophy, stress spectra, material data, and a damage theory to estimate the fatigue life. This estimate is then certified through a structural fatigue test, following which (or sometimes before) the aircraft operator collects service loads data [1] and puts together a management policy [2]. The process of collecting service load data is termed *fatigue monitoring* and airworthiness regulations require all fighter-type aircraft to be fitted with an onboard usage monitoring or operational loads monitoring (OLM) system [3]. In addition to specific design requirements, the United States Air Force (USAF)

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 Commonwealth of Australia. ISBN: 978-0-470-05822-0.

institutionalized the requirements for aircraft structural integrity program (ASIP) management through the development and issue of MIL-STD-1530A in the mid 1970s.

Fatigue monitoring serves a number of purposes:

- Fulfill airworthiness requirements to ensure aircraft are not operated beyond an acceptable level of risk.
- Determine the fatigue life status of a fleet of aircraft throughout its life based on an operational spectrum.
- Determine the actual service load history (since many operators have found that operational usage of an aircraft is significantly more severe than the design spectrum) to ensure that aircraft are not operated beyond the fatigue damage accumulation threshold for various components as demonstrated through full-scale testing.
- Improve or optimize the structural integrity management of the fleet (when done in conjunction with a program based on tracking each aircraft in the fleet). The assertion here is that the utilization of each aircraft is different and that using an average value is inaccurate when monitoring the whole fleet.
- Detect occurrences of structural overloads in a timely fashion, thus enhancing fleet safety; and
- Assist in the definition of a flight load spectra for new aircraft of the same type.

This article presents a summary of Royal Australian Air Force (RAAF) fatigue monitoring philosophies, systems, fatigue models, and practices for agile fighter-type aircraft. Current processes are presented and comprehensively examined, and, where appropriate, the benefits and drawbacks of the respective methods are stated. The history of fatigue management is briefly presented as an introduction followed by an outline of usage programs currently used by operators. It examines the issues of strain gauge utilization and calibration, collection of flight parameter data, data integrity, data handling, comparisons with fatigue test results, and fatigue damage models. The article also includes a discussion on the problems that have arisen in the last decade due to high angle of attack capabilities and redundant structures of fighter aircraft (for more details, see [4–8]). Discussion in this article is delineated to fatigue monitoring of fixed wing fighter-type aircraft, where military transport type aircrafts are discussed in **Fatigue Monitoring in Military Fixed-wing Aircraft** and **Operational Loads Monitoring in Military Transport Aircraft and Military Derivatives of Civil Aircraft**.

2 HISTORY OF FATIGUE MANAGEMENT OF AGILE AIRCRAFT

Many Air Forces have experienced their share of fatigue problems. For example, in the RAAF, an MB326H suffered a wing fatigue failure that lead to the loss of that aircraft [9], while two Royal Air Force (RAF) Buccaneers [10] and an USAF F-111 experienced catastrophic fatigue failure [11]. The catastrophic wing failure of the F-111 occurred in 1969 after only 100 h of flying. More recently, wings on the RAF Hawks were replaced at about two-thirds of their design life [10].

The USAF experience in 1958 with B-47 fatigue failures [12] initiated the development of an ASIP [11], Air Force Regulation 80-13 in 1976 [13], incorporating damage tolerance requirements as per MIL-A-83444 [14]. The ASIP was intended to ensure that structural integrity is a consideration from design to throughout the service life of each new aircraft entering service with the USAF. This led to the mandatory utilization of usage monitoring systems.

In the early days of fatigue management of fighter aircraft, the only means of managing the fleet was through documenting the number of flight hours or landing cycles. When the aircraft reached a certified number of hours, they would be retired. Advances in the science of fatigue allowed the development of cycle counting methods [15] that related loads and stresses to fatigue damage. Subsequently, the peak-count method (of both maxima and minima) led to the concept of the fatigue meter. Fatigue meters (also called *g-meters*) compile a count of preset positive and negative g-levels exceedances during service. Consequently, low amplitude cycles that fall between two discrete levels are not counted. Fatigue meters (or counting accelerometers) and strain range counters were developed in 1952 [16–19] and received widespread use on UK military aircraft post-1954 [20, 21]. This method was extended to range-pair

or hysteresis loop counting, which considered both the amplitude and the mean of the load [22] and pairs turning points into cycles that relate to closed stress–strain hysteresis loops. The first range-pair counter was developed in Australia in the early 1970s [23–26].

Also velocity–normal acceleration (V–g) "slides" were used to generate gust statistics for aircraft fatigue design. In the early 1950s, velocity–normal acceleration and altitude (V–g–h) recorders came into use in the United States [27–29]. Later, swing-wing aircraft identified the need for more sophisticated recording systems than the V–g–h recorder [30].

"Scratch strain gauges" were developed in the early 1970s [31, 32] as self-contained mechanical extensometers capable of measuring and recording total deformation (and thus average strain) over the effective gauge length of the member to which it is attached.

Fatigue meters are still in widespread use with many aircraft types; however, they are being superseded by modern computers and recording systems. Direct derivation of stress using strain gauges or parametric equations or artificial neural networks [33, 34] has developed in more recent times. Recently, fiber-optic strain gauges have also been applied to fatigue monitoring [35], though, not at a military fighter aircraft level.

Current fatigue usage monitoring tools are summarized in Table 1, along with their advantages and disadvantages. Manufacturers continue to develop digital systems and sensors that record more flight parameters at higher frequencies than ever before and can be or are used in fatigue monitoring. The remainder of this article critically reviews these philosophies, tools, data processing procedures, damage models, and the interpretation of fatigue test results and their application to fleet management.

Military airworthiness authorities have long understood the potential detrimental impacts of fatigue to safety, availability, and cost of ownership and have hence taken steps through structural design standards to ensure that fatigue can be tracked and managed throughout the service life. The major military structural design standards are the UK MOD DEFSTAN 00–970 [3] and the US DOD JSSG-2006 [36]. These standards provide structural design and management requirements for SHM systems and are summarized as follows:

> **DEFSTAN 00–970**:
> 3.2.21: Every aircraft in the fleet shall be provided with instrumentation for the purpose of estimating the fatigue life consumption of fatigue critical structure and validating the assumptions made during substantiation. Provision shall be made for this instrumentation during production. For those components that are not individually monitored by an advanced direct strain measuring technique, a continuous or periodic Operational Loads Measurement (OLM) programme is a condition of compliance with these requirements and shall be agreed with the relevant Service Policy Authority.
> Fatigue Safe Life Substantiation—Leaflet 35: Section 6.1: It is emphasised that all aircraft must be fitted with basic instrumentation and that a continuous or periodic OLM program is a condition of compliance with the requirements of Clause 3.12. Section 6.2: According to whether most fatigue damage is accumulated towards the top or bottom of the S-N curve, a factor of 1.5 on life or 1.2 on stress must be applied to unmonitored structure.
>
> **JSSG-2006**:
> **A.3.15 Force management.** Force management will be applied to the airframe structure during operational use and maintenance of the air vehicle. A data acquisition system is required that collects, stores, and processes data which can be used to support the force management systems/program.
>
> **A.4.15 Force management.** Verification of 3.15 and subparagraphs shall be accomplished by analyses and tests to ascertain that all requirements are met.
> Analyses. Analyses which support the force management and maintenance concepts of the procuring activity are required to verify, for each fatigue critical location, that the individual aircraft tracking (IAT) methodology is updated and well correlated to full scale durability, damage tolerance, and flight load test results.
> Tests. Demonstration tests shall be performed to verify that the data acquisition system records and processes all required aircraft systems and flight parameters necessary for the IAT methodology.

These military design requirements protect the safety, availability, and cost of ownership of a platform. The discovery of unforeseen cracking through in-service failure or via inspection to the level where residual strength is compromised has a direct effect on the ability of an air vehicle to operate and hence

Table 1. Monitoring tools

Tools	Advantages	Disadvantages
Flight hour, flight/landing cycle counting	Minimum equipment needed Simple and cheap	Assumes each aircraft flies identical spectrum (no mission variability) Cycle counting is only applicable to landing and pressurized structure Additional conservatism required to compensate for lack of fidelity
Fatigue meter (N_z-based counting accelerometer—normally augmented by pilot recorded flight time, mission type and stores information. Weight is assumed to be constant for entire flight)	Simple and cheap Lightweight Robust Minimal postprocessing required	Relatively low accuracy Only components affected by N_z can be monitored N_z is the normal acceleration usually recorded at a fixed nominal center of gravity Difficult to validate data Difficult to account for missing data Asymmetric loads not considered Fixed N_z "trigger" levels Time history is lost, hence sequence effects cannot be accounted for Weight and point-in-the−sky must be assumed (conservative) Transfer function between N_z and stress at critical location required
Range-pair counters	Relatively cheap Some data processing conducted onboard	Time history lost PITS must be assumed Difficult to validate data Difficult to account for missing data Sensor calibration difficult due to data format
Multichannel recorders (parametric systems, neural networks)	Can monitor many flight parameters Time history retained Can be used for other investigations (incidents, overstressing) May record data from other sensors like strain gauges. Allows automation of health checks Can potentially be used to tailor flying operations to minimize damage	Large loads development program required (numerous flight conditions required and equation development is time intensive and intricate) Accuracy of loads estimated outside original data set is questionable Abrupt maneuvers, gust, and buffet loads may not be accurately accounted for Expensive and normally production interfaced with flight computer and related software Prone to data spikes and errors Software and postprocessing intensive Data validation needed
Strain gauges	Directly monitors principal load component (wing root bending moment) Responsive to abrupt maneuvers, gust, and buffet loads. Directly comparable to fatigue test Accounts for weight changes during flight Fiber Bragg grating sensors, *see* **Fiber Bragg Grating Sensors** [35]: Insensitive to electromagnetic interference Higher reliability than electrical resistance strain gauges High strain resolution Not prone to electronic drift	Difficult to determine gauge locations Gauge installation and maintenance is difficult Gauges require calibration Reliability of strain gauge and amplifiers can be poor Software and postprocessing intensive Electrical resistance strain gauges are sensitive to electromagnetic interference Fibre-optic gauges need further development

impacts capability. Appropriately designed and verified SHM systems are fundamental to the retention of capability, maximization of availability, and minimization of cost of ownership. As detailed in DEFSTAN Leaflet 35, to assure safety, the omission of an appropriate tracking system reduces the service life or inspection interval by a third. The availability and cost of ownership implications of not conducting fatigue tracking are generically presented as follows:

- **Availability**

For a transport fleet or fighter-bomber aircraft, the opportunity for structural inspections is only during deeper maintenance (DM) servicing. The time spent in DM can be estimated as approximately 20% of service life. Hence, for a fleet of 24 aircraft, 5 are in DM for structural inspections at any one time. If there is no fatigue tracking system for these aircraft, then the intervals are reduced by a factor of 1.5, increasing the time spent by each aircraft in DM to 30% of the service life meaning that seven aircraft are unavailable. From an aircraft availability perspective, the penalty for not tracking results is 10% of the fleet not being available for day-to-day operations.

- **Cost of ownership**

If the basic unit price for a fighter aircraft is assumed to be US$50 million and estimating that in-service costs are approximately twice that of the initial purchase cost, then, for a fleet of 100 aircraft operated over 30 years, the total cost of capability can be estimated as

$$3 \times \$50\,\text{million} \times 100 = \$15\,\text{billion}$$
$$\text{or } \$500\,\text{million per year} \qquad (1)$$

Now assume that this fleet of fighter aircraft is based on safe-life and no SHM system exists. Assuming no reduction in availability or capability then, either more aircraft would be needed or the fleet retired at an earlier date and another purchased. As such, the total cost of capability can be estimated as

$$3 \times \$50\,\text{million} \times 100 \times 1.5 = \$22.5\,\text{billion}$$
$$\text{or } \$750\,\text{million per year} \qquad (2)$$

On the basis of RAAF experience, the cost of tracking over 30 years can be estimated as follows:

$$\begin{aligned}&\text{Initial purchase} + \text{RAAF verification}\\ &\quad + \text{in-service cost} = \$1\,\text{million} \times 100\\ &\quad + \$0.5\,\text{million} \times 30 + \$5\,\text{million}\\ &= \$120\,\text{million} = \$4\,\text{million per year}\end{aligned} \qquad (3)$$

Hence, the cost of not tracking is approximately $250 million per year, compared to the cost of tracking of $4 million. While this example is simplistic, it indicates that the benefits of fatigue tracking far outweigh the cost by approximately one to two orders of magnitude.

3 FATIGUE MANAGEMENT PHILOSOPHIES

Operators do not follow one standard method of fatigue management as no detailed specifications exist. Design philosophies that feed into fatigue management programs are varied, fatigue test results are interpreted in different ways and different scatter factors are applied to the fatigue test spectra and fatigue test result. Operators continue to "experiment" with a number of fatigue monitoring tools as the technology changes rapidly. Some collect raw data while others process the data on board the aircraft. Others calibrate the data and the fatigue damage model to determine the crack lengths or fatigue indices and few operators use the same fatigue damage model [4].

An objective of fatigue or structural integrity management is to ensure that the life of the type of an aircraft at least meets the operator's planned withdrawal date [9], under normal operating loads and within approved flight limitations without collapse or unacceptable deformation. The philosophy to be followed to achieve this depends in part on a number of factors such as the ability to inspect and repair or replace the component and the result of complete failure of a component. The fatigue management process starts with a design philosophy that incorporates these factors.

As an example, RAAF aircraft structural integrity (ASI) management incorporates a combination of safe-life and damage tolerance philosophies for the

various aircraft as described in each aircraft's aircraft structural integrity management plan (ASIMP), e.g., [37]. In the case of the F/A-18, a safe-life philosophy is used, with a safety-by-inspection approach applied to extend the service life of inspectable structure in the aft fuselage structure. The F-111, which began service in Australia in 1973, was initially managed on a safe-life basis, but later, a safety-by-inspection approach was justified through analytical calculations, a durability and damage tolerance analysis, and proof load testing [9]. (The safety-by-inspection philosophy is equivalent to a damage tolerance philosophy.)

The aircraft design philosophy, however, is but one aspect of the overall fatigue management process. The fatigue management process should also

- consider that fleet aircraft cannot be operated beyond the factored equivalent damage accrual demonstrated in a fatigue test and any life extension must be substantiated by further fatigue tests to determine the next critical location (appropriate repairs followed by testing to failure is required);
- seek to manage fleet structural integrity based on fatigue test results;
- incorporate a load monitoring program on each aircraft to routinely measure load cycles in primary structure (as opposed to "hot spots" [8]);
- employ an economic and reliable fatigue monitoring system;
- ensure data integrity;
- include the calibration of operational data with fatigue test data;
- consider the method of processing fleet data (i.e., either raw data collection for ground-based processing or onboard processing);
- include a damage model that provides an accurate estimation of fatigue accrual on a scientifically robust basis; and
- provide the operator with regular feedback.

These elements are considered in the following sections.

4 INDIVIDUAL AIRCRAFT MONITORING PROGRAMS

Among other factors, the variation in the operational loading experienced by a fighter-type aircraft throughout its life and the need to identify operational overloads make IAT programs necessary. Furthermore, to assess the consumed fatigue life of an aircraft structure, knowledge of the actual load experienced by that structure is essential [38]. And even where a safe-life may be stipulated, some aircraft are retired at a different number of flight hours due to their calculated rate of fatigue damage accumulation being higher or lower than the target rate because of operational variations.

Prime factors driving IAT are the unique combination of loads experienced by different aircraft in the fleet and the availability of a good onboard monitoring computer. Traditionally, it was assumed that if the fleet N_z load factor exceedances matched or were within that of the design spectrum, the aircraft could safely be operated until the original equipment manufacturer (OEM) promulgated design life. Today, however, each operator of modern aircraft is likely to have a different usage spectrum to the design spectrum. The wing root bending moment (WRBM) is the primary factor to monitor instead of N_z (due to nonlinear aerodynamic and adaptive controls) and a fleet-wide average load spectrum is not viewed as being accurate enough for agile combat aircraft [39, 40], unless severely limiting unmonitored factors are applied.

While heavy military transport aircraft have very strict mission profiles, agile fighter, trainer, or attack type aircraft are well known to experience substantial variability in their missions (see [41] and the next section). Therefore, they cannot be tracked on the basis of mission hours alone and it is the authors' view that an IAT program is necessary for agile combat-type aircraft. For the RAAF F/A-18 fleet, IAT is conducted with every F/A-18 in the fleet instrumented with the same basic operational usage system, this being the maintenance signal data recording system (MSDRS) [40].

One of the greatest benefits of an IAT program is that loads monitoring can take place without a prior knowledge of the exact critical location. Ideally, provided that a sufficient number of primary load carrying structures are routinely monitored, stresses at all critical locations could be determined from strain surveys and/or finite element modeling, with a transfer function relating the monitored load to the critical location stresses. Therefore, a change in the critical location can be accommodated through

the development of a new transfer function to the new critical location.

Some of the benefits gained from the RAAF IAT program is that it enables

- a comparison between design and usage spectra for each aircraft;
- an estimation of the fatigue life or damage status of major components on each aircraft based on loads monitoring in the primary structure of that aircraft and related to fatigue test results;
- planning maintenance actions according to fatigue life estimates;
- modifying operations to stabilize the rate of fatigue life consumption;
- building an operational load database, in conjunction with flight trials, for application to a fatigue test and to compare with early fatigue test data, e.g., [42];
- identifying the variability in response between aircraft in the fleet under the same flight conditions through the assessment of mission severity, effects of stores, and point-in-the-sky (PITS) affects;
- gaining a better understanding of the loading environment (in conjunction with flight trials data); and
- obtaining a better understanding of issues introduced by buffet and structural redundancy at vertical tails [8].

Data obtained from IAT programs can also be used to

- better design future aircraft or be smart buyers in the acquisition of new aircraft for the same role; and
- define (in conjunction with flight trials data) which parameters might be measured on new aircraft or new systems for the same aircraft to allow more accurate calculation of the fatigue life of critical structural components.

4.1 Fleet usage variability

Once critical locations are identified in the design stage and in fatigue tests, IAT programs are used to accumulate and analyze load data from each aircraft in the fleet to predict the damage status at the critical locations. Hence, the fatigue life status of each aircraft throughout its life, based on its own operational load spectrum, is determined. From this information, the amount of fatigue life consumed and the remaining life for each aircraft in the fleet may be calculated independent of other aircraft in the fleet.

Calculating a life based on individual spectra, reveals a wide spread in the rate of fatigue usage as shown in Figure 1 for RAAF data collected over 135 000 operational hours on over 70 F/A-18 aircraft. The fatigue accumulation rate is the individual aircraft fatigue damage value, calculated using

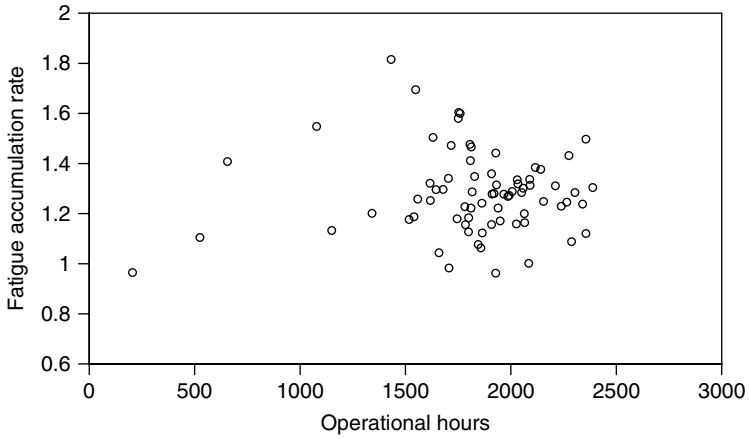

Figure 1. Rate of fatigue damage accumulation for a fleet of aircraft. (The fatigue accumulation rate is the individual aircraft fatigue damage value normalized by the aircraft's operational hours.)

the standard RAAF F/A-18 method, and then normalized by the aircraft's operational hours. It can be seen that using a fleet average would be unwise since some aircraft accrue fatigue damage at almost twice the rate of others. The figure also shows that left unchecked, these trends do not "average out" over the life of the fleet. Of significance, Figure 1 provides an opportunity to assess the 1.5 unmonitored factor required by DEFSTAN. The mean accumulation rate in Figure 1 is approximately 1.3, and applying a factor of 1.5 to this figure provides $1.3 \times 1.5 = 1.95$, which captures the outliers in this sample. As such, the scatter observed in Figure 1 supports the 1.5 factor provided by DEFSTAN.

4.2 Comparison between design and usage spectra

It has previously been stated that "if differences in mission mixture between aircraft remain systemic and significant, there is a case for individual airplane tracking" [41]. This systemic difference is now common and very significant in agile fighter aircraft. In fact, it is rare for two agile aircraft of the same type to experience identical loads for the same type of mission; hence, the need for IAT to examine usage spectra is justified.

New aircraft are serving multiple roles and expectations of enhanced performance are leading to higher operational demands being placed on them. Hence, the operational spectrum of a new aircraft type may be expected to be more severe than the same aircraft type just retired from the fleet. The experience of many operators is that the average usage spectrum is more severe than the design spectrum [41], as was the case initially experienced in the RAAF F/A-18 fleet, as indicated in Figure 2.

Operational loads spectra may be more severe than the assumed design spectra due to variations in the role, the way the aircraft is operated (pilot technique), weight growth, or more severe maneuvers being experienced for the same given mission. Their definition can be useful in identifying trends in aircraft usage, to determine whether the flying has become more benign or more severe, and to schedule operations accordingly.

4.3 Maintenance action

IAT programs can further be used to establish the inspection and modification requirements, and schedules for fleet management, to reduce the cost of unscheduled repairs or extend servicing intervals. In addition to a safety related structural failure, the last thing a military operator wants is an unanticipated detection of "damage". In RAAF experience approximately 10 years is required to plan and implement a fleet-wide structural modification program. Since IAT allows individual rates of fatigue usage or crack growth rates to be estimated, inspections, repairs, or any other maintenance action can be carried out based on accumulated fatigue values or crack lengths

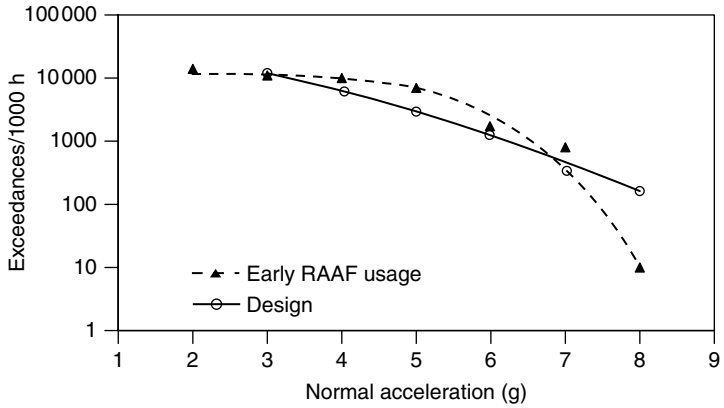

Figure 2. Comparison of design and operational usage for early flying on a RAAF combat aircraft. [Reproduced from Ref. 4. © Wiley-Blackwell Publishing Ltd., 2000.]

instead of flight hours or other simplified usage monitoring. If operational usage is found to be less severe than design estimates, the incorporation of structural modifications, repairs, or inspections based on design certification testing can be delayed. IAT programs can also highlight when operational limits are exceeded and identify the need for maintenance action.

4.4 Modify operations

IAT is particularly useful if large variability exists between squadron operations, between missions, and perhaps between pilots. With agile fighter aircraft, missions of the same type will lead to the accumulation of different amounts of damage [41]. For example, current RAAF F/A-18 operations are broken down into 44 different types of missions. A breakdown into mission type has revealed that the variation in fatigue damage accrual rate within a mission type is substantial (at least one order of magnitude). In fact, the variation seen within one mission type can be as large as that between missions [41]. Hence, it cannot be assumed that a change in mission from one type to another will necessarily result in less fatigue damage for fighter aircraft.

IAT can be used to determine how the structural life of an aircraft varies with aircraft operations. These can be customized (by varying the PITS flown) to meet operational and maintenance needs or to determine the cost of specific operations. Particularly damaging flight regimes may be identified and their occurrences may be reduced.

IAT programs also allow for identification of usage trends over time at fleet, squadron, mission, or pilot levels. The effect of changes in roles, mission types, and mission content on the fatigue life can all be examined and appropriate changes to aircraft operations can be made if warranted.

4.5 Operational loads measurement

While the IAT program means that all aircraft are fitted with the same standard equipment, it is also beneficial to have at least one aircraft in the fleet equipped to perform a loads development or strain survey program. In the RAAF, the F/A-18, Hawk 127, and F-111 fleets have at least one aircraft each fitted with the standard IAT equipment as well as additional strain gauges, accelerometers, and sophisticated data acquisition systems for loads development work. In the case of the F/A-18, one of the fatigue critical locations are the three center fuselage bulkheads, which absorb the wing bending loads, and it is worthwhile collecting flight data at these locations to verify the loads used on the fatigue test.

4.6 Aerodynamic buffet

A major performance improvement to fighter aircraft over the last two decades has been the increased angles of attack that they have been able to achieve. This improvement has given rise to unsteady aerodynamic buffet loads that excite the flexible modes of the wing and empennage. This has led to structural problems with the F-111 TACT [43], F/A-18 [44], F-15 [45], Jaguar [46], Hawk [47], T-45 [48], and numerous other aircraft. IAT and flight test programs can also be used to examine phenomena such as outer wing and empennage buffet and their effects on the fatigue life of critical structure. With sophisticated fatigue monitoring systems such as those on the F/A-18, an extensive database was developed to identify the conditions at which these phenomena occur and to further investigate the problem.

Fatigue monitoring of the vertical tail can be difficult due to complexities such as buffeting, a redundant structure and nonlinear relationships with the normal acceleration at the aircraft's center of gravity [49]. Strain gauges have been fitted to the F/A-18 empennage for the purposes of fatigue monitoring. Time spent in certain fatigue-damaging angle of attack and dynamic pressure regimes have also been examined [44] to quantify buffet affects.

5 FATIGUE MONITORING SYSTEMS

Historically, substantial effort has gone into system design, manufacture, and data collection in fatigue monitoring systems. However, the rapid improvement in the computing power of structural fatigue monitoring systems has also led to a sharp increase in the amount of data collected and thus in the costs involved with data processing, software development,

and data analysis. Importantly, the integration of the fatigue monitoring systems with aircraft software can be problematic, as even simple changes to the flight critical software are expensive and difficult to implement. Therefore, to minimize the effort required in modification and data processing, there is an incentive for the operator to choose the right monitoring system at the outset.

In fleet operations, the accuracy of the fatigue life or crack length prediction depends primarily on two factors, viz., the fatigue monitoring tools that are used in the IAT and the accuracy of the model being used for the prediction. Usage monitoring, based solely on recording "administrative" parameters such as flight hours, mission type, mission duration, pilot name, configuration, takeoff, and landing weight have been used in the past. However, the advent of sophisticated data acquisition systems has lead to more accurate methods being developed. Flight hour or N_z counting are poor options (Table 1) for modern Air Forces operating technologically advanced fighter aircraft. The individual and combinations of tools used vary greatly among aircraft and even among operators of the same aircraft [4]. The most popular combination consists of a strain gauge–based system supplemented by flight parameters as recommended in references [4, 8].

When considering the tools to be used for fatigue monitoring, aside from the cost, perhaps the most important considerations are the volume and accuracy of the data. Other factors such as maintenance of the system, data compression, data integrity, data retrieval, upgrade cost, size, and weight must all be considered. Modularity of the system, the number of channels, memory, programming, and data sampling frequency must also be given consideration. Many aircraft today are undergoing avionics upgrades, and fatigue monitoring systems are being reviewed with these upgrades. Sampling rates of the systems are increasing and "megasamples per second" are common. Parameters should be sampled at sufficiently high rates to account for dynamic loading. Fleet structural integrity managers must take into consideration possible upgrades in computer systems, and hence data handling compatibility between different systems is a significant concern. When data are not transferable between systems, it becomes difficult or impossible to accurately account for data from early periods of flying. This difficulty in filling in missing data and other problems associated with midlife upgrades highlight the importance of getting it right at the time the aircraft is introduced into service.

The direct method of loads monitoring using strain gauges is the method advocated by the authors. However, these should be complemented by the indirect or flight parameter–based method to "fill-in" missing or corrupt data and to validate and calibrate strain gauge data [8]. Other advantages of this combination include the ability to analyze flying on a PITS basis and the option of using a parameter-based secondary system to validate data from the primary system [40].

Commonality in the ground-based processing across all aircraft types, for each Air Force, is highly desirable albeit probably uneconomical and impractical. While it may not be necessary for all the systems to be identical, similarity in the systems can lead to cost savings through commonality in ground-based software.

5.1 Strain gauges

Historically, concerns with the inability to monitor stress activity near the wing root by a fatigue meter alone lead to the development of strain measuring devices capable of responding primarily to the WRBM. Strain gauges were installed near the wing root to monitor the effects of weight changes with fuel burn and weapons release during flight, etc.

Today, judicious placement of the strain gauges can account for these effects at various PITS constituting the flight envelope. The location of the strain gauge must be such that its response is predominantly influenced by the principal loading inducing the fatigue damage at the relevant critical locations. In particular, care must be taken to ensure that the location of the strain gauge is

- able to be calibrated to the damage inducing load;
- dominated by the principal load (e.g., WRBM) and insensitive to other loading actions;
- in an area of low stress gradient;
- able to be directly related to the stress at critical structural locations (preferably by a linear relationship for both positive and negative loads);

- not prone to gauge "drift" (varying response to a nominal load over time—the F/A-18 wing root lugs are an example of this);
- not subject to load redistribution due to redundant load paths or structural changes such as bushing migration;
- accessible for easy replacement;
- positioned as close as practicable to a backup strain gauge in the advent that the primary strain gauge fails or drifts;
- replicated at a "mirrored" location to estimate the asymmetrical component of the loading;
- replicated on the fatigue test article so that direct comparisons can be made (often overlooked in many IAT programs); and
- accurately positioned and protected from the environment and service wear.

Strain gauges (or equivalents) have the advantage of being sensitive to load, and thus aerodynamic phenomena, and provide an indication of the loads the structure experiences. The magnitude of the effects of phenomena such as buffet and gust loads can only be accurately measured by strain gauges or accelerometers [48, 49] and generally not by flight parameters or fatigue meters. The installation of a gauge must be done precisely with a template (location and orientation are critical) and the gauge must not be fragile or erratic. Procedures must be in place to frequently check the condition of the gauges and erroneous gauges must be found and replaced quickly. Ideally, both (left and right) sides of the attachment locations (especially the wing root) should be monitored [40]. Operational data have shown that the accumulation of fatigue damage on the two sides of the aircraft may not be even, as was demonstrated by left and right F/A-18 wing root strain being different depending on the maneuver [4].

The number of channels available on the data acquisition system may restrict the number of gauges that can be placed. Currently, about seven gauges appear to be standard, but this number may vary in future aircraft [4].

Critical point or "hot spot" strain measurement is still common practise, for example, see [4], but is not recommended for IAT [6, 7]. The major problem with hot spot gauges is that they are placed in regions of nonuniform strain that make calibration and replacement difficult. A good example of the former problem was with the F-16 mechanical strain recorders (MSR) where a variation in strain from 85 to 155% was observed over the length of the MSR [50] for a given load case. (The MSR is 203-mm-long with a gauge length of about 13 mm and is installed on the lower flange of a center fuselage wing carry-through bulkhead.) Furthermore, a high strain gradient and the relatively large gauge length implies that the maximum strain is not recorded as uniform strain through the strain gauge is not present. Finally, hot spots may not be known or anticipated until after the conduct of the full-scale fatigue test.

While the benefits and drawbacks of "hot spot" monitoring have been mentioned [8], the authors' views are that strain gauges used in IAT programs should be for structural load monitoring only. In that application, the loads measured by the strain gauges are related to stresses at a critical point via a transfer function, instead of being used directly for maximum stress measurement. Hence, the aim is not to place gauges to determine their lower or upper limits, but to measure loads in the main paths leading to the critical areas.

Gauges should be sampled at frequencies of about 10 times the natural frequency of the *highest most damaging resonant mode* of the structure for areas that are suspected to be dynamically affected. This will ensure that the maximum peak and valley of each cycle are captured.

5.1.1 Strain gauge calibration

Since the fatigue usage of a military aircraft is normally calibrated against the damage accumulated on a fatigue test article, calibration of strain gauges located in nominally identical locations to those on the fatigue test article is essential in order to obtain an accurate estimate of the fatigue life. That is, the gauges are calibrated such that loads derived from operational strain gauges are directly related to loads derived from the equivalent strain gauge on the fatigue test article. To verify the fatigue test loading, the test article gauges may also have been calibrated against the response of a loads development aircraft.

Furthermore, two gauges placed at nominally identical locations, but on different airframes, may not respond equally to a nominally equal global load due to slight differences in airframe build quality, strain gauge alignment, adhesive thickness, and gauge

factor or gauge/amplifier sensitivity. Multiple load paths in a redundant structure may also cause varying gauge response arising from differences that are "built-in" before delivery. In the extreme case, this variability has been observed to be as much as 50% in vertical tails of the RAAF F/A-18 fleet [51].

Calibration is also necessary to account for drift in the strain gauge reading. With the F/A-18, the wing root strain gauge is known to drift as a result of the wing pin attachment bushings causing a redistribution of stress near the strain gauge [40]. This strain gauge is calibrated by comparing operational data with that produced by a reference WRBM applied to the appropriate fatigue test article [8, 40].

Analytical predictions of the calibration factor should be adopted because it is very expensive to physically conduct a ground calibration of each aircraft. While the RAAF F/A-18 fleet of approximately 70 aircraft is relatively small, a major effort would be required to calibrate each aircraft (as was done in RAF Tornado [52]). Hence, analytical methods involving the identification of similar operational PITS and configurations, were developed and validated by ground calibration of 10 fleet aircraft from various squadrons [51–54]. The ground calibration involved application of a distributed or point load to the structure in question and the simultaneous recording of the strain experienced by the strain gauge. This procedure was used to identify the strain per root bending moment (from regression analysis) for the wings, vertical tails, and horizontal stabilators to validate the analytical methods. Alternatively, gauges may be calibrated in flight, under certain configurations and regimes that are flown often. For example, the 1-g trimmed condition under a common stores and weight configuration could be used. The major advantage of this method is that it can be automated and postprocessing efforts reduced.

5.2 Flight parameters

Many military aircraft today have a sophisticated computerized control system that relates flight parameters to control surface deflections. These control systems, together with fatigue monitoring systems, are sometimes integrated into the mission computer. With flight parameter–based systems, loads in the major load carrying members are calculated from flight parameters using regression techniques or neural network techniques [33, 53–56]. These loads, in turn, are related to stresses at critical locations via transfer functions. The load equations are often developed for a certain range of strain (i.e., separate equations for tensile and compressive loads) and for symmetrical or asymmetrical flight, supersonic, and subsonic conditions. Further studies have shown that separate equations are also required for different stores configurations [53–56]. Flight parameters should be integral to an IAT system and may be used to

- calibrate strain gauges;
- validate strains and estimate strains when data are corrupted;
- produce aircraft utilization statistics;
- determine significant loads; and
- provide an independent check of the damage calculated via the strain gauges, as recommended in [40].

In order for flight parameters to be used in the first two cases, sufficient synchronously monitored parameters are required to estimate the recorded strains to a desired level of accuracy. For example, it has been shown [53] that for empennage strain gauges, the following parameters (among others) are significant:

- angle of attack, α;
- stabilator deflection, δ_{elev};
- rudder deflection δ_{rud};
- trailing edge flap deflection, δ_{TEF};
- yaw rate, r;
- pitch rate, q; and
- aileron deflection, δ_{ail}.

6 DATA HANDLING AND PROCESSING

With the growing volume of data being captured by the monitoring systems, data handling procedures that are efficient, inexpensive, and simple must be in place. While much of the data handling procedures are being outsourced by operators, it is important for the operator to determine the level of involvement they have in the overall process. The level of involvement feeds back into the decision as to whether an

aircraft should have onboard data manipulation and analysis software to produce a final damage value for each flight or only capture data with all processing being executed on-ground by the operator or a contractor. It is imperative that the operator has access to the unprocessed data in order to independently validate the accuracy and reliability of the system.

6.1 Onboard versus ground-based processing

The amount of onboard processing may vary. As a minimum raw N_z, strains and flight parameter data may be recorded. A form of onboard data compression is the storage of only peaks and valleys of the signals (where low amplitude or low mean cycles are "discriminately" omitted). If only the peaks and valleys are stored, then it is highly recommended that each peak and valley trigger be "time-stamped" to enable data checking at a later date [57]. Typical onboard processing today includes data checking routines, a stress calculation for each location, cycle counting, damage calculation, and result storage [58]. An example of a fighter aircraft where onboard real-time fatigue calculations are conducted is the Eurofighter 2000 (which is known as *the SHM system, see* **Fatigue Monitoring in Military Fixed-wing Aircraft** and [59]).

At the other end of the spectrum, the F/A-18 is an aircraft where minimal processing is carried out onboard and extensive processing is done on-ground. Although onboard processing appears attractive, it has many significant pitfalls [4]. Data that are collected onboard but compressed cannot be easily verified, validated, or calibrated after the flight. On the basis of the experience of the authors, onboard damage calculation cannot be recommended if raw data is not stored with the final damage values. Onboard systems are good if they work, but present a dilemma if they provide clearly nonintuitive results and the maintainer has no ability to directly evaluate the raw data.

The frequency of data downloading and the time spent in downloading is a major maintenance consideration and downloads after every flight are not desirable as this consumes much time. A download frequency of about once every 50 h appears acceptable, depending on the reliability of the system. For unreliable systems, it is recommended that downloading and checking occur at reasonable intervals such that system malfunctions can be detected and rectified in a timely manner.

