The types of environment sensors vary according to the inputs required for the CPM. However, time of wetness (TOW), chloride level, temperature, RH, and, possibly, pH are considered as the main parameters to be monitored. Pressure is not essential; however, because it is related to altitude, it does provide a method for checking other monitors such as TOW and temperature. In general, the role of strategically placed corrosion sensors is to provide onboard validation of the output of the CPM. When the corrosion sensors are located beneath a coating within joints or fasteners holes, they may also provide an indication of when coatings have failed and corrosion has occurred.

2.4 Paint coating/sealant failure

Corrosion does not generally occur until a protective coating fails. This failure may be induced by mechanical damage in the course of maintenance, but it is more usual for a coating on aircraft components to mechanically fail because of stress and environmental factors. Stresses arise from operational loads such as those around working joints and fasteners, thermal cycles (e.g., from -30 to $+80\,^{\circ}$C would not be uncommon for military combat aircraft, with less extreme upper limits for commercial and military transport aircraft), the freezing of moisture absorbed into a paint coating, and blistering resulting from moisture accumulating at the paint–metal interface. The environmental factors most relevant to an SHM system, which impact on paint failure and corrosion, are those that develop inside the aircraft. They are condensation resulting from the thermal cycle, the "hot box" effect associated with enclosed spaces, or prolonged exposure to high temperatures if near an engine or just beneath the outside skin (which may be heated by frictional stress of air flow). Following paint failure, attack on the exposed metal generally follows when the inhibiting pigment included in the paint coating is depleted by leaching.

Currently, models that predict coating failure under the combined action of all these variables do not exist. There have been studies to identify the rate of depletion of inhibitors from primers once the coating has been breached; however, these results are empirical and have usually focused on a particular test environment such as the neutral salt spray (NSS)

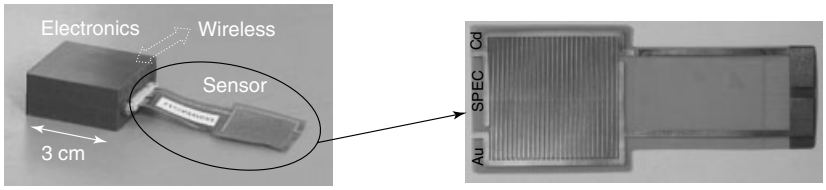

Figure 2. US Navy SPEC galvanic sensor. (Dimension of sensor is typically 28 mm square).

test [6, 7]. It is generally accepted that the NSS test is quite extreme and is neither typical nor representative of the environment around an aircraft component, which is more likely to be subjected to condensing droplets of moisture and periods of drying.

While paint coating failure models are necessary, it is also important to have some sensors strategically located onboard for detecting coating failure, and to allow for onboard validation of these models. One approach for an SHM system would be to locate sensors under coatings in areas of interest, for example, in joints or fastener holes, under the lavatory and galley areas, at doors and door edges, etc., which indicate when corrosion on the sensor elements occurs, thus indicating not only when deterioration of the coating has occurred but also when inhibitors in the coating have been depleted.

3 ENVIRONMENTAL AND CORROSION SENSORS

In this article, various types of sensors and monitors that may be considered for use in an airspace, similar to those described in Section 2.3, are discussed (*also see* **Nanoengineering of Sensory Materials**; **Miniaturized Sensors Employing Micro- and Nanotechnologies** and **Environmental Monitoring of Aircraft**).

3.1 Corrosion and galvanic sensors

The SPEC Inc. galvanic (TOW) sensor system developed by the USN is based on the galvanic interaction of interdigitated electrodes of two dissimilar metals, gold and cadmium, deposited on a thin polymer substrate. The electrodes are connected to a miniature data logger about the size of a matchbox. The unit and the sensing element are shown in Figure 2. The current flow between the two dissimilar metals when covered by moisture is measured as a function of time—thus the sensor indicates the time at which the component is wet. The logger is self-contained and battery powered, and the data may be downloaded via a wireless link. The sensor system has been tested on USN P-3C and Seahawk aircraft.

An earlier version of this type of sensor was developed by the DSTO in 1998 [8]. It is much larger in size than the USN version, and relies on a galvanic couple of copper and tin to provide a current output and to measure the TOW. The DSTO sensor has been flown for many years in the tail section of a Royal Australian Air Force (RAAF) P-3C Orion and the forward equipment bay of an RAAF F-111.

Analatom supply the linear polarization resistance (LPR) corrosion sensor as shown in Figure 3 (*see* **Miniaturized Sensors Employing Micro- and Nanotechnologies**). This sensing system was developed by the DSTO [9] and licensed to Analatom in the USA [10]. The system uses the electrochemical technique of LPR, and involves measuring a current response following an application of a small potential to microelectrodes. The sensing elements are made from the alloy of interest using either micromachining or lithography techniques. The LPR sensor not only provides a measure of the corrosion rate for the alloy from which the sensor element is made but is also a TOW sensor. Analatom AA7075 aluminum alloy LPR sensors have been flown in the forward cargo hold of a Delta Airlines Boeing 737 [11].

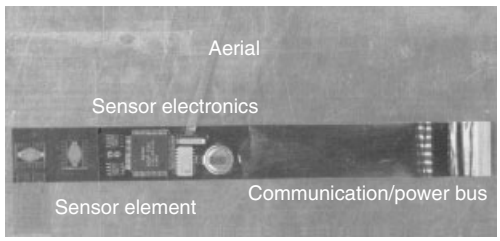

Figure 3. Analatom sensor system. (The LPR sensor is approximately 10 mm square).

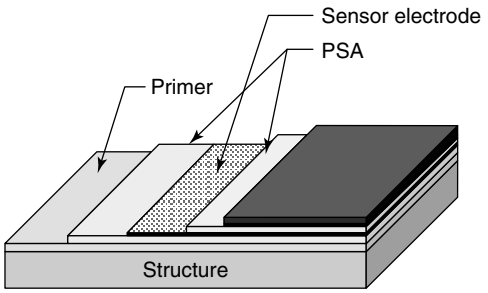

Figure 4. DACCO smart appliqué [12].

DACCO SCI Inc. has developed a smart-appliqué corrosion sensor. Smart appliqués are peel-and-stick fluoropolymer films containing an embedded sensor electrode as depicted in Figure 4 [12]. The appliqué is applied over primer coatings in lieu of a topcoat. The sensor is interrogated using electrochemical impedance spectroscopy (EIS) with the embedded sensor as one electrode and the aircraft structure as another. Currently, it requires the use of external potentiostat/impedance instrumentation when the aircraft returns to base. This type of sensor would enable detection of damage of the coating system, including the appliqué, as well as detection of the start of corrosion of the metallic substrate. At this time, no miniaturized electronics package is provided to interrogate the electrodes *in situ*. Further work is also being undertaken to apply the concept of this sensor to typical aircraft coating schemes.

The BAE Systems Advanced Technology Centre (BAES ATC) galvanic sensors use a galvanic couple of gold and aluminum or gold and tungsten and is shown in Figure 5(a). The interdigitated tracks of the two different metals (the thickness of the deposited tracks is approximately 1–2 μm) are vapor deposited onto a silicon wafer. The potential generated between the two metals when moisture is present is measured using a high impedance voltmeter. The sensor acts as a TOW sensor and the measurement of the potential as opposed to current provides a longer lifetime for the sensor electrodes.

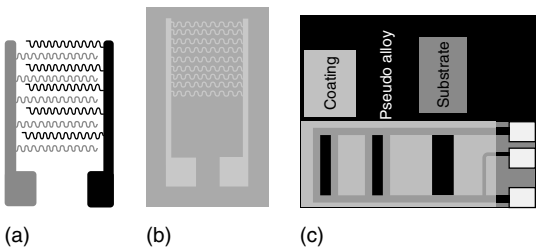

Figure 5. BAE Systems (a) galvanic sensor, light = Au, black = Al or W, (b) resistance sensor, and (c) sentinel sensor.

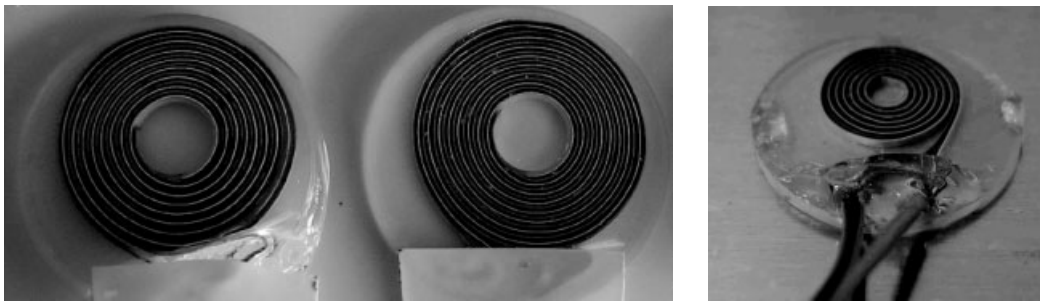
The BAES ATC resistive sensors consist of nine tracks of an aluminum alloy, e.g., Al–Si–Cu, vapor deposited onto a silicon wafer (Figure 5b). Pitting or general corrosion of the tracks results in sectional losses of the tracks causing an increase in the track resistance. The resistance changes are logged, and they provide an indication of corrosion development and possibly corrosion rate.

The BAES ATC sentinel sensor is approximately 25 mm × 25 mm and is made from material similar to the BAES ATC resistance sensor (Figure 5c). This sensor has three electrodes, and each electrode is masked with different size slots. The sensor is primed and topcoated, it is then bonded to the airframe, and the slots are then unmasked. The different-sized slots simulate different sizes of damage in the coating. It is claimed that the sensor resistance changes as the ability of the corrosion inhibitor in the various slots in the primer is exhausted [13].

The galvanic corrosion sensors, developed by CSIRO (Figure 6), consist of coils of dissimilar metals made using 0.1-mm-thick foils of copper and aluminum, both with a purity of 99.9% [14]. The dissimilar metals generate a current flow when exposed to corrosive conditions because of the differing solution potentials that exist at each electrode. The nature of the dissimilar metals may be changed depending on the alloy substrate of interest. For example, laboratory studies using aluminum coupons and aluminum–copper coil sensors allow the correlation of pitting damage in the aluminum coupon with the sensor output. Like the LPR sensor, outputs from this sensor not only provide a measure of the corrosion rate for the alloy from which the sensor element is made but also provide an indication of the TOW.

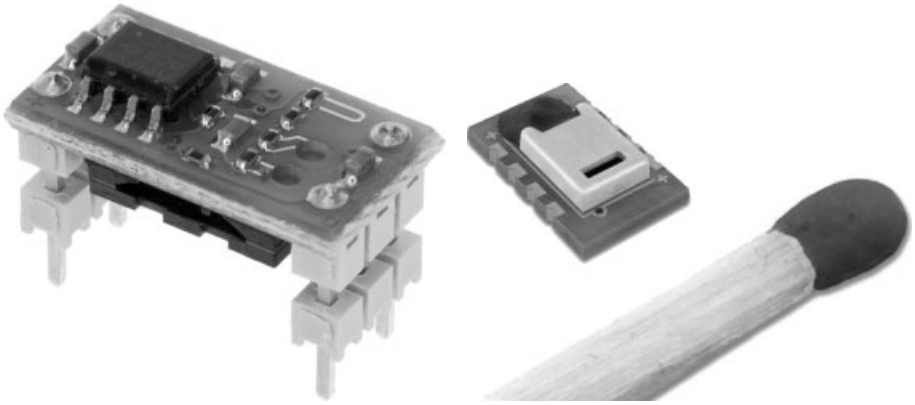
3.2 Environment sensors and monitors

Several commercial sensor systems are available to monitor RH, temperature, and pressure. Some typical solid-state temperature and humidity sensors are produced by Humirel Ltd and Sensirion (Figure 7a



(a) (b) (c)

Figure 6. Galvanic coil sensors. (a) Zn/Cu, (b) Al/Cu Type A, and (c) Al/Cu Type B.



(a) (b)

Figure 7. Humidity and temperature sensors: (a) Humirel HTF3130 and (b) Sensirion SHT1x.

and b, respectively). Both units are very small modules (Humirel and Sensirion units are about 18 mm × 9 mm and 8 mm × 5 mm, respectively), designed to have high resistance to shock and vibration, with a fast response time. Both devices are based on a capacitive polymer sensing element to measure RH. It is claimed that they have a high resistance to a range of chemicals and that they are unaffected by water. These are desirable properties for sensors to be fitted to aircraft.

CSIRO has also produced thin-film sensor arrays which monitor both the environment and corrosivity [15]. As illustrated in Figure 8, the arrays are produced on printed-circuit boards using traditional techniques for etching copper tracks and physical vapor deposition to produce thin films of aluminum. The design incorporates an aluminum–copper galvanic sensor, where the surface area of the copper electrode is minimized to increase the lifetime of the thin film of aluminum (which is oxidized upon being placed in corrosive environments). A thin-film aluminum electrical resistance sensor enables

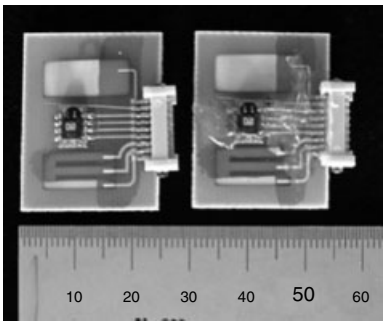


Figure 8. Thin-film sensor arrays support electrical resistance and galvanic corrosion sensor elements and a surface-mounted Sensirion RH/temperature sensor.

a second measurement of corrosivity. The printed-circuit-board design enables the incorporation of a surface-mounted RH/temperature sensor (Sensirion, SHT1x). In addition, a 50-nm-thick evaporated layer of alumina is deposited over the general area of the sensor to encourage the metal elements to wet when the sensor surface is in contact with moisture. This allows the sensor surface to replicate the improved wetting properties of aging metals.

4 SYSTEM ARCHITECTURE

The initial objective of the SHM system was to monitor corrosion damage in a number of corrosion-prone areas within an aircraft, such as in joints or fastener holes, under the lavatory and galley areas, at doors and door edges (as discussed in Section 2.3). The development of the system involves the nontrivial issue of *in situ* sensor conditioning, signal processing, data storage, and system networking. The systems need to achieve sufficient sensitivity, reliability, and robustness to be able to attain data measurements with reasonable confidence (*see* **Sensor Network Paradigms**). The system employs the following principles:

1. Clusters of sensors in small local regions measure local microclimatic parameters, including temperature, humidity, surface wetness, pH, and conductivity of surface moisture. The sensor cluster would also include sensors for measuring corrosion rate such as the Al–Cu galvanic corrosion sensor or the aluminum alloy LPR sensor.
2. Corrosion damage information is obtained from the sensor readings either through CPM or through validated relationships between corrosion damage on aluminum alloy test specimens and sensor readings, established in environmental chamber tests (Section 5).
3. The system has the capability to learn about damage progression from "similar" regions of the structure in which the damage is further advanced and, ultimately, from other aircraft within a fleet.

4.1 Intelligent agents (CSIRO approach)

The approach used here to make the system robust, to allow it to be more readily extendable (scalable), and to minimize communications traffic is to adopt a system architecture based on the use of hardware "agents" [4]. Each agent consists of a cluster of sensors that make measurements in a local region, along with data acquisition, processing, and communications hardware: it is an autonomous sensing unit. The electronic hardware of the agent should be located close to the sensors to minimize effects of cable impedance and noise pick up. The aim for each agent is not only to acquire data from its cluster of sensors but also to carry out any processing of the data that depends only on the local data. Thus, each local agent can analyze the data time series from its sensors, and perform a local diagnosis—thus enabling local checking of the consistency of sensor data, to provide a level of confidence that the sensor measurements are accurate.

The agents communicate with a central processor, which contains global knowledge of the structure, and of each individual agent's location within the structure. A schematic diagram of this system architecture is shown in Figure 9.

The central processor, also known as the *information technology* (IT) platform, provides any required location-related information to an agent, possibly including learnt information from similar locations, which may relate to the agent's local data processing. The agent communicates reduced information to the central processor, rather than raw sensor data.

One of the features of this system is that it is able to predict corrosion damage at some points that do not have sensors, as long as their materials, geometry, and microclimate are sufficiently similar to those at sensed points that they can be reliably deduced from the characteristics of the sensed points. This is done explicitly by the use of "virtual agents" located within the IT platform, which generate diagnostic information from the information obtained from the most appropriate real agents. Clearly, the virtual agents cannot predict the occurrence of specific incidents that may contribute to corrosion (e.g., a water spill), but they may be useful in locations in which unpredictable incidents are unlikely, or in which the probability of such random incidents is similar to that in a sensed location.

Information regarding the airframe structure, and situational information for the individual agents, is maintained within the IT platform in software structures known as *intelligent objects* [16]. Typically, an intelligent object defines a structural component

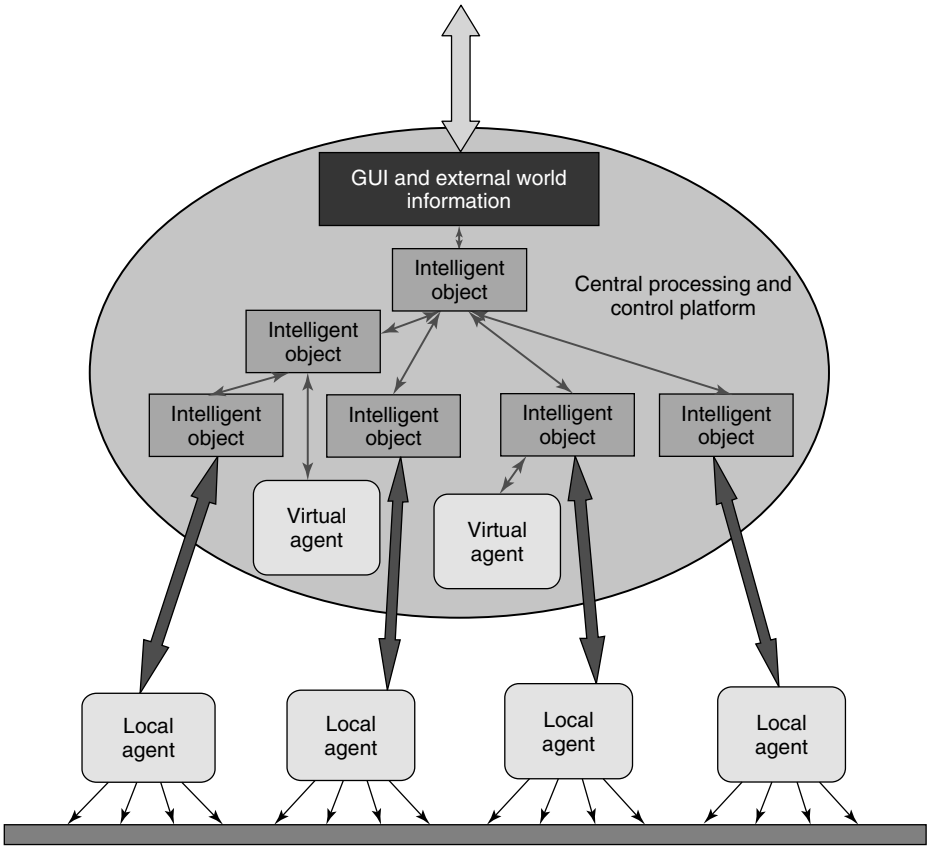

Figure 9. Schematic diagram of one possible system architecture, including (1) local agents that consist of a group of sensors and processing hardware, communicating with a central processor and (2) the IT platform which consists of virtual agents, the intelligent objects and the graphical user interface (GUI). The agents communicate diagnostic information to the intelligent objects.

or a substructure: it contains information about the geometry and materials of the object, and defines the relationships and connections with other objects to form the complete structure. Intelligent objects may be aggregated to form objects representing larger components of the structure. One or more local agents and/or virtual agents may relate to a single intelligent object. Figure 9 contains schematic details of this IT platform architecture, which also contains the interface to the outside world.

A laboratory demonstrator containing 11 sensing agents based on an under-floor region of a large commercial aircraft was implemented in an environmental chamber and has been running for more than 18 months. Single-agent systems, operating purely as data loggers, are operating on two operational aircraft (one commercial and one military). These are described in Section 7.1.

4.2 Sensor nodes (DSTO approach)

A combined sensor interface and networking technology is under development with the following key features [17]:

- low power for long endurance when battery powered;
- packaging of the sensor signal conditioning, network interface, and sensors in one small lightweight package;
- remote software upgrade capability;
- ability to handle large networks of sensors;

- software and hardware adaptability to accommodate new sensors;
- a software interface that is flexible enough to accommodate single or multiple sensors;
- reduced network bus traffic by using local data storage and processing, and local timing for data logging.

Critical to achieving these features is the use of low-power, microcontroller technology that incorporates a wake-on-demand protocol. Using this approach, a sensor node may be in one of three states, namely, disabled, enabled (with only the sensor node network communications active), and active (where the sensor node is fully operational).

The sensor node switches from the disabled to the enabled or active state on receipt of a special serial communications byte or an internally generated interrupt such as a timing signal. The sensor node moves to the disabled state either when it is deselected by the network controller or under internal program control.

Both the hardware and software are modular, consisting of electronics and applications for specific sensors interfaced to an invariant core communications and processing module (Figure 10). The software division is taken to the extent that the memory stack for sensor applications is separate from the CPU stack. A call-back methodology is used for sensor applications to access routines in the core module. The software modules for specific sensors are associated with user-defined command names, known as a *tag*, and both of these are externally downloaded into ROM under control of the core processes. Tag lists that consist of a list of tag names, like a list of function calls, can also be downloaded. Addressing of individual sensors is achieved by assigning them different tag names. The downloadable tag and tag list approach facilitate debugging and development of sensor-specific code. Core processes control all input and output, memory management, the sensor state etc., and also include a number of utility functions to manage the tags. The core routines only occupy 18% of the available ROM, leaving significant space for sensor interfacing code and any desired local data processing. This hardware and software modularization allows for the rapid incorporation of new sensors.

A number of nodes have been developed, including the following:

- high impedance, two-electrode electrochemical sensors;
- inter-integrated circuit (I^2C) compatible temperature and humidity sensors;
- metal foil strain gauge rosettes;
- microelectromechanical system (MEMS) accelerometers (three axis);
- single frequency impedance (amplitude and phase) measurement;
- any sensor that requires a 3–5 V excitation and produces a voltage between 0 and 5 V;
- any sensor that has an open/closed circuit response.

To date, small sensor networks have been implemented in the laboratory, monitored by desktop and embedded PCs. A larger project is underway to install a sensor network consisting of roughly 30 nodes and 100 individual sensors on a medium-sized boat.

5 CORROSION-PREDICTION MODELS

Once coating failure occurs, and corrosion-inhibiting pigments have been depleted to a level where protection is no longer effective (available from laboratory studies), it is reasonable to assume that corrosion will quickly occur. Corrosion models are required that will predict the depth and distribution of corrosion damage with time, whether it is pitting or intergranular corrosion, since it is such damage that may act as fatigue crack initiators and jeopardize aircraft structural integrity.

5.1 Functional approach (CSIRO)

To enable accurate corrosion predictions, a sound understanding of the relationship between the actual damage occurring on structures and the output from corrosion sensors must be established. The corrosion sensors measure the rate of accumulation of damage to the sensors themselves, not to the underlying material of the aircraft frame. To date, the damage occurring on several materials of relevance to aircraft structures, under accelerated corrosion conditions, has been evaluated and related to the output of the corrosion sensors [4]. The materials studied include

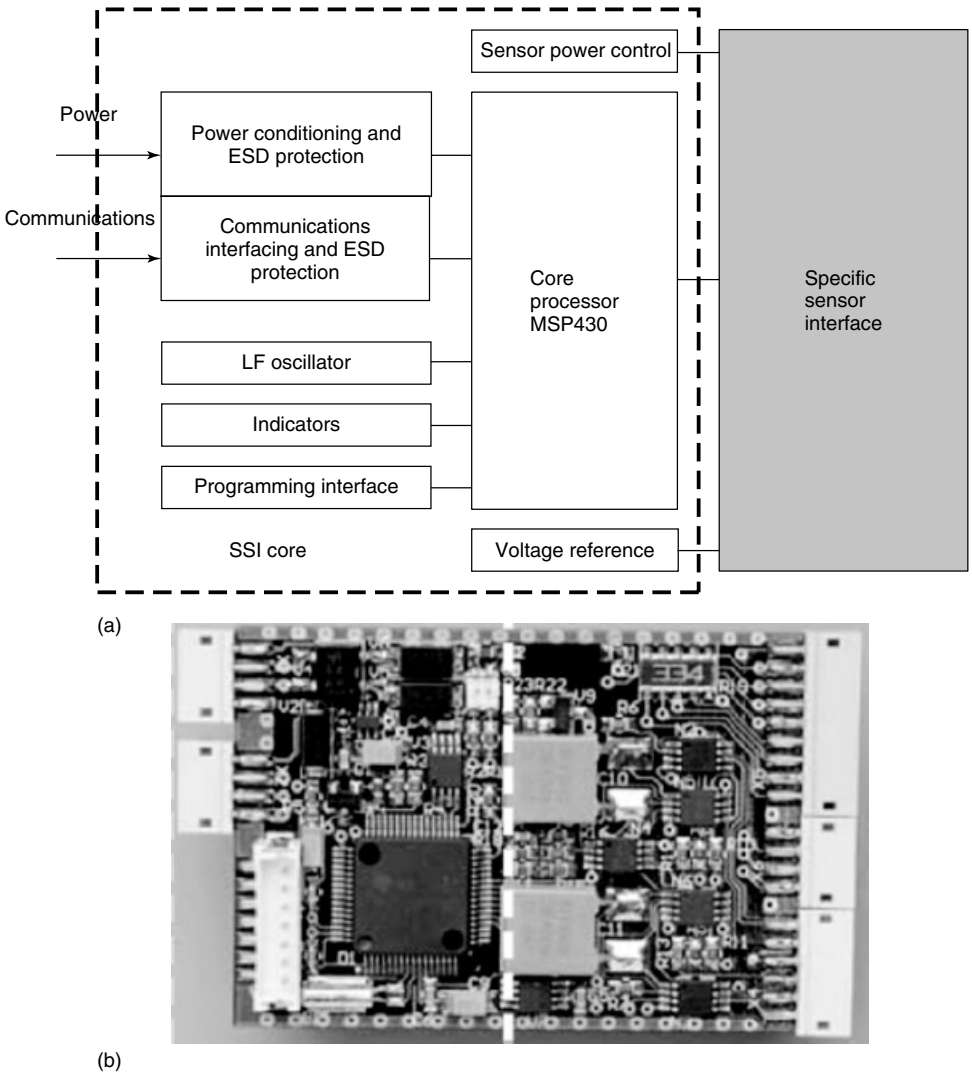

Figure 10. Sensor interface is modular with both (a) the software and (b) the hardware divided into a core communications and processing module (left-hand side of a and b) and software and hardware specific to the sensor (right-hand side of a and b).

- AA2024 (major alloying additions Cu and Mg)
- AA7075 (major alloying additions Zn, Mg, and Cu)
- painted AA7075 with chromate conversion coating and epoxy-polyamide primer.

Corrosion sensors and panels of the aluminum alloys have been exposed to accelerated corrosion environments. The test cycle parameters were defined by General Motors Standard GM9540P [18], with some modifications to make the environment more aggressive.

The degradation of the uncoated aluminum panels was evaluated by determinations of mass loss, pit depth, pit area, and pit density using standard techniques. The most reproducible parameters for aluminum alloy damage assessment were found to be mass loss, the average maximum pit depth, and the average maximum pit dimension. In this case, the average pit dimension is defined as the average pit

width × the average pit depth. Pit-size characterization is usually perceived as being a more important and realistic damage parameter for aluminum alloys, particularly where fatigue crack initiation is of concern.

The degradation of the coating on the painted panels has also been evaluated using EIS and Raman spectroscopy to monitor the depletion of the chromate inhibitor. With EIS, the impedance modulus at 0.1 Hz was adopted as a measure of the barrier properties of the primer as a function of time. This measure is based upon the work of Potvin *et al.* [19]. Using Raman spectroscopy, maps of epoxy, chromate, and titania species were established on the basis of the baseline-corrected intensities of absorption peaks, which occur at known wave numbers. Good correlation was achieved between the two methods of evaluating the degradation of the coating (Figure 11).

Using these analysis techniques, relationships were developed for the degradation of the materials with respect to the number of cycles of the environmental test. Having determined the failure modes of the materials, these needed to be related to the output from the corrosion sensor (Figure 12). During accelerated testing, the temporal data output from 10 galvanic corrosion sensors was collected to enable correlation with the state of the simultaneously exposed aluminum alloy panels.

To predict damage, relationships are sought to link the damage (corrosion) sensor outputs with the causes of corrosion, as measured by an array of microclimate sensors. Using an approach that combines aspects of both physics-based modeling and statistical analysis, these relationships are established and updated on

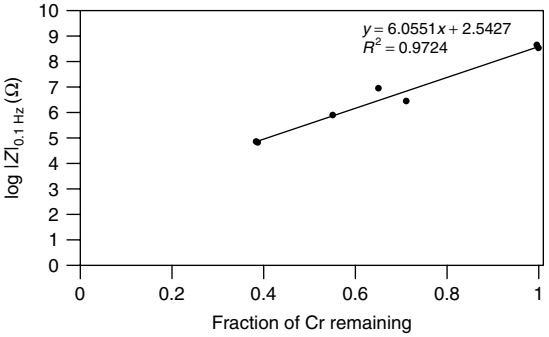

Figure 11. Correlation of the two measures of coating deterioration, EIS, and fraction of Cr remaining (determined from Raman spectroscopy).

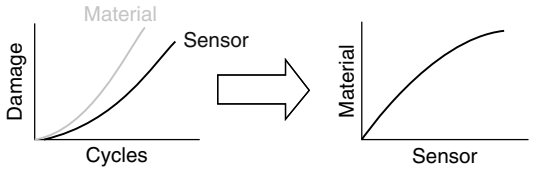

Figure 12. The material degradation and sensor outputs are initially related to the number of cycles of environmental testing. A relationship between the material damage and the sensor output is then derived.

an ongoing basis as more data is received by the agents. The system does not attempt to investigate the underlying factors controlling the microclimate or damage; rather the relationships between sensed damage and sensed surface response are determined using mathematical manipulations of the raw data.

Predictions of future corrosion behavior are made by using the relationships established on current data with a predicted future microclimate scenario.

5.2 Physics of failure approach (DSTO)

When surfaces are contaminated by NaCl and/or sea salts, and wet due to deliquescence, discrete moisture droplets are formed [20]. The number and size of these are dependent upon the contaminant density and the ambient RH. For low contaminant densities, discrete droplets form, but as the contaminant density increases, the droplets may merge to form larger droplets. These droplets constitute the local corrosion cells upon the surface and can be considered to be independent of each other. To predict the number and size of pits formed, the number, size, and composition of these droplets needs to be determined. This is achieved by using atmospheric science combined with atmospheric parameters that are practical to measure, using sensors.

The environmental model has been formulated with a requirement to have only simple atmospheric variables as inputs. In this way, the sensor requirements are reduced, and the use of simple commercial off the shelf sensors can be realized. To this end, a sensor suite proposed for the DSTO corrosion SHM system consists of a combined atmospheric temperature and RH sensor, a surface temperature sensor, and a TOW sensor. However, these sensors are required to be monitored continuously. The sensor suite may also be expanded to introduce redundancy

in the measurements and by the use of more exotic sensors, for example, paint degradation or pH sensors. Hence this approach could be made more universal, allowing its use where more complex contaminants occur. The sensors used in this approach consisted of the USN TOW, Sensirion RH/temperature, and National Semiconductor LM35 surface temperature sensor. These were selected after numerous trials of potential sensors as they were found to give accurate responses to rapid environmental changes. The results of testing of these sensors in an environmental chamber are shown in Figures 13 and 14 [21].

From Figure 13 it can be seen that the RH sensor was able to follow the programmed chamber RH closely with a maximum error of approximately 5%. The temperature of the chamber as measured by the Sensirion sensor (Figure 14) was an identical match to the programmed temperature. The temperature as measured by the surface sensor (LM35) responded more slowly to the changing temperature due the thermal mass of the surface to which it was attached (Figure 14). The difference in the two temperature measurements is important, as it will affect the condensation and evaporation of moisture from the surface.

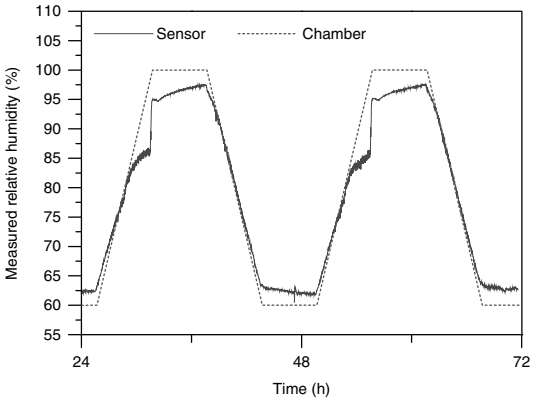

Figure 13. Sensirion RH sensor output versus programmed environmental chamber condition [21].

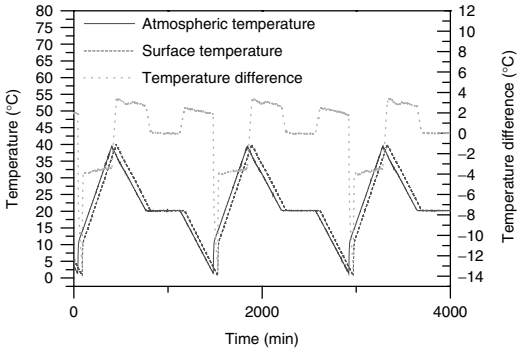

Figure 14. Atmospheric and plate temperature sensor outputs plotted with temperature differences [21].

The results from the TOW sensor showed how the measured current is scalable with wetness. Figure 15 shows the response with a high salt density on the surface and Figure 16 is the response of the TOW sensor with a low salt density.

5.2.1 Environmental model

The function of the local environment model is to take the raw sensor data and determine those parameters that are required to predict corrosion levels. The inputs and outputs from this model act as inputs into the atmospheric corrosion model that are listed in Table 1.

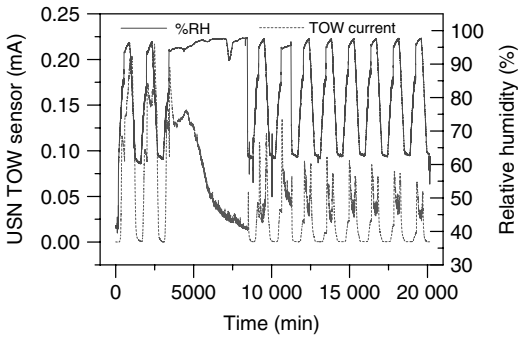

Figure 15. Response of USN TOW sensor to varying RH when doped with 5 g m^{-2} NaCl [21].

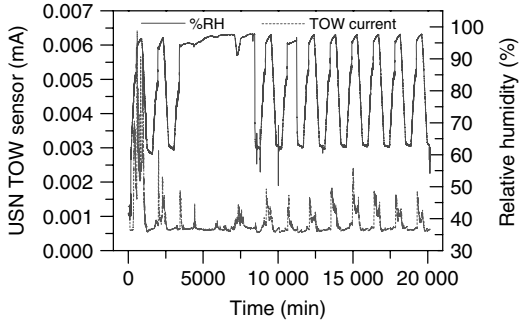

Figure 16. Response of USN TOW sensor to varying RH when doped with 0.1 g m^{-2} NaCl [21].

Table 1. Inputs for and outputs from the local environment model

Local environment modeling inputs	Local environment modeling outputs
Time of wetness	Periods of wetness (minutes)
Relative humidity	Extent of wetness (percentage wet)
Atmospheric temperature:	Surface salt coverage (milligrams per square meter)
Plate (aircraft structure) temperature	Number of moisture droplets
	Distribution of droplets areas
	Pollutant composition
	Droplet concentration (moles per cubic decimeter)

The outputs from the local environment model were calculated using atmospheric physics [22–24]. For example, the surface moisture concentration was calculated using the measurement of RH and the relationship shown in Figure 17. The interactions between multiple sensor outputs can also be used; for example, the salt crystal density can be calculated using the extent of wetness, from a scalable TOW sensor, combined with the RH, as shown in Figure 18. The period of wetness is obtained directly from TOW readings and the droplet size distribution is calculated using crystal salt densities and RH measurements in combination with probabilistic mathematics.

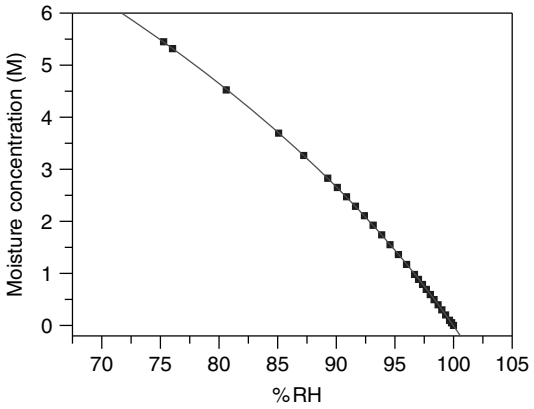

Figure 17. The dependence of surface moisture concentration on RH for NaCl [21].

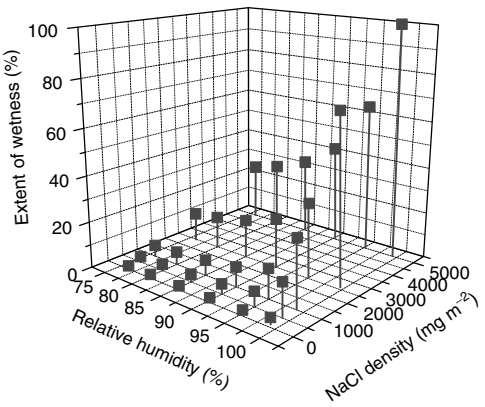

Figure 18. The dependence of salt crystal density on relative humidity and the extent of wetness for NaCl [21].

5.2.2 Corrosion modeling

As detailed above (Section 5.2), the atmospheric pitting corrosion of aluminum alloys occurs in packets when the surface is wet. To model the corrosion, the environmental sensor data is first sorted into wetness periods and the environmental parameters are calculated for each time interval. The time-resolved environmental parameters are then used to build corrosion models. The current corrosion model determines the number and size of corrosion pits; however, further models are being designed to predict intergranular and exfoliation corrosion. The pitting corrosion model has two components: a pit-creator algorithm and a pit-growth algorithm. The pit-creator algorithm employs probabilities of pitting calculated electrochemically and the pit-growth algorithm employs electrochemically measured kinetic parameters. These two algorithms work synergistically to determine the corrosion damage.

Pit-initiation algorithm

The pit-initiation algorithm employs stable pit probabilities calculated from electrochemical measurements. Pit probabilities are calculated using the method explained elsewhere [25], but will be described briefly here. The technique electrochemically determines the distribution of the largest metastable pit sizes occurring on the alloy of interest in the expected droplet solution—a typical experimental curve is displayed in Figure 19. The current spikes in the potentiostatic trace indicate metastable pitting events occurring on the aluminum alloy electrode.

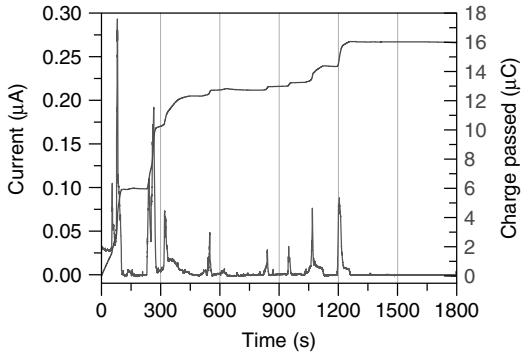

Figure 19. Potentiostatic current response of AA2024-T3 in NaCl solution [25].

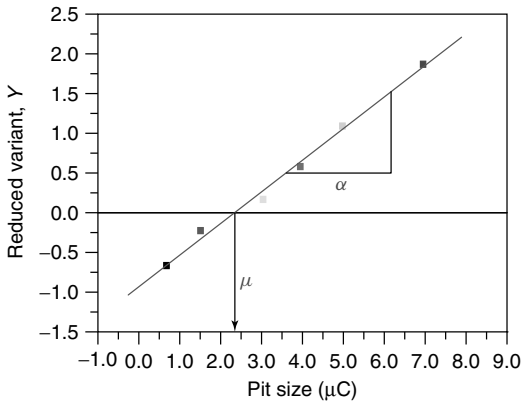

Figure 20. Maximum pit sizes for each plotted versus reduced variant, $-\ln(-\ln(1-(i/(n+1))))$ for n data points where i = 1, n [25].

The integrated area under the current spikes may be converted to pit depth using Faraday's law. The largest transients (current spikes)—metastable pits—measured are used in an extreme value statistics procedure to determine their distribution (see Figure 20, [25]). This distribution is then used to calculate the probability for a metastable pit larger than that required for the pit to become stable, "stable pit criteria" will occur, as shown in Figure 21. Multiple probability determinations are undertaken to ensure all possible droplet electrolyte compositions are covered. The matrix of probabilities is then used to generate a function that describes the distribution of probabilities that is used in the pit-initiation algorithm. In this manner, the electrolyte composition predicted in the environmental model is an input into the function to determine the initiation of a corrosion

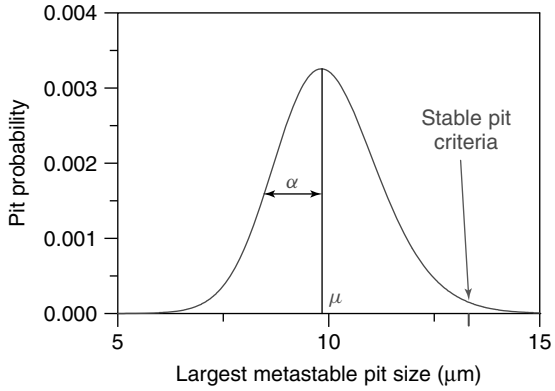

Figure 21. Distribution of maximum pit sizes predicted from extreme value statistics showing cut of size for stable pits [25].

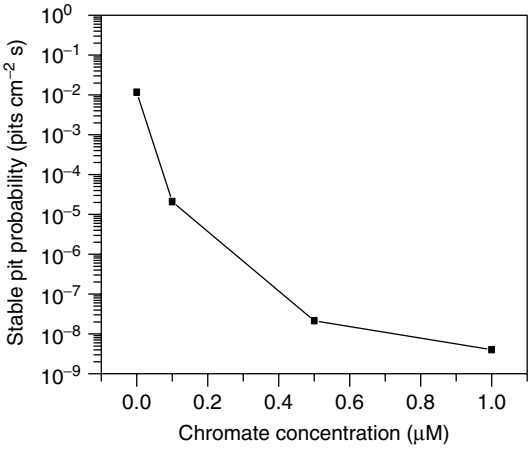

Figure 22. Stable pit probabilities calculated for AA2024-T3 in 3.5% NaCl at different chromate levels [25].

pit. As an example, the calculated probabilities for AA2024-T3 in 3.5% NaCl in the presence of varying concentrations of chromate are shown in Figure 22.

The method described above is time consuming and needs an experienced electrochemist to undertake the analysis. Hence current activities involve the development of a simpler less time consuming analysis to predict stable pit probabilities.

Pit-growth algorithm

The pit-initiation algorithm determines if and when a pit is created, by comparing the pit probability to a random number using a Monte Carlo simulation. If a pit is created, it is then grown by the pit-growth

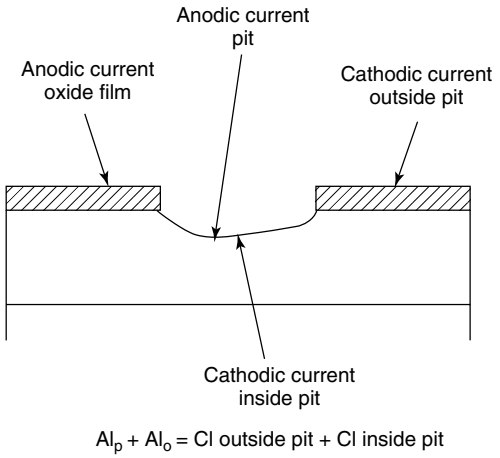

Figure 23. Schematic of a growing pit.

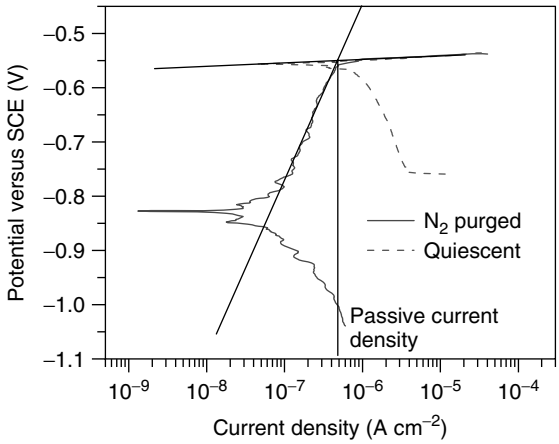

Figure 24. Potentiodynamic scans of AA2024-T3 in 1 M NaCl with and without nitrogen purging [25].

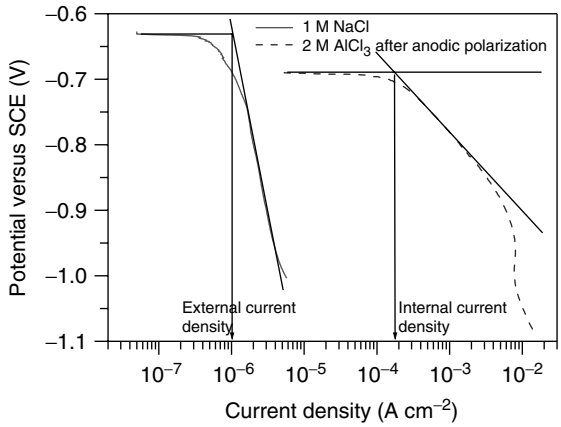

Figure 25. Cathodic polarization curves for AA2024-T3 in 1 M NaCl and 2 M $AlCl_3$ after anodic polarization [25].

algorithm. This algorithm performs an electrochemical kinetic current balance of the cathodic and anodic reactions taking place within a droplet. If we consider the schematic in Figure 23 for a growing pit on an aluminum surface, the sum of the anodic current producing the oxide film (AI_o) and the anodic current feeding the growth of the pit (AI_p) is equal to the cathodic current associated with the reduction of oxygen outside the pit (CI_o) plus the current associated with the evolution of hydrogen within the pit (CI_i). For various alloys, polarization data have been produced to give values for AI_o, CI_i, and CI_o. Of these four currents, only the anodic pitting current is unknown, and it can be calculated as a pit grows by performing a simple balance between the anodic and cathodic currents. However, in the early periods of pit growth, the pit does not grow at this rate, but is limited by the transport of metal ions out of the pit and counter ions into the pit, and not by the supporting cathodic reaction rates. This period of time, where the pit is not large enough to consume the available cathodic current, is when the pit grows at the fastest rate. It is assumed all pits grow at this rate.

The rates of the anodic and cathodic reactions are measured electrochemically using potentiodynamic polarization, as shown in Figures 24 and 25. In cases where the pitting potential was coincident with the open circuit potential (the case for many aircraft aluminum alloys in chloride solutions), a nitrogen-purged potentiodynamic scan was also conducted to enable the passive current density in an aerated solution to be estimated (Figure 24).

To determine the internal-pit cathodic current density, potentiodynamic polarization was conducted in 2.0 M $AlCl_3$ after removal of the surface oxides by the initial application of 1 V versus saturated calomel electrode (SCE) for 5 min. The 2.0 M $AlCl_3$ solution closely represents the chemistry of the solution within pits. The internal cathodic current density in the model environment was significantly higher than the external cathodic current density as shown in Figure 25. When the total area of pitting i.e., sum of the area of individual pits (assuming each pit is a hemispherical) times 1 mA cm^{-2} exceeds the cathodic

current outside the pits plus the cathodic current inside the pits, minus the current to grow the oxide film, the growth of a pit becomes cathodic current limited, and the total current available is shared by all pits. Thus the size of a pit and density of pits at any time may be calculated.

6 MAINTENANCE DECISIONS

Traditional corrosion inspections are undertaken at specified intervals (often based on flying hours) and are set by safety and economic considerations. In many cases, these inspections involve pulling apart seals (sometimes factory seals) and may cause more harm than good. In fact, a significant proportion of the corrosion effort arises from the cost of looking for corrosion. Clearly, there are significant incentives to reduce the number of inspections. It is one of the aims of corrosion SHM programs (as shown in the flow diagram of Figure 26) to ultimately decrease the frequency of traditional inspections with a system of sensors and models that inform the maintainer about the structural condition of the aircraft. Figure 26 is a simple representation of the way a corrosion SHM system fits together, and the types of decisions to be expected from it, when complete. There are, however, significant technical and regulatory hurdles that need to be overcome before the structural condition information inferred from a corrosion SHM system could be used in preference to condition information acquired through traditional inspections.

In order that a corrosion SHM system be used in lieu of traditional visual inspections, it will need to be capable of predicting corrosion in a joint in a remote area. This will require that the system be capable of diagnostically determining when the protective coating has failed, both physically via cracking, and chemically via the leaching and removal of corrosion inhibitors from the area. While the BAE Systems' *Sentinel* sensor [13] goes some way to this end (see Section 3.1), in that it provides information regarding the depletion of the corrosion inhibitors given physical defects in the sealant, no present day corrosion SHM system is capable of determining when the coating has failed both physically and chemically. However, efforts within DSTO and the ADF are designed to produce interim capabilities that will assist in the current management practices of ADF aircraft and will facilitate the acceptance of the SHM approach to corrosion management by the operator and maintainer. Examples of such interim capabilities are shown in Figure 27: The roadmap for DSTO's corrosion SHM technologies. This figure is a schematic illustration of how improvements in the corrosion SHM system capability result in increased aircraft availability. For

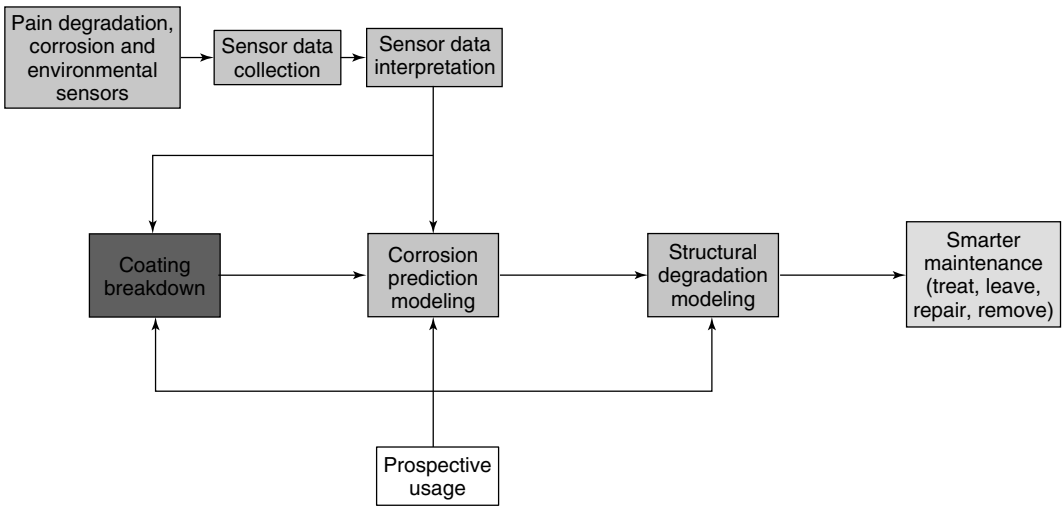

Figure 26. Schematic of the components of the DSTO SHM system for corrosion maintenance.

The color of the point indicates the level of technical maturity, where green (light grey) corresponds to existing capabilities and red (dark grey) corresponds to capabilities that have not yet been achieved.

each point on the roadmap, the enabling capability (or technology) is italicized, while the resulting information (outputs) made available to the maintainers is shown in bold. For example, the first point on the roadmap illustrates that a system of *off-board sensors* can provide information regarding the **corrosivity of the base environment**. Each point is also colored according to the level of technical maturity, green (light grey) corresponding to existing capabilities and red (dark grey) corresponding to capabilities that have not yet been achieved. What is clear from the roadmap is that there is a wealth of information that the existing system can provide to the operator/maintainers including

1. the corrosivity of the base environment (including hangars, shelters, or the flight line);
2. the corrosivity of the actual internal spaces within the aircraft;
3. the effect of mission type on the corrosivity within the aircraft;
4. the build-up and concentration of pollutants (salts etc.) on the aircraft, which can indicate when or how often the aircraft needs to be washed as well as how effective the wash is at removing pollutants;
5. the effectiveness of dehumidification systems, especially their efficacy in hard to access locations or locations containing high-value equipment;
6. when corrosion preventative compounds no longer provide protection and therefore need to be replaced;
7. information regarding the progress of corrosion where the inhibitor is depleted;
8. input to corrosion based reliability centered maintenance analyses.

In short, the existing system can advise the maintenance process and enable the forward prediction of maintenance requirements, including preventative maintenance, with the result that aircraft availability will increase and maintenance costs will decrease.

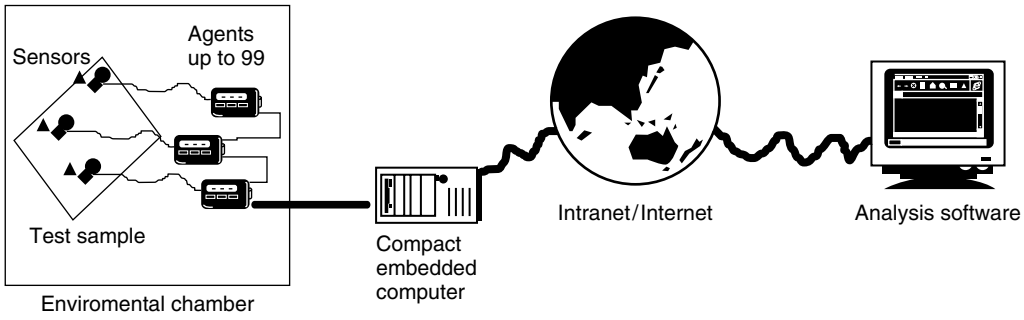

Figure 28. A schematic representation of the laboratory demonstrator.

7 LABORATORY AND FLIGHT DEMONSTRATORS

7.1 Functional approach

A laboratory demonstrator system has been set up to evaluate and demonstrate the methodology of this approach. A subsection of an aircraft (the subfloor region of the lavatory/galley area of a Boeing 747-400) has been set up with 11 sets of sensors and agents (Figure 28) [4]. The whole system has been placed in an environmental chamber and subjected to a continuing cycle of temperature and humidity fluctuations. Some variations in environment have been provided by undercooling of some areas (using a Peltier device) and sprays of contaminating liquids likely to be found in the lavatory/galley area. The demonstrator has been running for 18 months and has provided data for testing the analysis algorithms.

A set of sensors with a data logger has also been placed on a Boeing 747 aircraft regularly flying across the Pacific and the data collected from these trials has also been useful in validating the analytical approach. A similar set of sensors and data logger have been installed in an operational military aircraft more recently.

Data from the demonstrator and flight trials have been analyzed using the proposed technique and the results are illustrated in Figures 29 and 30. Figure 29 is based on the sensor outputs from one of the agents on the laboratory demonstrator. It shows the corrosion sensor (damage) output and predictions derived from different subsets of the data. In each case, the data

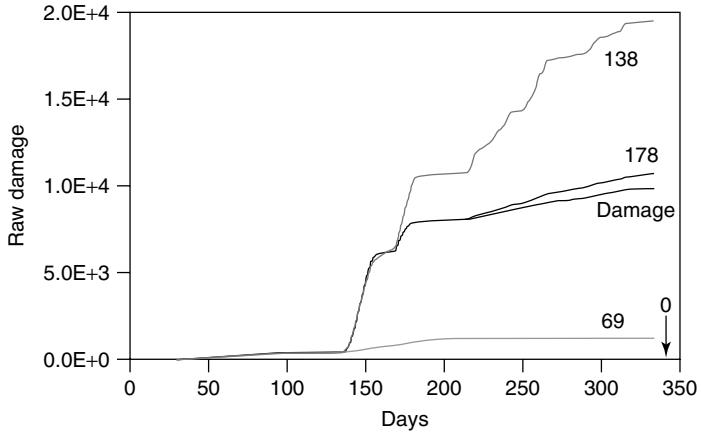

Figure 29. Fit of models with measured damage (cumulative corrosion current in microamperes) for galvanic corrosion sensor at one position on the laboratory demonstrator. The models are generated from nine days of data starting at day 0, 69, 138, and 178. The line 0 runs coincident with the x axis and is not visible.

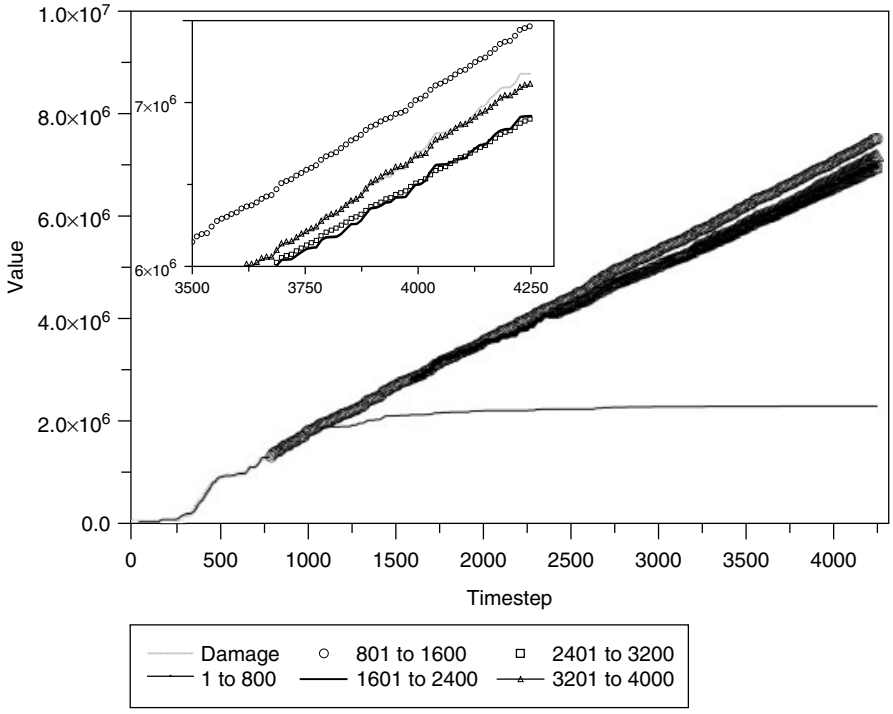

Figure 30. Analysis of real in-flight data using moving windows to generate models.

model is calculated from about nine days of data and then applied to predict the data for the rest of the time sequence using the measured microclimate parameters. Thus the lines marked 0, 69, 138, and 178 are predictions derived from data 0–9, 69–78, 138–147, and 178 to 187 days respectively, and then applied into the future. This analysis demonstrates that the models can closely fit the damage stream from the microclimate data and can successfully predict damage into the near future. It also illustrates how the damage/microclimate relationship changes as damage develops, since early models do not remain valid. Thus the method of continuously regenerating the model that is embedded in the software will ensure that the prediction will remain accurate.

The analysis of in-flight data is shown in Figure 30. Again the models are trained on different portions of the data and used to predict into the future using the microclimate data. This shows that predictions can be made with good accuracy into the immediate future given that sufficient data is available to establish the modeling relationships. It also illustrates that the technique is applicable to real in-flight data.

In these illustrations, the raw output from the corrosion sensor has been used, and the relationships developed to map this onto actual damage of aluminum materials (discussed in Section 5.1) have not been integrated into the calculations.

7.2 DSTO model validation

The physics-based CPM developed to date predicts the occurrence of pitting corrosion at damaged sites in paint coatings on aircraft. The CPM has been validated in the laboratory with this use in mind by exposing the sensor suite and corrosion coupons in an environmental chamber programmed with two varying RH and temperature cycles. The first cycle was designed to induce few and small corrosion pits and was called the *benign cycle*, and the latter was designed to produce many and larger pits and was denoted the *severe cycle*. These two cycles are displayed in Figures 31 and 32. The benign cycle has a maximum RH of 90% and no rapid condensation

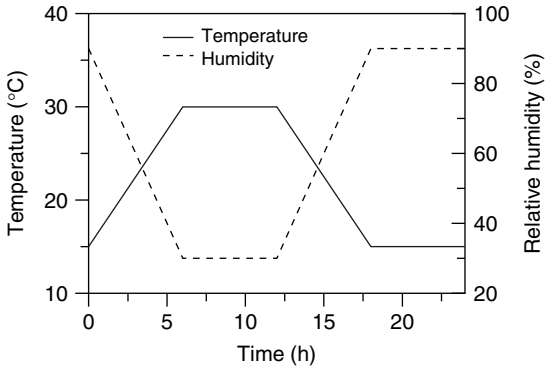

Figure 31. Benign environmental cycle.

period, whereas the severe cycle has a maximum RH of 100% and a rapid condensation period.

Coupons of aluminum alloy AA7050 from the rolled surface of a 100-mm plate were finished to 1200 grit. The coupons were left unpainted to mimic areas of exposed aluminum on aircraft after the paint has degraded. The coupons had an area of 1 cm^2, to give a representative group of pits, but the model could have easily used smaller exposed areas of bare metal, such as those experienced on aircraft. The corrosion coupons and sensor suite were doped with NaCl to two different salt densities before exposure. The first salt density was 5 $g\,m^{-2}$, a level designed to result in full coverage of the surface with condensed moisture, and the second salt density was 0.1 $g\,m^{-2}$, a salt density typically found on ADF aircraft [5]. The sensor suite was bonded to aluminum specimen (see Figure 33a) and the sensors were interrogated using a DSTO designed data logger system. The sensor system has also been miniaturized for deployment onboard aircraft and is shown in Figure 33(b).

The corrosion model predicts, using Faraday's equation, the number and size of pits occurring on aluminum surfaces from the measured coulombs of charge. The volume of the pits on the corrosion coupons was estimated from the measured depth, width, and length using the equation for the volume of a spherical segment. This volume was then normalized into an equivalent pit size for a hemispherical pit of the same volume. In this manner, the predicted and measured pit sizes were compared.

The modeled pit diameter distributions generated from both the one-week and two-weeks sensor data in the severe cycle doped with 5 $g\,m^{-2}$ NaCl were very similar to the measured pit diameter distributions (Figures 34 and 35). The largest difference between the measured and modeled results, for both periods, was for the lowest pit diameter bin where the modeled number of pits was greater than the measured number of pits. However, experimental verification is difficult for small pit sizes and due to time constraints and the very large numbers of these small pits on these coupons, a cutoff size (dependent upon the number and size of pits present) was imposed, where pits smaller than this size were not measured. However, they were predicted by the model.

The results displayed in Figures 36 and 37 are for exposure to the severe cycle with 0.1 $g\,m^{-2}$ NaCl doped surfaces. In this test, the modeled and measured pit diameters were similar in number, maximum size, and also in size distribution. Again

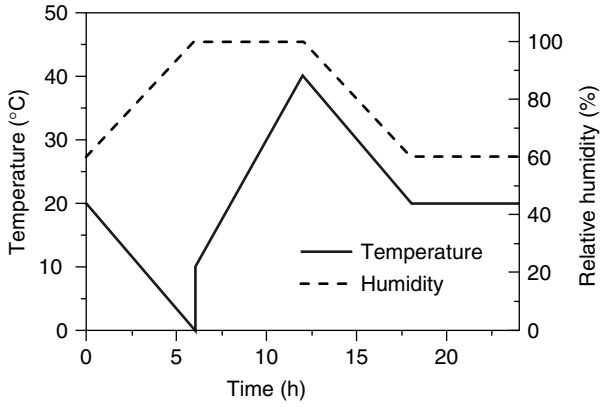

Figure 32. Severe environmental cycle.

(a) (b)

Figure 33. This figure shows (a) validation test apparatus and specimen, and (b) miniaturized sensor system (with dimensions 54 mm long by 38 mm wide).

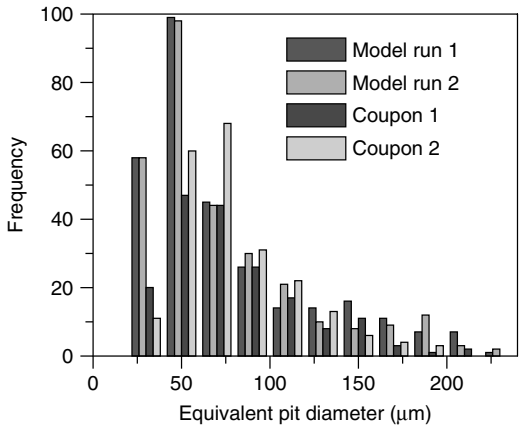

Figure 34. Pit sizes for AA7050 exposed for one week to the severe cycle after being doped with 5 g m^{-2} NaCl.

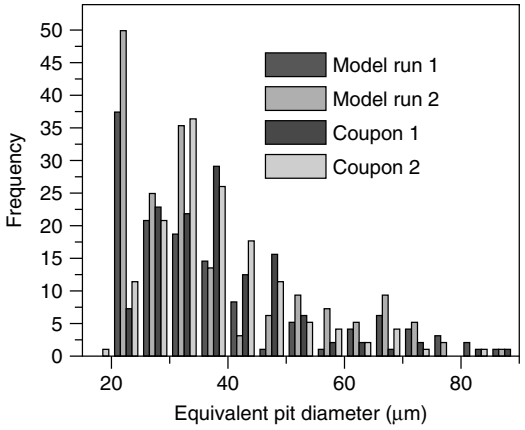

Figure 36. Pit sizes for AA7050 exposed for one week to the severe cycle after being doped with 0.1 g m^{-2} NaCl.

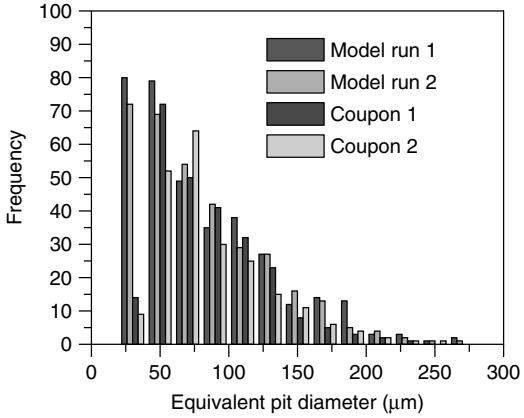

Figure 35. Pit sizes for AA7050 exposed for two weeks to the severe cycle after being doped with 5 g m^{-2} NaCl.

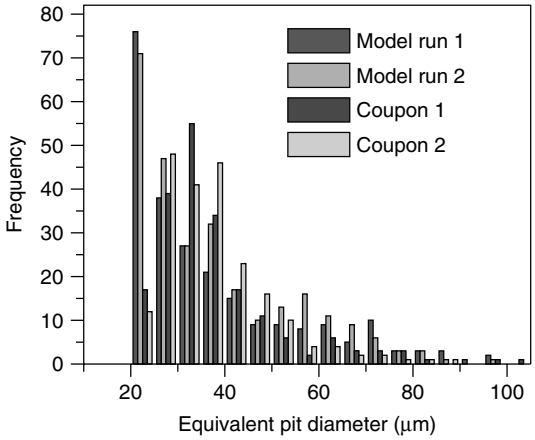

Figure 37. Pit sizes for AA7050 exposed for two weeks to the severe cycle after being doped with 0.1 g m^{-2} NaCl.

the pit numbers for the smallest bin were higher for the modeled distribution than the measured distribution due to the measurement cutoff at the small sizes.

For the test conducted in the benign cycle with 5.0 g m^{-2} NaCl doped surfaces, the modeled pit diameters were similar to the measured pit diameters in this test with respect to numbers of pits and maximum pit sizes. However, there were some differences in the shapes of the distributions (Figures 38 and 39). The reasons for this are variations in the pit probabilities at higher chloride concentration that have not yet been incorporated into the modeling. That is, the benign cycle did not include a condensing period and the maximum RH was 90%, resulting in chloride concentrations above 2.5 M at all times. In concentrated chloride solutions, the probability of pitting was reduced dramatically because of the lower solubility of oxygen.

The pit diameters modeled and those measured were in approximate agreement for maximum pit size and pit numbers, but again the distribution was dissimilar for the test conducted in the benign cycle with 0.1 g m^{-2} NaCl doped surfaces (Figures 40 and 41). The reason for this is the higher NaCl concentrations expected at the lower RH as discussed above.

The modeled results predicted using environmental sensor inputs were in good agreement with those

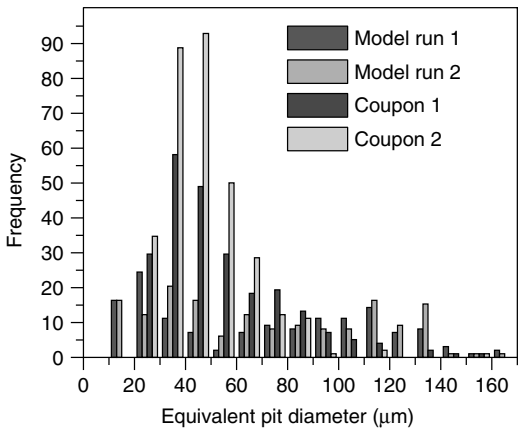

Figure 38. Pit sizes for AA7050 exposed for one week to the benign cycle after being doped with 5 g m^{-2} NaCl.

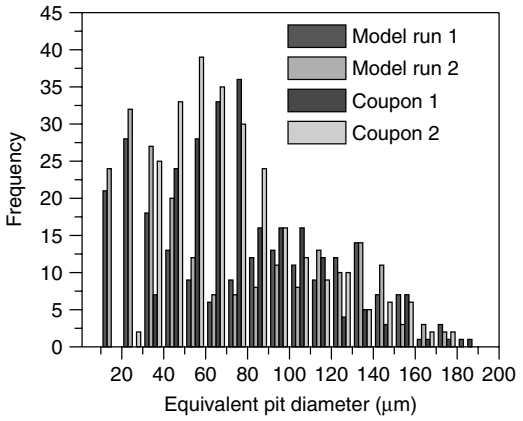

Figure 39. Pit sizes for AA7050 exposed for two weeks to the benign cycle after being doped with 5 g m^{-2} NaCl.

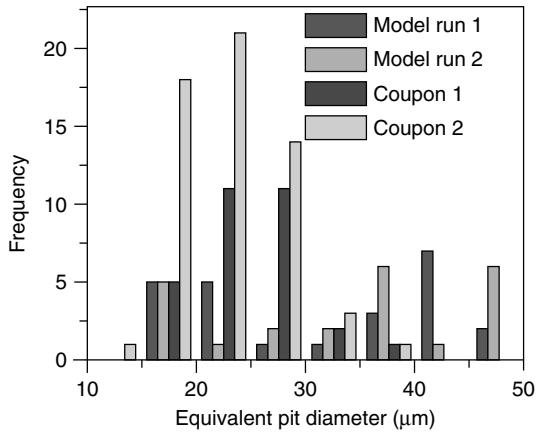

Figure 40. Pit sizes for AA7050 exposed for one week to the benign cycle after being doped with 0.1 g m^{-2} NaCl.

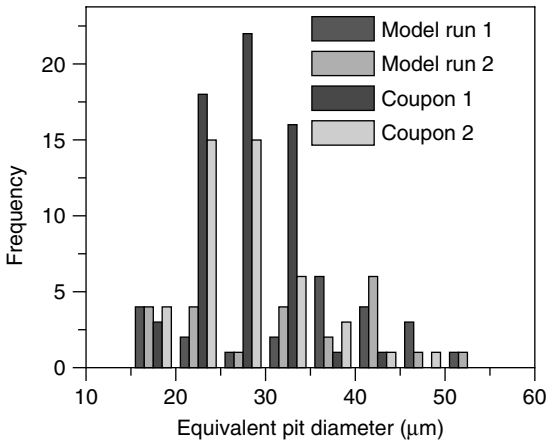

Figure 41. Pit sizes for AA7050 exposed for two weeks to the benign cycle after being doped with 0.1 g m^{-2} NaCl.

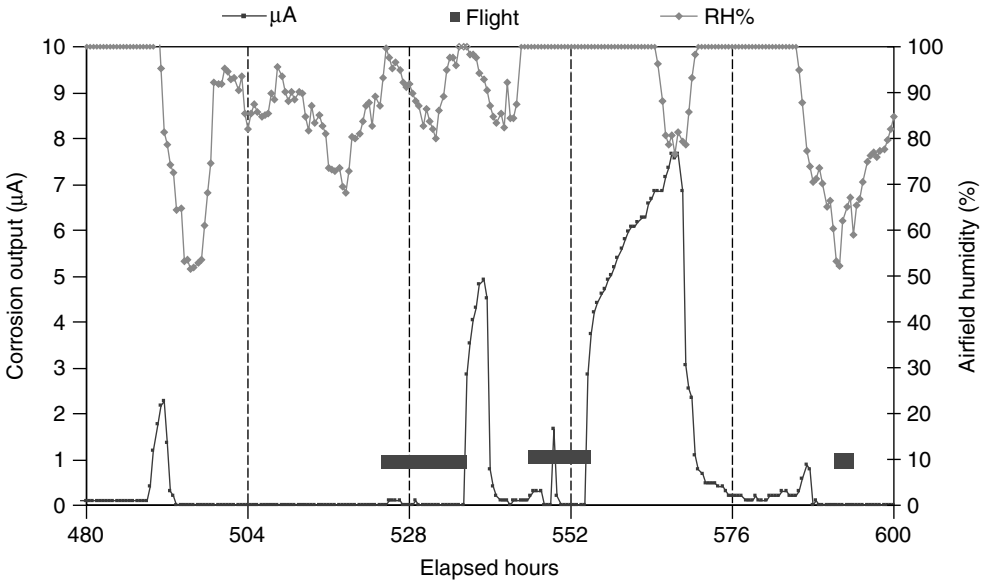

Figure 42. Typical output from a corrosion monitor located in the tail section of an RAAF P-3C maritime patrol aircraft.

measured from corrosion coupons exposed adjacent to and treated the same way as the sensors. This was especially true for the test panels exposed to the severe environment where the pit numbers, pit sizes, and pit-size distributions predicted by the corrosion model were in close agreement with those measured. The pit sizes and pit numbers predicted for panels exposed to the benign environment were also in close agreement, but the pit-size distributions were different. The reasons for these differences are the reduction in pit probabilities in concentrated NaCl solutions.

Overall, the use of corrosion/environment sensors with mechanistic-based modeling has been demonstrated to be capable of predicting, with some accuracy, the different levels of pitting corrosion observed on AA7050 exposed to a variety of simulated aircraft exposures of different severities.

7.3 In-flight demonstrators

A DSTO-developed TOW monitor was first mounted in the tail section of an RAAF P-3C Orion maritime patrol aircraft in 1998 [8]. This section is unpressurized, and the internal structure is exposed to the atmosphere via various vent and actuator holes. Some of the corrosion activity from the monitor could be attributed to the ambient conditions at the base while the aircraft was between flights. Corrosion activity was present during flight on many occasions, but only on flights lasting more than 1 h. There was no significant correlation of mission type or flight duration with corrosion activity. However, the data analysis revealed that a very significant amount of activity occurred shortly after the aircraft landed. This "postflight" activity was attributed to condensation when ambient air entered the structure, which had cooled below the dew point during flight. The amount and duration of this activity varied with the ambient humidity. If the RH was above 80%, nearly half the flights had condensation after landing, while if the RH was below 50%, only about a tenth of the flights experienced condensation. Typical output from the monitor is shown in Figure 42. The thin black data is the output from the monitor in microamperes (μA), and the gray data is the RH at the airfield. The solid black lines represent the time the aircraft is in flight. Some corrosion activity occurs while the aircraft is on the ground, the high humidity (100%) indicating rain. Significant peaks have also occurred immediately after landing, with the output being higher, and of a longer duration, when the airfield humidity is high [8].

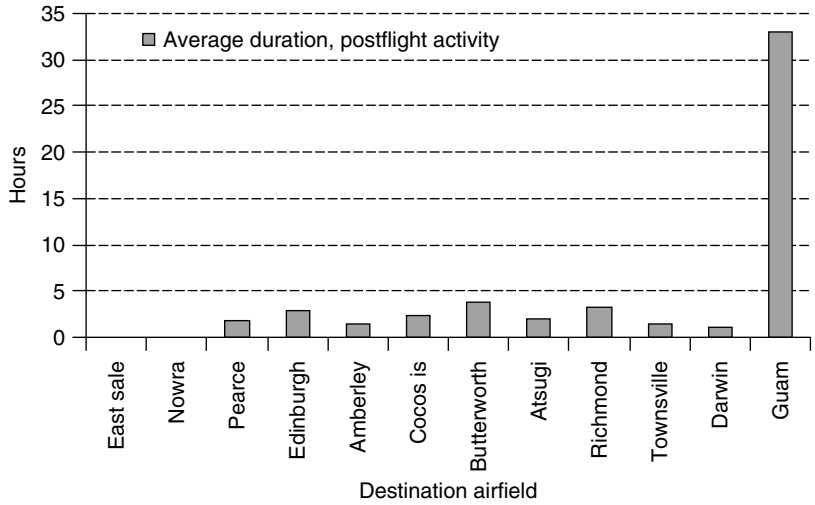

Figure 43. Duration of postflight corrosion activity at various airfields.

In the F-111, the monitor was located in the forward section of the weapons bay, also unpressurized (P. Trathen, private communication, 2007). In contrast to the P-3C, no condensation occurred after landing, in the F-111. This difference in behavior is attributed to the temperatures reached during flight. The P-3C, being a propeller-driven aircraft is significantly slower than the F-111. It is estimated that the P-3C would cool to $-25\,^{\circ}C$ in high-level flight. The F-111, a fast jet, would rarely go below ambient temperature, and, in fact, the skin temperatures could heat to $100\,^{\circ}C$ or higher during a typical mission owing to frictional heating from airflow. The significance for aircraft maintainers is that flights on P-3C may be a significant contributor to corrosion damage, due to the postflight activity. The F-111 corrosion is likely to depend entirely on ambient conditions at the base and be unrelated to flight. The importance of geographic location was demonstrated by the P-3C flights to Guam, where all flights to this small island base produced sustained corrosion activity, as shown in Figure 43.

The USN SPEC galvanic sensor system has been fitted to two Royal Australian Navy (RAN) Seahawk helicopters. Initial results from this trial have shown significant activity from sensors fitted externally, but less from those mounted inside the structure. Data is being collected from both land-based and ship-based aircraft.

8 SUMMARY

SHM systems that provide diagnostic and prognostic information on corrosion-related damage will enable maintainers and operators of aircraft to manage the prevention and control of corrosion in structural aircraft components on a condition basis rather than on the basis of an elapsed number of (flying) hours. The purpose of this article has been to outline various concepts, methodologies, and technologies involved in a corrosion SHM system that could provide corrosion diagnostic and prognostic capability. SHM systems for predicting corrosion damage are still under development; however, the results presented above show that the development of various corrosion-prediction models, using physics of failure and statistical approaches, is progressing rapidly. The fine-tuning of these models will depend on model testing and validation using laboratory and onboard environment monitoring systems. While further improvements in sensing capability would be desirable, major deficiencies in current systems at this time are (i) the absence of models that predict the mechanical and chemical failure of paint coatings and (ii) the lack of capability to predict the corrosion state in unsensed regions.

Current programs in place are designed to produce interim deliverables, which will assist in the current management practices of aging aircraft fleets. For example, the outputs from environment monitors

on ADF aircraft have identified mission types and base locations that are associated with high corrosion activity. This type of information may lead to more efficient and effective corrosion preventative maintenance.

ACKNOWLEDGMENTS

The authors would like to acknowledge the assistance of Peter Vincent and Ian Powlesland with their inputs on the DSTO sensor system, and Wayne Ganther for his contribution to the CSIRO testing program.

Chapter 103

Experience with Health and Usage Monitoring Systems in Helicopters

Dy Dinh Le

Federal Aviation Administration, Air Traffic Organization, William J. Hughes Technical Center, Atlantic City International Airport, NJ, USA

1 INTRODUCTION

The health and usage monitoring systems (HUMSs) in the late 1980s comprised one or more stand-alone and basic analog monitoring units to monitor vibrations and exceedances in the engine, gearbox, drive system, or bearings (*see* **Health and Usage Monitoring Systems (HUM Systems) for Helicopters: Architecture and Performance**). Early systems were used to provide warnings of impending failures of rotorcraft components or subsystems. Current HUMS technologies include analog and full digital systems to provide health and some limited maintenance credits such as rotorcraft track and balance. However, the HUMSs along with a ground-based station have not been certified by the Federal Aviation Administration (FAA) to provide usage or condition-based monitoring for maintenance credits. "Maintenance credit" means to give approval to a HUMS application that adds to, replaces, or intervenes in industry-accepted maintenance practices or flight operations.

In the 1990s, HUMS technologies had been advanced significantly in many areas, including flight regime recognition, usage monitoring, diagnostics and prognostics, data fusion, and sensors. The advancement of HUMS has begun to allow the civil as well as military operators of rotorcraft to discuss HUMS potentials in approaching a true condition-based maintenance or in determining maintenance credits.

Currently, the HUMSs along with the ground-based station (GBS) have not been certified by the FAA to provide usage or condition-based monitoring for maintenance credits. Certification of a HUMS for maintenance credit purposes is considered to be a complex endeavor. The Advisory Circular (AC) 29-2C, Section MG-15, hereafter referred to as the *HUMS AC*, is the only FAA document providing guidance for HUMS airworthiness approval [1]. The HUMS AC provides guidance for transport category rotorcraft to achieve airworthiness approval for installation, credit validation,

ISBN: 978-0-470-05822-0.

and instructions for continued airworthiness for a full range of HUMS applications. The HUMS AC establishes an acceptable means, but not the only means, of certifying a rotorcraft HUMS regardless of complexity or intended usage to modify maintenance and/or operational actions.

Section MG-15 of AC 29-2C was developed by the Rotorcraft Health Usage Monitoring System Advisory Group and first released in 1999. This advisory group consisted of representatives from the FAA Aircraft Certification Services, FAA Aircraft Evaluation Group, US Industry, European Industry, and Joint Airworthiness Authority. The HUMS AC was written in a generic manner such that it provides the basic requirements and guidance for certification of HUMS. Since no HUMS has yet to be certified in accordance with this AC on a maintenance credit basis, the FAA is conducting research to assist in the substantiation of the certification guidance. Additionally, HUMS research efforts are to develop, validate, and/or demonstrate HUMS operational requirements; applicable technologies including processes, methodologies, and algorithms, and other required information including data to guide the certification of HUMS. The results of these Research and Development (R&D) efforts will also allow the FAA to incorporate any lessons learned into the certification process.

2 APPLICATIONS OF HUMS

2.1 HUMS benefits

HUMS technologies for health monitoring have been widely used in the past 20 years to detect impending failures of rotorcraft mechanical systems (*see* **Health and Usage Monitoring Systems (HUM Systems) for Helicopters: Architecture and Performance**). There have been numerous studies to quantify the impacts and benefits of using HUMS. One study, conducted by the Civil Aviation Authority (CAA), involved HUMS-equipped helicopters [2] flown between 1992 and 1996, and was based on 500 000 h of rotorcraft operation in the North Sea. According to the CAA data presented by Shell Aircraft International [3], HUMS can successfully detect 69% of mechanical defects in critical rotating parts before catastrophic failures (Figure 1). In the United Kingdom, the Civil Aviation Publication 693

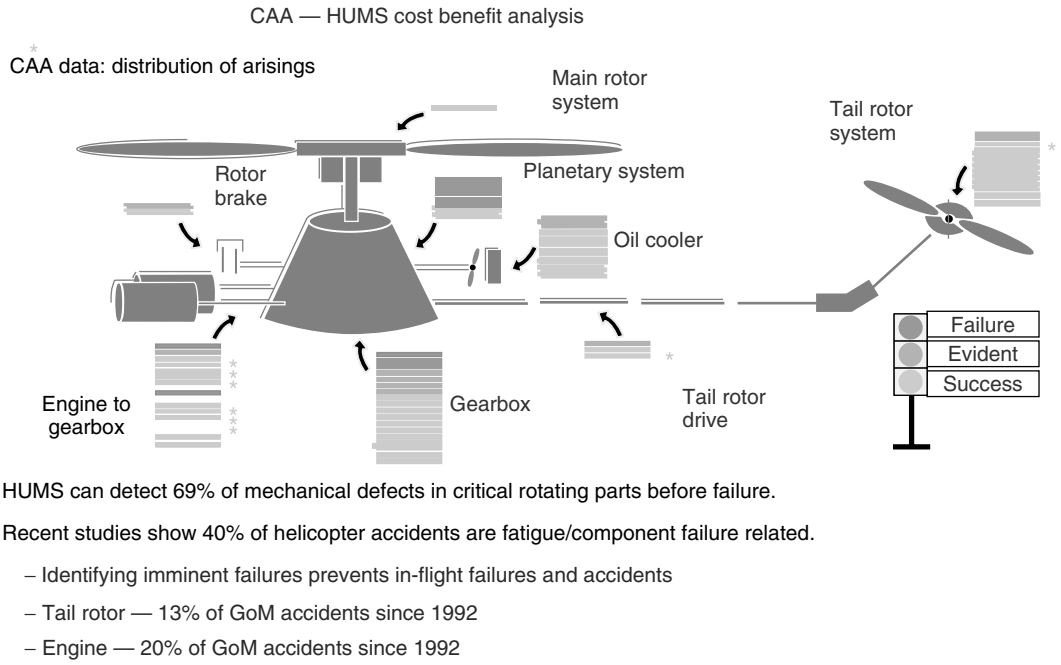

Figure 1. HUMS detection rate. [Reproduced with permission from Ref. 3. © Sheffield, B.]

entitled "Acceptable Means of Compliance Helicopter Health Monitoring" issued in May 1999 [4] states "the first generation of HUMS ... has already demonstrated the ability to identify potentially hazardous and catastrophic failure modes, and has already reduced fatal accident statistics."

2.2 HUMS technologies

2.2.1 Certification issues

A low degree of qualification is required for installing a basic HUMS that monitors rotorcraft parameters, identifies exceedances, and provides advisory data to maintenance personnel. A much higher degree of qualification is required to certify a HUMS to provide onboard warnings to the pilot or for usage or condition-based maintenance credits. So far, the FAA has only certified a few HUMS for health monitoring and one HUMS for limited maintenance credits. The lessons learned from the initial certification of HUMS provided valuable insights on how the future HUMS are to be certified for full usage and maintenance credits. Current certified HUMS maintenance credits are restricted to providing rotor track and balance solutions. Usage data and recorded exceedances are only used for maintenance advisories. Future HUMS will potentially take advantage of the state-of-the-art technologies to alter maintenance requirements and schedules using actual usages and the state of aircraft health monitored by HUMS.

Currently, no rotorcraft HUMS with a GBS, which is typically a commercial off-the-shelf (COTS) system, has been certified to provide usage or condition-based maintenance credits. Certification of such a COTS HUMS is considered to be very difficult and faces many challenges because it has not been certified to the same level of criticality used for airborne fixed-wing systems (*see* **Agile Military Aircraft**; **Operational Loads Monitoring in Military Transport Aircraft and Military Derivatives of Civil Aircraft**). Many issues still need to be resolved. For example, the use of a floppy drive, flash memory card, local area network, or the Internet to install software has the potential to introduce viruses and worms into the system. The processed data stored in the GBS will ultimately be used to make decisions on whether actions are required to address the safety or continued airworthiness of rotorcraft. Since the GBS is one of the important links of HUMS, it must have high integrity and accuracy.

Technologies for usage credits

The next generation of HUMS for usage credits will become more integrated and equipped with advanced technologies such as fault or damage detection, flight regime recognition, direct measurement, and/or data fusion to accurately capture the actual usage (how the aircraft is being flown) or to detect a crack in rotorcraft drive train systems before it reaches its critical length. Advanced tools used in HUMS for usage credits cover a wide spectrum of technologies, which require extensive knowledge of numerous areas.

The physics of proposed credits also needs to be fully understood and validated. Technologies used to substantiate the physics of proposed credits may include damage tolerance (DT), probabilistics, prognostics, and other HUMS-related methodologies. The next generation of HUMS can also be used to address the DT requirement. HUMS-DT technologies will, therefore, be inevitably combined to optimize safety benefits. A probabilistic approach and statistical tools are also critical in managing the uncertainty that may be inherent in HUMS data and information. These technologies can be used to develop statistical confidence measures to demonstrate the reliability and robustness of the technique used in deriving characteristics of collected HUMS data.

2.3 HUMS for enhancing safety and continued airworthiness

2.3.1 Rotorcraft safety concerns

The use of HUMS for usage monitoring is also becoming critical in an effort to reduce the rotorcraft accident rate. According to a summary report of the International Rotorcraft Safety Symposium [5] held in September 2005 in Montreal, Canada, the US civil rotorcraft accident rate per 100 000 flight hours is 8.09 (the fatal accident rate is 1.48). These accident rates were based on the 2004 US rate of an estimated 2 225 000 total flight hours. The US commercial transport aircraft carrier (14 CFR Part 121) accident rate, however, is 0.159 (the fatal accident rate is 0.011). By comparison, the rotorcraft accident rate is 51 times higher than the commercial transport aircraft

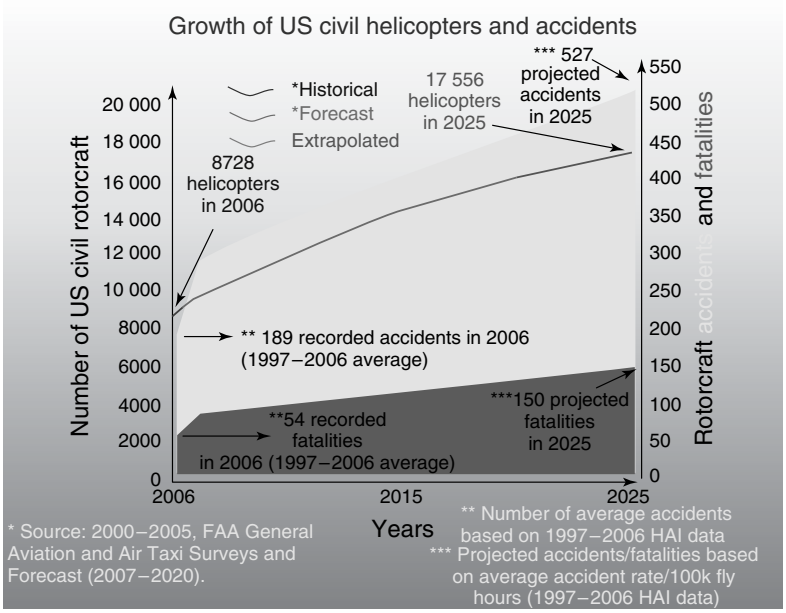

Figure 2. Forecast of the number of US civil rotorcraft and accidents.

accident rate. In 2003, the US Congress enacted legislation requiring the FAA to conduct the research and development to achieve five different goals including the reduction of the rotorcraft accident rate [6]. Additionally, the US Congress also mandated the FAA to develop a plan to implement and support the next generation air transportation system by 2025 [7].

Figure 2 shows the forecast of growth of the number of US civil helicopters by 2025. In 2006, according to the FAA General Aviation and Air Taxi Surveys [8], the US civil rotorcraft fleet has 8728 helicopters. It is projected that the total number of the US civil helicopters may increase to 17 566 by 2025. The figure also shows the historical rotorcraft accidents and projected occurrences in 2025. According to the Helicopter Association International data collected from 1997 to 2006 [9], on average, there were 189 rotorcraft accidents occurred per year. It is projected that the rotorcraft accidents may increase to 527 in 2025. Similarly, the fatalities may increase from an average of 54 deaths in 2006 to 150 in 2025. These projections are based on the estimated flight hours per year for rotorcraft. If 80% reduction in accidents can be achieved, the total number of accidents and fatalities may drop to 105 and 30, respectively. The 80% reduction goal was adopted and pursued by the industry during the International Helicopter Safety Symposium in Montreal, Canada, in September 2005 [5].

2.3.2 Rotorcraft usage monitoring

The US military released several thousands of its surplus helicopters into the commercial sector and these were designed, manufactured, and assembled prior to the early 1960s. Hence many helicopters flying in commercial and restricted category service today are from this pool. A large number of these helicopters are currently being used under contract by the US Forest Service for firefighting and logging in US national parks. 'The original military requirements that were reckoned in designing and developing these helicopters are much different from those governing their current usage. The fatigue design for these surplus rotorcrafts was based on, at that time, the perceived utility mission. Archived data for the loads and fatigue calculations are sparse and not available for the more recent missions being flown. In fact, there is no known existing database that has recorded the repeated heavy lift missions, including logging and firefighting. Most of the flight load data that exist are for the utility mission. Scripted flights have not

been accomplished in these types of environments to determine the scatter data associated with how different maneuvers are flown in heavy usage situations.

Modern helicopters are also experiencing significantly more complex and variable loadings than in the past. Therefore, the spectrum data that are currently used by the FAA to certify designs and modifications have limited relevance to current operations. Since stress states that reflect actual operations are critical for achieving accurate lifetime predictions for both safe-life and DT approaches, an up-to-date and comprehensive mission spectra database is needed. As the rotorcraft DT philosophy becomes widely used among the US rotorcraft industry, obtaining sufficient data to determine accurate typical mission spectrum is even more critical for the success of DT applications.

The insertion of HUMS technologies, including direct load measurement and flight regime recognition to determine component loads and how helicopters are flown, is critical for usage monitoring. Using flight regime recognition, the actual helicopter usage can be obtained and compared with certification usage spectrum. An accurate determination and measurement of helicopter gross weight, center of gravity, and other key structural loads is also critical for establishing loads for rotorcraft components and determining their consumed fatigue life. Depending on how helicopters are actually flown, HUMS data can be used to enhance safety or reduce operating costs.

To assure the continued airworthiness of the civil rotorcraft, the FAA has begun to collect usage data using HUMS on selected rotorcrafts. Further efforts are being planned to cover more US civil rotorcraft operations usages. Scripted flights using HUMS and other equipment and accessories are being adapted to obtain statistically valid data on the percentages of time that given specified maneuvers are being executed in modern rotorcraft operations. These data will span the range of current and potential future missions, including long-line heavy lift, emergency medical service, offshore support, and corporate transport.

The FAA also plans to establish a database of usage spectrum and loads from helicopters that are flown in the restricted category environment. Additionally, HUMS-equipped helicopters with instrumented devices to record various strains in critical components can also be used for scripted flights. Using HUMS, data can be collected, transmitted to, and maintained by the FAA for analysis. The analyzed flight load data can then be compared with the original or extrapolated loads used for the design of the military surplus rotorcrafts to determine the need for safety actions. Using the measured flight loads and recorded usage of helicopters, fatigue life of life-limited components can be determined and compared with the original fatigue life of the military helicopters being used for civil operations.

2.4 FAA HUMS research efforts for future maintenance credits

2.4.1 Damage tolerance design of rotorcraft components using HUMS usage spectrum

In the past 15 years, the FAA has funded numerous research projects to collect usage data using HUMS. One of the efforts involved the use of helicopters flown in numerous missions [10]. Three usage spectrums, namely, Atlanta Short Haul Mission (ASHM), Gulf Coast Mission (GCM), and Utility Mission in Morgan City (UMMC), were obtained using HUMS. The ASHM usage spectrum was considered severe usage involving many short maneuvering flights to provide pickup and delivery services at the Atlanta Olympics. The GCM usage spectrum was considered mild usage involving long cruise flights. The UMMC involved cruise flights along with some shorter flights for pickup and delivery services. The UMMC usage spectrum was more severe than the GCM but less severe than the ASHM.

Using the certification and other usage spectrum collected by HUMS, an analysis was conducted to calculate the fatigue crack growth in selected critical dynamic components, which were designed based on the safe-life method. On the basis of the analysis results, the selected components were theoretically redesigned to successfully meet the DT requirement with acceptable inspection intervals. Two major conclusions can be drawn from this hypothetical study.

1. HUMS can be used to determine the true flight spectrum of modern helicopters, which leads to a full understanding of how they are being flown. The successful determination of the rotorcraft usage spectrum will help determine accurate

retirement times or help in the establishment of the effective inspection intervals of rotorcraft life-limited components. If the actual usage spectrum collected using HUMS is more severe than the certification usage spectrum, life-limited components may be removed before their retirement times are fully consumed. This will enhance the aircraft safety and potentially reduce the rotorcraft accident rate.

2. If the actual usage spectrum collected using HUMS is less severe than the certification usage spectrum, the retirement times of selected components may be extended, resulting in reduced operating costs.

2.4.2 Determination of maintenance credits using HUMS flight regime recognition and usage monitoring

Using the developed FAA HUMS R&D strategic plan [11] and roadmap (shown in Table 1), the FAA is currently supporting research efforts to develop

HUMS processes, methodologies, and validated data to substantiate proposed maintenance or usage credits. One of the programs is the demonstration of HUMS on a newly designed transport helicopter using existing usage monitoring and flight regime recognition technologies. In this demonstration program, a process for developing fleet-wide and component usage-based maintenance credits is being established. The program is collecting HUMS operational data including flight regime, gross weight, center of gravity, and other associated helicopter operational parameters. The collected data are then used to determine the retirement times of selected components. Usage-based maintenance credits are determined by comparing the calculated retirement times based on HUMS data with current component retirement times based on the existing life calculation methodology for the worst-case spectrum and maximum loads. From the collected information and analysis results, the FAA can establish and validate the credit validation, introduction into service, and instructions for continued airworthiness plans.

3 CONCLUSIONS

The current civil rotorcraft accident rate remains high. The FAA safety goal is to reduce the rotorcraft accident rate to a level equivalent to that of fixed-wing transport aircraft. Therefore, there is a need to deploy state-of-the-art equipment and advanced technologies to address the safety goal. HUMS, if installed, can detect impending failures of rotorcraft components or subsystems. HUMS with advanced functionalities and technologies including the regime recognition capability can be used for usage monitoring to enable the accurate determination of rotorcraft flight profile and, eventually, the precise evaluation of the load distribution in rotorcraft components. If the actual usage spectrum is more severe than the certification usage spectrum, life-limited components may be removed before their retirement times are fully consumed. This will enhance the aircraft safety and potentially reduce the rotorcraft accident rate. If the actual usage spectrum is less severe than the certification usage spectrum, the retirement times of selected components may be extended, resulting in reduced operating costs.

The FAA has been conducting HUMS research including flight testing to validate and demonstrate HUMS technologies for maintenance credits. The validated technical information including methodologies, processes, and data will be incorporated into the HUMS AC for use in certification.

1 INTRODUCTION

As part of the qualification process of any aircraft, it is mandatory to test the full-size (also known as *full-scale*) aircraft under static and fatigue loading. The full-scale fatigue test allows the fatigue behavior of the aircraft structure to be characterized, thus defining its repair scheme. This article focuses solely on the world's largest aircraft, the A380. Such an aircraft obviously takes longer to inspect. Moreover, the airline industry is keen on hastening the inspection time, while maintaining the current high level of aircraft safety. One solution to achieving the aforementioned is structural health monitoring (SHM) [1–9]. The potential of SHM is well understood in Airbus [10] and in the airline industry, and several research projects are aimed at such a technology. Various SHM sensors have been implemented on the A380 full-scale fatigue test specimen (also called *A380 EF*), as this specimen was available at the time of sensor implementation. There are, however, no plans to implement or retrofit SHM sensors on the in-service A380.

SHM technology can be considered as part of the nondestructive test (NDT) technology family. Both NDT and SHM are used or intended to be used on various structures; however, this article focuses only on aircraft structures.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

Previous papers [2, 10] have emphasized the major benefits and potentials of SHM compared with the current NDT and visual inspections of aircraft structures. It is nevertheless expected that SHM will ultimately result in fundamentally changing the way an aircraft inspection is done. The current focus on the A380 EF case is on surface-bonded or sandwiched SHM sensors, rather than embedded ones. In the case of A380 EF alone, most interrogation units are installed near the specimen for the duration of the testing. However, data processing by the interrogation unit was carried out just prior to the NDT or visual inspections, that is, just as in any other inspection method. This work is obviously in addition to the existing NDT and visual inspections, but any findings from the SHM systems are, in any case, investigated for research and development purposes.

A full-scale structure like the A380 EF provides a realistic loading condition vital for evaluating the performance of the SHM technology. Moreover, it is easy to install and maintain the SHM systems and sensors on a full-scale specimen, such as the A380 EF, compared to installing them onto an aircraft that is already part of an operating fleet. Implementation on aircraft ready for flight test is, of course, the next step and is not discussed in this article.

The article deliberately does not describe SHM technologies as have other articles of this encyclopaedia. Instead, it focuses on the A380 EF specimen and its mechanical testing equipment [11, 12]. This article also describes the various requirements in the selection of a potential SHM technology for future use in structural tests only.

2 STRUCTURAL TESTS

Ultrasonic, eddy-current and X-ray techniques as well as visual inspection are currently the main methods of testing for structural damage. These well-known techniques are used to detect surface or hidden cracks, such as at rivet holes or countersinks. With the typical service conditions and because of the large inspection intervals, the aircraft design allows for the detection of damage from 2 mm in length with high-frequency eddy-current technique [13] and 4.5 mm in length with ultrasonic testing technique [14]. Although classical NDT techniques can detect much smaller damage, these tests are not carried out between the given inspection intervals. Since SHM sensors are permanently on board the aircraft, the effective inspection interval can be drastically reduced, resulting in our being able to detect smaller damage and, therefore, initiate a potentially smaller, lighter, quicker, and cheaper repair than with the current inspection techniques.

SHM can be used differently on ground-based structural test monitoring, compared with in-flight structural monitoring. Indeed, the required information on ground tests is “when did the crack initiate?” or “what was the initial flaw concept?” This information could then be used to identify more accurately in time the damage initiation, for further optimizing the in-service inspection programme of the monitored aircraft structure, resulting in potential increased aircraft availability.

An expected future requirement is to demonstrate, throughout the lifetime of the aircraft, that its structure remains free of multiple site damage (MSD), which may influence one another. This urges the need to develop new monitoring techniques, such as SHM technologies, to detect small cracks (down to 1 mm in length) with a satisfactory degree of overall reliability.

Another benefit of SHM is its continuous monitoring of structures, helping to determine the time or flight cycle number at which the damage was initiated. Today, on coupon specimens, for instance, the specimens have to be disassembled, checked for damage, and reassembled. This exercise has to be repeated several times to obtain the load cycle number at which the damage initiates. The frequency of inspection must be as high as possible to prevent missing the damage initiation, to further discovering a much larger damage, resulting in not rating the specimen being tested. Evidently, such a test is time consuming and the use of SHM would provide a more cost-effective technique to greatly improve such a process.

Similarly, on component (e.g., 5-m single-shell) and full-scale fatigue tests, the load cycle has also to be interrupted to determine the point in time of damage initiation.

A range of benefits can be derived using continuous SHM techniques on structural test specimens. These can help minimizing test interruptions, detecting initial flaws, reducing human error as well as monitoring hot-spot and wider areas. They can also

monitor the structures in hidden and difficult access areas. The other advantages of SHM are that all the above can be carried out simultaneously and instantly, reducing drastically the inspection time as well as avoiding the classical NDT or visual inspections on areas without damage, leading to a more directed maintenance concept.

However, the aforementioned benefits from SHM techniques must be validated on test benches, such as the A380 EF and future structural test specimens.

3 REQUIREMENTS

The SHM technology to be implemented for structural testing is not solely for that application but can also be a validation toward in-flight use. Therefore, it is expected that the selection criteria for the SHM technology for structural testing should also include requirements for airborne applications. If some SHM equipment does not fulfill airworthiness requirements, such as durability, it is understood that it might still be usable for structural testing.

As part of the requirement definition process, the preparation of specifications for qualifying SHM systems is to be taken into consideration. Contrary to the current procedures applicable to the NDT technology, the qualification of SHM systems requires new specifications. They are a prerequisite for qualification and thus certification.

The SHM system comprises a sensor and the interrogation unit. The sensor also comprises the sensing item, any additional conditioning unit (such as a preamplifier), the connector, the cable, the sensor/structure bondline, and any protective layers, such as sealant and topcoat. The interrogation unit usually includes a data-acquisition unit, a postprocessing and management data unit, and a data-storage unit. Some or all parts of the interrogation unit can be an existing part of aircraft avionics, such as remote data concentrator (RDC), or a stand-alone piece of equipment, for both aircraft retrofit and structural testing.

3.1 System

The general SHM system requirements include performance, reliability, and commercial aspects, such as availability, hotline support, and cost effectiveness.

The performance of the SHM system must be well above those of classical NDT techniques to have a chance of replacing them in the near future. Indeed, the overall sensitivity must be below 4.5 mm to compete with eddy-current technology, for instance. High accuracy and resolution are vital to monitor the damage size and its growth. Ideally, the system should also be able to monitor a wide range of damage types (crack, corrosion, delamination, debonding, etc.) and sizes, as well as various material types (metallic, composite, and sandwich structures) and thicknesses, with the same interrogation unit and sensors.

The reliability level [15] expected from SHM is relatively high for it to at least support structural inspection by replacing classical NDT, with neither positive- nor negative-false alarms. The reliability of the overall system, linked to the development assurance level (DAL), necessitates the use of redundancies in the sensor network, in the interrogation unit hardware as well as in the use of a few self-diagnostic tools.

Commercially, the SHM system (including spares) must be available worldwide. In addition, in-field and hotline supports are paramount in aircraft operation. The same applies to full-scale fatigue testing where any downtime can cost and compromise the programme certification whenever the SHM technology is used as a replacement of classical NDT or visual inspection, which is still not the case today.

Additional commercial requirements contain the element defining the business case. Indeed, an attractive business case imposes the use of low-cost SHM system, low-cost installation and maintenance of the system on the aircraft. The SHM system should also be lightweight to reduce the fuel consumption cost generated by the system weight. The SHM equipment must also be appealing to the user and therefore has to be quick and easy to use, to have a user-friendly human interface, and with only the off-board equipment being portable. The mean time between failures (MTBF [13]) of the system needs to be as long as the application lifetime to further reduce the need of maintenance and therefore improve the business case.

For structural tests mainly, low-cost systems could suggest the use of commercial, off-the-shelf (COTS) components. These components could also be used

for airborne application, as long as obsolescence of such components is carefully controlled.

3.2 Sensor

The main top-level sensor requirements are obviously the way the sensor shall be connected to the structure (surface bonded, sandwiched, or embedded), as well as its size with regard to any geometric limitations and the complexity related to its calibration.

Additional requirements are associated with the type of sensors, its physical principle with respect to the damage to be monitored and its environment, preferably wireless-data-transfer-enabled, costs of sensors, costs and time of sensor installation, weight of sensors/cables/fixtures, type of bonding process (cold, warm, etc.) for both sensor and its protective coating, data processing time, electromagnetic interference, durability of equipment within its working environment for 30 years, compliance to typical Airbus specifications, maintainability of sensor, and robustness of sensor design to reduce maintenance needs. The sensor should also survive external mechanical interference, such as loads, vibrations, impacts, pressure, and temperature changes.

It is also important to install the sensor on the existing paint system at the surface of the structure, since removing it may affect corrosion protection.

For structural test monitoring, it is recommended to use surface-bonded sensors for easing its installation. In the case or A380 EF, it was compulsory not to modify the structural integrity (therefore, no embedded sensors).

3.3 Interrogation unit

The sensors must be connected either to the onboard evaluation unit or via a node (connector, router, etc.) to an external connector of an evaluation unit. Depending on the technology used, cables (electrical) or hoses (vacuum technique) would be installed. The main top-level requirements for the interrogation unit are similar to that of the sensor, with some exceptions. The list of requirements is however not exhaustive, as it highly depends on the application. Nevertheless, the goal of such a list is to support the selection of an interrogation unit for structural tests, including full-scale specimen monitoring. The interrogation unit should be small, light, cheap, durable, easy to install, reliable with a high MTBF, and compliant with specific application requirements. The interrogation unit should support the sensor in offering high accuracy and resolution information. It also combines a self-diagnostic tool determining whether a system component is malfunctioning or not functioning or if the sensor partly or completely disbonded from the structure.

4 SHM TECHNOLOGY DEVELOPMENT

Extensive investigations have to be carried out to demonstrate that the requirements placed on an SHM system have been met. The Airbus list of requirements follows the NASA US DoD TRL concept, where TRL6 signifies the end of technology development. At TRL6, the system is considered as almost the finished product, and two requirements dominate such a TRL: reliability and durability.

To ascertain reliability, a combination of both probability of detection (PoD) and pyramidal testing is used. The PoD is similar to that of classical NDT, based on various techniques such as the 90/95 method. The PoD investigation also provides what is the minimum damage size that the SHM system is qualified for. The pyramidal testing, shown in Figure 1, emphasizes first the need to carry out a large number of coupon tests in order to evaluate the performance and capabilities of the SHM system under investigation. The system is then evaluated on several subcomponent tests, generally on specimens around $5\,\text{m} \times 3\,\text{m}$. The system is then validated on a full-scale specimen, such as, in this case, the A380 EF. Implementing the system on in-service or flight test aircraft during ground testing can also further complement the validation. This test is mainly to emulate some environments that were not captured during previous mechanical tests, such as influence of vibration caused by the aircraft engine onto the SHM system functioning and performance. In all cases of reliability evaluation and validation, the SHM system must provide clear evidence of neither positive- nor negative-false alarms when monitoring a given damage.

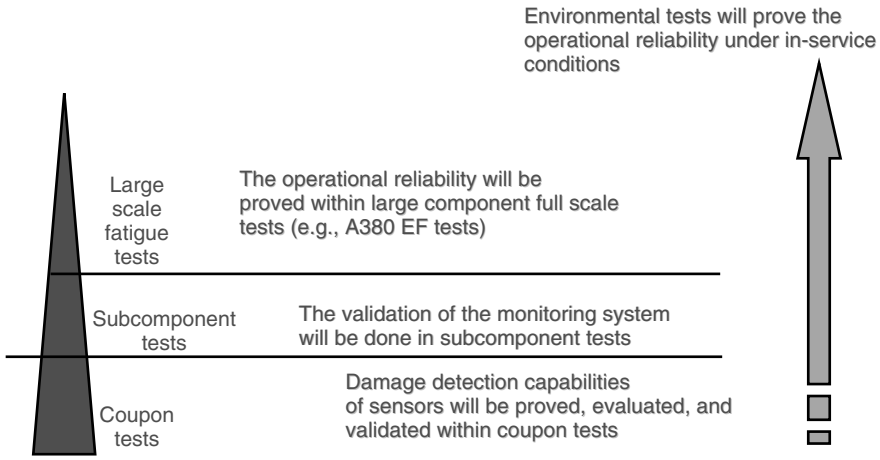

Figure 1. Technology development plan.

Parallel to the reliability testing, the durability of the SHM system must be characterized to ascertain whether the system (mainly the sensor in this case) is capable of coping with the harsh aircraft environments for a period of 30 years.

Universities and institutes are typically initiating such SHM systems, with maturing levels ranging from TRL3 to TRL5. Industries then adapt such technologies for their needs and requirements as well as commercialize the technology to reach TRL9. It is at that point where the user's requirements, in this case the aviation industry, come into play and enable the technology to be translated to the respective applications.

The A380 fatigue test specimen provides ideal conditions for testing the SHM sensors under realistic loading conditions on the ground. In parallel, the sensors are easy to access for data-acquisition and maintenance purposes. Today's objective for this kind of activity is not to monitor the A380 fatigue test with SHM (that is currently the role of NDT techniques), but the further development and gathering of experience for further optimization of the different sensor types applied to the specimen at this point in time.

Currently, the A380 specimen is equipped with a number SHM sensor types, each of them covering specific areas of the test structure (see Figure 2):

1. Comparative vacuum monitoring (CVM^{TM})
These sensors are mainly used in areas where quick access is possible. For the fatigue test, this means typically different locations along the fuselage, from both inside and outside the specimen.

2. Acoustic emission (AE) Vigilant
AE sensors have been applied to the wing sections of the specimen. The analysis of the AE data and the correlation of these data with fatigue finding along the specimen are currently under analysis by the experts.

3. Eddy-current foil sensors (ETFS)
ETF sensors are tested in the root joint area

4. Crack-wire sensors
Crack-wire sensors are well-known sensor types, which are used to follow crack growth of fatigue damage during the test performance phase. These crack wires are modified for airborne applications.

Some further SHM sensor types are to be installed during the remaining test performance phase. These are

5. Imaging ultrasonic (IU)

6. Acousto-ultrasonic (AU)

5 A380 EF DESCRIPTION

This section provides a general overview of the A380 fatigue test and a brief description of test requirements and features of the test setup.

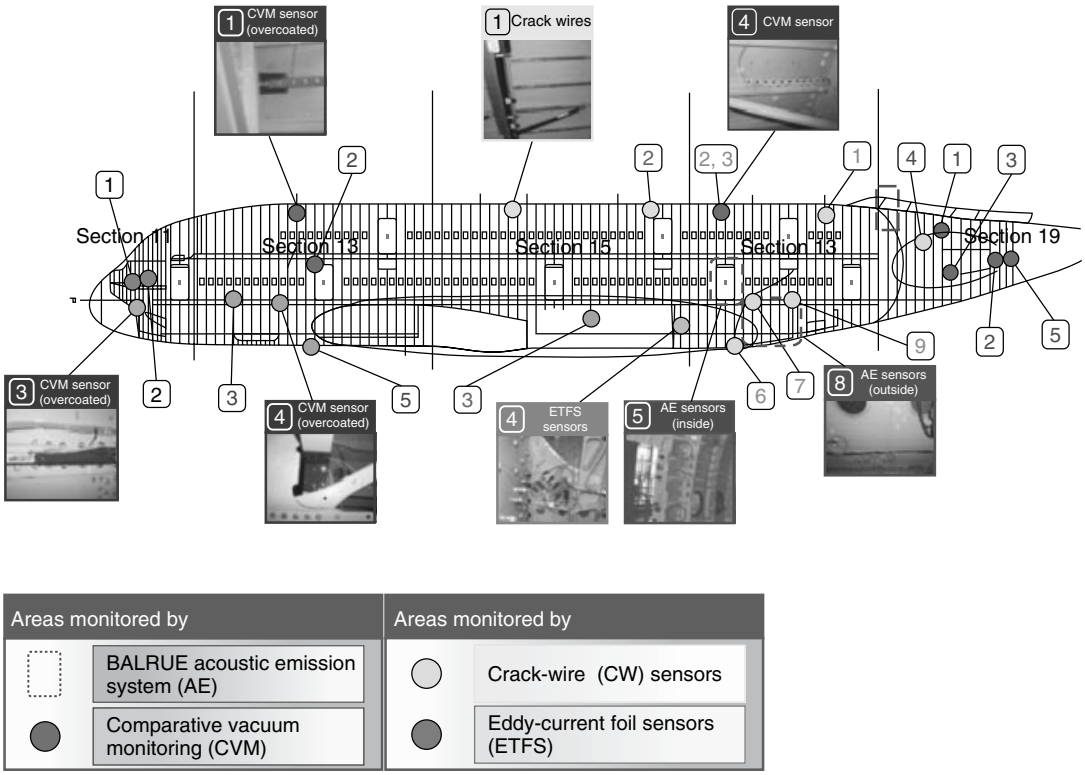

Figure 2. SHM sensor position on the A380 EF specimen.

For the type certification of any Airbus aircraft family, a large number of structural tests are carried out at various levels. On top of the variety of different component tests, Airbus is conducting three major structural tests:

- the static test of the entire aircraft structure (known as *A380 ES*);
- the full-scale fatigue test of the entire aircraft structure (the focus of this article, known as *A380 EF*); and
- a combined static and fatigue test of the rear fuselage and empennage (known as *A380 RET*).

The A380 EF ("Essai Fatigue"—the A380 full-scale fatigue test) is used as means of compliance to reach the so-called type certification of the A380 programme. The main objectives of this test are the validation of fatigue life and crack propagation of A380 primary metallic structure as well as the validation of structural repair manual (SRM) and maintenance programme. The A380 EF inspection results are also used for cross-checking and validating the simulations and structural design tools in terms of structural fatigue behavior.

The A380 fatigue test project first started in 2001 within Airbus. The test is currently performed by Airbus and its subcontractor IABG in Dresden, Germany, further shown in Figure 3. The A380 EF is used to prove the fatigue worthiness and the damage tolerance of the metallic aircraft primary structures. The design service life goal—the guaranteed service life—of the A380 family comprises either 25 years of operation or 19 000 flight cycles or 140 000 flight hours, whatever comes first. For a successful type certification, the A380 EF must prove that within this design service life goal no critical damage is caused by structural fatigue.

After successful accomplishment of the initial 5000 simulated flight cycles in December 2005, this contribution to the A380-type certification had been achieved.

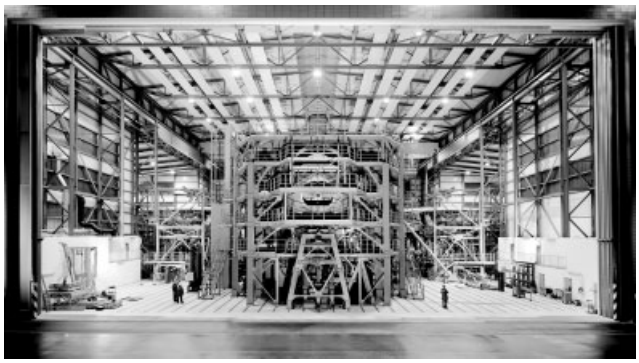

Figure 3. A380 EF test hangar and test setup.

The A380 EF test will be fatigued for a total of 47 500 simulated flight cycles for validating the structural design tools. These 47 500 simulated flight cycles represent 2.5 times the required 19 000 flight cycles of the design service life goal and thus allowing Airbus to analyze the initiation and propagation of natural cracks based on the fatigue behavior of the materials used. In addition to these natural damage, a number of artificial damages (cutting into shells, cutting of stringers or comparable stiffeners, removal of bolts, etc.) have been introduced to analyze the damage tolerance behavior of the dedicated structure.

The structural health of the A380 test specimen is inspected the same way as on in-service aircraft. Each individual inspection utilizes a range of techniques, such as visual and detailed visual inspection as well as NDI tools (e.g., eddy-current and ultrasonic systems, and in some specific cases X ray).

6 A380 EF TEST SETUP

The A380 EF test setup can be divided in different subsystems, such as the test specimen (representing all metallic primary structure), the dummy structures and the load introduction features (e.g., whiffle trees with load pads), test rigs, hydraulic loading system, pneumatic loading system, control and monitoring system (CMS), and data-acquisition system (DAS), each of them consisting of various subsystems.

The test specimen comprises all metallic primary structures for the entire fuselage and the wing as well as all other structural elements contributing to the global stiffness of the fuselage and wings, as shown in Figure 4. In some areas, secondary structure is also included (wing-fixed leading edge and trailing edge, as well as the belly fairing) as all those contribute to the overall stiffness. In the case of the empennage, dummy structures are representing the horizontal tail plane and tail cone. Additionally, a stub vertical tail plane torsion box is used as load introduction dummy to the empennage.

A number of dummy structures replace specific components of the aircraft for load introduction purposes. Namely, the engines and pylons, flap and slat tracks, and all landing gear legs are replaced by stiff steel structures allowing for hydraulic jack attachments and introducing the loads into the corresponding attachment fittings of the aircraft. The same is valid for the horizontal tail plane that is not a part of this test and that is represented by a dummy steel beam. All of these aircraft components represented by dummy structures are certified through separate component tests.

In addition to those load introduction structures representing aircraft components omitted for the A380 EF, further load introduction structures are used to distribute the loads to a large number of load introduction points along the fuselage and the wings. In most cases these additional load introduction structures are designed as whiffle trees, as shown in Figure 5.

A push–pull loading principle is used to minimize the required number of hydraulic jacks. Consequently, tension and compression loads are to be considered for the design of all whiffle trees.

The test rigs of the A380 EF test setup comprise in total more than 1.800 t of steel used for the fuselage, wing, and pylon rigs. The loading rigs are used for supporting the hydraulic actuators and their

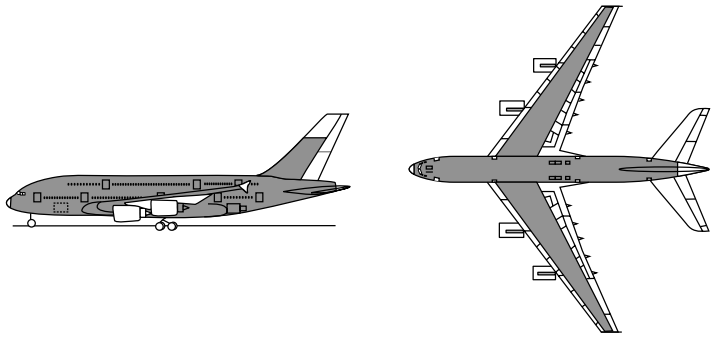

Figure 4. Overview A380 EF test specimen.

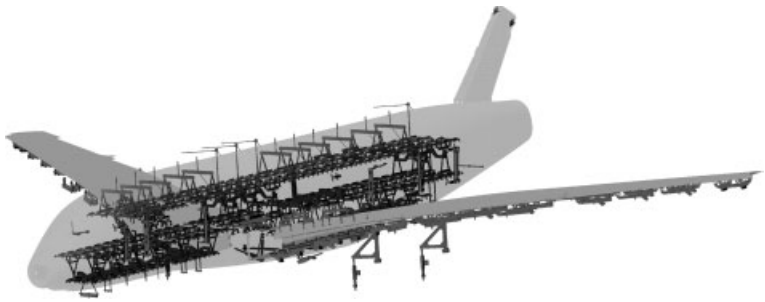

Figure 5. Specimen loading features.

counterweights as well as for transferring the reaction forces of these hydraulic actuators into the strong floor of the test hangar.