Fleet reprocessing may sometimes be required to account for errors or improvements in the software. In such cases, it may be necessary to identify the status of the fleet (from the date of acceptance) using the improved software. For example, RAAF experience has shown that reprocessing the raw data for a fleet of 70 aircraft can be completed in approximately a fortnight and, on average, will be required between 2 and 4 times over the service life.

6.2 Data integrity and fill-in methods

Recording systems are affected by external factors that lead to a loss of data or to the recording of spurious data. It is common for data losses to be between 10 and 20% [30]. About two decades ago, this figure was in the order of 50% [60]; hence it may be expected that the current figure will decline to half its current value in another decade. Data errors may have various sources:

- instrument malfunction, faulty sensors or unserviceability errors;
- recording system failure leading to no data being recorded for portions of or for complete flights;
- data download errors leading to loss of data;
- recording errors in the system that lead to data spikes;
- system input errors that lead to excessive data (e.g., too many turning points in a particular time being captured due to a discriminant being set too low); and
- other reasons that lead to corrupt data (where the data recorded is unrealistic, such as where data is duplicated across various portions of a flight).

Hence, for each parameter or combination of parameters, the following checks should be conducted:

- range operational envelope limit checks;
- maximum rate of change;
- excessive recording;
- data cutting out in the middle of a flight (continuity);
- spikes;
- data repetition;

- initialization; and
- synchronization between parameters (for time lags).

Spurious data are found on every system and lost or bad data from a fraction of a second or a whole flight must be accounted for. As an example, with the RAAF F/A-18, single bad points in the wing root strain gauge are accounted for (filled-in) using V–g–h parametric methods, while whole flights are filled-in using a method based on the typical damage accumulated by the type of flying conducted [40]. Owing to the variability in missions stated earlier, the fill-in method should be conservative in its estimate of the life (i.e., predict a shorter life value) to ensure safety of the aircraft. The conservatism can be introduced by factoring the mean accrual of that mission type.

7 DAMAGE MODELS AND FATIGUE TEST RESULTS

A purpose of any fatigue monitoring program is to determine the fatigue life status of a fleet of aircraft based on their operational spectrum. All fleet structural integrity programs are established on the results of analytical studies and full-scale fatigue tests. However, with a difference between operational and design spectra, interpretation of fatigue test data and application to the fleet can be difficult.

Full-scale fatigue tests seek to [61]

- identify the most critical parts of the overall structure, which are susceptible to fatigue damage;
- compare analytical design data with fatigue test data;
- substantiate a life extension program;
- determine the safe-life or damage tolerance limits;
- determine the onset of widespread fatigue damage; and
- determine crack growth characteristics and accordingly formulate inspection and maintenance schedules.

The results of the fatigue test are required in order to implement a fatigue monitoring system. It is then the fatigue behavior at each critical location that fatigue damage models seek to simulate. It should be noted, as highlighted in this article, that the "damage model" is only one component of the overall monitoring system. Each component contributes to the overall accuracy of the monitoring system. Regardless of the basis of the damage model, be it crack initiation, total life, or crack growth, the other components should be common.

These fatigue models should be calibrated using the full-scale fatigue test results complemented by material coupon test, component tests and/or from in-service defects. It must be shown that the damage model can scale between the fatigue test result and the extremes of fleet usage. Therefore, the spectrum applied to a fatigue test must be accurately interpretable using the fatigue damage model chosen for IAT purposes. In the case of the F/A-18, the damage model was validated against a coupon test program, which tested upward of five F/A-18 spectra, ranging from benign to severe, and at five stress levels per spectrum [62].

Many aims of an OLM or an IAT program can only be achieved through the conduct of a fatigue test. These aims include identification of fatigue critical locations, substantiation of analytical test lives, and the identification of potential services failures due to high loads. Hence, there is a strong relationship between the full-scale fatigue test result and the IAT program.

8 CONCLUSIONS

A review of the philosophies and requirements in fatigue monitoring of agile aircraft has been presented, examining systems and tools, fatigue models, and fatigue test interpretation. Experience with Australian fatigue monitoring programs has been drawn on to highlight deficiencies in certain practices and forecast future trends.

It has been shown that due consideration in the management of fighter aircraft fatigue must be given to the application of fatigue test results to fleet data, an IAT program, a reliable and economical fatigue monitoring system, validation of damage models and data calibration.

It has been shown that IAT has been beneficial in comparing operational and design usage, in the planning of maintenance action, in modifying operations, and in the understanding of structural problems. Importantly, structural design and

management standards mandate the requirement to conduct OLM or IAT, or incur penalties, which substantially increase cost and reduce availability over the service life. The various options for fatigue monitoring systems have been presented and a way forward using a combination of direct and indirect methods has been recommended.

In summary, the fatigue management program should not be an afterthought to the design. Careful consideration must be given to the design philosophy, the monitoring system, the fatigue test, and the application of its results to the fleet, early in the process.

1 INTRODUCTION

One of the ongoing challenges faced by the aircraft loads community is to assess the validity of the assumptions used in the aircraft design process. Do these assumptions accurately reflect operating conditions? This article describes a program established to assess the validity of aircraft landing impact conditions.

Although commercial jet transport landing loads are evaluated as part of the test and certification program, no known program exists to analyze operational service loads imposed during commercial operations. Prior to this program, there was very little operational landing data available for commercial aircraft design, and none for wide-bodied jet transports. The implementation of survey procedures using new video technology permits the Federal Aviation Administration (FAA) to determine structural load information for commercial aircraft operations.

For both military and civil applications, visual survey methods have the following advantages over using onboard instrumentation:

- The analysis requires no installation of equipment on the observed aircraft.
- Records are obtained without interference with normal operations.
- Records yield a large number of aircraft approach and initial contact parameters.
- The system enables the study of a large number of landings at minimal cost.
- Permanent records are available for reference purposes.

Since the primary goal of all surveys is to collect statistical information on actual operations, the identity of individual operators, flight numbers, and dates are deliberately omitted from published reports. Landing performance is analyzed only on the basis of aircraft category, model type, weather, and other

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

runway conditions. This operational landing data collection program has proved to be a highly valuable resource for conducting fatigue and damage tolerance assessments of landing gear and its support structure, and in developing design and certification requirements for future jet aircraft.

2 BACKGROUND

The use of image data to evaluate the landing performance of aircraft has been used since jet aircraft were introduced into military service. The US Navy developed a system to characterize the typical carrier-landing environment and develop and implement procedures to make carrier-arrested landings safer [1]. The Navy developed a system to acquire aircraft landing and approach data from the tracking and analysis of recorded 16-mm film images of the arrestment. The basic concept was developed in 1947. The National Aeronautics and Space Administration (NASA), in 1954, developed a similar system using a 35-mm camera and conducted a number of surveys of commercial airplanes, the last one in 1959 [2–7]. Only one NASA survey contained actual jet operations. The significant difference between the two systems was that the Navy photographed from a head-on aspect along the runway apron or aircraft carrier catwalk, while NASA's camera was positioned perpendicular to the runway, approximately 274.32 m from the runway centerline.

In 1967, the Navy [8] enhanced its system by replacing the 16-mm cameras with 70-mm cameras. This provided considerably greater image resolution and, consequently, greater accuracy. Using these film systems, the Navy conducted over 30 landing parameter surveys and has an active carrier-landing survey program.

The Navy's survey techniques required access to the edge of the runway or landing deck to adjust and reload the film cameras. Federal Aviation Regulations require equipment positioned near the runway apron to be both frangible and less than 22 in. above the surface. Subject film system was neither.

Since the film system data reduction was very labor intensive, the Navy, in the late 1980s, replaced their film cameras with specialized high-resolution video cameras. This system permitted the collection of image data remotely and significantly reduced the need to access the edge of the runway. Documentation that the performance and accuracy of the video camera system is comparable to the Navy's 70-mm film system is provided in [9] and [10]. In addition, the system's automated image-tracking capability greatly expedited the data-reduction process. This system technology change enabled the use of the Navy's techniques at commercial airports. Subsequently, a joint FAA/US Navy research effort to collect landing impact parameters at commercial airports was established. Figure 1 shows a camera in operation on a commercial runway. The FAA funded the modifications of the Navy's equipment from a single video camera to a multiple-camera arrangement. This was necessary to increase the camera's coverage area to account for the anticipated wider scatter in touchdown distances from the runway

Figure 1. Video camera in operation during commercial landing parameter survey.

threshold for commercial operations as opposed to those of the military.

3 SYSTEM DESCRIPTION

The development of video technology permitted the Navy to transition its landing parameter data analysis system from one using photographic film to one recording video images. The Navy video system, used for both its own surveys and the FAA surveys is known as the *Naval Aircraft Approach and Landing Data-Acquisition System* (NAALDAS). The system consists of high-resolution frame grab video camera(s), a laser disk recorder, and a computer control unit. The data collection equipment is shown in Figure 2. The key to the NAALDAS system is a highly modified video camera. The camera's enhanced vertical resolution (double that of standard video formats) permits highly accurate measurement and tracking of aircraft position data. The camera is supported by an image analysis system using image processing technology. Particular image features (landing gear wheels, wing tips, flaps, or engine inlets) are tracked in consecutive images, and used to determine the relative motion of the aircraft. These image feature positions are used to derive position–time curves for each image feature. Either linear or second-order regression routines are applied to the data as appropriate. Velocity information is derived from these position–time curves, which are evaluated at the last image frame prior to touchdown. Derivatives of aircraft wheel height curves provide sink rates and derivatives of aircraft range–time curves provide closure speed to the camera. Figure 3 shows the landing height versus time plots for one of the more dramatic landings observed during the survey at New York's John F Kennedy Airport. The other parameters reported for these surveys are derived from these basic measurements. The combination of camera resolution and image processing technology permits the location of image features to be determined within 0.1 pixels. This technique is as accurate, but more efficient than the Navy's 70-mm film system.

The original NAALDAS design used a single camera, which covered the restricted touchdown area on an aircraft carrier. To support the commercial application, the FAA funded the design and development of a modified, multiple-camera configuration of NAALDAS using multiple video cameras situated along the apron of the runway and usually in line with the runway edge lights. The images from these cameras are recorded sequentially as the aircraft passes through their field of view. This modification expands the system coverage area to approximately 609.6 m along the anticipated touchdown

Figure 2. NAALDAS video system, data-acquisition hardware aboard aircraft carrier.

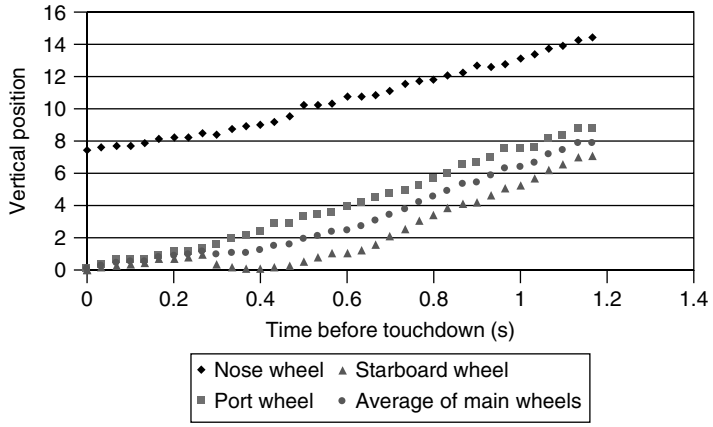

Figure 3. John F Kennedy Airport Survey, landing # 293, landing gear position versus time curve.

region of the runway. Some of the more recent surveys used as many as seven video cameras, thus increasing the camera coverage even further. Fiber-optic signal cables are used to eliminate interference and line losses between the cameras and the recording station.

NAALDAS video camera(s) are installed facing the approaching aircraft; the camera's aim is fixed and does not track the aircraft. The NAALDAS video cameras have a fixed field of view and each camera is aligned and calibrated against targets that are placed temporarily on the runway. These targets are placed in surveyed locations, and the target images are recorded as a calibration sequence (Figure 4). This sequence is processed to generate a transformation matrix, which relates image measurements to the airplane's position on the runway.

During Navy surveys, the NAALDAS data recording system is operated from a compartment near the aircraft carrier's port catwalk. The camera is located in the port catwalk facing the flight deck landing area. A typical camera installation on an aircraft carrier is shown in Figures 5 and 6.

For field surveys, both Navy and commercial, the NAALDAS is operated from a vehicle parked at a safe distance from the runway edge, yet in the vicinity of the touchdown region of the surveyed runway. Temporary cabling is run from the vehicle to the cameras and the vehicle remains in the chosen location during flight operations. The system is

Figure 4. NAALDAS video system calibration targets.

Figure 5. Video camera installed onboard aircraft carrier.

Figure 6. View of carrier flight deck as seen by video camera.

powered entirely with portable electrical generators. NAALDAS is limited to the coverage of one end of a runway and cannot be relocated to accommodate runway changes. This restriction exists since the cameras must be precisely aimed and recalibrated if they are relocated, which requires that the runway be closed. Most camera installation and calibration is conducted during overnight hours.

Video images of each airplane's touchdown are captured and stored on an optical laser disk recorder for subsequent analysis on the NAALDAS analysis system workstation. Approximately, 60 landings can be stored on one disk. An identity number is assigned to the disk, and event numbers are assigned to each video sequence. The use of video disks eliminates film processing cost and time.

Image enhancement and automatic data point tracking are performed using the analysis workstation. The Navy video system introduced the use of these technologies, replacing the manual data point tracking required using photographic film. The analysis procedures remained the same. Image features on the aircraft, usually landing wheel positions, are tracked and the airplane's position and range from the camera are determined for each film or video frame. Figure 7 shows the track windows used in tracking the landing gear wheels of a transport category aircraft. Knowledge of actual aircraft dimensions is necessary to determine the aircraft's range in each image frame, and geometric corrections account for apparent image foreshortening in the video image. These corrections are established during a system

Figure 7. Video image of transport aircraft showing tracking windows used to extract analysis data.

calibration and are dependent on the survey location and conditions. Details of the procedures used to determine these landing parameters are documented in [1, 8, 11].

The analysis station, shown in Figure 8, consists of a Sun computer workstation with an image processing board, laser disk player, computer monitor, high-resolution monitor, and associated power regulator and cables. The station operator automatically tracks the video image features during the landing sequence. By positioning windows over the desired image feature, the operator prepares the system to track that feature through the entire sequence. Multiple-image features can be tracked simultaneously using multiple windows. The operator has the capability to select image threshold levels, image enhancement formats, and algorithms. The operator can also select the type of tracking (edge or centroid) to be used. These selections allow the system to automatically track the image, thus eliminating the errors in data reduction, which were inherent in the manual tracking procedures used with the 16-mm or the 70-mm

Figure 8. NAALDAS video system analysis station hardware.

film systems. The centroid-tracking algorithm enables the system to locate image features with subpixel accuracy.

Once the image sequence is tracked, the pixel information is transformed, digitized, and entered into the landing parameter analysis software. This software takes image position information, determines the change in image feature position of successive frames at a rate of 30 frames/s, and generates position time curves for the feature.

In addition to the video images, from which the ground contact parameters are derived, other data describing each landing are collected during the video survey to determine which set of geometric data to use in the analysis. An anemometer, temporarily installed near the survey site, collects wind speed and direction for each landing. The operators provide an estimate of the touchdown landing weight. After all of the landings on a survey are processed, the landing parameter data is presented as statistical summary tables as well as listings of the parameters for the individual landings. Table 1 is a sample statistical data summary and Table 2 is a partial table of individual landings. Other forms of data presentation include scatter plots, histograms, and "box-and-whisker" plots. The results of all the FAA surveys published to date are available in [12] and [13].

4 OBSERVATIONS FROM MEASURED USAGE DATA

Figure 9 presents a plot of carrier cable engaging speed versus landing weight. As the landing weight increases, the typical engaging speed increases as well. Since carrier landings operations specify a fixed glide slope, the touchdown sink speed increases along with both landing weight and engaging speed. Figure 10 presents a frequency histogram of carrier-landing sink speeds. Sink speed as high as shown in this figure are well within those specified in the military specification.

Figure 11 presents a box-and-whisker diagram of the DeHavilland Dash-8 sink speeds at three commercial airports: London City (LCY), Philadelphia (PHL), and John F Kennedy (JFK). "Box-and-whisker" plots contain the minimum and maximum values of a frequency distribution along with the median, 25th percentile, and 75th percentile. These are used to present a visual comparison among multiple statistical distributions. Clearly, sink speeds

TD-touchdown.

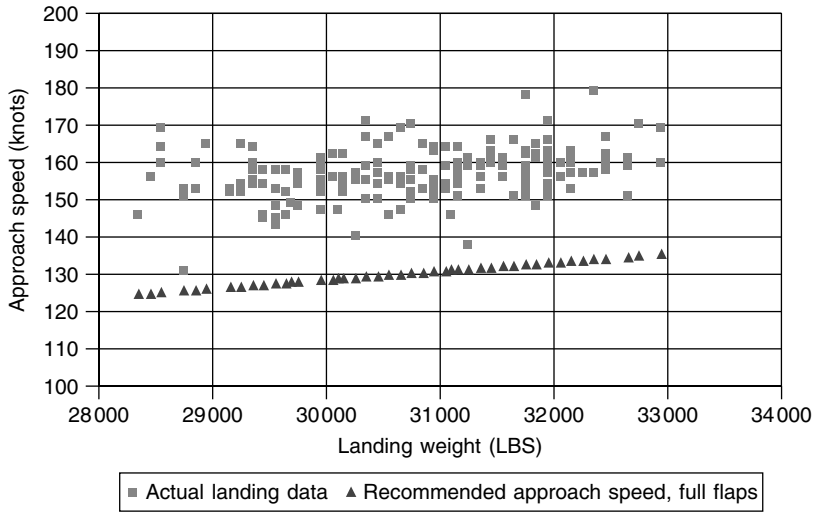

Figure 9. Scatter plot of typical approach speed versus landing weight curve, carrier landings.

at smaller airfields are typically higher than those at longer airfields. Sink speeds at airfields using a higher glide slope are higher than the lower glide slope results.

MIL-A-8863 contains a distribution of sink speeds, which are typically used for military transport aircraft. This probability distribution is compared with the probability distribution for KC-10 aircraft on Figure 12. MIL-A-8863 probabilities and those of the KC-10 are a close match, and thus MIL-A-8863 sink speeds are reflected in actual usage.

The same is not true for civil aircraft. Figure 13 presents a probability distribution of NASA usage spectrum for narrow body civil transport jets. Aircraft

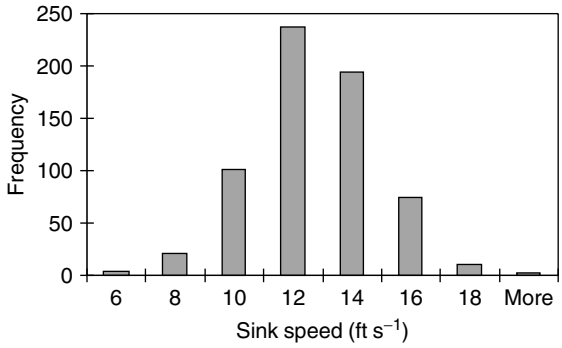

Figure 10. Typical sink-speed histogram, carrier landings.

manufactures have typically used sink-speed data from this NASA report [5] as their sink-speed fatigue spectrum for both testing and fatigue and damage tolerance analysis. If we compare the measured commercial wide-body aircraft usage with the NASA spectrum and the MIL-A-8863 for transports, one can easily observe that the MIL-A-8863 spectrum is more suited for design than the old NASA values. Even narrow body probability distribution levels of Figure 13 are higher than the NASA levels, especially those for narrow body aircraft operating into shorter runways.

5 CONCLUSIONS

The findings from both military and civil video landing parameter surveys are as follows:

- For military transports, the sink-speed fatigue distribution (mean sink-speed of 1.097 m s^{-1},

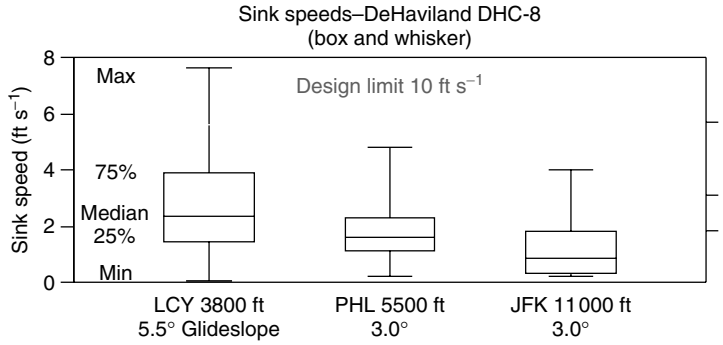

Figure 11. Typical box-and-whisker plot.

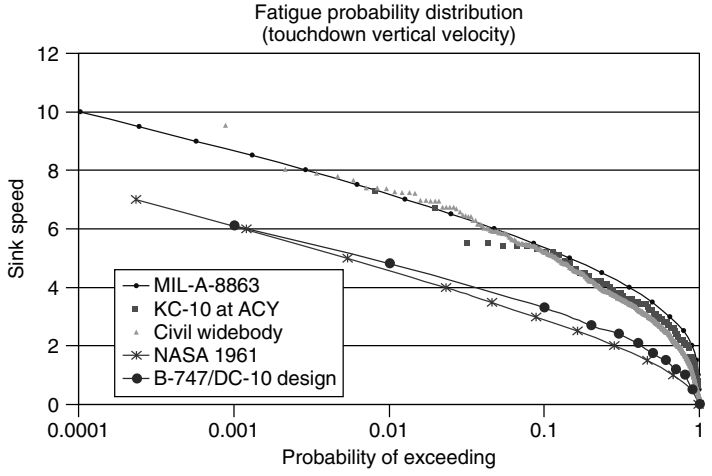

Figure 12. Sink-speed fatigue spectrum—widebodies.

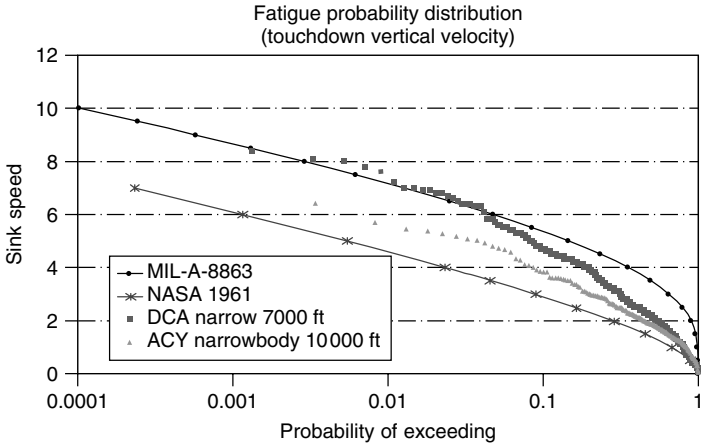

Figure 13. Sink-speed fatigue spectrum—narrowbodies.

standard deviation of $0.405\,m\,s^{-1}$ and skewness factor of 0.5 specified in MIL-A-8863) accurately characterizes typical operations of military transports.

- For civil transports, the limit load of $3.048\,m\,s^{-1}$ for 14 CFR Part 25.473 is accurately reflected in the operations for jets. For turboprops, the $3.048\,m\,s^{-1}$ would appear to be conservative.
- For civil transport jets, the sink-speed fatigue probability distribution shown in NASA TN D 4529 and typically used for design by airframe manufacturers is highly unconservative. Commercial aircraft survey results indicate that the transport aircraft fatigue probability distribution is similar to MIL-A-8863 and more accurately represents typical civil jet operations.
- For civil transports, landings occurring on shorter runways or runways with higher than normal glide slope produce higher sink-speed probability distributions.
- Military surveys allow the US Navy to evaluate the impact of procedural and equipment changes on the landing parameters of carrier aircraft. The validity of operational guidance and standard procedures can be verified.
- Results from military landing parameters surveys has been used to calibrate aircraft flight recorder acceleration data to establish "hard landing criteria" for military aircraft.
- Navy survey sink-speed data was used to document the difference in fatigue loads on aircraft operating from various airfields and aircraft carriers. This information was subsequently used to adjust airframe maintenance schedules.
- In unusually high wind conditions, a Navy landing parameter survey identified unexpectedly high aircraft closure speeds (ground speed) during numerous carrier landings. This data identified the cause of excessive loads on the ship's aircraft arresting gear [14].
- Military landing load survey results have been utilized in preparing detailed specifications for new or modified naval aircraft [14].

It is very important for aircraft manufacturers, operators, military, and regulatory authorities to have a good understanding of the usage of aircraft used in both civil and military service. Analytical models exist, which estimate stress from measured loads. The stress histories are subsequently analyzed to calculate remaining structural life. Without a robust structural health monitoring (SHM) program, operational stresses have to be estimated, consequently, the operator and manufacturer have no way of knowing if the in-service loads are consistent with original design. Continued operation of their airplanes without SHM will occur with higher levels of risk.

Chapter 115
Monitoring of Aircraft Engines

Visakan Kadirkamanathan and Peter Fleming

Rolls-Royce University Technology Centre, Department of Automatic Control and Systems Engineering, University of Sheffield, Sheffield, UK

1 INTRODUCTION

Aircraft engines are complex systems composed of highly advanced mechanical engineering systems and tightly coupled electronic control systems that operate in harsh environments. Though the reliability of the engines is very high, engine performance degradations due to the wear and failure of components will be inevitable over the operational lifetime of the engines. The cost of in-flight engine shut downs and unscheduled engine removal and repair combined with increased safety have been strong drivers for aircraft engine health monitoring systems to be developed. Condition-based maintenance or predictive maintenance, where unnecessary additional downtime and maintenance costs are reduced, requires a functional engine health monitoring system to support it.

Engine condition or health monitoring systems have two main functionalities:

- *Diagnosis:* detect the presence of faults, identify location, and estimate the nature of the fault;
- *Prognosis:* predict the performance degradation, detect early symptoms of a fault, and estimate the timing of maintenance.

The methodologies employed in the construction of the monitoring system depend on the nature of the engine variables measured and the detectability of the fault from those measured signals. The difficulty in obtaining all the necessary measurement signals from aircraft engines and the poor repeatability and detectability of the faults of interest have seen a suite of different approaches being proposed for condition monitoring.

Civil aircraft engine health monitoring systems have historically suffered from high false-alarm rates. Stringent aviation authority certification issues, cost of implementing, installing onboard monitoring systems, and use of unreliable methodologies are also additional factors.

The challenges, therefore, are to derive and develop better fault diagnosis and prognosis methods that are

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

robust, reliable, and can detect the subtle signature patterns associated with weakly detectable faults.

The engine condition monitoring techniques employed can be categorized into model-based methods, model-free methods, and hybrid methods. The model-based methods are based on explicit or derived knowledge of the engine behavior whereas model-free methods are mostly data driven. A different categorization of the methodologies is to divide them into conventional statistical methods and intelligent systems approaches that involve the use of neural networks, fuzzy logic, and evolutionary computation. Often, intelligent systems are used in the hybrid methodologies, which combine model-based and model-free methods in providing information-fusion-based diagnosis and prognosis.

2 ENGINE OPERATION, MEASURED SIGNALS, AND FAULTS

Development of health monitoring approaches depend on how the system being monitored functions, what signals are available from which to infer the system state, and the nature of the system faults to be detected and predicted.

2.1 Engine components and operation

The gas turbine engine is the most economical jet engine used to power civil passenger aircraft. It is analogous to a four-stroke internal combustion piston engine. There are four phases in the engine process—induction, compression, combustion, and exhaust, which are continuous in gas turbine engines as seen in Figure 1. The engine can be divided into three main sections: compressor, combustion chamber, and turbines.

The basic operation of the gas turbine engine is as follows [1]: air enters the air inlet, passes to the compressor where the air-stream pressure is increased through compressor rotor blades and stators, discharges into the combustion chamber where it is mixed with fuel and combusted. The hot, high-pressure gas enters the turbine providing kinetic energy to rotate the turbines with the remaining air ejected via the exhaust. The aircraft motion results from the thrust generated in all three parts of the engine.

Figure 1. Aircraft gas turbine engine cross section.

The compressor, with its large number of rotating components, is a part that is associated with a number of potential engine failures [2]. The high temperatures in the combustion chamber can lead to serious failures in this section of the gas turbine engine. The turbine section consists of fast-rotating blades in very high temperature environment and are, therefore, the most vulnerable for failures. Each stage of the turbine has a stator with stationary vanes and a rotor with rotating blades (turbine wheel) that absorbs energy from the hot high-pressure gas and converts it to mechanical shaft power.

Engine performance parameters define the performance levels of an engine and are therefore a suitable set of parameters that define the health of an engine. Degradation of these parameters may indicate the presence of a fault or of an impending fault. Some of the overall engine parameters of interest are the efficiencies of the compressor, combustion chamber, and the turbine, air mass flow rate, specific fuel consumption, and total pressure loss.

2.2 Measured signals and monitoring

Monitoring from measured signals require a suite of sensors mounted on the aircraft engine that depend on the complexity of the engine, identification of the key variables, and their measurability. A number of key engine variables are measured for the purposes of electronic engine control and for cockpit monitoring. They are [3]

- *temperatures*—inlet temperature, ambient air temperature, exhaust gas temperature, compressor temperature, turbine temperature, bleed air temperature;
- *pressures*—inlet pressure, compressor pressure, discharge pressure, lubrication oil pressure and bleed air pressure;
- *speeds*—spool speeds from the engine stages;
- *vibration*—rotor vibration, shaft vibration, bearings vibration, and accessories vibration;
- *oil system*—oil quantity, oil consumption, oil debris, and oil contamination;
- *life usage*—operating hours, flight cycles;
- *others*—exhaust pressure ratio, fuel flow, throttle position.

An example of on-engine sensors and measurements is shown in Figure 2.

Unique identification of faults in a complex system such as aircraft engines is challenging because of the difficulty in measuring the aerothermal parameters directly. Given the lack of knowledge of many of the symptoms associated with failures, monitoring

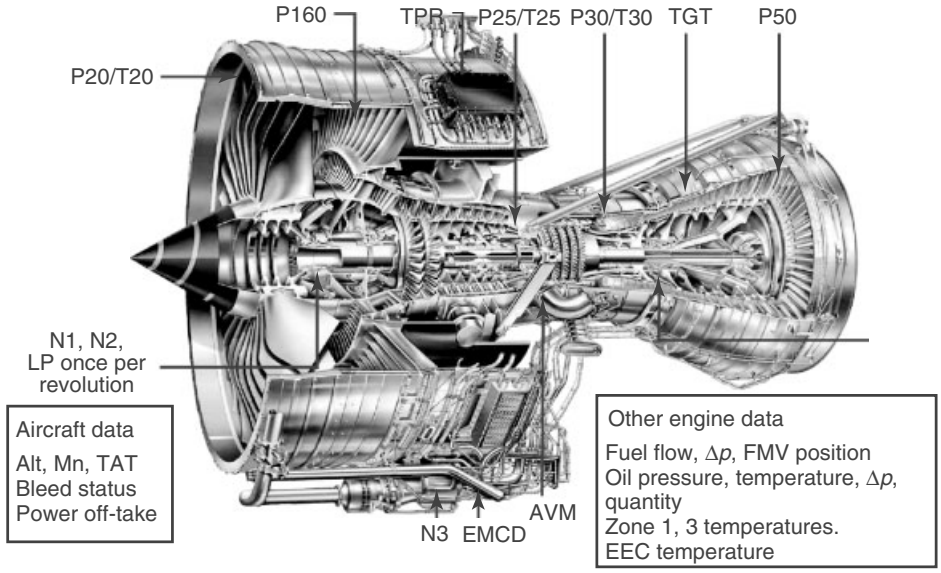

Figure 2. Sensors mounted on an aircraft gas turbine engine.

systems have focused on anomaly-detection methods that discriminate between the nominal operational characteristics and faulty characteristics, particularly when the faults are incipient and slowly developing.

The onboard monitoring system is typically contained within the full authority digital engine control (FADEC) where all measured signals are collected. The data are collected at high sampling rates during flight for onboard on-line monitoring and control, but are not stored for off-line ground-station analysis. The onboard system performs built-in tests (BITs) that traditionally have led to high false alarms resulting in the problem of no fault found in the subsequently removed line-replaceable units. If the onboard monitoring based on limit checking detects an event, then the performance data are recorded for on-ground analysis [4]. For civil aircraft, typically, only a snapshot of data at a small number of operational conditions such as during takeoff, cruise, and landing are transmitted to the ground station for condition monitoring.

2.3 Engine faults

Engine performance changes can be mapped to abrupt faults (rapid short-term deterioration) or incipient faults (gradual long-term deterioration). Analyses of abrupt faults are the functions of a diagnostic system, whereas the analyses of incipient faults are the functions of a prognostic system.

The traditional maintenance strategy involves periodic inspections after a specific number of operational hours and/or flight cycles, often determined from the life limits of critical parts such as compressors, turbine blades, and disks. Unscheduled maintenance can arise from the detection of specific events during engine operation. Some of these are [2]

- *Foreign-object damage* can lead to small scratches or to complete destruction of the engine. It is typically associated with vibration signature patterns and changes in nominal operating parameters. Damage to compressors or turbines often result in an increase in exhaust gas temperature, decrease in engine pressure ratio, and a change in the ratio of shaft speeds.
- *Over-limit operation for temperatures* is often caused by malfunction of the engine fuel control or a malfunction in the engine and results in high exhaust gas temperature at start-up. Operating the engine at excessive temperatures can lead to cracks, burning, metal distortion, and metal loss.
- *Over-limit operation for speeds* impacts on the rotating assemblies of the engine and can cause fan blade and vane damage and fan rotor damage.
- *Engine stall* is also a condition that can cause damage to the engine.

However, the ability of engine health monitoring to predict, rather than detect, these and other impending failures, where possible, is what is required of a condition monitoring system. The measured signals that are required to determine aerodynamic performance include engine pressure ratio, fuel flow, shaft speeds, and the exhaust gas temperature. The parameters needed to evaluate mechanical performance include vibration and oil consumption.

The engine failures that are amenable to detection and prediction via condition monitoring systems are [2]

- **Failures due to air leakage from compressor cage**

A number of compressor section failures may be due to the failure of bleed air duct external to the engine, a stuck overboard bleed valve, or failure of the engine casing. The drop in engine pressure ratio due to this failure is compensated by the increased fuel flow and hence the increase in rotor speeds and other parameters.

- **Compressor contamination**

Contamination due to operation near salt water, use of impure water, oil leak leading to dust accumulation on blades etc., can degrade engine performance. The reduced compressor efficiency again leads to increased fuel flow to maintain required engine pressure ratio and hence to increased shaft speeds and other parameters.

- **Mechanical failures**

These failures involve only a few blades or vanes, unlike compressor contamination, though it also affects the compressor efficiency, albeit by a small value. Severe failures, however, show up during high power operation during which exhaust gas temperatures are very high and/or compressor stalling occurs. Downstream foreign-object damage may also occur

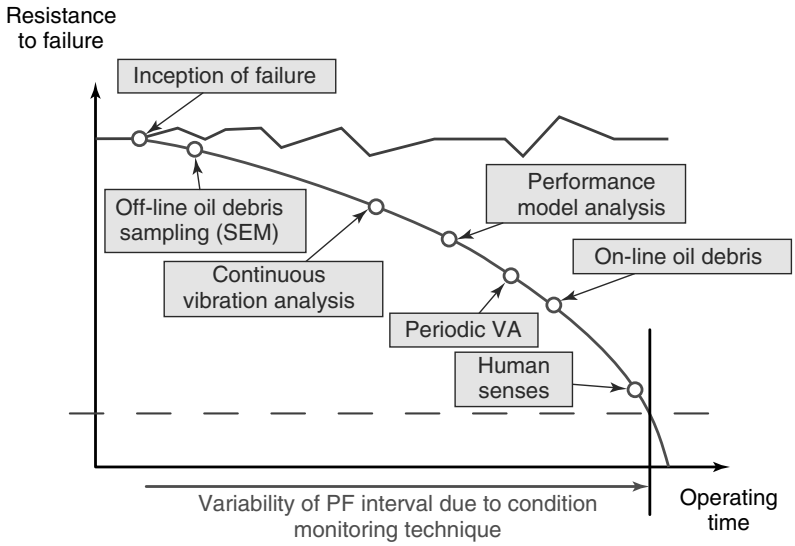

Figure 3. Aircraft engine condition monitoring methods and their failure detection times.

from flying parts. Bearing malfunctions and broken blades lead to signature vibration patterns.

- **Combustion section**

Failures are due to blocked fuel nozzles, fuel line leaks, and the failure of the burner. Since obtaining measurements from this section is difficult, detection of failures must be carried out from parameters from other sections. This, in turn, makes the detectability of these failures very weak.

- **Turbine failures**

Loss of turbine efficiency due to broken blade or seal erosion is the primary failure of interest in this stage. Loss of efficiency increases fuel flow to maintain required engine pressure ratio while the ratio between shaft speeds is likely to have changed.

3 AIRCRAFT ENGINE CONDITION MONITORING

Engine health monitoring systems, whether onboard or off-board, divide the analysis into four distinct categories requiring different approaches to be used:

- Mechanical parameters monitoring—vibration;
- Gas path analysis and performance parameters trending;
- Oil and debris monitoring;
- Remaining useful lifetime estimation.

The four different methods enable detection of faults at various times from the onset, as illustrated in Figure 3.

Advanced health monitoring systems usually perform information and decision fusion from the different category monitoring systems.

3.1 Vibration monitoring and analysis

The vibration signals measured are typically high bandwidth accelerometer signals attached to the casing of the engine. Principles of piezoelectric sensors for accelerometer signals are given in **Piezoelectricity Principles and Materials**. Alternative candidates such as eddy current (*see* **Eddy-current *in situ* Sensors for SHM**) and acoustic emission sensors are also available to monitor such mechanical parameters. With the aircraft engine containing rotating components, the vibration signals contain distinct frequency components. For monitoring and analysis, the time domain accelerometer signals y_t are therefore converted to the frequency domain through fast Fourier transform (FFT) or other spectral

estimation techniques:

$$y(f) = \mathcal{F}(y_t) \tag{1}$$

for $f = 1, \ldots, F$ frequency points. Spectral analysis, in the context of general structural health monitoring, can be found in **Statistical Time Series Methods for SHM**.