The inspection rigs provide access to the specimen for the inspection staff. The fuselage rig, however, is the only rig that combines the inspection and loading rigs, as shown in Figure 6.

The hydraulic loading system consists of the hydraulic power supply, the hydraulic piping, the hydraulic accumulators, and the hydraulic actuators, as shown in Figure 7.

Twelve hydraulic pump modules provide in total a hydraulic oil supply of up to 6000 l min^{-1}, to be controlled via the two main hydraulic valve manifolds and to be distributed via the hydraulic main piping system to the 182 hydraulic actuators mechanically loading the specimen. At specified positions near those hydraulic actuators with the longest stroke, a system of hydraulic accumulators has been introduced to provide extra power for most severe peak phases.

The hydraulic actuators provide a stroke of up to 6.5 m and loads of up to 150 t. They are equipped with double channel load cells and control valve blocks controlling the activated loading via two independent short-circuit control loops independent from the CMS for the A380 EF test setup.

The pneumatic loading system is powered by three compressor units feeding three pneumatic accumulators with an air pressure of 7.5 bars. For each individual flight, during the flight-by-flight simulation, the differential air pressure is provided through a pneumatic piping system including acoustic dampers via 16 dummy windows into the specimen, as shown in Figure 8. A pressure level of 1.67 bar is generated within the 2200 m^3 volume of all three decks (passenger upper and main deck as well as cargo deck) within 45 s.

The CMS is displaying the overall test information provided by the decentralized architecture based on a number of field cabinets being distributed all over the facilities. This CMS allows a high-speed test cycling at uncompromised loading accuracy.

These field cabinets, in addition, carry subsystems for the A380 EF DAS, which allows measurement campaigns of up to 7000 measurement channels, collecting data via data-bus lines.

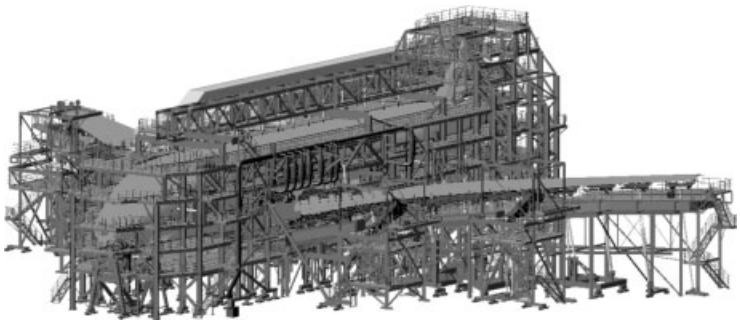

Figure 6. Test and inspection rig.

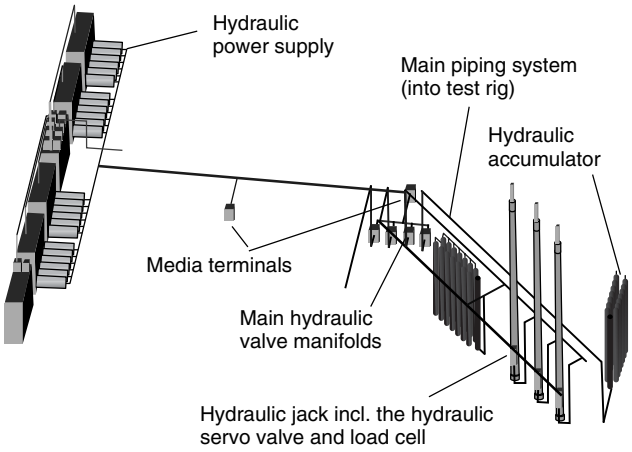

Figure 7. Hydraulic loading system.

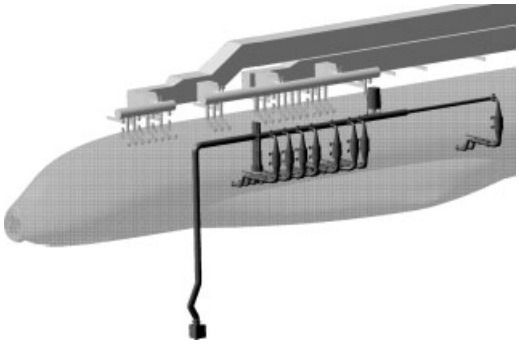

Figure 8. Overview pneumatic loading system.

Both static and dynamic measurement campaigns can be run automatically. In addition, a video system, controlled by the CMS, can be used for automatic visual inspection and recording for specific items, see Figure 9.

7 MECHANICAL TEST RESULTS

The A380 EF fatigue cycling had started on September 1, 2005. The contribution to the A380-type certification process had successfully been accomplished with the 5.000th simulated flight conducted on December 24, 2005.

Since that initial fatigue cycling phase, the remaining 42.500 simulated flights are being performed at a test speed of about 1000 simulated flights per week during test run phases. This is achieved in a three-shift 24/7 test run scheme. These test run phases are interrupted for carrying out scheduled inspections combined with specimen modifications, which are required either for keeping the test specimen at the latest serial production standard or for introducing structural technology innovations for test validation in preparation for future Airbus aircraft programmes.

Figure 9. Operator view of the A380 EF control and monitoring system.

8 SUMMARY

The article has presented and described the A380 EF specimen, with its extensive infrastructure to provide mechanical loading, fuselage pressure, maintenance, and structural inspection access. The article then discussed the benefits of the SHM technology for both in-service and structural test monitoring. The SHM technology requirements were provided to support possible technology down-selection for structural test monitoring as well as in-service applications. An SHM technology development was herein described. The SHM sensors were successfully implemented on the A380 EF and further results are expected at the completion of the A380 EF test campaign.

Chapter 99

Flight Demonstration of a SHM System on a USAF Fighter Airplane

Matthew C. Malkin
Phantom Works, Boeing, Seattle, WA, USA

1 INTRODUCTION

The F-16 station 341 fuselage bulkhead is susceptible to fatigue crack growth due to a maintenance-induced crack initiation site. The bulkhead is a single-piece machined structure, and replacement of a damaged bulkhead is time consuming and costly. Adhesively bonded repairs were developed by South West Research Institute and applied to the structure as an alternative to replacing damaged bulkheads. A health monitoring system was developed in order to assess the health of the repaired structure.

Health monitoring systems for composite bonded repairs have been applied to structures in laboratory environments [1–3]. Throughout 2004 and 2005, the United States Air Force Research Laboratory and Boeing have performed increasingly complex laboratory tests of structural health monitoring (SHM) systems for bonded repairs. Basic coupon testing has been performed, followed by component-level testing, building up knowledge and experience that led to the flight demonstration on an in-service F-16 airplane, and this is discussed here [4].

This article attempts to capture the lessons learned from the experience of overcoming the difficulties encountered in developing and installing a laboratory-level SHM system on a complex, in-service structure. It is hoped that this knowledge will smoothen technology transitions in the future.

2 STRUCTURAL HEALTH MONITORING SYSTEM OVERVIEW

Two structural failure modes of the repaired bulkhead, crack growth under the repair and disbonding of the

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

repair from the structure, motivate the use of SHM for this application. The SHM system for this application responds to structural changes that occur due to either failure mode.

A piezoelectric-based SHM system was selected for this application. A network of piezoelectric transducers was permanently attached to the structure near the repair. To assess the health of the repaired structure, an electrical signal is sent to the piezoelectric transducers. The transducers convert this signal into an ultrasonic strain wave that travels through the structure and is detected by other piezoelectric transducers in the system. These transducers convert the signal into a voltage, which is read by the data-acquisition system.

A data-acquisition computer directs data collection. The computer is connected to the transducers with an electrical cable. The data-acquisition computer contains a signal generator, an actuation signal amplifier, the switching hardware, a sensor signal amplifier, a data-acquisition board, and the control software.

When damage is present in the structure, the transmitted strain waves change causing changes in the detected electrical signals. These changes are interpreted to give an indication of the damage.

3 SENSOR LAYER DESIGN AND MOCK-UP

One principal difference between SHM and conventional nondestructive inspection is that the sensing portion of the SHM system is permanently attached to the airplane. The transducers for this application are piezoelectric disks, each of a diameter of 6.35 mm and a thickness of 0.25 mm, permanently mounted on a polyimide substrate material. Wiring is printed on the substrate, and a connector is integrated for electrical access to the sensors.

Structure in the keel area of the F-16 station 341 bulkhead is complex, with material interfaces, fastened joints, and system penetrations. Figure 1 shows two views of the area in the main landing gear wheel well of an F-16 airplane.

Designing the sensor involved locating the transducers, routing the flat wiring, and properly positioning the data cable connector on the airplane. A paper mock-up of the sensor layer was created on an actual airplane. Mocking up the sensor on an actual airplane maximized chances that the installation fits properly and does not interfere with any airplane systems.

An iterative, design-analysis process was not followed for designing the transducer network. Layout of the transducers and wiring was performed by examining the structure and placing the transducers in locations that covered the repairs with sensor–actuator paths, while remaining within the constraints imposed by the geometry of the airplane structure. The number of transducers was limited by the number of channels available on the data-acquisition computer. A paper mock-up of the transducer layer was created. After the paper mock-up was complete, a sensor layer was fabricated to match the paper mock-up. This design process, as is any design process, was based on the experience and knowledge of the engineers performing the design. The analysis and simulation of SHM system designs would allow for iterative design and improved system performance.

4 INSTALLATION

The demonstration sensor was installed on aircraft tail number 87-0395 at Hill Air Force Base (Ogden,

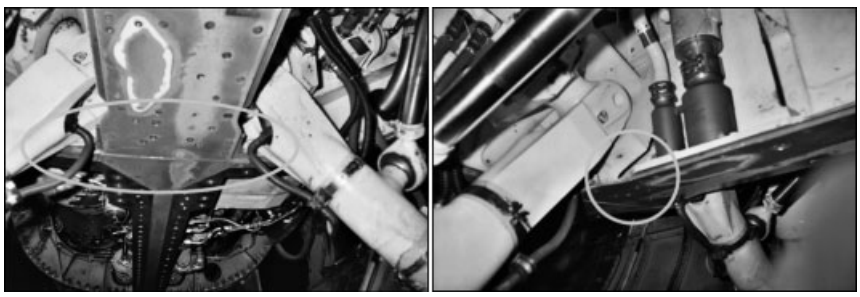

Figure 1. The main landing gear wheel well of an F-16 contains complex structure and multiple system installations.

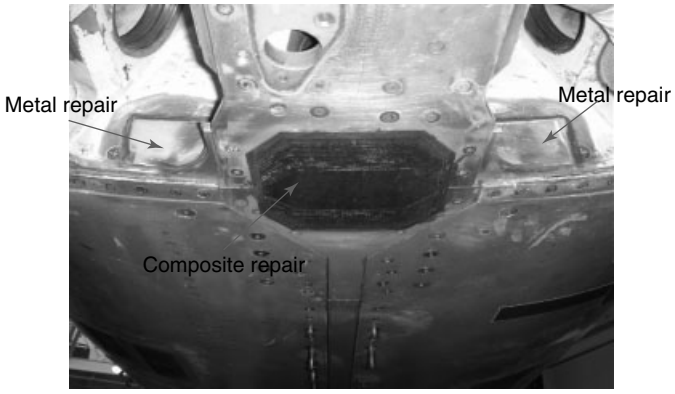

Figure 2. Three repairs, two metal and one composite, were installed in the keel area of the station 341 bulkhead.

Utah, USA) in February 2006. The repairs, pictured in Figure 2, were installed by Southwest Research Institute, and thermography was performed to validate the initial installation of the repairs.

After the repair installation was completed, the SHM sensor installation began. The first step in the sensor installation was to lightly abrade the airplane surface with sandpaper and clean the surface with isopropyl alcohol. Epoxy adhesive was mixed and applied to the sensor layer and structure. As shown in Figure 3, the sensor was adhered to the structure and fixed temporarily with clamps and tape.

Neither heat nor vacuum pressure was applied to the sensor during cure. After cure, the tape and clamps were removed, the region outside the sensor was masked off, and an overcoat of epoxy adhesive (Figure 4) was brushed on the exterior of the sensor layer. This is the first application of a sensor of this type to the exterior surface of a supersonic airplane.

Figure 3. The sensor was carefully wrapped around the repairs, positioned, and adhered to the structure.

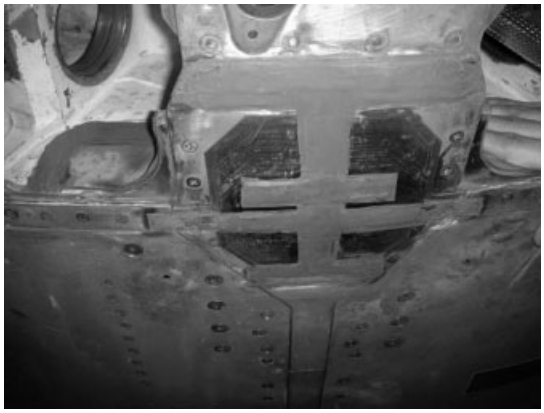

Figure 4. An overcoat of adhesive was applied over the sensor layer.

Even with a careful mock-up during sensor design, the clearance between the landing gear door and the portion of the sensor layer that wraps around the keel structure from the interior of the wheel well to the exterior of the airplane could not be verified. After the repair, the sensor and the landing gear were installed, and a gear swing was conducted as part of a normal maintenance. When the landing gear doors closed, there was approximately 3.18 mm (0.125 inches). clearance between the sensor layer and the inboard edge of the landing gear door.

The connection between the on-aircraft sensor and the off-aircraft data-acquisition system was carefully designed to ease access and ensure reliability. Easy access to the electrical connector for the sensor helps

to minimize the data collection time. A 90° backshell was installed on the connector on the data cable in order to work around clearance problems with wiring and adjacent structure in the wheel well. A self-locking protective cap fits over the airplane-mounted connector when the mating plug on the data cable is not in place. Wiring interfaces in SHM systems are critical and should be carefully engineered.

With the sensor layer installed, data collection began. Initial baseline data sets were taken after the adhesive cure cycle was complete. After the airplane completed a postmaintenance test flight, it was painted. Data was collected from the SHM sensor before and after paint was applied. The sensor was ready for service.

5 SERVICE EXPERIENCE AND THE DATA-ACQUISITION SYSTEM

After maintenance on airplane 87-0395 was completed at Hill Air Force Base, the airplane entered service at Luke Air Force Base outside of Phoenix, Arizona, USA. The SHM data-acquisition system was brought to Luke Air Force Base (AFB) for use by United States Air Force (USAF) personnel. The data-acquisition equipment is roughly the size of a small desktop computer. In order to make the data-acquisition system as transportable and easy to use as possible, a self-contained system was assembled. The system, shown in Figure 5, includes a battery backup unit, a monitor, a keyboard and mouse, a data-acquisition computer, and a data cable. All components were mounted inside a wheeled case with a retractable handle. The system can be rolled out to the airplane and data can be collected without a need for external power.

6 SENSOR DURABILITY

After approximately two months in service, it was discovered that two of the sensors had been torn off of the airplane. The reason for the departure of these sensors is not known. Possible causes for the loss of the sensors are poor initial surface preparation, strain at the adhesive bondline due to the sensor wiring

Figure 5. A self-contained data-acquisition system was developed for collecting data while the airplane is in service.

bridging the interface between two structural components, aerodynamic loads on the sensor, interference between the sensor and the center fuel tank pylon, or interference caused by other maintenance actions. These two sensors were repaired in the field on June 10, 2006.

The wheel well of an F-16 is a harsh environment for a fragile piezoelectric ceramic sensor and thin copper traces printed on a polyimide substrate that can easily tear. Testing is useful for determining if sensing systems can survive the service environment. Tests based on MIL-STD-810, a US government standard defining a variety of environmental tests for flight vehicle components, were conducted in 2006 to assess the capability of these sensors to withstand the wheel well environment. The testing showed that for test specimens with well-bonded sensor layers, the layers could adequately withstand the expected environment.

After several more months in service, the left side repaired sensor began showing signs of disbonding. It is possible that a good bond was not obtained during the repair because of the difficulties with in-service surface preparation, which explains the current disbonding of the sensor. As SHM sensing elements are mounted on structures, the sensing systems must be maintainable, and effective maintenance practices must be developed for the sensing systems.

As the system continued in use, additional anomalies were discovered. The right-side metal patch transducer wiring broke and is not repairable without removing the landing gear. It is not known how the wiring failed. One contributing factor may be that when the sensor was originally installed, some of the sensor wiring did not bond to the structure. For sensors on a flexible substrate, a good bond to the host structure is critical for system longevity.

The copper traces in the layer are slightly exposed where the sensor layer wiring wraps around the edge of the keel structure on the left side of the airplane. The effect of the exposed traces on transducer signals is unknown. An optimum configuration would allow for adequate clearance and protection to keep wiring traces covered.

This in-service wear of the system provides information about the effects of the environment in which SHM systems need to perform. By performing this demonstration, it has been shown that sensors can be flown, and that data can be collected by Air Force Personnel in the field. Areas have been found in which further development is needed before a production system is fieldable, at least for an environment like a landing gear enclosure.

7 TECHNOLOGY NEEDS

This demonstration unearthed a variety of technology needs before practical, wide-scale implementation of *in situ* sensors. To start, SHM system design methods need study and advancement. The system flying on the F-16 was not designed with any analysis or modeling. A design method for SHM systems that includes a requirement-based iterative design process with system-level simulation is needed.

Algorithm development is required to correlate signals received at transducers with the physical phenomena occurring within the structure. The objective of the damage evaluation portion of a SHM system is to localize and size damage. Localization means providing the position of damage, and sizing is to provide the extent (dimensions and shape) of damage. Damage evaluation must be possible with the structure in the environment (electromagnetic noise, dirt, temperature, and fluids) appropriate to that sensor installation. Algorithms to provide this capability are under development for *in situ* sensor-based SHM systems.

Miniaturization and strengthening of data-acquisition equipment are needed, and improvement of the user interface is required. For a system to operate in the field by personnel not familiar with SHM system principles, a lightweight, simple-to-operate system that meets field operation requirements is required. In the not-too-distant future, systems with energy harvesters, onboard data processing, and wireless data links to ground systems will replace bulky equipment and cumbersome connectors. Minimizing the skill level and difficulty involved in sensor installation, system maintenance, and system operation will minimize the recurring cost of production installations.

Further development of a SHM-based maintenance philosophy is needed. The US Air Force is gaining experience with *in situ* structural sensors on fixed wing aircraft. Data paths for SHM information need to be established, including feedback to allow modification of the usage of the airplane. The calculation of residual strength and remaining life could modify maintenance actions. Existing rotorcraft health and usage monitoring systems and health management methods of the systems are leading the way. SHM needs to fit into the US Air Force structural maintenance plan.

8 CONCLUSION

The installation of an SHM sensor system on a bonded repair of an F-16 airplane has been demonstrated. With the successful installation and operation of the sensor, experience with fielding a laboratory-level SHM system was gained. Technology needs related to SHM are great—improvements in design methods, algorithms, data-acquisition equipment, and the maintenance philosophy will all improve SHM-based maintenance practices in the future.

1 INTRODUCTION

Structural health monitoring (SHM) technology is perceived as a revolutionary method of determining the integrity of structures involving the use of multidisciplinary fields including sensors, materials, signal processing, system integration, and signal interpretation. The aim of the technology is not simply to detect structural failure but also to provide an early indication of physical damage. The early warning provided by an SHM system can then be used to define remedial strategies before the structural damage leads to failure [1–3].

Recent advances in sensor technology, material processing, damage modeling, and system integration have enabled new developments in structural evaluation and inspection technologies to overcome the shortcomings of existing inspection systems. An SHM system consists of three major components: a sensor network, integrated hardware, and diagnostic software to monitor *in situ* the condition of in-service structures. Among several types of sensors that can be used for SHM, piezoelectric sensors are being widely used because they can be used as either active or passive sensors due to their piezoelectric effect (*see* **Piezoelectric Wafer Active Sensors**; **Piezoelectric Paint Sensors for Ultrasonics-based Damage Detection**).

Unique SHM technologies have been developed [4–6] through the use of built-in distributed piezoelectric sensor networks integrated with composite and metal structures. As shown in Figure 1, the basic idea of the technology is to use a network of

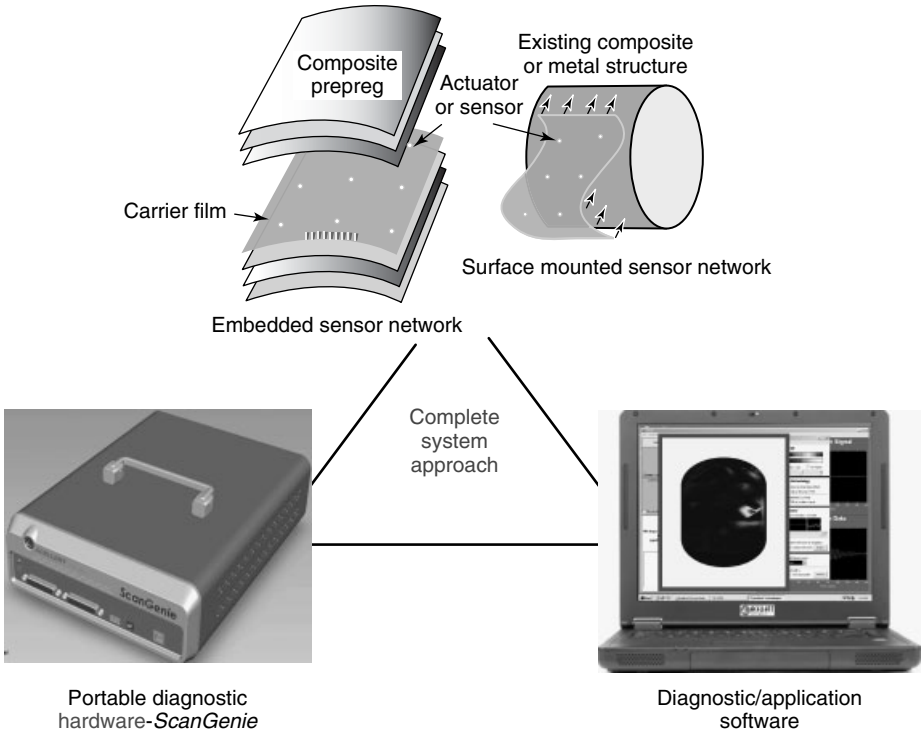

Figure 1. Complete system approach.

distributed piezoelectric sensors/actuators embedded in a thin dielectric carrier film called the *SMART Layer* to monitor and evaluate the integrity of a structure. A portable diagnostic hardware unit called *ScanGenie* is used to collect and process diagnostic signals obtained by the SMART Layer during the monitoring process. The signals obtained can then be analyzed to determine the integrity of the structure.

The SMART Layer technology has the unique ability to provide wide structural coverage for gathering diagnostic data with a network of transducers embedded in a layer, thus eliminating the need for each transducer to be installed individually (*see* **Stanford Multiactuator–Receiver Transduction (SMART) Layer Technology and Its Applications**). There are two types of SHM systems defined by their functionalities: the active-sensing system and the passive-sensing system [7–10]. The SMART Layer can work with both the active-sensing system and the passive-sensing system.

In terms of aerospace applications, there are two operation modes of SHM systems: onboard and off-board modes. The onboard mode considers the system to record data during flight, while off-board mode only considers data to be taken when the aircraft is on the ground. The former is therefore the more challenging approach, since it requires the complete monitoring system (signal and power generator, sensors, signal acquisition, writing, and processing unit) to be placed onboard the aircraft, and, as a result, it requires certification of a very high degree of airworthiness, since the system is due to operate in flight. Off-board monitoring can be considered more as a substitution of conventional NDT methods where only the transducers and part of the wiring (or the antenna system in the case of wireless monitoring) have to stay on board the aircraft.

Both operation modes have advantages, since each of them very much depends on the application. A passive monitoring system, such as acoustic emission, can only be run on board. The same applies for impact detection or any loads to be monitored and occurring in service. Off-board monitoring is useful when a structure is allowed to tolerate damage, such

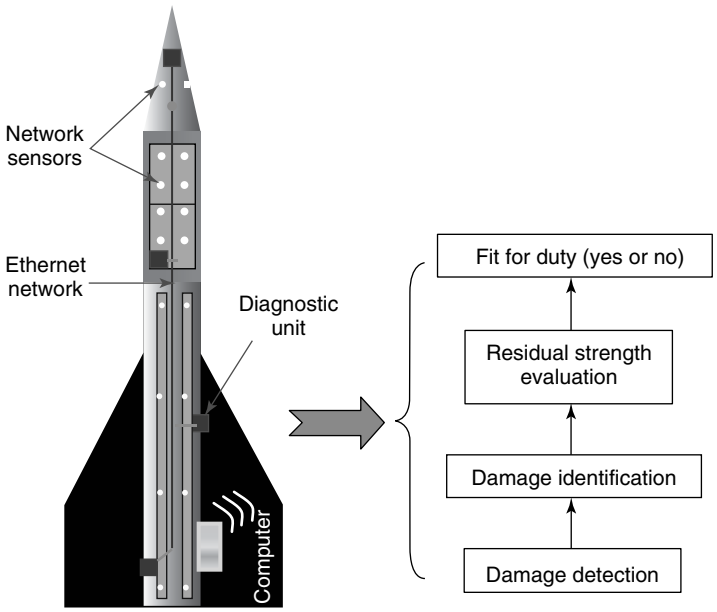

Figure 2. Overview of an onboard SHM system.

as when it is applied to a large number of metallic structures with regard to fatigue and fracture in a damage-tolerant design. An example for an onboard system is provided in Figure 2, while an off-board system is shown in Figure 3.

Within this article, a variety of applications are presented for both onboard and off-board usage to demonstrate the success of the systems in the real world. The applications include monitoring damage in large composite structures, cracks in the pipes of liquid rocket engines, multisite damage in riveted joints, bondlines in composite repairs, detection of impacts on the thermal protection systems (TPS) of space vehicles, and monitoring composite rocket motor cases. Further background regarding SMART Layer technology can be found in **Stanford Multi-actuator–Receiver Transduction (SMART) Layer Technology and Its Applications** and partially also in **Hybrid PZT/FBG Sensor System**.

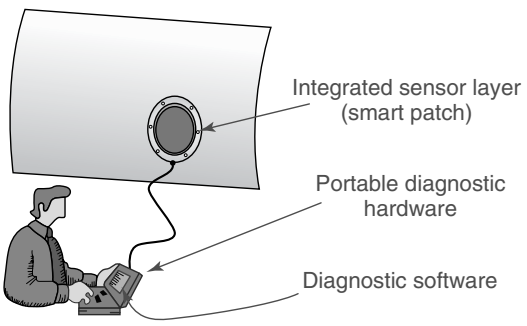

Figure 3. Overview of an off-board SHM system.

By using a passive onboard system, parameters such as impact time, location, and energy can be monitored. When the structure is struck by a sufficiently large force due to an external mass, the transducers (such as piezoelectric materials) that are bonded on the structure pick up the stress waves traveling through the structure. Upon triggering, all sensor measurements are recorded and stored in a data file for analysis. The data are immediately passed to a signal-processing and interpretation algorithm, which analyzes the measurements to estimate the location and also energy and/or peak force level of the impact.

Key issues for the passive onboard system include correct triggering, exclusion of electromagnetic interference, large hardware memory space; guaranteed continuous operation; and real-time monitoring. Simulation models need to be used to predict the possible damages on the basis of the impact location and energy. Similar issues may apply if the system is used for active onboard monitoring. The

diagnostic units integrated with the hosting structure will initiate, upon request, a damage scan of the area covered by the sensor network, collect and condition the data coming from the sensors, and send them through the Ethernet structure network to diagnostic software hosted on a computer for analysis. Key features, currently developed for an active onboard system, include miniaturized lightweight hardware, self-diagnostics and adaptive algorithms to automatically compensate for damaged sensors, reliable damage detection under different environmental conditions, and generation of probability of detection (POD) curves [11].

2 APPLICATIONS OF ONBOARD SHM SYSTEM

Some developments for potential applications of onboard SHM systems, including both active sensing and passive sensing, are summarized in this section.

2.1 Monitoring of impact damage in a composite pressure vessel

Fiber-reinforced composite materials are widely used in aerospace, automotive, shipbuilding, and other industries because of their high strength-to-weight and stiffness-to-weight ratios. However, composite materials, specifically those based on carbon fibers, lack plasticity when compared with metals. Whenever an accidental damage occurs, it is fairly difficult to determine the extent of damage without employing a fairly sophisticated NDT approach. However, it is important to have up-to-date information on the integrity of the composite structure. This is especially true for composite rocket motor cases because of the cost and liability associated with each launch failure. To ensure the safety and reliability of rocket components, they require frequent inspections to identify and quantify damage that might have occurred during manufacturing, transportation, or storage [12].

An integrated SHM system using a built-in sensor network for detecting impact damage in filament-wound composite structures such as storage tanks for space vehicles has been developed [13] and has been described from the sensing point of view in **Stanford Multiactuator–Receiver Transduction (SMART) Layer Technology and Its Applications**. A prototype of a filament-wound composite bottle with embedded SMART Layers was fabricated successfully at NASA Marshall Space and Flight Center is shown in Figure 4.

Once a set of baseline data has been collected from the sensor network on the bottle, impact damage is introduced onto the bottle to look at its effect on the sensor signals. Another set of data for all paths is obtained after introduction of the impact damage. The scatter signals for all possible actuator–sensor diagnostic paths on the bottle can then be processed and displayed at the same time to produce a comprehensive image that illustrates very clearly the location and size of the damage, as shown in Figure 5.

2.2 Monitoring of impact damage in a large composite fuselage barrel

The issues discussed with the composite pressure vessel above also apply to composite aircraft fuselages, which are increasingly being designed to be built out of carbon fiber-reinforced polymers these days. As shown in Figure 6, a large composite fuselage barrel was fabricated as a proof-of-concept demonstrator for a new airplane development project at the Boeing Company, in 2001. This composite

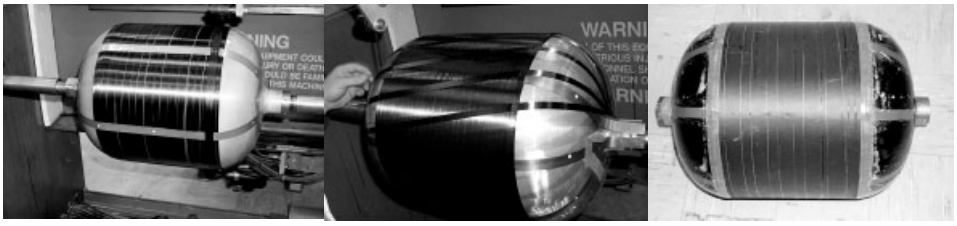

Figure 4. Filament-winding process incorporating the SMART Layers into the composite bottle.

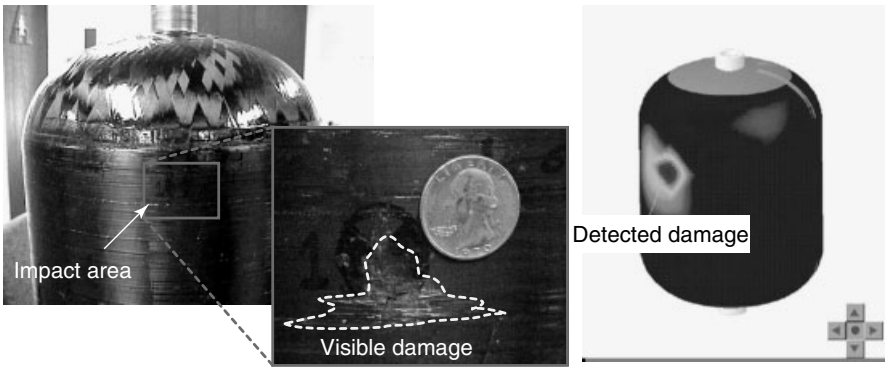

Figure 5. The damage identification result using signals collected by a network of built-in sensors.

structure provided a unique and realistic opportunity to investigate the use of SHM systems on a test specimen that represents a full-scale flight vehicle structure. Three big SMART Layers, of the type shown in Figure 7, were successfully installed and operated on this large-scale structure. The test demonstrated the feasibility of the sensor network-based active SHM system [14].

2.3 Detection of impact damage on a full-scale UCAV composite wing

The unmanned combat air vehicle (UCAV) is an affordable weapon system that increases tactical mission options for revolutionary new air power. Because of some significant advantages of composites, UCAVs, such as the X-45 UCAV, include a significant amount of composite materials. To ensure the safety and reliability of the UCAVs, it is very important to have up-to-date information on the integrity of composite structures; this is because, in wartime, structures are likely to be affected by battle damage, which is a fairly unpredictable damage condition that might have to be handled by a ground crew. Further issues in that regard are discussed to a wider extent in **Unmanned Aerial Vehicles**.

Figure 6. A large composite fuselage barrel.

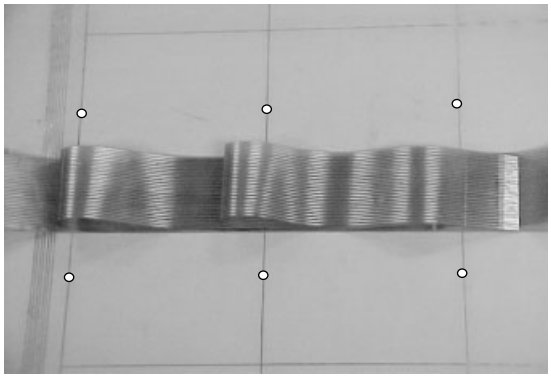

Figure 7. A 609 mm × 914 mm SMART Layer with 24 PZTs embedded.

The feasibility of using the SMART-Layer-technolog-based SHM system to detect impact and delamination damage in a full-scale UCAV composite wing has been evaluated at the Boeing Company in Seattle, Washington, in 2006. Twenty-one lead zirconate titanate (PZT) elements on SMART Layers were mounted on the upper skin of CAI-T4 wing to detect impacts on the skin, while another 40 PZT elements on eight SMART Layers were mounted on the skin around four paste-bonded joints to monitor the impact damages and any growth during fatigue testing. From these test results, it is clear that

the SMART-Layer-technology-based SHM system can successfully detect impacts and monitor impact damages in the UCAV composite wing under real environmental conditions. The basic concept of an SHM system for UCAVs is shown in Figure 8.

Figure 9 shows another example of the composite wing of a vehicle that has been instrumented with the SMART Layers for structural monitoring. The SMART Layers were designed and integrated into the wing during the manufacturing process itself, and used to detect changes in the structure when subjected to impact load. The wing was also shot at with a rifle [15].

2.4 Monitoring of cracks in liquid rocket engine pipes

Pipes of pressure vessels in liquid rocket engines can fail due to many causes including pitting, stress corrosion cracks, seam weld cracks, and dents resulting from internal or external impacts. The detection of defects and the monitoring of their growth is important, as it will address the need for safe as well as reliable advanced space exploration vehicle/propulsion systems. An active SMART Tape system for monitoring crack growth in a liquid rocket engine pipe has been developed and tested; this has been further described in **Stanford Multiactuator–Receiver Transduction (SMART) Layer Technology and Its Applications**. Test results demonstrated that the system can detect a surface crack as small as 4 mm and a through-wall crack as small as 2 mm in the high-pressure engine pipe made of Alloy 718 in laboratory conditions [6]. It was also demonstrated that the developed system can withstand operational levels of vibration and shock energy on a representative rocket engine duct assembly, and is perfectly functional under the combined cryogenic temperature and vibration environment [16]. The setup for the combined cryogenic temperature and vibration test is shown in Figure 10.

Besides the applications mentioned above, the onboard active SHM system can also be used to

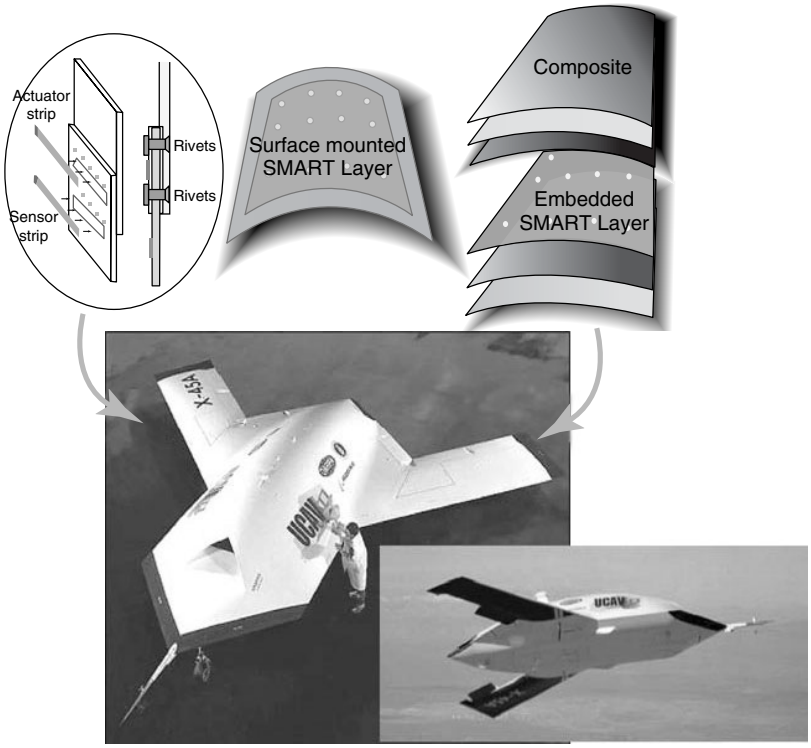

Figure 8. The concept of an SHM system for UCAV.

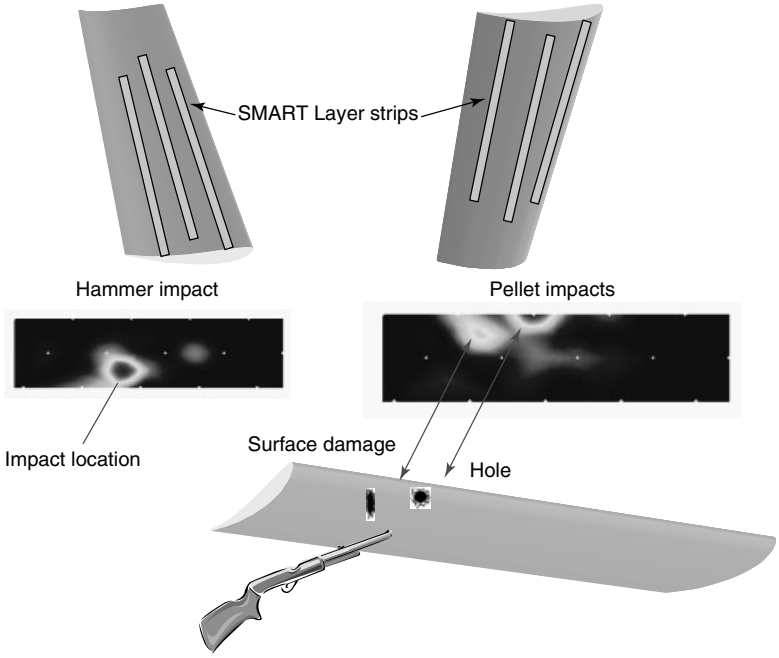

Figure 9. Monitoring the integrity of a composite wing.

monitor the integrity of structures in many other applications in both aerospace and civil engineering [5, 15, 17].

2.5 Monitoring of impacts on TPS panels

The TPS is an important component of space vehicles and provides protection from extreme high-temperature damage. Strong impacts on the TPS panels can cause severe damage to the panels and endanger the whole spacecraft as was made obvious by the Challenger accident. When a space vehicle starts reentry from outer space, the actual temperature is approximately 1650 °C (3000 °F) on the surface of the leading edge, and the temperature at the base of the TPS mounting bracket is approximately 175 °C (350 °F). Therefore, the sensor network has to be mounted at the base of the TPS panels to avoid the high temperature. A test performed for bolt-loosening detection by Stanford University on a TPS panel showed that the PZT sensors mounted at this location could function normally under a very challenging environment [18].

A demonstration of impact detection on the TPS panels is given below. As shown in Figure 11, a set of TPS panels designed and manufactured by Lockheed Martin Space Systems was used to build a test bed. There were a total of nine panels installed in the test structure surrounded by a metal frame. The TPS panels are mounted on a metal-stiffened back panel using brackets. The signal and ground traces for the sensors are implemented on a flexible dielectric substrate instead of conventional coaxial cables in order to reduce the weight for this application. The PZT sensors are individually mounted on the brackets. There are 16 sensors mounted in all. When an external impact is applied to a TPS panel, the mechanical stress waves propagate on the surface of the TPS panels, and then travel through the legs of the brackets to reach the PZT sensors.

The impacts were generated by using a hammer to hit the panel with different forces, in the range of 10–200 N. Both impact location and force can be determined by using the system identification method [19]. In order to monitor the impacts for a large area on a space vehicle, a multichannel-distributed impact detection system, as shown in Figure 12 [20], needs to be developed because the

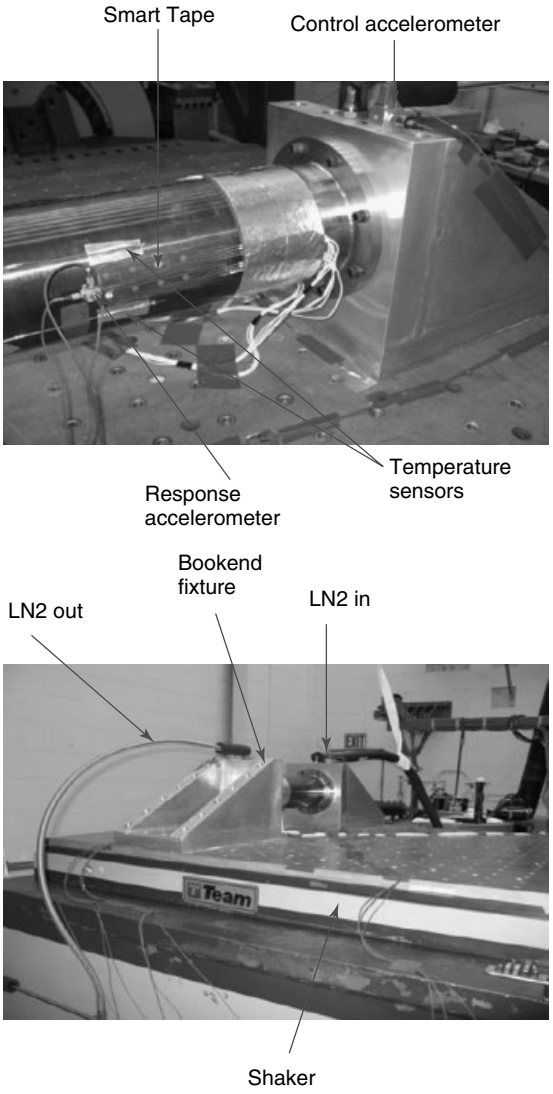

Figure 10. The setup for the combined cryogenic temperature and vibration test.

sensors required to cover the monitoring area might be up to hundreds.

2.6 Monitoring impacts on composite rocket motor cases

As another example, the onboard passive-sensing system for use in monitoring impacts on composite rocket motor cases was also developed and evaluated [21]. Figure 13 shows the implementation of the overall impact monitoring system. To demonstrate the impact detectability, including both location and force reconstruction, impact tests were conducted on a GEM60 rocket motor case instrumented with SMART Layers at Vandenberg Air Force Base (AFB).

Empirical approaches to structural characterizations and sensor network calibration, along with implementation techniques, were successfully evaluated. The simplistic empirical characterization approach, along with the robust/flexible sensor grids and the battery-operated portable logger, shows that the system can increase confidence in the composite integrity for new products progressing through manufacturing processes as well as existing assets that may be in storage or transportation.

3 APPLICATIONS OF OFF-BOARD SHM SYSTEM

Typical developments for potential applications of off-board SHM systems are summarized in this section.

3.1 Riveted lap joints in metallic structures

Off-board monitoring of metallic aircraft structures is possibly the most classical application of the SMART Layer system. A wide range of activity has been, and still is, related to monitoring riveted lap joints. A novel type of sensor layer that has become a standard in that regard emerged from a series of tests performed on multiriveted aircraft panels with multisite damage [22]. The novel sensor layer is the SMART Layer strip in which piezoelectric elements are placed at an equidistant pitch similar to the rivet pitch, as shown in Figure 14.

Since this requires a remarkable number of piezoelectric transducers to be placed, and hence an adequate amount of contacting on the SMART Layer, this led to the development of a stacked SMART Layer as shown in Figure 15. This configuration principle can even be applied along a fairly narrow spacing of rivet lines.

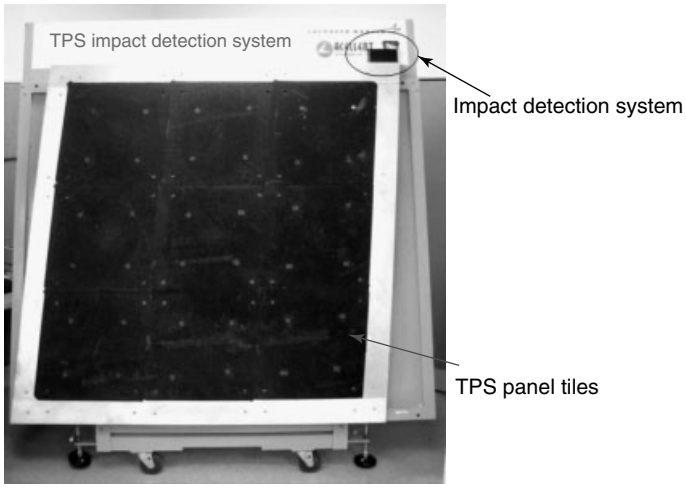

Figure 11. The TPS panel with the impact detection system.

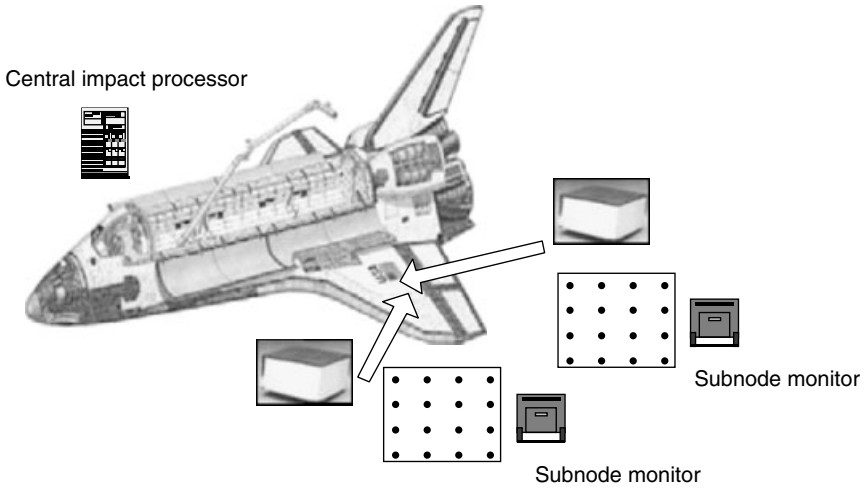

Figure 12. The distributed impact detection system.

Results obtained with this type of monitoring have shown that cracks of a length of 5 mm or more can be well detected, which is an adequate measure when compared to conventional NDT.

3.2 Monitoring of composite-bonded repair

Another application of the off-board SHM system in aerospace is the monitoring of composite-bonded repairs over fatigue-cracked areas. Metal structures such as fixed wing aircraft, helicopters, and other transportation systems are likely to develop fatigue cracks under cyclic loads and corrosive service environments. Repair methods such as bonded repair patches are used on hot-spot damaged regions. These repairs provide an efficient method for restoring the ultimate load capability of the structure. The bonded repairs offer several advantages over bolted repairs, including minimal changes to aerodynamic contours, weight saving, reduced cost, and formability to complex shapes [23–25]. A typical bonded patch repair is shown in Figure 16 [25]. Aircraft

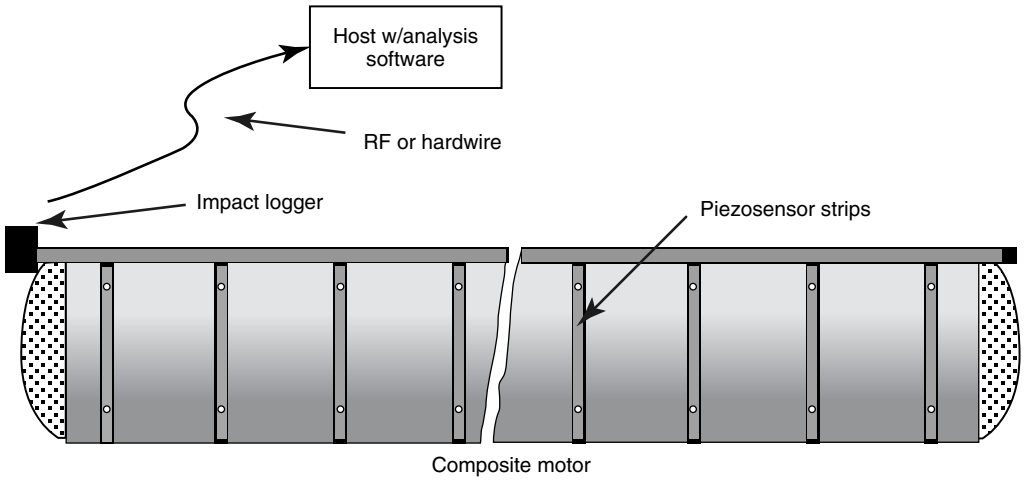

Figure 13. Overall system implementation for impact monitoring.

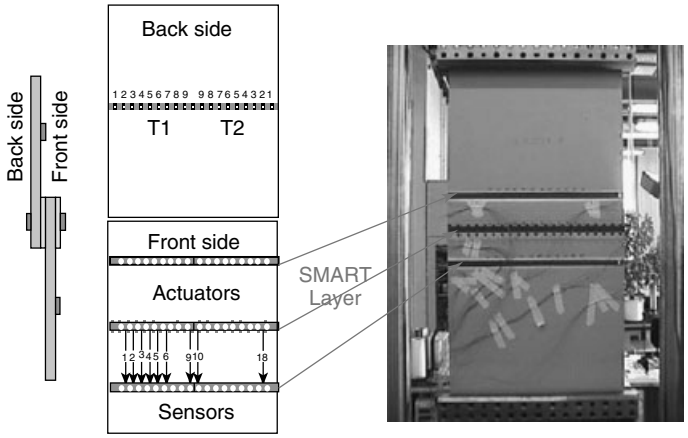

Figure 14. SMART Layer for monitoring multisite damage in riveted joints.

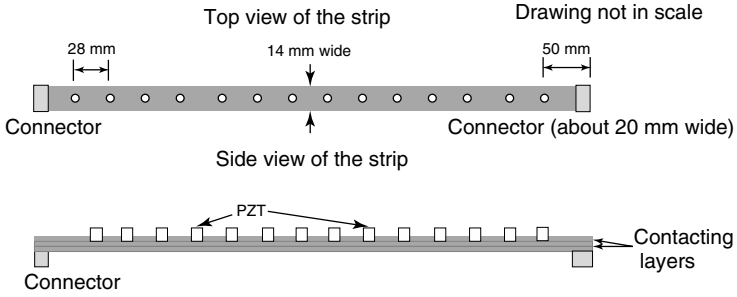

Figure 15. The stacked SMART Layer strip.

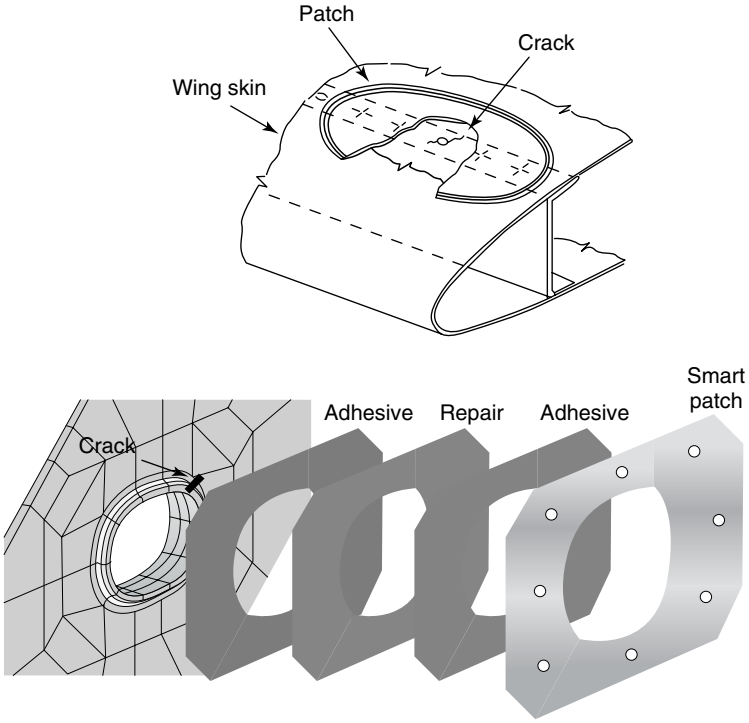

Figure 16. Bonded patch repair.

maintenance organizations generally require that the repaired structure undergoes inspection at the same time intervals as the unrepaired structure. This "fail-safe" approach essentially assumes that the repair is not effective in retarding crack growth of the original structure. In addition to potential bondline degradation, flaws and damage can have a detrimental effect on the integrity of the bond strength. Disbonds can arise from fatigue loading, impact events, or improper processing. Therefore, inspection of bonded repairs is an essential part of regular aircraft maintenance.

The SHM approach, such as also explained in further detail in **Design, Analysis, and SHM of Bonded Composite Repair and Substructure**, uses PZT sensors placed in, on, or around hot-spot regions to monitor damage initiation and damage growth. The sensor network built-in SMART Layer can be easily attached to existing aging structures without changing the local and global structural dynamics. The SMART Layer can also be embedded inside composite patches to closely monitor for internal flaws. These PZT elements in the layer can act as both actuators and sensors.

3.2.1 Monitoring of initial bond quality of bonded repair

Figures 17 and 18 show an example of SMART Layer technology applied to monitor the initial bond quality in a bonded repair coupon [26]. As shown in Figure 17, two specimens were prepared, one with fully bonded repair and the other with a 15 mm × 20 mm artificially induced disbond under one corner of the composite repair.

The signals from the specimen with a fully bonded composite patch were used as reference baselines. The damage index (DI), which was developed to extract features in sensor signals related to damage in the structure [27, 28], was calculated for each actuator–sensor path. Figure 18 shows an image generated by the DIs from all actuator–sensor paths. The white dots in the figure give the locations of PZT transducers. A heightened intensity of brightness indicates a bigger DI. From Figures 17 and 18, it is clear that the 15 mm × 20 mm disbond area can be well detected.

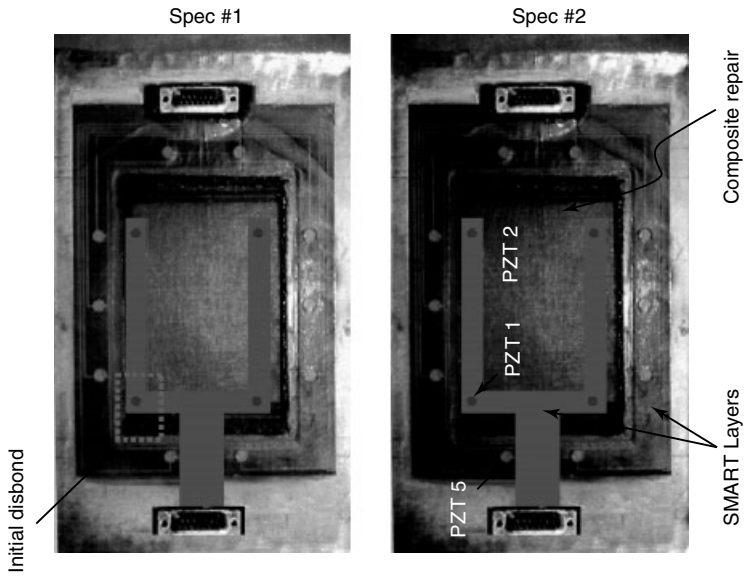

Figure 17. Test specimens with sensor network.

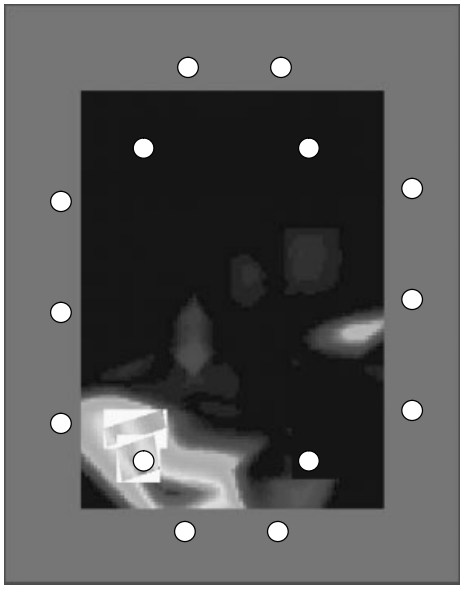

Figure 18. An image of detected disbond.

3.2.2 Monitoring of crack growth under bonded repair

Figure 19 shows another example of the active SHM system applied to detect crack growth under the bonded composite repair during fatigue cycling [26, 29]. The test was conducted at the US Wright-Patterson Air Force Base as part of a program to assess candidate SHM technologies for bonded composite repair patches. The results of fatigue testing can be viewed via diagnostic imaging shown in Figure 19, or quantified in a tabular form shown in Table 1.

To help quantify the damage size, a semiempirical method has been developed to give quantitative measurements of damage growth in real time, giving a few initial data points. Signal changes from each path are used to calculate DIs, from which DI curves are generated [26–28]. To calibrate the DIs to the damage sizes, several measurements of real damage size measured by conventional methods are used. The more the measurements used, the better are the estimates of the damage size. In this test, four measurements of the crack length by using an optical microscope were used to help quantify the crack size. The damage size estimates, along with the calculated uncertainty, are presented in Table 1.

As shown in Figure 20, the above-mentioned approach has also been used to monitor the repair in the center keel area of the F-16 fuselage station 341 bulkhead. More details about this application can be found in the literature [30] (also see **Validation of SHM Sensors in Airbus A380 Full-scale Fatigue Test**).

4 CONCLUSION

This article summarizes a series of aerospace applications of the SMART Layer technology, which have been differentiated as onboard and off-board systems. Onboard systems require all system elements of the SHM system to be included on board the air vehicle, since it requires monitoring during flight. An onboard system is unavoidable if the SMART Layer system is to be applied for load monitoring such as impact loads or in a passive mode such as with acoustic emission. The easier means of monitoring

and thus possibly the most attractive in the short term is the off-board system, since it only requires the SMART Layers to stay on board the air vehicle while the remaining signal generation and acquisition hardware with supporting software can be plugged in on demand. The application of the SMART Layer technology in aerospace is fairly wide and ranges from monitoring cracks in metallic, delaminations in composite structures, and repairs, in general, of conventional aircraft structures, to pipes, pressure vessels, or thermal protection shields for space vehicles. For all of those applications, the concept and functionality has been proven. The developed and finally qualified specific solutions demonstrated that the SMART Layer technology could work as established solutions in the future.

ACKNOWLEDGMENTS

The authors would like to acknowledge the financial support of US Army, US Air Force, Missile Defense Agency, DARPA, and NASA for sponsoring some of the developments listed in this article. The authors would like to thank Ms Irene Li, Dr Amrita Kumar, Dr David Zhang, and other colleagues at Acellent for their technical consulting and assistance for the development of the technology. The authors would also like to thank Mr Jim Gibson for his help in editing this article.

1 INTRODUCTION

Aircraft are costly complex assets with significant maintenance support requirements. Structural health monitoring (SHM) [1–5] is part of a new proactive aircraft management approach to maintaining vehicle safety and significantly reducing costs. The ultimate vision of SHM is a system of permanently installed, continuously monitoring microsensors that provide timely information about the condition and integrity of safety-critical structures [6]. The application of SHM systems to aircraft is envisioned to not only provide real-time or near-real-time characterization of structural integrity for improved aircraft lifecycle management but also opportunities for adaptive flight control, enhanced vehicle mission flexibility, and changes in the approaches to aircraft design.

The significance of these SHM benefits varies according to the intent of the aircraft: transport, space exploration, or defense. In the case of commercial air transport, the challenge is to make the aircraft as profitable as possible by safely maximizing revenue-generating activities and minimizing support requirements. Any events that reduce aircraft operation, e.g., inspection, maintenance, holding loops, bad weather, accidents, or any other obstructions, detrimentally impact the aircraft's profitability and the operator's bottom line. A number of studies have examined the benefits of SHM [7–9] as well as the steps necessary to meet the regulatory requirements for introducing this technology [10, 11]. As a consequence of these findings, virtually every large aircraft manufacturer and aircraft subsystem manufacturer is exploring how the SHM technology vision can be implemented on real aircraft. Airbus [12–14] Boeing [15, 16], EADS Military Air Systems [17, 18], the US Air Force [19, 20], and Honeywell [10, 21] have all expressed their interest in this technology.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

This article presents some current views on the potential role of SHM in commercial fixed-wing aircraft. Although aircraft accidents due to structural failures have become increasingly rare, historically there were a number of incidents that have influenced the advancement of SHM approaches. The discussion starts with a review of how SHM was initiated in response to unforeseen structural failures and has evolved into a technology that, along with other health-management technologies, is leading the way toward a change in how aircraft are managed and maintained.

2 THE HISTORICAL MOTIVATION FOR SHM

2.1 Safe life and fail-safe design

Despite a generally excellent track record, there have been a number of milestone aviation accidents that have motivated and impacted the development of SHM system for fixed-wing aircraft. Fatigue failure has been a concern to aviation since as early as 1908 when the Wright brothers had to postpone their first powered flight due to fatigue failure of a propeller shaft. However, it was in January and April of 1954 that two De Havilland Comets drew worldwide attention to the problem of fatigue in the aircraft fuselage [22] as well as the aircraft structure in general. The Comet was the first commercial high-altitude jet transport plane offering passengers superior performance, higher cruising altitudes, and comfort. It was designed to support a significantly higher cabin pressure differential than its contemporaries—the propeller-driven transports. Yet two Comets crashed after they had undertaken only 1286 and 903 flights, following an explosive decompression of the fuselage. The fleet was grounded for extensive investigation, including full-scale pressurization tests, which revealed that unstable crack growth and an underestimation of notch sensitivity had caused the catastrophic failures. Fatigue failures of military aircraft were also occurring during this time.

Shortly thereafter, regulations were introduced to ensure that the *safe life* or service life of a vehicle could be demonstrated and validated using laboratory tests. To obtain certification, the platforms were tested to failure using simulated service loads conducted in a laboratory. Safe life was defined as the test life to failure divided by a safety factor of three or four to account for uncertainties. Once the safe life was reached, the vehicle was to be taken out of service. In addition to certification of safe life, *fail-safe* design principles were introduced in the late 1950s. By definition, fail-safe systems are designed to become safe when they fail or cease to operate. For aircraft, this doctrine mandates that the structure must be capable of withstanding significant damage before safety is compromised. Commonly, the requirements were met by employing multiple load paths and well-established residual strength requirements to accommodate failure or significant partial failure of a structural element. In addition, the structure was to be designed so that damage could be easily detected before safety was compromised.

2.2 Operational loads monitoring

A form of SHM known as *operational loads monitoring* first appeared in the mid-1950s in response to the crashes of the two De Havilland Comets. These systems are designed to help provide more effective fatigue life management. The loads monitoring approach is particularly relevant for military aircraft where the vehicles are often flown to their limits, experience operational damage, and unpredictable environmental conditions. Unfortunately, monitoring aircraft operational loads is far from an easy task, since they cannot be measured directly. The most popular way of monitoring them is by measuring strain. Strains, however, can be quite localized and therefore require the use of a large number of sensors to obtain an understanding of the entire vehicle. This leads to a prohibitively large increase in the aircraft's complexity and raises questions of sensor reliability and consequential overall aircraft reliability. As a result, many military aircraft manufacturers have adopted a strategy of inferring operational loads from global data collected by a small number of sensors and exploiting, to the maximum extent possible, any data from sensors that already exist on the aircraft for other reasons.

Early loads monitoring systems were therefore based on a small collection of accelerometers distributed over the aircraft. Probably the first to implement an accelerometer-based counting device was the UK Royal Air Force, who, in response to the Comet accidents, gradually equipped two-third of their active fleet with fatigue meters, Figure 1 [23]. This technology insertion also promoted and preceded a variety of developments in North America on the F-18 [24] and C-130 [25], and in Europe on the F-16 [26], AMX [27], and Tornado [28] (*see* **Fatigue Monitoring in Military Fixed-wing Aircraft**) aircraft. The more sophisticated systems used a series of g-meters, which counted the number of load exceedances for different g-levels. The system implemented in the Eurofighter Typhoon represents a modern state-of-the-art system and is based on one of two approaches: (i) a system comprised of 16 conventional strain gauges (UK and Spanish version) or (ii) a flight parameters-based system (German and Italian version) [29]. In either system, the time-domain data is fed into the digital loads model, which virtually calculates the load-time sequence at each specified location of the aircraft. This information can then be used to calculate the fatigue life consumed and hence the time when fracture is expected to occur.

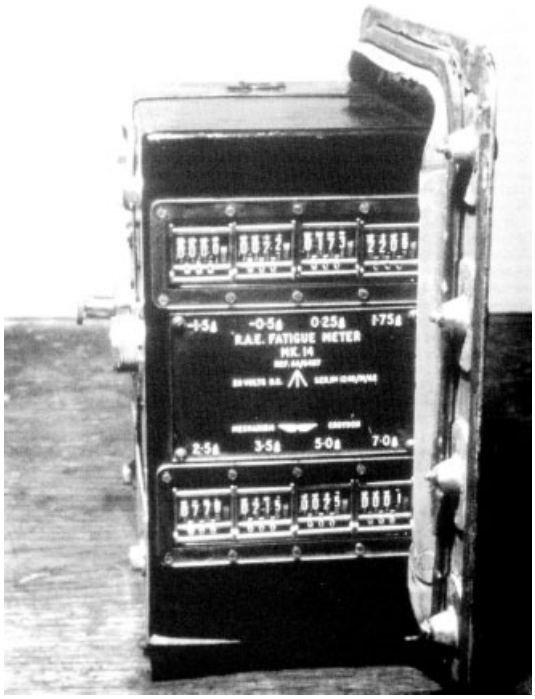

Figure 1. Fatigue meter used in UK RAF fleet since 1954. [Reproduced with permission from Ref. 23. © NATO, 1998].

Specifically, it has been the work around Tornado [28] that triggered Airbus, in the 1980s, to also explore an operational loads monitoring system (OLMS) [30] the logic of which is shown in Figure 2. This system, which considered monitoring hard landings and limit load exceedances was abandoned in the early 1990s. However, recent developments show that monitoring of hard landings and limit load exceedances is very relevant for commercial aircraft; more details can be found in other articles in this encyclopedia (*see* **Loads Monitoring in Aerospace Structures**; **Operational Loads Monitoring in Military Transport Aircraft and Military Derivatives of Civil Aircraft**; **Video Landing Parameter Surveys**; **Landing Gear**).

2.3 Damage-tolerance design

The safe-life principles dominated both military and commercial aircraft design until 1969 when the crash of a General Dynamic Corp F-111, a swing-wing fighter–bomber, caused engineers to rethink the safe-life approach. The F-111 had a safe life of 4000 flight hours and as such had been subjected to 16 000 h of laboratory fatigue testing, but the F-111 #94 failed after only 107 service hours while pulling 3.5 g, only half its design limit load. Investigation into the crash uncovered a troubling revelation, the failure fracture surface clearly showed that a flaw of significant size had been present on the first day that the airplane had entered service. Only a small extension of the flaw was necessary before catastrophic failure occurred. This, along with other evidence, caused the United States Air Force (USAF) to rethink the safe-life philosophy. A new approach emerged based on the belief that aircraft structures needed to be tolerant to an initial damage state.

The new *damage-tolerance* philosophy assumed that flaws existed in all critical locations. Structural integrity programs were implemented to find and repair damage before failure occurred, resulting in an approach that could extend the structural life beyond it design service life, Figure 3. The inspection intervals used in the maintenance programs were

based on models for crack growth driven under a presumed loading spectrum using initial flaw sizes defined in Military Spec 83444. These flaw sizes vary with location and geometry but are often referred to as 1.27 mm according to the specification of a surface-breaking crack. There is also a provision for designing structures that will not be inspected during their service life. This is an extremely useful design variable for accommodating areas where inspection is prohibitively difficult. These areas can still be classified as damage tolerant, provided they can be qualified for slow flaw growth, which requires that the flaw be incapable of growing to size where failure can occur during the design service life. Owing to the more stringent requirements, these sections are heavier than their inspectable counterparts. Since 1970, the USAF has required damage-tolerance programs for all its aircraft.

3 MODERN COMMERCIAL AIRCRAFT

3.1 SHM as an aid to the inspection process

Modern commercial aircraft also have to meet damage-tolerance regulations according to FAR 25.571—Amendment 96 with safe-life designs being used in limited cases for landing gear and certain helicopter applications. As discussed by a number of researchers, this provides an opportunity for SHM systems to modify the attendant inspection procedures. SHM can improve present inspection processes with onboard automated inspection technologies based on simple sensing devices permanently attached to the component of interest. As discussed in detail in other sections of

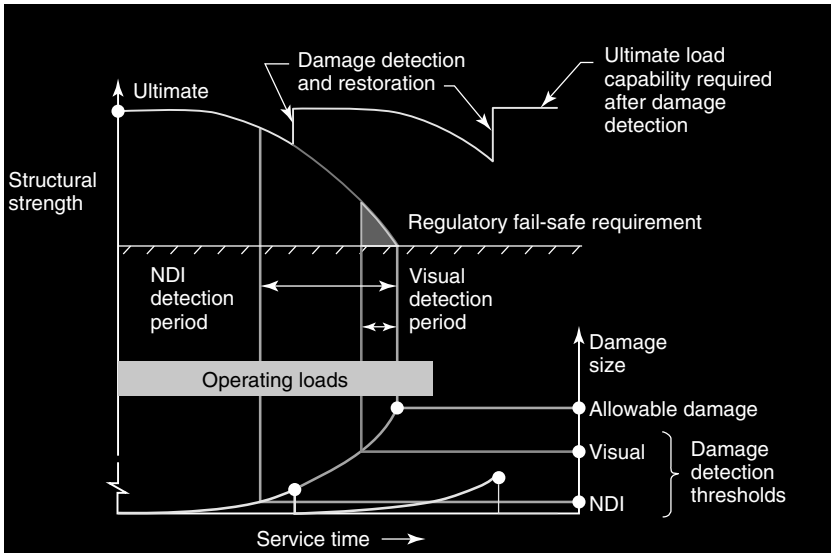

Figure 3. Damage-tolerance design philosophy and inspection approach.

this encyclopedia, such SHM sensing devices often operate on familiar principles explored and exploited by the nondestructive testing (NDT) community: ultrasonic [31–33], eddy current [34, 35], and acoustic emission [36, 37]. These and other novel approaches, such as comparative vacuum monitoring [35], fiber-optic sensors [38, 39], and electrical impedance methods [40], are just a few examples of approaches that hold the promise of improving safety and reducing the inspection burden. However, to succeed, it is commonly agreed that they must achieve certified maintenance credits that can be used to decrease the costs associated with maintaining an aircraft.

For modern air transport markets, vehicle design and maintenance requirements must satisfy both safety and economic considerations. Although inspections are mandatory when using a damage-tolerant design approach, they are also time consuming and subject to human error. Easy inspections and long inspection intervals are desired. Today, as in the past, the scheduled structural inspections of commercial jets rely primarily on the use of visual techniques. Thus, the inspectability and accessibility of the aircraft structure should allow visual methods to confidently make a damage assessment over a majority of the structure. As a result, aircraft designers try to limit the number of areas requiring directed inspections with sophisticated equipment and inspections in areas that are difficult to access. When inspections in these areas cannot be avoided, the components are designed to require infrequent inspection. Nonetheless, there are areas that are difficult to access where additional effort is required to dismantle subsystems and gain access. Examples include the frames and stringers of an aircraft fuselage located behind galleys, lavatories, or the air-conditioning system. These areas, and areas requiring more frequent inspection than originally anticipated, are good candidates to be considered for automated SHM.

3.2 Reconsidering structural design

Now consider the discussion above from a slightly different perspective, the design perspective. Damage tolerance is the approach used to ensure that the structure can withstand fatigue, corrosion, manufacturing defects, and accidental damage (AD) throughout the life of the aircraft and thus is critical in establishing the dimensioning criterion applied to the structural members. Allowable crack lengths are defined on the basis of how well they can be reliably detected. Regions that are difficult to inspect must be designed to support cracks that may grow for a substantial period of time before they can be reliably detected.

Examples include complex lapped joints where a crack can travel a significant distance before it emerges at an external surface where it can be reliably detected using the visual inspection protocol. In the case described above, the effort to dismantle galleys, lavatories, or air-conditioning systems to facilitate inspection of the underlying frames and stringers is high, and thus the designer chooses not to inspect these areas frequently and to account for this omission by designing to a more severe damage-tolerance scenario. Without regular inspection, the frames and stringers have to be considered as fully broken for the damage-tolerance analysis and any detectable initial crack found at the fuselage panel surface is assumed to experience higher stress loads and, therefore, propagate at high speeds.

Knowledge about the status of the internal members can be improved through the application of SHM and then be used in concert with an external inspection regiment. In this case, the damage-tolerance analysis and subsequent design could consider less severe crack scenarios e.g., a skin crack over an intact internal member [41]. This modified inspection approach could be used to increase the time between inspection intervals while maintaining the allowed stress levels, or increase the allowed stress levels while maintaining the inspection interval, Figure 4. Both circumstances are advantageous but the design benefit of being allowed to increase the stress levels would lead to a significant weight saving estimated to be between 13 and 20% [41]. Figure 5 shows a schematic comparison of allowable stress versus resulting inspection intervals for a fuselage panel with inspectable and noninspectable stiffening elements.

3.3 Aging aircraft

Another area where SHM shows significant relevance is the area of geriatric or aging aircraft. The problem of aging aircraft first gained widespread awareness in the aviation community after the May 14, 1977 Dan Air Boeing 707 crash. Investigation revealed that fatigue failure of a rear spar lead to the separation of the entire right-hand horizontal stabilizer just prior to landing. At the time of the crash, the aircraft had accumulated 47 621 flight hours of the intended design life goal of 60 000 flight hours. Although the stabilizer had been designed according to fail-safe principles, in practice, the area did not afford a significant and easily detectable damage condition before safety was compromised. The crash caused regulatory authorities to reconsider the problem of fatigue in older aircraft. As a result, they concluded that the existing inspection methods and schedules were inadequate for aging aircraft, and that supplementary inspections were needed.

The problem of aging aircraft was again brought to light by the Boeing 737 Aloha Airlines Flight 243 accident in 1988. The aircraft was old, having experienced more than 89 681 flights almost 15 000 more than the vehicles economic design life of 75 000 flights—although it should be noted that the maximum pressure differential were not reached for many of the flights. The Aloha accident was the result of many interrelated factors contributing to a heretofore unknown failure mechanism. Corrosion-induced disbonding at a cold, bonded skin splice allowed the cabin pressure loads to be transferred to joint rivets, which then induced multiple fatigue cracks at the rivet–skin interface. The numerous small fatigue cracks went undetected until the collinear

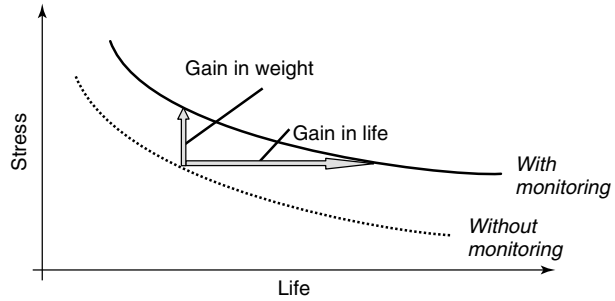

Figure 4. Comparison of stress-life behavior of fuselage skins with monitored and nonmonitored stiffening elements. [Reproduced with permission from Ref. 41. © DEStech Pub, 2007.]

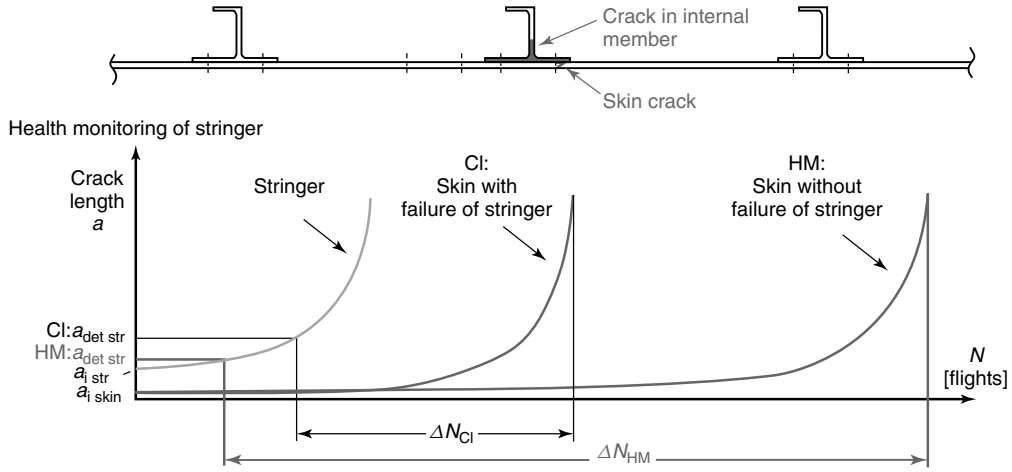

Figure 5. Comparison of fuselage skin crack propagation life for a nonmonitored and monitored frame, respectively. [Reproduced with permission from Ref. 41. © DEStech Pub, 2007.]

cracks rapidly linked up and caused explosive decompression of a major section of the fuselage. This damage mechanism came to be known as *multiple site fatigue damage* (MSD), which is a subset of *widespread fatigue damage* (WFD), itself defined as the simultaneous presence of multiple cracks of sufficient size and density to render the structure incapable of meeting damage-tolerance requirements. The newfound awareness to WFD lead to significant worldwide activities by manufacturers, operators, regulatory authorities, and researchers to develop new regulations and better understanding that would ensure the safety and integrity of aging aircraft. As a result, it is now a standard practice that many fracture-prone components be inspected at much shorter intervals if the aircraft is operated beyond its original design life. This significantly increases the amount of inspections needed in these circumstances.

The mean age of commercial and military aircraft fleets has been steadily increasing over the past few years. The relevance of this situation becomes clear in the commercial aviation sector where the demand for air transport capacity is high, but older aircraft must still be capable of operating in a cost-effective manner despite the increased maintenance load. Figure 6 shows the fleet age of the most common commercial aircraft types. This figure illustrates that operators often use airplanes well beyond their original design lives and that the majority of the planes are either in a mature or aged phase of their life cycle.

Aging aircraft is also of significant relevance to the defense sector. The average age of the B-52 bomber is 46.6 years and the KC-135 between 46 and 48 years Table 1. The USAF fleet now stands at an average age of 24 years and is expected to achieve an average of 26.5 years in 2012. The USAF would need to boost aircraft purchases by about 170 a year to reverse this trend. However, there are no such plans, so the military fleet will continue to age and there will be an ongoing need to economically maintain this aging fleet. Also, note that this situation is not exclusively an USAF problem but is repeated around the globe.

It is clear from the evidence and the preceding discussion that as aircraft age their maintenance requirements increase. In the Advisory Circular AC 91-60A, *The continued airworthiness of older airplane*, the US Federal Aviation Administration (FAA) notes that it is essential to have regular assessments of the airframe structural integrity as the aircraft ages. Furthermore, additional maintenance of the structural components will be required at structural points—a list of 28 such specific areas is given in the advisory circular. This increased burden includes inspection, repair, as well as engineering design support and results in

- shorter inspection intervals and hence more inspection effort, especially when the aircraft are designed fail safe;
- more frequent replacement of spare parts when components reach their end of life;

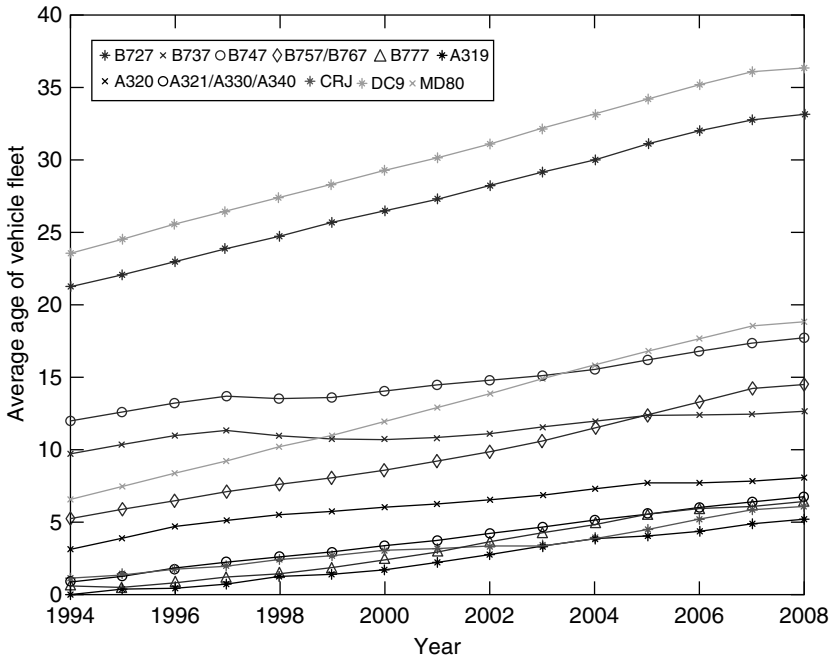

Figure 6. Fleet ages for common passenger jet aircraft.

- higher engineering effort to implement special repair due to poor spare parts availability.

The Air Transport Association (ATA) of America concluded that as an aircraft ages, the additional mandated or recommended maintenance requirements would increase the workload during heavy maintenance visits by up to 50% initially and 10–15% during subsequent visits [42]. However, they also noted that advanced technology methods could offset

Table 1. Aging military aircraft overview

Aircraft type	First service flight	Total in service	Average age
Boeing F/A-18 A/B/C/D Hornet/Super Hornet	1978/1983/1987	1203	13.6
Boeing B-52 A/B/H Stratofortress	1952/1955/1962	94	46.6
Boeing KC-135 E/R/T Stratotanker	1956	568	49/47 (E/R)

MiG-29 (many variants)	1985	1047	
Northrop T-38/A/C	1959/1961	636	
Panavia Tornado IDS	1974	505	

the need for more frequent scheduled inspections. SHM could be an important factor in improving the effectiveness of these inspections by enabling a focused, condition-based maintenance approach to be used.

The identification of critical structures is an evolutionary process and thus damage from critical fatigue or corrosion is often identified in unanticipated locations as the aircraft matures. To guarantee that this type of unexpected event does not lead to catastrophic damage, fleet leaders—the aircraft in a specific fleet that has accumulated the largest number of flights—are analyzed in detail and are used to trigger service bulletins that adjust the maintenance practices for all other aircraft in the fleet. For these scenarios, SHM is probably best applied once the aircraft has begun to manifest its operational-specific inspection needs. Thus, SHM has a role in improving safety and/or minimizing the inspection burden for both new and aging aircraft.

4 MAINTENANCE PRACTICES

4.1 Scheduled maintenance development

Up until this point, examples of metal fatigue failure as they relate to SHM have been discussed for historical and pedagogical reasons. But fatigue in metals is far from the only damage mechanism that influences aircraft structures. It is well recognized that there are three principal sources of aircraft structural damage: fatigue, environmental, and accidental damage (AD) Figure 7. The initial scheduled inspection requirements for these damage sources on a new aircraft are developed through an evaluation process defined in the (Maintenance Steering Group) MSG-3 guidelines document [43]. This document is published by the ATA, but is written collaboratively through the combined efforts of aircraft and engine manufacturers, regulatory agencies, airline, and government organizations. In the case of structural items, the assessment considers the significance of the items to continued airworthiness, susceptibility to various forms of damage, and the degree of difficulty in detecting damage to develop a scheduled structural inspection program.

Once the MSG-3 process is complete, the results are used to develop a maintenance review board report (MRBR), which outlines minimum inspection requirements for a particular airplane type certification. On the basis of the MRBR, the aircraft manufacturers create a maintenance planning data (MPD) document. Thus, one step for SHM to be accepted as part of the initial maintenance procedures is to be recognized within the MSG-3 document. New content in the MSG-3 that will outline the use of SHM is under discussion. Initially, the SHM system may collect data on a real-time basis but would probably

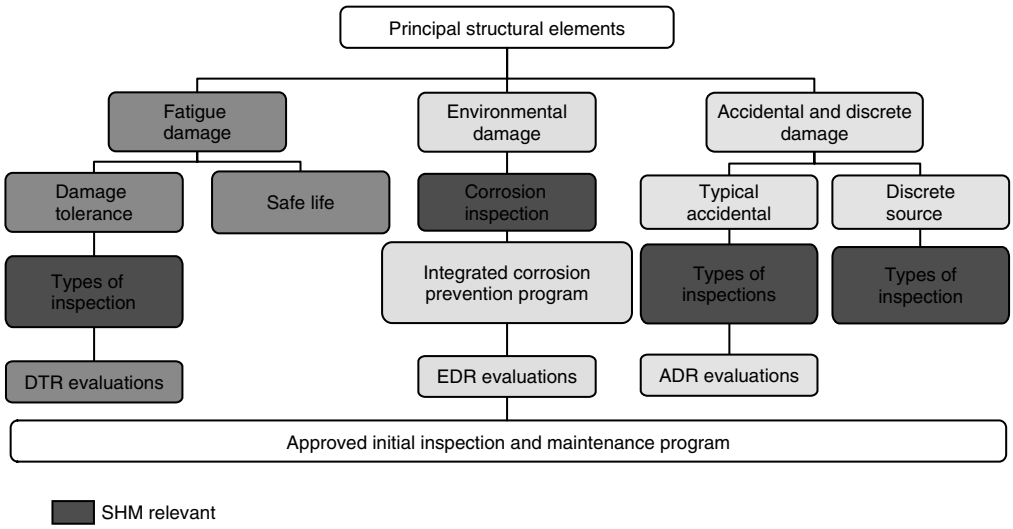

Figure 7. MSG-3 process for developing a maintenance program based on damage sources.

download the data at predetermined MRBR/MPD intervals similar to the traditional structural inspection periods. It is expected that until the SHM systems have been validated through comparative field tests, the traditional maintenance program, as outlined in the MPD document, will be used in tandem with an SHM system. Areas where SHM may become relevant in the MSG-3 process are highlighted in Figure 7.

4.2 Accidental damage

When assessing the inspection requirements for accidental damage, the MSG-3 recommends that all sources of damage such as impact from ground and cargo handling equipment, foreign objects, bird strikes, hail, runway debris, and the artefacts of human error be included in the assessment. This type of damage occurs for metallic as well as composite materials and can be of significant concern and frequency. While inspections due to fatigue damage may be unnecessary for nonmetallic materials, if the aircraft design has been based on a *no-damage growth* design philosophy, AD and environmental damage mechanisms are applicable to all aircraft when they first enter service.

It is important to note that some types of AD have a degree of predictability. AD due to ground vehicle and equipment collisions predominantly occurs in the same locations and therefore concentrates the need for inspections into an area of high rates of incidence. The same scenario of a high incident rate occurs for runway-induced damage from stone impacts in the vicinity of the landing gear and flaps damage due to hail. Impact damage on sensitive aerodynamic structures such as the radome and leading edges of the aerodynamic profiles bear special consideration, making these additional examples, along with the areas of high incidence rates, good candidates for potential SHM applications.

AD events often invoke the need for unscheduled maintenance. Unscheduled maintenance is a basic element of the continued airworthiness maintenance program developed by the commercial aircraft operators in addition to the scheduled maintenance program described above and approved by an appropriate regulatory agency such as the European Aviation Safety Administration (EASA) or FAA [44]. These programs address procedures for correcting discrepancies noted during scheduled maintenance tasks as well as performing unscheduled maintenance to correct issues that arise due to operational malfunction or abnormal operation. For example, the need to perform unscheduled maintenance can be invoked when the aircraft structure is exposed to unforeseen events such as hard landings, overweight landings, tail strikes, or lightning strikes.

Aircraft routinely depart from an airport within the acceptable maximum takeoff weight, but return before sufficient fuel is burned to reduce the aircraft weight below the maximum allowed landing weight. The pilot may, for example, discover the need to return to the airport immediately after takeoff without enough time to burn off sufficient fuel and avoid causing an overweight landing event. When an overweight landing occurs, an inspection of components such as the landing gear and landing gear mounting points is required. The occurrence of a hard landing, high drag, and side-load landings also invoke inspection procedures since the outcome from these events can vary in seriousness from simply causing mild passenger discomfort to situations resulting in serious vehicle damage. Currently, there are few planes that are equipped with even rudimentary aircraft condition monitoring systems (ACMSs) that can indicate the severity of a landing. Commonly, it is the pilot's decision alone, based on his/her impressions of the event, as to whether a structural inspection is necessary following a hard landing. Owing to the paucity of monitored data, guidance to determine if a high drag or side-load landing has occurred is given in terms of qualitative assessment criteria, such as "the airplane skidded on the runway sufficiently to make you think damage occurred." Load exceedance monitoring, aircraft condition monitoring, and other type of SHM systems could be used to help detect and classify the nature of a landing, as well as monitoring, assessing, and advising the maintenance crew on any damage sustained as a result of the event.

4.3 Environmental deterioration

As defined within MSG-3, environmental deterioration is the structural deterioration that occurs because of chemical interaction with the environment. Damage assessment programs need to cover

corrosion, stress corrosion cracking, and deterioration mechanisms that attack nonmetallic materials. After fatigue, corrosion is the second most prevalent reason for aircraft component failure, followed by overload and wear/abrasion. Yet in terms of expense, corrosion is the single most important measure affecting maintenance costs. As previously discussed, we again observe that the level of maintenance depends strongly on the age of an airplane. Breaking the service life of the aircraft into three phases: new, mature, and the aging or postdesign life, we find that for an aircraft experiencing 2500 flight hours per year, that it behaves like "new" for its first five to six years, and then enters a mature phase for five to six years, and beyond this, the airframe enters its aging phase. It is during the aging phase that an aircraft goes through the fastest rate of increase in the aging process, and incurs maximum maintenance expense [45].

There are various forms of corrosion: uniform, pitting, crevice, exfoliation, galvanic, and stress corrosion, and each poses a different problem to aircraft structures. The most pernicious of these is stress corrosion since it is mechanically assisted and leads to cracks that can undermine the component fatigue strength. As a result, *mass loss* is not a good indicator of the detrimental effect that stress corrosion cracking, nor, for that matter, pitting or intergranular corrosion can have on the integrity of a structure. Stress corrosion cracking was found to be particularly troublesome in some early high-strength aluminum alloys such as 7079 and 7075-T6.

Although modern design practices have made significant headway in the design of aircraft to control corrosion through the appropriate choice of materials, application of coatings, effective use of drainage, sealants, and corrosion-inhibiting compounds, there remain areas where inspection is difficult such as hidden corrosion and areas that require additional effort to gain access. Accidental water spillage around galleys and lavatories leads to enhanced corrosion, so they are target areas for SHM corrosion monitoring systems. The environment under which an aircraft operates is also a significant factor that drives corrosion. When the aircraft is operated in a severe environment, the FAA AC 43-4A [46] recommends that inspections are carried out every 15 days (calendar, not flight-hour based) in addition to the daily routine and preflight inspections. These inspections should include trouble areas and internal cavities, which often require removal of access panels and plates. SHM could be an important factor in improving the effectiveness of these inspections, but as we proceed, we will show that SHM is more than just another technique to perform inspection, it is a new approach to maintenance that has implications to a larger operational environment that includes logistic, supply chain, and fleet management.

5 INTEGRATED VEHICLE HEALTH MANAGEMENT

Integrated vehicle health management (IVHM) is defined variously as "the set of activities performed to identify, mitigate, and resolve faults with the vehicle" [47] as well as the act of "monitoring, assessing, and predicting the health of aircraft materials and structures using networks of sophisticated onboard sensors" [48]. Despite differences in the definition of IVHM, there is an agreement that SHM is part of an emerging set of health-management technologies that when combined can radically change how we operate and maintain aircraft. NASA believes that IVHM technologies have the potential to substantially improve aviation safety. Major airframe manufacturers expect that IVHM can reduce the effects of aging aircraft, reduce operational logistic footprints, reduce training requirements, more effectively manage operational objectives with maintenance requirements as well as enable a proactive maintenance response wherein the vehicle is maintained according to a condition-based maintenance (CBM) philosophy and not according to a schedule.

IVHM is more than just SHM and includes the critical element of prognosis. Consider the Joint Strike Fighter (JSF) Program, a example of state of the art aircraft IVHM. Existing and purpose-built sensors supply data that is preprocessed and then submitted to reasoners dedicated to each of the aircraft's major subsystems. There are area-level reasoners and system-level, model-based, reasoners hierarchically partitioned within the IVHM design. Prognosis data is used as input into ground-based management tools, which then optimize the maintenance and manage the

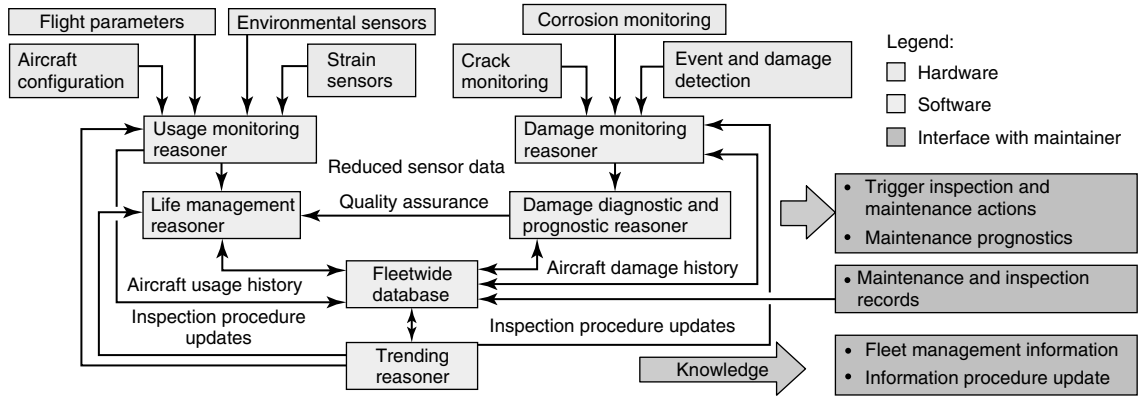

Figure 8. A Boeing commercial aircraft IVHM approach that incorporates SHM functionality. [Reproduced with permission from Ref. 49. © The Boeing Company, 2008.]

supply chain for individual vehicles as well as the fleet.

In the commercial sector, IVHM capabilities currently exist on Boeing 777 and 747-400 airplanes, but these IVHM systems do not presently include SHM functionality. Figure 8 shows a Boeing concept for including SHM prognostic capability as part of an IVHM system. A variety of sensor and flight parameters address the three fundamental aircraft structural damage mechanisms as shown in Figure 7. Load monitoring includes monitoring of strain, and a variety of environmental parameters such as temperature and various flight parameters. These data are then used to establish airframe exposure. Reasoners are used to perform both diagnosis and prognosis, which then drive ground-based decision algorithms for triggering inspections, maintenance actions, and planning at both the platform and fleet level. Figure 9 illustrates where the onboard components of such an SHM system would be included within the existing airplane health-management architecture.

The present Boeing 777 and 747-400 IVHM systems are third and fourth generations of vehicle health-management systems that began from humble beginnings, Figure 10. In the early 1980s, airplane systems and flight decks were transitioning from electromechanical instruments to software-intensive digital computers. As a consequence, significant technological evolution of the nature of the airplane system faults changed dramatically. A serious problem arose as mechanics were unable to use their traditional approach to troubleshooting. Equipment was being replaced under a *shotgun* mentality that lead to a large number of no *fault-found* when the replaced avionics item was returned for repair. In response, industry cooperated with the Aeronautical Radio Inc (ARINC) to develop a standard that provided guidance on how avionics equipment could

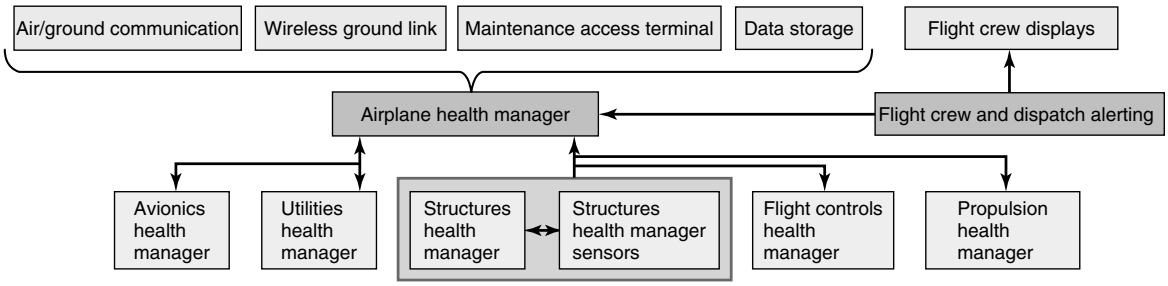

Figure 9. The schematic for the onboard portion of an integrated vehicle health-management approach. [Reproduced with permission from Ref. 49. © The Boeing Company, 2008.]

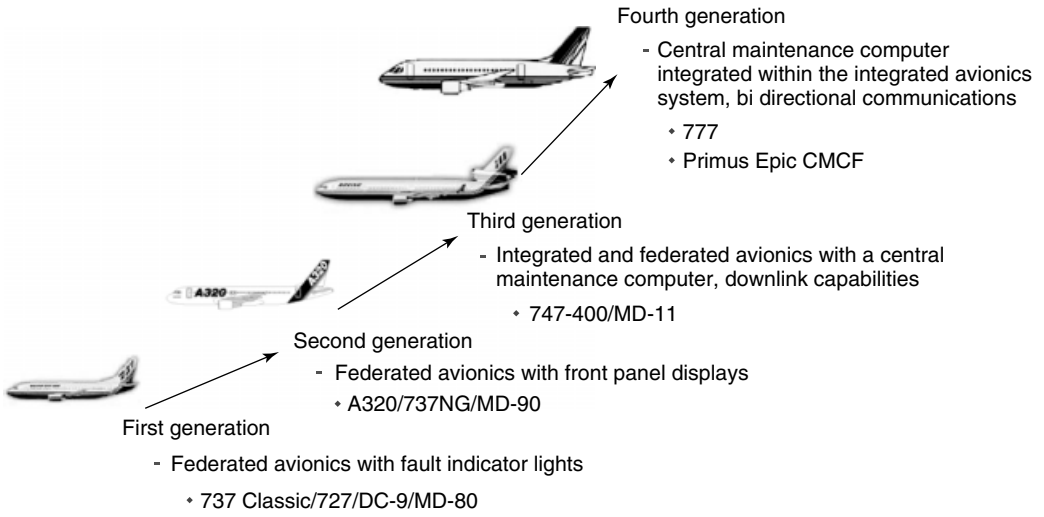

Figure 10. Vehicle health-management evolution in commercial aircraft.

make a self-check obviating the need for external test equipment: ARINC-604 *Guidance for design and use of built-in test equipment* [21].

The Boeing 747-400 pushed the concept forward by consolidating the symptoms from multiple line replaceable units (LRU) into a central maintenance computer (CMC), which could act as a centralized diagnostics reasoner. In the Boeing 777 onboard maintenance system, an Aircraft condition monitoring system (ACMS) provides additional capabilities in the form of simple prognosis. The ACMS is used to trend data and record specific data sets based on triggering conditions. This has proven to be useful for life extension of engines, monitoring fuel consumption, troubleshooting intermittent problems and trying to predicting failure events before they occur. The Boeing 787 will also use the Honeywell patented CMC and ACMS technologies within a networking infrastructure that allows airborne and onboard function to interact with ground-based tools. As indicated by Figure 9, the SHM functionality can be added into these IVHM architectures as a member system enhancing the value and providing a truly integrated and complete vehicle health-management system. It should be noted that alternative approaches and architectures for IVHM systems have been explored. Most notably, the Open System Architecture for Condition-based Maintenance (OSA/CBM) (*see* **Open Systems Architecture for Condition-based Maintenance**), based on the machinery information management open system alliance (MIMOSA) [49]. This approach has received significant research attention but it has yet to experience the same level of aerospace industry acceptance.

As the IVHM system grows in value, by providing a more complete awareness of the vehicle's health or a greater degree of future state prediction, so does the value of e-enabled operations. With propulsion systems leading the way, the powerful combination of IVHM, information technology, and modern network communications is poised to change the entire process of how the commercial air transport industry manage their assets. It will be an e-enabled maintenance revolution. Advanced knowledge of when a system or component is going to fail in combination with a mitigation strategy, such as positioning replacement parts where they can be installed with the least interruption to service, will result in dramatically fewer maintenance delays and flight cancellations. However, for e-enabled maintenance to succeed, it must be able to exploit a foundation of proactive and predictive maintenance, a requirement that SHM supports.

6 CONCLUSION

A number of examples have been given where SHM systems can be used to supplement or replace existing

inspection approaches to improve safety and/or minimize the inspection burden. Discussions on when in an aircraft's life-cycle SHM solutions should be introduced continue but a few conclusions seem clear. Load monitoring can be beneficially used when an aircraft enters service to monitor an aircraft's operational conditions and through numerical modeling estimate the accumulated loading experienced at any structural location. This monitoring would also ensure that loads exceeding the assumed design spectrum are appropriately noted and used to adjusted inspection procedures. AD that occurs randomly in time, but predictably in a certain area, is a scenario where SHM can be beneficially applied to both new and older planes. SHM could be an important factor in improving the effectiveness and reducing the burden of additional inspection that will inevitably result as the commercial aircraft fleets continue to age. As a member system within an IVHM implementation, SHM is a significant component of a truly integrated health-management approach where e-enabled maintenance could exploit the diagnostic and prognostic capabilities of the intelligent vehicle and dramatically change the aircraft support processes within a network centric model. In the future, SHM could play a significant role in how airplanes are designed, controlled, and tasked. SHM technologies will enable an intelligent vehicle scenario where the ability to automate, reconfigure, and adapt the vehicle has a major impact on operational scenarios.

Chapter 118
The Character of SHM in Civil Engineering

Helmut Wenzel
VCE Holding GmbH, Vienna, Austria

1 INTRODUCTION

Bridges are the flagships of civil engineering. They attract the highest attention within the engineering community. This is due to their small safety margins and their great exposure to the public. Early bridges were the backbone of powerful empires from China to Rome and the Incas in America. Currently, the transportation infrastructure is directly related to the economic success of a nation. Bridges are admired not only for their function but also primarily for their aesthetic impact. Imagine New York without bridges, Japan without the Honshu Shikoku project, or Europe without the Greatbelt Link. This article deals with the preservation and maintenance of these important elements of modern society.

Structural health monitoring (SHM) is the implementation of a damage identification strategy to the civil engineering infrastructure. Damage is defined as changes to the material and/or geometric properties of these systems, including changes to the boundary conditions and system connectivity. Damage affects the current or future performance of these systems.

The damage identification process is generally structured into levels:

1. damage detection, where the presence of damage is identified;
2. damage location, where the location of the damage is determined;
3. damage typification, where the type of damage is determined; and
4. damage extent, where the severity of damage is assessed.

Extensive literature has developed on SHM over the last 20 years. This field has matured to a point where several accepted general principles have emerged. Nevertheless, these principles are still being challenged and further developed by various groups of interest. The strategies in mechanical engineering or aerospace are taking different approaches. Nevertheless, the civil engineering community can considerably benefit from these efforts.

Separate approaches are necessary while considering each civil engineering structure as a prototype.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

2 HEALTH MONITORING FOR CIVIL ENGINEERING STRUCTURES

In civil engineering, the procedure and tools are best developed for bridges. Some kind of SHM always existed in this sector. Figure 1 shows how these procedures have developed from simple inspection routines to highly sophisticated monitoring campaigns.

The extent of monitoring mainly depends on the required results. Currently, five levels are used in order to determine the depths of investigation. These are as follows:

Level 1: rating
It represents the conventional assessment of the structure starting with a visual field inspection that provides a subjective impression of the condition of the structure. Some preliminary analytical investigation is performed to provide a rating as a basis for decisions. This would be the typical application of a bridge management system like PONTIS or DANBRO. Many bridge owners use databases to store the results.

Level 2: condition assessment
A rough visual field inspection has to be an element of any SHM campaign. After that a decision has to be made whether the conventional approach is

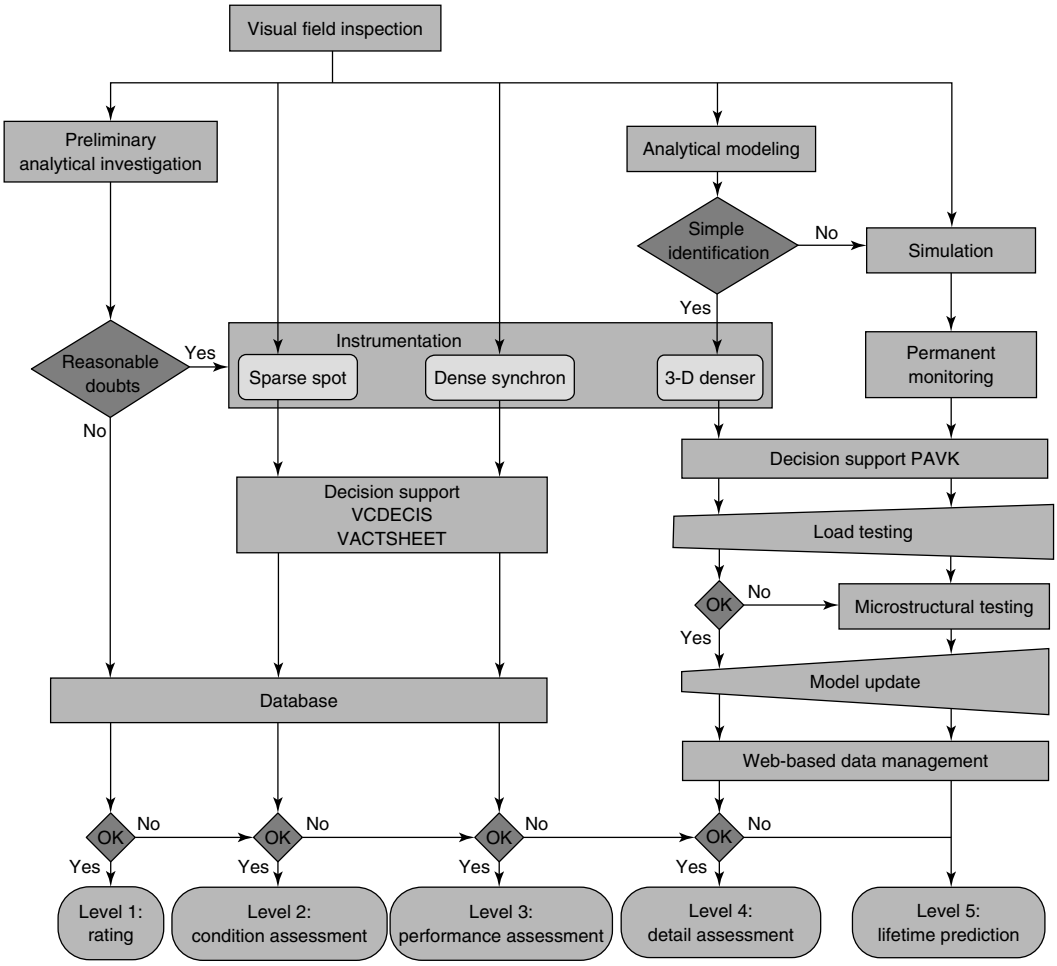

Figure 1. Typical hierarchical concept for SHM procedure for bridges.

satisfactory or an extended or even sophisticated additional approach is to be taken. This determines the type and quantity of instrumentation. For condition assessment, a simple instrumentation is sufficient and a simple decision support system will provide the necessary additional information. Storage and treatment of data should also be done in the existing database. A link to existing conventional tools is available. The monitoring can be performed at single spots only.

Level 3: performance assessment
This intermediate level uses the same procedure described under level 2. The level of assessment and performance elaboration in the decision support process is considerably higher as additional information like mode shapes is measured and elaborated. This provides additional indicators for the assessment and demonstrates the performance of the structure. It obviously requires a denser instrumentation and synchronous monitoring.

Level 4: detail assessment and rating
The next step is to establish an analytical model representing the structure. The model is compared with the monitoring results. In case that identification is simple, a step back toward level 3 might be taken. In case phenomena that cannot be explained from the records are detected, further steps have to be taken to deal with the situation. The most obvious thing is to introduce a permanent record over some period of time to capture the necessary phenomena valid for this specific case. Load testing also has been proven successful to establish performance parameters. With these results, a simple model update can be performed to assess the results and provide a rating. Extensive monitoring is required. The records shall cover at least 24 h, but shall rather be much longer to capture environment and traffic situations.

Level 5: lifetime prediction
For a serious lifetime prediction, the records available have to be long enough to cover at least three cycles relevant for the structure. This is normally in the order of three years. Simulation should be run from the analytical model to achieve a theoretical performance to be compared with. To handle the major quantity of data, special software for decision support is required. Load testing should be targeted and extensive. In addition, microstructural testing might be useful in order to look into the performance of individual elements of a structure. The update process will be extensive considering several conditions of the structure. This includes, in particular, the loaded and unloaded case and all the nonlinearities involved. In the case of reasonable doubts, this monitoring system shall be operated on-line and web based with a warning computed by the decision support. The final lifetime prediction can then be performed as described in **Condition Compensation in Frequency Analyses—a Basis for Damage Detection**.

The costs related to these procedures are given in Figure 2. These costs mainly depend on the extent

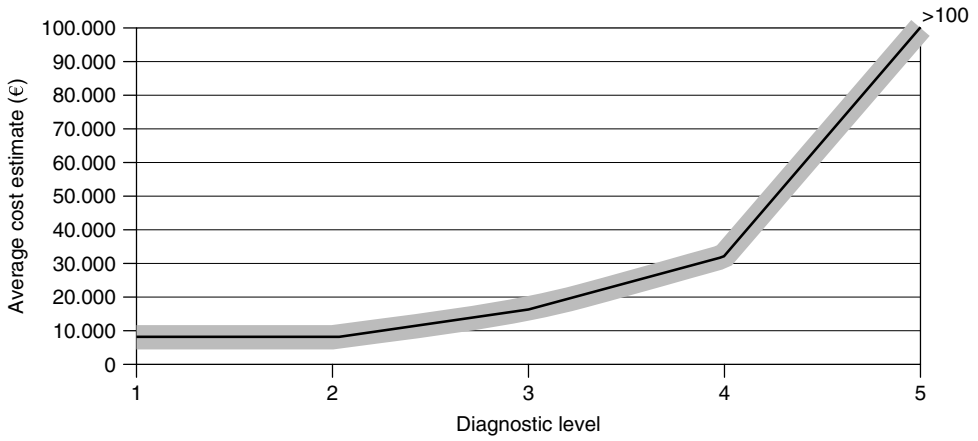

Figure 2. Cost of monitoring campaigns for a typical three-span bridge (€, base 2006).

of the monitoring campaign and the number of man hours to be invested in modeling, simulation, and update procedures. The figures provided in the graph are based on the prices in 2006 for a typical three-span bridge with an average length of 150 m. The prices can also be influenced by the number of spans, by the type of the structure, and also, in particular, by the condition for the monitoring campaign. It is expected that the prices will be rather reduced than increased. This can happen through the introduction of time-saving modeling procedures and sophisticated monitoring software. Nevertheless, these are still to be developed.

3 CLIENT REQUIREMENTS AND MOTIVATION

The construction sector is conservative. The implementation of new technologies needs a clear requirement and motivation to be accepted by owners and operators. It has been recognized that the current practice does not satisfy the needs of shrinking budgets and aging structures. Nevertheless, it satisfies valid codes and standards. Before a breakthrough in the implementation of new technologies can happen, the requirements and motivation have to be clearly understood and argued against potential clients.

There are three main drivers in the promotion of SHM. The motivation to apply and order services based on the new technologies are as follows:

- responsibility-driven motivation, which means that the new methods, to become standard applications, are supported by codes, standards, and guidelines;
- economically driven motivations, such as in situations where a ranking of structures to be rehabilitated is necessary because of insufficient budget available or the need to use a structure for a certain time period longer than designed for; and
- curiosity-driven motivations comprise those cases where clients would like to know more about their important and complicated structures. Results can also lead to better planning for future structures.

From the above-mentioned motivation, the following requirements can be derived; these are typical services requested from the technology providers.

- A certificate that a structure satisfies the requirements with respect to codes, standards, and guidelines comprises a main business opportunity. Many recommendations already consider the increase in maintenance periods in case these measurements are taken. The provision of such certificates by engineers is common practice in Europe. Other parts of the world do not apply this system. It has led to an impressive evolution of bridge technology in Europe, which has been exported worldwide. It creates the environment for quality construction.
- The transfer of liabilities and responsibilities for structures in terms of technical and operational matters takes place with the huge privatization drive that we can observe currently. Clients are systematically transferring the stock of structures into private hands. The new players involved are open to new applications that are able to support innovative and economic maintenance strategies.
- Special structures require special attention. The necessary top expertise may not always be available with every owner or operator. The top experts for each region require the newest technologies for their work.
- A shortage in capacities of personnel to carry out the routine maintenance and assessment works at the bridge stock also leads to new opportunities. As these services are normally tendered, new technologies might have an economic and technology edge.
- In case of emergency or accidents, the generation of a secure situation is desired by affected owners. Any assessment based on the results of measurements is more likely to be accepted than subjective assessment by the expert. The clients want to sleep well because somebody else is permanently watching and assessing their structures.
- *Ad hoc* assessment in case of doubts or emergency also comprises this application area. The subjective conventional assessment produces too many negative scores on structures and doubts are raised. A quantitative assessment is desired.
- The optimization of maintenance concepts requires input on which this process can be performed. The more data are available, the better the organization will be and better maintenance concepts will be available. The reduction of the remaining

risks helps to make decisions with lower safety margins.
- The determination of priorities, through a quantification based on measurements, helps to satisfy the growing demand in combination with shrinking budgets. This assessment can come up with better scores, minimizing the number of structures requiring immediate intervention. Decision support for investment planning can be offered on the basis of the above-mentioned services. Every new measurement improves the database and as such improves the quality of the results and supports the necessary decision making.
- Life-cycle cost determination helps to increase the periods where budgetary planning is necessary. The demand for retrofit and maintenance can be estimated over the whole life period of a structure or even a fleet of structures.
- The direct link of structural performance to the operation of a structure can be established. Very often information about an optimal speed or frequency in the traffic can be determined, which shall be used by the operation personnel of a transportation infrastructure and communicated to the drivers through telematic devices.
- Hot-spot identification technologies are very often requested in case the weakest point of the system or a significant accumulation of incidents is observed. Clients would like to know where to look first and what the background of certain phenomena could be.
- The prediction of structural performance for future loading scenarios is a further specific item requested, particularly when a nonlinear behavior can be expected, special expertise becomes necessary.
- Fleet observation when the number of structures is huge is desired to improve the quality of assessment. For this the conception has to be subdivided into stages depending on the depth of information required.

The selection of a suitable observation concept has to be based on mainly external factors. These are the number of structures to be observed in combination with the budget available. For this purpose, it is necessary to offer services on increasing quality levels. The levels can be subdivided into spot, periodic, permanent, and on-line assessment campaigns at structures. The respective features are as follows:

- A spot observation shall comprise a very quick measurement campaign with a few simple-to-handle sensors only. It shall bring information on the general condition of a structure in order to create a ranking.
- Periodic assessment means a measurement campaign on a structure, which is repeated after a specified period of time, to generate information on the performance over time. This spot information might comprise rather long periods.
- Permanent observation and assessment of structures becomes necessary when certain limits are passed. This observation allows a very detailed assessment based on permanent recordings and can help to implement quick decision making.
- On-line observation and assessment allows warning through electronic media, be it an SMS in the simple case or an on-line status through the Internet. Decisions might be taken by the computer based on the measurement data. These alert systems will only be applied at extremely critical structures.

In general, it has to be stated that clients need and desire a support of their work and not issues that makes it more complicated. Also, in this respect, the procedures have to be carefully watched and permanently improved. The information policy also plays a major role in the client–consultant relationship. The new methodologies are rather complex and require a deep understanding of structural dynamics, physics, and measurement techniques. Owing to the fact that this expertise is rarely available at the owners engineering department, the fear of being exposed to unknown black box applications has to be taken off their shoulders. On the other hand, they are spending considerable amount of money and would like to be informed frequently about progress and results. Therefore, we have to assure them that the technology part is in good and competent hands and that they will receive the necessary information they desire. The best results have been achieved with very simple reporting techniques. A periodic report received by e-mail comprising single page information is preferred. The example shown in Figure 3 provides such a typical weekly report. The main information is provided in a single window, where upper and lower normalized thresholds are given and the measurement results within this period are placed

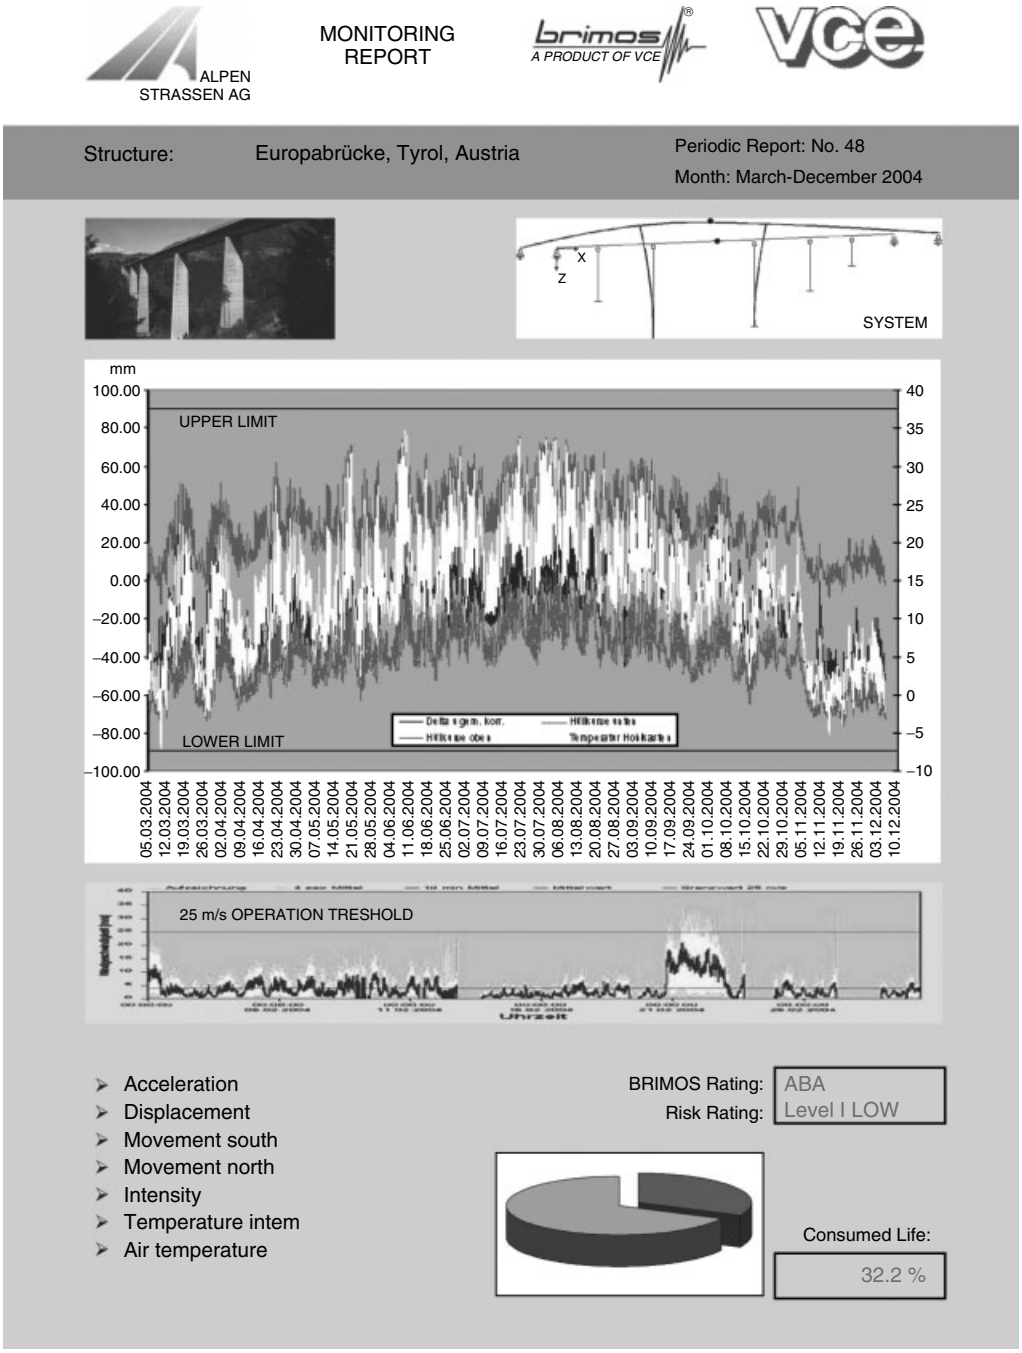

Figure 3. Periodic SHM report of a bridge.

within these thresholds. With one look at this graph, the personnel can immediately see whether any of the thresholds has been exceeded. The client is satisfied because all indicators are green and the ordered observation is permanently working.