Since the engine rotational speeds can vary during the operation, the spectral patterns also vary. However, the frequency components in the vibration signals are primarily the rotational frequency and its higher and subharmonic components. The amplitudes of the signal at these frequencies of interest define the signature pattern for the vibration signal and are referred to as tracked orders [5]:

$$\mathbf{x} = \left[y(f_1), \ldots, y(f_n)\right] \tag{2}$$

These features are excellent candidates for detecting mechanical faults and an example of a spectral pattern is given in Figure 4. The tracked order signal shows interesting patterns associated with an anomalous event.

In addition to tracked orders, broadband energy amplitude, side bands energy, resonance and jumps could also be used as features for monitoring vibration signals. Health monitoring based on vibration signals analyze the tracked orders of the engine for changes from its signature. However, these signature tracked orders vary with the engine speed and, therefore, the engine signature is represented through a series of tracked orders at specific engine speeds. Other frequency-domain feature extraction methods such as wavelets can also be applied [6].

The extracted vibration signal features consist of information sufficient to characterize normal engine behavior across the fleet of engines. However, no explicit mathematical model exists that relates engine parameters to the specific vibration signatures. Hence, model-based approaches cannot be used for monitoring vibration signals. Vibration engineering expert knowledge and experience has led to the proposition of simple heuristic rules in the form of fault signature matrices relating specific changes in vibration

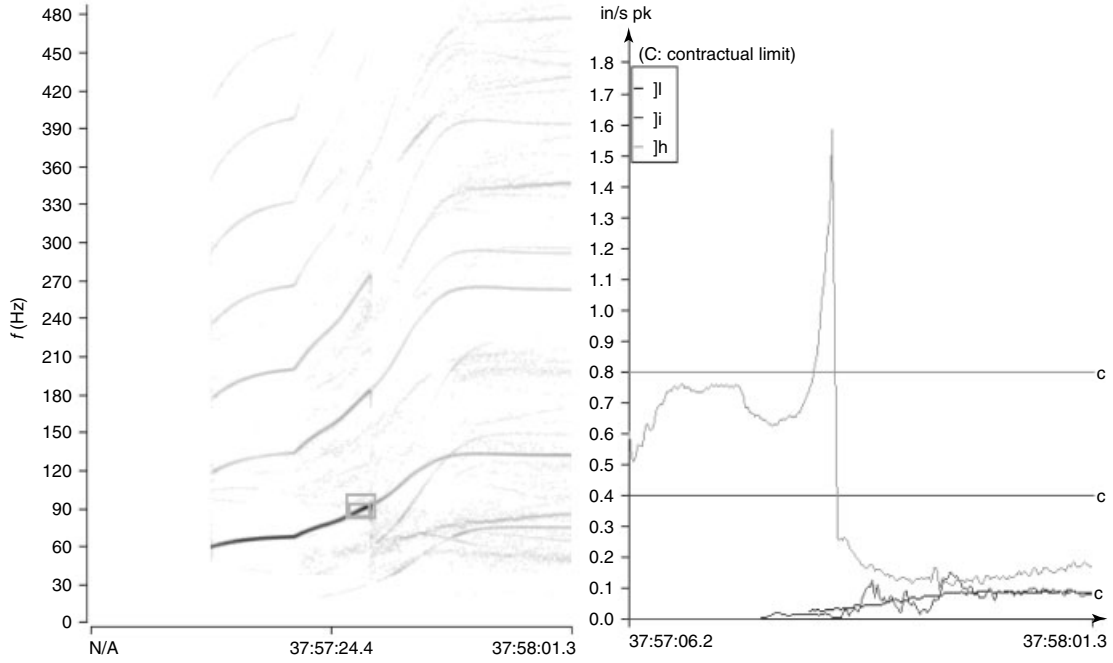

Figure 4. Spectral patterns showing high energy in resonant frequencies (left) and the tracked order signal amplitude (right).

signature pattern to specific faults, but these matrices are very sparse and imprecise. Vibration signal monitoring methods have therefore been based on data-based methods, mostly addressing the problem of anomaly detection [7]. Slowly developing engine faults such as blades and bearing failures can often show early symptoms in vibration patterns. It is therefore important to detect deviations in these vibration patterns through anomaly-detection approaches. Statistical, machine learning and dynamic system identification approaches have been used for novelty detection in vibration signals [5, 7]. Often, they are also combined with visualization methods based on dimensionality reduction for decision support to the engineers [5].

Even though these anomalies cannot be associated with any specific fault at the time of detection, subsequent engine overhaul and analysis can lead to specific faults being associated with the vibration patterns that are precursor symptoms to that fault. A library of such vibration signature patterns can be created and these can then be used to analyze historical engine data using data-mining approaches. A high-performance neural network time-series pattern matching of the tracked orders has been developed for monitoring specific vibration characteristics changes in a fleet of aircraft engines using such a library [8]. This pattern-matching system is integrated with a case-based reasoning intelligent system that learns the association between the signature patterns and the underlying faults.

3.2 Gas path analysis

Gas path analysis is also known as *module performance analysis*. The key idea is to estimate the level of degradation in the main stages of the engine in the gas path, based on the signals measured [9, 10]. It is based on the basic notion that engine component faults that are the changes in engine parameters will lead to changes in the measured signals. These measured signals are very noisy and some trending analysis is required to detect the incipient changes in the performance measures, an example of which is shown in Figure 5. Gas path analysis methods have proved effective in detecting faults in aircraft engines.

The first gas path analysis methods devised were model based, utilizing mathematical models derived from physical processes. The earliest gas path analysis is the parameter sensitivity analysis in which

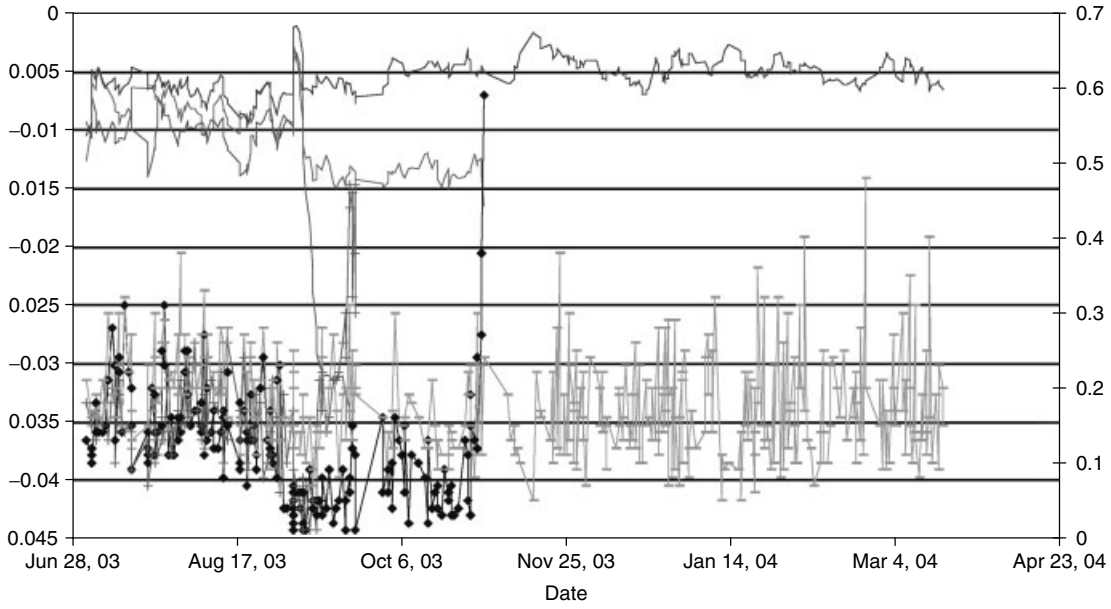

Figure 5. Compressor efficiency performance parameter of engines with and without faults.

linearized models around the operating conditions are used in determining the sensitivity matrix between the engine parameters and the measured signals [11]:

$$\Delta \mathbf{y} = \mathbf{H}\Delta \mathbf{x} \tag{3}$$

where $\Delta \mathbf{y}$ is the change in measured signals and $\Delta \mathbf{x}$ is the change in engine performance parameters. The sensitivity matrix $\mathbf{H}$ is known. Then, the problem of estimating the fault is determining the inverse function $G(\cdot)$ of the model:

$$\Delta \hat{\mathbf{x}} = G(\Delta \mathbf{y}) \tag{4}$$

While it may be possible to isolate single and multiple faults, it may not be possible to estimate the level of fault in all cases due to the nonuniqueness of the inverse model. However, additional constraints can be imposed to improve this accuracy, such as flow capacity, and efficiencies deteriorate over time. A particular advantage of the sensitivity approach, and other model-based approaches, is that the estimated parameters such as combustion efficiency and turbine efficiency are physically meaningful.

To overcome the limitations of the parameter sensitivity analysis, dynamic model-based methods were devised. The physically derived mathematical models describing the dynamics and the measurements are represented as state space models and the problem of estimating the faults are cast as state estimation problems. This allows advanced state estimation filtering-based methods such as Kalman filters for engine health monitoring [11]. Instead of Kalman filters, other state estimators such as observers and even a full complex simulation model [12] can be used.

3.3 Oil and debris monitoring

Surface failures lead to debris formation, which also leads to oil contamination. By measuring the size and quantity of particles in oil, unacceptable wear and fatigue failures of engine components can be detected. Off-line debris particles are analyzed with X-ray fluorescence instruments or energy dispersive scanning electron microscopes, which can identify the material type, thereby providing fault isolation [13]. On-line debris monitoring, sometimes included in gas path analysis, uses magnetic and electric chip detectors. Faults such as blade rubs, nozzle-vane erosion, and combustion-chamber burn can be detected by monitoring the electrostatic charge associated with the debris in the gas turbine engine exhaust gas. By monitoring the lost metal particles in the oil, degradation trends can be identified for early bearing fault detection. It is considered a promising technology for detecting precursors to failures. The Joint Strike Fighter aircraft engine has engine distress monitoring based on the debris monitoring principle [14].

3.4 Life usage monitoring

The life usage monitoring approach traditionally relied on the simple principle that critical engine components have an average lifetime based on the engine operation in-flight hours or in-flight cycles [15]. The average lifetimes are derived from historical reliability statistics and do not take into account a single engine condition. The key assumption here is that each engine is operated in a typical expected flight profile. A better estimation of the remaining useful time of an individual component can be made with improved damage accumulation modeling and use of information from measured signals. For example, component degradation may impact on the engine efficiency, which is reflected in the maximum engine speed and maximum turbine temperature. Additional measurements such as blade-tip deflection and torsional vibration can improve remaining life estimation. Life usage monitoring is particularly important for tracking damage due to fatigue, oxidation, and creep [14]. The algorithms are derived using damage models that are empirically adjusted from operational experience.

4 METHODS FOR ENGINE MONITORING

The standard method of monitoring parameters is for anomaly detection based on simple limit checking of the deviations from nominal operating values. In the absence of knowledge of faults and their symptoms, the limits are usually kept tight, leading to a high rate of false alarm. Performance parameter changes exceeding limits and vibrational amplitudes at the relevant frequencies exceeding average base line

signatures are events that point to developing faults. This functionality can be achieved via a multitude of approaches, some of which are given here. Dimensionality reduction is a powerful tool for diagnostic decision support systems that aids visualization for the engineer. Automatic diagnostic systems require methods that can build on the available knowledge and/or learn from data. Intelligent systems approaches and model-based approaches are two of the main class of methods for aircraft engine condition monitoring.

4.1 Dimensionality reduction

Visualization is a powerful approach to aid operators monitoring the condition of an aircraft engine. The multidimensional measurement signals, extracted features, and performance parameters must be projected down to a lower dimension to aid visualization. Dimensionality reduction can also be used for extracting features that contain most of the informative part of the measurements.

One of the most popular approaches to dimensionality reduction is principal component analysis (PCA), which is a linear projection method. It is a multivariate statistical method that identifies the orthogonal directions of largest variance in the data. Let the observed data be normalized (centered and scaled) to be zero mean and unit variance and be denoted by $\tilde{\mathbf{y}}_t$ for $t = 1, \ldots, T$. Then the PCA projects the data on to the lower dimension via,

$$\mathbf{x}_t = \mathbf{T}\tilde{\mathbf{y}}_t \tag{5}$$

where $\mathbf{T} = [\mathbf{u}_1 \cdots \mathbf{u}_n]^{\mathrm{T}}$ is the transformation matrix with $\mathbf{u}_i$ as the ith eigen vector (ordered by decreasing eigen values) of the data covariance matrix $\mathbf{P}$,

$$\mathbf{P} = \frac{1}{T}\sum_{t=1}^{T}\tilde{\mathbf{y}}_t \tag{6}$$

By representing the normal variation in the monitored parameters, it is possible to visualize deviations that are anomalous and thereby identify faults in engines [16]. Additional anomaly detection procedures may be required to ensure that abnormal behavior is detected. Linear projection methods will not capture nonlinear correlations that are present in the multivariate data.

An example of nonlinear projection method is the Sammon's mapping, which attempts to preserve the distance in the high-dimensional multivariate space to be the same in the projected low-dimensional space. It seeks to identify the projection data by minimizing the sum of squared error,

$$E = \frac{1}{\sum_{i<j}\delta_{ij}}\sum_{i<j}\frac{(d_{ij} - \delta_{ij})^2}{\delta_{ij}} \tag{7}$$

where $d_{ij} = \|\mathbf{x}_i - \mathbf{x}_j\|$ and $\delta_{ij} = \|\mathbf{y}_i - \mathbf{y}_j\|$ are the low- and high-dimensional space distances between the i and j data points. Neuroscale algorithm is a radial basis-function neural-network-based extension of the Sammon's mapping, which has been used for visualization of engine vibration parameters [5]. Further details of dimensionality reduction for structural health monitoring can be found in **Dimensionality Reduction Using Linear and Nonlinear Transformation**.

4.2 Learning with intelligent systems

4.2.1 Expert systems

Obtaining detailed and precise mathematical models for complex systems such as aircraft engines is difficult. Where expertise and experience of engine behavior, faults and their symptoms are available, rule-based expert systems can be used for engine diagnostics. The rules mimic the fault manual information and/or the rules applied by a troubleshooting expert. Rule-based systems may be used to verify whether the evidence for a specific fault is supported using the backward-chaining algorithm or to identify the rules that best match the observed evidence using forward-chaining algorithm. The advantage of the rule-based systems is the transparency offered in how the diagnostics was arrived at, like knowledge capture from experts [17]. However, knowledge transfer from expertise and experience to a set of rules for complex systems can be fraught with challenges including conflicting rules, tracking the internal state of the system, and completeness and correctness of the derived rule base. They are also difficult to adapt to changes over time. Use of expert systems for gas turbine engine prognostics and diagnostics can be found in [18].

4.2.2 Case-based reasoning

Case-based reasoning is a knowledge-based problem-solving paradigm that resolves new problems by adapting the solutions of previous similar problems [19]. It allows consolidation of the rules extracted from knowledge and uses a probabilistic matching-based reasoning. Case-based reasoning permits the development of a diagnosis system incrementally and allows multiple information sources to be integrated, making it a technology suitable for reasoning with complex systems. It is ideally suited to fault diagnosis when the problem being addressed is poorly understood and data are available to characterize a range of operating conditions and faults.

The case-based reasoning system consists of a case base of data from historical cases and a reasoning engine, which has four key steps:

- *Retrieval:* Given a new problem with observed attributes, retrieve the best past cases from the case base.
- *Reuse:* Adapt solutions from matched cases to form a new solution to the present problem.
- *Revise:* Evaluate the outcome of the solution and provide reasoning. Continue until an acceptable solution is found.
- *Retain:* Incorporate the new and successful solution into the case base.

The case base represents a knowledge repository for engine faults, symptoms, maintenance actions and outcomes. Best practice of maintenance experts and experienced engineers are also represented in this case base. Even though case-based reasoning systems can be applied in an autonomous fashion to diagnose faults and health conditions, it is also a powerful interactive data-mining tool for an engineer. For example, restricting searches to relevant attributes and time windows may lead to knowledge discovery about recurring faults and the identification of relevant symptoms. An example of engine cases associated with a specific problem within a case-based reasoning system is shown in Figure 6.

Case-based reasoning systems have been used in a portable PC-based flight-line maintenance advisor to correlate and integrate fault indicators from the engine monitoring systems, built in test equipment (BITE) reports, maintenance data, and dialog with maintenance personnel to allow troubleshooting of faults. It has also been applied to the Rolls-Royce and general electric (GE) gas turbine aircraft engines for engine maintenance decision support and in fault identification [20].

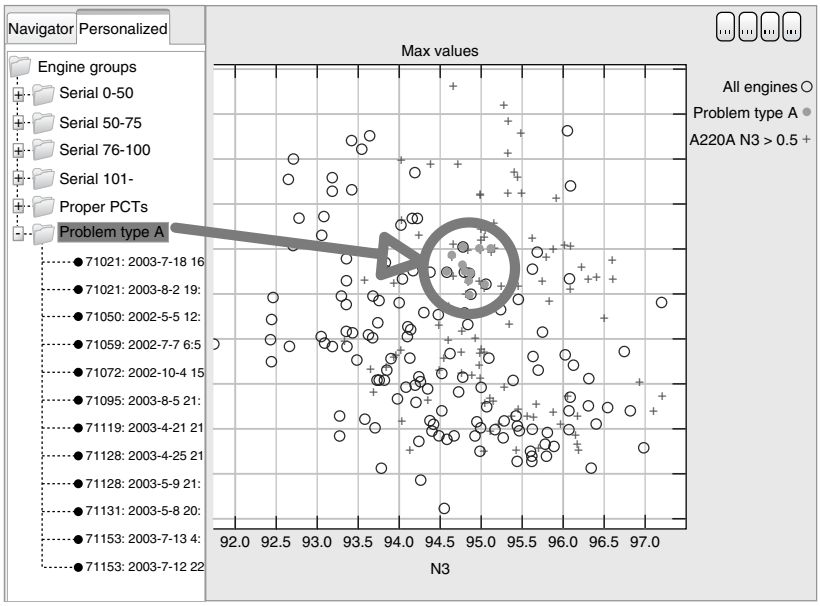

Figure 6. Condition monitoring with case-based reasoning.

4.2.3 Neural networks

Neural networks have been applied to engine health monitoring in two different ways: as function maps that find association between parameters and as classifiers [14]. Neural networks construct nonlinear functions of the form

$$h(\mathbf{x}) = \theta_0 + \sum_{k=1}^{K} \theta_k \phi_k(\mathbf{x}) \tag{8}$$

where $[\theta_0\ \theta_1\ \cdots\ \theta_K]$ are the set of weights and $\phi_k(\mathbf{x})$ are the basis functions, which depend on the form of the neural network and themselves are parametrized. The common forms of neural networks are the multilayer perceptrons, radial basis-function networks, and support vector machines [21, 22]. The universal approximation property of the neural network allows it to map arbitrary nonlinear functions to a specific level of accuracy. Neural networks are trained from a collection of input–output data with the training algorithm determining the weights and the basis-function parameters.

The key principle for the approach based on classification is that different faults lead to differences in the measured signals or extracted features. Faults can be mapped to partitions in this signal or feature pattern space. Neural networks are used as discriminant functions $f(\mathbf{x})$, which create nonlinear partition boundaries and improve classification performance over general linear classifiers. Neural networks are constructed or trained using example fault signature patterns from known faults. Their application to gas turbines have shown comparable performances to Kalman filter-based fault-isolation methods [11]. They can also be used for anomaly detection by identifying boundaries of normal operation. Conditions associated with anomaly lead to measurement signals or features falling outside the boundary [7, 23]. Novelty detection and neural networks for structural health monitoring can be found in **Artificial Neural Networks**; **Novelty Detection**.

4.2.4 Fuzzy systems

Fuzzy logic approaches have proved valuable in engine health monitoring because of the fact that the available knowledge and information about engine characteristics and fault symptoms are incomplete and/or imprecise. The fact that fuzzy systems are universal function approximators like neural networks, but with the advantage of being expressed in linguistic terms allowing easy interpretation has made this approach powerful and yet transparent. Accurate gas turbine engine fault isolation has been demonstrated [24]. The approach utilizes the linearized sensitivity model to generate the fuzzy rules with isolation being carried out by determining the fault with the highest degree of membership for the given set of measurements. The imprecision in the linearized model and the uncertainties associated with the random variations are accounted for by the fuzzy inference process, resulting in a robust fault-isolation scheme in relation to the traditional sensitivity analysis.

4.3 Model-based tracking, detection, and identification

Model-based methods rely on a descriptive dynamic model characterizing the behavior of the system and the measurement model for the engine performance parameters (*see* **Model-based Statistical Signal Processing for Change and Damage Detection**). Often, the model is linear and is described in state space with states $\mathbf{x}_t$, inputs $\mathbf{u}_t$, and measurements $\mathbf{y}_t$:

$$\mathbf{x}_{t+1} = \mathbf{A}\mathbf{x}_t + \mathbf{B}\mathbf{u}_t + \mathbf{w}_t \tag{9}$$

$$\mathbf{y}_t = \mathbf{C}\mathbf{x}_t + \mathbf{v}_t \tag{10}$$

where $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ are the model parameters assumed known and $\mathbf{w}_t$, $\mathbf{v}_t$ are random disturbance and noise respectively. Other forms of models can be in the form of input–output models such as autoregressive (AR) models, transfer function models, or complex physical models for system simulation, shown in Figure 7.

The general dynamic model-based condition monitoring systems employ the approach of residual generation followed by residual analysis. The residuals are generated by differencing the actual measured signals from the model predicted output. If the system is faulty, then the residual signal pattern can be associated with specific faults. The accuracy of these approaches are critically dependent on the accuracy of the derived models and the detectability of the faults.

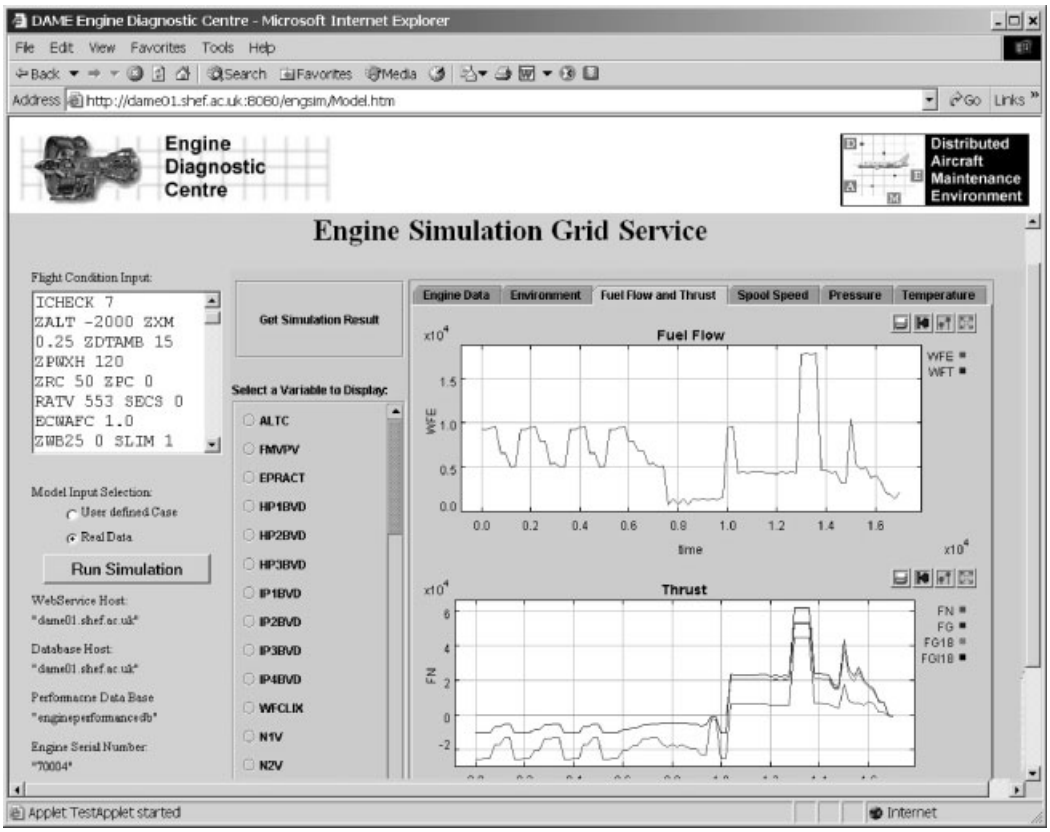

Figure 7. A simulation of key parameters from a detailed empirical model of an aircraft engine.

4.3.1 Filtering and residual generation

Model-based methods offer the greatest promise for prognosis in which engine performance parameter changes have to be tracked. This is a filtering and smoothing problem that is best approached from a model-based perspective. Kalman filters are the minimum mean square optimal linear filters and are popularly used in tracking time-varying parameters [25]. The states or parameters of interest are updated as

$$\hat{\mathbf{x}}_{t+1} = \hat{\mathbf{x}}_t + K_t e_t \tag{11}$$

where K_t is the Kalman gain, which multiplies the residual prediction error $\mathbf{e}_t$ (difference between the actual and model predicted measurements) to provide the update for the states,

$$e_t = \left(\mathbf{y}_t - \hat{\mathbf{y}}_t\right) \tag{12}$$

An example application of the Kalman filter for aircraft engine prognosis is found in [11].

Kalman filtering is also used for fault detection and diagnosis. When the aircraft engine is normally operating without any faults, the model prediction will closely match the actual engine measurements. Thus, the residual prediction error will typically be white noise. By monitoring the sum squared residual over a specified time window, by using generalized likelihood ratio test or other residual-based change-detection methods, emergence of an abrupt fault can be detected [26]. The use of a model in this context is known as *matched filtering approach* where the model or filter is matched to the system operating normally. Kalman filters can be replaced by others such as observers and parity space approach to residual generation and fault detection [27].

One approach to model-based fault diagnosis is based on the multiple-model approach [22]. First,

a number of models each matched to a specific fault in the system (including the normality conditions) are constructed and residuals generated from each. By comparing the residuals and using detectors based on, for example, the generalized likelihood ratio, fault isolation and estimation can be performed as in [26]. This approach with a bank of Kalman filters have been used for aircraft engine fault diagnosis [28].

4.3.2 System identification

One of the popular model-based techniques is the system identification-based condition monitoring. These methods abandon the physics-based models and represent the system dynamics in terms of parametrized black-box models such as the autoregressive models with exogenous inputs (ARX), state space models, or neural networks and estimate these model parameters from observed signals. They offer advantages over other model-based approaches, since the identified models are constructed from measured data. This removes the effect due to model imperfections that can reduce performance of other model-based methods derived under homogeneity and ideal conditions. Once the model is identified, fault detection is then carried out either by monitoring the changes in the model parameters or by monitoring the residuals formed from model predictions. An application of this approach to aircraft engines in which a state space model is identified for fault diagnosis can be found in [5]. Use of nonlinear models based on neural networks can also be identified [29].

5 CURRENT AND FUTURE DIRECTIONS

The challenges faced by the problem of aircraft engine health monitoring is in developing robust, reliable engine health monitoring systems with improved detection, diagnosis, and prognosis capabilities. The developments toward achieving better diagnosis and prognosis have seen increased instrumentation and data gathering from aircraft engines, test beds, and overhaul and repair facilities. The abundance and variety of data and engine fleetwide information have not only made the development of sensors and condition monitoring algorithms challenging but have also placed an emphasis on the system architecture and infrastructure.

Aircraft engine health monitoring requires new sensing mechanisms that permit the estimation of the engine performance parameters more accurately and which are sensitive to the engine faults of interest. A network of integrated sensors with embedded microprocessors offer a smart sensing technology that can aid fault detection isolation [30]. Development of novel fiber-optic sensors that can provide data on the distribution of variables, such as pressure along the engine, facilitates better diagnosis while creating a need for new analysis tools (*see also* **Novel Fiber-optic Sensors**). New developments in microelectromechanical systems (MEMS)-based wireless network of sensors permits direct health monitoring, for example, the temperature monitoring of bearings to predict failure rather than using indirect analysis based on oil analysis. On the algorithmic front, recent advancements in model-based diagnosis and prognosis can be applied to aircraft engine condition monitoring such as particle filters [26]. The physics-based models are also being improved in their sophistication such as finite element models of microstructures for monitoring cracks in structures [14]. The paradigm of semisupervised learning [31] also promises improvement in data-based approaches, which traditionally tend to suffer from the fact that faulty data are scarce, particularly for the highly reliable aircraft engines. Along with the improvements in methods for the different monitoring areas such as vibration and performance parameters, integrating and fusing the different decisions from condition monitoring is a challenge that is beginning to be addressed [32].

The Distributed Aircraft Maintenance Environment (DAME) project [8, 20], a UK e-Science pilot project involving Rolls-Royce, developed a grid computing architecture-based diagnostic workbench, which seamlessly integrates geographically disparate data and analysis tools. The distributed grid architecture creates a virtual organization environment for collaborative decision-making between multiple stake holders such as engine manufacturers, engine operators, and maintenance analysts and experts. This framework includes wireless mobile handheld devices providing access to the distributed system

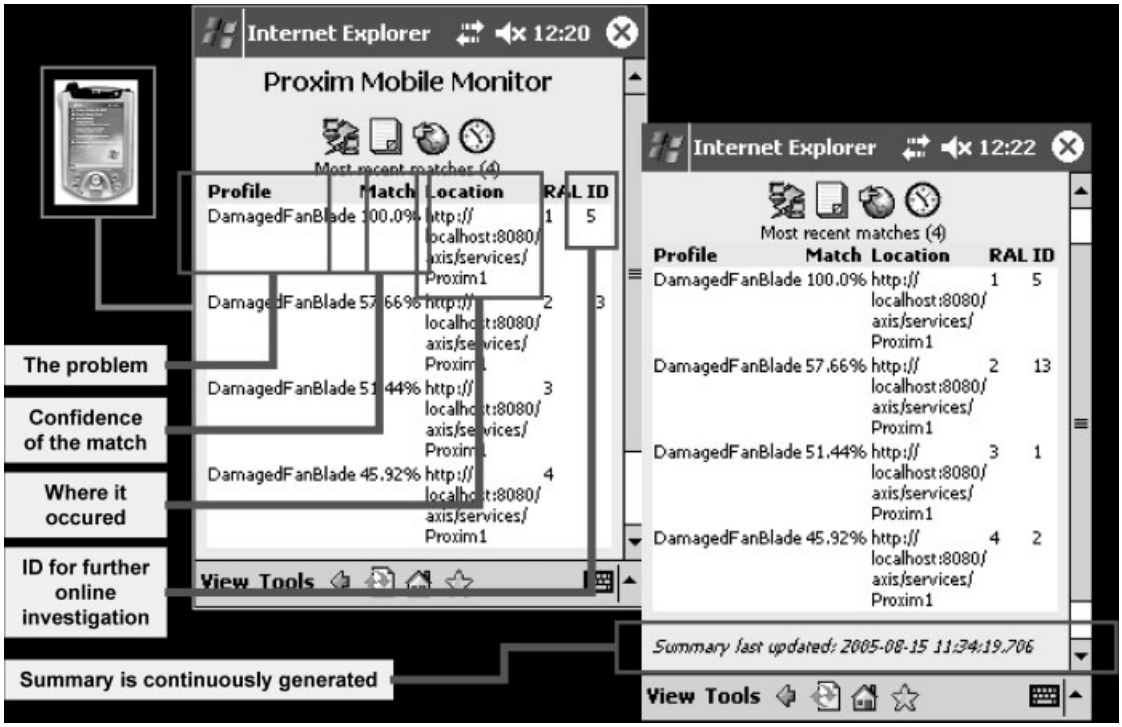

Figure 8. Mobile distributed aircraft engine condition monitoring.

enabling full diagnosis and prognosis capability while working in remote locations, an example shown in Figure 8. The DAME system consisted of diagnostic services for vibration and performance parameters feature extraction using novelty detection methods, data management, and data mining of time-series patterns using neural networks, physical model-based simulation, and case-based, reasoning-based decision support [8]. Such a distributed system with heterogeneous monitoring tools, user interaction, and automated analysis with collaborative decision-making is a powerful system that holds great promise for the future.

Chapter 114
Landing Gear

R. Kyle Schmidt[1] and Pia Sartor[2]

[1] *Messier-Dowty SA, Vélizy-Villacoublay, France*

1 INTRODUCTION

The landing gear of an aircraft is a unique component. It must bear extreme and varying loads when an aircraft maneuvers on the ground or alights, yet it must be lightweight and compact because it is stowed and unused during most of an aircraft's flight. The landing gear is both a structure and a machine. In its simplest form, it is a structure with energy absorption capability. However, in its modern incarnation, it is a complex machine with controlled articulation, multiple axes of energy absorption, and the sole structure that supports the aircraft.

In most applications, landing gears have no structural redundancy. This, coupled with the conflicting design requirements of high load carrying capacity versus minimum weight and size, results in a landing gear being predominantly manufactured from very high-strength (but relatively low toughness) steel, aluminum, and titanium alloys. This is in contrast to most airframes and other aircraft structures, which are typically made from ductile aluminum alloys that can withstand relatively long cracks that grow over time.

The significant difference between the aircraft structure and landing gear is also reflected in the fact that aircraft design and approval methodologies are quite different between the airframe structure and the landing gear. For example, many airframe designs use "damage tolerant" design methodologies, which allow cracks of known sizes to exist in structural members, whereas landing gears use "safe life" design methods, which do not permit cracks. Therefore, many of the technologies relating to health monitoring of the airframe, such as measuring crack growth and assessing the location and size of cracks, are not useful when considering health monitoring of landing gear structures.

The landing gear also has movable elements that form part of the structure. These components must

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

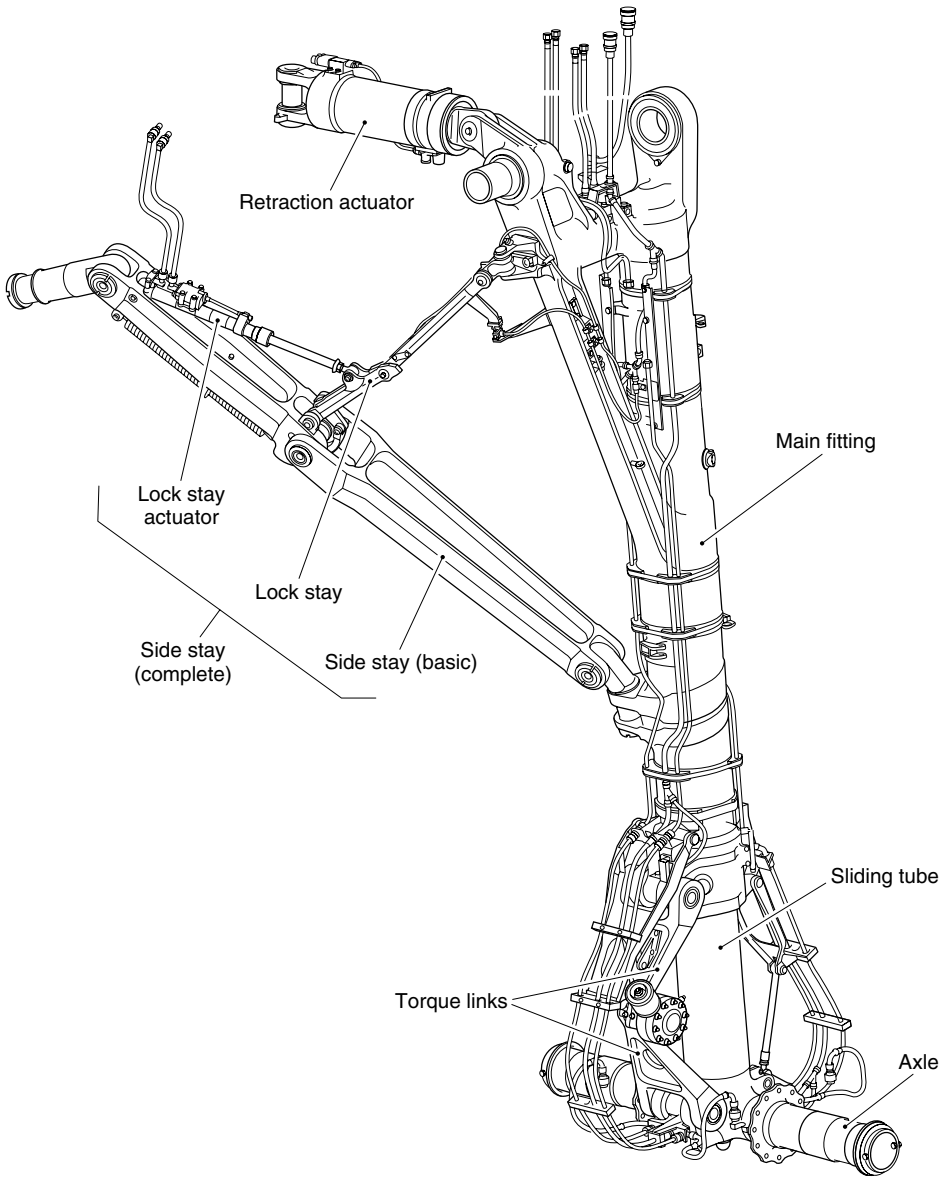

Figure 1. Typical main landing gear structure. [Reproduced with permission. © Messier-Dowty Ltd.]

be considered when taking into account monitoring of the entire landing gear structure.