The periodic report should provide on this single page the following information:

- A photo and a system plot of the structure under observation for easy and quick identification.
- A window with the periodic results placed within the relevant thresholds over the observation period.
- Eventually, a second window with special information required by the client, such as wind speed information or any other quantity desired.
- Finally, a rating shall be provided, which is based on the measurements taken in the reporting period. This rating shall enable the client to immediately see whether any changes have happened.
- Eventually, the specification of a remaining life capacity can be provided if the necessary data are recorded.

Besides this one-page record for the client, a scientific report shall be generated by the system for the expert. This shall enable a quick assessment of all the single measurements in order to obtain necessary expertise or learn from the performance. Every year, on an average, the system shall be calibrated with the information gained. This might also comprise a change in the rating and will update the remaining life capacity based on the existing knowledge.

Chapter 120
The Influence of Environmental Factors

Helmut Wenzel
VCE Holding GmbH, Vienna, Austria

1 INTRODUCTION

The following analysis is based on investigations on the Europabrücke—a well-known Austrian steel bridge near Innsbruck, opened in 1963—which is part of one of the main alpine north–south routes for urban and freight traffic. A long-term preoccupation of VCE with BRIMOS (BRIdge MOnitoring System) on the Europabrücke (since 1997) led to the installation of a permanent monitoring system in 2003 [1]. Currently, the bridge is stressed by more than 30 000 motor vehicles per day (approximately 20% freight traffic). The superstructure is represented by a steel box girder (width = 10 m; variable height along the bridge length 4.70–7.70 m) and an orthotropic deck and bottom plate (Figure 1). This motorway bridge with six spans of differing lengths (the longest span of 198 m, being supported by piers with an elevation of 190 m) and a total length of 657 m comprises six lanes, three in each direction distributed over a width of almost 25 m.

To reach the already defined goals, a permanent monitoring system has been developed in a stepwise manner (Figure 2). It consists of 24 measuring channels (sampling rate 100 Hz) representing the accelerations of the main span, the pier, and the cantilever, and the dilatation, wind speed and direction, and temperatures of the abutment at several locations.

2 EXEMPLARY PROCEDURE OF ENVIRONMENTAL COMPENSATION

The bridge's reference sensor (3-D forced balance accelerometer) is installed within the main span, at a distance of 0.4 times of the span's length from pier II. At this base point, global stiffness and its dependence to several environmental influences are assessed (sampling rate = 100 Hz, file length = 330 s).

By evaluating the results (frequency spectra) of several measurements, telescoping them together and

Figure 1. Europabrücke—overview.

viewing them from above (so-called trendcards), the following visuals are obtained (Figure 3), which exemplarily show the main span's relevant vertical stiffness patterns of a particular day with a distinctive progression of temperature.

For the sake of completeness, the corresponding frequency spectra themselves are shown in Figure 4, again over a period of this day. An individual procedure has been developed in [2], which contains some measurement preconditioning (offset elimination and band-pass filtering). To enable a more stabilized automatically performed peak picking in different ranges of frequency, the response spectra are smoothed in the course of frequency assessment.

The permanent monitoring system exhibits a remarkable loading impact, as the bridge is currently stressed by more than 30 000 motor vehicles per day (approximately 20% of them constitute freight traffic). By applying the previously described method to the reference sensor's measurement data for the whole day, a progression of stiffness, which consists of 281 single peaks is obtained (Figure 5a, b) and represents randomly occurring ambient and forced vibration conditions (scatter diagram).

The complementary relation between stiffness and the air temperature (registered at the bridge's base point directly above the pier II) is obvious and can be interpreted as a long sinusoidal wave of the main span in the vertical direction. In the course of the described procedure, it should be considered to omit band-pass filtering and replace it by a further optimized smoothing of the frequency spectra in order to stabilize the accuracy of peak picking.

3 STIFFNESS VERSUS TEMPERATURE

To describe the verified phenomenon mechanically, we focus on the temperature dependence of the roadbed's asphalt layer, since the change of steel characteristics under varying climate conditions is negligible. In the first step, a characteristic relationship of the dynamic Young's modulus in dependence of temperature is used [3].

Owing to this relation, temperature-sensitive asphalt layer is implemented into the cross sections of the global structural analysis model, leading to a distinctive progression of the flexural rigidity of the midspan (Figure 6a, b).

$$f_i = \frac{\lambda_i^2}{2\pi L^2}\left(\frac{EI}{m}\right)^{1/2} \tag{1}$$

According to the widely known equation (1), the frequency of vibration is proportional to the square root of the moment of inertia [4]. For that reason, a frequency curve needs to be generated (Figure 7b) for the next step, when the temperature-based stiffness path is eliminated from the overall trend (Figure 7a–c).

The obtained trend shows very clearly the remaining impact due to the freight traffic itself, which has maximum effect during the time between 5 a.m. and 10 p.m., when trucks pass over the bridge; this causes the two characteristic offsets during the course of the day as shown in Figure 8.

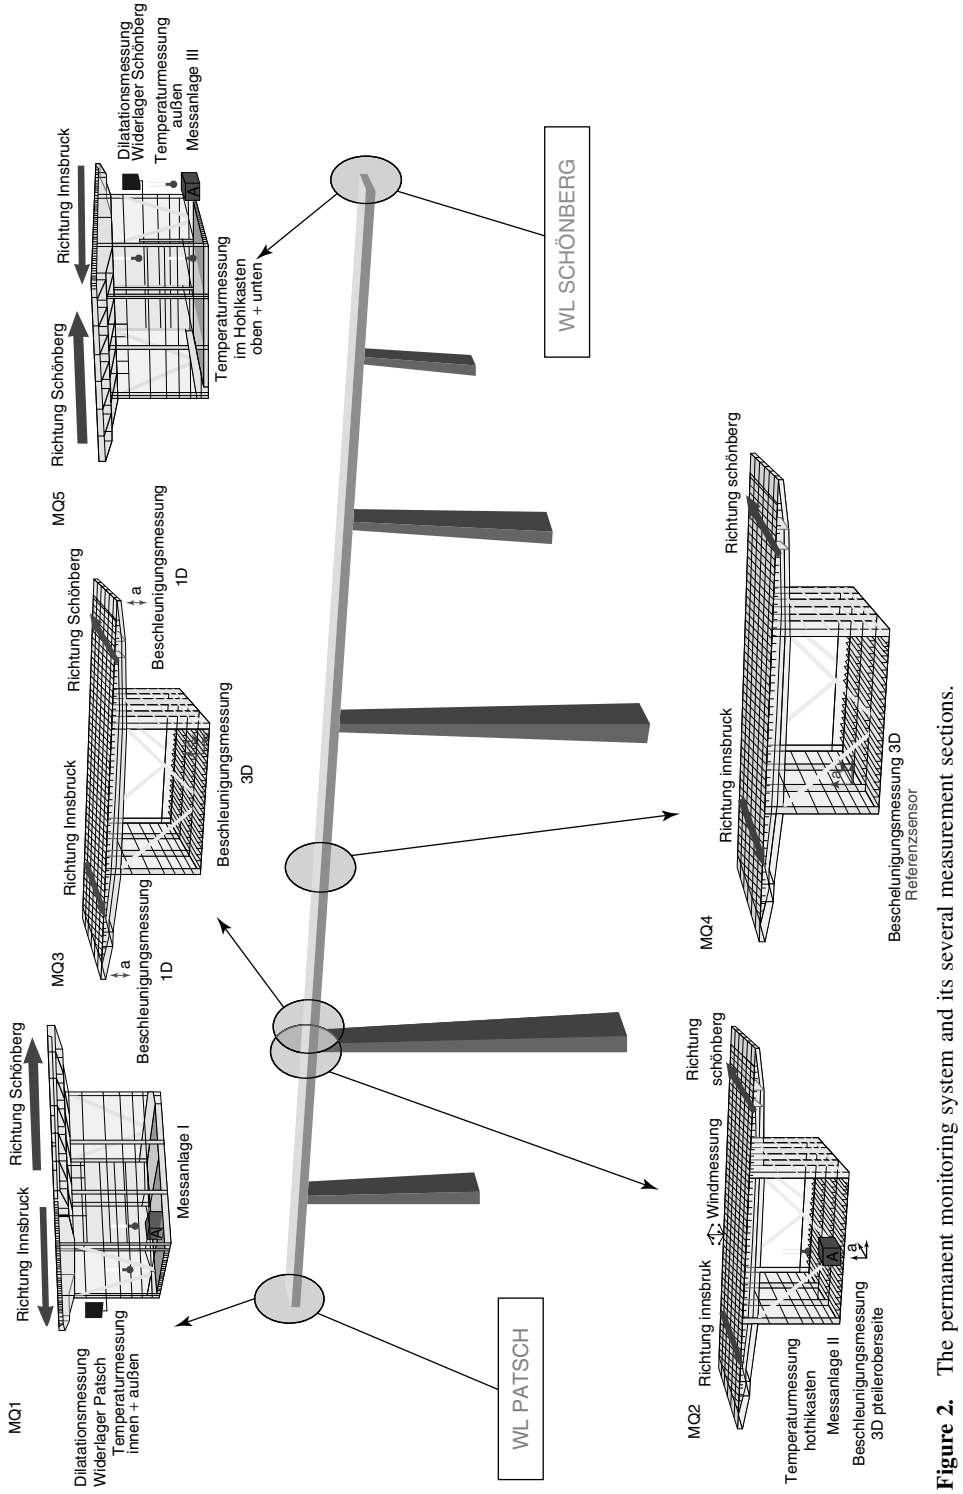

Figure 2. The permanent monitoring system and its several measurement sections.

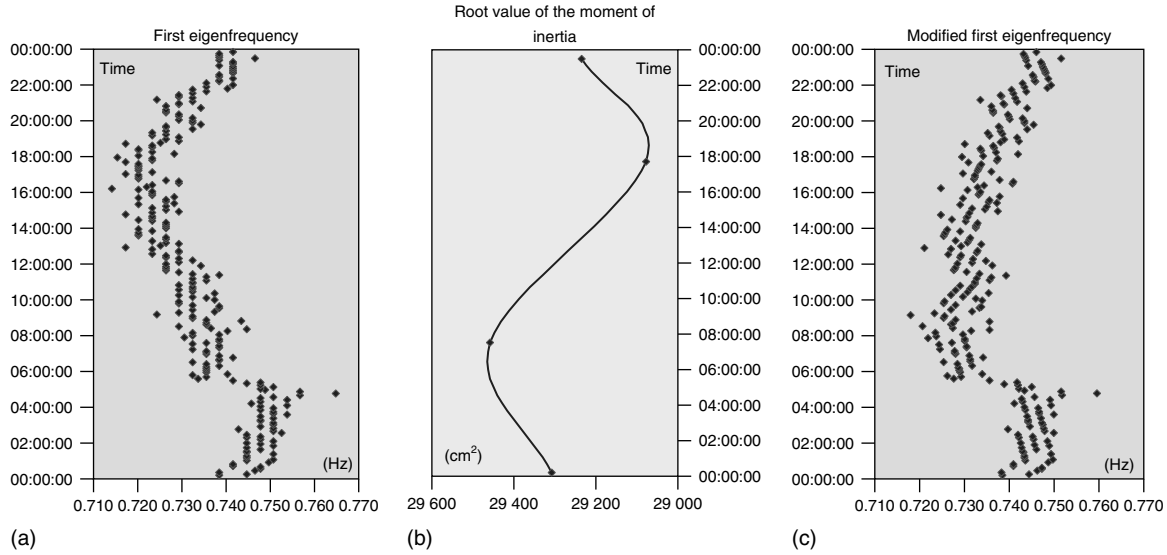

Figure 7. Pattern of the first eigenfrequency before (a) and after (c) compensation of temperature (b).

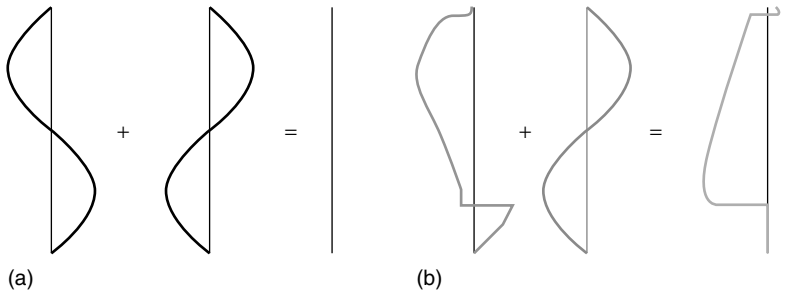

Figure 8. Comparison of expected (a) theoretical and (b) actual (the pattern considering traffic and other loads) consequences of temperature-compensated natural frequency patterns.

4 COMPENSATION OF ADDITIONAL (MOVING) MASSES

The modified trend of the stiffness of the main span includes a number of characteristics of the prevailing freight traffic progression. Unfortunately, traffic data from the competent authorities are available only per hour (Figure 9). For some introductive exploration on approximate additional mass compensation, further steps need to be taken.

The frequency of vibration, based on equation (1) again, is inversely proportional to the square root of the mass. This means that live loads cause an increase in effective mass, which leads to hourly calculated factors, to modify the fluctuating frequency. Owing to this relation, the scattered trend of frequency is straightened in dependence of modal contribution of trucks per hour (Figure 10).

In fact, the present configuration of the permanent monitoring system makes it possible to develop a more sophisticated and more reliable, method strictly based on the measurement data. Forced balance accelerometers located at a defined distance along the cantilever's outer edges—in both directions of the traffic flow—enable the verification of recurring truck passages and their related velocity and tonnage without any disturbance to the traffic. A dynamic freight traffic registration system was

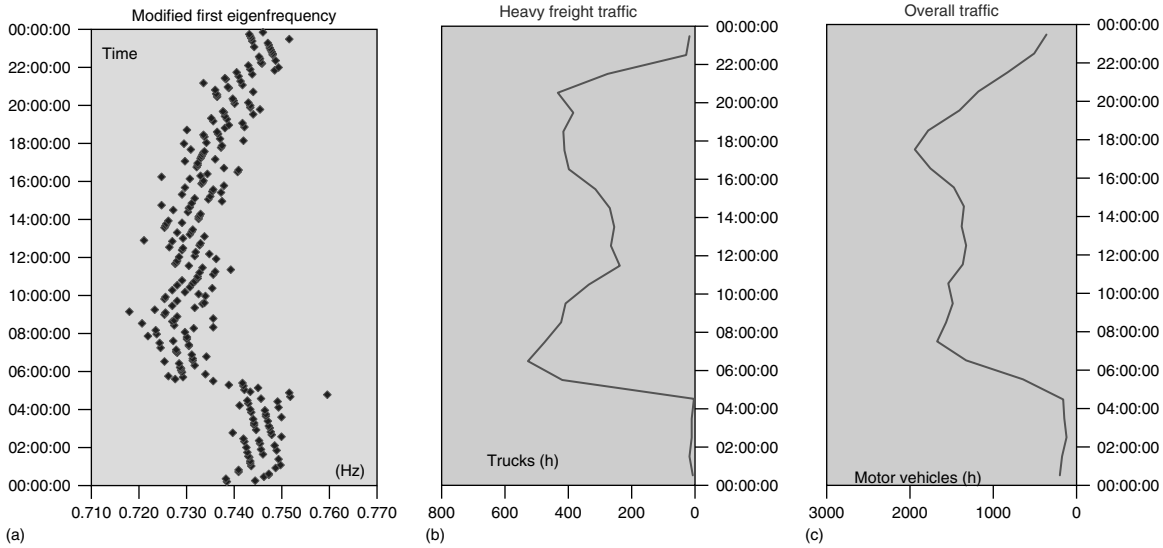

Figure 9. Modified pattern of stiffness (a), strongly affected by traffic loading (b, c) (moving additional masses as measured by the monitoring system).

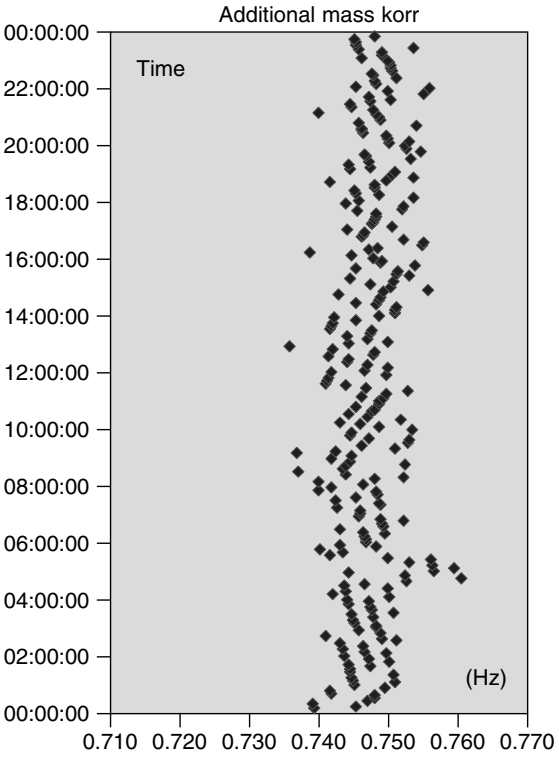

Figure 10. Stiffness pattern after approximate compensation of additional masses.

developed (a certain pattern-recognition procedure as introduced in [5]), which utilizes accelerometer-based methods to reproduce cantilever deformations. In this manner, the moving loads within each measurement file—passing the main span simultaneously—could be identified; this leads to a shifting of the single peak in the frequency response spectrum, which represents the registered time history of each measurement file (Figure 11).

5 CONCLUSIONS

As permanent monitoring systems produce huge amount of data, they have to be processed systematically in order to exploit the information fully. For easy handling, it is proposed that statistically based threshold levels are calculated (Figure 12). In this manner, continuous monitoring systems that provide information about changed modal parameters under "normal" operational conditions can be used to trigger warning and alarm levels with regard to damage.

The acquisition and elaboration of the measurements that are provided by the installed instrumentation allow the setting up of a structural behavior model that is considered to be the "regular model" (baseline model). The periodic analysis of

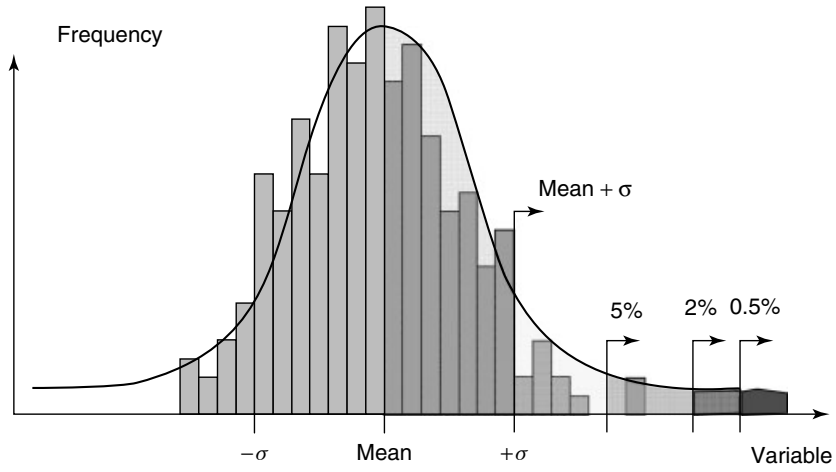

Figure 11. Histogram and best-fit distribution-based determination of threshold values.

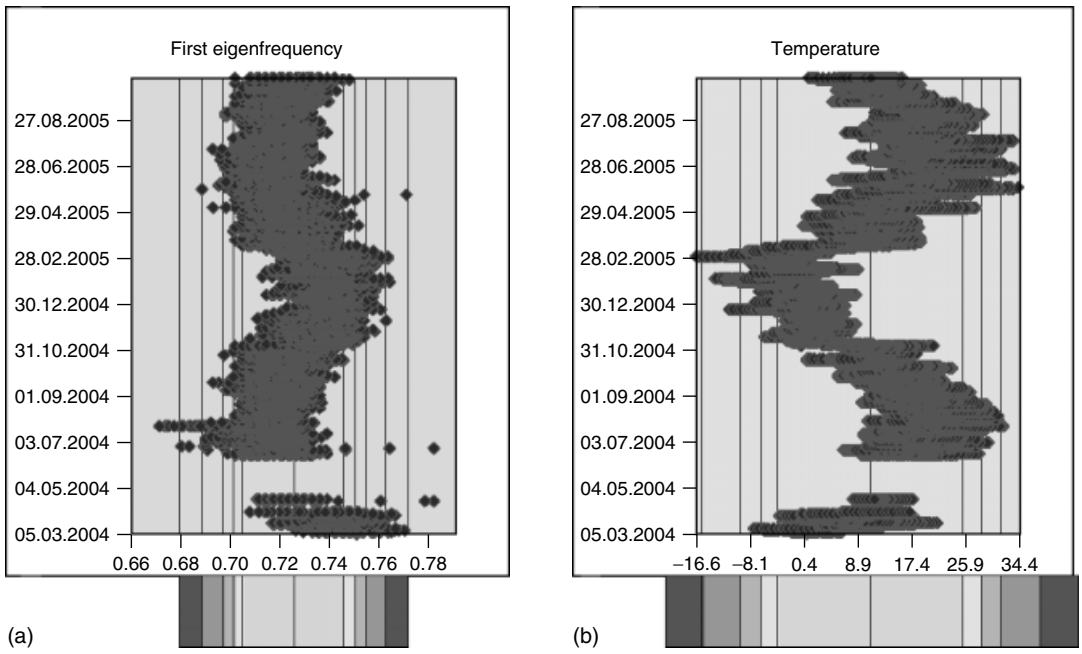

Figure 12. Response for 18 months using threshold levels (a) (statistical time history) with 5/2.75/2.5/1/0.135% probability of exceedance Related temperature (b).

the acquired measurements and their comparison with the baseline model help to point out indicators of potential structural damages. Periodic surveys of the cause quantities, moreover, allow setting up statistical models of the structural behavior, where the structural response is statistically correlated to the trend of the cause quantities. These models allow a control in time of the structural response by locating the "weight" of the cause quantities. The definition of alert threshold levels from an analysis of historical database (e.g., extreme-value analysis) may thus be illustrated.

6 OUTLOOK

The discussed approach—benefited by permanent monitoring—allows the expected goals to be reached, even if the results already obtained with the applied methods are somewhat approximate in nature. The results are quite promising, although the approach uses the effects of air temperature instead of that of structural elements. This approach represents an innovative method in the assessment of stiffness, which is appropriate for long-term application. The goal of generating frequency progressions over time without major environmental and operational impact has come within reach.

The procedure can be optimized progressively, once the already introduced cantilever-sensor-based approach is implemented.

Chapter 119
Ambient Vibration Monitoring

Helmut Wenzel
VCE Holding GmbH, Vienna, Austria

1 CONSERVATIVE DESIGN

The monitoring of over 400 bridges clearly shows different behavior in structures designed following different philosophies. Bridges designed conservatively are not affected by dynamic phenomena that generate concern or trigger damage. Bridges with designs that are constrained by economic considerations very often do not have any reserves to cover the extraordinary loads that they are subjected to in reality. The difference in dynamics becomes obvious in Figures 1 and 2. Conservative bridges show a high system damping with distinct characteristics. Economic designs very often result in resonance in certain areas. This resonance might have a very local and limited effect, but it leads to damage in structures over time.

From bridge management, we know that an additional investment in 10% higher quality makes a difference of over 200% in costs over the life cycle of a bridge of 100 years. Drastic examples include a bridge composed of single-span I-girders, designed to the limit, which has consumed 220% of the investment costs in retrofit over a period of 25 years. This may be compared with the resistance of a duly designed box girder bridge that survives a displacement of a single pier of 110 cm that could be retrofitted at reasonable costs.

2 EXTERNAL VERSUS INTERNAL PRESTRESSING

Damage found on grouted internal cables triggered a dramatic change in design philosophy. Some countries, like Germany, specified that new bridges have to be built using external cables only. This is for the purpose of inspectability and eventual replacement. The experience gained while testing 30 bridges built in the late 1950s and early 1960s showed that damage of the cables was found in only one of the structures.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

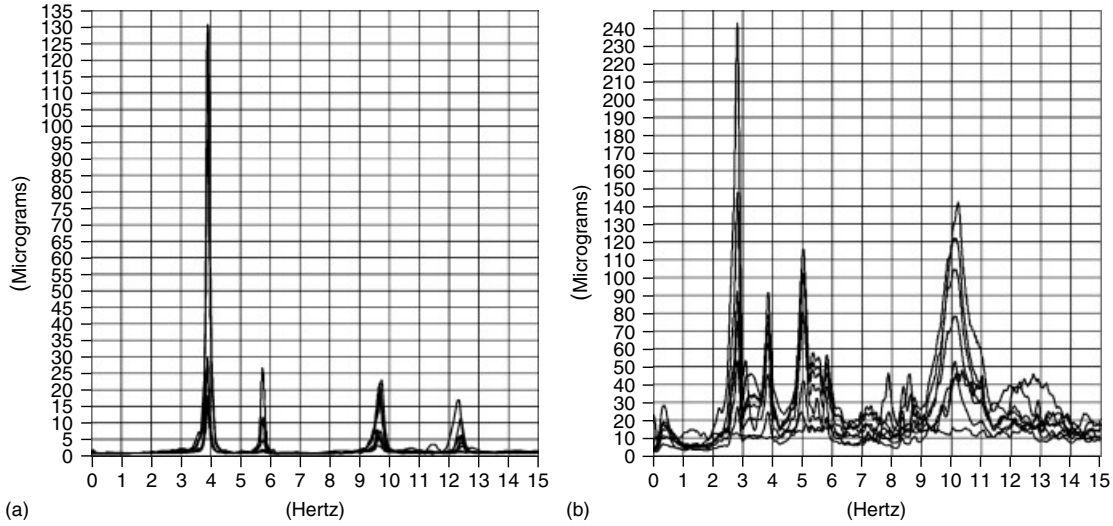

Figure 1. Spectrum of a sound bridge (a) and spectrum of a damaged bridge (b).

(a)

(b)

Figure 2. Resistant box girder (a) and costly I-girders (b).

In all other bridges where damage was suspected, no evidence of corrosion or wire breakage had been detected. The only damaged bridge also was far from malfunctioning. On the other hand, the bridges with external prestressing often show cracks in the anchoring parts and are often unequally stressed. The best results have been received on bridges where grouted tendons embedded in concrete in combination with external cables had been chosen.

3 INFLUENCE OF TEMPERATURE

The design codes for bridges provide clear instruction as to how to consider the temperature effect in bridge design. These instructions normally give a high and low temperature to be considered, and eventually a temperature gradient between the bottom and top of a structure. No reference is made to the type of bridge or the material used. Monitoring provides the chance to exactly record the actual effects of temperature on structures. The lessons learned are actually easy to accept:

- slender structures react very close to the provisions of the codes;
- stiff structures very often deviate considerably from the expected stress distribution;

- the temperature gradients actually recorded on stiff structures by far exceed the values of the design;
- temperature load cases can be the decisive load cases; and
- temperature changes do not trigger a linear behavior. A clear stiffening effect is recorded below 5 °C.

The stiffness of concrete bridges depends on temperature. The relation is given in Figure 3, which shows an almost bilinear condition measured on a classical posttensioned concrete box girder bridge. This has to be considered in the interpretation of monitoring results.

Steel bridges show quick reactions on changing temperatures. The records of a 5-m-high steel box girder are shown in Figure 4. There is a difference between heating or cooling periods. The sensors represent the outside temperature and the inside temperature on the bottom slab and the deck slab. The patterns shown here are representative.

Temperature changes in the annual cycle are rather homogeneous. Figure 5 shows the behavior of a concrete mass supported on bridge bearings in a railway tunnel. There is no influence of sunshine. Temperature conditions of the surrounding soil are rather stable, but the trains transport air from outside through the tunnel. The graph shows the homogeneous behavior of the structure over the years. The maxima and minima values measured are actually higher than expected. A concrete bridge (Figure 6) where concrete is used in the shape of a box girder with cantilever arms also shows a rather homogeneous cycle. The maximum and minimum temperatures according to the codes are never reached. The structure reacts moderately to warming or cooling. No clear daily cycle can be isolated.

A typical steel structure shows a rather violent reaction on temperature changes (Figure 7). The reaction is quite quick and produces strain in the system. This might be because of bearing friction, which is released suddenly causing a displacement of the structure. This effect can not only be particularly harmful to the expansion joints but also to the bearing. Particular bridges, which are not straight in plan, might develop exceptional forces into weak axes of the outfitting.

The consequence of these experiences should be an individual application of temperature loads depending on the type of the structures and conditions they have to bear. The following implications might be considered:

- to increase the loads from differential temperatures in stiff structures;
- to increase the temperature range considered in steel structures; and
- to look at the effects of quick temperature changes on the global behavior.

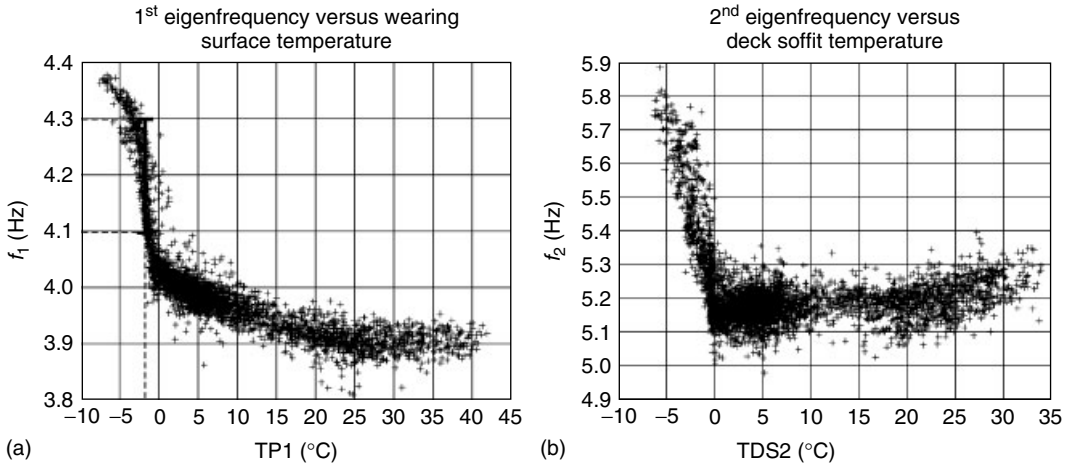

Figure 3. (a) First eigenfrequency versus wearing surface temperature [1] and (b) second eigenfrequency versus deck soffit temperature [1].

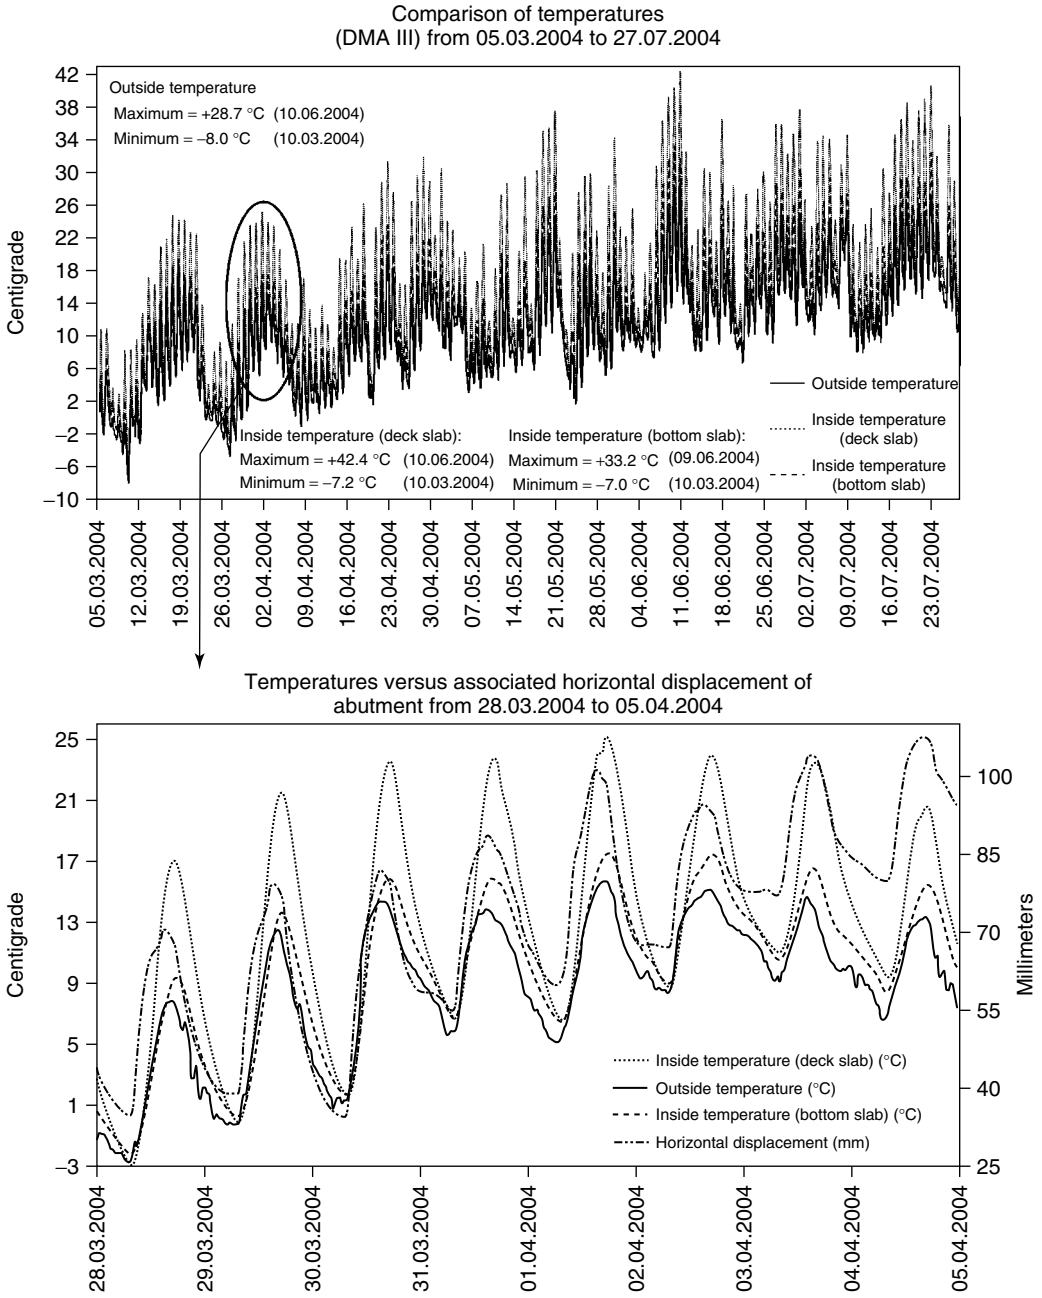

Figure 4. Representative temperature sensor records and longitudinal displacement of the steel bridges' abutment.

4 DISPLACEMENT

Bridges are flexible and displace under various loads. Displacements are calculated using structural models or finite element calculations (see Figures 13, 14, 15). Very often, these models do not reflect reality. A typical case is the displacement of a certain steel bridge due to temperature changes, which are shown

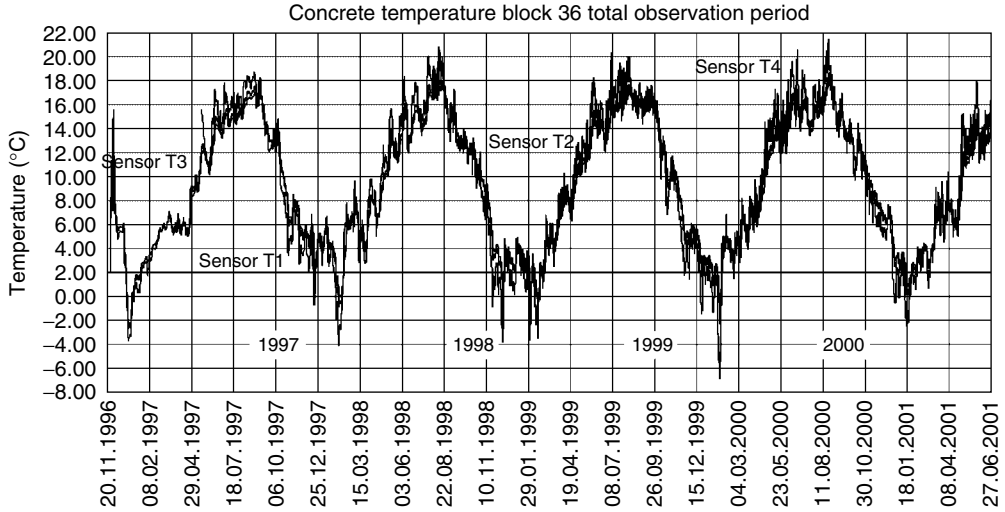

Figure 5. Long-run behavior of a concrete mass supported on bridge bearings in a railway tunnel.

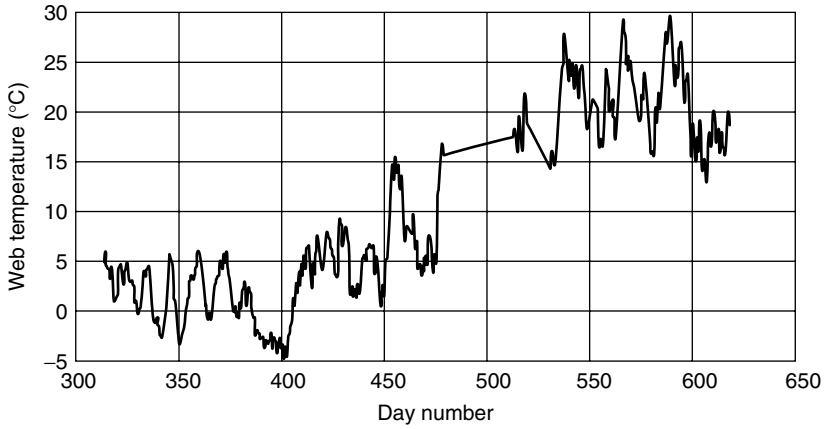

Figure 6. Variation of web temperature of the Z-24 bridge observed over a period of one year [2].

in Figure 8. Contrary to that, the monitoring results provided displacements according to Figures 9 and 10. Especially, the latter demonstrates the fact that the displacements of this steel bridge's abutment are approximately twice as much as those obtained from theoretical, linear elastic calculations. The difference is mainly related to the following facts:

- the stiffness of the columns depends very much on the degree of fixation of the pier in the foundation;
- bearings do not show a linear behavior at all times and rather tend to be stiff until a certain minimum force has been reached; and
- a certain stress limit has to be reached before restoring forces are activated, particularly when elastomeric bearings are provided.

In major bridges, sudden displacements of ± 50 mm have been recorded, which have to be attributed to sudden release of restoring forces of bearings. This displacement is normally within the regular limits of allowable displacement, but the sudden reaction might trigger secondary problems, such as restraints in the expansion joint. A number of failures of expansion joints have to be attributed to these phenomena. The frequency of such phenomena is

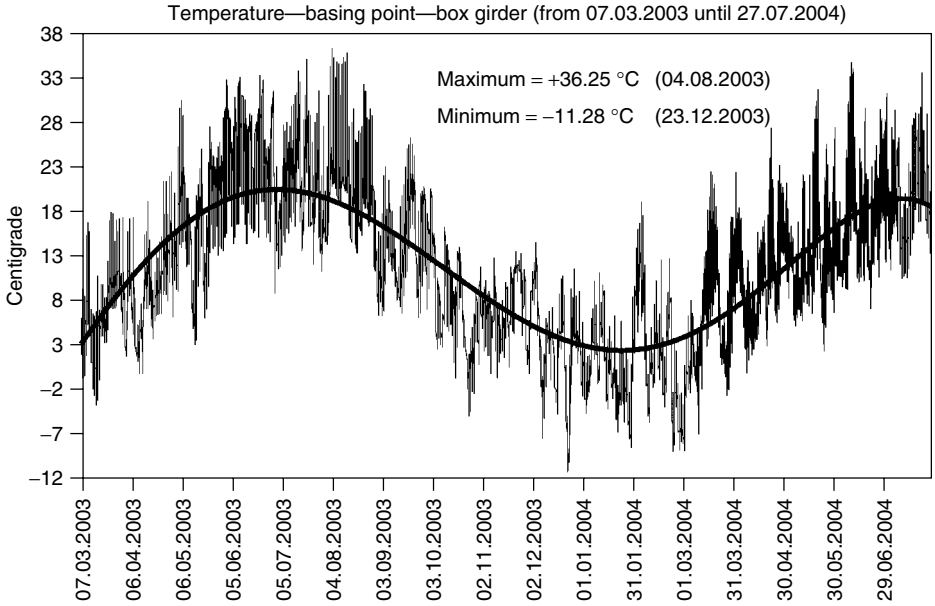

Figure 7. Temperature conditions inside the steel box girder at the *Europa Bridge* of the *Brenner Motorway*.

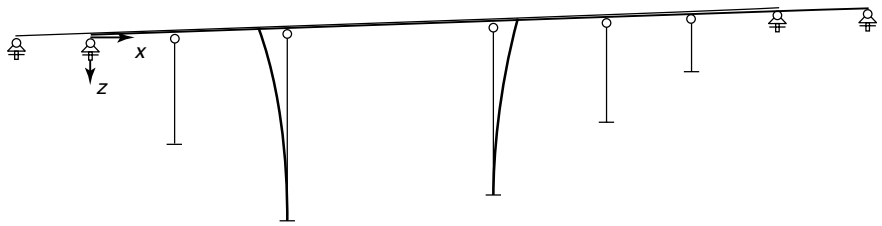

Figure 8. Displacement of a bridge due to temperature changes affecting only the superstructure.

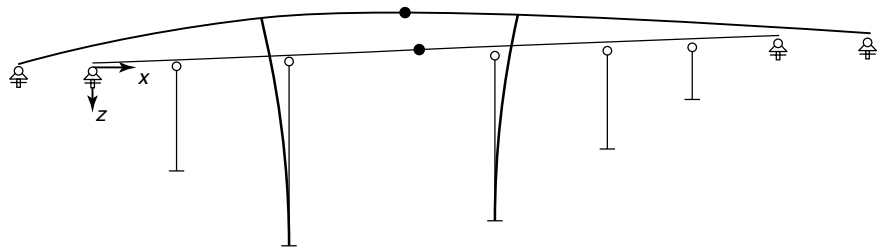

Figure 9. Displacement of a bridge due to temperature changes recorded by monitoring.

not sufficiently documented yet. In a six-month-long record of a major steel bridge, three such occasions have been detected (Figures 11 and 12).

The consequences from these records are that the realistic behavior of a structure can be found through monitoring, which might explain damage in the outfitting. The displacements calculated for bearings and expansion joints might be not enough to cover extraordinary events as described. The center of expansion of a structure can be dozens of meters away from the theoretical center and influence the design of bearings and expansion joints (Figure 9).

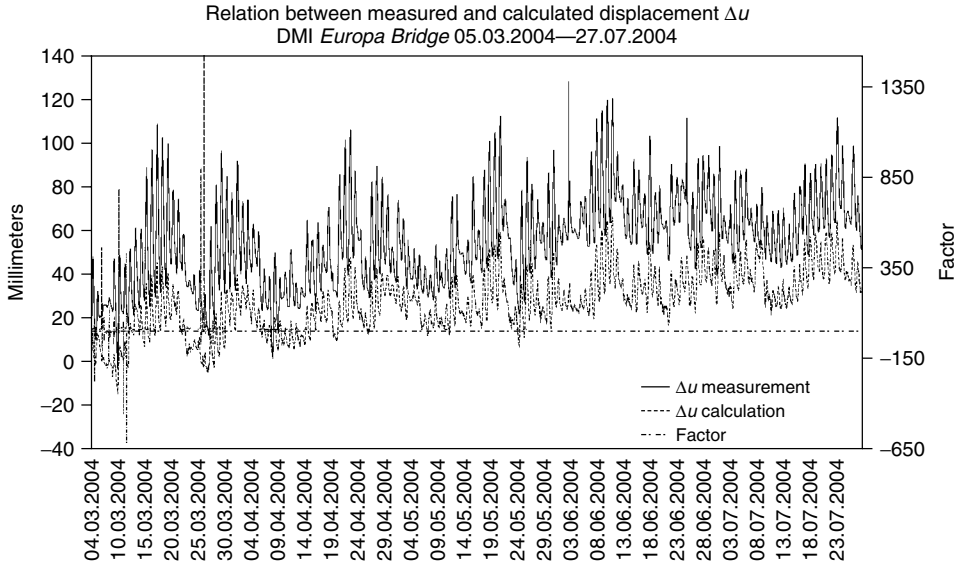

Figure 10. Comparison between measured and finite element (FE)-based displacements of a steel bridge's abutment.

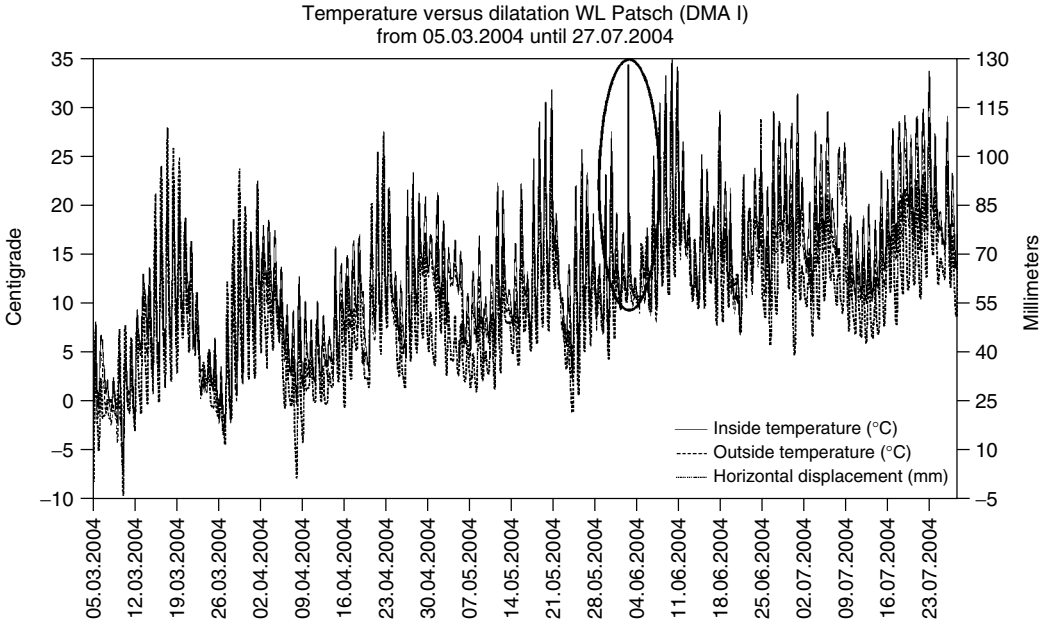

Figure 11. Uncommon, sudden reactions in the abutment's displacement recordings over a period of five months.

5 LARGE BRIDGES VERSUS SMALL BRIDGES

In the beginning, monitoring concentrated on large and important bridges. This has led to the impression that bridges normally perform very close to the theoretical behavior determined and based on the design assumptions. The subsequent assessment of small bridges showed that it is considerably more difficult to achieve good results, the smaller the

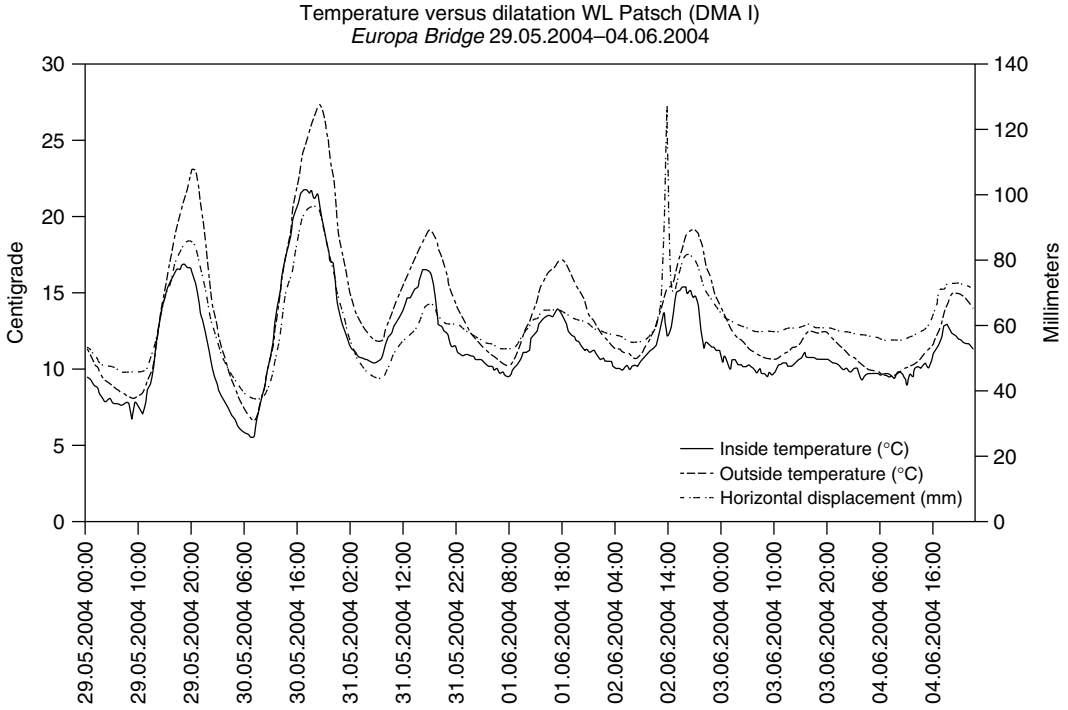

Figure 12. Focus on Figure 11 over a period of a certain week including one of the observed sudden reactions.

structure is, because of different approaches taken toward these, considered not so important, structures. Another fact is that boundary conditions are much clearer in large structures.

The lesson learned from monitoring is that even higher attention should be paid to smaller bridges and that a number of provisions of construction codes fit very well for large structures, but underestimate small ones. Here, in particular, the subject of temperature, as explained in another article, has to be highlighted. Furthermore, the correct modeling of the boundary conditions has to be taken care of.

6 VIBRATION INTENSITIES

The subject of resonance in pedestrian bridges is well known and taken care of. Frequencies close to resonance, particularly those of structural members, such as cantilever slabs, are not yet subject to consideration. Experience has shown that the evaluation of the vibration intensities measured for a structure can give considerable information on fatigue and related problems. The assessment of vibration intensities, therefore, can give indicators on the expected lifetime of a structure and on local problems to be expected on structural elements in the near future. It has been clearly demonstrated that bridges, where high vibration intensities have been recorded (Figure 16 and 17), most probably develop local problems in expansion joints, bearings, outfitting, and particularly in waterproofing.

7 DAMPING VALUES OF NEW COMPOSITE BRIDGES

Measurements taken at a number of new composite bridges show that the damping values determined at the newly built structures are considerably higher than the normal values of comparable concrete bridges or steel bridges (Figure 18). This might be attributed to the fact that the composite effect has to be established through a number of load cycles. After some time, the damping values of these bridges have been stabilized in normal ranges. Further conclusions on these phenomena have not been drawn yet, but

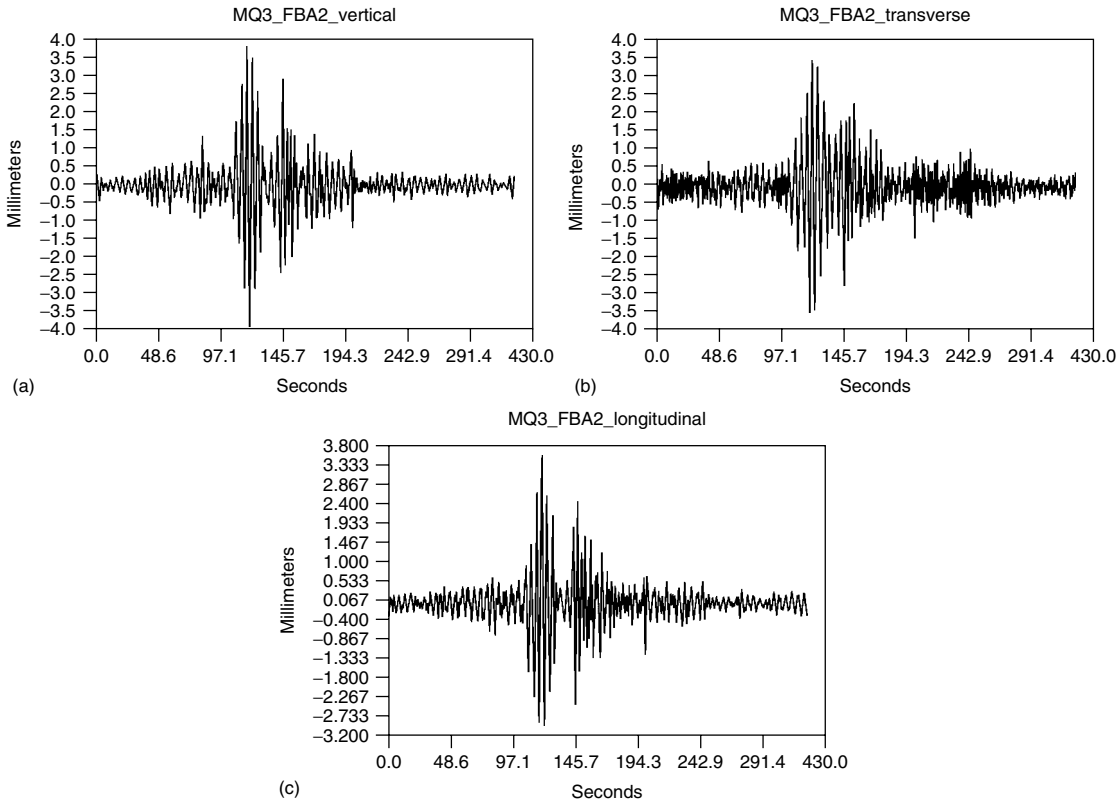

Figure 13. Relative displacement due to sudden occasions of restraint recorded with a 3-D acceleration transducer at the top of a 200-m-high pier subdivided into the vertical (a), transverse (b), and longitudinal (c) direction.

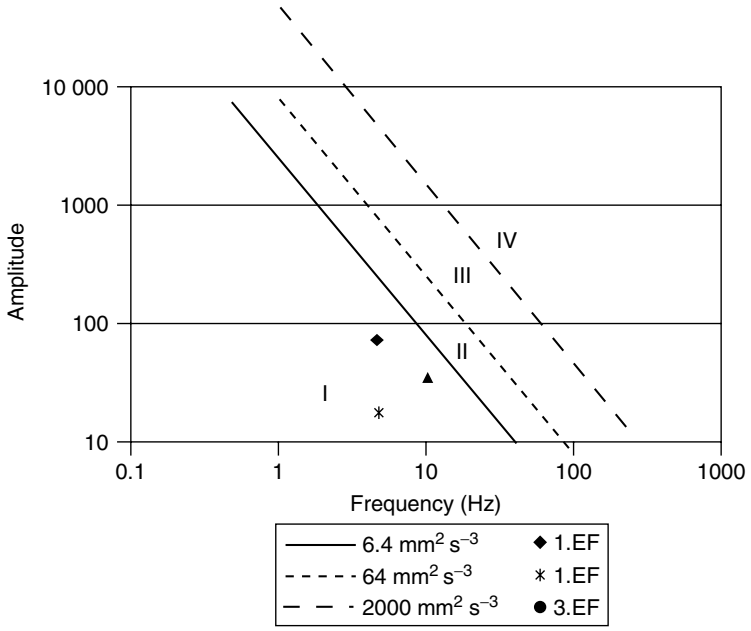

Figure 17. Intensity chart at the *S 36 Bridge* of the *A1 Motorway* (representing low vibration intensities).

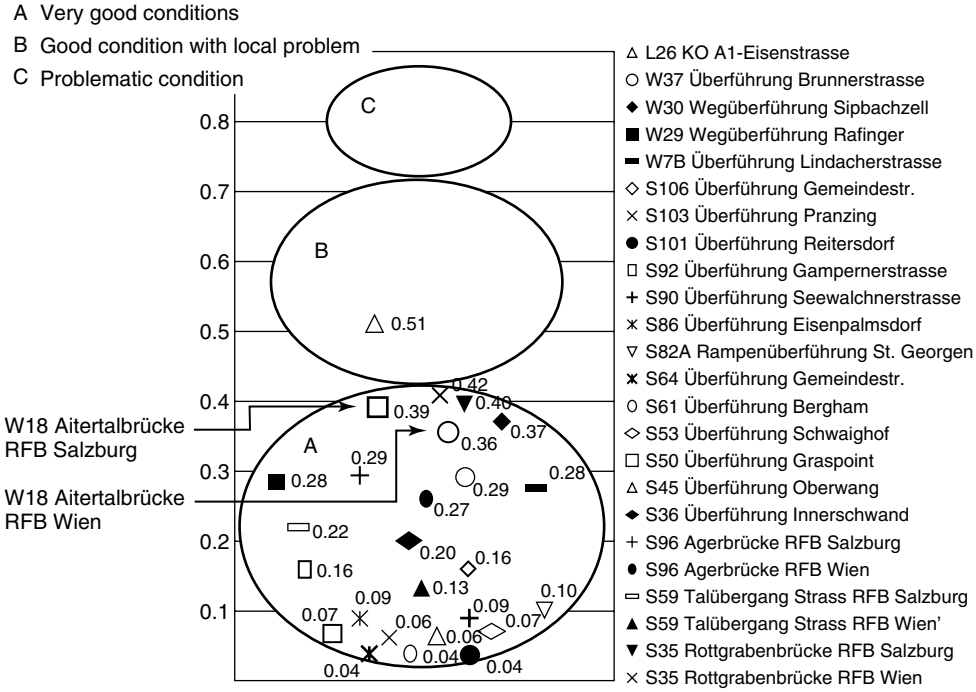

Figure 18. Classification of prestressed concrete and composite bridges according to their damping values.

it might be expected that a sharp drop in damping indicates eventual problems with bonding or the triggering of a hidden local damage.

8 VALUE OF PATTERNS

Certain elements of bridges exist in a repetitive form. It has to be expected that all members show the same dynamic performance under service. One of the valuable approaches of monitoring is to recognize patterns and to observe the performance of comparable components. Any deviation from the pattern indicates a malfunction or an extraordinary situation that can be identified.

As an example, the case of a concrete box girder bridge with a distinct cantilever is shown. The monitored performance of the cantilever minus the action of the global system provides information on the cantilever eigenmodes. Related symmetric modes can be determined and displayed. This should provide a distinct pattern, where every deviation indicates a problem. On the basis of colored frequency cards, so-called trend cards, the relevant cantilever eigenfrequencies have been determined, which are marked in Figures 19 and 20.

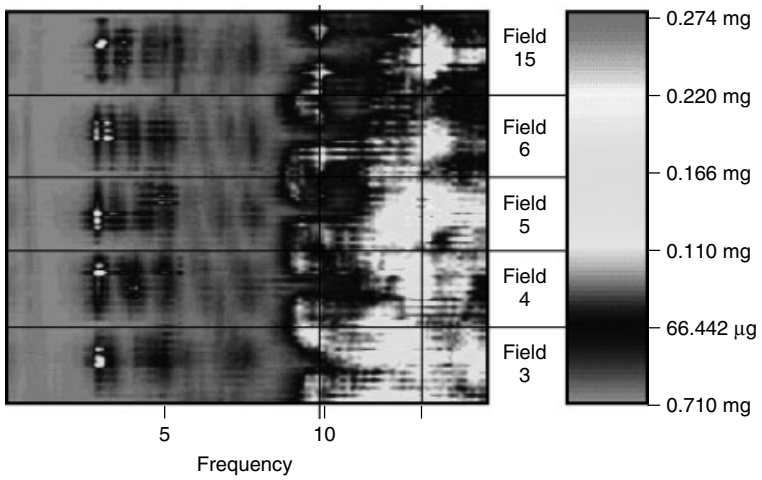

Figure 19. Course of frequencies at a certain concrete box girder bridge—structure south.