The differences between landing gear systems and other aircraft systems mean that often, an alternative approach has to be taken with the structural health monitoring solutions of the landing gear. Historically, landing gears have only been fitted with the minimum number of sensors required to indicate the position of the structure or state of articulation. As aircraft system complexity has increased, so has the level of sensing on the landing gear. Several commercial aircraft presently fly with monitoring systems installed to sense tire pressure and brake temperature [1]. Newer aircraft are being fitted with systems to monitor the health of the shock strut element [1]. Direct measurements on the landing gear to determine the weight

of the aircraft have been attempted several times in the past [2]. This article discusses past and present approaches for monitoring the movable aspects of the landing gear, methods for transient overload detection, techniques for measuring the forces seen by the landing gear structure, and methods for determining the fatigue state of the landing gear structure. Figure 1 shows a typical medium-range commercial passenger aircraft main landing gear (MLG) structure. It is assumed that the reader has a prior knowledge of landing gear design and operation. For reference, the design and operation of landing gears are discussed extensively in Norman S. Currey's *Aircraft Landing Gear Design: Principles and Practices* [3].

2 LANDING GEAR TIRE, BRAKE, SHOCK STRUT, AND ACTUATION MONITORING

The movable portions of the landing gear demand utmost care and maintenance, and as such have lent themselves to the introduction of monitoring systems earlier than the purely structural portions. Typical of these systems is the tire pressure indication system (TPIS) available from Messier-Bugatti, which is now in its third generation of development [4]. Alternative systems for tire pressure monitoring are available from other vendors, such as Crane [5]. A tire pressure monitoring system eliminates the regular maintenance actions to inspect the pressure of the tire. This type of monitoring system increases the overall safety of the aircraft by helping to avoid incidents due to underpressurized tires, as well as reducing the overall maintenance burden.

Brake temperature monitoring systems detect the temperature of brake components and report the data to the pilots in the cockpit. The temperature information can also be used to directly control brake cooling fans. Monitoring of brake temperature permits the flight crew to make educated decisions regarding the dispatchability of the aircraft. Knowledge of brake temperature profile and braking performance can be used to determine the remaining brake life [6].

Shock strut servicing indicators, whether as a ground support aid or through the aircraft central maintenance computer, would help to ensure that the shock strut is performing as designed, thereby prolonging landing gear and aircraft life. Health monitoring of any oleo–pneumatic, single-state shock strut requires measurements of nitrogen gas pressure, hydraulic fluid volume, temperature, and shock strut position to determine the status of the landing gear shock strut.

Currently, to ensure that the landing gear is properly serviced, the ground crew measures the shock strut extension and nitrogen gas pressure and compares the measurements with the servicing chart on the shock strut. If the gas pressure is found to be too low, more nitrogen is added. However, low pressure could actually be due to a loss of hydraulic fluid rather than nitrogen. Therefore, this technique can lead to improper servicing. The only reliable way to know that the hydraulic fluid is at an acceptable level is to take the aircraft out of operation and perform full hydraulic fluid and nitrogen gas servicing or to perform the servicing check at two different aircraft weights, which is time consuming and expensive.

In the ideal situation, it would be possible to monitor the shock strut by measuring all four parameters with sensors. For example, Goodrich Corporation has developed a method for an oil volume sensor assembly [7] and NASA has developed a capacitive fluid level measurement system [8], both of which would be internal to the shock strut. In each of these cases, however, field repair would be impossible and an additional hole would have to be drilled in the shock strut wall for the extraction of measurement wires. Two ultrasonic approaches to fluid level measurement also exist—an external manual method [9] and an internal pulse echo method [10].

An alternative approach to measuring oil volume would be to include the element of time in the measurement so that the volume sensor is not included and two measurements are made at different shock strut positions. The simplest approach would be to make one of these measurements prior to landing and the second one when the shock strut has settled, potentially at the gate. This "two-point" method would allow the shock strut state to be determined reliably with conventionally available pressure, temperature, and position sensors.

Currently, in the case of temperature and pressure measurements, these can be obtained using a temperature–pressure sensor. For example, Messier-Bugatti has developed an oleo pressure monitoring system (OPMS), which is currently installed on

the A380 [11]. The OPMS takes shock strut pressure and temperature measurements and transmits the information to the cockpit, where the information is displayed on the multifunction displays. Any abnormal measurements are alerted to the flight and maintenance crew to ensure that maintenance is performed.

For shock strut position measurement, a rotary variable differential transformer (RVDT) could be used on both articulated and cantilevered gears. This piece of equipment is currently used extensively in landing gear systems. For an articulated landing gear, an RVDT could be used to measure the angle between the trailing arm and the main fitting and, using geometry, the amount of shock strut compression could be calculated. For cantilevered landing gear, an RVDT could be installed at a point that permits measurement of the torque link rotation. Although three pivot points are available for measurement, the upper torque link to the main fitting attachment point typically offers the greatest simplicity in terms of rigid mounting of the sensor and static harness routing. Alternatives for the position sensor include synchros and resolvers for rotation measurement. These devices are aerospace grade and their advantage is their larger rotary measurement range at the expense of a greater number of wires in the harness. The use of rotary potentiometers is also possible but not recommended because of the severe operational environment on the landing gear.

In any case, a rotary measurement method would be superior in most respects to a linear contrivance. The linear systems, which are currently used for flight test instrumentation, are too fragile for use on revenue aircraft since the exposed translating member could be easily damaged. If, however, the linear system is contained within the shock strut it may be protected from damage, but repair or replacement becomes onerous.

It should be noted that multistage shock struts offer some additional challenges, primarily on the computational side of determining the service state. At a minimum, an additional pressure and temperature sensor is required in the secondary chamber. It may also be required to know the position of the floating piston.

Currently, a more detailed study of shock strut servicing is being performed through a European Union (EU)-funded 6th Framework project, known as *TATEM* (*Technologies And Techniques for nEw Maintenance concepts*) [12].

Monitoring of the bearing interfaces on landing gear is not currently done, but several possibilities exist that could be exploited. The extension and retraction operations of the landing gear can be monitored using the conventionally installed proximity system. By trending the times for extensions and retractions, deviations from the norm could be identified, which may indicate excessive friction in the joints or problems with the actuation system. Wear of wheel bearings can lead to local overheating of the bearing lands and a subsequent softening of the material. Vibratory monitoring as employed on engines (*see* **Monitoring of Aircraft Engines**; **Gas Turbine Engines**) and other rotating machines (*see* **Large Rotating Machines**) could be employed to detect the early stages of bearing wear. Local temperature sensors—perhaps as an extension of the brake temperature monitoring system—could be employed as an alternative detection system.

3 LANDING GEAR TRANSIENT OVERLOAD DETECTION

One of the primary areas of interest in landing gear monitoring is the determination of transient structural overloads. Owing to the general high structural reliability of landing gears, these transient incidents are of utmost interest to aircraft operators. Aircraft landing gear overload can occur when any part of the landing gear exceeds the design/certification loads of its components. These overload events can include hard landings, overweight landings, off-runway events, runway/taxiway/apron incursions, or problems during towing operations. After any overload event, the operator needs to know whether the landing gear is suitable for safe dispatch. Presently, when an overload event occurs and a pilot makes a declaration, visual and nondestructive testing (NDT) inspections may be performed on the landing gear. In addition, information from the flight data recorder (FDR) may be downloaded from the aircraft and analyzed with the use of dynamic aircraft models to generate estimates of the loads seen during the event.

Given the amount of work required when an incident occurs, there has been significant interest in the

development of hard landing indicators. The potential solutions can be divided into three classes. The first is by the use of dynamic measurements, such as acceleration, velocity, and displacement indications. The second is by the use of purely mechanical devices to indicate if an overload event has occurred. The third method is by the use of force measurements, such as pressure and stress/strain.

Interest in monitoring the performance of the aircraft during the landing stage began as early as 1919. Dr Zahm developed an aircraft accelerometer, intended for research and not operational use, that consisted of a number of helical vertical springs with "styluses" attached to them. This device traced the sudden loads and shocks encountered during landing. However, it gave a discontinuous record of accelerations [13]. In 1934, the National Advisory Committee on Aeronautics (NACA) had developed and tested a seismographic "landing shock recorder" that gave a time–displacement record of movement in a given direction during the impact of an aircraft landing. Although the original intent of the device was to confirm the reliability of the accelerometers in use, this landing shock recorder was also able to make measurements to determine the accelerations under aircraft landing impact conditions [14].

This early work on the measurement of landing impacts is instructive as the vast majority of hard landing detection systems developed and employed use acceleration to determine whether any given landing was an overload event. Presently, acceleration data from digital FDRs is analyzed to provide information when a suspected overload event occurs. This analysis is time consuming and is hindered by the generally low recording rates of the parameters of interest to the landing gear versus the short time taken to perform a landing. This has led to the development of stand-alone hard landing detectors.

One intriguing example of a passive hard landing detector is a mechanical latching accelerometer developed in the 1960s. This indicator is composed of a pivotally mounted metallic mass/spring arrangement such that when a predetermined acceleration is exceeded, the mass pivots and is held in place by a magnet, giving an indication [15]. An electronic single-axis accelerometer approach is used on the Gulfstream IV. This aircraft has a gravity force "G" monitor system, which records the maximum vertical acceleration experienced by an aircraft during landing. The landing acceleration is indicated to the flight crew on a cockpit display. Any suspected hard landing can be checked by comparing the peak vertical acceleration against a plot of allowable accelerations versus aircraft mass. The disadvantages of this system are that it records only the peak acceleration in the vertical axis, and only near the aircraft's center of gravity.

Messier-Dowty has developed a hard landing indication system that records high-rate accelerations and roll rates in three dimensions from several remote inertial measurement units (RIMUs), as seen in Figure 2. The data from the RIMUs are then fused with the data from the aircraft's data bus. A computer can compare the data to predetermined threshold parameters to indicate if the aircraft has experienced a hard landing [16]. The main advantages of this system are that it can easily be retrofit onto any aircraft; it has several measurement units that can be placed close to the landing gears (to avoid the influence of the aircraft's structural dynamics) and it provides a go/no-go indication following each landing.

NASA has developed a bolt-on/bolt-off "Vehicle Health Monitoring Architecture", which could also be used to indicate overload events. This design is made up of a Remote Data Acquisition Unit (RDAU), Command and Control Unit (CCU), and Terminal Collection Unit (TCU). One or more RDAUs are located on the aircraft landing gear, with up to eight sensors being used. In the testing performed, these

Figure 2. Messier-Dowty remote inertial measurement unit (RIMU). [Reproduced with permission. © Messier-Dowty Inc.]

sensors included accelerometers. The CCU is located within the aircraft and all RDAU data are sent to the CCU. The TCU is located at the fleet terminal, and at the end of a flight, the aircraft's CCU analysis is forwarded to the TCU. Here the TCU can determine whether there are any common anomalies within the fleet and forward any relevant information to the maintenance personnel [17].

The major disadvantage of using kinematics to determine landing gear overload is that accelerations, velocities, displacements, roll angle, and roll rates are not direct measurements of the loads experienced by the structure. Ultimately a model needs to be employed to correlate the measured kinematic parameters with the landing gear loads.

Efforts to avoid the measurement of kinematic parameters and the use of models have centered on purely mechanical devices for the indication of an overload. Anecdotal evidence suggests that some Russian aircraft shock absorbers were fitted with lead targets opposite a hard indenter. If the shock strut was compressed beyond the normal range, an indelible mark would be left in the lead target. Another approach to this overtravel indication is a small pin that is permanently deformed upon exceeding the limit. Either example is easily implemented and detected using a visual inspection. The downside is that they provide an indication of vertical overload only—and only if the shock strut is properly serviced at the time of the incident.

An alternative approach to the shock strut overtravel system is to design a structural element that acts as a fuse: it fails in a noticeable way when overloaded. The difficulty in landing gear design is that there are typically no redundancies that would permit a full failure of any component. This has been approached by the development of links that take a permanent set when a limit is exceeded (but has sufficient strength margin to carry the full ultimate load). Another approach developed by Messier-Dowty is the pin-within-a-pin approach. A thin shelled pin is designed to fail at the overload limit, whereas a backup pin within the fuse pin carries loads up to the ultimate load [18]. A dye or other indicator can be used that escapes once the outer fuse pin ruptures, providing a visual indication of the overload [19].

These mechanical solutions are potentially good solutions when knowledge of only one load is required. They are also able to give a simple visual indication that a load has been exceeded, with no data processing. Unfortunately, landing and ground maneuvering loads are multidimensional in nature, and since these mechanical solutions are only able to provide indication in one axis, they provide a small amount of information. Historically, they have also been difficult to implement because of the need for careful calibration to set the correct trigger levels.

The technically superior option is to directly measure the forces acting on the landing gear in all axes. These forces could be measured using pressure or stress/strain. Recording of force data at sufficiently high rates to capture the landing event would provide a definitive answer in overload cases.

4 LANDING GEAR FORCE MEASUREMENT

In the 1950s, the use of accelerometers and strain gauges to directly measure the loads on landing gear was implemented for aircraft test programs. In 1954, NACA developed a method for measuring drag loads on small landing gear using angular and linear accelerometers [20]. In 1958, a large research aircraft was instrumented with strain gauges on the axle, linear, and angular accelerometers, as well as other instruments to measure vertical velocity, angular velocity, drift angle, and mean tire deflections for each wheel. The vertical, drag, and side forces imposed on the MLG under actual loading conditions were then measured [21]. At that time, however, there was concern that strain-gauge instrumentation applied to the landing gear would be subject to the effects of hysteresis and that the results would require correction for inertial effects occurring from the elastic response of the structure [20].

Subsequent work with strain gauges on the landing gear axle to measure landing loads was also the basis for developing alternative weight and balance systems for aircraft. Here, weight refers to the mass of the aircraft, fuel, occupants, and cargo, and balance refers to the position of the center of gravity of the aircraft. Both of these values are calculated before each flight to ensure that the aircraft is within its weight and balance limits.

The benchmark weighing system, a stationary scale onto which the aircraft is rolled to measure weight through the landing gear, is an impractical method for regular use since the weighing procedure usually takes a significant amount of time and scales cannot be easily transported [22]. Therefore, in an attempt to measure the loads of an aircraft through the landing gear, onboard aircraft systems were developed beginning in the late 1960s.

In 1969, BLH Electronics Inc. placed strain-gauge-based transducers in the hollow axles of the landing gear to measure the wheel axle shear forces caused by the vertical loading forces. These vertical loading forces were then used to calculate the gross weight and center of gravity of the aircraft [23]. In 1973, Electro Development Corporation proposed using force transducers, originally intended for an aircraft weight and balance system, on a landing gear axle to measure the shear force upon ground contact [24]. Recently, Boeing presented the idea of placing strain-gauge transducers on the critical components of the landing gear so that forces could be measured [25]. The idea of using strain gauges continually on an aircraft landing gear, and not just in flight testing, has its limitations. For example, strain gauges suffer from a lack of longevity owing to their reliance on adhesive bonding of the gauge to the area of interest. Furthermore, there are issues with corrosion where the electrical leads are terminated to the strain gauges because these terminations exist in a harsh environment. For strain gauges to survive in the landing gear area, they need to be completely encapsulated and protected from the environment.

Recently, Messier-Dowty has been working on the development of load-measuring pins to replace conventional pins in the landing gear. These instrumented pins contain strain gauges that are protected from the environment [26]. The drawbacks of this approach are that the load pins would have to be manufactured for each specific type of landing gear and the cost of retrofitting these load pins would be high. Messier-Bugatti has placed strain gauges into a cell, which could then be fit into the bore of a pin. This would allow for the cells to be easily installed on any type of landing gear, without requiring the cell to be dimensioned specifically for each application [27].

A weight and balance system certified in 1993 for all Airbus A330/A340 type aircraft used four variable reluctance sensors per landing gear to measure the shear deflection of the axle by directly measuring the displacement of the landing gear axle (which is proportional to the aircraft's weight) [2]. These variable reluctance sensors [28] were mounted on lugs, which were milled out of the landing gear axle or bogie beam [29, 30]. The system was expensive owing to the need to machine the lugs on a part that would normally have been turned on a lathe and was also difficult to calibrate and use [22].

Optical displacement methods have also been proposed as a means of measuring the structural deflection and loads on a landing gear axle. Both Airbus [31] and Messier-Dowty [22] have proposed devices using a laser-beam-emitting device connected at one end of the axle and a light position sensing device at the other end of the axle, which are able to determine the position of the laser beam and thereby calculate the load acting through the axle.

There are a variety of other potential methods to measure the loads directly on a portion of the landing gear. The use of fiber Bragg grating sensors (*see* **Fiber-optic Sensor Principles**; **Fiber Bragg Grating Sensors**)—housed in a suitable container—could provide an alternative to strain gauges. Another approach is the use of fixed Barkhausen noise sensors for the measurement of stress in the material [32]. This approach to loads measurement does not require the sensor to be mechanically strained with the loaded component, simplifying installation and increasing robustness.

Pressure can be used to determine landing gear loads. Segerdahl and Greene [33], Lindberg and Thomas [34], and most recently Nance [35, 36] had been developing Elfenbein and Mueller's 1970s approach to determining the weight over a landing gear, by measuring the fluid pressure in the shock strut [37]. Although Elfenbein and Mueller's approach did not compensate for friction inside the shock strut, methods developed by Segerdahl, Lindberg, and Nance did account for this friction. These approaches typically require complicating the shock strut of the landing gear with various valves, tubes, and actuators that by their existence reduce the reliability of the landing gear [22]. However, much of this work on weight and balance systems became the basis for measuring landing gear shock strut fluid levels, monitoring landing gear shock strut health, and

determining overload events, which can be seen in work done by Airbus [38].

5 LANDING GEAR FATIGUE MONITORING

For landing gear structural health monitoring, it is important to know the fatigue state of the landing gear at any point in its life cycle. While the benefits of landing gear servicing determination and event recording are direct and measurable to the landing gear operator, the determination of the landing gear fatigue state is an area where the benefits are not seen immediately, but are seen over the life cycle of the landing gear. For example, with knowledge of the landing gear's fatigue state during its life cycle, it is possible to remove landing gear components prior to failure, resulting in a potential reduction of landing gear–related in-service incidents and therefore increased safety. With these benefits in mind, one might determine the fatigue state of aircraft landing gear by "asking the material", using a sacrificial component or using one of the loads monitoring approaches.

5.1 Ask the material

The ideal approach to fatigue state determination would be to "ask the material" since the actual loading for any component is unique. The ability to ask the material would have to be nondestructive, as it is important to know the fatigue state at any point in the landing gear's life cycle. In addition, there may not be a single solution to determine the fatigue state in metals of different types (steel, aluminum, titanium, etc.) or for different metal chemistries (300M, 4340, etc.).

Given the foregoing, there are some measurement approaches that offer hope of determining fatigue state in steels. Both known techniques correlate the fatigue damage with magnetic properties of the metal. These techniques are the measurement of magnetic permeability, using MWM-array (*see* **Eddy-current Methods**; **Eddy-current *in situ* Sensors for SHM**) sensors offered by JENTEK Sensors Inc., shown in Figure 3, or using the MAPS system offered by ESR Technology, and the Barkhausen noise measurement,

Figure 3. Jentek MWM-array sensors fixed to the landing gear structure. [Reproduced with permission. © Messier-Dowty Inc.]

using sensors provided by a number of companies. These approaches, while having some success demonstrated in the laboratory and in specific in-service instances, still require significant development and correlation effort before they reach maturity.

5.2 Sacrificial component

Another approach to fatigue monitoring is to use a sacrificial component that is subjected to the same loading as the component of interest. Ideally this sacrificial component would have electrical, optical, or other properties that changed as its fatigue life was consumed. Thus, a simple measurement could be made, which could be correlated against the consumed fatigue life of the part of interest.

Such a component has been proposed and developed at a research level. A recent paper by Zhi reports on a modified strain gauge with consumable life [39]. This demonstration builds on the work of D. R. Harting in developing an S/N fatigue life gauge [40]. This type of modified strain gauge offers the promise of a simple approach to fatigue life determination. However, it does have a number of downsides. Extensive testing and correlation work is required before the part goes into service to relate the readings from the gauge to the actual fatigue life consumed in the part. The gauges are for single-axis systems and it may be difficult to locate or correlate on landing gear

components that are loaded multiaxially. The gauge gives no indication of the magnitude of the loads applied and this may be an issue in situations where a large but not excessive load early in the part life is the root cause of a premature fatigue failure.

Another alternative in this category is the integral strain gauge (ISG) offered by ISG Preventive Technologies Inc. of Canada. Essentially a sacrificial foil gauge, the foil material undergoes a visible reaction to increasing fatigue usage. Although unaided visual inspection can provide a rapid check on the fatigue state, microscopy and numerical analysis methods can reveal a more precise determination of the fatigue life consumed [41].

5.3 Loads monitoring

The last approach to fatigue life determination is based on loads monitoring (*see* **Loads Monitoring in Aerospace Structures**; **Fatigue Monitoring in Military Fixed-wing Aircraft**; **Agile Military Aircraft**; **Operational Loads Monitoring in Military Transport Aircraft and Military Derivatives of Civil Aircraft**). There are many approaches within this subset as it represents the most established approach to fatigue life determination. Very broadly, there are two subcategories within this group: direct approaches and model-based approaches.

5.3.1 Direct approaches

The two direct approaches are both comparison approaches: applied load comparison and energy comparison.

Applied load comparison
In the applied load comparison approach, the loads into the landing gear are measured or otherwise determined and compared against the design loads, which are specified by Federal Aviation Regulations (FAR) or Joint Aviation Regulations (JAR). Any excessive load is then flagged for analysis.

This idea is expressed in an invention by Delest *et al.* [42] where, in a preliminary step, design loads, which are representative of the loads that the aircraft will be subjected to, are defined. At the moment of landing, input parameters such as the mass of the aircraft, accelerations, roll angle, roll rates, and load data are gathered from sensors. A computer receives these input parameters and load data, and a comparison algorithm evaluates the real values measured against the calculated allowable value of the design loads.

However, this applied load comparison approach gives, at best, only a rough estimation since the input loads can vary in so many ways from the design loads, whether in magnitudes, combinations, or repetitions. Therefore, a comparison in a real life situation would be difficult, if not impossible, to make.

Energy comparison
The energy comparison approach measures the loads input into the landing gear and the loads from the landing gear into the aircraft structure. When these loads are compared on an energy basis, any difference represents energy absorbed by the landing gear and therefore material damage.

The energy comparison approach represents a method for determining landing gear damage without requiring extensive time histories to be recorded. However, there are some significant challenges. The first is that the landing gear contains an energy absorbing device, the shock strut. This device, when operated nominally converts the energy from landing into heat. Any energy comparison device would have to exclude the shock absorbing element from its analysis, or else monitor the shock strut to quantify its energy conversion. The other challenge is the sheer number of measurements required to be made: landing gear wheel or axle input loads, landing gear attachment loads, and shock strut energy conversion. Beyond these complexities, the concept is very clever—the difference between energy in and energy out, when corrected for shock strut effects (by employing a numerical model of the dynamic response of the oleo–pneumatic strut), is energy that went into damaging the material of the landing gear.

5.3.2 Model-based approaches

The model-based approaches represent the most conventional approaches to determining part damage. Essentially, the landing gear wheel or axle input loads are determined by directly measuring them or by inferring them from aircraft reference frame measurements. These loads are saved as a time history for later analysis. A plain analysis of the input

loads is equivalent to the applied load comparison approach described in the section titled "Applied load comparison". However, if the input loads are converted into landing gear structural loads by developing a structural analysis model of the gear, such as a beam model, time histories of the applied load for each structural element of the landing gear can be developed. A fatigue analysis of each element could then be conducted to determine the amount of damage in each part.

Messier-Dowty has developed a strain logger concept that has been certified for installation by Transport Canada on the Bombardier Regional Jet landing gear. The technology, developed as a 4-channel or a 12-channel device, combines pulsed-power excitation to the strain gauges with onboard data analysis and a combined battery–memory module to facilitate in-field removal and replacement of the memory unit [26]. The four-channel strain logger can be seen in Figure 4.

The strain logger process of determining the life consumed in a landing gear part is as follows: measurement of in-service loads, conversion of these loads to input ground loads, conversion of these loads to critical section load histories by means of the landing gear beam model, rainflow counting of critical section loads, and computation of the damage in the part considering the section and material properties.

The above-mentioned process involves a significant amount of computation. To ultimately perform onboard computation of part damage, it is proposed to precalculate a matrix of damage coefficients for a given section. Each damage coefficient would relate to the damage input by one cycle of a particular range–mean pair of loads. The coefficients would be calculated to match the range–mean pairs generated by the rainflow counting of loads for a specific section. Thus, the calculation of damage would become a multiplication and accumulation calculation. The dot product of the rainflow count matrix and the damage matrix could be taken. Then a summation of all resulting values could be taken to arrive at the damage number. This approach would reduce the onboard computation difficulties to the calculation of the input ground loads (algebraic computations) and of running of the beam model.

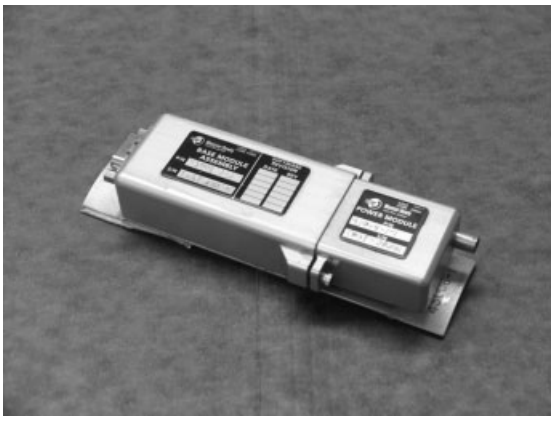

Figure 4. Messier-Dowty four-channel strain logger. [Reproduced with permission. © Messier-Dowty Inc.]

There are some significant challenges with this admittedly brute force approach. Data retention over long periods of time would be necessary. Extensive mathematical analysis capability would be required such that each landing gear component in the fleet would possess its own fatigue spectrum that would have to be updated regularly. Data must be conserved across a significant number of aircraft; an approach must be developed to deal with missing or incorrect data; and the infrastructure must exist to track damage data with a part-through operation and maintenance cycles. Lastly, the model-based approach still suffers from the limited understanding of the mechanisms of fatigue, such as scatter factor, a value used to account for statistical variation in fatigue.

Even given the limitations of the understanding of fatigue, the concept of measuring landing gear loads and recording them for later analysis provides significant advantages. Some of these advantages include utilizing the data by performing "one-off" analyses of the loads for incident investigations, performing a statistical analysis of ground loads so that fleet behavior could be tracked (usage outside of the norms could be identified), and collecting data that could be used to refine the design values for future aircraft.

6 CONCLUSION

Aircraft landing gear systems continue to develop. Structural and performance monitoring is being added to landing gears in operations where an economic or safety need exists. At the time of writing this article, most of the large aircraft landing gear systems

include monitoring of the brakes and tires, both to increase safety and to increase aircraft utilization. New aircraft are incorporating monitoring systems for the shock absorber in order to permit reduced maintenance effort.

Several technologies exist to permit more direct monitoring of the landing gear structure and to permit the material condition to be directly measured. Work continues in the development of robust sensors and effective algorithms to allow the commercial fielding of structural health monitoring for landing gear that offers reduced total cost of ownership along with improved awareness of the landing gear's condition.

As aircraft structures, and indeed landing gear systems, continue on their inexorable march toward lower weight, the ability of structural monitoring to track component life and identify potential failures before they occur will become indispensable.

ACKNOWLEDGMENTS

The authors would like to thank the following friends, colleagues, and fellow employees (past and present) of Messier-Dowty for their invaluable assistance in the development of landing gear structural monitoring systems and the drafting of this article: Mr Cosimo Commisso, Mr Lukasz Hul, Mr Stuart Lacy, Mr Ian McCluskey, and Ms Julia Payne.

1 INTRODUCTION

Flight management and engine control of today's airplanes are highly dependent on electronics. However, despite the importance of electronics to all modern aircraft, avionics have a relatively low-volume market, and have many special requirements, especially in terms of emphasis on mission success, safety, and long-term reliability. Nevertheless, affordability of leading-edge technologies mandates that the avionics industry is largely dependent on commercial-off-the-shelf (COTS) electronic components, modules, and assemblies not originally designed for avionics (but for the consumer, computers, and telecom industry). The result is that COTS electronics reliability and prognostics (the forecasting of failure and prediction of remaining useful life) is a major concern of the aerospace community [1]. This concern is compounded by other concerns, such as part obsolescence, high maintenance costs, and the aerospace's response to the potential for a worldwide legislative ban on lead and other hazardous materials in all electronic devices.

The first efforts in health monitoring of avionics involved the use of built-in test (BIT), which is defined as an onboard hardware–software diagnostic means to identify and locate faults. A BIT can consist of error detection and correction circuits, totally self-checking circuits, and self-verification circuits. Two types of BIT concepts have been employed in avionic systems: interruptive BIT (I-BIT) and continuous BIT (C-BIT). The concept behind I-BIT is that normal equipment operation is suspended during BIT operation. The concept behind C-BIT is that equipment is monitored continuously and automatically without affecting normal operation.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

Studies [2, 3] conducted on the use of BIT for fault identification and diagnostics showed that BIT can be prone to false alarms and can result in unnecessary costly replacement, requalification, delayed shipping, and loss of system availability. However, there is also reason to believe that many of the "false alarms" were "real" failures, but intermittent in nature [4]. In any case, BIT has generally not been designed to provide prognostics or remaining useful life. Rather, it has served primarily as a static diagnostic tool.

With increasing functional complexity of onboard autonomous avionic systems, there is an increasing demand for system-level health assessment, fault diagnostics, and prognostics, especially to meet critical safety and mission requirements. This is of special importance for soft faults and intermittent failures, which are some of the most common failure modes in today's avionics.[a] As a result, there is a need for effective and efficient reliability prognostics for avionic systems using algorithms that can fuse sensor data, discriminate transient (intermittent), and false alarms from actual failures, correlate faults with relevant system events (e.g., aircraft mode changes), and reduce redundant processing elements that are subject to common mode failures. Finally, there is the need to assess remaining useful life to aid in forecasting maintenance and system life.

Prognostics and health monitoring (PHM) techniques combine sensing, recording, and interpretation of environmental, operational, and performance-related parameters to assess a system's health and health trends (often in terms of remaining life). Product health monitoring can be implemented through the use of various techniques to sense and interpret the parameters indicative of performance degradation, such as deviation and trending of operating parameters from their expected values; changes in physical or electrical degradation, such as material cracking, corrosion, interfacial delamination, electrical resistance, or threshold voltage; and changes in a life-cycle environment, such as usage duration and frequency, ambient temperature and humidity, vibration, and shock.

2 APPROACH TO AVIONICS HEALTH MONITORING, DIAGNOSTICS, AND PROGNOSTICS

A heath monitoring and prognostics framework for avionics is shown in Figure 1. The first step involves a virtual life assessment, where design data, expected life-cycle conditions, failure modes, mechanisms, and effects analysis (FMMEA), and physics-of-failure (PoF) models, which were used in the product design for reliability (DfR), are the inputs to obtain a reliability (virtual life) assessment. On the basis of the virtual life assessment, it is possible to prioritize the critical failure modes and failure mechanisms. The existing sensor data, bus monitor data, and

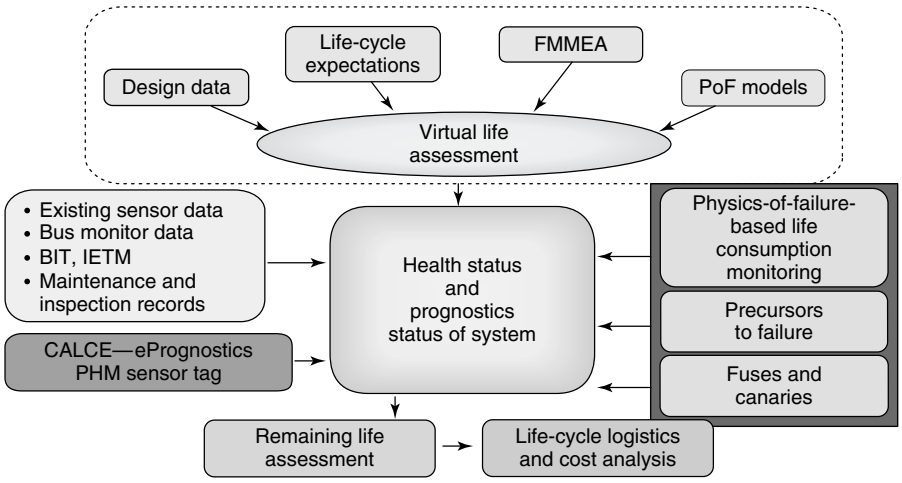

Figure 1. Prognostics and health management methodology for avionics systems.

maintenance and inspection records can also be used to identify potential weak items, as well as potential abnormal conditions and parameters. On the basis of this information, the monitoring parameters and sensor locations for PHM can be determined.

The input for the fault detection (diagnostics) and prognostics is the real-time system-level sensor data of the operating and environmental conditions. Operating condition data can also comprise the output of canary circuits (or fuse networks), as well as soft variables such as system loads and other performance metrics.

On the basis of the sensor and other input data, three approaches, including combinations of these approaches, to prognostics for avionics can be implemented. These are (i) the use of fuses and canary devices; (ii) monitoring and reasoning of failure precursors; and (iii) monitoring environmental and usage loads for damage modeling. It is then possible to assess the product life-cycle usage profile, health, and conduct failure prognostics.

2.1 Health monitoring and extraction of anomalies

Health management systems are programs that respond in a preemptive and opportunistic manner to the anticipation of failures. The health state of an avionics system is characterized by extracting features from the real-time data, taking into account varying operational (parameter) ranges and profiles that constitute a "healthy system".

Generally, a healthy system is defined from a training model. The training model captures "known healthy" system data and uses feature extraction to establish conditions of acceptable health. These conditions are then used to assess whether a monitored system can be classified as healthy.

Feature extraction data is also fed into fault algorithms that generate classifications and probabilities of "unhealthy" or fault states as well as define the scales appropriate for fault detection (i.e., some faults are detected on a nanosecond timescale, while other degradation mechanisms can have failure timescales that are equivalent to the system life). An anomaly can be further classified by analyzing it through fault algorithms, using statistical approaches for trend analysis. When the fault algorithms show positive trending or meet a fault classification, then the next step is to conduct fault and/or failure prognostics.

2.2 Parameter and fault isolation

The objective of the fault prognostic algorithms is to assess faults (parameter and fault isolation) and then predict failures within a reasonable time and prevent false alarms as well as missed alarms. Missed alarms are prevented by the fault prognostic algorithms independently accessing the health monitoring data and analyzing the probability of transition from a health state to a fault state. Evaluation of the transition probability, as well as the fault classification, is used to identify potential precursor(s) to failure. A no-fault-found (NFF) event may not have a well-defined (classified) fault; however, it can still change the fault prognostics by changing the transition probabilities of the states in the data-driven approaches and thus can be captured. Then, by combining data-driven fault isolation with PoF, the fault can be isolated and the root cause for failure identified.

Damage can be calculated from the PoF models to obtain the remaining life. Then PHM information can be used for maintenance forecasting and decisions that minimize life-cycle costs and maximize availability of some other utility function.

The output from fault prognostic algorithms can be stored for off-line analysis. Off-line models derived from real field use data offer more effective and efficient maintenance planning and can also influence mission scheduling, future designs, as well as line replaceable unit (LRU) selection and sparing. Another advantage of these off-line models is that maintenance algorithms can be tailored to look at much longer or finer windows of data that may be computationally intensive. For example, printed circuit board (PCB) faults are usually intermittent in nature and may not fully reveal their nature during the on-line model analysis. However, these intermittents can be tracked and correlated to assess features including excessive delay, electromagnetic interference, and cross talk [4]. Using PoF techniques and off-line models, failure signatures can be developed and further abstracted into failure states that can then be implemented into the on-line framework.

3 RELIABILITY REQUIREMENTS FOR ANALYSIS

Three key requirements that the avionics community considers to be critical in the implementation of diagnostic and prognostic techniques and algorithms are as follows: (i) robust on-line data fusion and state determination to discriminate transient and false alarms from actual failures, (ii) data analysis algorithms to correlate "soft" avionics faults with other relevant events (e.g., aircraft mode changes), and (iii) prognostic algorithms to track degradation and predict remaining useful life for avionics systems. The following sections discuss these requirements in terms of algorithm features and dependencies and how they relate to system reliability.

3.1 Robust on-line data fusion and state determination algorithms to discriminate transient and false alarms from actual failures

Failures in complex electronic systems can be extremely difficult to isolate and identify [5]. An electronic system that has been observed to fail in the field often functions correctly during subsequent fault-finding activities. Consequently, fully functional units are often replaced, which leads to ineffective cost management, or worse, to maintenance practices that permit returning a potentially faulty unit to the field, which can be a safety hazard [2].

Various terms such as "cannot duplicate (CND)", "retest OK (RTOK)", "no fault indicated (NFI)", "NFF" and "no trouble found (NTF)" are used to describe this phenomenon. These are also defined as *soft* faults. Typical causes of soft faults include transient failures due to particle radiation, power supply fluctuations, intermittently occurring faults due to loose connections, partially defective or deteriorating components, and poor hardware design. A soft fault also arises due to the inability of the laboratory environment to duplicate the field load conditions exactly and due to the self-healing of failures such as solder joint cracks during testing. In certain cases, the occurrence of soft faults indicates the use of inappropriate diagnostic procedures or that the total fault spectrum is larger than the fault coverage.

Intermittent failure causes of NFF can be grouped into five categories: PCBs, components, interconnects, connectors, and software. Figure 2 is a fishbone diagram for intermittent failures at an assembly (LRU) level.

In situ diagnostics is necessary to catch most soft failures. On-line data fusion refers to an algorithm's ability to analyze performance variables on all scales of actual measurement *in situ* to operation. At the same time, diagnostic and prognostic algorithms must be able to discriminate between events related to faults and common mode operational process outliers. For example, outliers can be present in the data due to natural changes in a process, due to intrusive changes, or simply due to noise, instrumentation, and human error.

One approach has been to center-normalize the data to remove differences in scale. Variants of this approach may be necessary to enable customization of scales and reduce noise dependent on the measurement metrics. Reduction and filtering techniques (affine projection using principal component analysis (PCA), Sequential Bayesian filtering, and regressive moving average) are ways to separate noise and extremes in data.

State determination in PHM refers to an algorithm's ability to make decisions pertaining to the health trends of a system. Data trending methods can be used to detect potential anomalies and, in some cases, to discriminate transient and false alarms from actual failures, but these methods only examine changes from a predefined normal (healthy) state. Unless there exists a history of failure data (degradation patterns in which the system degrades and ultimately fails), data trending is not sufficient to predict failures. In such cases, the association of an anomaly and trend to a failure mechanism and failure mode requires a PoF approach.

3.2 Data analysis algorithms must correlate "soft" avionics faults with other relevant events (e.g., aircraft mode changes)

To correlate "soft" avionics faults with other relevant events, especially intermittent failures and false errors, a correlation scheme of the system parameters linked to the related system characteristic or features

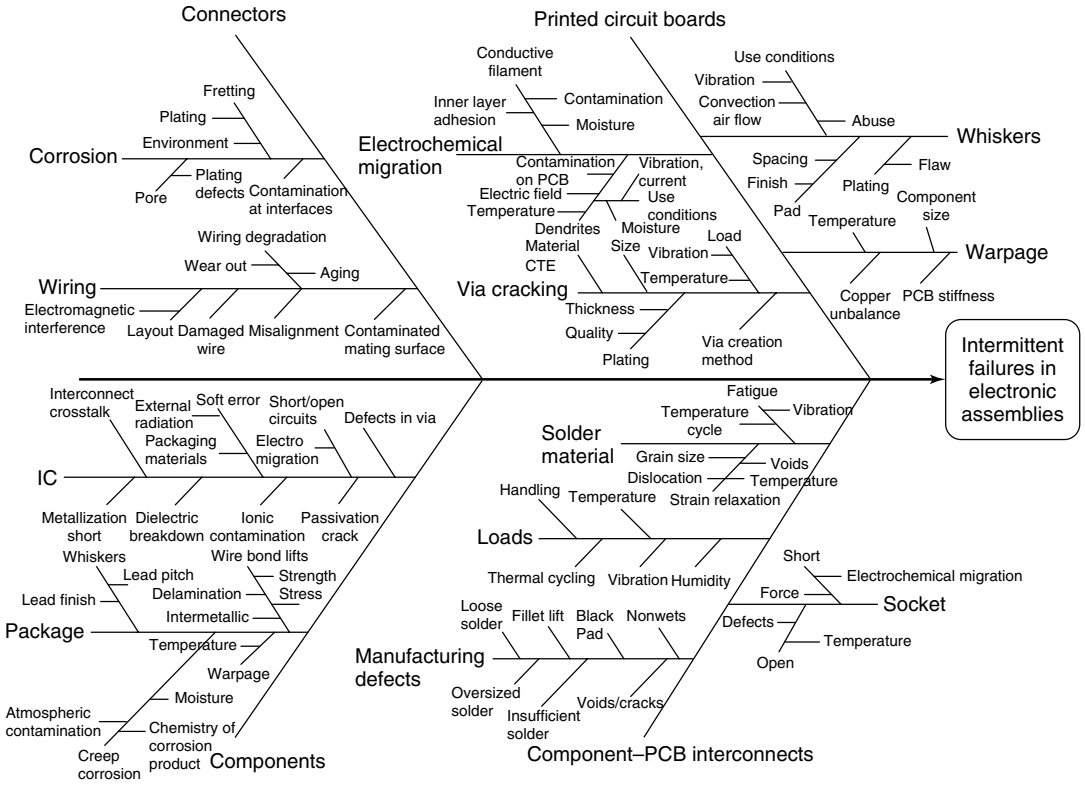

Figure 2. Cause-and-effect diagram for intermittent (soft) failures in electronic line replaceable units (LRU). [Courtesy of CALCE—University of Maryland.]

is a preferred approach. The critical task, however, is to select criteria to uncover the associations to the event of interest (e.g., aircraft mode changes). Again, this requires understanding of failure modes and mechanisms, which are the links to system-level performance. One approach is to use FMMEA to aid in the analysis.

FMMEA is based on understanding the relationships between product requirements and the physical characteristics of the product (and their variations in the production process), the interactions of product materials with loads (stresses at application conditions), and their influence on the product's susceptibility to failure with respect to the use conditions. FMMEA combines life-cycle, environmental, and operating conditions and the duration of the intended application with knowledge of the active stresses and potential failure mechanisms.

FMMEA prioritizes the failure mechanisms based on their occurrence and severity to provide guidelines for determining the major operational stresses and environmental and operational parameters that must be accounted for in the design or be controlled. The life-cycle profile is used to evaluate failure susceptibility. If certain environmental and operating conditions are nonexistent or generate a very low-level stress, the failure mechanisms that are exclusively dependent on those environmental and operating conditions are assigned low occurrence. Severity ratings are obtained from the failure modes associated with the mechanism and there can be more than one failure site mode for the same mechanism. The high-priority failure mechanisms identified through combination of occurrence and severity are the critical mechanisms. Each critical failure mechanism has one or more associated sites, modes, and causes in an FMMEA result.

Failure mechanisms are the physical, chemical, thermodynamic, or other processes that result in failure. Failure mechanisms are categorized as either

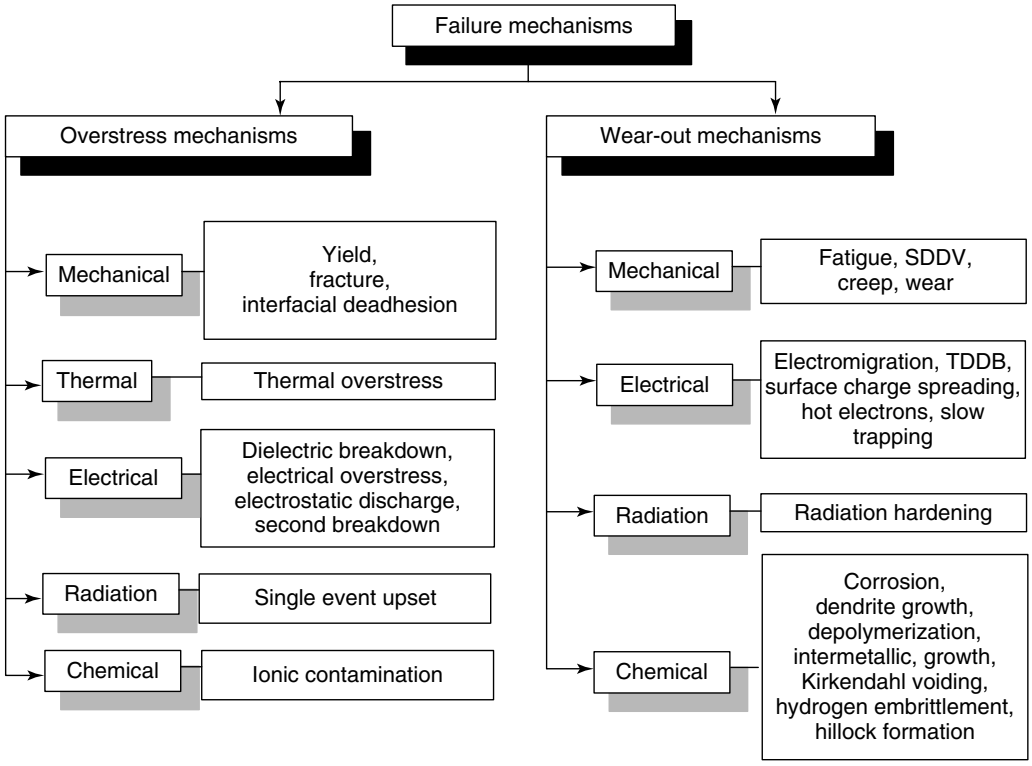

Figure 3. Example of failure mechanism breakdown into overstress and wear out for electronic products.

overstress or wear-out mechanisms (see Figure 3). Overstress failure arises as a result of a single load (stress) condition, which exceeds a fundamental material strength. Wear-out failure arises as a result of cumulative damage due to loads (stresses) applied over an extended time or number of cycles. Within current technology, prognostics can only be applied to the wear-out failure mechanisms [6].

3.3 Prognostic algorithms must track degradation and predict remaining useful life

Prognostic algorithms take time-dependent data history, extract a trend, and estimate the value of the function at some future time. The objective function for prognostics is the health state of the system. Time series, neural networks, support vector machines (SVMs), Markov chains, and parameter estimation are some popular techniques for forecasting avionic systems. However, PoF prediction is most often required to set the failure criterion and make the determination of the remaining useful life.

Mathew *et al.* [7, 8] applied a PoF-based PHM methodology to conduct a prognostic remaining-life assessment of circuit cards inside the space shuttle solid rocket booster (SRB). Vibration time history recorded on the SRB from the prelaunch stage to splashdown was used in conjunction with physics-based models to assess damage. Using the entire life-cycle loading profile of the SRBs, the remaining life of the components and structures on the circuit cards was predicted. It was determined that an electrical failure was not expected within another 40 missions.

Tuchband *et al.* [9] presented the use of prognostics for a military avionics LRU based on their life-cycle loads. The study was part of an effort funded by the Office of the Secretary of Defense to develop an interactive supply-chain system for the US military. The objective was to integrate prognostics, wireless communication, and databases through

a web portal to enable cost-effective maintenance and replacement of electronics. The study showed that prognostics-based maintenance scheduling could be implemented into military electronic systems. The approach involved an integration of embedded sensors on the LRU, wireless communication for data transmission, a PoF-based algorithm for data simplification and damage estimation, and a method for uploading this information to the Internet. It was shown that the use of prognostics for electronic military systems could enable failure avoidance, high availability, and reduction of life-cycle costs.

4 PROGNOSTICS

The identification of the variation trend in the parameter values of a system can provide information on drift and/or degradation in performance. Time series analysis techniques are efficient tools for capturing such trends. Other methods being considered by the avionics community include autoregressive moving average (ARMA), autoregressive with exogenous inputs (ARX), autoregressive moving average with exogenous inputs (ARMAX), and autoregressive integrated moving average (ARIMA). Symbolic time series analysis (STSA) is an extension of these traditional time series analysis techniques; it discretizes the continuous dynamic system in time and space, and represents the trajectories of observed variables/parameters as a sequence of symbols. Although time series methods perform well in parametric degradation forecasting, they are not well suited for failure forecasting, which requires prediction algorithms (usually PoF) capable of working with abrupt and quantized data.

SVMs are also being used for forecasting the system health [10, 11]. SVMs minimize an upper bound of the generalization error, through the use of kernel functions and the structural risk minimization principle, and generally achieve higher generalization performance than traditional neural networks in time series forecasting. However, they also suffer from difficulties in predicting failure occurrence without the use of PoF models.

Precursors to failure are the characteristic features that will help enable predictions of the system health. However, the metrics to assess the precursors is of critical importance in this step. For example, in an experiment conducted on intermittent failures of LRUs, it was shown that data trending prognostic methods provided no value. However, by embedding PoF relationships to directly modify scales of measurement, tremendous insight can be obtained and subsequent predictions made [12].

5 CONCLUSIONS

The avionics community has begun to implement fault event detection techniques using PoF-based methods for successful diagnostics. These include algorithms that extract cyclic ranges and means, ramp rates, dwell times, and dwell loads, and then correlate all these load parameters with PoF models to enable fault isolation and prognostics. In some instances, statistical projection pursuit, feature extraction, and pattern-recognition algorithms have also been used to detect and isolate faulty parameters, but mostly in experimental studies (products subject to accelerated aging conditions). In this case, PCA techniques have been utilized to build the projection models, cluster analysis techniques of multivariate data sets were used for anomaly detection, and multivariate state estimation technique (MSET), sequential probability ratio test (SPRT), and PoF-based hybrid methods were used to conduct the prognostics.

The next step for the avionics prognostics community is to extend these studies and provide

- efficient and cost-effective root-cause evaluation tools (software), which couple the PoF and time series PHM approaches to discriminate false alarms from actual failures;
- rapid fault identification and prognostics (software), which use SVM and STSA coupled with feature extraction, pattern recognition, and PoF analysis to predict system degradation, malfunctions, and remaining useful life of critical avionic systems;
- validated prognostic methods (algorithms) to detect and predict degradations, malfunctions, and failures on an LRU/line replaceable module (LRM) (including intermittent failures, soft faults, and random false alarm events); and
- demonstrated methods and algorithms to determine return on investment benefits.

END NOTES

[a.] An intermittent failure, which can lead to diagnostic conclusions of "CND", "RTOK", "NFI", "NFF"), and "NTF", is the loss of function for a limited period of time, and subsequent recovery of the function. This "failure" may not be easily predicted, nor is it necessarily repeatable. However, an intermittent failure can be, and often is, recurrent.

Chapter 110

Design Benefits in Aeronautics Resulting from SHM

Hans-Juergen Schmidt and Bianka Schmidt-Brandecker

AeroStruc—Aeronautical Engineering, Buxtehude, Germany

1 INTRODUCTION

The primary objective of the aerospace industry is to offer products that meet improved goals in terms of payload and range, resulting in a significant reduction of the direct operating cost (DOC) for the airlines. These goals require an integrated approach considering advanced materials, new design principles and improved inspection procedures, e.g., structural health monitoring (SHM).

One of the primary focuses of SHM applications has been on the reduction of the weight as proposed by Schmidt and Schmidt-Brandecker at Airbus [1] for metallic structures and by Goggin *et al.* at Boeing [2] for structure made of carbon fiber reinforced plastics (CFRPs).

Modern aircraft have to meet the so-called damage tolerance (DT) regulations according to the Paragraph FAR (Federal Aviation Regulations) 25.571-Amendment 96 independent of the material, design principles, and manufacturing methods. DT is the attribute of the structure to withstand fatigue, corrosion, manufacturing defects, or accidental damage without catastrophic failure throughout the operational life of the aircraft. This can only be assured with an adequate inspection program based on DT evaluation determining crack growth and residual strength, i.e., the number of flights between a detectable and critical damage (crack) as shown in Figure 1.

DT is the dimensioning criterion for the majority of the fuselage and wing panels; i.e., this criterion is responsible for the weight of these panels. The fuselage and wing panels are stiffened panels, which consist of the skin and internal stringers as well as frames or ribs, respectively. With respect to the difficult access to the internal structure, the traditional inspection concept consists of repetitive inspections of the external skin and less inspections of the internal structure. Consequently, the DT evaluations have to consider a "skin crack above a broken internal member", which is the most severe scenario and leads

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

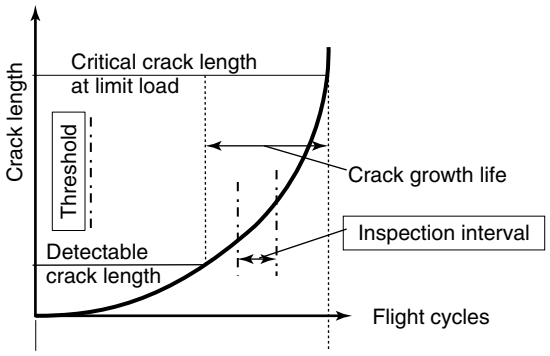

Figure 1. Primary objective of damage tolerance evaluation.

to the shortest crack growth period and the lowest allowable stresses for design.

The knowledge about the status of the internal members of in-service aircraft can be significantly improved by the application of SHM. In this case the DT analysis may consider less severe crack scenarios, e.g., "skin crack above an intact internal member" and/or "skin crack between intact members". Both scenarios lead to longer crack growth periods and higher allowable stresses. The advantage gained by the modified inspection procedure, i.e., external visual and SHM, can be used in different ways as shown in Figure 2:

- increased inspection interval while maintaining the allowable stress level and
- increased allowable stress level while maintaining the inspection interval.

Both improvements are of interest for the manufacturer and airlines. However, the design benefits seem

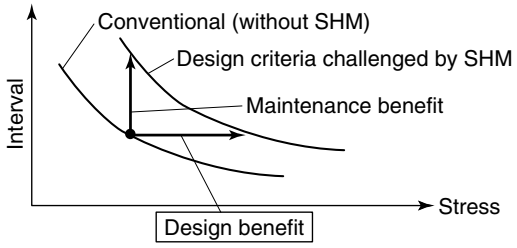

Figure 2. Principal maintenance and design benefits due to the application of SHM.

to be more interesting, because a significant weight saving can be realized to reduce the DOC.

In general the metallic fuselage structure is dimensioned for several design criteria. SHM provides significant weight or maintenance benefits to areas mainly dimensioned by DT, i.e., crack growth and residual strength. For other areas, dimensioned mainly by, e.g., static strength, deformation, and/or durability, SHM may provide maintenance benefits only. In the latter case, the allowable stresses and the weight cannot be improved.

2 FUNDAMENTALS

The DT evaluation for stiffened fuselage panels, which are biaxial loaded, considers three crack scenarios (I, II, and III) in circumferential direction and three crack scenarios (IV, V, and VI) in longitudinal direction as shown in Figure 3. In case of SHM application the most severe scenarios (I and IV) can be excluded, which leads to the benefits described in further detail below.

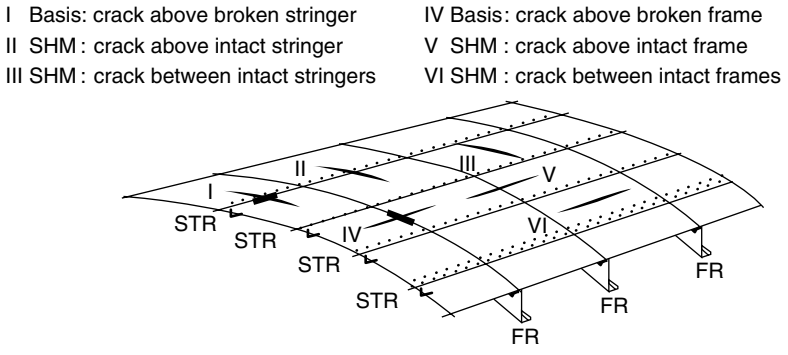

Figure 3. Crack configurations for DT evaluation with and without SHM.

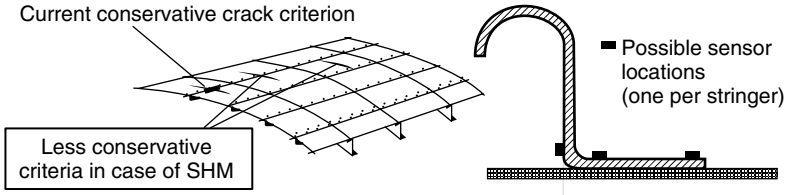

Figure 4. Location of sensor for crack detection at stringers.

The exclusion of scenario I for circumferential cracks requires a repetitive monitoring of the stringers for cracking or failure. Since cracks may originate from fastener holes in the stringer foot, this location is the favorable area for SHM application, see Figure 4. The SHM sensor should allow the detection of the complete failure of the stringer foot, which has a width of about 20 mm.

For longitudinal skin cracks, the structural behavior depends on the status of the frames and/or the skin. As principally shown in Figure 5, there are two possibilities for SHM application to allow higher stress levels resulting in significant weight savings, and these include

- skin monitoring for longitudinal cracks that will allow all scenarios IV, V, and VI to be eliminated. The circumferential crack sensors can be applied at the inside of the skin with a distance of approximately one frame bay;
- an alternative possibility in periodic measurement of the stresses at the outer frame flange considering the redistribution of skin loads into the adjacent frames in case of longitudinal cracks in the skin. The most severe scenarios IV and VI could be eliminated in case of SHM application. Since a significant longitudinal skin crack increases especially the stresses in the outer frame flange, this location is the optimum for the SHM sensor on the frame.

The weight and/or maintenance benefits due to SHM application can be determined by crack growth and residual strength analysis using less severe crack scenarios. A conventional linear analysis procedure is generally applied to fuselage structures using Forman, Paris or Walker equations [3]. Most of the computer codes are valid for the analysis of stiffened panels made of metal under uniaxial external loading. Comparisons of analyses using these codes and representative test results from curved stiffened panels tested under internal pressure and external loads revealed that these analyses are very conservative for the failure mode "crack above a broken stiffener", i.e., for scenarios I and IV [4]. The reason for these differences is the biaxial loading of the test panels, which is not represented in the analyses. Therefore, the modified analyses used in this article consider the following features:

- flexibility of skin-to-frame joint due to fastener flexibility and clip connection;
- bulging of the fronts of longitudinal cracks due to internal pressure causing out-of-plane bending;
- load (stress) distribution between skin and stringers due to internal pressure; and
- nonconstant stress distribution between frames.

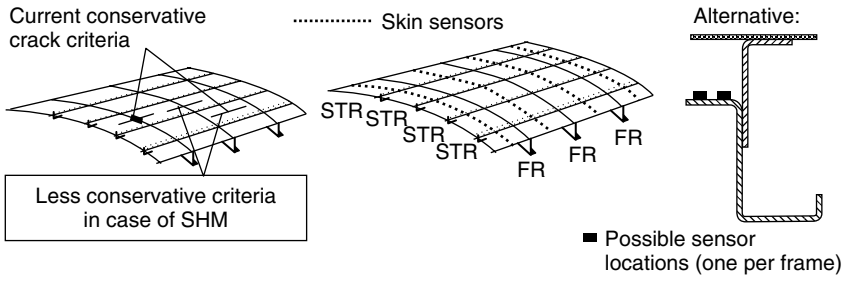

Figure 5. Location of sensors for stress measurement at frames and crack detection at skin.

Reference 4 contains the details of the modified crack growth analysis program providing excellent results, which are in line with the experience from representative tests with large curved panels with similar design and loaded by internal pressure as well as external longitudinal and circumferential loads.

3 QUANTIFICATION OF WEIGHT REDUCTION FOR TYPICAL FUSELAGE STRUCTURE

A correct application of SHM allows higher design stresses and therefore a reduction of the design weight. This can be realized in the fuselage areas where DT is the dimensioning load case. No weight benefits can be achieved in the areas dimensioned by static strength, e.g., in the forward bilge area of the rear fuselage. However, the weight benefits for panels with SHM located in different fuselage areas are not the same owing to different geometric configurations, stresses, and local load spectra. Therefore, all relevant panels have to be analyzed to determine the overall weight reduction.

For demonstration of the complexity of the issue, this article reports the analysis of the weight reduction for four fuselage locations of a modern wide-body aircraft used for medium range. These examples consider typical fuselage structure, i.e., the stiffened panels containing skin, stringers, frames, and frame-to-skin connections by clips. All design elements are made from 2024 material (AlCu alloy). Figure 6 shows the four locations selected and the ratio between the steady stresses in circumferential and longitudinal direction during the flight phase "cruise". The steady stresses consider the effect of the cabin differential pressure and the 1-g condition.

The DT analyses, i.e., crack growth and residual strength calculations, consider steady stresses as well as incremental stresses, e.g., due to gusts, maneuvers, and ground loads. Figure 7 shows the crack growth results for circumferential cracks in the aft upper panel of the rear fuselage, where $\sigma_{\text{skin circ}}/\sigma_{\text{skin long}} \approx 1.0$. The crack growth periods are given from an initial crack length of 76.2 mm to critical crack length. Scenario I is the dimensioning configuration, which can be excluded in case of stringer monitoring for cracks. With the stringer monitoring, the stresses can be increased by 15%, which results in a weight reduction of 13%.

Figure 8 shows the crack growth results for longitudinal cracks in the same panel. The given percentages are related to the basic crack growth period for scenario I in Figure 7.

In case of the described skin monitoring by SHM, the crack scenarios IV, V and VI will be detected before reaching a critical size. Therefore, the stated percentages (70, 170, and 60) for 15% higher stresses are not relevant, i.e., the weight reduction of the panel is defined by the results of the circumferential cracks.

All weight reductions for the four analysis points are presented in Figure 9. The weight reductions of the stiffened panels in the described locations are between 13 and 20%. These benefits can be achieved by SHM monitoring of either locating the sensors on the stringers, or the skin, or on both. These sensor locations are the result of the ratios of the steady stresses and the effect of the incremental load spectra.

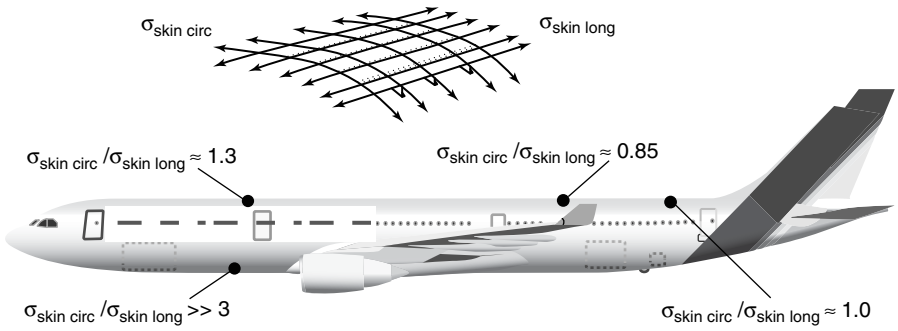

Figure 6. Fuselage analysis areas and ratio of steady stresses during cruise.

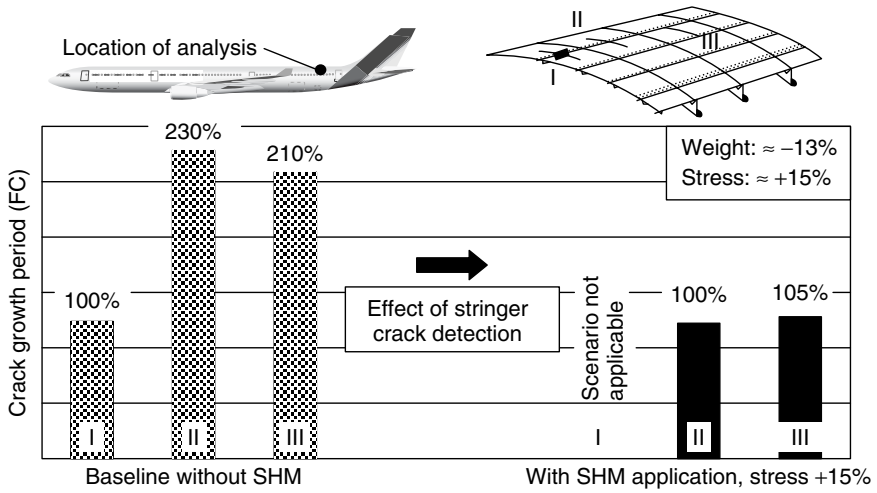

Figure 7. Crack growth results in the aft upper panel of the rear fuselage—circumferential cracks.

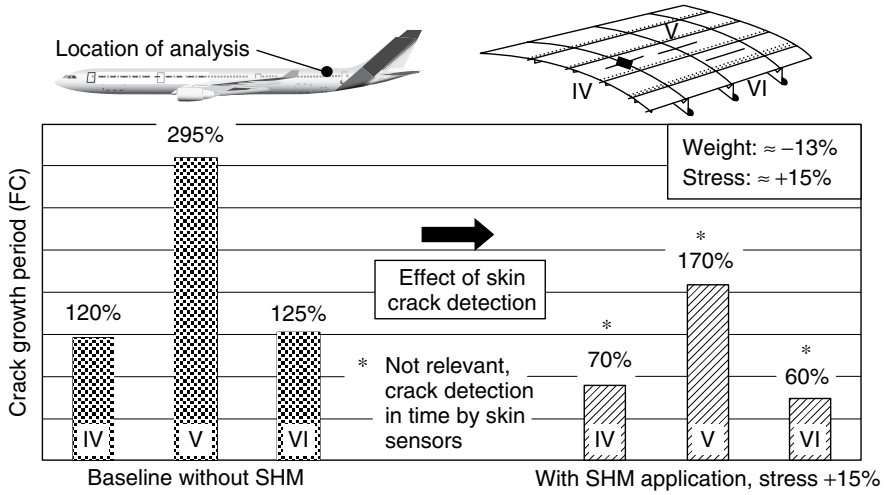

Figure 8. Crack growth results in the aft upper panel of the rear fuselage—longitudinal cracks.

In addition, the weight benefits for circumferential cracks are influenced by the level of the steady stresses. Lower stress levels lead to higher benefits given in percentage when scenario I (without SHM) is replaced by scenarios II and III (both with SHM). As an example Figure 10 shows a generalized chart about possible stress or weight benefits for the upper panels of the rear fuselage. The lower curve applies to panels without SHM, where crack scenario I is dimensioning; the upper curve applies to panels with SHM, i.e., scenarios II and III are to be considered. However, the external surface of the skin has to be inspected for circumferential cracks during heavy maintenance checks besides the SHM monitoring of the stringers.

The proposed skin monitoring shown in Figure 11 will allow the detection of all crack scenarios (IV, V, and VI) in time. Therefore the crack growth of longitudinal cracks according to scenarios IV, V, and VI is no longer a design criterion. In this case the critical crack length $2a_{\text{critical}}$ for limit load condition must be longer than the distance b between adjacent sensors.

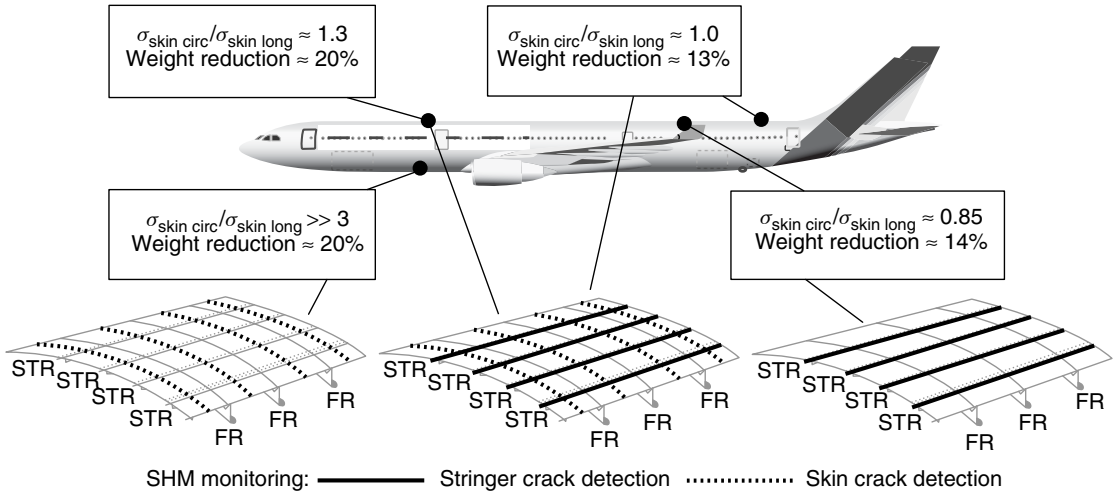

Figure 9. Weight reductions and location of SHM sensors for all analyses locations.

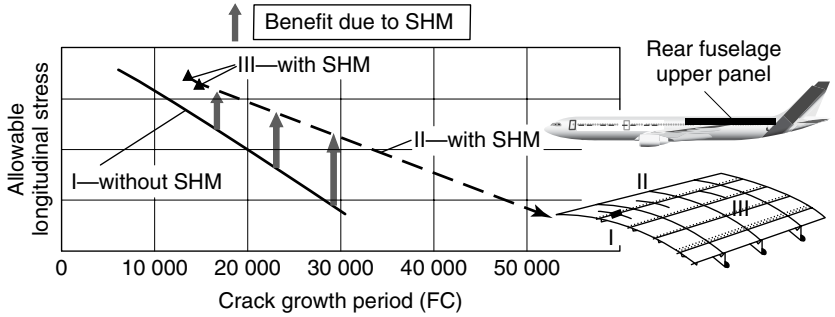

Figure 10. SHM benefits, allowable longitudinal stress for the upper panels of the rear fuselage.

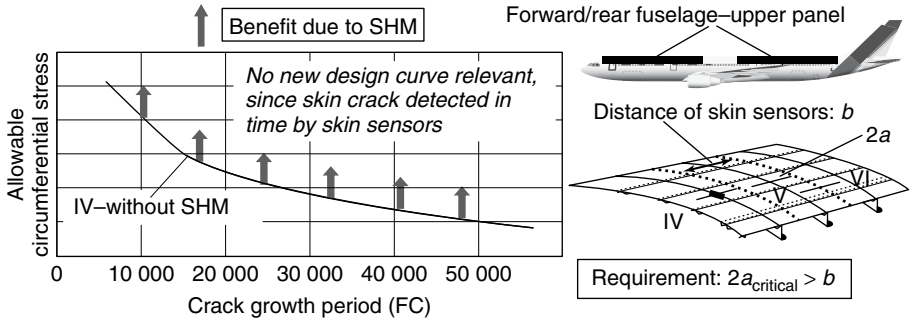

Figure 11. SHM benefits, allowable circumferential stress for the upper panels of the forward and the rear fuselage.

After application of the circumferential sensors no inspection of the external skin is necessary to detect longitudinal fatigue cracks. Therefore this criterion is not relevant anymore (see Figure 11). The alternative strain measurements at frames, as shown in Figure 5, lead to similar weight savings. However, the inspection of the external skin has to be maintained to detect longitudinal fatigue cracks, which is a

disadvantage compared with the skin monitoring proposed above.

4 CONCLUSIONS

The SHM application during the development and design of new metallic aircraft structure offers significant advantages for areas, where DT is the dimensioning criterion. In these areas the stringers or the skin or both elements have to be monitored for cracks by SHM. Alternative to the skin crack monitoring, the frames may be monitored for increased stresses. However, the benefits can only be realized if the SHM system is reliable during the entire life of the aircraft.

The possible weight reduction for four different panels of a typical metallic fuselage, analyzed as examples, is between 13 and 20%. The differences in these percentages are mainly the result of the different stress environments. The optimum definition of the SHM application requires similar DT analyses for all panels as performed for the examples presented in this article.

Chapter 17

Lamb Wave-based SHM for Laminated Composite Structures

Constantinos Soutis

Aerospace Engineering, University of Sheffield, Sheffield, UK

1 BACKGROUND

The development of nondestructive systems to detect and monitor the extent of damage in carbon fiber reinforced plastics (CFRP) during service life is a key challenge in many practical applications, especially in the aircraft industry. The lack of such a technique has severely limited the extensive use of composite materials [1]. Owing to concerns about the integrity of damaged composite structures, engineers are forced to overcompensate during the design process such that the advantages originally expected from composite materials are not fully achieved. An improved understanding of the behavior of sensor and actuator devices and how measured signals relate to damage will contribute to the development of an active system capable of continuously evaluating the condition of a structure. This technology could lead to improvements in composite design, the development of more rapid and appropriate repair strategies, and the withdrawal of expensive periodic maintenance inspections. Thus, the ability to evaluate the integrity of a structure without removing the individual structural components has become an important technology challenge. Several nondestructive evaluation (NDE) methods exist and are used in composite structures. Visual inspection, radiography, ultrasonics, shearography, and thermography are among the most common NDE methods in use. Despite their wide use and improvement in the last decades, the majority of NDE methods are not suitable for implementation in smart structures (self-diagnostic systems). Applications that require a movable probe to obtain data and scan a large area are disregarded as the basis for the development of self-diagnostic systems since they need the direct intervention of humans or a robot to perform the inspection. In principle, a smart in-service health monitoring system would imitate a biological system, where attached or built-in sensors continuously interrogate the structural

integrity throughout the component's life. Therefore, techniques that can operate from fixed locations in the structure while inspecting large areas are prime candidates for the development of a structural integrity monitoring system (SIMS). Furthermore, by fixing (attaching or embedding) the transducers, many variables affecting the reliability and repeatability of measurements are removed allowing the precise assessment of minute changes in structural behavior that permit the early detection of damage occurrence. Smart structure-based methods of large-area inspection using continuously sampled data would ideally supplement the use of existing NDE inspections that are performed off-line.

An attractive technique for the development of a SIMS is the use of Lamb waves. Their application has long been acknowledged as a potential solution for large-area nondestructive inspection because they are able to travel relatively long distances allowing the material between transmitter and receiver to be interrogated [1]. Hence, a line scan is achieved with each pulse rather than the comparatively slower point-scanning performance of conventional ultrasonic techniques. Fundamentally, this method involves the analysis of the transmitted and/or reflected waves after interacting with the test part at boundaries or discontinuities. The presence of damage is identified from changes in the response signal of subsequent tests when compared to the reference response of the undamaged configuration taken earlier in the structure's life.

Lamb waves can be excited and detected by a variety of methods, such as the use of interdigital transducers (IDTs) [2, 3], fine point contact transducers [4], air-coupled ultrasonic transducers [5], laser-generation methods [6], and the widely employed angled perspex wedge [7]. However, among these methods, only IDTs appear suitable for implementation in applications to smart structures, where a small and lightweight, permanently attached transducer system design is required. Still, IDTs present some limitations in the Lamb wave inspection of thick sections that are commonly employed in practical structures. When used in ultrasonic applications, piezoelectric materials are normally operated at their thickness-mode (d_{33}) resonant frequency, which is determined by the thickness of the element and the longitudinal wave velocity in the material. The thickness of piezoelectric elements for practical use varies from a few microns to a few millimeters; thus, the frequency range of piezoelectric transducers extends from the low megahertz (0.5) for thick elements to a few hundred megahertz for very thin films. The lower operational frequency of a transducer imposes an upper limit on the thickness of the plate that can be inspected at values under the cutoff frequency–thickness (fh) product of high-order Lamb modes. For instance, for frequencies less than 250 and 100 kHz, respectively, it would be necessary to have only the fundamental Lamb modes (A_o and S_o) propagating in typical composite aerospace laminates (multilayered plates), which have thicknesses ranging from 6 to 15 mm [8]. To generate the higher modes you need to operate at a higher frequency-thickness value, see Figure 2. Of course the advantage of the proposed method operating at low frequency and generating the basic modes is the simplicity of the signal analysis with the ability to detect relatively small defects in multi-layered composite structures. Likewise, if a 12-mm-thick steel plate is to be tested, frequencies below 136 kHz [9] must be utilized.