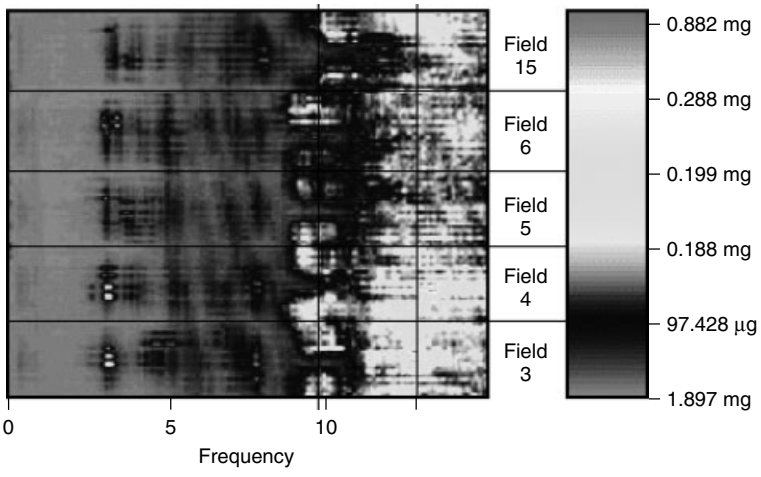

Figure 20. Course of frequencies at a certain concrete box girder bridge—structure north.

By comparing the response spectra of both box girders and their cantilevers, the share of cantilever vibration can be displayed directly as shown in Figures 21 and 22.

A detailed evaluation procedure analyzing the relation between the response spectrum and its energy content within the relevant frequency ranges leads to a certain behavior pattern of the cantilevers along the bridge. Deviations from this pattern are typically indications of irregularity.

Figures 23 and 24 show the pattern of an undamaged cantilever compared to a cantilever with minor corrosion damage of the transverse reinforcement.

This method is not good enough for detail localization of the problem, but it provides sufficient information on the quality of function of a structural element.

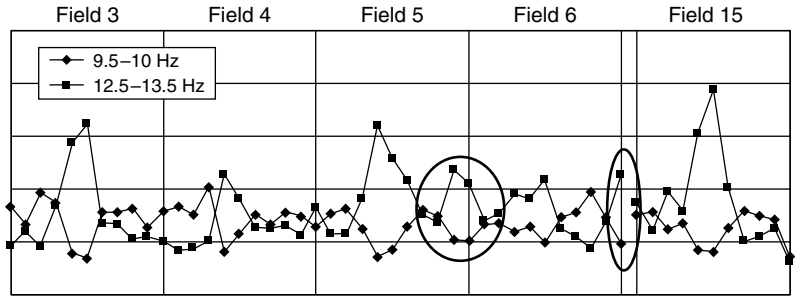

Figure 24. Behavior pattern of the cantilevers with indications of irregularity.

By a very quick and cheap test, it can be determined whether action is required.

8.1 Understanding of behavior

Complex bridge structures are often modeled in a rather simple way neglecting the behavior of the structure in the three-dimensional space. Monitoring is the recording of the actual behavior of a structure. This comprises eventual drift or strain from temperature, as well as eventual construction mistakes, such as wrong placement of bearings or nonrelease of restrainers. Figure 25 shows a case where a temporary fixture during construction has not been removed at the time of handover. The performance of the bridge has been considerably different than estimated. By monitoring this difference could be detected and immediate correction measures taken (Figure 25).

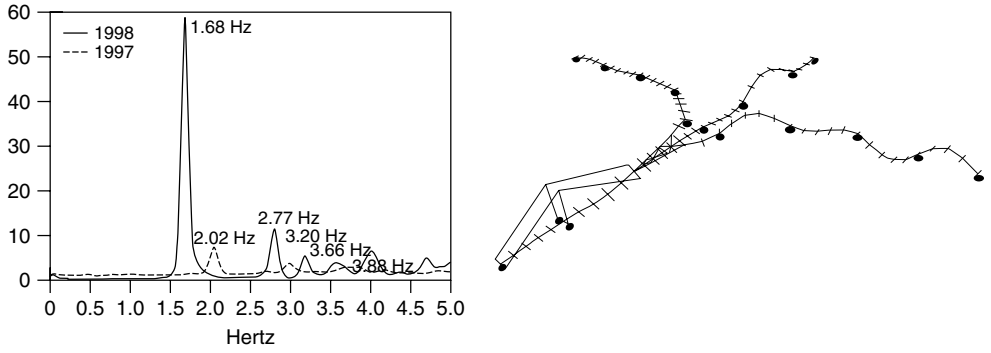

Figure 25. Frequency spectrum of *Inn Bridge Hall West* 1997–1998.

Figure 26. *Steyregg Bridge*.

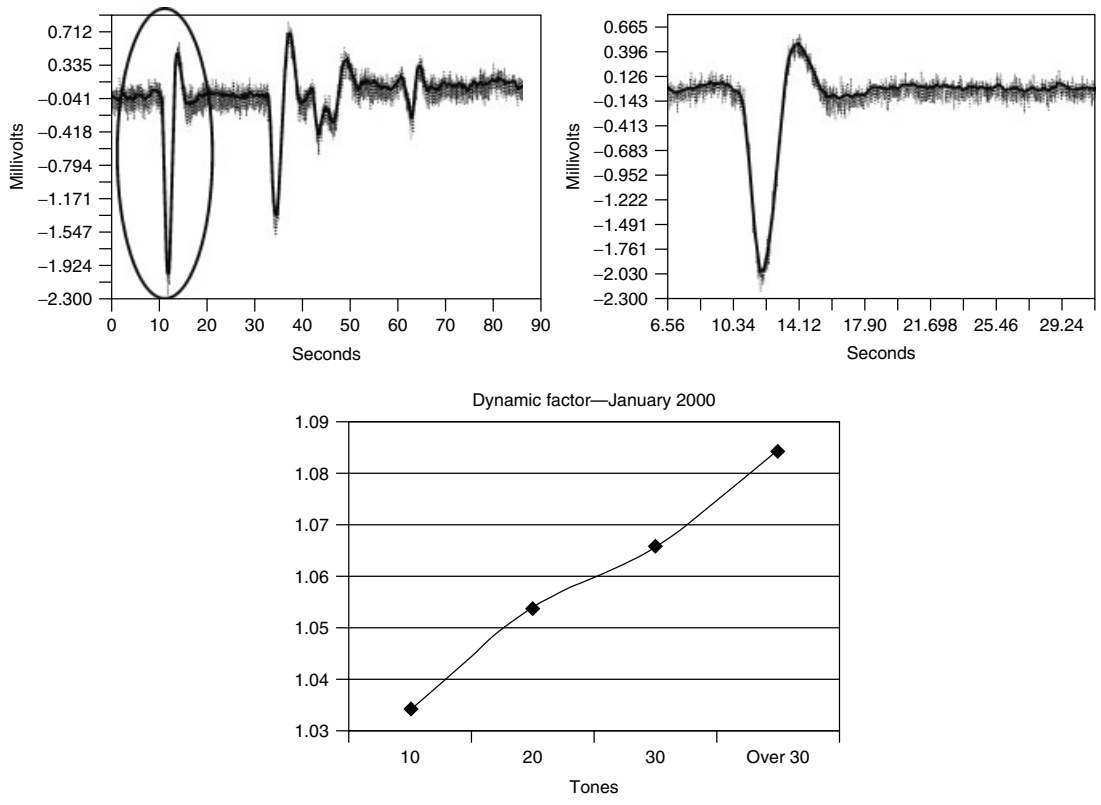

Figure 27. Dynamic factor of the flyover *St. Marx*.

Another important value is information on the actual displacement of a structure, particularly with regard to complicated cable-supported structures, where such displacements could generate problems in traffic clearance or related interfaces.

Another way of finding problems is to compare the expected behavior with the measured one. In case of stay cables, protected by steel tubes against vandalism, the contact of the cable to the tube has been found through monitoring. The effective

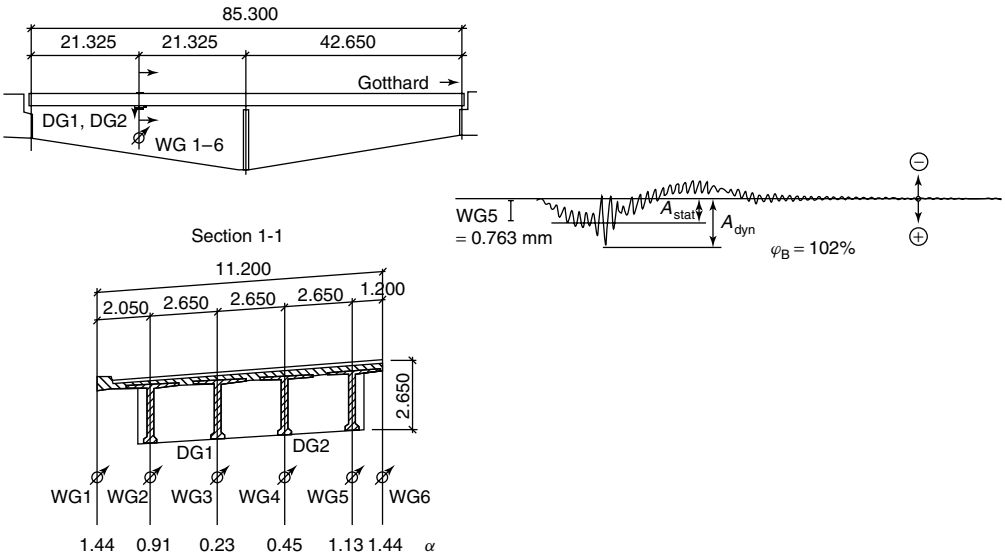

Figure 28. Dynamic factor of the *Boeschrüti Viaduct* due to induced impact loading. [Reproduced with permission from Ref. 3. © EMPA, 1983.]

vibration length of the cable has been shortened by this contact. Such a problem can lead to drastic damage at a cable providing a sharp edge, which introduces unintended bending. Monitoring is able to identify these problems (Figure 26).

9 DYNAMIC FACTORS

Current bridge design codes ask for dynamic factors mainly depending on the bridge span. The factor is considered to be 1.40 for components or directly effected members and varying between 1.00 and 1.40 depending on the span of a bridge. The lessons learned from monitoring are as follows:

- The dynamic factor provided by the code depending on the span length is actually conservative. All bridges so far showed smaller dynamic factors.
- The dynamic factor for components sometimes exceeds the values considerably. The record factor measured has been 2.20.
- The dynamic factor is also considerably dependent on the speed of the vehicles. This can eventually be controlled by speed limits.

The consequences are that overloaded vehicles that drive slowly will not produce harmful stresses. The low increase always has to be seen in conjunction with eventual speed effects. Consequently, dynamically sensitive elements should be avoided in design.

Another lesson learned is that the dynamic behavior also depends on the type of structure designed. Bridges with box girders (Figure 27) are considerably less vulnerable to dynamic effects than bridges of other types of design (Figure 28).

The dynamic vulnerability of a structure depends on the acting mass. This is also clearly shown in monitoring records. Concrete bridges with a mass of $1.5\,t/m^2$ or more are very little affected by dynamic amplification. Continuous girders react less violently to any impact. Elements with major differences in stiffness produce an inharmonic behavior unfavorable for the structure.

Chapter 121

Long-term Monitoring of Dynamic Loads on the Brandenburg Gate

Werner Rücker

Division VII.2 Buildings and Structures, BAM Federal Institute for Materials Research and Testing, Berlin, Germany

1 INTRODUCTION

The Brandenburg gate (Figure 1) is the best-known German national monument. It was constructed by the architect Carl Gotthard Langhans between 1789 and 1791. The architect orientated the design (Figure 2) of the gate on ancient buildings. The construction was erected with sandstone. It consists of six pillars with an architrave section on the top. Above the architrave, there is the so-called quadriga, a very well-known work of art. To the left and right of the gate there are two gatehouses, which were also constructed like Greek temples. The total dimensions of the gate are 22 m high, 65 m wide, and 11 m deep (without quadriga). During World War II, the gate was heavily damaged. After the war, the reconstruction was carried out until its completion in 1959 by the former German Democratic Republic (GDR).

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

2 THE PROBLEM

After the reunification of Germany in 1989, the senate of Berlin was interested to open the gate again for traffic use. Ahead of a political decision on that, an inspection of the structure was made. The inspection revealed the extent of damage on the building itself as well as the zones where the gate is connected to the neighboring two gate houses. There were unusual settlements and vertical and horizontal cracks (perpendicular and along the gate) visible at the foundation structure and the architrave. As can be seen from the examples given in Figure 3, the crack opening is about 2 mm and more. The shear deformation of the architrave is limited by a shear tension band. Figure 4 shows the construction details and the cracked clamping system. Based on the inspection results, the following questions were raised:

Figure 1. The Brandenburg gate.

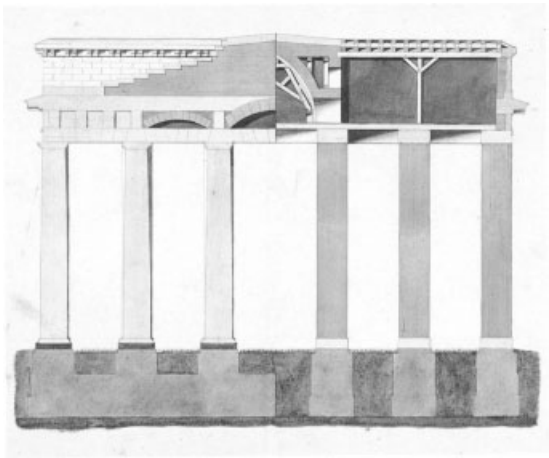

Figure 2. The architect's drawing.

- Is the railroad and road traffic around the gate the main cause of the damage?
- Is it possible that the damage can be exacerbated by traffic?
- Are there reasons other than traffic possibly responsible for the damage?

In order to answer these questions, the responsible city administration asks for an investigation concept. The results of the investigation should serve as a basis for the development of the best technical and economical rehabilitation measures and also for the decision to open the gate for traffic or not.

3 IMPACTS TO THE STRUCTURE

As mentioned above, the most important impacts to the structure seem to be road and railroad traffic.

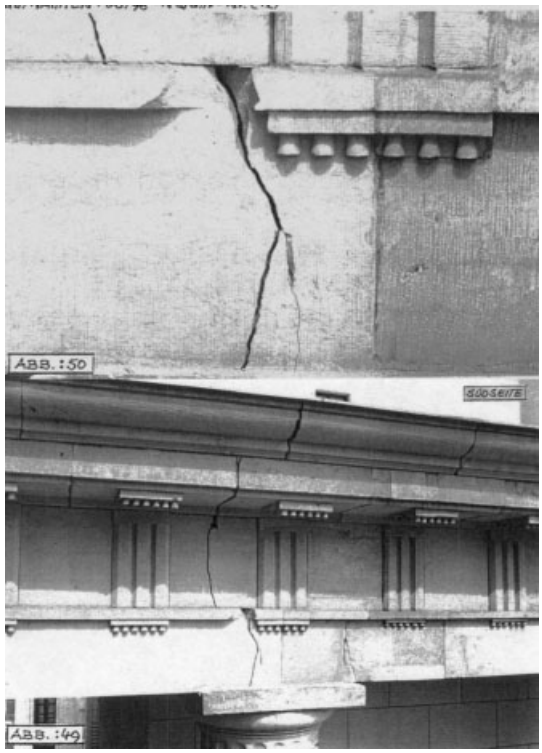

Figure 3. Observed cracks at the architrave.

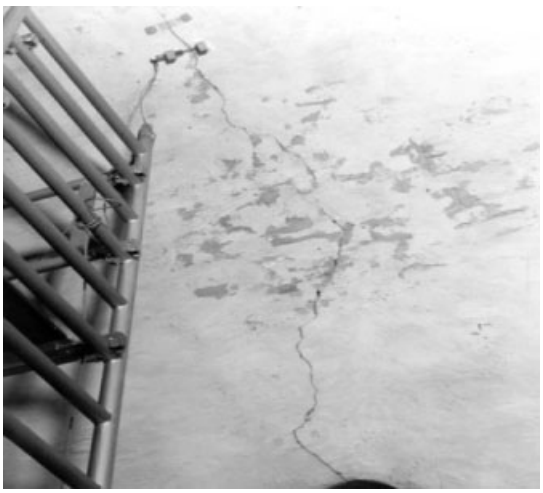
The traffic generates dynamic forces, which are transmitted to the gate and the neighboring gate houses through the soil. Owing to the interaction effects between the building and the soil, the vibration transmitted from the soil to the foundation will be normally reduced; but in the ongoing structure, amplification depending on the modal behavior and damping of the structure will take place. If the vibrations reach threshold values, cracks and other damage can occur. However, the settlement of soil under and beneath the foundation can induce great stress in the structure, resulting in cracks. Besides traffic, construction work in the surrounding area of the gate can also generate vibrations, causing additional damage. Since the gate is located in the middle of two long straight-line streets, the influence of wind may also contribute to the damage. A special event that takes place every year in the surrounding area of the gate is the "love parade". During the event, a number of concerts happen and create high air pressure (Figure 5). This may also have an influence on the gate because the very low frequencies of the

(a)



(b)

Figure 4. Examples for observed cracks Tension band (a), Architrave wall (b).

music may excite Eigen frequencies and Eigen modes of the gate. As known from the measurements on bridges and towers, the temperatures also have a great influence on the development of cracks and other damage to the structure. Therefore, the influence of the following impacts (see Figure 5) to the structure has to be considered in total:

- railroad and road traffic
- construction work
- wind
- love parade and
- temperature.

4 THE INVESTIGATION PROGRAM

To characterize the static and dynamic behavior of the structure and to assess the different impacts and their damaging effects to the structure, a three-level investigation program was developed. The program consists of the following elements:

- modal analysis of the complete building;
- definition and derivation of threshold values; and
- permanent monitoring of the structure at certain significant spots for acquisition of all significant influences.

Through modal analysis (*see* **Modal–Vibration-based Damage Identification**), the global vibration behavior of the Brandenburg gate and the gate houses was examined. The results provided the basis for the following permanent vibration measurement and the permanent condition monitoring with which all the mentioned effects on the building were to be measured in quantity and character (*see* **Continuous Vibration Monitoring and Progressive Damage Testing on the Z24 Bridge**). The interaction of dynamic excitation with known cracks should have been examined at the same time. From those results, the reasons for the cracking between the gate and the neighboring gate houses should also be investigated. In Figure 6, the measurement layout for the investigation by modal analysis is shown. Measurement points were located at the foundation, at the pillars, and at the architrave. For the measurement, velocity transducers were used. The operating frequencies of these transducers are approximately between 0.5 and 1000 Hz.

Furthermore, possible changes in the dynamic behavior of the Brandenburg gate (if there are any) should be discovered and quantified (*see* **Risk Monitoring of Civil Structures**). For this reason, the changes in the width of known cracks, strains in special structural elements like the diagonal anchor in the Attica area, and local temperature were supervised at selected locations. In addition to the influence of all kinds of traffic (road and rail), other excitation processes like tunnel drilling and pile driving beneath the foundation of the gate and special events like the love parade have also been measured by installing and operating a condition monitoring

Figure 5. Examples of impact to the Brandenburg gate (traffic (a) and love parade (b)).

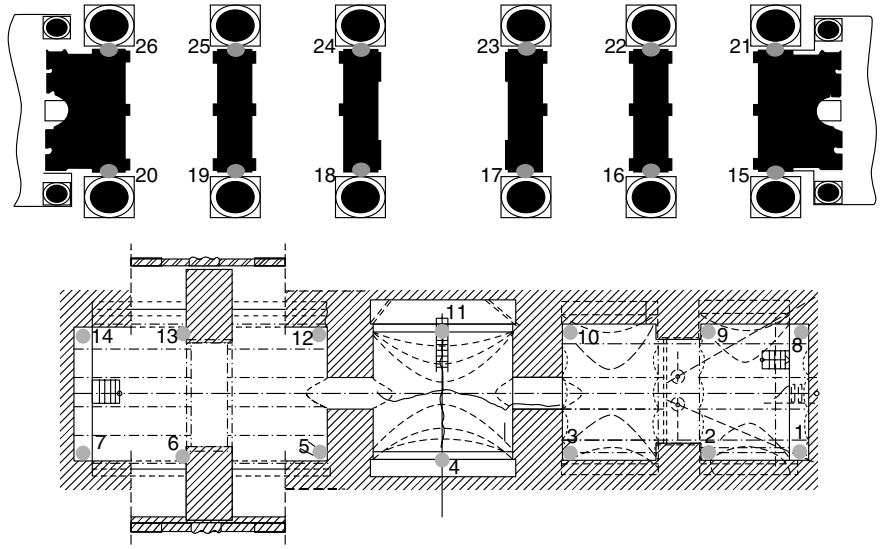


Figure 6. Measurement layout for modal analysis at the Brandenburg gate.

system (*see* **Ambient Vibration Monitoring**). In all, over 48 significant points were observed permanently (Figure 7). Most of the evaluation of the data was done in situ. The evaluation includes statistical quantities like maximum, minimum, RMS values, and their deviations. Frequency evaluation by FFT was also done at the site (*see* **Statistical Time Series Methods for SHM**).

5 THRESHOLD VALUES

In order to assess the measured dynamic quantities, threshold values have to be specified. For this purpose, national and international standards, own experiences on comparable buildings, as well as results of the modal analysis were used. Threshold values are defined as permissible values for the vibration velocity in vertical direction at the foundation and in both horizontal directions (i. e. direction "north-south" and direction "west-east") at the architrave. Besides the maximum value of vibration, the kind of vibration and the number of maximum values consecutively are also regarded. Following these criteria, the threshold values given in Table 1 were prescribed for permissible vibration velocities, depending on the kind of excitation process [1].

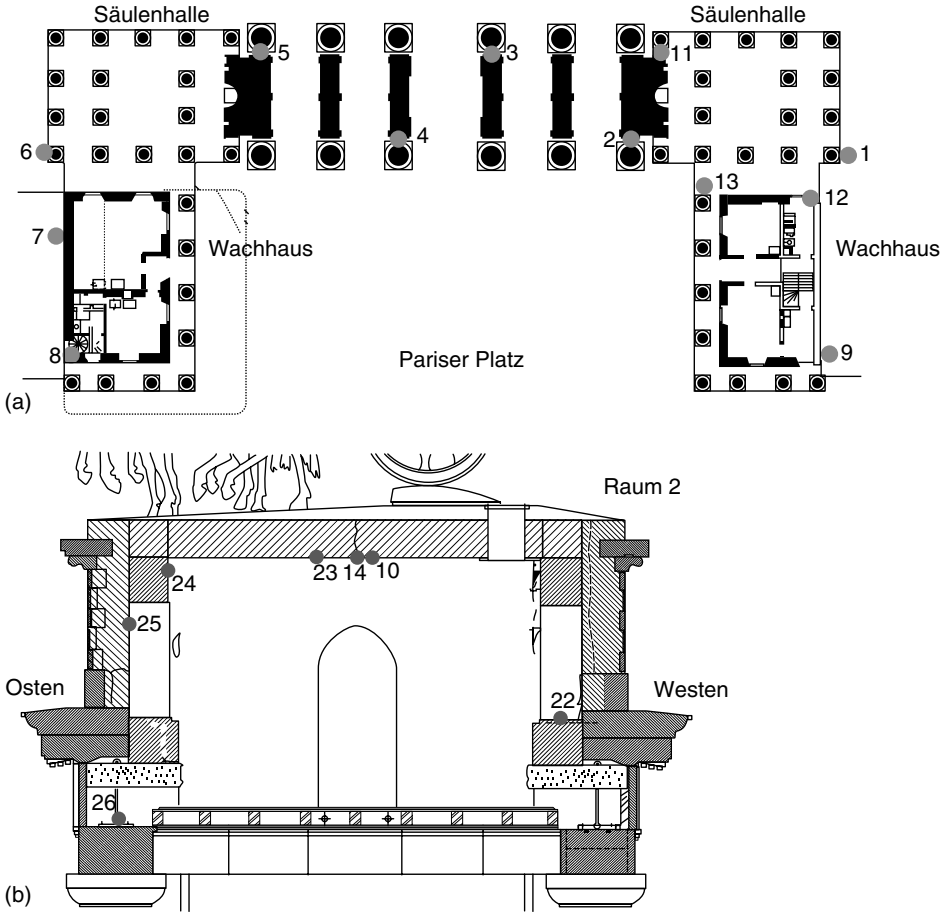

Figure 7. Measurement layout for monitoring at the foundation (a) and the architrave (b).

Table 1. Threshold values

Measuring level	Max V (mm s^{-1})	Manner of use	Permitted transgressions
Foundation	≤ 1	Durable	None
Architrave	≤ 2	Durable	None
Foundation	≤ 1	Temporal	Maximum 100%[(a)]
Architrave	≤ 2	Restricted	Maximum 50%[(a)]

[(a)] Threshold values are permitted to exceed for the duration of 1 min at the most by a frequency of three times in 24 h at the most.

6 MAIN RESULTS OF THE MODAL ANALYSIS

For the experimental modal analysis of the Brandenburg gate, ambient vibration excitation has been used. The extraction of modal data (Eigen frequencies, mode shapes, and damping) has been done by software with "output only" option. The essential results of these examinations are given below.

The main natural frequencies (Figures 8 and 9) of the Brandenburg gate with the accompanying main

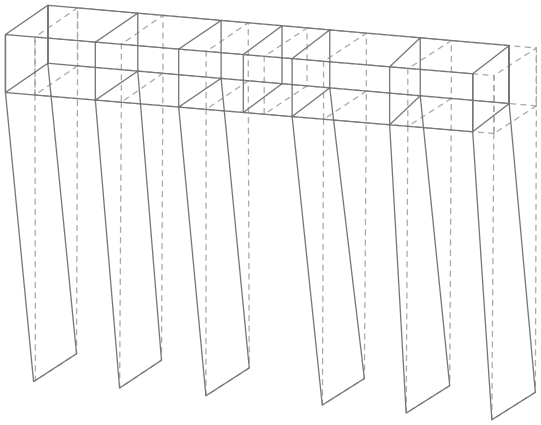

Figure 8. First Eigen mode with 1.77 Hz.

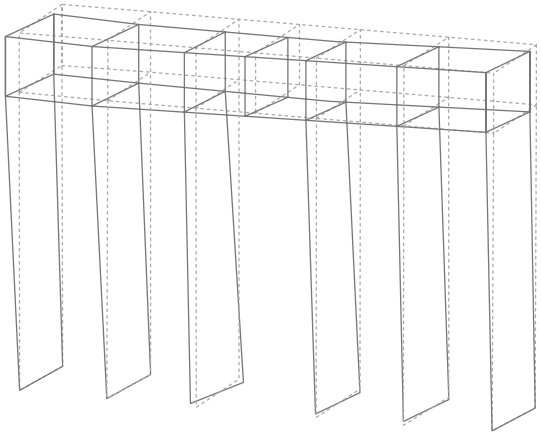

Figure 9. Second Eigen mode with 2.44 Hz.

movement directions are as follows:

$f_1 = 1.77$ Hz (rotation)
direction north "German Reichstag"

$f_2 = 2.44$ Hz (rotation)
direction east "Unter den Linden"

$f_3 = 3.17$ Hz
direction east "Unter den Linden"

$f_4 = 7.26$ Hz
direction east "Unter den Linden"

The Eigen modes to the first Eigen frequencies f_1 and f_2 have a small damping value (<1%). The damping of a structure is normally influenced by the so-called material damping and by radiation damping in the soil (influenced by movement of the foundations). The values of radiation damping are much higher than the values of material damping. Both effects result in the observation that measured damping is normally much higher than the well-known values of material damping. Therefore, in the present case, these modes can be excited easily by wind and also by heavy trucks and buses, which have first Eigen frequencies close to the Eigen frequencies to the gate.

The dominant natural frequencies of the two gate houses are not equal and differ also with those of the gate. This leads to different movements between the gate, the two gate houses, and the connection zone. In order to avoid additional cracks between the gate and the gate houses, the stiff connections that have been added to the gate at the reconstruction after the Second World War are not good measures and have to be removed.

Higher Eigen frequencies and Eigen modes with frequencies above 7–8 Hz belong to bending modes of the architrave, in general. Those modes can be excited by all vibration sources mentioned above.

7 MONITORING RESULTS

According to the results of the modal analysis, a program for the permanent condition monitoring of the gate was developed. A monitoring system having 48 measurement channels was used for the supervision task [2]. In general, vibration values, crack widths at certain locations at the gate, the two gate houses, and the transition zone between the buildings as well as temperatures were measured and recorded permanently. The measurement locations were chosen according to the results of the experimental and numerical modal analysis. From the permanent monitoring, the following results were achieved.

The relevant frequency domain of the measured vibration amplitudes is between 1.4 and 25 Hz (Figure 10). The greatest vertical vibrations at all measurement points at the gate arise from traffic excitation (mainly buses and trucks), while the horizontal movements can be explained mostly by free vibration. The influence of road traffic excitation is much more important than the influence of railroad traffic due to the S-Bahn. The reason for that is that the S-Bahn

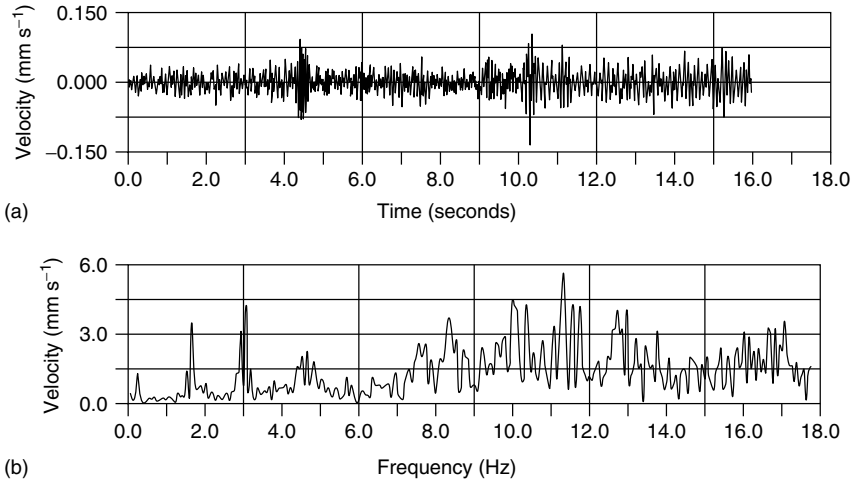

Figure 10. Time signal (a) of passage of a bus with associated frequency spectrum (b).

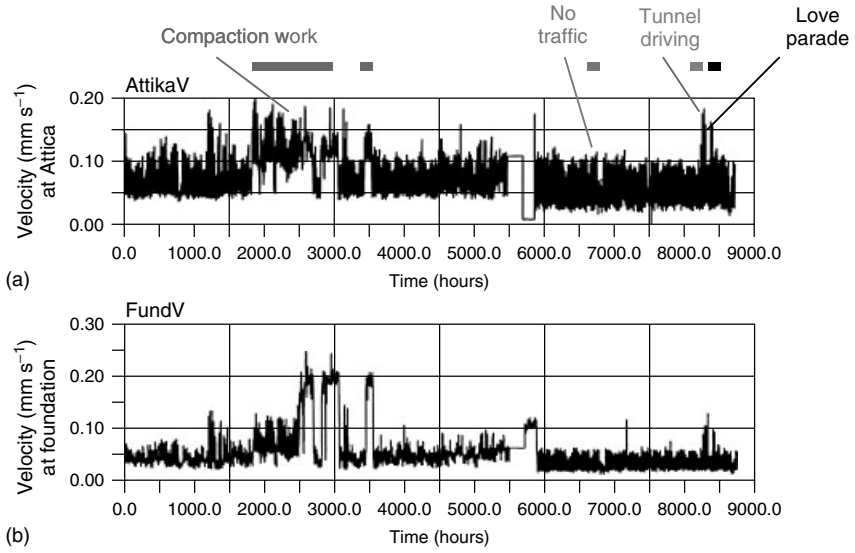

Figure 11. Comparison of vibration values of different impacts.

tunnel is only close to the southern part of one of the gate houses and therefore the vibrations transmitted through the soil are highly damped.

In Figure 11, a comparison between the different measured impacts to the gate is given. The measured impacts are railroad and road traffic, compaction work, and tunnel drilling near the gate and, last but not least, the influence of the love parade. As can be seen, the most important vibration occurs at the Attica of the gate. There is an amplification of the vibration from the foundation to the upper part of the structure. Regarding the maxima vibration values shown in Figure 11, one can see that the values initiated by the love parade and tunnel drilling are even more important than the values coming from the "normal" road and railroad traffic.

In general, the vertical vibrations are much greater than the horizontal ones. Regarding the horizontal

vibrations, those in the eastern direction (Unter den Linden) are normally much higher than those in the northern direction (German Reichstag). The maximum amplitudes in every measurement direction depend on the respective traffic events, which are given by the traffic conditions, vehicle type, and speed.

The supervision of the crack widths leads to the result that temperature is the most important cause (Figure 12). For all three monitored cracks, the long-term change of the crack width correlates strongly with the measured building temperature. This relation is about 0.1 mm/°C and behaves reciprocal to the temperature, which means that the crack opens

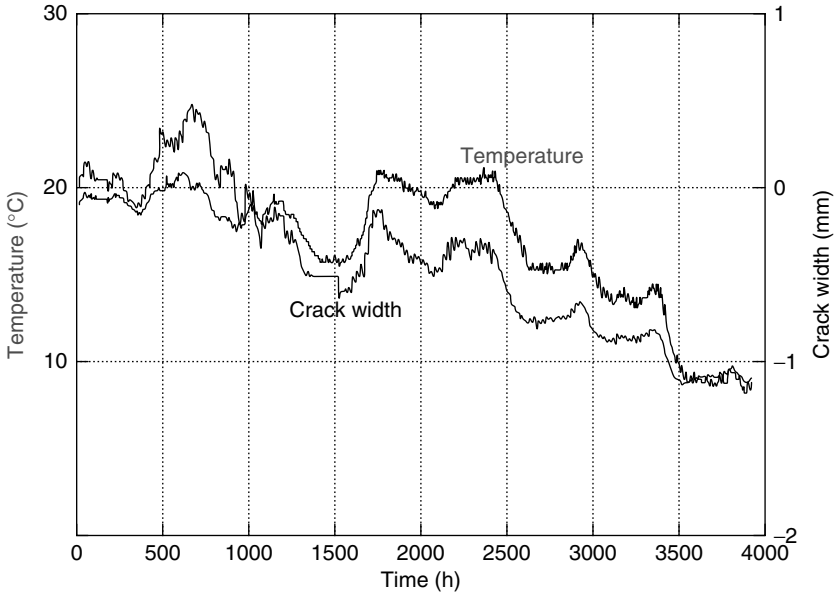

Figure 12. Crack monitoring.

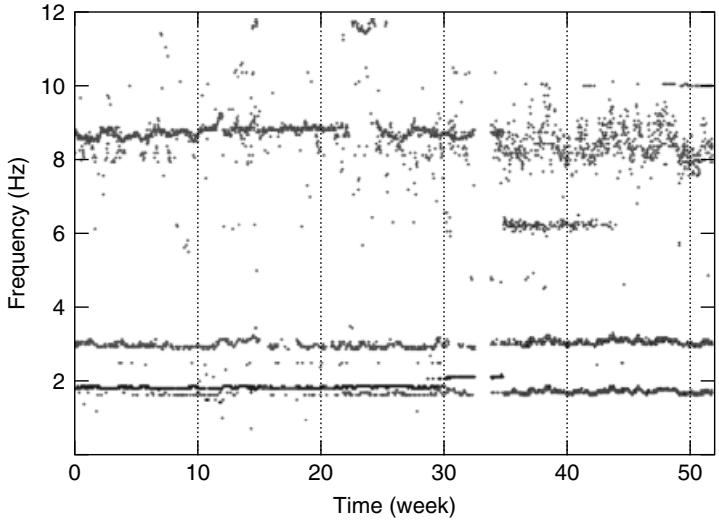

Figure 13. Frequency tracing diagram.

with decreasing temperature and vice versa. Another association between the measured crack width and the observed natural frequencies is that of a reduction in the natural frequencies when there is an increase in crack width.

For the global monitoring of the condition of the structure, a frequency observation was used. This frequency observation is done by evaluating "peak value frequency spectra" at constant time intervals and plotted versus time. This leads to a frequency tracing diagram as given in Figure 13. Natural frequencies are represented in this diagram as horizontal lines. Relevant damage of the structure is shown by deviation of the horizontal lines. Under normal conditions, the damage must be strong enough to have an indication in the frequency tracing diagram. However, in the present case, there is a significant shift in the first Eigen frequency approximately in the "33rd" week of monitoring.

If we look at the values for the first five Eigen modes (Table 2), we see that there is a decrease in all natural frequencies. Searching for the reason, we recognized that the changes occurred during the process of tunneling of a metro line beneath the foundation of the Brandenburg gate. The Eigen modes (Figure 14) belonging to the first natural frequency, was orientated in the direction of the "German Reichstag" (north) before the beginning of the work but after completion of the tunneling work, a dominant movement in the direction of "Unter den Linden" (east) can be seen.

Table 2. Eigen frequencies before and after the tunnelling work

Mode number	Eigen frequencies (Hz)	
	Before the tunnelling work	After the tunnelling work
1	1.77	1.59
2	2.44	2.29
3	3.17	2.90
4	7.26	5.80
5	8.91	8.3

Also, if we consider the mean average values of the foundation vibrations obtained by the monitoring system, it can be seen that these values are much higher than they were earlier. This observation supports the assumption that the dynamic behavior of the structure has changed because of the tunneling work (Figure 15).

In order to give an explanation for the observed behavior, simple numerical systems for the gate and the soil (including the interaction effect) were constructed and analyzed. This analysis reveals that the observed changes in the modal behavior are initiated by a decrease of the stiffness in the soil under the gate foundations.

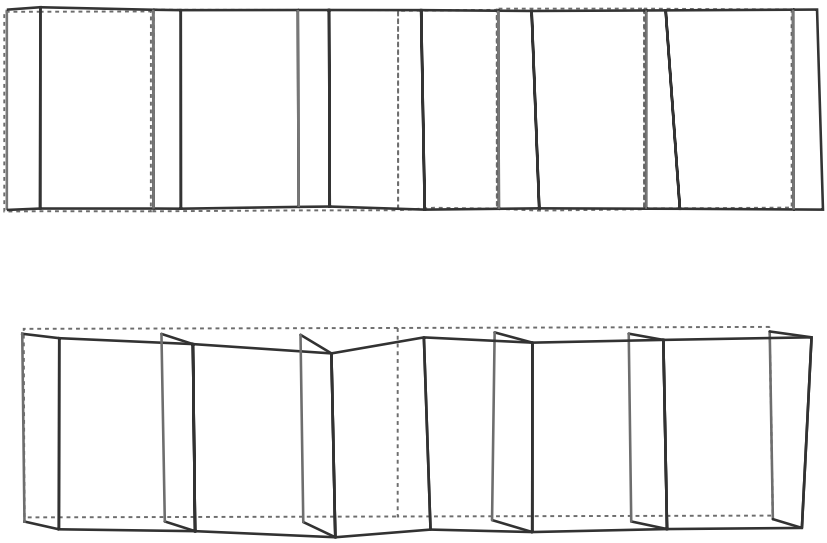

Figure 14. Mode shape for frequency 1.7 Hz before and after the completion of tunneling work.

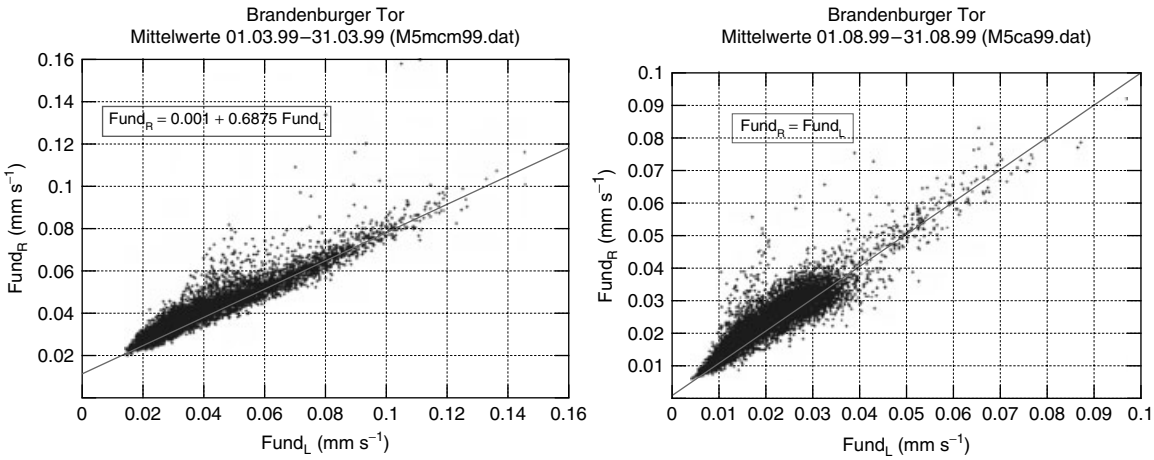

Figure 15. Regression of foundation vibrations between the left and right parts before and after the tunneling work.

8 CONCLUSIONS

After the reunification of Germany in 1989, the senate of Berlin was interested to open the Brandenburg gate again for traffic. In the context, a technical inspection of the gate was carried out, which revealed a lot of cracks and other damage at the gate and the neighboring gate houses. By an investigation program, the causes for the damage were found. To characterize the static and dynamic behaviors of the structure and to assess the different impacts and their damage effects to the structure, a three-level investigation program was developed (modal analysis, derivation of threshold values, permanent monitoring). First of all, a modal analysis of the complete building was done. Threshold values were defined by standards, own experience, and the results of the modal analysis. An important result of the modal analysis was that the first Eigen frequencies have a small damping value and can coincide with the first natural frequencies of heavy trucks and buses. Also, wind can excite the structure easily in this low-frequency domain. Another outcome of analyzing the mode shapes is that the existing stiff connection between the Brandenburg gate and the neighboring gate houses has to be removed to avoid further cracks between them. A comparison made between the different excitation sources shows that the vibration impacts induced by events like love parade are more damaging than the impacts of the normal road and rail traffic. Furthermore, it has been demonstrated that frequency tracing together with the monitoring of relevant mode shapes may be a significant damage indicator of the structure.

1 INTRODUCTION: MONITORING OF LONG-SPAN BRIDGES

Structural health monitoring (SHM) is a paradigm that enables an integrated systems approach for a reliable measurement-based understanding of the loading environment of major bridges, and how their structural systems carry their loads as they operate and fulfill their functions [1]. The SHM paradigm enables a comprehensive and integrated evaluation of the entire spectrum of performance expected from a major bridge. Management of bridge operations, response to accidents and emergencies, routine inspections, preventive maintenance as well as any structural repair or retrofit may be integrated and optimized in a rational manner based on objective, quantitative criteria customized to a specific bridge.

Currently, most of the major decisions by managers of long-span bridges are made on the basis of the visual inspections. There is evidence that visual biannual inspections of major bridges cost significantly while restricting operations for many months. Yet these inspections may miss many of the early initial signs of deterioration and damage even when these may be visible, as there are natural limitations to the ability of even experienced human eyes to scan hundreds of members and connections that may have dimensions in the order of a hundred feet.

Many bridge engineers concur that there are too many limitations and shortcomings in the current approaches to inspection, evaluation, maintenance, rehab and retrofit design, and construction of existing major bridges. Applications of SHM to existing major bridges that exhibit premature aging, distresses, and performance problems and/or to bridges that have aged beyond their anticipated design life cycles

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

offer exceptional payoff. Whether the conventional approaches to the maintenance management of such bridges are effective, especially after their aging, is a valid question. Another important question is that whether the effective implementation of SHM techniques and technologies are in such a way that the root causes of problems are detected, solutions are formulated, and finally repair and retrofit are developed to mitigate existing or future problems [2].

2 STRUCTURAL HEALTH MONITORING OF A LONG-SPAN TRUSS BRIDGE

In this study, an overview of a comprehensive monitoring project of the longest cantilever truss bridge in the United States is presented. For long-span bridges, some of the most pressing challenges are solving performance problems that are related to objectionable movements and geometry changes, displacements, vibrations, and visible signs of aging. To respond to deterioration, distress and damage to materials, elements, and connections, it is essential to first clearly identify the root causes before it is possible to design the most effective maintenance or renewal measure that can mitigate the root cause. In most cases, monitoring over an extended time may be necessary for definitively identifying the root cause(s) and mechanisms leading to symptoms of deterioration or damage. A lack of durability and serviceability limit state performance of many long-span bridges often translate to major increases in life-cycle cost, and properly designed monitoring may offer an excellent payoff by considerably reducing life-cycle cost.

2.1 Description of a long-span truss bridge

The Commodore John Barry Bridge (CBB) (Figure 1) spans the Delaware River between Chester, Pennsylvania and Bridgeport, New Jersey. The bridge has five traffic lanes and currently serves more than six

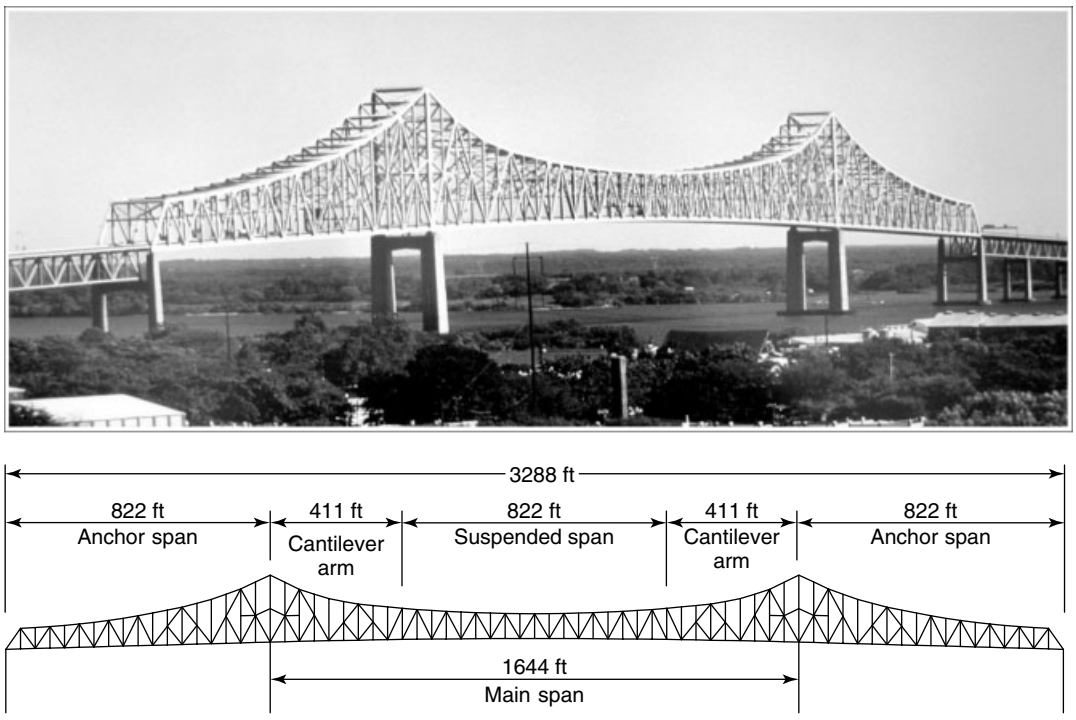

Figure 1. Commodore Barry Bridge through-truss structure (Overall Length is 1002 m with 501 m main span length).

million vehicles annually, a significant percentage of which is heavy truck traffic. It was opened to traffic in 1974 as the longest cantilever steel truss bridge in the world with a main span length of 501 m (1644 ft) and a total bridge length of 4240 m (13 912 ft). The focus of the study and subsequent discussions are directed to the principal long-span through-truss component shown in Figure 1.

The substructures of the through-truss comprised of four reinforced concrete piers that are shown in the photo in Figure 1. The piers were constructed on pile foundations. The two principal trusses of the through-truss are spaced 22 m (72.5 ft) apart. Each truss has 73 panel points spaced at 14 m (45.7 ft) intervals. The top and bottom chords of the trusses are constructed from welded box sections. A combination of welded box and I-sections are used for the vertical and diagonal truss members.

Lateral "wind" bracing is provided by K-bracing at the top and bottom chord levels, and by portal and sway frames located at various panel points throughout the structure. The suspended span of the bridge is connected to the cantilever arms via vertical hangers, which are pinned at their upper and lower extremities. Truss members with axial and rotational releases transition the top and bottom chords between the suspended span and the adjacent cantilever arms. The floor system of the bridge is an 20 cm (8 in.) thick lightweight reinforced concrete deck that is composite with nine steel beams laterally spaced at 2.1 m (6.9 ft). The beams are continuous over the floor beams in either four-span or five-span increments. Figures 2–4 further illustrate various aspects of the structure.

2.2 Purpose and expected outcomes from SHM

Given the general characteristics of the long span, the specific objectives of the study were established. A research work plan was designed to accomplish the integration of experimental, analytical, and information technologies within a coherent health monitoring approach for the following objectives:

1. Conceptualizing the structural systems of the bridge, including the full recognition of the

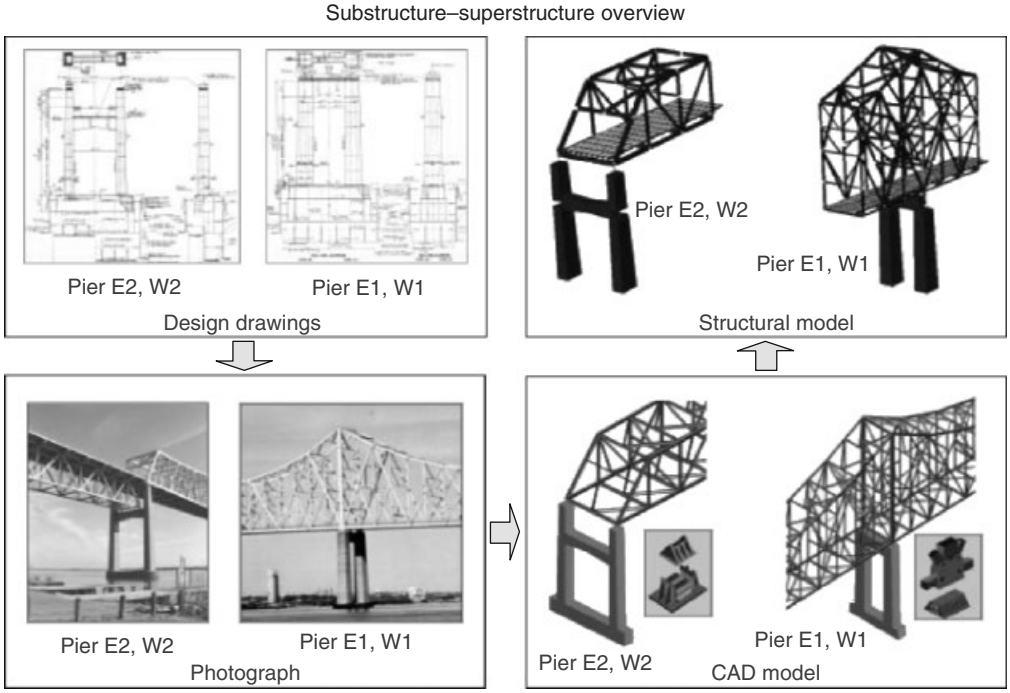

Figure 2. Design drawings, photos of bridge components, 3D CAD and FEM of the bridge.

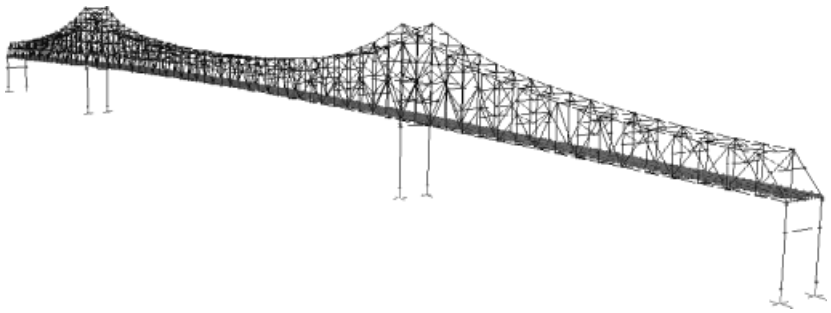

Figure 3. Finite element model of the Commodore Barry Bridge.

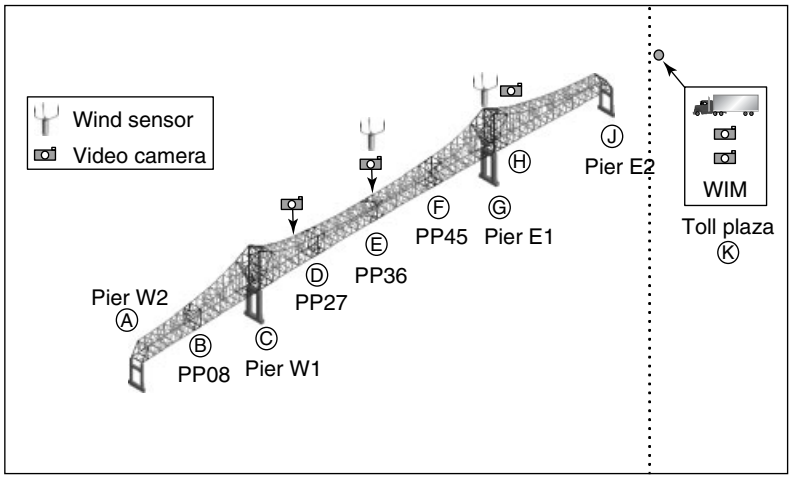

Figure 4. Sensor distribution and critical measurement locations.

natural–environmental and the sociotechnical systems that impact the bridge performance.

2. Analytical model development and calibration for detailed simulations and evaluations as well as for designing the monitoring system.
3. Development and demonstration of a complete SHM framework with Internet-based real-time monitoring modules, various sensors, data-acquisition systems, data management and communication protocols, and data analysis methods.
4. Development of various intermittent and long-term monitoring studies on the bridge to address issues such as operating vibrations, damper condition, electroslag weld evaluations, long-term behavior of critical structural members, and phenomena that is related to the performance of the concrete deck, which showed undesirable levels of cracking and deterioration.

3 ANALYTICAL ISSUES

3.1 Bridge characterization

Analytical model development for bridge characterization required a thorough review of the design and shop drawings for the bridge, inspection reports, and any additional relevant reports or documentation for the bridge to identify the current state of the structure including its performance and maintenance history [3]. Several site visits were necessary to visually examine and verify the condition and locations of complex member and connection details, retrofits to the structure, boundary conditions, and to establish access requirements for instrumentation. Photographic documentation of the critical structural details such as movement systems is generated. Using the existing design drawings and photographs, a 3D

visualization of the entire bridge as well as the critical structural details is generated by computer aided design (CAD) software (Figure 2).

A 3D finite element model (FEM) of the bridge, as shown in Figure 3, was constructed to assist in identifying the critical regions and behavior mechanisms of the bridge's structural systems and to estimate the limits of the forces, strains, tilts, displacements, and accelerations that may be necessary to measure. The FEM is calibrated through system identification procedures to permit reliable simulations based on the data from a health monitoring implementation. The data needed for system identification of the bridge and for subsequent calibration of the FEM were obtained from controlled experiments conducted on the bridge. These experiments included ambient vibration monitoring of the through-truss spans and a controlled load test using heavy cranes.

The calibrated FEM, which better reflects the true measured behavior of the bridge, may serve a number of purposes including accurate load rating analyses, vibration mitigation studies, vulnerability evaluations, maintenance/retrofit designs, as a benchmark for evaluating future changes in condition, as a foundation for evaluating system reliability and condition indicators for health monitoring, and as a starting point for any nonlinear analysis for failure limit state evaluations [3, 4].

4 LONG-TERM MONITORING ISSUES

4.1 Measured phenomena

The phenomena that should be monitored can be broadly considered in two categories. The phenomena that are understood or known, but cannot be reliably measured, analytically modeled, and accounted for in the design of the bridge, but that may affect the life-cycle performance of the bridge are in the first category. For example, the impact of settlements can be modeled and the intrinsic stress distribution can be identified by means of instrumentation or analytical modeling. The phenomena that are not clearly understood or modeled and accounted for (if at all) in design, but which may serve as causative effects for deterioration and damage are in the second category. For example, vibrations and displacements of the floor systems under various live load and wind combinations, and possible impacts of temperature shocks on movement and support systems are the phenomena that can be discovered only by long-term monitoring.

For the long-term health monitoring implementation of the CBB, the possible impacts of humidity, wind, temperature, radiation, long-term movements, tilts, slips and settlements on the intrinsic strains, and forces are measured [5]. Nonlinearity and nonstationary of boundary and continuity conditions and energy-dissipation mechanisms are recognized in the design of the health monitoring system.

The CBB health monitoring system was designed to integrate "vision" and "mechanical responses", the former by capturing streaming digital video images that monitor the traffic moving over critical areas of the bridge and the latter in the form of temperature, displacement, tilt, strain, and acceleration measurements distributed as shown in Figure 4.

4.2 Sensor characteristics, types, and quantities

In order to monitor the phenomena that have been identified in the earlier stages of the structural health monitoring (SHM) design, a number of different sensors are selected after extensive calibration and laboratory evaluation studies. The measurement phenomena are grouped into three distinct categories: (i) traffic, (ii) weather; and (iii) bridge response as given in Table 1.

4.3 Measurement and communication infrastructure

The CBB health monitoring system permits a combination of continuous, event-based, and time-based programmable as well as manually controlled online data-acquisition modes for interrogating specific sensor clusters. Since data in a long-term health monitoring implementation is generally obtained over large spatial (kilometers) and temporal spans (years to decades), and along a wide frequency band (various sensors may be interrogated once every quarter hour for ambient temperatures all the way to gigahertz frequency for acoustic emission

Table 1. Phenomena to be monitored with sensors and locations

Phenomena	To be monitored	Sensor description	Location
Traffic	Image streams	Real-time video image streams	D, E, J
	(weigh-in-motion) WIM	Bending plate scale	K
Weather	Air temperature	Self-contained weather station	G
	Humidity

sensors), space-time stamping and synchronization of the output from many different data-acquisition systems distributed through a bridge is a challenge. Data of different modalities (e.g., image streams vs a single strain reading) acquired by different systems add to the challenges of accurately time-stamping and synchronizing data. The sensing system for the CBB is interrogated over a local area network, the architecture of which is illustrated in Figure 5.

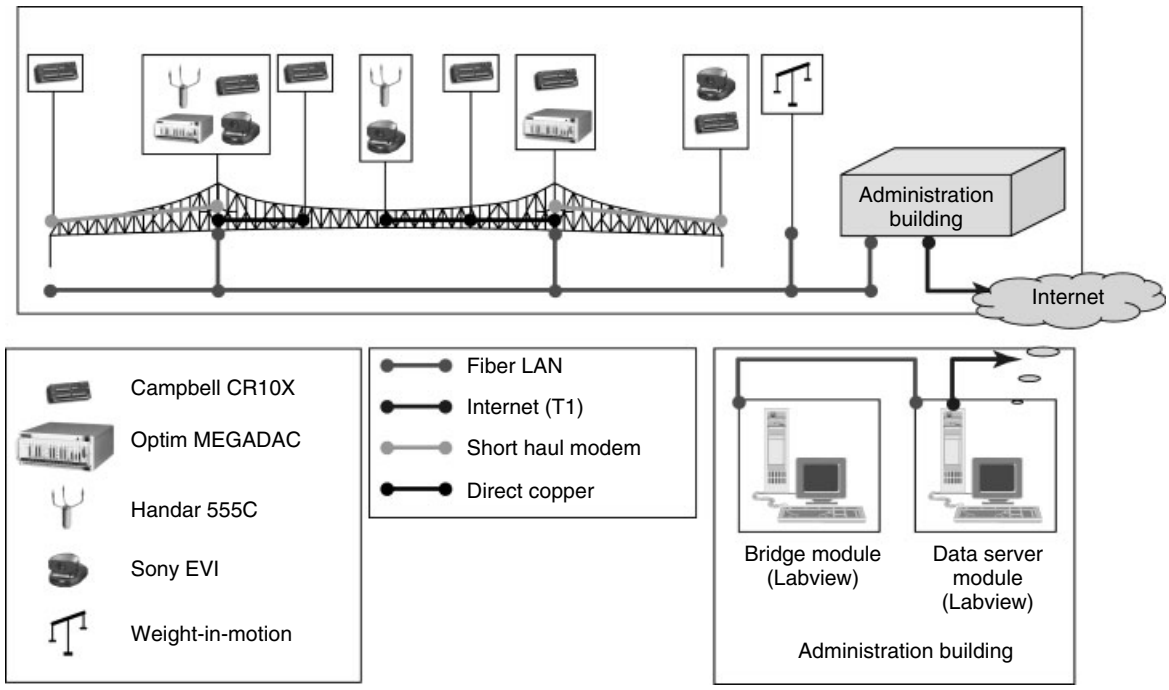

Figure 5. Measurement and communications infrastructure at the Commodore Barry Bridge.

The figure further depicts how the various data-acquisition system components are distributed and networked along the bridge. The data-acquisition systems are controlled, synchronized, and integrated by the software developed in Labview. Wind, temperature, radiation, and humidity interrogation is done with a data-acquisition system from Handar–Vaisala, vibrating-wire-based displacement, tilt, and strain sensors capture variations in the intrinsic responses over the long term and are interrogated by a dedicated data-acquisition system from Campbell Scientific, Inc., and the cameras are controlled by yet another dedicated system. The high-bandwidth strain, displacement, and acceleration sensors for high-speed responses captured over short-time increments are interrogated by a system from Optim Electronics, Inc.