This work discusses the generation of Lamb waves for the NDE of composite laminates using surface-mounted piezoelectric elements in narrow strips, operated in the longitudinal mode (d_{31}). When voltage is applied to a bonded piezoelectric patch, it expands and contracts parallel to the surface inducing a bending moment in the structure. If the voltage applied is a sinusoid with a few cycles, the piezoelectric elements produce a transient flexural wave whose transmission, propagation, and subsequent reflections at the specimen's boundaries can be analyzed and used to identify the size and location of damage. The advantage of using longitudinal or radial modes (related to width and length, or diameter) of the piezoelectric element rather than the thickness mode is that the former can be excited at much lower frequencies, which allows the inspection of thicker laminates while keeping the fh product low, thus generating only fundamental Lamb modes. This condition is important in the use of Lamb waves for NDE applications since the excitation of a single Lamb mode favors signal interpretation. The study also examines the modal response of narrow beam specimens for wave velocity measurements using continuous wave excitation [9, 10].

2 EXPERIMENTAL PROCEDURE AND MEASUREMENTS

2.1 Materials and instrumentation

Tests are performed on narrow beam specimens made of aluminum and composite material. The composite beam is cut from a 24 ply $[\pm 45^{\circ}/0^{\circ}/90^{\circ}]_{3s}$ carbon/epoxy laminate of size 660 mm × 570 mm. The laminate is fabricated using T300-924C prepreg tapes. Individual test specimens 629 mm × 25 mm and 2.7 mm thick are cut from the laminate using a diamond-wheel saw. The elastic properties of the unidirectional ply are $E_{11} = 162$ GPa, $E_{22} = 11$ GPa, $\nu_{12} = 0.34$, $G_{12} = 5.7$ GPa, and the density is $\rho = 1536\,\mathrm{kg\,m^{-3}}$ [11]. The dimensions of the aluminum specimen are 814 mm × 16 mm and 3.3-mm thick. The beams are instrumented with two piezoelectric patches, 20 mm × 5 mm, made of commercial brass-backed piezoceramic resonators, which are used as an actuator and a sensor, respectively, and bonded near the beam's end, as shown in Figure 1. National Instruments' LabVIEW® signal processing and an analog-to-digital card (PCI-MIO-16E-1) are used in conjunction with a personal computer to implement the data transmission/acquisition under an automated framework and to perform the sensor response analyses.

2.2 Phase velocity measurement

The wave velocity is the fundamental characteristic of a Lamb wave because wave propagation may be analyzed by the variation in its velocity as a function of the *fh* product for each Lamb mode, as shown in Figure 2. These relations (dispersion curves) are found by numerical solution of the Rayleigh–Lamb relation for wave propagation in isotropic plates, described comprehensively by Viktorov [12]. They can also be determined experimentally using the amplitude spectrum method [13] and the phase spectrum method [14].

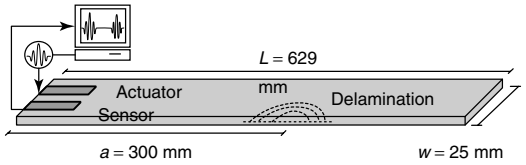

Figure 1. Experimental setup of the composite beam specimen.

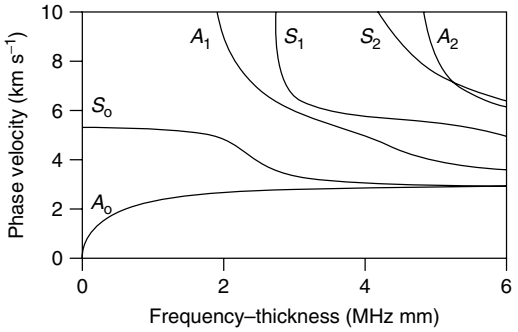

Figure 2. Lamb wave phase velocity dispersion curves for aluminum. [Reused with permission from Sergio H. Diaz Valdes and Costas Soutis, The Journal of the Acoustical Society of America, 111, 2026 (2002). © Acoustical Society of America, 2002.]

In this work, the dispersion curve of the A_0 Lamb mode in the low *fh* product range is determined experimentally from the mechanical resonant response of the beam specimens [15]. In a narrow beam of length L, the particle velocity at resonance consists of a series of standing waves whose frequency correspond to the condition that an integral number of half wavelengths fits in the sample. Thus, resonance exists when $2L = \lambda n$, where n is the harmonic integer and λ is the wavelength. Since the phase velocity is given by

$$c_{\mathrm{p}} = \lambda f \tag{1}$$

the nth mechanical resonance frequency can be expressed as

$$f_n = \frac{nc_{\mathrm{p}}}{2L} \quad \text{or} \quad \omega_n = \frac{2\pi nc_{\mathrm{p}}}{2L} \tag{2}$$

The resonance spectrum of the aluminum specimen is obtained using forced mechanical vibration. The actuator is excited with a 10-V sine-sweep signal [16], varying from 0.1 to 50 kHz in 0.2 s. The structural response captured with the sensor is sampled at a rate of 0.8 MHz and is then Fourier transformed to obtain the resonant frequencies as shown in Figure 3.

The well-defined peaks shown in Figure 3 correspond to the flexural modes of the beam, whereas the smaller peaks appearing above 20 kHz correspond to axial modes. Below 1 kHz, the resonance maxima are only poorly excited so that the modal number of each peak cannot be indexed reliably. Therefore, the appropriate value of n is estimated by comparison with theoretical values of the natural frequencies of

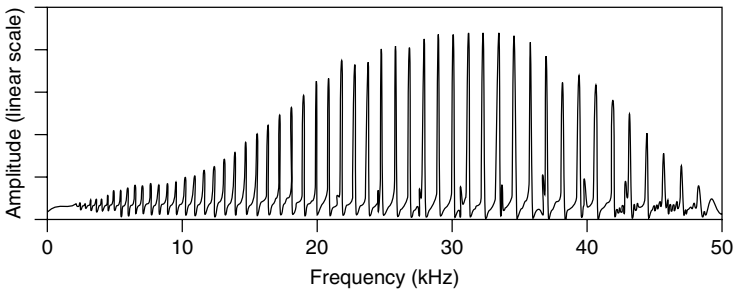

Figure 3. Resonance spectrum of the response of the aluminum beam to sine-sweep excitation.

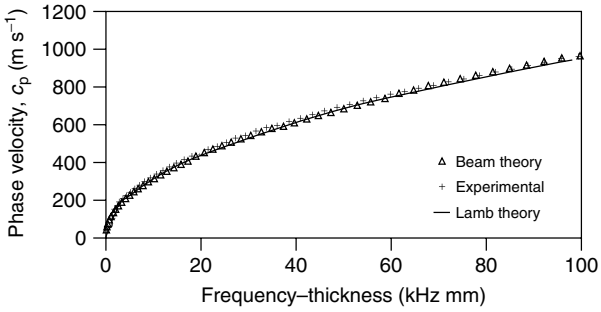

Figure 4. Phase velocity in a 3.3-mm-thick aluminum beam measured using the mechanical resonance method. Beam and Lamb wave theory estimates are also presented.

a uniform beam in transverse flexural vibration using the following expression [17],

$$f_i = \frac{\lambda_i^2}{2\pi L^2}\sqrt{\frac{EI}{m}}; \quad i = 1, 2, \ldots \tag{3}$$

where m is the mass per unit length of the beam, E is the modulus of elasticity, I is the second moment of area, and λ_i is the solution of the characteristic equation for the imposed boundary conditions (free–free).

Figure 4 shows the dispersion curve for the A_o mode in aluminum obtained using the resonance frequency values from Figure 3 that are substituted into equation (2). Also, the beam theory results derived using equations (2) and (3) are presented in Figure 4 along with the Lamb theory curve for aluminum and show excellent correlation with the experimental results.

The phase velocity of the A_o Lamb mode in the composite specimen is also measured using the resonance spectrum method. The sine signal used to excite the actuator is swept from 0.1 to 25 kHz in 0.2 s, and the structural response is sampled at a rate of 0.5 MHz. Figure 5 shows the experimental curve for the laminated beam along with the Lamb theory curve calculated using the average elastic properties of the orthotropic plate [18]. The experimental data shown in Figure 5 have the characteristics of the dispersion curve of the A_o Lamb mode, although the agreement between Lamb theory and experimental results is not quite as good as for the isotropic case, especially as the *fh* product increases (decreasing wavelength). The difference can be attributed to the fact that transverse shear deformation effects, which are neglected in the formulation of the classical plate theory, are significant in the case of laminated plates due to the relatively low transverse shear modulus [19]. It can be seen from Figure 4 that Lamb wave and beam theory can be used to successfully predict the dispersion curves of an isotropic material. However, for composite laminates, no obvious analytical solutions and numerical techniques are required to model such systems. In this study, dispersion curves are measured experimentally using the resonance spectrum method, which is a reliable procedure for measuring low-frequency, long wavelength, flexural wave phase velocity.

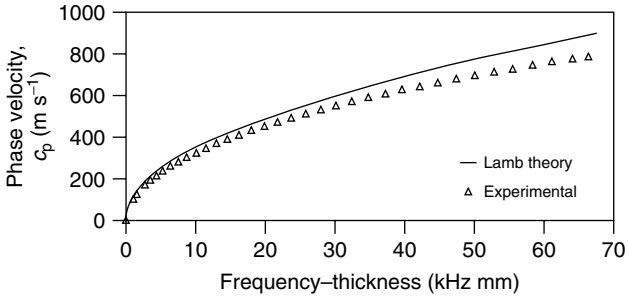

Figure 5. Phase velocity in a 2.7-mm-thick $[\pm 45^{\circ}/0^{\circ}/90^{\circ}]_{3s}$ composite beam measured using the mechanical resonance method. Lamb theory estimates are also presented.

2.3 Delamination detection

Owing to the relatively low interlaminar strength of composite laminates, damage in the form of delaminations can be easily introduced from low-velocity impacts during service, with the subsequent degradation of the mechanical properties of the laminate that can lead to the premature failure of structural components. In practice, composite laminates are designed to tolerate certain degrees of damage and it is often only necessary to find relatively large defects such as 10–20-mm-diameter delaminations [20]. For instance, the typical size of a critical defect in a composite structure for a Harrier aircraft is approximately 20–25 mm [8].

To study the ability of Lamb waves for delamination detection at low *fh* values, the composite beam is examined at different damage scenarios. The beam specimen is excited with short sinusoidal pulses rather than with continuous wave excitation, as was previously done for phase velocity measurements. The undamaged beam is tested and its response history is captured and kept as a baseline. Then a sharp and thin scalpel blade is inserted into the beam's midplane, 300 mm from the left end, as shown in Figure 1. The blade is forced into the material initially producing a small delamination, whose dimension is increased each time the blade is forced into the midplane. In this manner, the delamination area is gradually extended from a small incision located at one edge of the beam until it almost reaches a full-width delamination. This type of artificially induced delamination is thought to better represent damage patterns observed in fatigue loading [10, 15] than beams with a full-width delamination of fixed length, as is commonly found in the literature. The damage area, A_d, is measured at every stage by conventional ultrasonic C-scan, as shown in Figure 6.

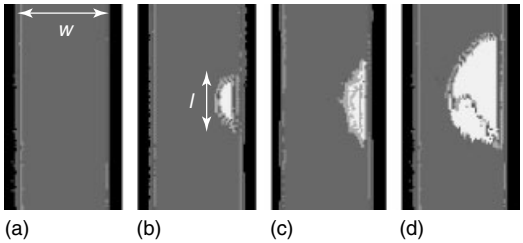

Figure 6. Ultrasonic C-scans of the composite beam: (a) no delamination, (b) $A_d = 22\,\text{mm}^2$, (c) $A_d = 47\,\text{mm}^2$, and (d) $A_d = 220\,\text{mm}^2$.

Figure 7(a) shows the response of the undamaged composite beam when the actuator is excited with a 15 kHz sinusoidal pulse of 5.5 cycles modulated by a Hanning window. The response history shows the input pulse followed by another large wavelet, which is the first reflection from the opposite end of the beam. The time delay between the transmitted and reflected signals corresponds to the propagation distance of the wave, which is twice the length of the beam. The second and third reflections are also identified using longer acquisition times, suggesting a propagation range well over 2 m. However, the response signals shown in Figure 7 only contain the first reflection. It can also be observed that the shape of the wave changes as it propagates along the beam due to the dispersive nature of the A_o mode at this *fh* value.

The same test is performed after damage has been induced, thus providing the specimen response at a different stage of delamination growth. In comparison to Figure 7(a), Figure 7(b–d) shows an extra reflection between the input pulse and the first reflection from the end of the laminate. It can also

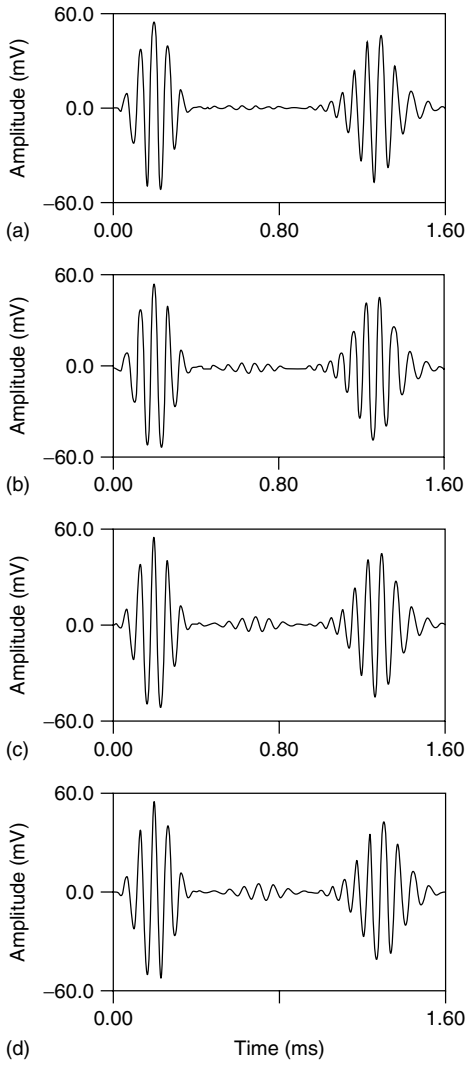

Figure 7. Measured response of the composite beam at different stages of damage: (a) no defects, (b) $A_d = 22\,mm^2$, (c) $A_d = 47\,mm^2$, and (d) $A_d = 220\,mm^2$.

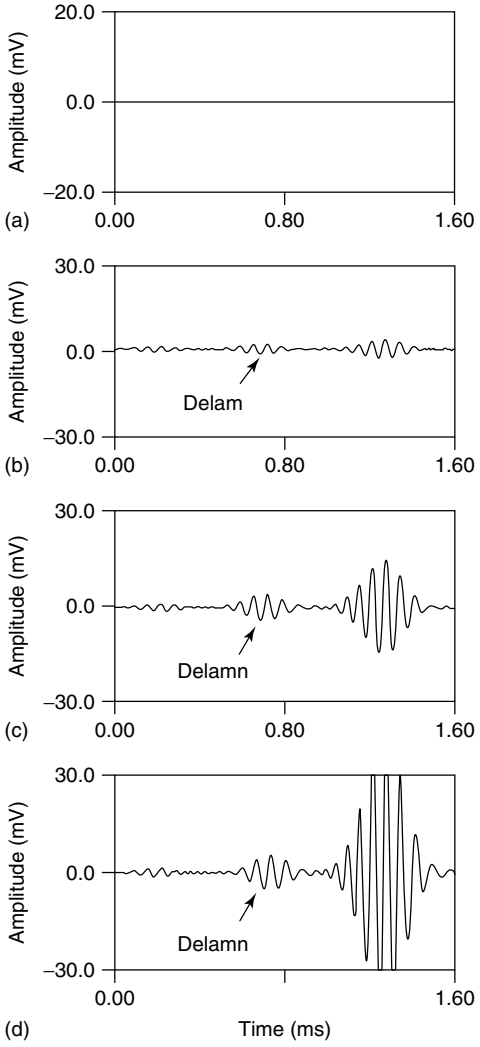

Figure 8. The arithmetic difference between the response of the undamaged and the response at different stages of damage: (a) no defects, (b) $A_d = 22\,mm^2$, (c) $A_d = 47\,mm^2$, and (d) $A_d = 220\,mm^2$.

be observed that the amplitude of the first reflection is affected (reduced) due to the presence of damage. These effects can be better appreciated in Figure 8, which represents the arithmetic difference between Figure 7(a) and each one of Figure 7(a–d), respectively. This basic operation allows each time history to be compared to the undamaged configuration, thereby eliminating the large amplitude sections of the response signals and making it possible to identify small changes in the propagating wave, such as variations in the amplitude and phase shifts. This procedure can be implemented in a health monitoring system, where damage occurrence would be identified by the appearance of ripples or wavelets in an otherwise straight-line signal representative of the undamaged structure.

The sensitivity of the propagating wave to even the smallest delamination can be explained in terms of the relative dimension between wavelength and defect size. In general, the sensitivity of a given

Lamb mode to defects will increase as its wavelength decreases [7]. The wavelength of the excitation signal can be calculated from equation (1). The pulse center frequency used is 15 kHz and the plate thickness is 2.7 mm, which yield a frequency–thickness product of 40.5 kHz mm. At this *fh* value, the phase velocity of the A_o mode obtained from Figure 5 is close to 640 m s^{-1}, from which the wavelength is found to be $\lambda \approx 42$ mm. From the C-scans shown in Figure 6, the l dimension (parallel to the length of the beam specimen) of the smallest delamination tested is found to be 10 mm indicating that even though the delamination size is only 25% of the wavelength, the system is capable of detecting it.

2.4 Delamination location

The position on the timescale of the reflection generated at the damage site and the reflection from the end of the laminate, shown in Figure 7, can be used to estimate the location of the defect along the beam span. The time difference (Δt_L) between the maximum peak of the input pulse and the maximum peak of the reflected signal from the end of the beam is about 1060 μs, which corresponds to twice the length of the specimen ($2L = 1258$ mm). Similarly, the time difference (Δt_{dam}) between the maximum peak of the input pulse and the maximum peak of the reflected signal from the damage site is about 490 μs, which corresponds to a round trip of the wave between the receiver and the delamination ($2a$). Substituting these values into equation (4), the location of damage (a) is found to be at 290 mm, which is a fair estimate of the actual location ($a = 300$ mm) of the artificially induced delamination shown in Figure 1. This measurement is only approximate since the shape of the wave packet does not remain the same during its propagation along the beam due to the dispersive nature of the A_o Lamb mode at this *fh* value.

$$a = \frac{L\ \Delta t_{\text{dam}}}{\Delta t_L} \tag{4}$$

These experiments demonstrate the potential use of Lamb waves at very low *fh* values for NDE applications. Along with a simple and effective signal-processing method, Lamb waves can be used for the development of an in-service, health monitoring technique capable of detecting delaminations in composite components. However, the specimens used were essentially narrow beam elements where lateral wave spreading effects are minimized. In the following section, the wave propagation on wide plates is studied using the finite element (FE) method [21]. Different actuation configurations are examined including the use of a linear array of actuators for the damage evaluation of large surfaces.

3 FINITE ELEMENT ANALYSIS

3.1 Wave propagation in wide plates

FE analysis is carried out in parallel with an experimental approach to study Lamb wave generation and propagation in quasi-isotropic beams and plates. Several models are used to qualitatively investigate the interaction of elastic wave at boundaries to predict the response of a surface-bonded sensor. A mesh in the xy plane is implemented to model the laminate using quadrilateral shell elements, where the nodes are defined on the midthickness of the shell and each node has both translational and rotational degrees of freedom. The x coordinate is aligned along the length direction and the z coordinate is aligned normal to the surface of the plate. The plate thickness is given as a geometrical parameter when the mesh is generated. The excitation of the plate using piezoelectric patches is modeled with uniformly distributed moments of opposite sign applied along two short parallel nodal lines (actuator width), which are separated by a distance equivalent to the length of the piezoelectric actuator as indicated with bold lines in Figure 9.

The excitation signal employed in all of the simulations is a 5.5 cycle, 20 kHz sinusoidal wave modulated by a Hanning window. It is defined in the FE code as a time-history variation of the amplitude

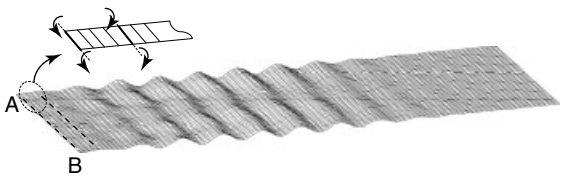

Figure 9. The predicted response of a 2-mm-thick laminate to a sinusoidal load applied at the locations indicated by bold lines along the AB boundary.

of the applied load. Then an explicit central difference scheme is employed in the *MARCH* module of the *FE77*, which carried out a step-by-step time marching integration to solve the wave propagation simulation.

Figure 9 shows a snapshot of the predicted response of the specimen at a certain time step after being excited by the described load case. It shows the propagation of the A_o mode across the surface of a 500 mm × 200 mm plate excited with a linear array of actuators distributed along its left edge (AB boundary). This arrangement produces a fairly uniform wave front across the width of the plate that is reflected by the right edge with minor lateral wave spreading. Such response favors the interpretation of the signal produced by a bonded sensor, because the input pulse and subsequent reflections are similar to those observed in the narrow beam and can be easily identified in the signal time history as shown in Figure 10. It presents two well-defined sinusoids and a fairly flat signal between them, similar to the observation for the narrow beam element in Figure 7(a).

3.2 Damage detection

The advantages of using a linear array of actuators for the inspection of large areas can be greatly enhanced if the actuators comprising the linear array of transducers are also used as sensors in a pitch–catch mode, thus exploiting the dual capabilities of piezoelectric materials as a receiver and a transmitter. This approach has been examined using a uniformly distributed sinusoidal load applied along the left edge

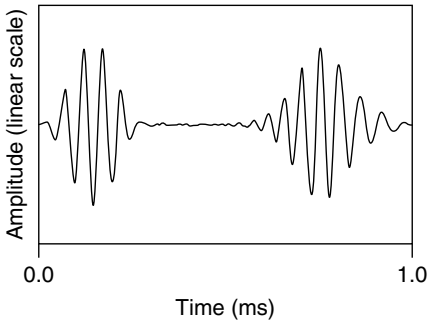

Figure 10. The predicted displacement history of a node located at the center of the AB boundary. The plate was excited with a sinusoidal load applied to the AB edge.

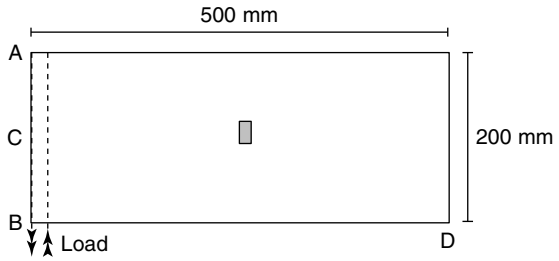

Figure 11. Sketch of the plate used in the FE calculations, showing a central area with reduced material properties.

of the plate model, the AB boundary on Figure 11, while monitoring the in-plane nodal displacement along that same edge. Both undamaged and damaged configurations are simulated and their responses are compared to identify the effects of damage on the model behavior. Damage is simulated by degrading the material properties of a selected number of elements within the mesh. This reduction of the mechanical properties varies from zero stiffness to 50% of the elastic properties of the undamaged material, thus representing the cases of an open hole and damage due to low-velocity impact, respectively. Figure 12 shows the response of the undamaged plate presented in a 3-D plot of amplitude of in-plane displacement, time, and plate width. Similar to the experimental results, the first part of the response shows the input pulse followed by another large wavelet, which is the first reflection from the opposite end of the plate. Figure 13(a) presents the response history of the plate containing damage in the form of a square (10 mm × 10 mm) cutout. This displacement history is, at first glance, similar to that of the undamaged model; however, evident differences between the two time histories are revealed in Figure 13(b), which represents the arithmetic difference between Figures 12 and 13(a). Qualitatively, similar results to those shown in Figure 13 are obtained in the case where the elastic properties in the damaged area are reduced by 50%, although the amplitude of the wave reflection generated at the damage site is lower than in the open-hole case. The presence of structural discontinuities can be easily inferred from Figure 13(b). In addition, the location of damage can be estimated from visual inspection of these figures or by correlating the position on the timescale of the wave reflection generated at the damage site with the laminate length as was done in the experimental section for the

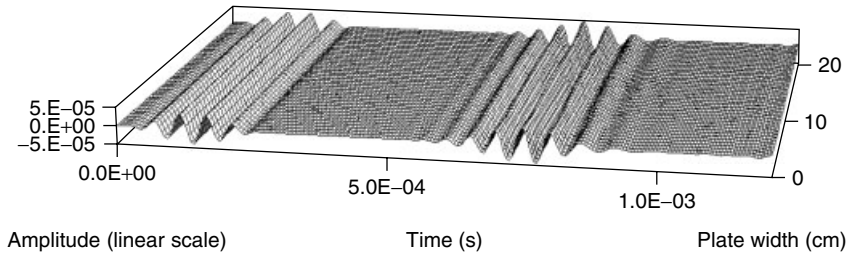

Figure 12. The predicted in-plane displacement history of the nodes located along the AB boundary of the undamaged mesh.

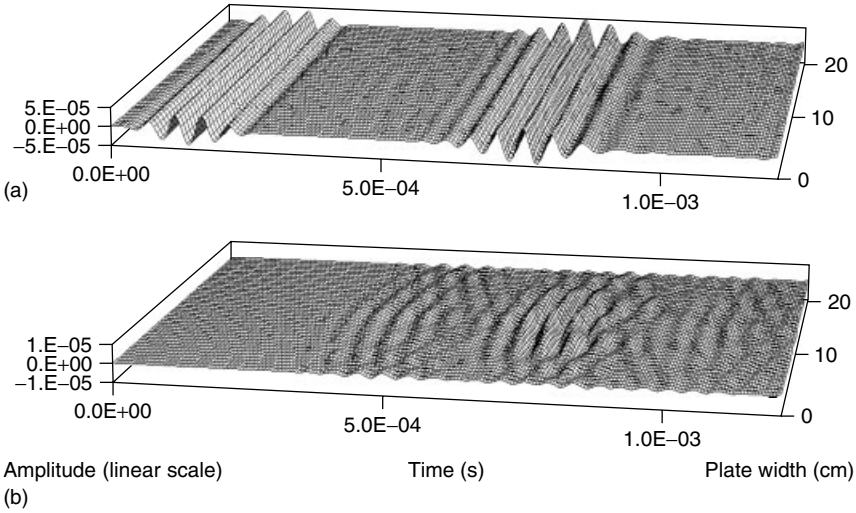

Figure 13. The predicted in-plane displacement history of the nodes located along the AB boundary of the damaged mesh. (a) Time history for the 10 mm × 10 mm open-hole case, (b) arithmetic difference between undamaged and damaged response histories.

narrow beam. Furthermore, the severity of damage can also be estimated because the amplitude of the waves appearing in Figure 13(b) directly relates to the damage size. These results strongly suggest that damage can be found in large-area specimens using a permanently bonded linear array of piezoelectric sensor/actuator elements.

3.3 Damage characterization

Defect detection has been demonstrated using experimental measurements and FE estimates. However, the determination of delamination size and position through the thickness of the laminate is still a challenge in the use of Lamb waves for NDE purposes. This subsection presents a methodology to determine these two parameters from changes in the time of arrival of a tone burst when it travels through a region with delaminations. The time of flight (TOF) of the input pulse, defined as the time it takes for the input pulse to complete a round trip along the length of the specimen, is altered in the presence of damage. In general, the wave velocity changes in the delaminated area because the waves must travel through a region with an effective thickness smaller than the undamaged laminate thickness. As a consequence, the *fh* value decreases and the phase velocity of the wave varies according to the dispersion curves of the material (Figure 2). The shape of the dispersion curve of the A_o Lamb wave in the low *fh* value region is such that a reduction of the

fh value produces a reduction of the phase and group velocities. Therefore, the TOF of an A_o Lamb wave traveling in a specimen with delaminations is greater than that of a wave traveling in the same undamaged specimen. This difference, ΔTOF, can be estimated assuming that through the delamination, the wave propagates via two sheets of material and that the thickest section is the fastest wave path, which is the one used for calculating the *TOF*. Therefore, the *TOF* of a wave propagating along an undamaged and damaged specimen are given, respectively, as

$$TOF_u = \frac{2L}{c_g} \tag{5}$$

$$\text{and} \quad TOF_d = \frac{2(L-l)}{c_g} + \frac{2l}{c'_g} \tag{6}$$

from which the ΔTOF is obtained, i.e.,

$$\Delta TOF = 2l\left(\frac{1}{c'_g} - \frac{1}{c_g}\right) \tag{7}$$

where L is the length of the specimen, l is delamination size, and c_g and c'_g are the group velocities in the undamaged and damaged regions, respectively. An inspection of equation (7) shows that ΔTOF is a function of delamination size (l) and its position through the thickness (d) because c_g is a function of d. Hence, for a given ΔTOF there are several combinations of l and d that satisfy equation (7).

To find the characteristics (l and d) of a given delamination, it is necessary to perform at least two tests of the ΔTOF at two different frequencies (different *fh* values) so that a unique combination of l and d would satisfy both ΔTOF values measured. To illustrate the method, consider a tone burst excited at 10 and 20 kHz, traveling along a 1000-mm-long (L) and 10-mm-thick (h) aluminum plate with a 20-mm-long (l) and 2-mm-deep (d) defect. Using dispersion curves for aluminum, the group velocity of a 20-kHz tone burst traveling through the undamaged ($h = 10$ mm) and damaged regions ($h - d = 8$ mm) are found to be 2284 and 2125 m s^{-1}, respectively. Substituting these values into equation (7) gives a ΔTOF of 1.310 μs. Likewise, a 10-kHz tone burst travels at 1775 and 1618 m s^{-1} through the undamaged and delaminated regions, respectively. Substituting these values into equation (7) gives a ΔTOF of 2.186 μs. Figure 14(a,b) shows ΔTOF as a function of damage size (l) and lines of constant depth (d) for a pulse generated at 20 and 10 kHz, respectively. The possible combinations of l and d for each ΔTOF previously calculated are those values where a horizontal line at 1.310 and 2.186 μs on Figure 14(a,b), respectively, intersects the lines of constant depth. These values are listed in Table 1 along with results for similar tests performed at 40 and 30 kHz. It can be observed from this table that the defect size that remains almost constant for all frequencies is that of $l = 20$ mm in the $d = 2$-mm-depth column (second column), demonstrating the use of this methodology.

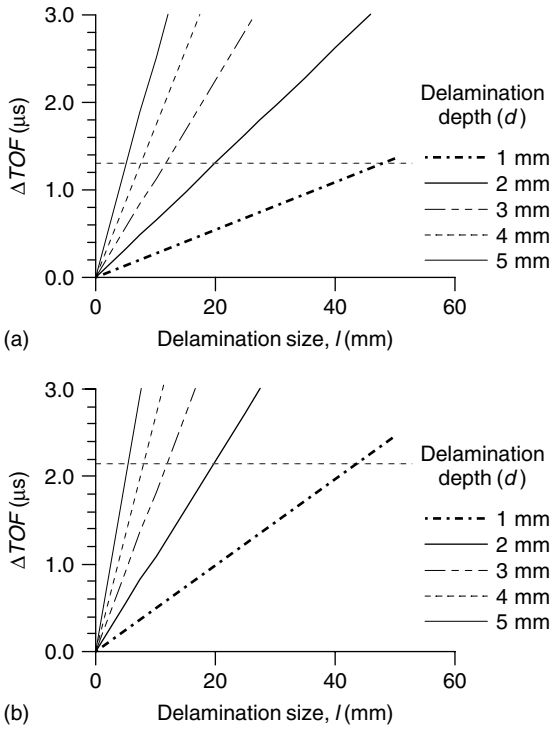

Figure 14. ΔTOF plots calculated for (a) 20-kHz and (b) 10-kHz pulse propagating in a 1000-mm-long, 10-mm-thick aluminum plate.

4 CONCLUDING REMARKS

The generation of low-frequency Lamb waves using small and thin piezoceramic patches has been presented for the development of an on-line, structural

integrity assessment system capable of detecting delaminations in composite laminates. The study offers a solution to some of the problems encountered with current Lamb wave generation techniques where the use of standard ultrasonic probes makes them unsuitable for the development of a built-in, health monitoring system due to their considerable size and shape. The inspection of CFRP laminates has been performed producing promising results at excitation frequencies in the low ultrasonic range (<100 kHz) where IDTs have certain limitations in operations that restrict their use for the damage inspection of thick laminates.

Simple and effective signal-processing techniques have been employed for the detection of small changes in the structural response. Their minimal computational demand makes these techniques appropriate for real-time continuous damage monitoring. Also, the good sensitivity to delaminations of relatively small size (1 cm^2), considerable propagation distances (over 2 m), and the very low requirement of electronic hardware offers a cost-effective solution for structural monitoring in terms of implementation and subsequent operation.

FE analysis has shown the potential use of a linear array of transducers to achieve large-area scanning from fixed locations. The measurement of in-plane displacement response to a given excitation has been demonstrated to be an appropriate procedure to detect, locate, and quantify damage. In addition, a methodology to determine damage characteristics (size and depth) was investigated, which is based on the velocity reduction of a wave passing through regions with defects that produce a measurable delay of its TOF. These analyses can be easily implemented in an array of transducers, providing additional capabilities toward the development of a fully integrated, continuous health monitoring system for large composite structures.

Recent work by the author and coworkers [22–25] involves the use of an arrays of sensors, whose optimum number and spatial distribution were determined from experimental and FE analyses, to detect damage in the form of resin (matrix) cracking and delamination in structural configurations such as composite sandwich panels, stiffened panels, and patch-repaired composite laminates. In these studies, it has been shown that inspection can be realized in large complex composite structures while economizing on hardware and processing complexity. The piezoelectric elements were individually bonded to the structure; however, the concept has been conceived to consist of a multielement array of ultrasonic transducers bonded to a thin flexible strip that can be bonded to new and existing structures. The possibility of embedding these devices into the laminate structure during the fabrication process also needs to be explored. Ultimately, to achieve the objective of enhanced structural reliability, research is required that will involve active sensor development, structure/sensor network integrated manufacturing, signal processing and interpretation, and system integration. This will lead to (i) revolutionary design and manufacturing concepts and analyses for the design of advanced ultrareliable structures for the new century and (ii) theoretical and computational models for predicting sensor performance, structural integrity, and damage-detection capabilities. A significant challenge here is to transition microscale material and structural behavior through mesoscale and macroscale behavior into full-scale structural system performance.

1 BACKGROUND

The proportion of fiber composite materials being used in aerospace, industrial, automotive, and marine structures is increasing year on year. Continuously reinforced thermosets are currently the most popular composite systems, which are offering higher specific stiffness and strength compared with conventional engineering materials. A number of different resins and reinforcements have been "qualified" for use in a number of different market areas. These structures are, without doubt, outperforming their forerunners when structural performance parameters alone are considered. However, the inherently brittle nature of composites makes them susceptible to damage caused by low-velocity impact. Consequently, it has been necessary to develop repair methods so that costly components are not scrapped owing to in-service damage. Current repair concepts of composites include a wide range of approaches from highly refined and structurally efficient but expensive flush patch repairs to the external mechanically attached metal or composite patch [1–3]. In all these repair methods, the main concerns are the prediction of both strength and durability of the repaired laminate and also the structural health monitoring of the bonded repair.

In this study, the mechanical behavior of bonded external patch repairs is examined; the compressive loading mode is more severe than the tensile mode

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

due to instability of delaminated plies, instability of the patch, and skin strength reductions occurring under elevated temperatures and absorbed moisture conditions. Using a simple "shear-lag" analytical model and a three-dimensional finite element (FE) analysis, design guidelines are produced for the selection of patch size, shape, and membrane stiffness; strength measurements of repaired laminates are also presented. Following some of these design guidelines, an aluminum plate with a cracked hole is repaired with a unidirectional boron/epoxy patch that contains two layers of piezoelectric transducers, which are used to monitor crack growth under fatigue loading.

2 BONDED REPAIR METHODS

Adhesively bonded repairs are the most common type of repair carried out with composite materials [4, 5]. *Cosmetic repairs* refer to damage that is not structurally significant (e.g., scratches, dents, or missing surface plies). The repair is made to restore surface smoothness. In these repairs, a potting compound or a liquid adhesive is spread into the damaged area and formed to the component's contour. *Injection repairs* are another type of repair procedure, which is used for minor disbonds or delaminations. In this procedure, a number of holes are drilled to the depth of the damage. Filler resin is heated to decrease its viscosity and injected under pressure until the excess flows out of adjacent holes. Pressure can be applied to the repaired area to ensure mating of neighboring regions. If serious damage is encountered, then more rigorous repair techniques must be employed. In this case, there are two types of bonded patch that can be used to repair structural damage, namely, *flush scarf patches* and *external patches*.

Flush scarf-type bonded repairs are used where surface smoothness is essential. This approach provides the highest joint efficiency of any repair method. Scarf repairs are used on critical components where load concentration and eccentricities, especially for compressive loading, must be avoided. Thick monolithic structures lend themselves to such repair since an external patch would cause excessive out-of-mouldline thickness and unacceptably high bond-line peel and shear stresses. The flush repair procedure requires careful preparation of the damaged area to obtain the correct scarf angle and dimensional tolerances; taper ratios of 20:1 to 40:1 are typical. The laminate orientation of the patch must match that of the damaged section that has been removed and the scarf patch can be cocured (cured on the damaged plate) or precured (cured and then bonded onto the damage).