4.4 Monitoring protocol, automated data acquisition and archival, and user interface

An authorized operator may take control of the CBB health monitoring system at anytime; however, the system is designed to operate in a programmed mode in which the inputs due to weather and traffic, and the entire set of vibrating-wire sensors are continuously interrogated at low frequency. The high-frequency sensors operate on time- or event-based triggered modes. For example, the system may be triggered to acquire and archive data from a subset of the complete sensor suite on the bridge, during the morning and evening rush hours when traffic levels on the bridge are highest, at midnight when traffic levels are very low, when the wind speed reaches a certain threshold value, or when a heavily loaded truck is detected by the weight-in-motion system. The frequency and duration of data and image collection, their processing, evaluation and dismissal, archival, presentation to a manager and/or alarm protocols will be eventually transformed to intelligent agents after researchers can more reliably establish the bounds of normalcy and possible indications or precursors of anomalies in operation or structural behavior. Clearly, data quality assurances, processing and archival practices represent the major information technology–related challenge in regard to health monitoring of a major bridge. Many tests are essential for data quality assurance even after the best possible sensor and data-acquisition design, operation, processing and archival practices are to be followed. Redundancy requirements in the application of sensors, integration of different types of sensors and measurement systems, calibration of the health monitoring system in the field by controlled testing, and, most importantly, justifying the output of any sensor based on the physics of the measured phenomena are techniques for data quality assurance.

The value of health monitoring applications, especially for operational and emergency management in conjunction with engineering purposes, is realized only by the visual display of critical images and data online in real-time (or near real-time). A challenge is in the integration and graphical display design of critical data streams so that users and owners may conceptualize the phenomena reflected in the measurements, in order to make timely decisions. Health monitoring design should involve the owners and engineers in charge of the operations, maintenance, and management of the bridge for maximum benefit. User communication, information and alert protocols, and training and maintenance support needs are major challenges related to monitor-user-organizational interface design. Figure 6 illustrates the interface designed for viewing real-time images from the bridge and information from the weight-in-motion system as well as the weather station.

4.5 Brief overview of findings

Approximately, 16 accelerometers were used to simultaneously capture the traffic-induced vibrations and their attenuations or amplification through the deck, the railing, the floor system, and the trusses. Frequency-domain transformations and cross correlations revealed the dominant input vibrations occurred at a frequency band of 5–15 Hz and with an amplitude of about 0.25 g at the deck, attenuating to an amplitude of 0.15 g at the truss lower chord. Impact-modal analysis of several railing elements revealed that the railing fundamental frequency in the lateral and vertical directions was about the same, 10 Hz, and this coincided with the frequency of the input excitation. The coupled lateral–vertical resonance of the railing elements caused extensive damage to the railing.

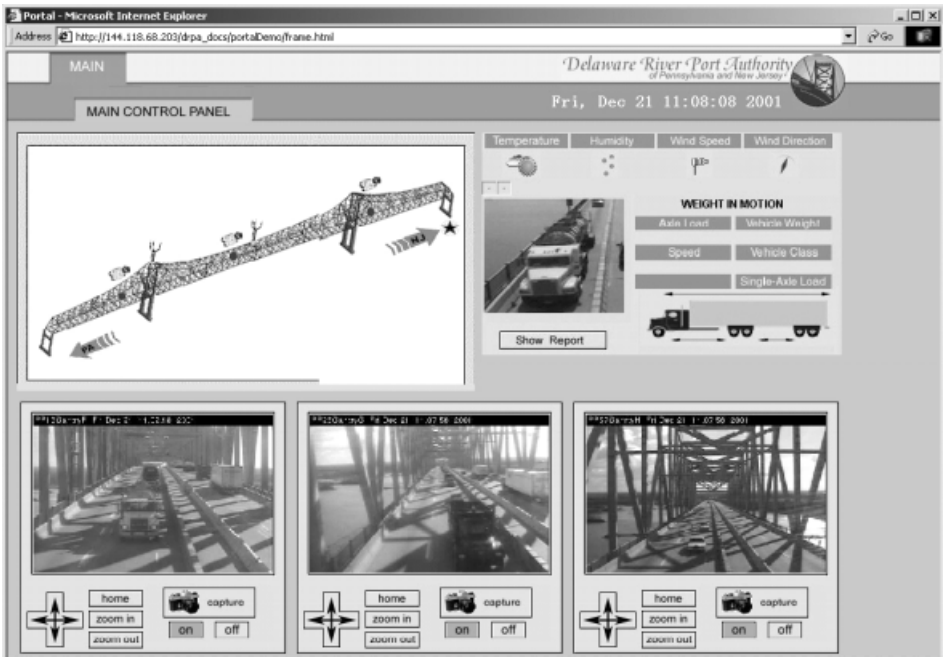

Figure 6. Internet-based user interface of the CBB health monitor system.

The time-histograms of member and damper acceleration responses monitored intermittently indicate that acceleration amplitudes that were about 0.15 g without the dampers are being reduced to about 0.06 g with the dampers. The importance of the dampers in controlling operating vibrations was therefore clear from monitoring these results. Dampers were found to have been well tuned to the member frequencies for optimum energy dissipation. The chemical and physical properties of the neoprene material were investigated further by cutting samples for chemical analysis. The results did not reveal any deterioration. Although the damper and member vibrations are yet to be monitored under sufficiently high wind that would cause wind-induced excitation of a member, it is clear that the dampers are highly effective and critical for controlling truss vibrations.

Temperature changes and solar radiation were observed to be the most significant load effect on the trusses. For example, Figure 7 shows the annual change in the intrinsic strains of one of the hangers, together with the temperatures recorded during the year. Strains are observed to vary significantly in the order of 41 kPa (6 Ksi) or more during days when large temperature changes occur within a short time. An annual seasonal variation of up to 69 kPa (10 Ksi) is observed in the intrinsic strains correlating perfectly with the temperature. This is a considerable stress when calculated dead load stresses varied between 138 kPa and 207 kPa (20 and 30 Ksi) at most truss members.

A closer scrutiny of the measured strain and temperature histograms indicated that the hanger intrinsic strains were affected by the complex movement and force-release systems at and in the vicinity of these members. A distinctly unsymmetric behavior of the long-term strains of the two instrumented hangers was attributed to a difference in the behavior of the movement systems at their respective boundaries on the north and the south trusses. In addition, an out-of-plane behavior was noted in the hangers that were expected to be concentrically loaded due to radiation and temperature changes.

In addition to continuous long-term monitoring, intermittent monitoring under operating traffic and known truck loads were conducted. Figure 8 shows a crane that was positioned with another crane in static configurations as well as crawled along the bridge for this test that required closure of the bridge.

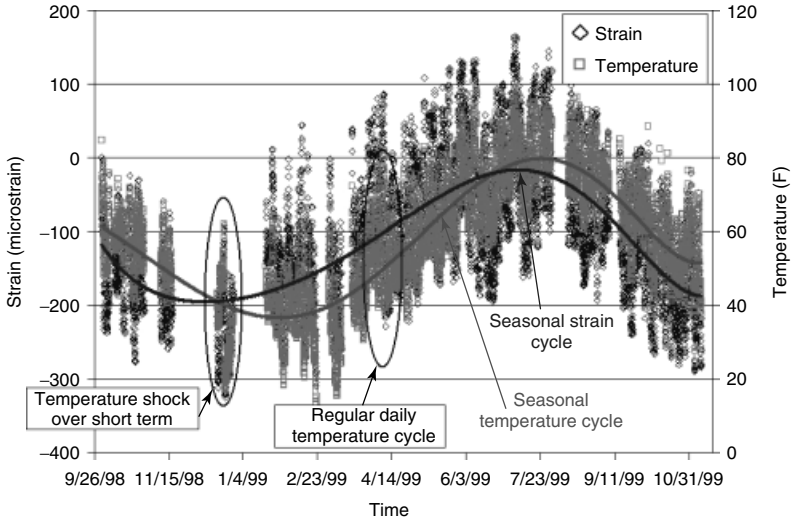

Figure 7. Long-term changes in intrinsic hanger strains with temperature.

Two 480 kN (108 Kip) cranes were used for loading and 52 high-speed strain gauges were used for recording critical member strains during the tests. Both the floor system and the truss responses were captured as the cranes were statically positioned at critical locations. Following this, a crane crawled on each of the five lanes throughout the bridge. By conducting the tests between midnight and 4 a.m., it was possible to maintain reasonably constant ambient conditions. Figure 4 shows the influence coefficients obtained for one of the hangers and a lower chord member at midspan by allowing the crane to crawl along each lane. These influence coefficients may be further normalized by decomposing them into influence coefficients corresponding to single-axle loads, and these may serve as an excellent index capturing the as-is structural behavior.

In addition to truck load test, ambient vibration tests were conducted to determine the global vibration characteristics and to provide data for finite element calibration. To maximize the spatial resolution of the mode shapes, one-half of the bridge was instrumented. It is possible to develop multiple instrumentation grids, which are then numerically spliced. However, roving the sensors reduces the reliability in the data and the roving option was eliminated. In order to verify that the test instrumentation grid will be adequate and for optimizing the sensor locations, a finite element analysis of the bridge was conducted. Analysis results helped to estimate the fundamental frequencies of the bridge, the frequency band of interest as well as the frequency spacing. 32 PCB Model 393C ICP and 13 PCB capacitive accelerometers were placed on the main truss using magnets. Two ICP signal conditioners and a capacity signal conditioner, in conjunction with an Agilent Technologies VXI system with three 16-channel E1432A boards, were used for data acquisition. The data sets were collected for 6-min intervals. For each sensor channel, time and frequency plots are defined using HP DAC Express software. This allowed real-time monitoring and quality control of the data both in time and frequency domains as it was acquired.

When the dynamic characteristics, i.e., mode shapes and frequencies, are compared, it is seen that the nominal FEM underestimated the global stiffness of the structure by as much as 40% (assuming that the inertia is properly modeled, a 20% discrepancy in frequency would correspond to over 40% discrepancy in stiffness). Obviously, unless a FEM is properly tested, calibrated and verified, it is not advisable to make critical decisions based on simulations. In addition, there were discrepancies between the measured stresses at critical elements and the FEM results. After understanding the impact of various assumptions on boundary and continuity conditions on the dynamic properties, the pier stiffnesses were increased substantially, and all

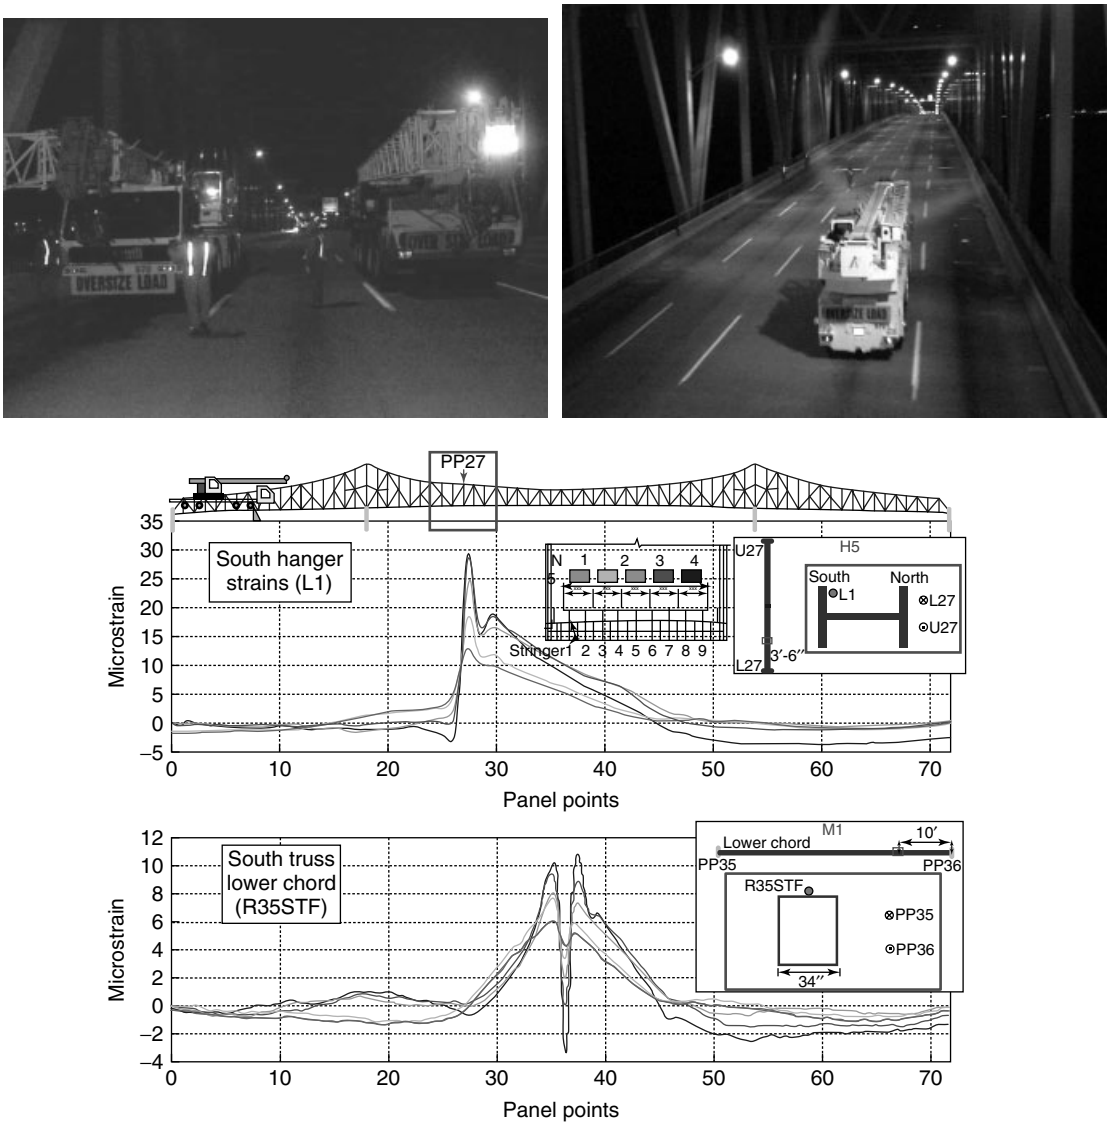

Figure 8. Loading cranes and sample influence lines from controlled testing.

the movement mechanisms were fixed before the model dynamic properties approached the measured properties. After a sufficiently close correlation was obtained between the measured and simulated global dynamic properties, the strains at the critical elements obtained during the controlled load testing were used for local calibration of the floor system element and connection stiffnesses. When a fully composite behavior of the deck and the stringers and full continuity between the stringers and the deck were simulated, the rms of the error, between measured and simulated strains at 20 measurement locations, was reduced from 55 to 24%. The assumptions on global and local stiffness and continuity brought the rms of the errors in the first six frequencies from 28 to 1.5%. Hence, the model was considered to be sufficiently calibrated. This FEM would be suitable for many purposes as discussed earlier.

5 CONCLUDING REMARKS

The health monitoring paradigm has been defined and described, potential benefits from its various application modes are suggested, and an ongoing application to a major long-span bridge has been summarized. The health monitoring applications to the CBB have provided a rare wealth of data and information about the loading mechanisms and behavior of the bridge, such as documenting the dynamic frequency band of the input excitation and how this creates near-resonance with various elements of the floor system. An in-depth intuitive understanding and quantitative documentation of the loading effects of wind, temperature, and traffic as well as the corresponding strains and forces were possible. The challenge is in developing monitoring systems that will help solve problems such as deck performance, which might be owing to many different factors such as material properties and excessive vibrations.

It is important that although the monitor system offered great promise as a technology that would potentially assist the bridge owner to develop and implement an integrated operational and maintenance management plan to minimize its life-cycle cost, this would have required a major investment into technology maintenance and technology management for the owner agency. At present, such a high level of technology maintenance and management expertise may be too costly for many of the bridge agencies in the United States. Both societal and organizational reforms are needed before technology-intensive paradigms such as health monitoring for operational and maintenance management may become a common application in the United States.

This brief review of the project articulated the need for an integrated systems approach to technology development and for the leveraging of technology in order to make a difference in how we manage major bridges. Integrated systems approach requires that we correctly identify, measure, understand, and then incorporate, in any management decision, the interactions between natural, sociotechnical, and constructed systems that govern the performance of all infrastructure components and systems. While technology advances are relatively easier to accomplish, these cannot be of great use unless they are accompanied by organizational and societal advances. The importance of technology management in infrastructure agencies is a most important issue following the experiences of the writers.

ACKNOWLEDGMENTS

The authors would like to acknowledge the invaluable contributions to the research made by their many multidisciplinary colleagues, researchers, and students at the Drexel Intelligent Infrastructure and Transportation Safety Institute. The research described in this article was sponsored by the Delaware River Port Authority and the Federal Highway Administration (FHWA). The support of these agencies is gratefully appreciated. The authors would especially like to acknowledge Messrs. Box, Faust, McCulloch and Bistline from DRPA for their collaboration. The authors also thank Dr Chase and Dr Ghasemi of FHWA for their continued support and interest over the years. Finally, the authors acknowledge National Science Foundation (NSF) for various grants that supported the authors' research on health monitoring of bridges.

1 INTRODUCTION

Bridge health monitoring is the tracing of the structural health conditions of the bridge in terms of the physical parameters categorized as environmental loads and status, traffic loads, bridge features, and bridge responses by reliably measured data and evaluation techniques, in conjunction with inductive reasoning and experience so that the current and expected future performance of the bridge, for at least the most critical limit events, can be predicted or evaluated. Bridge health monitoring system has been adopted in the past decade to monitor and evaluate the structural health conditions of cable-supported bridges in Hong Kong [1–5]. The bridge health monitoring system in Hong Kong is referred to as *wind and structural health monitoring system* (*WASHMS*). Bridge health monitoring system is currently considered as an integral part of bridge operation, bridge inspection, and bridge maintenance and has been included as a standard mechatronic system in the design and construction of most large-scale and multidisciplinary bridge projects such as Stonecutters Bridge (SCB) in Hong Kong [6], and Sutong Bridge [7] and Donghai Bridge in mainland China [8]. The experience gained in the design, installation, operation, maintenance, and development of the WASHMS for Tsing Ma Bridge (TMB), Kap Shui Mun Bridge (KSMB), Ting Kau Bridge (TKB), and the cable-stayed bridge in Hong Kong side of the Hong Kong-Shenzhen Western Corridor (HSWC) has a significant influence on the design of new structural

health monitoring systems (SHMSs) in Hong Kong and in mainland China. The WASHMS in Hong Kong, which is based on modular design concept, has been improved particularly in the aspect of data interpretation, health evaluation, and data management and such improvements have been incorporated in the design and installation of the WASHMS for SCB (SCB-WASHMS) [6].

2 SYSTEM ARCHITECTURE OF WASHMS

The modular concept of WASHMS [9–11], which is devised to monitor structural condition and evaluate structural degradation as it occurs rather than to detect structural failures, is composed of six integrated modules, namely, module 1—sensory system (SS); module 2—data acquisition and transmission system (DATS); module 3—data processing and control system (DPCS); module 4—structural health evaluation system (SHES); module 5—structural health data management system (SHDMS); and module 6—inspection and maintenance system (IMS). Figure 1 illustrates the modular architecture and input/output block diagram of WASHMS. Of these six modules, modules 1–3, which are the key modular systems for the execution of real-time structural health monitoring, are composed of different types of SSs, data/video logging systems, cabling network systems, servers and software facilities for data acquisition, transmission, and processing. The schematic layout of typical connections among modules 1–3 is shown in Figure 2. Modules 4 and 5, which are key modular systems for the execution of offtime structural health evaluation, are composed of servers, workstations, and software facilities for data interpretation, health evaluation, data management, and generation of reports. Module 6 is a set of portable computers (that store the system design information and operation and maintenance manual of WASHMS) and tools for carrying out inspection and minor maintenance of the WASHMS itself.

2.1 Module 1—sensory system (SS)

The SS that refers to the sensors and their corresponding interfacing units for input signals gathered

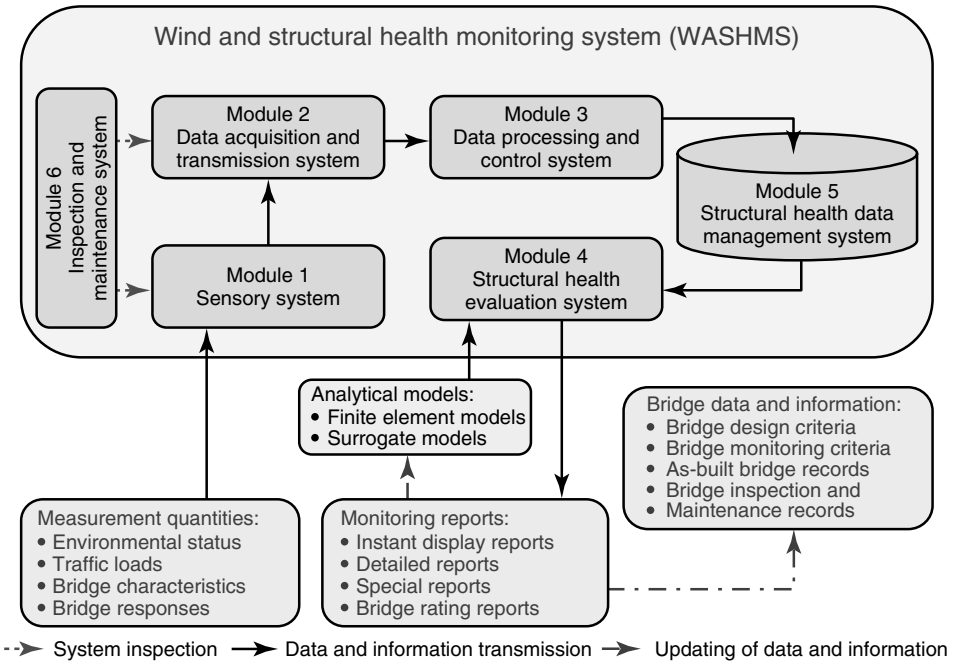

Figure 1. Modular architecture and input/output block diagrams of WASHMS.

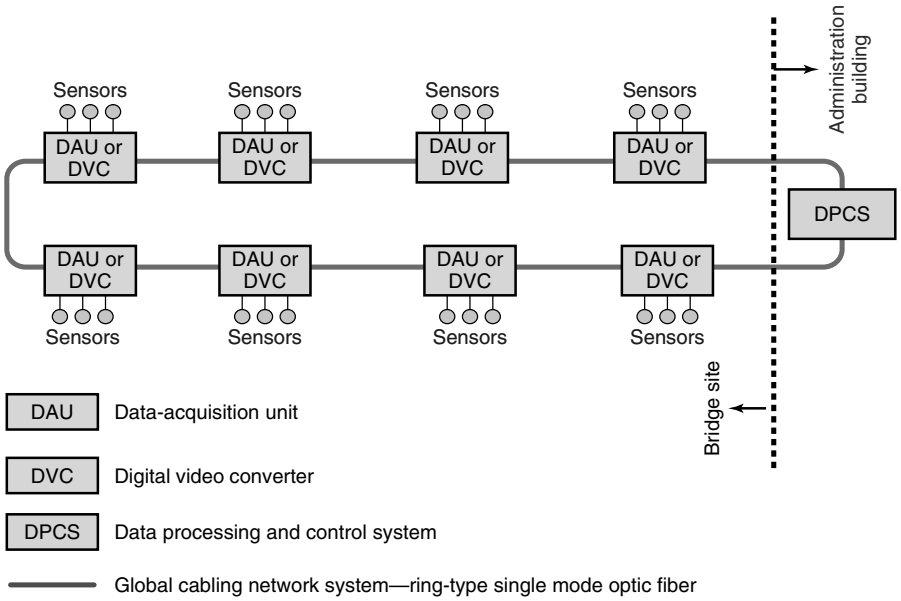

Figure 2. Schematic layout of module 2—data acquisition and transmission system.

from various monitoring equipment and sensors is categorized into four groups: (i) sensors for monitoring of environmental loads and/or status, which include anemometers (three-dimensional ultrasonic type and two-dimensional propeller type), temperature sensors (for the measurement of temperatures in respective air, asphalt pavement sections, structural concrete sections, structural steel sections, suspension cables, and stay cables), corrosion cells, hygrometers, barometers, and rainfall gauges; (ii) sensors for monitoring of traffic loads, which include dynamic weigh-in-motion stations, digital video cameras, and dynamic (weldable foil type) strain gauges; (iii) sensors for monitoring of bridge characteristics, which include fixed and removable/portable servo-type accelerometers, global positioning systems, level sensing stations, and dynamic strain gauges; and (iv) sensors for monitoring of bridge responses, which include dynamic strain gauges, static (vibrating wire type) strain gauges, displacement transducers, global positioning systems, tiltmeters, fixed servo-type accelerometers, buffer sensors, bearing sensors, and elastomagnetic sensors.

In the design/selection of the types and locations of SSs, the following six basic criteria should be fulfilled: (i) the SS should have the ability to capture the local- and system-level responses, which could be correlated or compared with the design values; (ii) the SS is required to integrate the predictive modeling and data interrogation processes with the sensing system design process; (iii) the SS should have the function to acquire data in a consistent and retrievable manner for long-term statistical data processing and analysis; (iv) all sensors should be chosen from the contemporary commercially available sensors that best match the defined sensing performance requirements; (v) the SS should include additional measurements by removable/portable sensors to quantify changing operational and environmental conditions; and (vi) at key locations, different types of sensors should be deployed so that cross calibration of sensors could be carried out.

The major parameters monitored by each type of sensors are listed in Table 1. Figures 3–7 illustrate the layouts of the SSs in TMB, KSMB, TKB, HSWC, and SCB on their respective full three-dimensional finite element models, which are built by MSC-PATRAN. The layouts of the SSs as shown in Figures 3–7 are deployed or arranged in such a manner that the measured raw data can be used to derive the information or parameters as listed in the fourth column of Table 1. These derived information and parameters are then used to compare/correlate with (i) the corresponding bridge

Table 1. List of required sensory systems and physical parameters for processing and derivation

Monitoring category	Physical quantity	Required types of sensory systems	Physical parameters for processing and derivation
Environments	Wind load monitoring	• Ultrasonic-type anemometers • Propeller-type anemometers • Barometers[a,b] • Rainfall gauges[a,b] • Hygrometers[a,b]	• Wind speed and wind direction plots (time-series data) • Wind speeds (mean and gust) and directions (histograms) • Terrain factors and wind speed profile plots • Wind rose diagrams • Wind incidences at deck level • Wind turbulence intensities and intensity profile plots • Wind turbulent time- and length-scale plots • Wind turbulent spectrum and cospectrum plots • Wind turbulent horizontal and vertical coherence plots • Wind response and wind load transfer function • Wind-induced accumulated fatigue damage • Histograms of air pressure, rainfall, and humidity
	Temperature load monitoring	• Platinum resistance temperature detector (RTD) type for temperature measurements in structural steel, concrete, asphalt pavement, and air • Thermocouplers for cables	• Effective temperatures in towers, deck, and cables • Differential temperatures in deck and tower • Air temperatures and asphalt pavement temperatures • Temperature response • Temperature load transfer function
	Seismic load monitoring	• Fixed servo-type accelerometers	• Acceleration spectra near tower and anchorage • Deck and tower response spectra • Seismic response and seismic load transfer function
	Corrosion status monitoring[a,b]	• Corrosion sensors[a,b] • Hygrometers[a,b]	• Potential risk of rebar corrosion in concrete towers, concrete piers in side spans, and concrete deck in side spans
Traffic loads	Highway traffic load monitoring	• Dynamic weigh-in-motion stations (bending-plate type) • Dynamic strain gauges • closed circuit television (CCTV) cameras[c–e] • Digital video cameras[a,b]	• GVW spectrum in each traffic lane • AW spectrum in each traffic lane • Equivalent number of SFV spectrum in each traffic lane • Equivalent number of SFA spectrum in each traffic lane • Highway-induced accumulated fatigue damage—SFV • Highway-induced accumulated fatigue damage—SFA • Overload vehicles detection • Traffic composition in each traffic lane • Traffic load response and traffic load transfer function

Table 1. (*continued*)

Monitoring category	Physical quantity	Required types of sensory systems	Physical parameters for processing and derivation
	Railway traffic load monitoring[c,d]	• Dynamic strain gauges[c,d] • CCTV video cameras[c,d]	• Bogie loads in each line of train • Train loading spectrum • Equivalent standard load (train) spectrum • Train-induced accumulated fatigue damage • Train load response and train load transfer function
Bridge features	Static influence coefficient monitoring	• Level sensing stations[c,d] • global positioning system (GPS)[b–e] • Dynamic strain gauges	• Lane stress history in each traffic lane—each vehicular type • Stress range of each type of vehicle in each traffic lane • Influence surfaces for combined deck plates and troughs • Line stress history of each type of train • Stress range of each type of train • Influence coefficients at tower tops and deck midspan
	Global dynamic characteristics monitoring	• Fixed and portable servo-type accelerometers	• Global bridge modal frequencies • Global bridge vibration modes • Global bridge modal damping ratios (derived) • Global bridge modal mass participation factors (derived)
Bridge responses	Cable forces monitoring	• Portable servo-type accelerometers	• Cable frequencies and hence cable forces • Cable damping ratios
	Geometry monitoring	• GPS[b–e] • Level sensing stations[c,d] • Displacement transducers • Servo-type accelerometers • Static strain gauges[c]	• Thermal movements of cables, deck, and towers • Wind movements in cables, deck, and towers • Seismic movements in deck and towers • Highway load movement in deck and cables • Railway load movement in deck and cables[c,d] • Creep and shrinkage effects in concrete towers[a,b]
	Stress monitoring	• Dynamic strain gauges • Static strain gauges[a,b] • Elastomagnetic sensors[b]	• Stress historical plots of instrumented components • Stress demand ratio plots of instrumented components • Principal stress plots of instrumented components • Force demand ratios plots of concrete–steel interfaces
	Fatigue life monitoring	• Dynamic strain gauges	• Total accumulated fatigue damage and hence, remaining fatigue life due to combined load effects • Accumulated fatigue damage and hence remaining fatigue life estimation due to individual load effects

design information and parameters for detection of any significant deviation from design values; (ii) previous similar measured/derived values for detection of any abnormal or adverse structural performance; and (iii) analytical results from numerical or physical models for estimating the extent of damage, if any. Portable or removable servo-type accelerometers are also deployed with the main purposes of (i) calibration of the full three-dimensional finite element model of the bridge and (ii) extraction of high-order frequencies and mode shapes from time history acceleration data for facilitating future damage detection works. The deployment of the measurement system should also be able to quantify the changing operational and environmental conditions and to provide information for developing future loading prediction models.

2.2 Module 2—data acquisition and transmission system (DATS)

The DATS is composed of four subsystems, namely, data-acquisition system (DAS), local cabling network

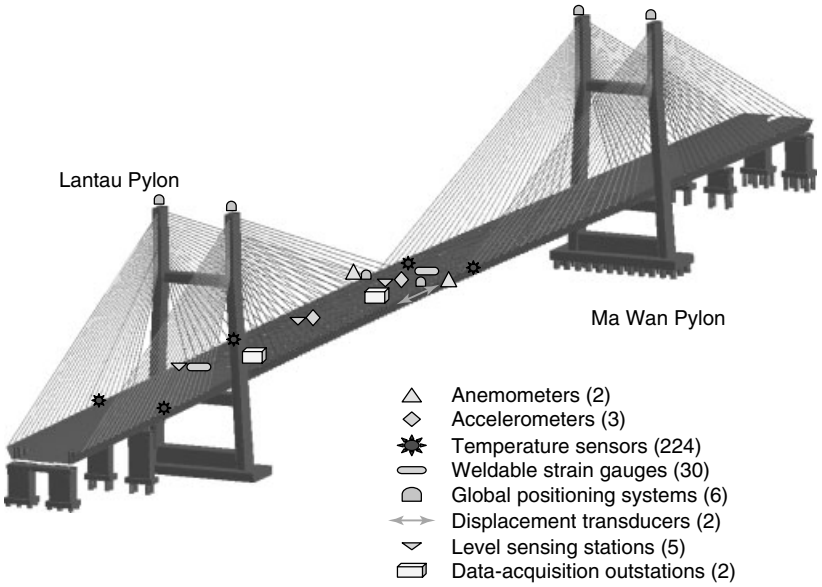

Figure 4. Layout of sensory system and data-acquisition system in Kap Shui Mun Bridge.

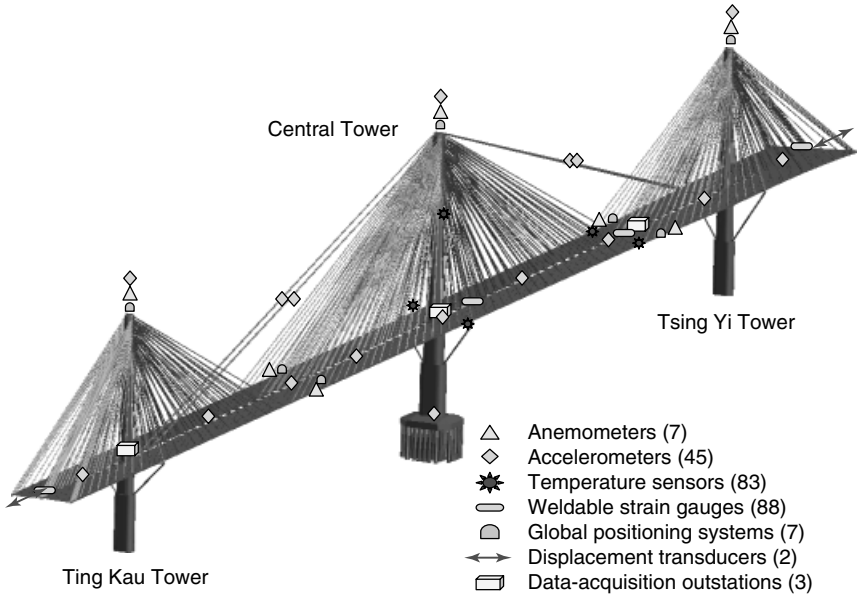

Figure 5. Layout of sensory system and data-acquisition system in Ting Kau Bridge.

system (LCNS), global cabling network system (GCNS), and commercial cabling network system (CCNS). The DAS is composed of fixed data-acquisition units (DAUs), portable DAUs, and digital video converters (DVCs) for collection of respective random and digital video signals. All DAUs and DVCs are PC-based equipment. The fixed DAUs and DVCs are permanently installed in the bridge deck and bridge towers for collection and processing of the signals received from SS (excluding corrosion cells).

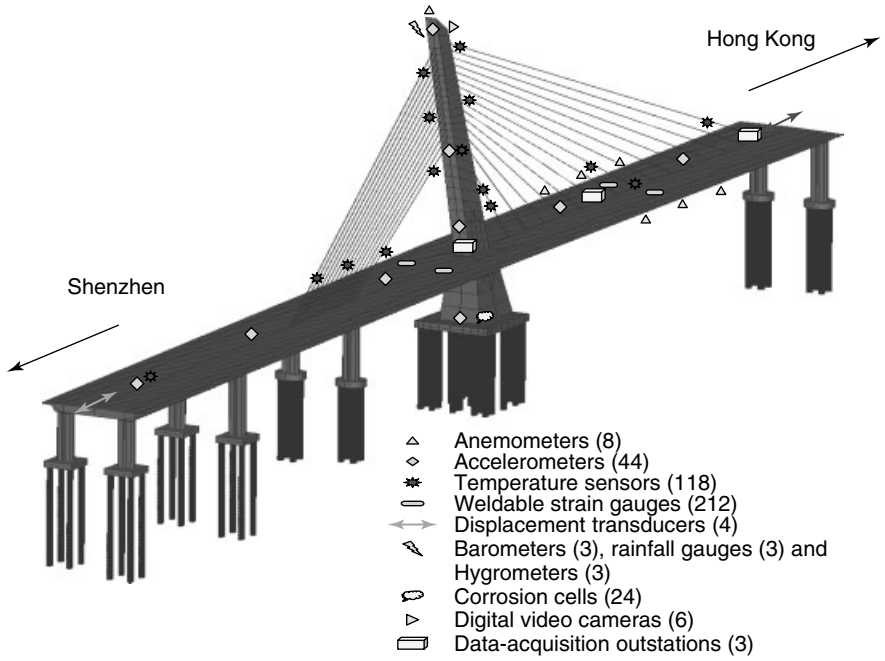

Figure 6. Layout of sensory system and data-acquisition system in Hong Kong–Shenzhen Western Corridor (Hong Kong side cable-stayed bridge).

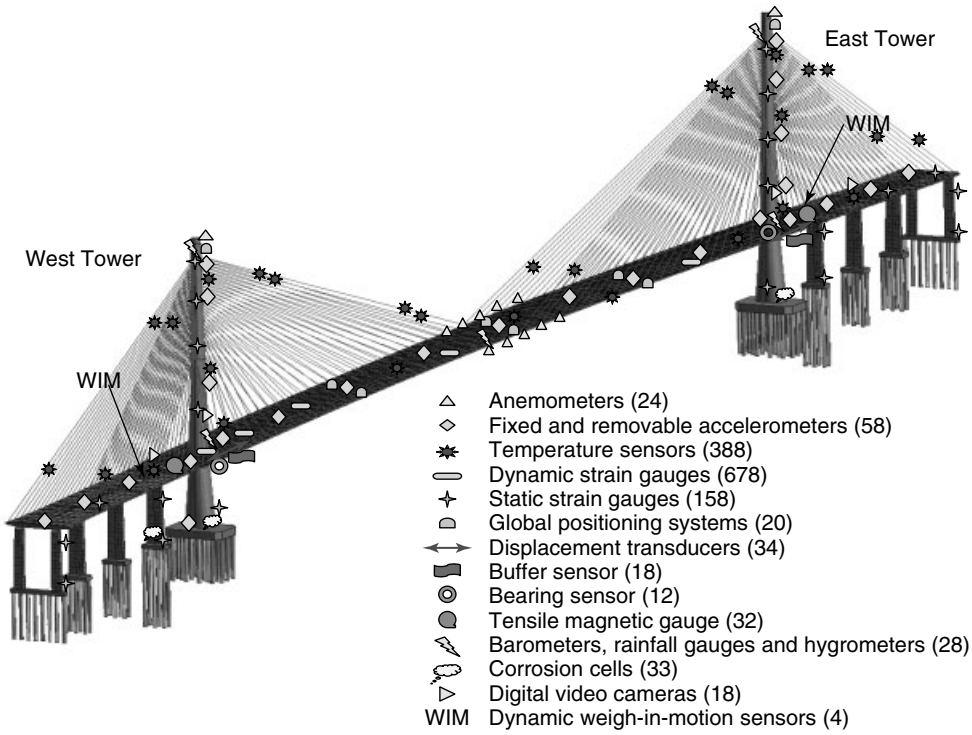

Figure 7. Layout of sensory system and data-acquisition system in Stonecutters Bridge.

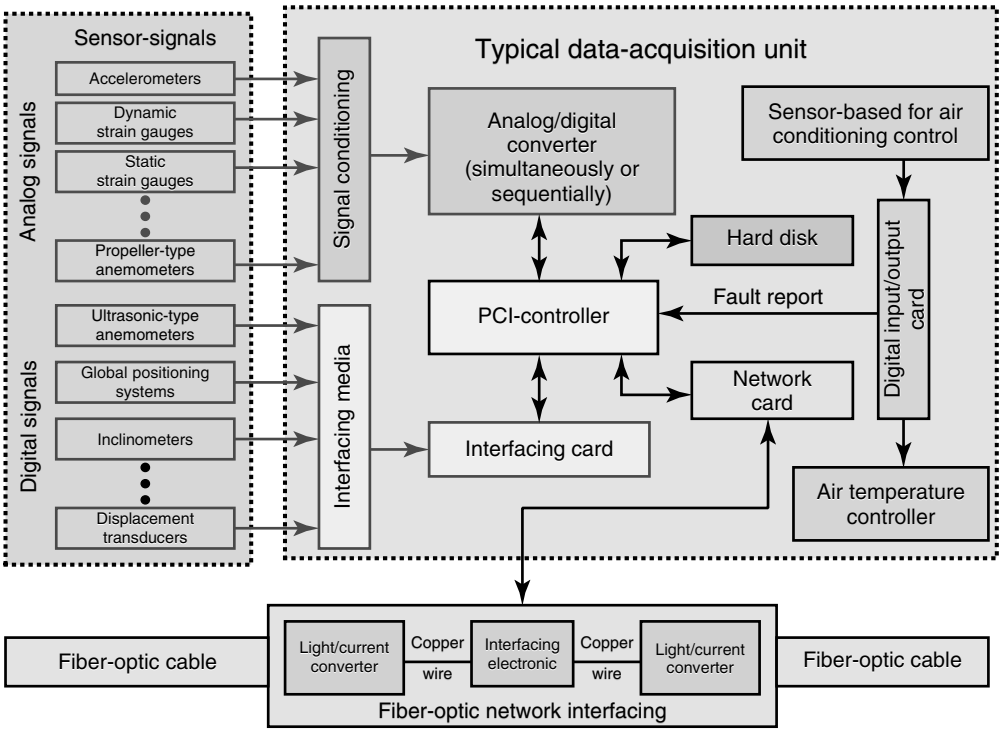

Figure 8. Schematic layout of typical connection among DAU, SS, and GCNS.

The portable DAUs are used to collect signals from portable servo-type accelerometers and corrosion cells during ambient vibration measurements and/or specified field measurement works.

Figure 8 shows the schematic layout of a typical connection among SS, DAU, and GCNS (fiber-optic cable). The major components in the DAU are the peripheral components interconnect (PCI)-controller, the signal conditioning device, and the analog-to-digital converter, and the proper selection/design of these components are the key steps to obtain measurement data with high quality. The LCNS is composed of two local cabling networks, namely, the copper cabling network for transmission of the signals from SS (excluding global positioning systems and digital video cameras, which are transmitted by fiber-optic cables) to DAUs for random signals and DVCs for digital video signals, as shown in Figure 2.

The GCNS is composed of two backbone cabling networks, namely, the random signal transmission cabling network for transmission of digitized signals (excluding digital video cameras) from individual DAUs to DPCS-1 and the digital video signal transmission cabling network for transmission of digital video signals from individual DVCs to DPCS-2. Both backbone cabling networks are ring-shaped single-mode fiber-optic cabling networks with a data transmission capacity of 1 Gbps.

The CCNS is the leased high-speed line with a data transmission rate of not less than 40 Mbps for data communication (i) between the data-acquisition outstations in bridge site of HSWC and the bridge monitoring room in West Control Building and (ii) between the bridge monitoring room in the Tsing Yi Administration Building at North Tsing Yi and the bridge monitoring room in West Control Building in South Tsing Yi (or Tsing Ma Control Area).

2.3 Module 3—data processing and control system (DPCS)

Figure 2 shows that the measured data collected from module 1 are preprocessed and transmitted by module 2 to module 3 or DPCS, which is composed

of two high-performance servers, namely, DPCS-1 and DPCS-2 for data processing and control of random (digital) signals and video (digital) signals, respectively. The DPCS is devised to carry out four operational functions, namely, system control, system operation display, bridge operation display, and post processing and analysis of data. Figures 9 and 10 illustrate the respective functions of DPCS-1 and DPCS-2 in block diagrams.

2.4 Module 4—structural health evaluation system (SHES)

Figure 2 shows the comparison part on evaluation criteria or the offtime structural health evaluation that is devised to be taken up by the SHES or module 4, which is composed of two high-performance servers (one mainly for MSC and MATALB software tools and the other mainly for ANSYS and MATALB software tools) equipped with appropriate software tools to carry out the following operational functions:

- **Finite element software interfacing capability**

That is, finite element models built by MSC/PATRAN can be transferred to and executed in ANSYS software without any manual modifications, and vice versa.

- **Integration of finite element models and measured data**

The automatic input of measured data into relevant finite element models and under relevant (predefined) solvers for execution is therefore required.

- **Analytical and experimental modal analyses**

The automatic extractions and plots of the global dynamic features of global bridge structural system and local bridge components from the measured time history acceleration data are required. Figure 11

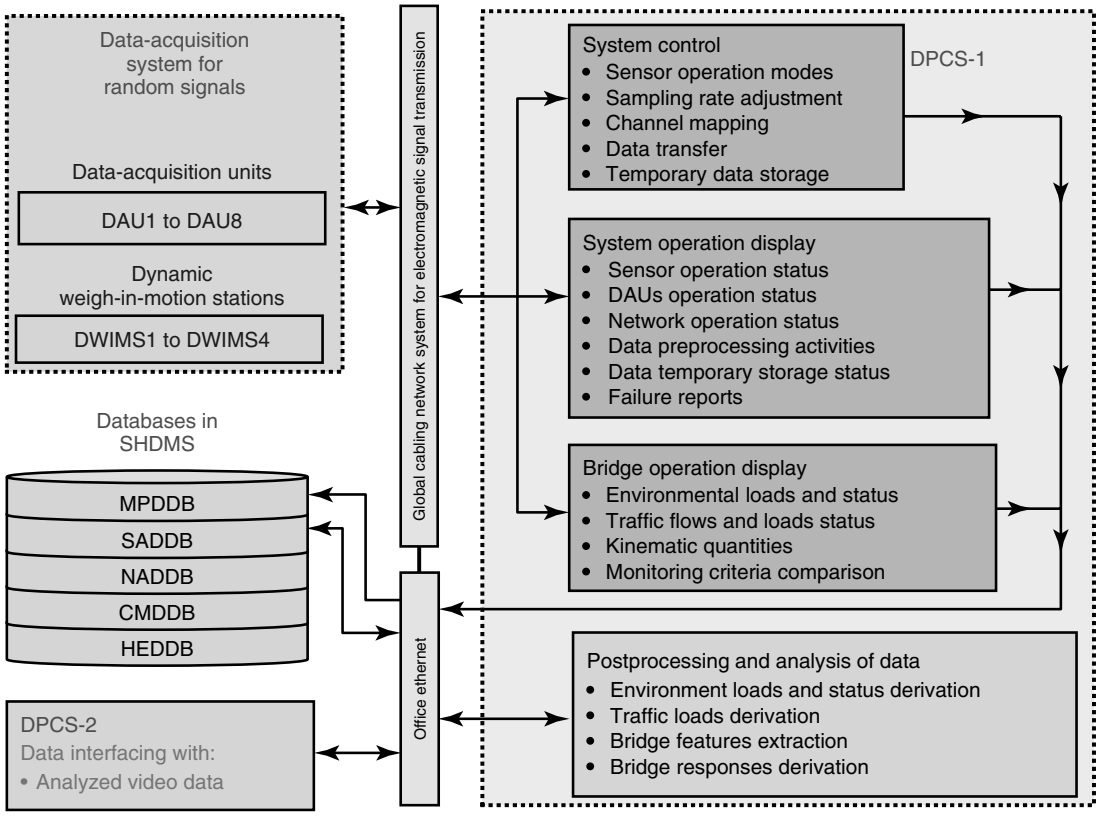

Figure 9. Functional block diagram of DPCS-1—module 3 for random signals.

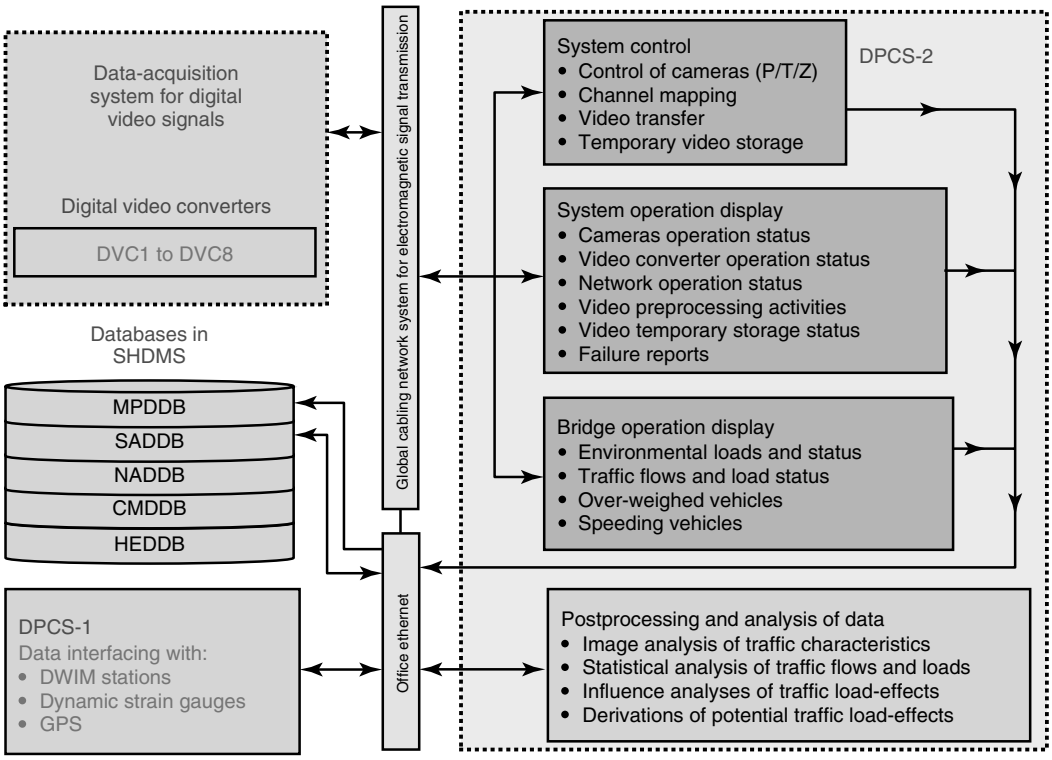

Figure 10. Functional block diagram of DPCS-2—module 3 for video signals.

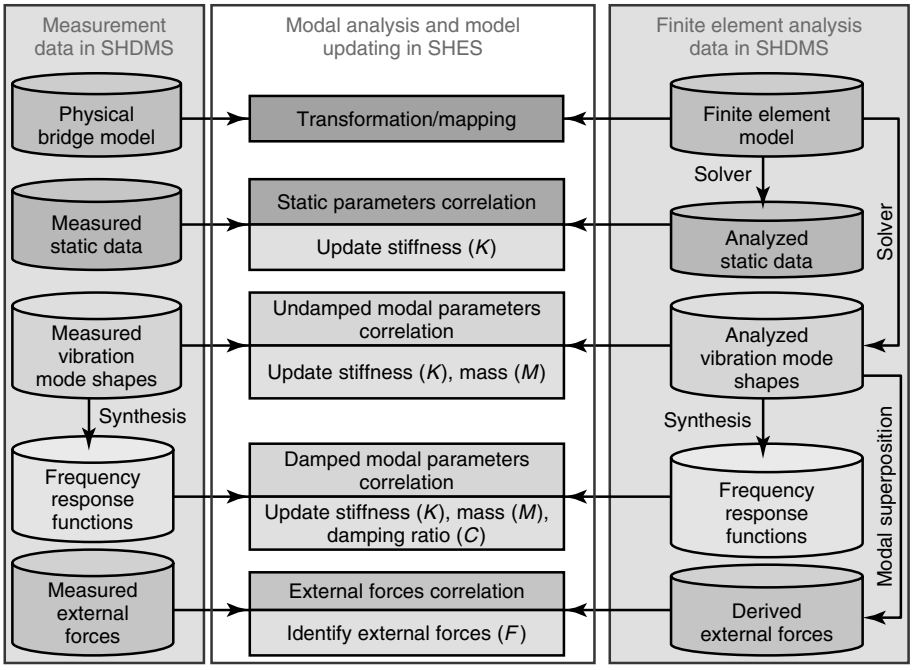

Figure 11. Modal analysis and model updating in SHES by interfacing with SHDMS.

shows the typical modal analysis and model updating works in SHES by interfacing with SHDMS.

- **Structural diagnosis modeling analyses**

For any key structural component or location with a measured and/or derived stress and/or displacement that exceeds 60–75% of its predefined monitoring criteria, structural diagnosis or assessment of the current state of the bridge structure and its history will be carried out in order to assess any adverse effects on the global structural system based on the current and historical environmental, and operational loading conditions. For the sake of facilitating such assessments, it is required to perform automatic execution of finite element analyses on those prebuilt models and under predefined typical types of structural analysis such as geometric nonlinear analysis of traffic and temperature loads, random response analysis of dynamic wind seismic loads, etc.

- **Structural prognosis modeling analyses**

The aim of structural prognosis is to assess the ability of the bridge structural system to carry out future loading conditions (derived on the basis of past and current measured loads) or extreme events. The applications of structural prognosis in WASHMS are (i) to predict/assess the remaining fatigue life of structural steel components based on a combination of finite element analyzed results, BS5400: Part 10: fatigue assessment rules, and measured strain results from WASHMS [12]; (ii) to investigate the different types of potential failure modes and the associated predictable and unpredictable loading conditions that cause damage and subsequent failure; (iii) to determine the potential consequences of each failure event or multiple events acting simultaneously; and (iv) to facilitate the planning of scheduled inspection and maintenance activities.

- **Visualization of analyzed results**

In order to increase the efficiency and accuracy in identification and quantification of abnormal features or defects, all the analyzed, measured, and derived results are presented in comparative plots (with animation, where necessary) and tabulated in the matrix form.

The execution of the above operational functions requires the development of a customized finite element interfacing software system (FEISS) to manipulate the operation of different software tools (including both finite element analysis tools and random data processing and analysis tools) under different hardware and software operating platforms. The FEISS is composed of five modules, i.e., modules A, B, C, D, and E, as shown in Figure 12. Module A includes the prebuilt finite element models of (i) full 3D global bridge model, (ii) full 3D local foundation bridge model, (iii) 3D global spine-beam or gird-beam bridge model, and (iv) full 3D local segmental bridge models. Module B includes the preconfigured finite element analysis types such as normal mode analysis, linear static analysis (influence coefficients' determination), nonlinear static analysis, random response analysis (buffeting and seismic responses determination), fatigue analysis, and impacting analysis. Module C includes the finite element and statistics solvers such as MSC-NASTRAN, ANSYS-Vertical Physics, MATLAB data analysis suite, etc. Module D includes post-posting and display software for generation of analyzed results and reports. Module E includes the interfacing and control software for the execution of (i) automatic/manual retrieval of measured/analyzed data from the relevant database in module 5 to module 4 for processing/analysis; (ii) automatic/manual inputting of the retrieved data into relevant prebuilt finite element or statistical model/models for predefined types of finite element or statistics analysis; and (iii) automatic/manual display and storage of the analyzed results.

2.5 Module 5—structural health data management system (SHDMS)

The SHDMS is composed of a high-performance server equipped with data management software, and is the interfacing platform for the interoperability of data and information so that the efficiency of fusion of data and information for decision making can be significantly enhanced.

The following five major databases are devised to be executed in the SHDMS for interfacing works:

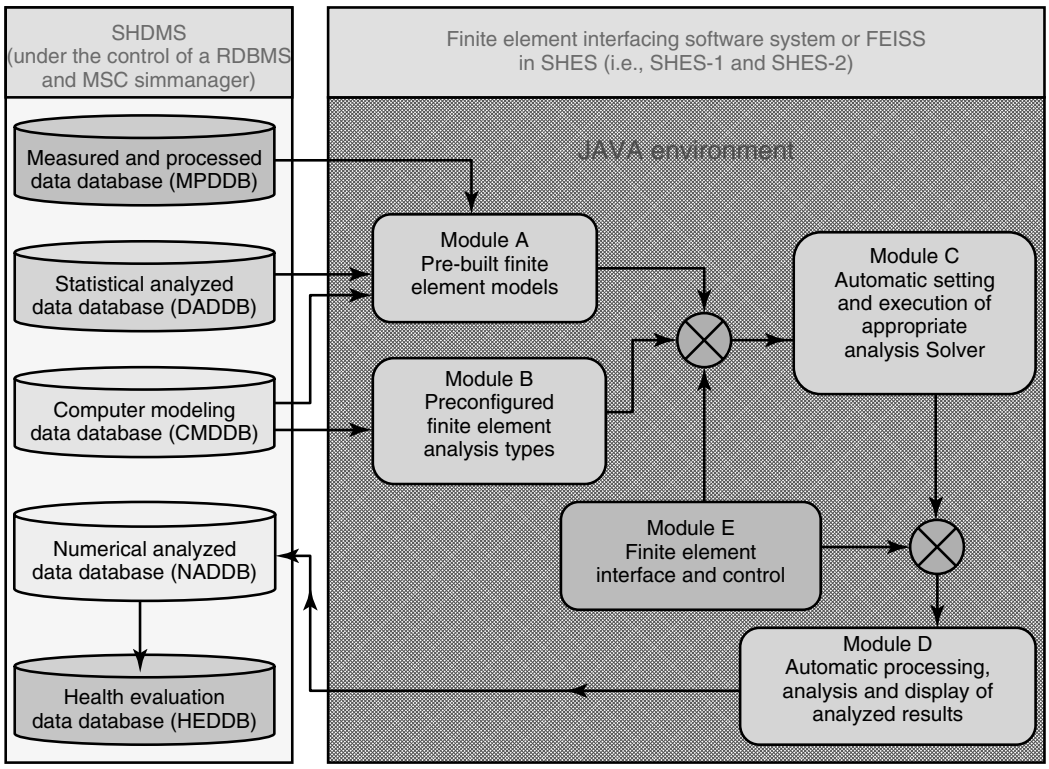

Figure 12. Layout of FEISS in SHES and its interfacing with the databases in SHDMS.

- **Measured and processed data database (MPDDB)**
All time-series data obtained from measuring sensors.

- **Statistical analyzed data database (SADDB)**
All data generated from signal/data processing and analysis software tools such as MATLAB—data analysis suite, NI—data processing and reporting, SD tools, etc.

- **Numerical analyzed data database (NADDB)**
All finite element analyzed/output data generated from finite element analysis software tools such as MSC-NASTRAN, ANSYS-Vertical Physics, MIDAS, LUSAS, etc.

- **Computational modeling data database (CMDDB)**
All finite element modeling/input data generated from finite element analysis tools such as MSC-PATRAN, ANSYS-Preprocessor, ANSYS-Workbench, etc.

- **Health evaluation data database (HEDDB)**
All updated structural health monitoring and evaluation criteria and concise monitoring and evaluation results of environmental loads and status, traffic loads, bridge features, and bridge responses.

These five databases are manipulated and managed by a data warehouse system, which is customized basing on "IBM DB2 UDB Warehouse Enterprise", and is equipped with data management and data analysis tools for integrating enterprise-wide corporate data into a single repository from which users or engineers can easily run queries, perform analysis, and produce reports. The data warehousing system in SHDMS is devised to carry out the following functions:

1. Systematic cleansing, reconciliation, derivation, matching, standardization, transformation, and conformity of data and information from all data source systems such as DPCS servers and SHES servers as shown in Figure 13.

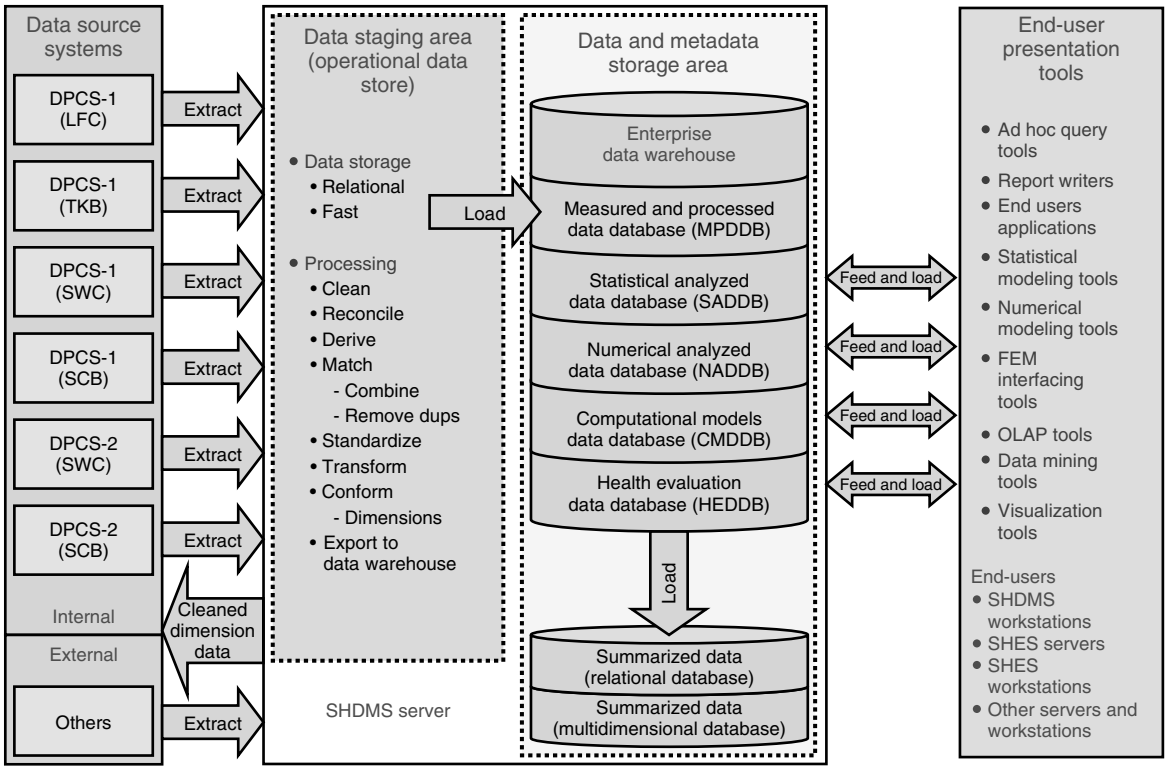

Figure 13. Architectural layout of SHDMS and its interfaces.