The external patch technique is simpler to apply and less critical in nature than a scarf approach. This type of repair is considered as temporary repair and aims to restore the mechanical strength required to permit aircraft operation until a permanent repair can be carried out. In this approach, the load is taken over and around the damaged area. Any bending strains due to the eccentric load path must be considered in the patch design. The patch must also be capable of withstanding the high peel and shear stresses, which develop at the edges of the overlap. Figure 1 illustrates the test specimen configuration studied in this article. The optimum patch size, thickness, shape, and lay up are identified by first analyzing a simple double-lap joint.

3 DOUPLE-LAP BONDED JOINT

The double-lap joint shown in Figure 2 is an idealized case of the bonding composite repairs with external patches on both sides. Hart-Smith [6, 7] showed that its strength is determined by the area under the shear stress−strain curve of the adhesive. Consequently, a stronger joint is obtained with a weaker, but ductile, adhesive if the area under its stress−strain curve is larger than that of a stronger, but brittle, adhesive. A further consequence is that although failure stress and strain will be altered by environmental effects, such as temperature change and moisture absorption, the joint strength will not be affected if the area under the stress−strain curve remains the same, and provided the integrity of adherend/adhesive interface is maintained. The simplest approach for solving stresses in a double-lap joint is the linear analysis due to Volkersen [8], the so-called shear-lag analysis; the shear deformation of the adhesive and the elongation of the adherends are the only factors considered.

The next section presents a theoretical method based on Hart-Smith's work [6, 7] for predicting the optimum patch geometry and the failure strength of a double-lap joint.

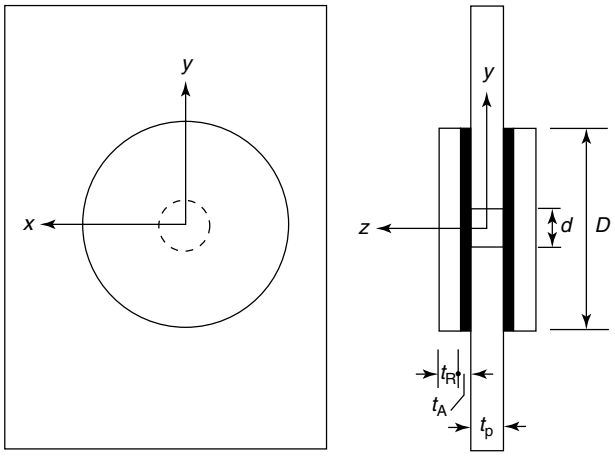

Figure 1. External patch repair.

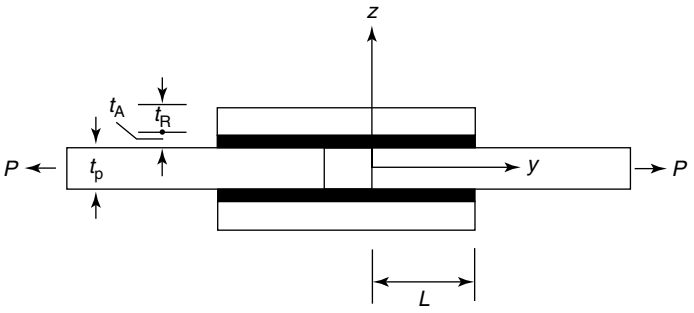

Figure 2. A schematic of a double-lap joint.

3.1 Adhesive shear model

Consider the double-lap joint shown in Figure 2 under in-plane loading P. The length of overlap is L. The thickness of the parent plate (adherend), the repair patch, and the adhesive layer are t_P, t_R, and t_A, respectively. The elastic moduli of the parent plates and the patch (repair) are E_P and E_R. The shear modulus, failure shear stress, and shear strain of the adhesive material are G_A, τ_s, and γ_s. The problem is simplified by making the following assumptions: (i) the parent plates and repair patches are predominantly subjected to direct stress along the x direction, (ii) the adhesive layer is mainly subjected to shear stress in the $x-z$ plane, (iii) the parent plates and the repair patches are elastic and the adhesive layers are elastic-perfectly plastic; ductile adhesives exhibit very high shear strains at failure, and for the purposes of strength prediction can be idealized as elastic-perfectly plastic, and (iv) the maximum shear–strain criterion is used to determine the failure of the adhesive material.

The detailed analytical solution and a Fortran program that estimates the stress distributions and the ultimate failure load of a double-lap joint are given in a previously published technical report [9]. Here, only the output stress results are presented; in particular, the following significant parameters that affect the stress distribution and joint strength are discussed:

1. Optimum overlap length

The overlap length has a significant effect on joint strength. The first question that the repair designer has to answer is how big the patch should be. Figure 3 shows the shear stress distribution in the adhesive layer of joints with short ($L = 5$ mm), medium

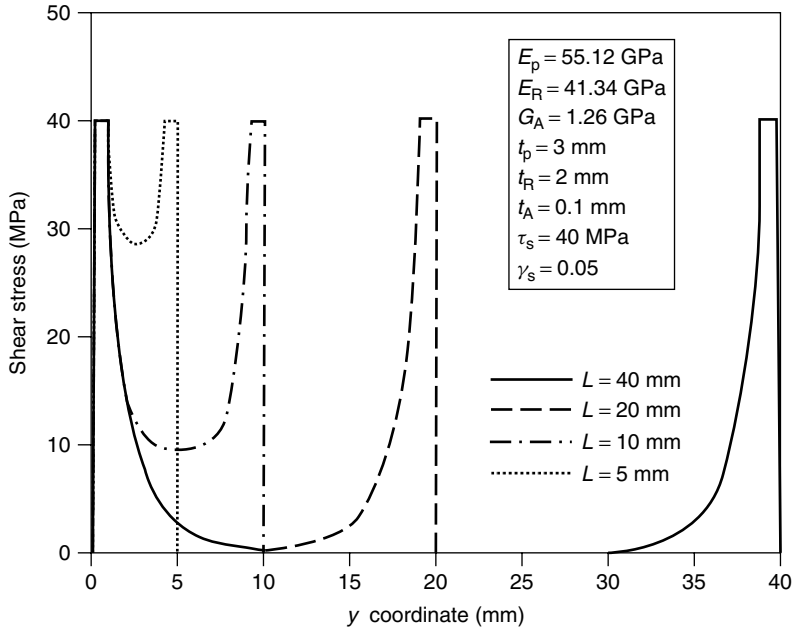

Figure 3. Shear stress distribution in the adhesive layer under ultimate load.

($L = 10$ mm), and long overlap length ($L \geq 20$ mm) under ultimate loading. With short overlap joints, all adhesive material is under high shear stress. For longer overlap joints, the great majority of the load is carried by the plastic adhesive zones separated by a lightly loaded elastic region (trough). Since the load transfer zones occur at the ends and eventually reach a constant length, no increase in joint strength is achieved once these zones are fully developed. The limiting value of joint strength, based on the failure criterion of total adhesive shear strain, is obtained in Figure 4. There is no point in increasing the overlap beyond this critical value, in this case, $\ell \approx 12$ mm, since no significant enhancement in strength, σ_{max}, results. However, considering various effects such as imperfect bonding, patch delamination, environmental effects, and a safety factor, the limiting overlap for current carbon fiber-epoxy systems is around $30t_R$, where t_R is the *repair patch thickness* defined in Figure 2; large flaws in the middle of such a joint would impose no loss of strength since there is no load being transferred there.

2. Optimum patch thickness

The influence of the membrane stiffness (i.e., the product of the elastic modulus and thickness) of patches is demonstrated in Figure 5. It is found that the optimum value of the total patch membrane stiffness ($2E_Rt_R$) is equal to the membrane stiffness of the parent laminate (E_pt_p). If the parent plate has the stiffness of Et, the optimum patch stiffness is $(Et)/2$. As expected, a joint with soft patches (patches are thin or with low elastic modulus) has low strength. However, using stiffer patches does not mean enhancing the strength of the joints. Figure 5 indicates that very thick or overstiff patches become harmful since they increase weight and reduce strength due to larger direct and shear stresses developed at the joint. As patch thickness increases, peel (through-thickness tensile) stresses become increasingly important and can become sufficiently large to limit joint strength and cause failure in an adherend with a low through-thickness tensile strength.

3. Influence of the adhesive

The strength properties of the adhesive certainly influence the strength of the joint, as shown in Figure 6. The present nonlinear analysis indicates that using stronger adhesive materials produces stronger joints; the ultimate adhesive shear strain affects the joint strength more than the ultimate adhesive shear stress does.

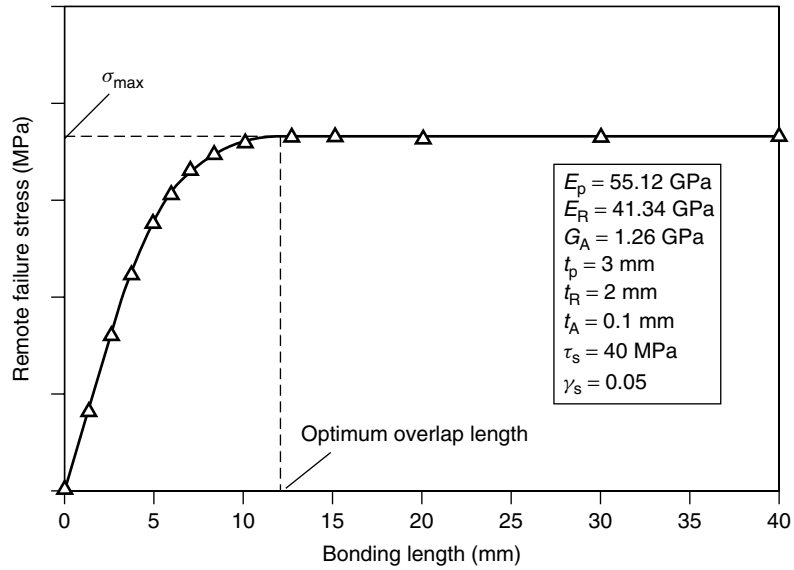

Figure 4. Remote failure stress of a double-lap joint as a function of overlap length.

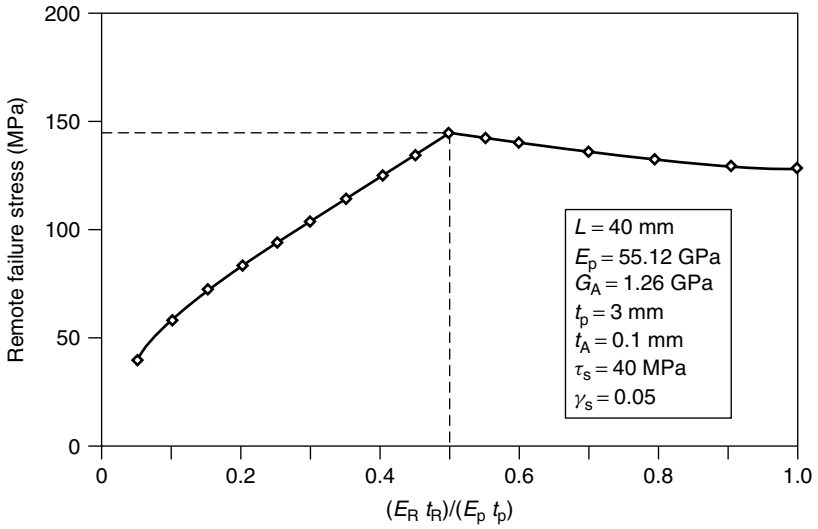

Figure 5. Remote failure stress of a double-lap joint with a large bonding length ($L = 40$ mm) against patch membrane stiffness.

Since high localized stresses are developed at the ends of the overlap, special care is required during the design process of the joint. Figure 7 indicates that the high shear strain can be markedly reduced by deliberately increasing the adhesive thickness at the edge of the overlap. A joint with patches tapered from inside (near the ends of the overlap) can create the local thickening of the bond and substantially reduce the stress concentration in the adhesive layer. However, it is important to remember that good adhesive bonds can be produced only in a small range of thicknesses (typically 0.125–0.25 mm) since thick bonds tend to be porous and weak while ultrathin bonds are too stiff and brittle.

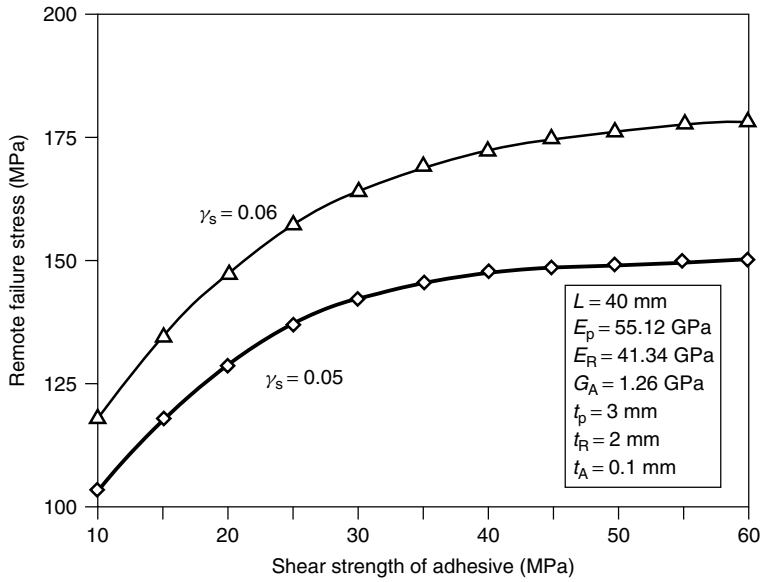

Figure 6. Influence of the ultimate adhesive shear strain on joint failure stress.

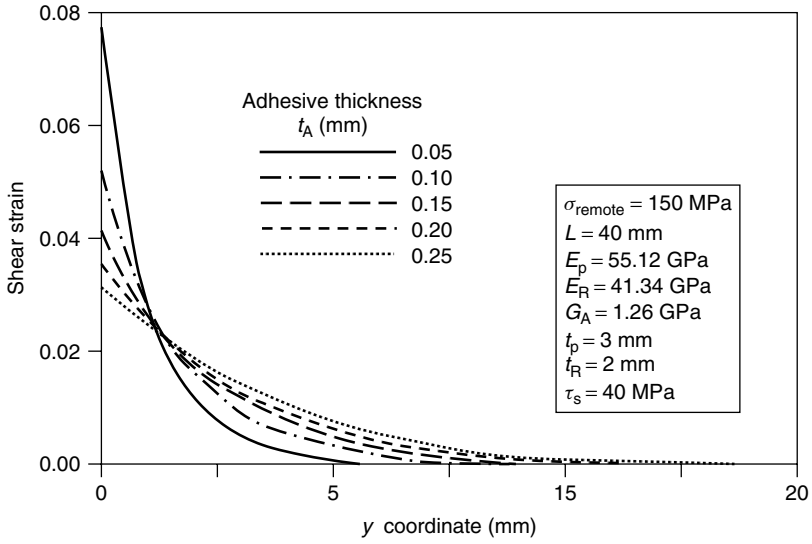

Figure 7. Influence of the adhesive thickness on the maximum shear strain at the end zone of the overlap.

4. Peel stress and optimum patch shape

Peel (through-thickness tensile) stresses can become significant in double-lap joints with thick adherends. High peel stresses are normally induced at the ends of the overlap. As the tensile allowable (through the thickness) for the adherends is generally less than that for the adhesive, failure occurs in the adherend [6, 7], as explained in Figure 8. The maximum peel stress induced in the adhesive and adjacent adherend at the end of the overlap is given by [10],

$$\sigma_{\text{peel}} = \tau_{\max} \left(\frac{3E_z(1-\upsilon_{xz}^2)t_R}{E_x t_A} \right)^{1/4} \tag{1}$$

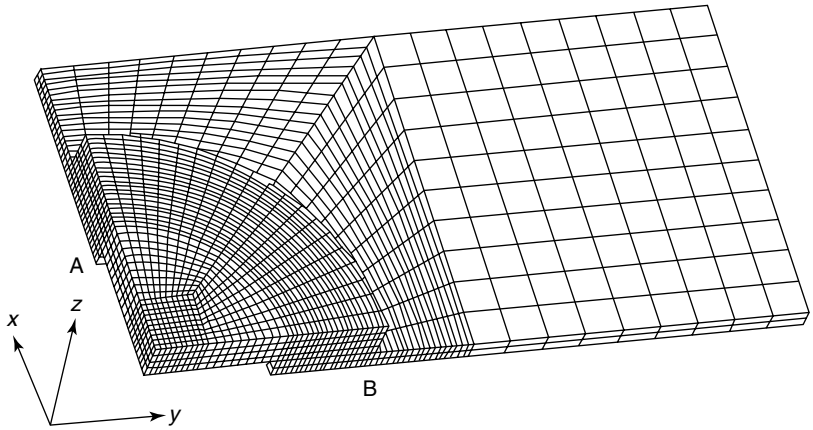

Figure 8. Typical finite element mesh used in the analysis.

where τ_{max} is the maximum adhesive shear stress, E_x and E_z are the elastic moduli of the adherend laminate in the loading direction and thickness direction, respectively, and ν_{xz} is the Poisson's ratio. Equation (1) indicates that the peel stress increases as the patch thickness t_R increases and decreases with increasing the adhesive thickness t_A. A reduction in the tip thickness of the repaired patch and a local increase in the adhesive layer thickness are beneficial since they reduce the peel stress significantly. As discussed in the previous section, this tapering is also advantageous in reducing the peak shear stress and strain in the adhesive. More detailed analysis of the optimum design for the double-lap joint examined here is presented in [11].

5. Maximum strength and failure modes

The failure load and modes of a double-lap joint are dependent on the adherend thickness. For sufficiently thin adherends, failure will always occur in the adherend outside the joint; adhesive strength is greater and the peel stresses are negligible. For slightly thicker adherends, adhesive failure will dominate and if the adherends are sufficiently thick, failure will always be by peeling apart the adhesive or the top layer of the composite laminate [11].

4 EXTERNAL PATCH REPAIR

The external patch repaired laminate, shown in Figure 1, is generally a three-dimensional (3-D) problem, which is oversimplified by the double-lap joint model described earlier. In a double-lap joint, all loads are transferred through the bonded patches. In fact, the parent plate can still carry load after losing the support of the patches (plate with an open hole). Therefore, the two-dimensional (2-D) analytical model underestimates the strength of the repaired laminate and a 3-D stress analysis should be performed. However, this is difficult to solve analytically and in the following section an FE method is used to calculate stresses developed in the patch, adhesive layer, and parent laminate.

4.1 Finite element model for a repaired laminate

Consider a symmetric laminate with a hole of diameter d, external patches bonded on both faces, and subjected to a uniaxial compressive loading, as shown in Figure 1. The $x-y$ plane of the Cartesian coordinate system lies in the mid plane of the laminate and the origin is at the center of the hole. This is an idealized case that simulates a situation where the impact-damaged laminate has been repaired by drilling a hole and then external patches are attached on both sides of the plate. An orthotropic lay up $[0/\pm\theta/90]_{ns}$ is selected; the total length of the carbon fiber-epoxy panel is 100-mm long by 50-mm wide, the hole diameter is 10 mm, and the laminate thickness is about 3 mm.

The FE77 FE package [12] is used and the analysis is based on displacement formulation employing

a curved isoparametric 20-node element. Owing to the symmetry of loading, hole location, and lay up, only one-quarter of the laminate is modeled; the FE mesh for the entire plate with circular patches is shown in Figure 8. The laminate and the patches are treated as homogeneous, elastic, and orthotropic materials with the following stiffness properties: $E_{xx} = E_{yy} = 55\,\text{GPa}$, $E_{zz} = 9.3\,\text{GPa}$, $G_{xy} = 20.95\,\text{GPa}$, $G_{xz} = G_{yz} = 4.4\,\text{GPa}$, $\nu_{xy} = 0.315$, and $\nu_{xz} = \nu_{yz} = 0.175$. The subscripts x, y, and z denote the loading, transverse, and thickness directions, respectively. The adhesive layer (Araldite 2005) of thickness $t_A = 0.1\,\text{mm}$ is modeled by using isotropic elements.

4.2 Stress results

The stress concentration factors (SCF) in the parent, patch, and adhesive materials are summarized in Table 1 for a repaired plate with external round patches.

In the parent laminate, the normal stress σ_{xx} is the predominant component, which may cause failure. Two critical positions suffering of high stresses are identified; point A at the hole edge, along the y axis and point B at the edge of the overlap, along the x axis (the load direction) (see inset in Table 1). The stress magnitude at points A and B depends very much on the thickness of the patch. As the patch thickness increases, the SCF at point A is reduced but when it exceeds a certain value, $t_R > 1.5\,\text{mm}$ ($0.5\ t_p$), high stresses appear at point B.

The patch is subjected to relatively low stresses. The maximum value (339 MPa) of the dominant stress component, σ_{xx}, is less than the remote loading (350 MPa), when the patch thickness is 1.5 mm (half of the parent plate). Therefore, patches are generally safe if they are not too thin (here, greater than 30% thickness of the parent plate).

The adhesive/adherend interface is another location where failure may occur. The interlaminar (between plies) shear stress, τ_{xz}, is the main stress component

Table 1. Stress concentration factors, critical locations of round external patch repair, and the influence of patch thickness t_R

to initiate failure. High shear stress concentration at the overlap edge may cause debonding of the repair patch. Only the narrow zones at the interface edges transfer load from the parent laminate to patches and most adhesive materials are in low stress state. High peel stresses, σ_{zz}, can also contribute to the final failure; they may cause the parent plate to delaminate because of its poor through-thickness strength.

The possible failure modes that can happen in the patch repaired configuration are identified in Figure 9, based on the stress results presented in Table 1 and a maximum stress failure criterion. For repairs with good bonding and thick patches ($t_R > t_p/2$), delamination may initiate at the edges of the bonding area (Figure 9a) due to high peel stress and fracture finally occurs across the net section after the loss of patch support. In repair configurations with strong bonding and thin patches, fracture initiates at the hole edges (point A, $SCF > 2$) and propagates across the plate width (Figure 9b). Finally, Figure 9(c) illustrates the case where the patch partially debonds resulting in large local stresses at the hole edge, point A, which then initiate fiber breakage (fiber microbuckling when loaded in compression), and final failure along a line almost perpendicular to the loading axis (Figure 9d and e).

In conclusion, the stress results presented in Table 1 suggest that the optimum external patch thickness is 1.5 mm, which, in this case, is half of the parent plate thickness; this is similar to the result obtained for the double-lap joint (Figure 5). Special attention should be paid to the bond shear and peel stresses, which markedly increase as the repair patch becomes thicker. Oversized patches are harmful because they increase structure weight and induce high stress concentrations in the repaired region.

5 EXPERIMENTAL EVIDENCE

In an earlier work by Soutis and Hu [13], repaired carbon fiber-epoxy laminates with specimen configuration, similar to that shown in Figure 1, were tested in uniaxial compression. Two different patch geometries were examined: (i) small overlap length, $\ell =$ 5 mm (10-mm hole, covered with 20-mm patches) and (ii) large overlap length, $\ell = 12.5$ mm (10-mm hole

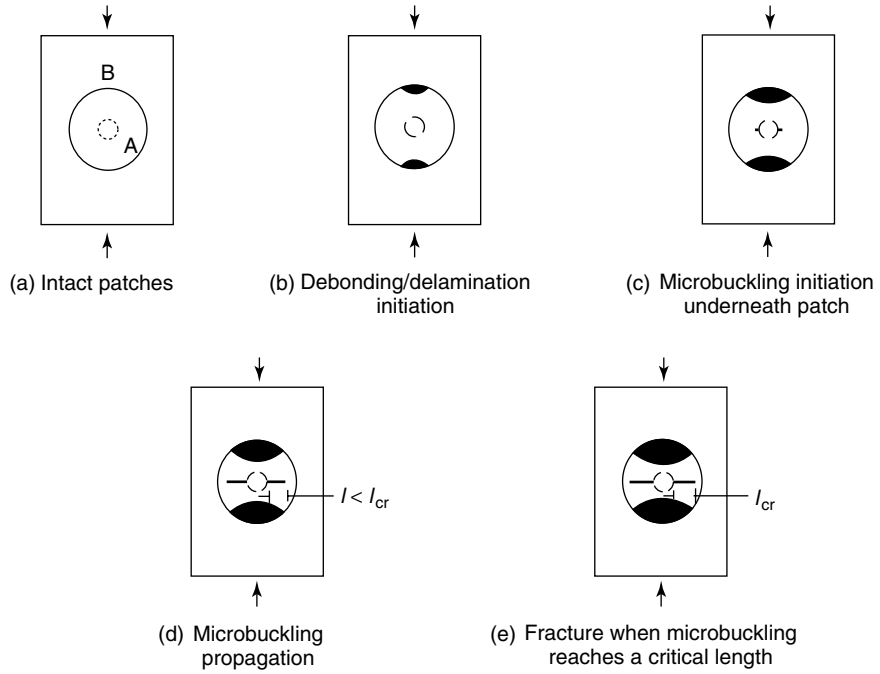

Figure 9. Possible failure mechanisms in a patch repaired laminate under compression.

Table 2. Compressive strength of repaired laminates

Overlap length (mm)	Square patch (MPa)	Round patch (MPa)
5	446.7	461.3
12.5	560	562

Gauge length = 100 mm, plate width = 50 mm, hole diameter = 10 mm unnotched strength = 680 MPa, notched strength = 437 MPa.

with 35-mm patch). The measured residual strengths of repaired laminates with round and square patches are summarized in Table 2.

The round patch geometry performs slightly better than the square patch owing to smaller stresses developed in the repair region. The small overlap length recovers 65–68% of the undamaged strength compared to more than 80% for the larger patch. Notice that the 12.5-mm overlap is that obtained from the double-lap joint analysis. If the composite were perfectly brittle, failure would occur when the maximum stress in the structure equals the unnotched compressive strength of the material,

$$\sigma_{\mathrm{R}} = \frac{1}{K_t}\sigma_{\mathrm{un}} \tag{2}$$

where K_t is the stress concentration factor at point A and σ_{un} is the unnotched compressive strength. In this case, $K_{\mathrm{t}} = 1.31$ (Table 1) and $\sigma_{\mathrm{un}} = 680$ MPa, predicting a residual strength of 519 MPa, which is only 8% less than the measured value (560 MPa). Some stress redistribution is possible owing to local damage in the form of resin cracking and fiber/matrix splitting that is not considered in the present analysis. It should be noted that the elastic stress concentration factor for the orthotropic plate with an open hole is 3.19 and can be substantially reduced by selecting an appropriate patch ($K_t = 1.31$) and accounting for the nonlinear response of the adhesive. Further experimental work is reported in [13–17], where local damage initiating from the patches is monitored using X-ray radiography and scanning electron microscopy. Analytical and numerical models that incorporate the load redistribution in the failure stress calculations can be found in these publications [13–17]. The following section discusses how a rectangular aluminum plate with a cracked hole is repaired with a unidirectional boron/epoxy patch that contains two layers of piezoelectric transducers to monitor crack growth under fatigue loading.

6 DAMAGE DIAGNOSIS OF A BONDED PATCH REPAIR

A rectangular aluminum plate (420 mm × 478 mm × 3.175 mm) with 2-mm-long EDM (electric discharge machining) notches at an 8-mm-diameter hole was repaired with a unidirectional boron/epoxy patch. The thickness of the boron/epoxy patch and aluminum plate was chosen on the basis of the stiffness match design criterion, $E_{\mathrm{R}}t_{\mathrm{R}} \approx E_{\mathrm{p}}t_{\mathrm{p}}$ (where $E_{\mathrm{R}} = 2.4E_{\mathrm{p}}$). The repair configuration and repair materials used are listed in Figure 10. It can be seen that the size of the patch is proportionately larger that the patch used in Section 5 to account for environmental effects, manufacturing defects, and fatigue loading, parameters that can affect the patch efficiency and were not considered in the static analysis presented in the earlier sections. The stiffness matrix of the boron/epoxy laminated patch was taken as $C_{11} = 210.1$ GPa, $C_{12} = C_{13} = 5.64$ GPa, $C_{22} = C_{33} = 26.3$ GPa, and $C_{23} = 4.5$ GPa, with shear stiffness $C_{44} = 10.3$ GPa and $C_{55} = C_{66} = 7.2$ GPa. A Young's modulus of 2.07 GPa and a Poisson's ratio of 0.34 were used for the adhesive layer. Two smart layers were fabricated [18, 19] with an embedded network of piezoelectric actuators/sensors and inserted into the patch at different ply locations (Figure 10). The lower smart layer (layer 10) was inserted right on the interface as close to the neutral axis as possible to excite a more symmetric (Lamb wave) mode [20]. Conversely, the upper smart layer (layer 3) was inserted near the top layer to excite a more antisymmetrical mode. Thus, the lower smart layer targets for the crack growth on the aluminum plate and the upper smart layer targets for the possible patch disbond from the aluminum plate. The locations of the piezoelectric actuator and sensors with damage diagnostic paths on the smart layers are shown in Figure 11. The repair layers and smart layers were stacked as seen in Figure 10 and cocured with aluminum plate, with a vacuum bag, under a constant temperature of 121 °C for 90 min. A smart suitcase [19] (a portable active diagnostic instrument designed to interface with piezoelectric transducers) was implemented to generate diagnostic signals and

record measurements from the smart layers. Using a built-in waveform generator, a windowed sine burst wave was generated as an input signal over a wide frequency range of 100–600 kHz.

The repaired specimens were loaded in tension–tension fatigue and the lower smart layer (layer 10, Figure 10) was used for monitoring crack growth. Sensor measurements from the lower smart layer

were taken at each specified loading cycle while the specimen was unloaded. The corresponding crack lengths were visually measured.

7 LAMB MODE IDENTIFICATION

7.1 Fiber direction

The boron/epoxy patch-adhesive layer-aluminum plate specimen was modeled numerically using the disperse code [21, 22] and the group velocity dispersion curves in various modes were generated (Figures 12 and 13). Owing to the directional properties of the patch, the group velocity dispersion curves can be obtained at various wave propagation angles using the code. Figure 12 illustrates the numerically calculated group velocity dispersion curve of the asymmetric and symmetric Lamb wave modes (a_0 and s_0) when the wave propagation direction is parallel to the boron fibers ($\theta = 0$) and compared to experimental measurements by the lower smart layer (that is used for crack detection and the diagnostic

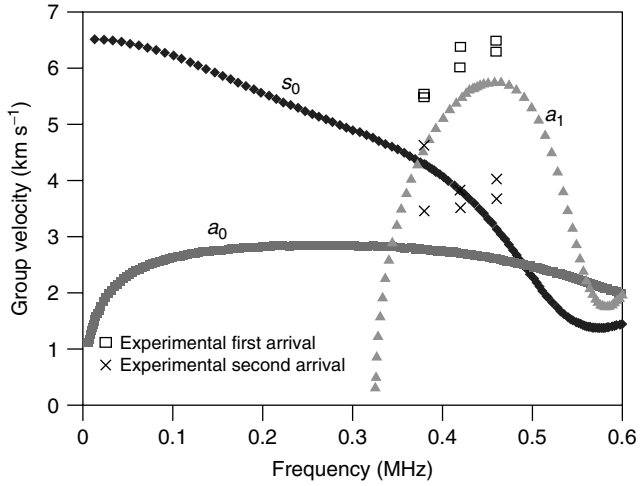

Figure 12. Group velocity dispersion curve of boron/epoxy-adhesive-aluminum (fiber direction, $\theta = 0$).

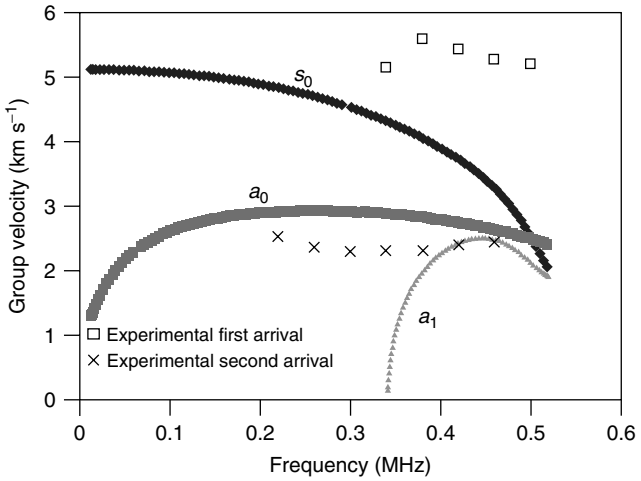

Figure 13. Group velocity dispersion curve of boron/epoxy-adhesive-aluminum ($\theta = 90^{\circ}$).

paths are parallel to the boron fibers). Similarly, in Figure 13 the equivalent results are presented when $\theta = 90$, i.e., wave propagation is perpendicular to the fiber direction; the experimental data in Figure 13 were from the upper smart layer that was designed to detect the patch disbond. A reasonably good agreement between analysis and experiment is observed. Sensor measurements were taken from the path E (Figure 11) in the upper smart layer and Figure 14 shows the amplitude spectrums of both the a_0 and s_0 modes before and after the debond damage where the amplitude was normalized by the maximum value of the a_0 amplitude spectrum. It appears that the fundamental antisymmetric mode a_0 shows higher sensitivity to the disbond damage.

8 DAMAGE INDEX RESULTS

8.1 Damage index

The damage index (DI) is defined as the relative ratio of the scatter energy contained in a Lamb mode wave packet to the baseline energy contained in the same Lamb mode wave packet. This ratio can be obtained by the time integration of the power scatter spectral density within a specified time window at a specified frequency, which can then be nondimensionalized by baseline information such that

$$\text{Damage index (DI)} \equiv \left(\frac{\int_{t_i}^{t_f} |S_{\text{sc}}(\omega_0, t)|^2 \, \mathrm{d}t}{\int_{t_i}^{t_f} |S_{\text{b}}(\omega_0, t)|^2 \, \mathrm{d}t} \right)^{1/2} \quad (3)$$

where S_{sc} denotes the time varying spectral amplitude of scatter signal, S_{b} is the time varying spectral amplitude of baseline signal, ω_0 is the selected driving frequency, and t_f and t_i denote the upper bound and lower bound of the selected Lamb mode in time domain, respectively. A time varying spectral amplitude $S(\omega, t)$ of a given signal $s(t)$ is obtained by the short-time Fourier transform:

$$S(\omega, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \mathrm{e}^{-i\omega\tau} s(\tau) h(\tau - t) \, \mathrm{d}\tau \quad (4)$$

where $h(t)$ is the Hanning window function. Typically, the DI selects the symmetric mode (s_0) for crack detection and the antisymmetric mode (a_0) for disbond-type damage.

8.2 Upper smart layer

The DI can be used for detecting both crack and debond damage by choosing the s_0 mode and a_0

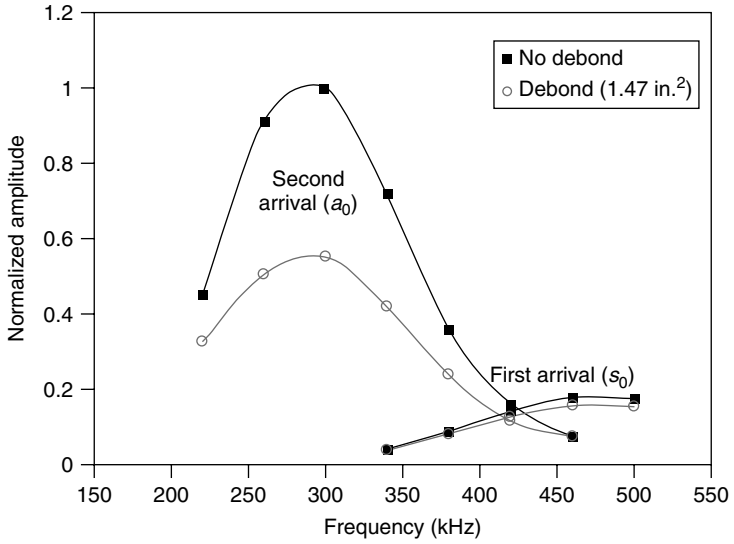

Figure 14. Normalized amplitude responses of the upper smart layer (path E) to debond damage ($1\text{in.}^2 = 645.16$).

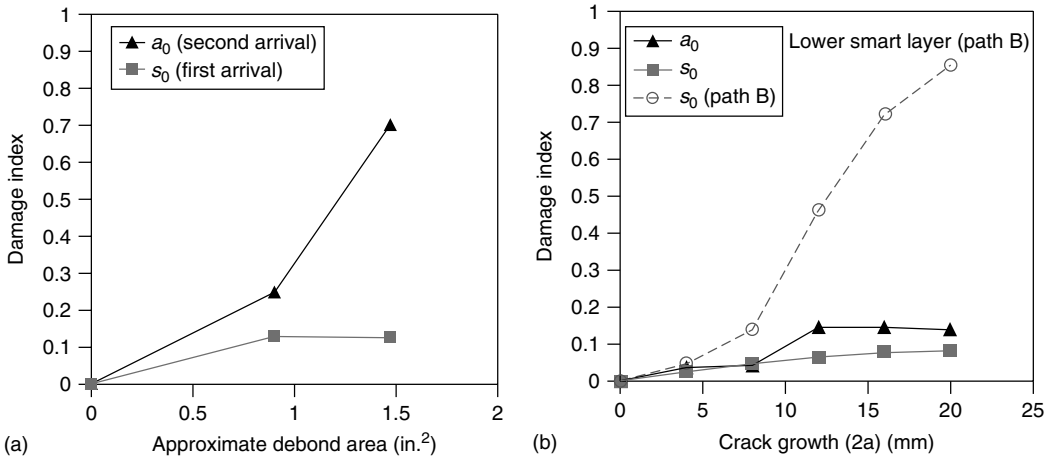

Figure 15. The response of s_0 and a_0 modes to (a) patch debond and (b) crack growth.

mode, respectively. Figure 15 shows the sensitivity of the s_0 and the a_0 modes generated by the upper smart layer to the debond damage and the crack growth. As previously observed in the amplitude spectrum plot (Figure 14), the fundamental antisymmetric mode (a_0) is more sensitive to debond damage than the s_0 mode. Both the a_0 and the s_0 modes generated by the upper smart layer were not sensitive to the crack growth when compared with the s_0 mode of the lower smart layer. The relatively low sensitivity of the s_0 mode of the upper smart layer (path E) is due to its wave propagation direction that is parallel to the crack propagation direction.

8.3 Lower smart layer

The sensor data from the 420-kHz input signal was used for the analysis as this data has the highest signal-to-noise ratio. The DI was evaluated on the basis of the time of arrival of the second wave packet. The new baseline was taken after the specimens were cycled until an initial crack growth of 2 mm had occurred. Further crack growth was visually identified and at the same time monitored by the DI, which was evaluated at different diagnostic paths as shown in Figure 16(a). The results are plotted in Figure 16(b), which indicates the clear crack growth detection capability of the DI. It also shows the higher sensitivity of the DI in a consistent manner, as the diagnostic paths (paths B and C) are closer to the initial crack-tip location.

8.4 Overall variations of damage index

As shown in Figure 17, various mechanical tests were conducted on the bonded patch specimen at different times, which are denoted as "serial events". The specimen was first tested only for the patch debond (that was introduced statically by pushing down the patch from the back face using a cylindrical rod) and then fatigued under cyclic loading for the fatigue crack growth. The initial sensor measurement at "event 0" or "pristine condition" was kept as a baseline for the entire evaluations to see the overall variations of the DI under different loading and time history. It can be observed in Figure 17 that the DI by the upper smart layer shows good sensitivity to the debond damage and remains with small variation afterward over time. On the other hand, the DI by the lower smart layer shows good sensitivity only to the crack growth. Also the DIs from both smart layers show no or minimal changes when there is no damage occurring during the cyclic loading.

9 CONCLUDING REMARKS

The analytical/numerical approaches presented in this work can improve the design of external patch repairs and estimate their strength with some success. For the cases examined, the optimum overlap length of the patch is approximately 12–15 mm. The optimum patch membrane stiffness (i.e., the product of elastic

modulus and thickness) is half of the parent stiffness. Overstiff or too-thick patches are harmful because they produce higher peel and shear stress concentrations and increase the weight of the structure. Tapering the patch edges and increasing the local adhesive thickness reduces the local stresses substantially. Using the optimum patch configuration, bonded repairs can recover up to 80% of the undamaged laminate strength. The through-thickness stresses can be analyzed by performing ply-by-ply

FE analysis and damage initiation predictions can be made using simple stress-based failure criteria. However, fracture mechanics needs to be applied to model the process of damage growth. Environmental effects (hot/wet) and durability of the repairs are also to be considered in the repair design, since moisture and temperature do alter the properties of the resin and affect the load-carrying capability of the repaired configuration. In addition, it is demonstrated that smart sensors could be embedded in the patch to monitor the structural health of the repaired configuration. A diagnostic system based on the active piezo sensor network was instrumented with an aluminum plate repaired by a boron/epoxy composite repair patch. The DI results from the two active-sensing layers inserted at different ply locations clearly indicate that crack growth underneath the patch and debond damage, although they are colocated, can be separately monitored. More details of the embedded active-sensing approach and the DI results can be found in the literature [23–26]. Of course, other damage inspection methods could be used to monitor the structural health of the repaired configuration. Radiography, ultrasonics, shearography, thermography, embedded optical fibers [27], shape memory alloy (SMA) wires [28], and fiber Bragg grating (FBG) sensors [29] are among the most commonly used, but it is demonstrated in this article that Lamb waves offer an attractive way for large-area nondestructive inspection, as the waves are able to travel relatively long distances allowing the material between transmitter and receiver to be successfully interrogated. The Lamb wave based approach could be applied to the health monitoring of wind turbines (*see* **Chapter 147**) and marine structures (*see* **Chapter 142**).

1 INTRODUCTION

Damage caused by the impact of foam insulation shed from the external tank of the space shuttle shortly after launch was suspected as a leading candidate for the cause of the loss of the space shuttle Columbia during reentry on February 1, 2003. As a result, an experimental test program was initiated during the accident investigation to reproduce this impact event and estimate the resulting damage to the thermal protective systems (TPSs) on representative shuttle wing structures. In addition to reproducing the impact and resulting damage that led to the accident, NASA had the foresight to use these impact tests to develop and demonstrate acoustic sensor technology to detect impact damage on future shuttle flights. Previous testing [1, 2] had already demonstrated that such sensors might be used to detect and locate micrometeoroid and orbital debris (MMOD) impact events on spacecraft. Although ascent debris damage was the focus of the Columbia investigation, MMOD had also been identified as a significant potential danger to both the shuttle and the space station [3]. Both low-frequency accelerometer and high-frequency ultrasonic acoustic emission (AE) sensors were evaluated for this purpose during the accident investigation.

Testing during the investigation successfully validated the capability of these sensors for detecting major impact damage. However, additional testing was necessary to develop this sensing approach for application to the remaining shuttle fleet. These

 ISBN: 978-0-470-05822-0.

tests have included the determination of sensor response to a range of energies of foam impact events on TPS materials including those that are near to and below the threshold of damage. Additionally, impact tests have been performed with a number of other potential impact materials that can damage the shuttle during ascent including ice, ablator, and metal. Also, since it is desirable to have the impact sensing system detect not only ascent debris impacts but also those of MMOD during orbit, testing has been performed to measure sensor response to hypervelocity impacts on TPS materials. In addition to impact testing on structural test articles, testing was performed on the shuttle Endeavor to study wave propagation effects and evaluate differences in structural configuration between Columbia test articles and the remaining shuttle fleet. An overview of these test results is presented, along with a discussion of results obtained from wing leading-edge impact-detection system (WLEIDS) sensors deployed on the space shuttles during recent missions.

2 COLUMBIA ACCIDENT INVESTIGATION FOAM IMPACT TESTING

At the onset of the Columbia accident investigation, it was not known exactly where the foam debris impacted the shuttle wing. Video images showed that it struck somewhere on the lower surface of the left wing. However, the views and resolution available did not indicate whether it struck the leading edge, which consists of reinforced carbon–carbon (RCC), or the lower wing surface, which has thermal protection consisting of tile. Thus, a variety of test specimens were fabricated to investigate the damage caused by foam impacts on these structures. In addition, preliminary testing to calibrate the foam mpact gun performance as well as test instrumentation configuration was performed using aluminum plate targets. Accelerometers and AE sensors were included on all of these tests and successfully detected the impacts in all cases.

As the investigation progressed, sensor data from Columbia and forensics of debris provided indications that the damage had occurred on the leading edge, specifically on RCC panel 8. The focus of the impact testing turned toward foam impacts on leading-edge panels mounted on a leading-edge support structure (LESS) as shown in Figure 1. This test article consisted of a section of leading edge spar using the honeycomb structural configuration from Columbia, to which leading-edge panels 5–10 were attached. Because of the enormous expense and limited availability of RCC panels, initial testing was performed using fiberglass replicas of the leading-edge panels, with final testing performed on flight RCC panels. An array of eight AE sensors (Digital Wave Corporation model B225-5) was attached on the interior side of the spar. The bandwidth of these transducers was specified by the manufacturer to be 30–300 kHz. However, responses well below 10 kHz were measured. Initial testing with the sensors arrayed close to the impact

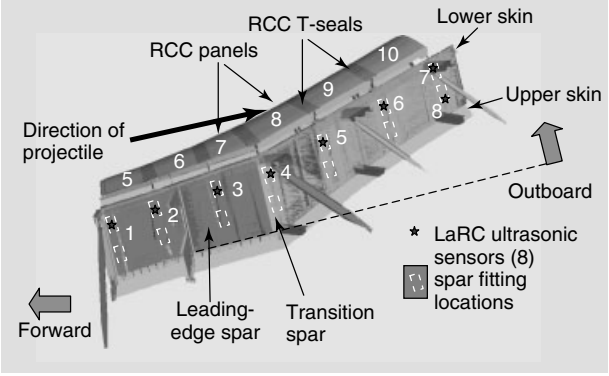

Figure 1. Leading-edge support structure with RCC panels 5–10 and T-seals shown. The locations of the AE sensors 1 through 8 are indicated with black stars.

point demonstrated that signals of significant amplitude were produced and that these signals propagated through the attach fittings into the spar. For later testing, the sensors were arrayed along the length of the spar as shown in Figure 1 to determine how well the signals propagated along the spar, and thus how remote the sensors could be located and detect the impact. As the foam impacts and the attenuation of the complicated structure resulted in very low AE frequency signal content, the AE data was acquired at a sampling frequency of only 500 kHz with a total of 32 K points acquired for each sensor.

For the defining test of the investigation, a foam block of 0.757 kg mass (1.67 lbs weight) was launched at a velocity of 237 m s^{-1}, striking panel 8 as indicated in Figure 1. This impact produced a significant hole in the RCC panel providing conclusive evidence for the Columbia Accident Investigation Board in determining the cause of the accident [4]. The AE signals that were detected from this foam impact event are shown in Figure 2. Only 6 dB of gain was applied to the signals from the AE sensors. As would be expected, the largest signal, arriving earliest in time, was that from sensor 5, which was nearest the impact site. Quantitatively, decreasing arrival times and amplitudes of signals from sensors located further away from the impact point were observed. Although not noticeable in this figure as all signals are plotted on the same scale, signals were detected all the way down to the location of sensor 1, suggesting that impact events can be detected by sensors mounted several RCC panels away, a distance of more than 1 m. Examination of the arrival times for signals from sensors 7 and 8 showed that the impact site could be localized with respect to the upper and lower surface of the leading edge.

3 RETURN TO FLIGHT TESTING

At the completion of the accident investigation, a number of questions remained regarding the capability of acoustic impact sensing on the shuttle. These included the detectability of much smaller foam impacts including those near or below the threshold of damage, the characteristics of signals caused by other potential impact source materials including ice, ablator, and metal at ascent velocities, as well as hypervelocity impacts to simulate orbital impacts. These effects needed to be assessed for impacts on both the leading edge as well as on the tile protected lower wing surface including the main landing gear door. Another issue was that the construction of the wing spar on the remaining shuttle fleet varied considerably from that of Columbia and the effects of this difference on acoustic wave propagation had to be investigated. Thus, a comprehensive test program was initiated to address these questions. As it is impossible, as well as expensive, to test all possible combinations of impact parameters, a simultaneous modeling effort was initiated to develop capabilities to model impact events on shuttle wing structures. One key experimental piece of data required for these models was the measurement of the transfer function of the acoustic signals from the RCC leading edge to the spar where sensors are located. Additional experiments were performed to acquire this critical data.

3.1 Launch debris impact testing

Additional foam impact tests were performed on RCC panels over a range of projectile sizes and impact velocities. These impact tests were performed on different panels on the LESS test article, as

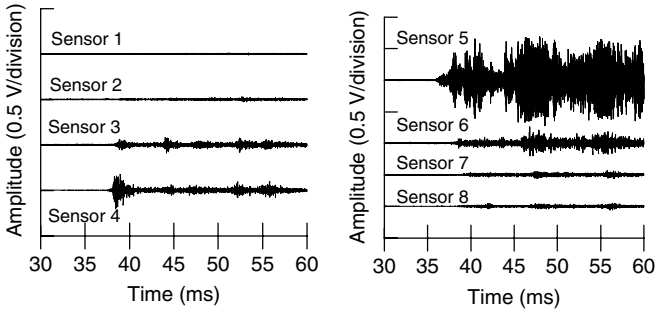

Figure 2. AE signals from foam impact on shuttle RCC wing leading-edge (LESS) tests.

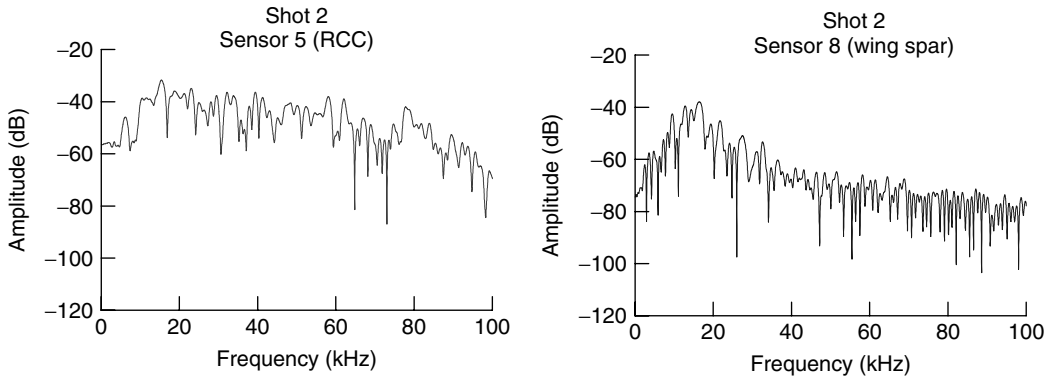

Figure 3. Frequency content of foam impact signals for sensors on RCC panel and wing spar.

well as on the T-35 test article, which represented a more outboard section of the wing. This test article allowed impact tests on panels 16 and 17 and further provided the opportunity to evaluate the effect of differing impact locations on measured signals. Signals from small projectiles and/or low-impact velocities producing impact energies below the threshold of damage were still readily detected. Variations in the signal amplitude correlated with the impact energy for a given type of impact material. However, different impact materials such as foam and ice exhibited different amplitude impact energy relationships. In addition to sensors on the spar, sensors were also placed on the RCC panel of the T-35 test article to measure the transfer function response from the RCC panel to the spar. The frequency response plots in Figure 3 show the significant loss in high-frequency signal content that occurs as the signal propagates from the RCC to the wing spar of Columbia construction. Preliminary testing on test articles with the wing spar construction of the remaining shuttle fleet suggests that this high-frequency attenuation might not be as severe.

Foam impact tests were also performed on lower wing specimens representative of regions on which the thermal protection material is tile. Specimens from this region of the wing also included a main landing gear door. Representative damage for a wing specimen impacted by foam at approximately $290\,\mathrm{m\,s^{-1}}$ is shown in Figure 4 in which a hole formed by a tile that was broken away by the impact can be observed. Again, AE transducers readily detected signals for all impact conditions studied.

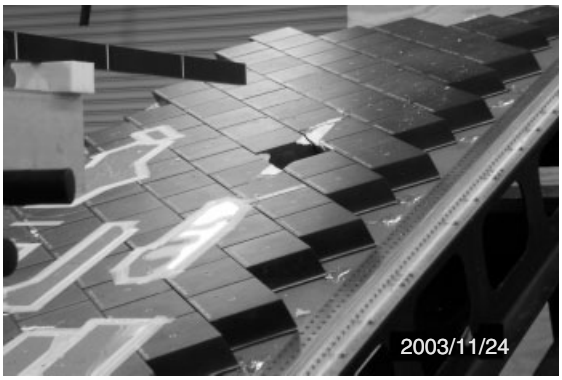

Figure 4. A wing acreage tile test article showing the resulting tile loss due to a foam impact.

Although the signals were very complex due to the complicated nature of the source and the complex structural geometry of the tile and wing specimen, source location could be determined using appropriate frequency filtering to selectively analyze the flexural mode of propagation.

Impact testing on RCC and tile specimens was also performed using other types of potential launch debris. These materials included ice, ablator, and metal. Again, the impact velocity and energy was varied over a range from below the damage threshold to that causing substantial damage. AE and accelerometer sensor data were obtained for all tests. Preliminary analysis shows that all impacts were successfully detected with both accelerometers and AE sensors, and that again there was a correlation between signal amplitude and energy of impact for a given impact material.

3.2 Hypervelocity impact testing

Hypervelocity impact tests were performed to simulate MMOD damage that can occur once the shuttle is in orbit. Initial tests were performed on flat metal and fiberglass plates to develop a database to support modeling efforts as well as to determine appropriate instrumentation settings. Figure 5 shows typical damage resulting from two hypervelocity impact events at 6.8 km s^{-1} in a fiberglass plate. A 2-mm-diameter aluminum projectile created the smaller impact while the larger was created by a 6-mm aluminum projectile, which fully penetrated the plate. Figure 6(a) shows the signals from a hypervelocity impact, while for comparison, a lead break simulated AE signal near the impact site is shown in Figure 6(b). Curiously, the flexural mode amplitude was generally smaller than the extensional mode, especially at the higher energy shots. This is interesting since low-velocity impact usually produces a large amplitude flexural mode due to the source motion perpendicular to the plate target. In the present case, the attenuators played a role in filtering the low frequencies that generally confirm the presence of a flexural wave. However, the source function for hypervelocity impact is quite a bit different than ball drop at low velocity or a lead break. It is also interesting to note in comparing these signals that there was 64 dB of attenuation applied to the signals from the hypervelocity impact as compared to 47 dB of gain for the lead break signal. There is a tremendous amount of energy in the hypervelocity impacts. Figure 7 shows the raw signal amplitude, after adjustment for the attenuation, from a series of hypervelocity impacts on a fiberglass plate as a function of impact energy. As shown in this figure, the raw signal amplitude increases with corresponding impact energy until it peaks at nearly 80 V for an impact energy of nearly 100 J. In the fiberglass plates, for impacts exceeding 100 J, the projectile penetrates the plate and a decrease in AE signal amplitude was observed. However, for actual RCC leading-edge specimens, a decrease in AE was not observed after impact penetration.

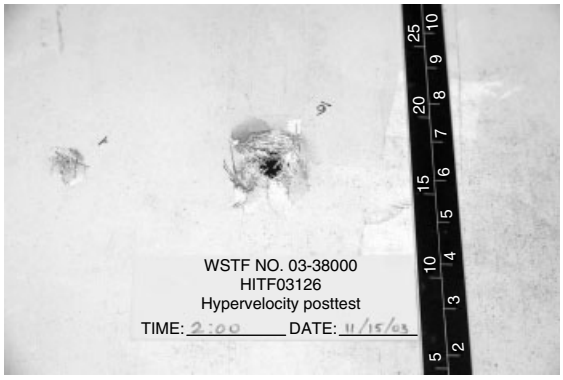

Figure 5. Fiberglass panel showing damage from two hypervelocity impacts.

Propagation effects on AE signals from the impacted material through attachment mechanisms to likely sensor locations on the spar were also investigated. Initial testing for this consisted of multiple plates connected by threaded rods, followed by testing on a realistic shuttle wing spar test article. Again, because of the expense of RCC panels, testing included hypervelocity impacts on a number of fiberglass replicas of a leading-edge panel, followed by shots on an

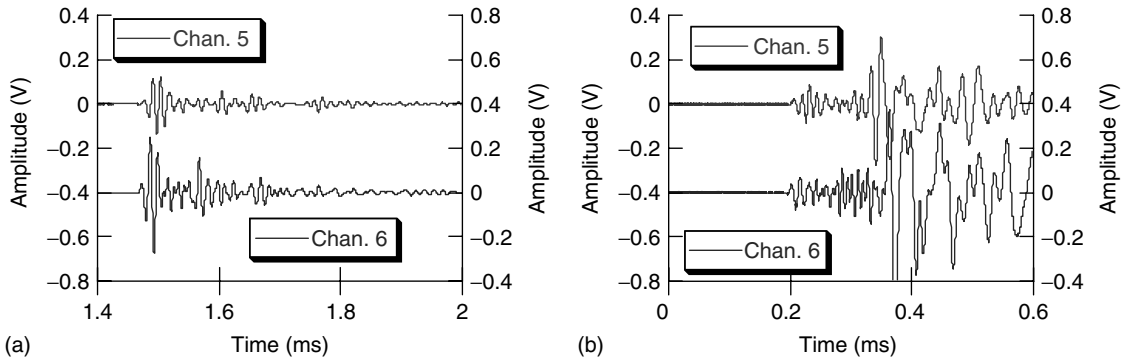

Figure 6. AE signals produced by (a) hypervelocity impact and (b) pencil lead break.

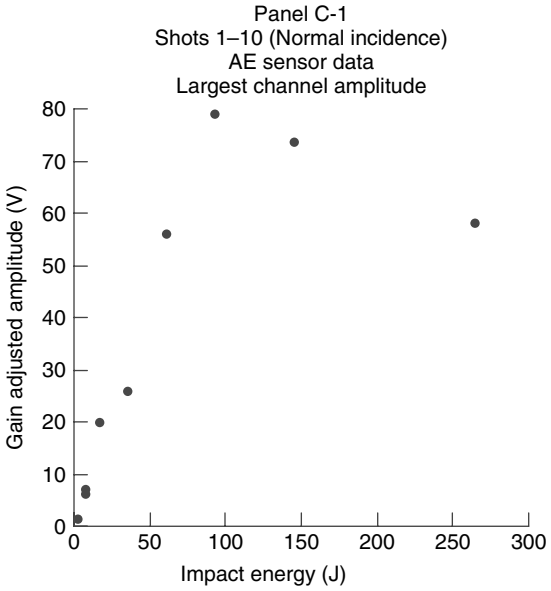

Figure 7. AE signal amplitude versus impact energy on fiberglass targets.

actual RCC panel. These tests demonstrated that the much higher frequency hypervelocity impact signals are much more heavily attenuated than was observed for the lower frequency foam impact signals. Further analysis was performed to determine the transfer function from the RCC to the spar where the sensors are located on the flight vehicle.

3.3 Impact hammer testing

Impact hammer and pulsed pitch–catch ultrasonic measurements were made on the wing spar of the shuttle Endeavor to investigate the effects on wave propagation due to differences in wing spar construction. As noted previously, the LESS and T-35 test articles represented the Columbia wing spar construction, which is different from the remainder of the fleet. Transducers were attached to the leading edge of the shuttle's wing, as indicated in Figure 8. At various locations, ultrasonic signals between 10 and 150 kHz were introduced and recorded on the fixed transducers. In addition, a series of low-energy instrumented hammer impacts (9.07, 27.22, 68.04, 113.40 kg) were performed on the wing's leading edge. Similar experiments were performed on the LESS and T-35 test articles to develop a correlation between the different structures. Figure 9 shows the frequency response of AE sensors to a hammer impact on the shuttle Endeavor wing spar as well as on the LESS test article. Although the overall peak amplitudes of the time-domain signal are similar, the frequency response shows that the peak amplitude is at a much lower frequency with much higher frequency attenuation for the LESS as compared to the shuttle. These differences are significant in that they indicate that higher frequency signal components may propagate from impacts on the shuttle to and along the spar. Such

higher frequencies may enable improved signal to noise for detection as the background noise is expected to decrease with increasing frequencies. However, no database exists for measurements of the background noise for ultrasonic frequencies on the shuttle.

4 SHUTTLE IMPACT-DETECTION IMPLEMENTATION

Although both accelerometers and ultrasonic AE sensors were demonstrated to be successful at detecting impacts on space shuttle structures, accelerometers were chosen for the implementation of the WLEIDS because of the availability of existing flight-qualified sensors and instrumentation. Arrays of 66 accelerometers have been deployed on each wing leading-edge spar of all space shuttles. The data from these sensors are recorded by arrays of 22 battery-powered data-acquisition/wireless transmission units mounted in each wing cavity. Each data-acquisition unit records the output from three accelerometers as well as one temperature sensor. The system records data from all sensors continuously during launch and ascent to orbit, digitizing the signals at a sampling frequency of 20 kHz. Then, to conserve battery life, the system is switched into on-orbit monitoring mode during which smaller sets of sensors are monitored to record any triggering MMOD impacts. Data is transmitted wirelessly to a laptop computer in the crew compartment and then downlinked to mission control

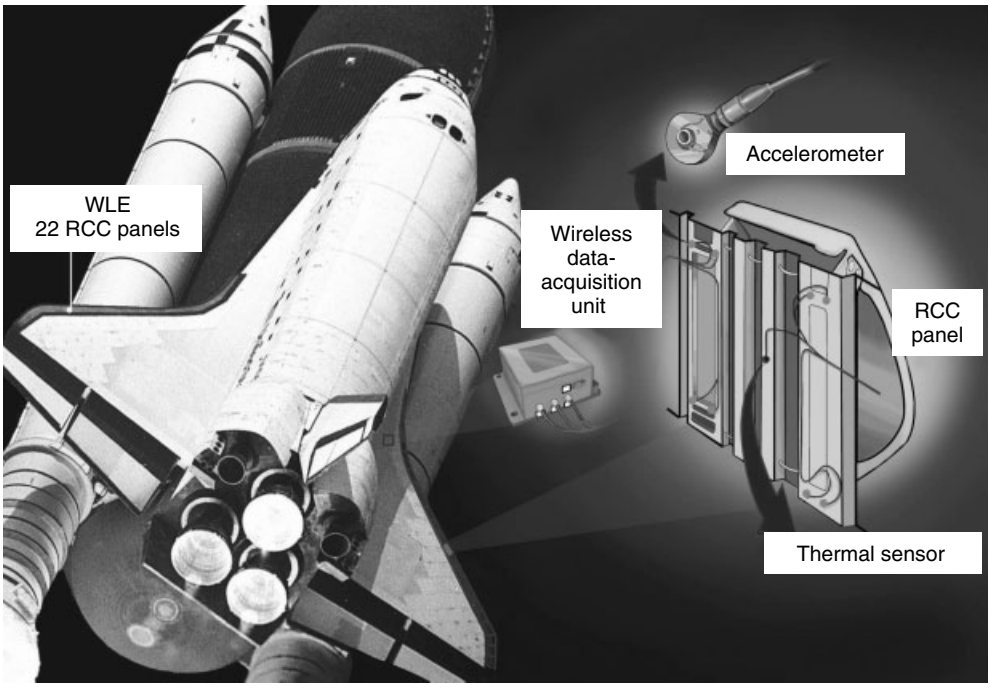

Figure 10. Key components of the shuttle wing leading-edge impact-detection system.

at the Johnson Space Center for analysis. Figure 10 shows the key components of the WLEIDS system.

Because of the limited data-acquisition unit battery life and telemetry bandwidth, the complete time-history data from all sensors cannot be transmitted to mission control for analysis during the flight. Preprocessing routines in the data-acquisition units calculate Grms (rms value of the g forces recorded by the sensors) values for the sensor units and then create summary files of the largest Grms peaks. These summary files are then downlinked for preliminary analysis. Grms peaks that occur globally across the wing are discounted as impacts and most often correlated with mission-specific events such as main engine ignition, solid rocket booster (SRB) ignition, maximum dynamic pressure, and tank and SRB separation. Local peaks are analyzed as potential impacts by downlinking and evaluating short intervals of the time-history response for multiple sensors near a suspected impact location. Additionally, suspected impact events are correlated with other data sources such as video and radar recordings of the vehicle during launch and ascent.

For all flights since Columbia, the WLEIDS has performed exceptionally well. All sensor data-acquisition units have successfully triggered at launch and data has been recorded from all sensors. The summary files have been successfully downlinked and a number of small probable impact events identified on each flight. None of these probable impact events have been of amplitude consistent with critical damage to the RCC leading edge and in-flight inspection at the suspected impact locations using the orbital boom sensing system have not revealed damage. The complete time-history data from all sensors is retrieved from the vehicle after each flight and is analyzed. The focus of this postflight analysis is to determine if any potential impacts were missed during the analysis of the summary files during the mission, and to develop and evaluate improved algorithms for impact signal identification during future flights.

5 CONCLUSIONS

AE sensors and accelerometers were used to monitor foam impact tests on shuttle test articles as part of the Columbia accident investigation. These tests demonstrated that acoustic sensing could be used to detect and locate impact events on the shuttle wing leading edge. Follow-on testing has demonstrated this capability for a wide range of impact conditions on both the leading edge as well as the lower wing surface. These tests have included much smaller impact energies at and below the threshold of damage, different impact materials, and hypervelocity impact conditions designed to simulate MMOD damage. Additional testing has analyzed the effects of different wing spar constructions on the propagation of impact generated acoustic waves along the spar.

As a result of this testing, a shuttle WLEIDS was developed and successfully deployed. Accelerometers are used in this system due to the availability of previously flight-qualified sensors and wireless data-acquisition units that could be easily integrated into the shuttle wing spar. The system has performed as designed detecting only a small number of probable impact events that have been of a magnitude small enough to have not caused damage. Postflight analysis of the complete data from each mission is performed to develop improved impact-detection methodologies for future shuttle flights.

1 INTRODUCTION

The development of corrosion in aircraft structural components over their operating life is largely due to the gradual deterioration and breakdown of protective paint coatings, anodized coatings, conversion coatings, metallic coatings, and sealants (*see* **Environmental Monitoring of Aircraft**; **Loads and Temperature Effects on a Bridge**). Unfortunately, most of the high-strength aluminum alloys and steels used for aircraft structural components are susceptible to corrosion (*see* **Design Principles for Aerospace Structures**). The frequency and time taken to detect, repair, replace, and repaint corroded components increases with aircraft age, and the corresponding increase in the overall costs are important factors in determining the eventual life of the aircraft.

In military aircraft, corrosion is responsible for a large proportion of maintenance time and expenditure. Studies by the United States Air Force (USAF) have revealed that the cost of corrosion was US$800 million in 1998 [1]. Corrosion prevention measures

accounted for 29% of the expenditure, while repair-related costs made up 71%. The United States Navy (USN) spends more than US$1.5 billion annually on aircraft systems on repair and maintenance due to corrosion [2]. In fact, a significant proportion of the corrosion effort arises from the cost of looking for corrosion. For example, the US Naval Air Systems Command noted that about 50% of the corrosion items processed were scheduled corrosion inspections, whereas corrosion repair accounted for about 20% of the items processed [3]. For support equipment, the figures showed that about 83% of man-hours were spent on inspecting, and only 2% were spent on repairing. Clearly, there are significant incentives to reduce the number of inspections. While these maintenance costs may be readily identified, it is the costs associated with not having the aircraft capability available for operational purposes that are harder to quantify, and which may be orders of magnitude greater. If prolonged corrosion-associated maintenance periods cause an aircraft to be unavailable for service, then the cost of that corrosion should also include the cost of hiring a replacement aircraft for that period.

Inspections for corrosion damage are usually time consuming and complex, require aircraft disassembly, and, quite often, reveal no corrosion damage. These inspections may also introduce additional costs resulting from incidental damage to the structure or increased likelihood of corrosion due to the replacement of factory seals by possibly inferior, less-durable seals. In an effort to reduce maintenance costs and increase aircraft availability, aircraft maintainers are considering condition-based maintenance centered around a structural health monitoring (SHM) system (with a prognostic capability) for aircraft structures, rather than inspections based on elapsed flying hours.

The philosophy of SHM of structures prone to corrosion damage is based on the concept of continually monitoring a structure to (i) identify when coatings have broken down, (ii) identify when corrosion has commenced, and (iii) characterize the nature of the environment in a particular area of the structure. The system is based on the concept of locating corrosion sensors and environment monitors in areas of aircraft structure that are generally difficult to inspect and/or are only inspected at major servicings, i.e., at three- to five-year periods for military aircraft. The basic tools for effective SHM are (i) the application of *in situ* corrosion sensors and environment monitors in a robust network to provide accurate, reliable local microclimate (corrosivity) and corrosion information, (ii) corrosion-prediction models (CPMs), and (iii) maintenance decision making approaches. An extension of an SHM system is a prognostic structural health monitoring system that should be capable not only of indicating the state of degradation (i.e., corrosion) and its effect on the structural integrity of the aircraft but also of predicting: (i) when protective coatings will fail; (ii) when corrosion is likely to occur in remote areas that are not monitored and difficult to inspect; and (iii) the rate of corrosion growth. The system should also be able to indicate how these predictions will change depending on the location of the aircraft's base and its mission type. With this information, components could be replaced before failure due to corrosion or fracture resulting from section loss, thus maintaining structural safety, increasing aircraft availability, and reducing recurring maintenance costs.

Subsequent sections of this article discuss the key elements required for a corrosion SHM system (*see* **Principles of Structural Degradation Monitoring**; **Design Principles for Aerospace Structures** and **Maintenance Principles for Civil Structures**). The main elements discussed here include

1. sensors to monitor the environment, state of the protective coating, and to detect and monitor corrosion in order to measure local microclimate environments and corrosion;
2. robust system architectures for a sensor network to enable the provision of accurate, reliable environmental and corrosion data;
3. novel parametric and physics-based CPMs, which use the sensor data to accurately predict the current state and future trends of corrosion in all locations of the aircraft, including areas with and without sensors; and
4. the appropriate maintenance decision for the operator or maintainer, such as whether the corroded components may be repaired, replaced, or treated and left in place until a more convenient inspection period (*see* **Design Principles for Aerospace Structures** and **Environmental Monitoring of Aircraft**).

In discussing the above elements, this article focuses on two slightly different corrosion diagnostic

and prognostic approaches. One approach led by the Commonwealth Scientific and Industrial Research Organisation (CSIRO), with the Boeing Company and the Australian Defence Science and Technology Organisation (DSTO), involves a novel parametric-based CPM and uses an agent-based approach to the sensor network system architecture [4]. The other approach, led by DSTO, involves the use of a physics-based CPM with a more conventional sensor network system architecture. The article also outlines current laboratory demonstrators of both approaches. A description of some current in-flight demonstrators within the Australian Defence Force (ADF) have also been included. These in-flight demonstrators consist of incorporating some corrosion and environmental monitors within military aircraft to produce interim deliverables, which will assist in developing smarter maintenance corrosion management practices for military aircraft and to facilitate acceptance of the SHM approach to corrosion management by the operator and maintainer (*see* **Principles of Structural Degradation Monitoring**).

2 BACKGROUND

2.1 Knowledge of corrosion problem areas

Information on corrosion-prone areas is readily available where a fleet of aircraft has been in operation for many years. For a new aircraft, it is difficult to know where corrosion may occur. However a knowledge of aircraft construction, experience in how environments develop within particular areas of the structure, and information about local stresses, the nature of structural joints, types of alloys and fasteners at these locations, and the type of protective coating system, all assist in making judgments on where corrosion may develop. Often, the onset of corrosion may be associated with human factors—either workmanship errors or issues that arise during service. While it is not possible to determine if workmanship errors will occur, it is possible to identify areas where workmanship errors could, if they occurred, raise the corrosion risk. Thus it is possible to assess the propensity of corrosion in a component by considering factors such as

- proximity to heat sources or heat sinks;
- proximity to sources of external air;
- orientation/location of components;
- features of components that may provide crevices (fasteners, lap joints);
- nature of material and coating;
- microclimate and factors that may influence microclimate (limited air flow, etc.).

2.2 Operating environments

It is generally accepted that most corrosion in aircraft structures occurs while the aircraft is on the ground or flying at low altitude. At high altitudes, temperatures are usually too low throughout most of the structure for the corrosion reaction to proceed. In the vicinity of engines or other onboard heat-emitting sources, those low temperatures will not be reached, and corrosion may take place. A detailed knowledge of what the environment is in the vicinity of particular components, e.g., how often the area becomes wet, what contaminants are present, and how these factors vary with mission type and base location is probably too difficult to obtain. However, the installation of sensors and monitors in the general area of interest can provide this information.

2.3 A conceptual model of SHM sensor and monitor location

SHM is most likely to be useful in areas of structure that are not accessible or easily inspected. Corrosion on exterior surfaces at rivets and joint lines, and within open areas such as landing gear bays and weapons bays, may be relatively easy to detect, and are not the main focus of an SHM system.

The schematic drawing in Figure 1 represents the model of an internal space in an aircraft structure.

Some joints and fastener holes are associated with the external surfaces of the space, e.g., wing plank to spar attachments contained within the space, and other joints within the space not associated with external surfaces, e.g., wing spar webs. Aircraft generally experience an external environment, which can be represented broadly as follows. On the ground, it may consist of rain, hail, snow, or high humidity and regular washing. In addition, if the temperature falls below the dew point and the air contains sufficient water vapor, condensation occurs. The external

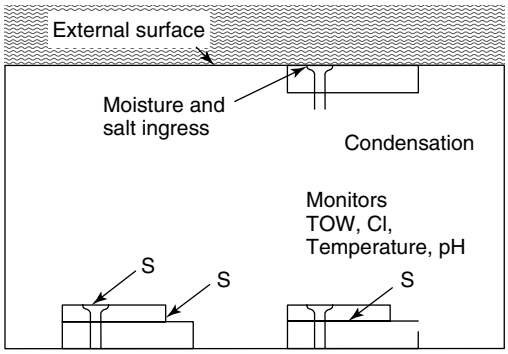

Figure 1. Schematic of the air space within an aircraft structure, where S indicates possible locations of sensors. The sensors indicated are to measure time of wetness (TOW), temperature (Temp), chloride concentration (Cl), and pH..

surfaces of the aircraft collect airborne contaminants such as sea spray during flights at low altitude over the ocean or sea spray carried inland by onshore winds from the ocean. Studies have shown that salt contamination on these surfaces may vary from 40 to 700 mg m^{-2} [5]. Other airborne contaminants such as oxides of nitrogen, sulfates, etc., may also be present. If the relative humidity (RH) is above the deliquescent RH for a particular salt contaminant, the salt wets out, providing a moisture film on the surface.

Moist air may be drawn into internal airspaces, but moisture also enters via internal joints adjacent to the skin through working fasteners and joints where cracks in sealants and paint coatings have developed. Because of the closed nature of many internal spaces, while the aircraft is on the ground condensation may occur because of the daily heating and cooling cycles and the "hot box" effect. When an aircraft descends from high altitudes, most internal surfaces are cold (e.g., $-40\,^{\circ}$C is not uncommon) and when ambient air is drawn into the space, condensation occurs. It is therefore clear that, once the coating has failed, all the necessary ingredients for corrosion to occur can penetrate, and corrosion can develop within the aircraft structure.

It is not possible or practical to locate corrosion and environment sensors and monitors everywhere within an internal air space. Under the SHM methodology, it is proposed to locate these at key points within areas of interest. The discussion that follows describes various methodologies to account for the other non-sensed regions.