2. Manipulation of all types of correlation analyses and features extraction plots, by online analytical processing tools and appropriate data mining tools, based on all data and information generated from the software tools in DPCS-servers and End-users' servers and workstations as shown in Figure 13.
3. Creation of data marts (summarized data in Figure 13), based on the results of aforementioned correlation analyses and plots, for the execution of the following monitoring and evaluation works:
   (a) reporting the current and future loading conditions (such as wind, temperature, seismic, and traffic) acting on the bridge;
   (b) reporting the current and future corrosion status on specified bridge components;
   (c) reporting the current and future structural health conditions of the bridge in terms of the physical parameters as listed in the fourth column of Table 1;
   (d) planning of scheduled bridge inspection and maintenance activities with bridge maintenance team; and
   (e) updating/calibrating the bridge rating system and computational (numerical and statistical) models for processing and analysis of data and information, where necessary.
4. Forming the center of data interrogation and metamodeling for bridge health diagnosis and prognosis through the integration of data and information from both measurement and computational systems. (Metamodels refer to the functional forms of statistical-based models, finite element models, neural networks, etc.)

2.6 Module 6—inspection and maintenance system (IMS)

The IMS is composed of two notebook computers (IMS-1 and IMS-2) and a tool-box (IMS-3). Its

function is devised to carry out inspection and maintenance works on SSs, DAUs, display facilities, LCNSs, and GCNSs. All information (drawings and records) regarding system design, system installation, system operation, and system maintenance is stored and operated in IMS-1 and IMS-2. The IMS-3 is a tool-box for carrying out inspection and minor remedial works.

3 OPERATION OF WASHMS

The system operation block diagram of WASHMS is shown in Figure 14, where the monitoring of kinematic quantities refers to the monitoring of bridge features and bridge responses. The figure shows two levels of monitoring, namely, the sensor-based comparison of the measured results and the monitoring criteria, and the model-based comparison of the derived results and the evaluation criteria. The former refers to the comparison of the measured results with the predetermined monitoring criteria (i.e., at about 60−75% of the design values at serviceability limit state), whereas the latter refers to the comparison of the derived results with the evaluated criteria (i.e., at 100% of the design values at serviceability limit state). The criteria for monitoring and evaluation are defined and calibrated in accordance with the updated requirements of the damage types as defined in the criticality and vulnerability ratings, i.e., structural damage (due to structural actions), environmental damage (corrosion), accidental damage, and wearing damage [13]. In Figure 14, it is shown that if the measured results exceed the monitoring criteria, structural diagnosis and prognosis works will be carried out. Both the structural diagnosis models and structural prognosis models are finite-element-based and/or empirical/statistical-based models, of which the former is used to assess the current and/or historical state of the global bridge structural system

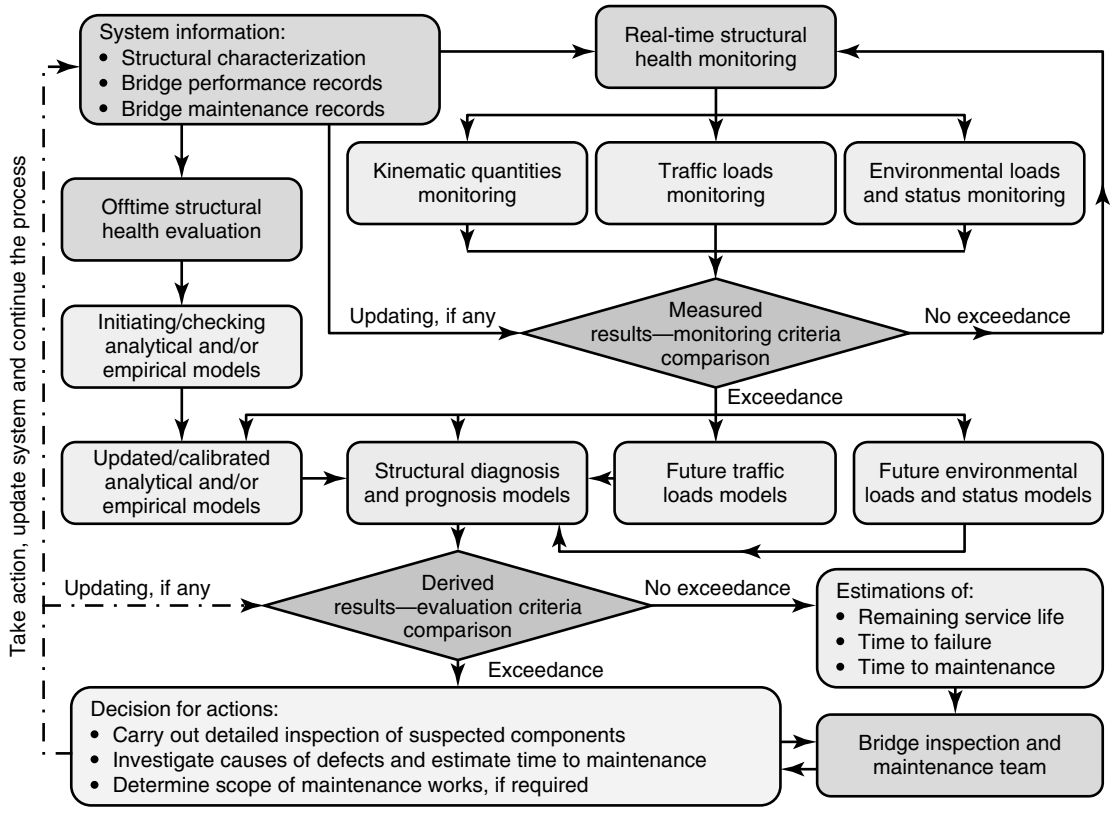

Figure 14. System operation block diagram of WASHMS.

and/or local structural components whereas the latter is used to predict the consequences under the assumed future operational and environmental loads and status.

4 CONCLUSIONS

This article has described a modular architecture that has been used in the design of SHMS for cable-supported bridges in Hong Kong. The architecture of the SHMS described consists of six integrated modules, namely, SS, DATS, DPCS, SHES, SHDMS, and IMS. Each module is well defined and encapsulated. In order to ensure the reliability of measured results, different types of sensors should be deployed at the same key locations and/or components where large displacements and stresses are expected to occur so that the measured results can be validated through correlation among themselves.

Since the hardware configuration of the DAS has a significant influence on data quality, the performance requirements on the linearity, temperature drift, accuracy, direct current resolution, bandwidth, etc., of the signal conditioning and the data-acquisition device should be identified and quantified. Appropriate customized software systems should also be developed and configured to process or derive the measured data in the data formats applicable to bridge health monitoring and evaluation.

Structural health monitoring and evaluation works should be executed through the correlation analyses and features extractions of (i) measured and analyzed results, (ii) current and previous measured results, (iii) previous and updated analyzed results, (iv) and derived results (from analysis and/or measurements) and assigned bridge performance criteria. As the correlation analyses and features extractions involve the synchronized processing of two or more data files/sets, the use of data warehouse system equipped with online analytical processing tools and appropriate data mining tools will facilitate the automatic execution of such synchronized data processing and analysis works.

It is concluded that the WASHMS for cable-supported bridges should at least be able to monitor the loading and structural parameters set by the bridge designer so that the bridge performance under current and future loading conditions can be evaluated, and such evaluated results should be able to facilitate the planning of bridge inspection activities, and be able to determine not only the cause of the damage but also the extent of remedial work, once the damage is identified.

1 INTRODUCTION

1.1 Bridge construction activities in Korea

Civil engineering projects constituted the backbone of the development and economic growth of Korea. In the domain of transportation infrastructures, particularly bridge structures, construction activities have been restlessly undertaken in the peninsula. The volume of road bridges in Korea increased rapidly during the three decades following the industrialization period of 1970s, when massive investments were done to strengthen the transportation network. The 9332 bridges covering 268 km in 1970 augmented to 22 937 bridges in 2006 with a total length of 1987 km. Figure 1 illustrates the evolution of the bridge stock and total length in Korea from 1970 to 2006 [1].

During this relatively short period, bridge engineering in Korea has achieved outstanding advances that resulted in the construction of numerous cable-stayed and suspension bridges since 2000. Youngjong Bridge, the first three-dimensional self-anchored suspension bridge in the world, is representative of the remarkable progresses made in Korea.

Since Korea is a peninsula surrounded on three sides by the sea and includes 70% of mountainous area, bridges are the key components for the development of its transportation network. Recently, bridge construction activities have been revitalized by the ambitious plan of the government to link some of the 3000 islands of the peninsula to the mainland (Figure 2) in order to promote balanced development of the national territory and renew urban environment

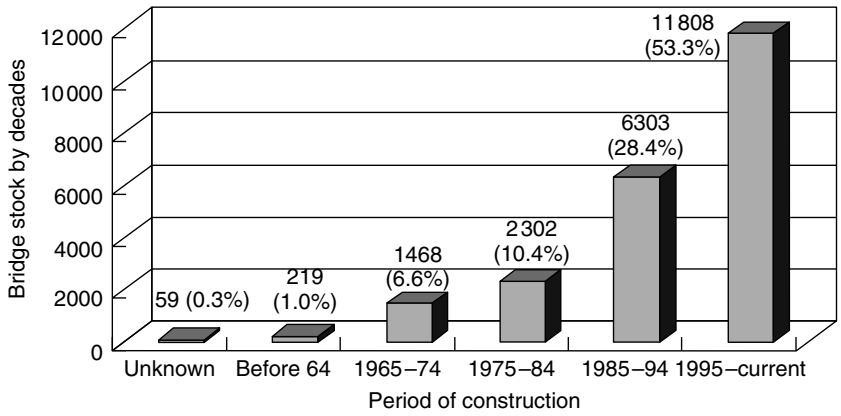

Figure 1. Bridge stock by decades in Korea.

[2, 3]. For example, the province of Jeollanamdo is undertaking construction projects of 102 sea-crossing bridges of which 32 have already been completed, 21 are under construction, and 48 are under planning.

Accordingly, the construction of bridges in the coastal areas is involved in the national amendment promulgated in August 2001. This amendment assigns the extension and construction of national roads no. 2, 24, and 77 with more than 65 km only in the maritime sections including about 50 major bridges (Figure 2) [2, 3].

Among these bridges, Incheon Bridge illustrated in Figure 3 is an offshore circular expressway with a total length of 12 343 km that will link Incheon International Airport to the new city of Songdo in the southern region of Incheon South Port. Its construction (Figure 4) began in October 2004 and the bridge will be completed in October 2009. The cable-stayed bridge $(80 + 260 + 800 + 260 + 80\,\text{m})$ has been designed to secure a navigation clearance of 715 m and overhead clearance of 74 m for the passage of shipping, and will rank at the fifth position among the longest cable-stayed bridges in the world.

Figure 5 presents a rendering (view) of the future 1545 Bridge giving access to Yeosu National Industrial Complex from Gwangyang Port through Myo Island in the Province of Jeollanamdo. The suspension bridge has been designed to allow crossing of 18 000 TEU container ships. The bridge with its main span of 1545 m will be the third longest bridge in the world after Akashi and Great Belt East bridges.

1.2 Initiation of bridge monitoring in Korea

Issues related to the lifetime and durability aspects of bridge structures are of critical importance. A lifetime of at least 100 years is now targeted while designing a bridge. Accordingly, active development and applications of structural health monitoring (SHM) systems for major bridge structures are continuously implemented as a tool to sustain such lifetime perspective in terms of safety, durability, and performance. Modern and integrated monitoring systems are actually introduced in newly built bridge structures since the design stage. Automatic measurement of instrumented civil engineering structures is now widely applied for behavior monitoring during construction in field as well as long-term monitoring for lifetime assessment of bridge structures. Efforts tending toward the increase and upgrade of the monitoring efficiency and performance through sensor-based bridge monitoring systems (SBBMSs) are also continuously undertaken to provide advanced innovative functions.

Korea implemented active development and application of SHM for bridge structures since the early 1990s. This activation was initiated primarily by the tremendously increasing number of deteriorated infrastructure systems, mostly built during the industrialization boom of 1970s, which often resulted in tremendous lack of quality. In addition, the successive collapses of Haengju Bridge during its construction and Sungsu Bridge in 1994, only 15 years after its completion, opened the eyes

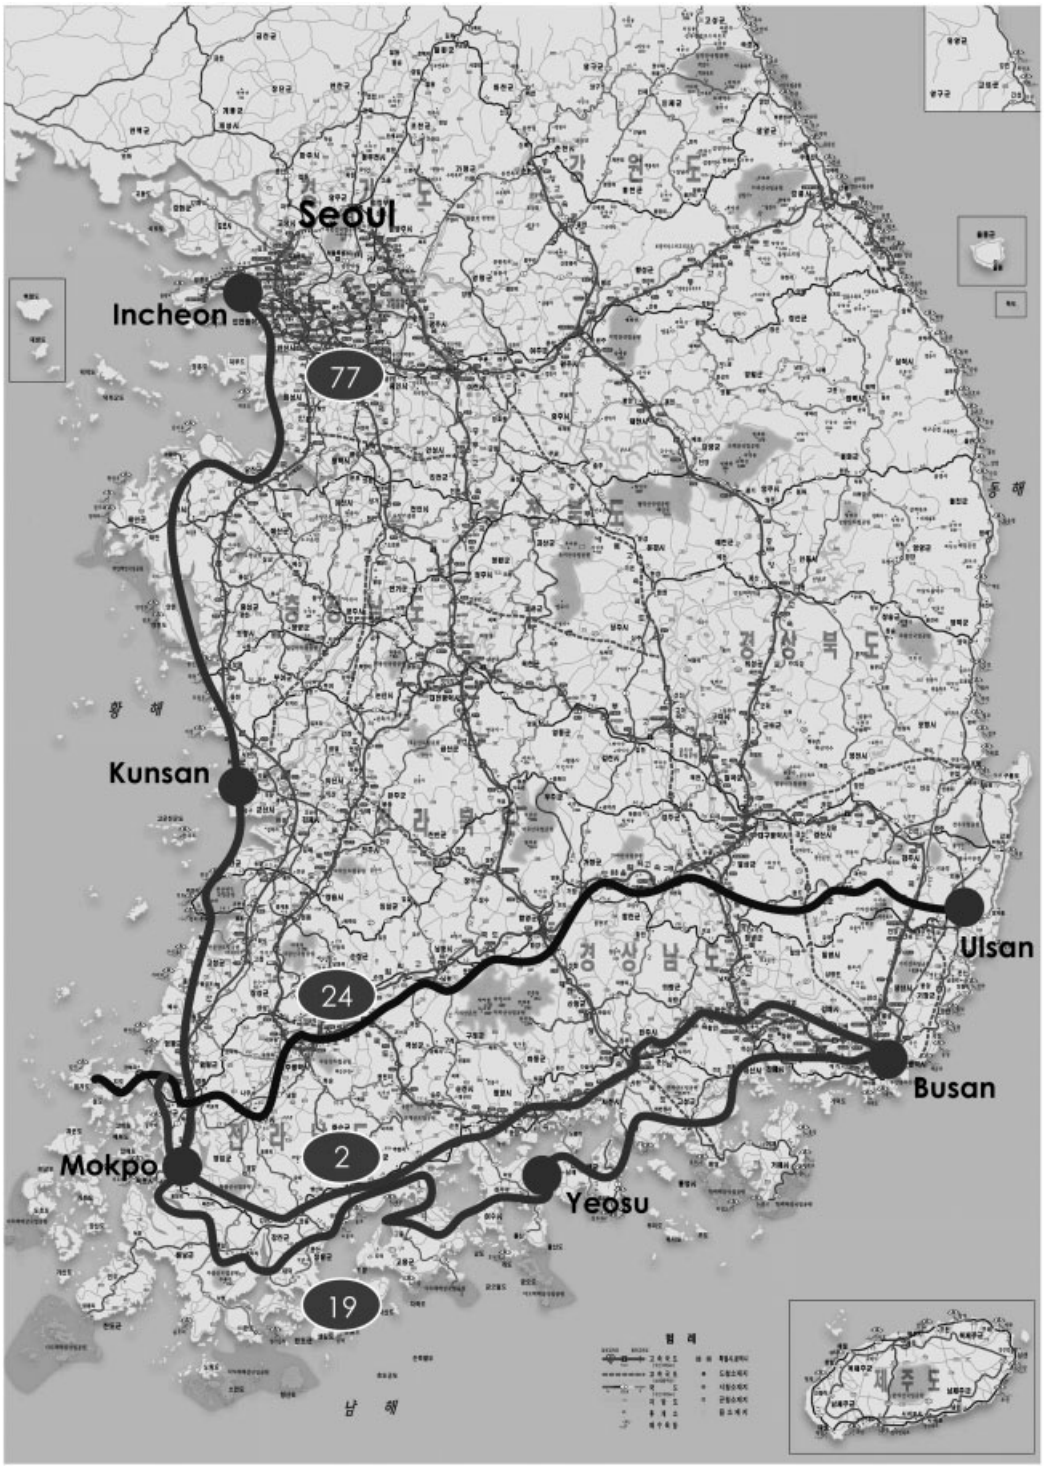

Figure 2. Extension of the national roads in the southwestern coast of Korea.

Figure 3. Rendering of the Incheon Bridge.

Figure 4. View of the Incheon Bridge under construction.

of the public to the importance of the management of bridges together with the increasing recognition of the potential devastating disruption of infrastructure

Figure 5. Rendering of 1545 Bridge.

systems due to manmade and natural hazards, i.e., typhoons and earthquakes. Consequently, attention has been first focused on bridge structures as the most expensive and vulnerable asset of the transportation network directly affecting the economy and public safety.

These accidents, combined with the fact that a large number of bridges before and during 1970s still remains in operation today, led the governmental authorities to issue more stringent requirements on bridge management and operational programs, including systematic visual inspection, instrumentation, load capacity tests and field measurements for design and construction verification, and long-term performance monitoring and assessment.

Figure 6 shows the evolution of maintenance investment together with the health level of the

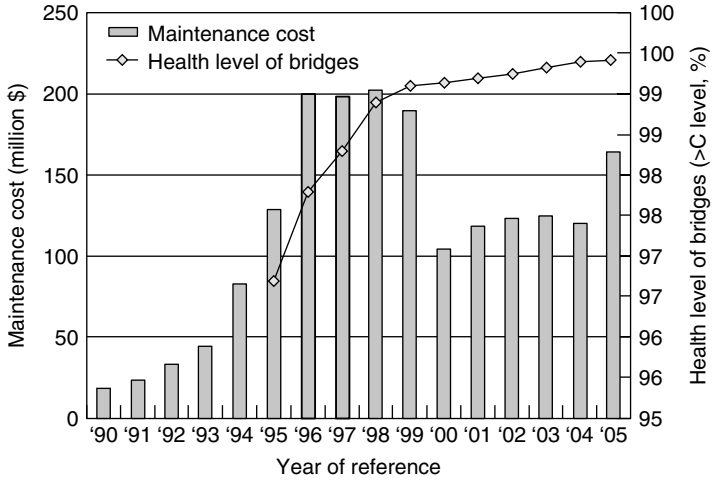

Figure 6. Records of maintenance and health level of the Korean bridge stock. [Reproduced from Ref. 5. © Korea Institute of Construction Technology, 2002.]

Korean bridge stock since 1995. "C level" stands for operational health level under normal conditions [4, 5]. Until the mid-1990s, attention was paid on the construction of bridges rather than on their maintenance. After the collapses of the Haengju and Sungsu Bridges, stress was given on the importance of bridge maintenance. Accordingly, systematic maintenance system was adopted, which made it possible to rationally invest maintenance costs within the budget limits and prevent large catastrophes. As a result, maintenance costs monotonically decreased since 1995 together with remarkable improvement of the health of the bridge stock even in a short period of time.

1.3 Evolution of bridge monitoring in Korea

In order to deploy a successful monitoring system, the requirements are proper instrumentation, reliable signal processing, and knowledgeable information processing. Along with the rapid and massive progresses made in the domain of IT for infrastructures, complete and integrated monitoring systems were systematically installed in all major bridges in Korea (Figure 7). Accordingly, the evolution of bridge monitoring system in Korea can be classified into three generations in terms of developing stage and functionality, which places Korea as one of the leading countries in bridge monitoring today.

The system corresponding to the first generation is characterized by a stand-alone field system consisting of sensors, field hardware, and online transmission to a computer on field. In the second generation, this stand-alone system evolved into an overall bridge management integrated system involving two kinds of integration: operational integration where multiple stand-alone systems operate together and functional integration where bridge monitoring system operates with different systems such as bridge management system (BMS) or vehicle monitoring system [6]. The third generation, also called *future system*, will provide advanced innovative functions like sensor fusion, reliable massive signal transmission, automated surveillance, adaptive signal processing, etc. Many research efforts are now led to develop the third generation system and enhance the performance of the current system by introducing new sensing techniques, power generation from bridge vibration, web-based operating system, or wireless signal transmission (*see* **Wireless Sensor Network Platforms**; **Web-based SHM**; **Microelectromechanical Systems (MEMS)**).

2 KOREAN BRIDGE MANAGEMENT SYSTEM (KOBMS)

Total BMS attempts to include inspection, evaluation, estimation, and rehabilitation of bridges in a systematized organization, which integrates SHM systems installed in bridges. BMS is an information-oriented system, which aims at the global supervision of all the information gathered in every bridge so as to help the supervisor in deciding current and future requirements for optimal management and rehabilitation of bridges (*see* **Maintenance Principles for Civil Structures**). Following this, to perform scientific and rational management and rehabilitation of bridges, the Korean Ministry of Construction and Transportation (MOCT) together with the Korean Institute of Construction Technology (KICT) developed the Korean bridge management system (KOBMS) in 1995, which has been in operation for ordinary road bridges since then.

The hardware of KOBMS is constituted by regional networks and high-performance and high-capacity computers to efficiently manage the huge volume of data gathered in bridges. Such network operates interactively by linking the KICT, road facilities of the MOCT, five regional offices, one R&D office, and 18 road management offices since 1996.

The software of the KOBMS (Figure 8) is composed by a database (DB) recording archives related to bridges, a program computing the investment priorities, a rehabilitation and retrofit techniques DB, a tunnel DB, a program outputting the current state of bridges, and a decision-making system performing the essential functions of the BMS. Especially, the BMS DB stores and compiles about 230 items per bridge including its characteristics, structure, inspection records, load-carrying capacity, etc. Investment

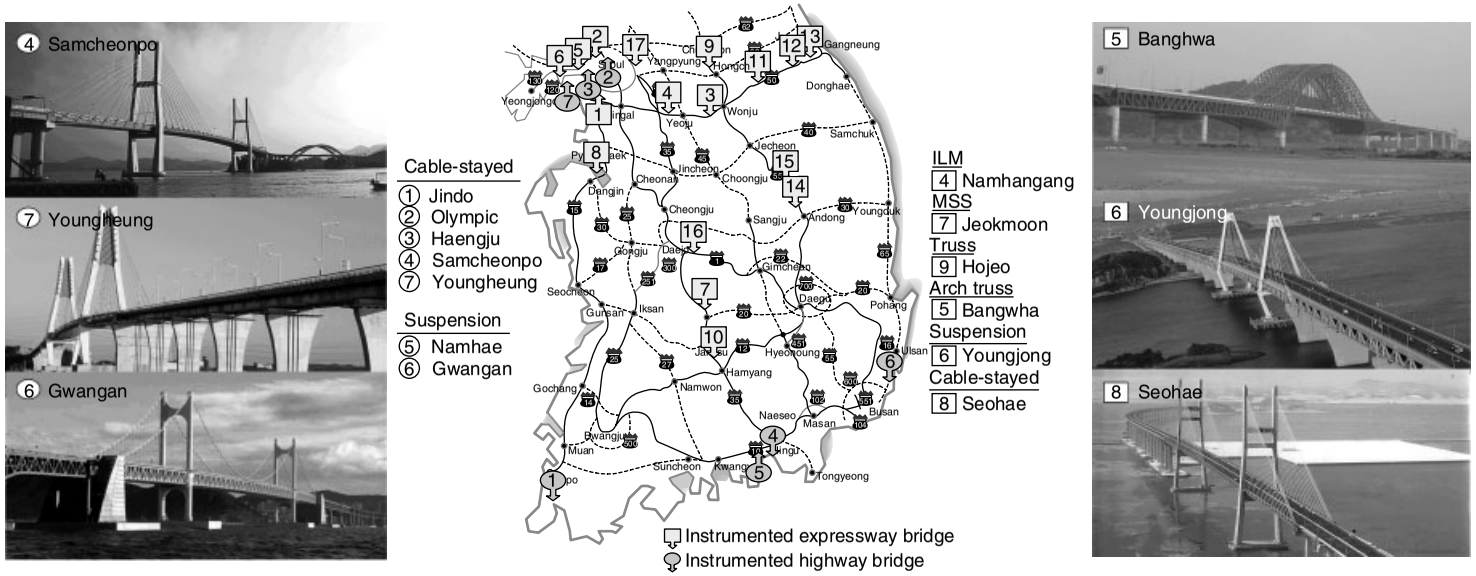

Figure 7. Major instrumented bridges of the national expressway and national highway networks of Korea.

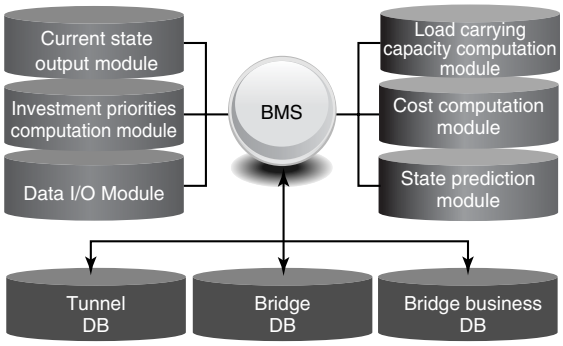

Figure 8. Software of the KOBMS.

priorities, as a basic function of the BMS, stand for the process by which one decides the sequence of bridges to be considered for management and rehabilitation in the budget planning. The KOBMS DB arranges 64 basic rehabilitation and retrofit techniques for bridges and defines 120 types of damage that may occur in bridges, so as to automatically select an appropriate rehabilitation and retrofit basic technique for each type of damage. Using the KOBMS DB, a report on the current state of the bridges is published annually, and it provides statistics of the basic parameters of the bridges and their current state according to their classification [7].

The KOBMS made it possible to efficiently manage the huge volume of bridge data in a systematic and effective organization. Its exploitation currently helps in systematizing state evaluation and records management of rehabilitation and retrofit for each bridge as well as for the whole bridge stock. The state of bridges has seen significant improvement while large reduction of the budget invested for their management, being rationally shared, has been obtained [8].

On the other hand, even if the KOBMS selects optimal maintenance measures for the whole bridge stock, it does not necessarily mean optimal measures for individual bridges. Therefore, developing a project level BMS that reflects the characteristics and conditions of each individual bridge networked with the DB collected from the SHM system of the bridge is currently under discussion for implementation. The introduction of an expert system considering the severity and range of eventual damage or anomaly occurring in the bridges is also under plan.

3 FIRST GENERATION: SHM SYSTEMS FOR EXISTING BRIDGES

The first applications of health monitoring systems in Korea began for existing bridges in order to collect field data by full load scale capacity tests for design verification and, subsequently, evaluate the health of the structures. Immediately after the collapse of the Sungsu Bridge in 1994, this first generation of monitoring systems was applied in the existing bridges of which two representative examples are described hereafter.

3.1 Namhae Bridge

Namhae Bridge, which was opened to traffic in 1973, is the first suspension bridge erected in Korea. It is a three-span suspension bridge ($128 + 404 + 128$ m) with main cables made of parallel wires and a stiffening girder consisting of welded steel box with an orthotropic steel deck. The joints of the streamlined box were welded on site. The bridge connects Namhae Island with the mainland in the southern coast of the peninsula.

At the time of its design, the load-carrying capacity prescribed in the codes was 30% smaller than the current one. Moreover, since its completion, the bridge experienced excessive vehicle weights due to the proximity of a large industrial zone. Accordingly, a safety evaluation conducted after 20 years of service in 1993 [9] revealed major defects, such as fatigue cracks at welding and corrosion of steel members. Accordingly, short-term strengthening and rehabilitation were carried out, and a long-term maintenance and health monitoring project were scheduled to extend the service life of the bridge and prevent further loss of load-carrying capacity. The objective was to monitor the structural responses of the bridge focusing on the identification of its deteriorating rate over a long period of time (*see* **Damage Measures**; **Principles of Structural Degradation Monitoring**; **Aircraft Structural Diagnostic and Prognostic Health Monitoring for Corrosion Prevention and Control**).

According to the project, the initial status of the bridge was evaluated by geometric survey and static loading test [10] prior to logging its long-term

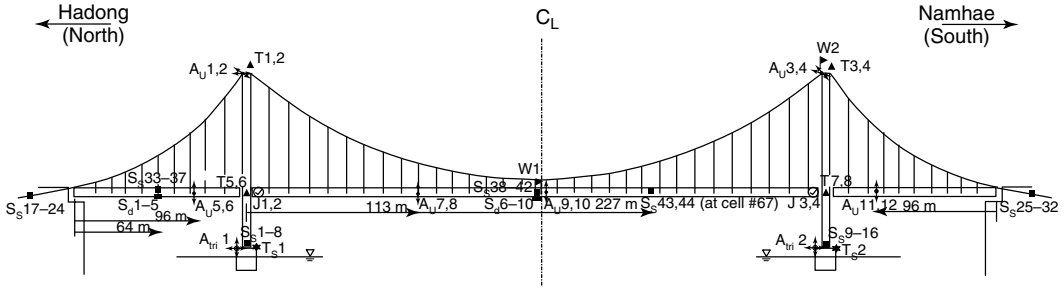

Figure 9. Overall layout of the instrumentation of the Namhae Bridge.

	DAQ system		2	GPS system

behavior by health monitoring. The deck geometry obtained from the survey was compared with the intended geometry of the original design. Thereafter, the bridge was instrumented with the health monitoring system illustrated in Figure 9. The monitoring system consists of 110 channels of both static and dynamic sensors such as strain gauges, accelerometers, tiltmeters, jointmeters, and anemometers (Table 1). In 1999, the dynamic measurement system installed in the bridge was used to identify its natural frequencies through vehicle loading test and ambient vibration test (AVT) *see* **Ambient Vibration Monitoring**. The whole acquisition of measured vibration data on the bridge took almost 2 weeks. A few natural frequencies were obtained through simple impact tests by identifying peaks in the power spectral density functions, and the monitoring system was also used to evaluate the effect of thermal variation on the change of the fundamental frequencies during 9 months. Impact test appeared to be adaptable, if only lower bending modes were of interest and traffic-induced vibration was found to be utilizable for this type of bridge. In addition, it was shown that when dynamic properties obtained from measured data were used to assess damage, variation of factors, such as temperature, should be considered [11].

3.2 Jindo Bridge

Jindo Bridge (Figure 10) is a three-span (70 + 344 + 70 m) semi-harp cable-stayed bridge. The bridge, completed in May 1984, has been the only way linking Jindo Island and the mainland at Haenam in the southwestern coast of the peninsula. The bridge has today a twin that is 20 years its junior with

Figure 10. View of the first and second Jindo Bridges.

the completion of a matching cable-stayed structure alongside. At the time of the design of the first bridge, design live load was DB-18 (total weight 34 tonf) corresponding to the second-grade bridge according to the categories of the current design codes. Close investigation in 1996 including load and vibration tests resulted in the closing of the bridge for trucks exceeding the design load.

An AVT was carried out in 1998. Mode shapes as well as natural frequencies were found to give a more precise description of the current bridge state (*see* **Ambient Vibration Monitoring**). During the AVT, the acquisition was carried out without traffic restriction, and the dynamic properties were computed from these ambient vibrations under normal traffic. With six accelerometers, a couple of weeks were needed to acquire all the vibration data [12].

Similarly to Namhae Bridge, though the traffic-induced vibration was used, very smooth and reasonable spectra were obtained. Finally, 26 natural frequencies and corresponding 16 mode shapes were found by AVT. No significant noise was found on the mode shapes, which demonstrated that traffic-induced vibration could be used for this type of bridge, since the mass of traffic is relatively small compared with that of the structure and the traffic could excite the structure with enough energy in the frequency band of interest. Such results are believed to provide a precious reference for future monitoring. Figure 11 draws the conceptual diagram of the SHM system installed in the Jindo Bridge.

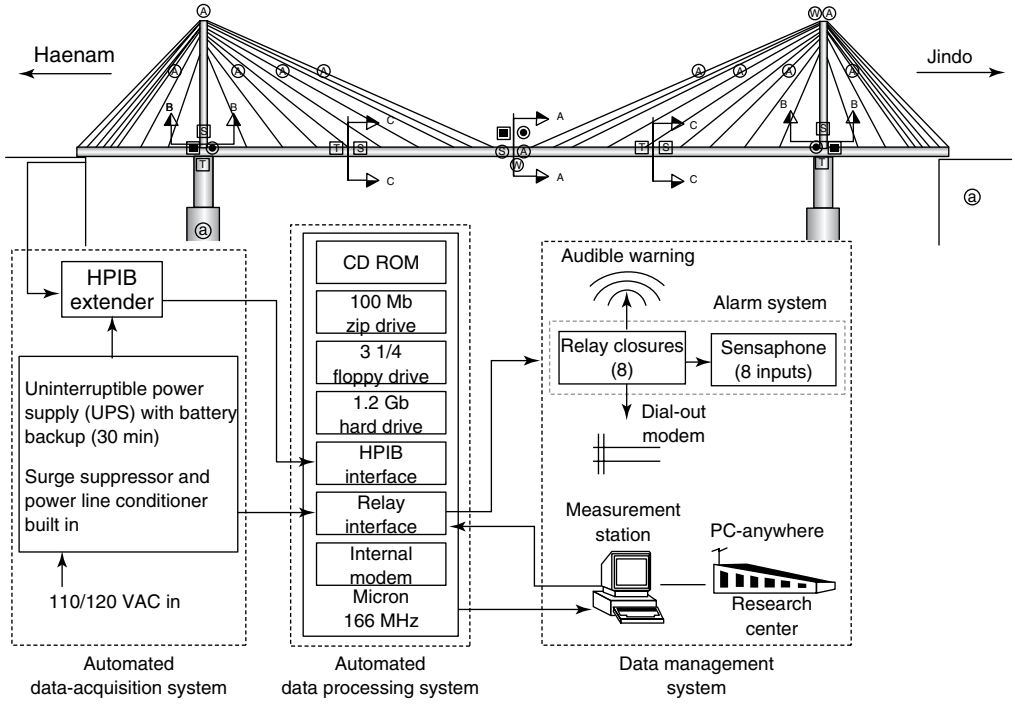

Figure 11. Conceptual diagram of the health monitoring system in the first Jindo Bridge.

4 SECOND GENERATION: INTEGRATED SHM SYSTEMS FOR NEW BRIDGES

Today, every newly built long-span bridge in Korea is equipped with modern monitoring systems. Unlike earlier applications of health monitoring systems installed in existing bridges, where conventional sensors, loggers, and transmission methods were used and individual systems served each bridge independently, this second generation of health monitoring systems exploits modern technologies from sensing to processing, i.e., many sensors and data-acquisition systems that measure the behavior of the bridge during its construction become part of

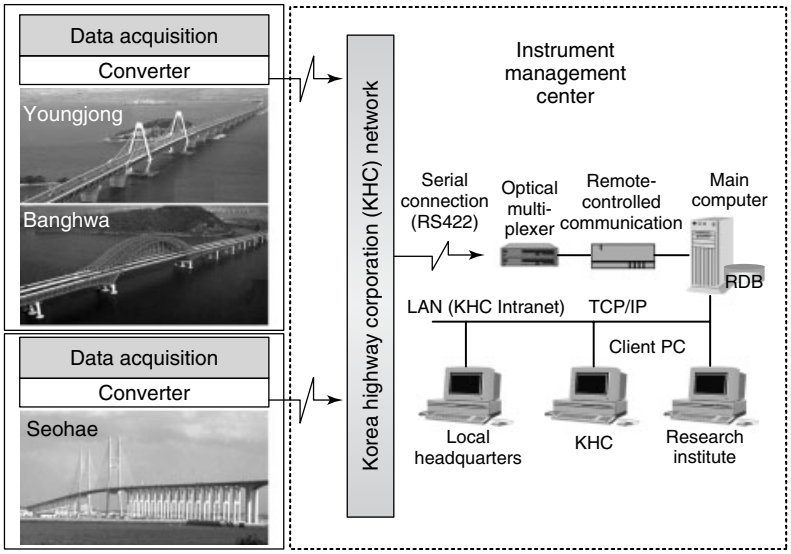

Figure 12. Integrated operating system of the Seohae, Youngjong, and Banghwa Bridges.

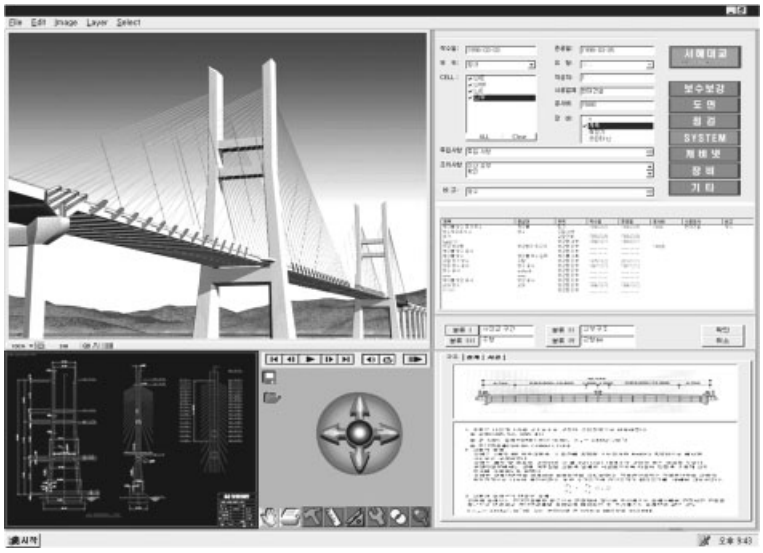

Figure 13. Functional integration of SHM system with BMS (Seohae Bridge).

the long-term health monitoring system, in order to monitor long-term performance and durability of the bridges in the scope of systematic inspection and maintenance programs.

This second generation of health monitoring system has been applied to newly built bridges since the design stage, by integrating the systems of several bridges together to reduce costs and significantly increase the management efficiency. This integrated system includes BMS for systematic decision making and budgeting of inspection, estimation, rehabilitation, and repair (*see* **Usage Management of Civil Structures**). The integrated system for Seohae, Youngjong, and Banghwa Bridges may be cited as the best example of the current monitoring system. The data collected at each bridge are processed exclusively at each field station for real-time monitoring and alarming sudden abnormal behavior. Data that are useful for long-term evaluation of bridge condition, as well as periodical inspection data, can be transmitted through high-speed internet line to the management center located far away from the site (Figure 12). Once data are collected at the center, integrated BMS (Figure 13) handles them to classify, store, and retrieve. This integrated BMS is able to itemize bridge maintenance details and manage status assessment, rating, repair, and strengthening histories.

Figure 14. Aerial view of the Youngjong Bridge.

4.1 Youngjong Bridge

Youngjong Bridge (125 + 300 + 125 m), completed in November 2000, is part of the Incheon International Airport Highway, which connects Seoul and the Incheon International Airport. Being the first bridge that foreign visitors see when arriving in Korea, particular attention has been paid on its design with unique features such as three-dimensionally profiled suspension cables, self-anchoring, and double decks for both automobile and train traffic (Figure 14).

A total of 393 sensors, including static and dynamic strain gauges, and 23 data loggers are distributed over the bridge (Figure 15, Table 2).

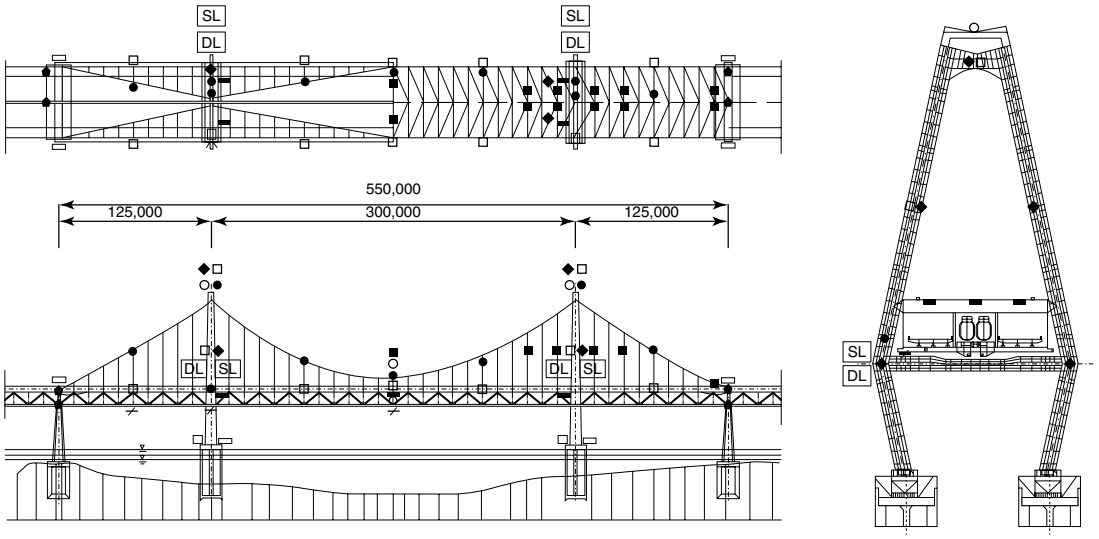

Figure 15. Overall layout of the instrumentation of the Youngjong Bridge.

Table 3. Dynamic characteristics of the Youngjong Bridge identified by forced vibration test

Dynamic characteristics	Natural frequency		Damping ratio	
	Design	Measured	Design	Measured
Flexure	0.422	0.487	0.03	0.06
Antisymmetric flexure	0.716	0.810	0.03	0.03
Torsion	0.781	1.060	0.02	0.023
Antisymmetric torsion	1.195	1.700	0.02	0.05

The hardware system was designed to collect data remotely, and the software system was developed to process data and display results in a custom-designed format. The monitoring system has been completed in 2001 and a huge volume of signals have been collected up to date. These signals were carefully analyzed for verifying the system performance and for assessing the bridge health [13].

The SHM system was exploited at first to identify the dynamic properties of the bridge before opening, by means of field loading test using two vibrators to generate flexural and torsional vibrations of the bridge. Comparison of the measured data such as natural frequencies, vibration modes, and damping ratios with design values in Table 3 showed good correspondence attesting for the reliability of the bridge [6].

During the system stabilization period, signals showed regular pattern of fluctuation along with the daily and seasonal temperature changes (*see* **Model-based Statistical Signal Processing for Change and Damage Detection**). Some typical signal patterns are described hereafter [13].

Accelerometers were mounted on 12 hangers to evaluate tension forces. Frequencies computed from acceleration responses, measured under ambient vibration during 15 months, were used to evaluate

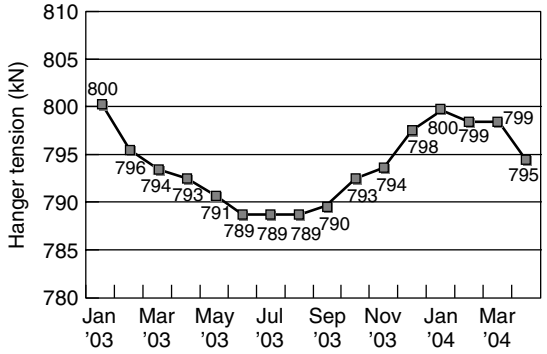

Figure 16. Seasonal variation of the average hanger tension observed during 15 months in the Youngjong Bridge.

hanger tension forces. The resulting average tension force for the whole set of hangers displayed a pattern corresponding to seasonal variation (Figure 16). The same seasonal pattern, according to the variation of temperature, could also be observed for the vertical and lateral displacements at midspan of the stiffening girder measured by means of laser displacement sensor (Figure 17). Joint displacements at both ends were also seen to present quasi-linear relationship with temperature, with a displacement averaging 46 mm for a thermal variation of 10 °C in ambient temperature. Acceleration data measured under ambient vibration were exploited to analyze the dynamic properties of the bridge, and the frequencies of the first and second modes were measured to be 0.494 and 0.831 Hz, which correspond fairly to the results of field vibration tests (0.487 and 0.810 Hz) listed in Table 3.

Long-term responses of the Youngjong Bridge were thus verified to be governed by daily and seasonal variations of the temperature, which revealed that the bridge behavior is as expected.

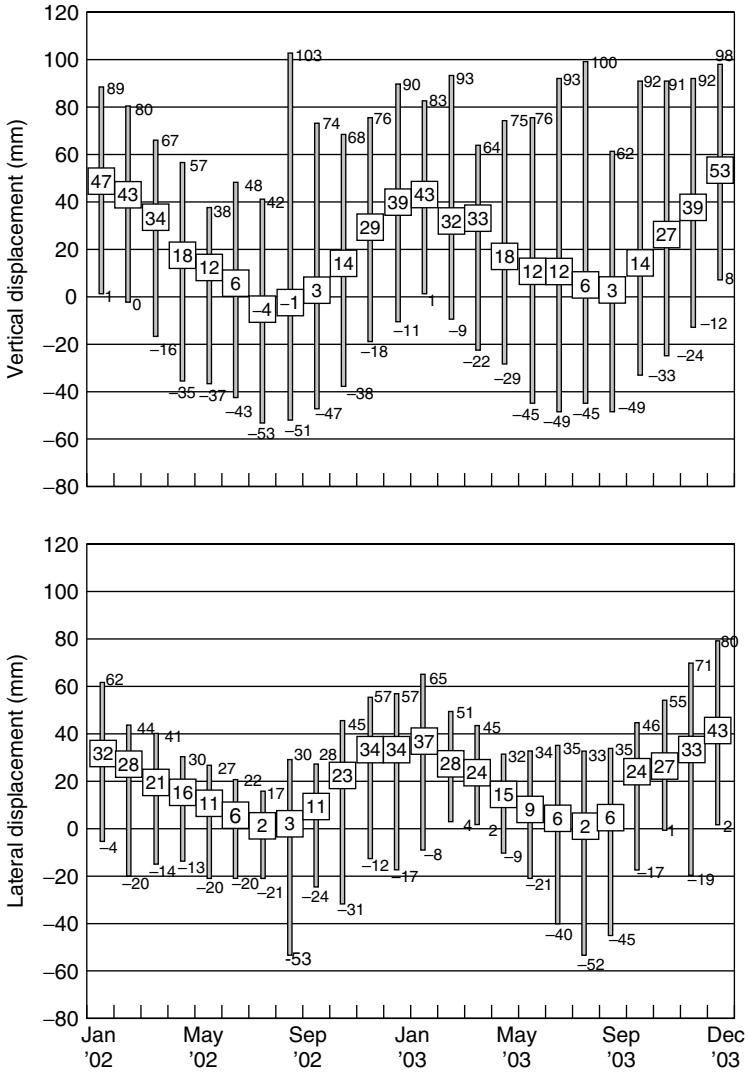

Figure 17. Vertical and lateral displacements at midspan observed during 2 years in the Youngjong Bridge.

4.2 Seohae Bridge

Until the completion of the Incheon Bridge ($80 + 260 + 800 + 260 + 80$ m) in 2009, the Seohae Bridge ($60 + 200 + 470 + 200 + 60$ m, Figure 18) will remain the longest cable-stayed bridge in Korea. Its five spans are constituted by stiffened steel girders with precast slab. Figure 19 schematizes the history of the development of the monitoring system of the bridge beginning from its planning to its operation. More than 180 sensors of 10 types are actually installed in the major parts of the cable-stayed (Figure 20, Table 4) PSM and FCM approach bridges [6, 8].

The structural behavior of the cable-stayed bridge was observed and analyzed during the first 2 years following its completion. Results showed that the annual variation of the vertical deflection in the stiffening girder satisfies the allowable design limit with a range of -320 to 30 mm and that the deflection due to live load presents a range of 189.7 mm, which represents only 25% of 808.8 mm, the design limit. The stress range in the stiffening girder due to live loads showed good correlation with the volume of traffic monitored during 2 years. Stress margin appears to remain considerable since measured stresses represent only 5–12% of the design stress. Accordingly, it seems that the actual highway bridge design specifications in Korea are producing excessively conservative structures.

The thermal deformation of expansion joints at the extremities of the bridge was verified to exhibit correlation of about 96% with theoretical predictions (Figure 21). The tensioning force in the cables ranged from 95 to 104% of the initial value. Seohae Bridge

thus appears to be healthy in view of its long-term behavior [14].

5 THIRD GENERATION: SENSOR-BASED BRIDGE MONITORING SYSTEMS

More recently, efforts tending to increase and upgrade the monitoring efficiency and performance of the second generation, that is SBBMSs, have also been effectively introduced in newly built bridges.

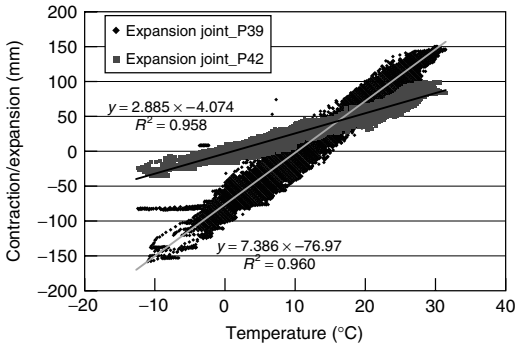

Figure 21. Thermal expansion/contraction at the end expansion joints of the Seohae Bridge.

The purposes of SBBMS are to provide information (i) to assess the behavior of the bridge, (ii) to ensure serviceability and safety during its service life, and (iii) to help design, construction, and maintenance. Application of SBBMS can be found in Gwangan and Samcheonpo Bridges.

The hardware system performs measurement and data acquisition of the bridge behavior by remote sensing, using sensors and data loggers, and the software system achieves data processing, storage, analysis, and display in customized form (Figure 22).

5.1 Samcheonpo Bridge

Samcheonpo Bridge is a three-span cable-stayed bridge with composite girder, located in the Hallyeo maritime national park and connecting Sacheon city to Changsung Island [15]. The health monitoring hardware system for the management of Samcheonpo Bridge (Figures 23 and 24 and Table 5) is similar to that of Gwangan Bridge presented later.

5.2 Gwangan Bridge

Gwangan Bridge, the central part of Gwangan principal road, is located in front of Gwangan town beach and is the longest suspension bridge in Korea with its 900-m overall length. It is an earth-anchored suspension bridge with a double-deck warren truss girder carrying roadways. The pylons are steel towers where the main cable is sustained with its stiffening girder at 105-m height.

The health monitoring hardware system for the management of Gwangan Bridge was designed to perform real-time monitoring of its structural behavior. Composed by dynamic monitoring instruments like laser displacement sensor, anemometer, accelerometer, and by static sensors such as tiltmeter, thermometer, and jointmeter, the monitoring system processes signals, analyzes data, and stores the data acquired from the sensors in the monitoring center. Figure 25 illustrates the location of the instrumentation and Table 6 lists its specifications.

The SHM system was used to produce alarm/warning during the crossing of Maemi typhoon in September 2003. Measurement of the wind speed at the pylon and midspan of the bridge (Figure 26) helped to make decision of blocking and reopening of the bridge to traffic so as to ensure public safety during the typhoon. Traffic was blocked with respect to an average wind speed at midspan of $20\,\mathrm{ms}^{-1}$ and was reopened when this speed was less than $10\,\mathrm{ms}^{-1}$.

Health monitoring after the crossing of the typhoon was also performed using the measured inclination of the pylon (Figure 27) and displacement at the expansion joints. The corresponding natural frequencies (Figure 28) were computed and the results showed that natural frequencies remained within safety limits, which made it possible to conclude that the bridge was not affected by the typhoon.

6 CONCLUSIONS

Remarkable developments have been made in health monitoring within a very short period of time, which has enabled to obtain more reliable information on the actual state of the structures. This is a challenging task where domestic and international researchers are exerting efforts to develop and enhance the performance of the current system by introducing new sensing techniques, power generation from bridge vibration, web-based operating system or wireless signal transmission in order to achieve advanced innovative functions like sensor fusion, reliable massive signal transmission, automated surveillance, adaptive signal processing, etc.

Recent development and applications of SHM for newly built bridges have been addressed through a review of the evolution of bridge instrumentation in Korea, which make Korea as one of the leading countries in bridge monitoring today. The observations obtained through integrated SHM system as well as SBBMS were seen to be exploited effectively for verifying design, calibrating analytic model, assessing long-term behavior, and giving alarm when abnormal behavior is detected.

Although health monitoring system itself plays an important role in studying real behavior of structures in real environment and in reducing uncertainties in further design process, it has been combined with other technologies such as SI and damage detection theory, BMS, and artificial intelligence (AI) to give overall estimation of bridge condition and to make proper maintenance decision and, finally, to lengthen the service life of structures. Current researches are focusing on implementing decision algorithm for repair and strengthening method, priority, and budgeting as well as on improving hardware performance of health monitoring system. Accordingly, current researches focus on developing systematic decision algorithm for repair and strengthening, and improving SHM hardware performance so as to lengthen service life of bridges and ensure serviceability and safety.

1 INTRODUCTION

Development of bridge monitoring in Japan has been highly influenced by the geographical and socioeconomical conditions of Japan. Natural disasters such as earthquakes and typhoons are some of the major concerns for civil engineering construction. Therefore, sensing technology for natural disasters is well developed and various bridges have been instrumented for decades to evaluate these uncertain loading associated with natural disasters. Although based on similar sensing technology, these instrumentations are mainly focused on environmental and load effect on structures, but not necessarily aimed to detect damage or other structural health monitoring purposes. Historically, Japanese monitoring has laid more emphasis on environmental measurement for verification of design assumptions.

Owing to aging of infrastructure built during the post-WWII rapid economic growth between 1955 and 1975, evaluation of structural performance and/or damage of existing structures has become more and more important for rational and efficient stock management. Structural health monitoring is currently attracting wide interest as one of the key solutions to this problem. At the same time, social concern for safety is higher than ever for public infrastructure following recent failures of major bridges in Japan, as well as in the United States. Therefore, monitoring technology not only to keep average stock condition for stock management but also to prevent extreme failure event is strongly needed. Although these two requirements appear to be similar, practical implementations for these two needs are different. Stock management would focus more on the average condition of the entire stock, whereas safety and risk management would focus on extreme values, which are very unlikely to occur. These two features of health monitoring are treated separately in the current article.

In Section 2, background of development for Japanese monitoring technology is summarized to

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

include the following: (i) environment and natural disasters, (ii) stock management, and (iii) risk and safety. In the following sections, examples of implementation of monitoring for bridges are explained under these three categories.

2 BACKGROUND OF DEVELOPMENT

2.1 Environment and natural disasters

Japan is located in the seismically active and typhoon-prone area of the Pacific Rim. In the 1995 Kobe earthquake, more than 6000 people were killed and major infrastructure was heavily damaged as shown in Figure 1 [1].

Figure 2 shows the number of deaths, and the damage costs for public facilities in Japan since 1950 [2]. The decreasing tendency of the number of deaths and slight increase in loss in public facilities can be observed in Figure 2. Extreme values for both human and property losses are observed at 1995, due to the Kobe earthquake. Although the damage cost for public facilities is only a fraction of the entire damage loss including the private sector whose statistics are not available on consistent bases, it is considered to give the representative indicator for the entire damage.

Figure 3 shows the government expenditure related to disaster prevention. Steady increase in the disaster reduction budgets is observed, especially after the 1995 Kobe earthquake. Because annual public-facility damage is about 1–2 trillion yen and the disaster reduction budget is about 3–4 trillion, every year, approximately 4–6 trillion yen is spent for natural disasters by the public sector of in Japan.

Figure 1. Damage after the 1995 Kobe earthquake.

Sensing technology forms the basis for not only evaluation of meteorological risk, but it has also been playing a major role in seismic risk evaluation. Seismometers are densely distributed throughout Japan, and seismic intensities are reported right after the earthquake [3]. Tokyo Company Gas has its

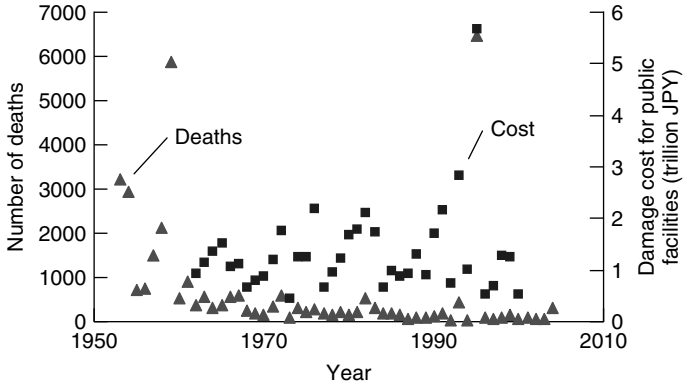

Figure 2. Damage loss due to natural disasters in Japan.

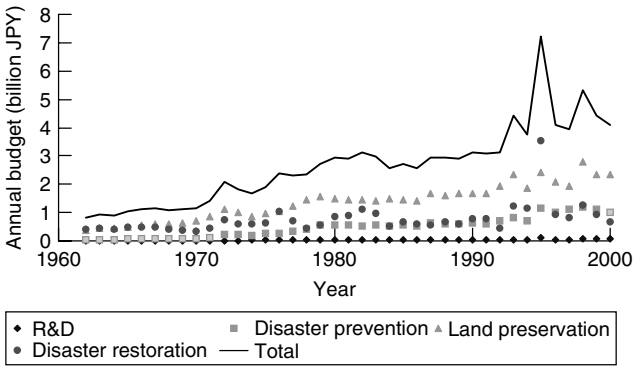

Figure 3. Government expenditure for disaster reduction.

own network of seismic sensors and utilizes the information to shut down the network to prevent fire and explosion after major earthquakes [4].

From 2007, earthquake early warning is issued by the Japan Meteorological Agency [5]. The earthquake early warning system automatically calculates the focus and magnitude of the earthquake and estimates the seismic intensity for each location by detecting the ground motion (i.e., the P-wave, or the preliminary tremor) near its focus. An earthquake early warning is then given within a few seconds to a few tens of seconds before the arrival of the S-wave, or principal motion. This technology was first developed for seismic protection of Shinkansen trains several decades ago, and is now applied nationwide [6].

Another geographical condition, which influences the Japanese infrastructure, is that the country consists of mountainous islands. Therefore, many of the bridges are built near seashores or to cross channels such as the world's longest Akashi–Kaikyo Bridge (Figure 4). These bridges are exposed to severe environmental deterioration conditions with high chloride-ion density and humidity. In the Akashi–Kaikyo Bridge, a dry-air injection system (Figure 5) has been installed to protect the main cable by humidity control [7]. Figure 6 shows other sensors in the monitoring of the Akashi–Kaikyo Bridge [8].

Because of the geography, land use is also concentrated, and severe traffic loadings are often observed, especially in metropolitan areas as shown in Figure 7.

These environmental conditions impose a burden on infrastructure, forcing additional spending to keep the integrity of the infrastructure system. Reduction in this expenditure and enhancement of safety would naturally be the motivation for structural health monitoring.

Figure 4. Akashi–Kaikyo Bridge.

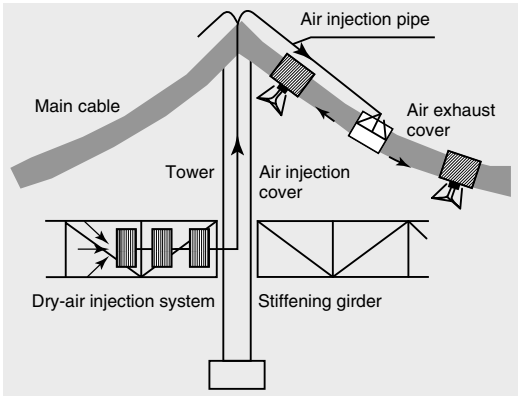

Figure 5. Dry-air injection system of the Akashi–Kaikyo Bridge.

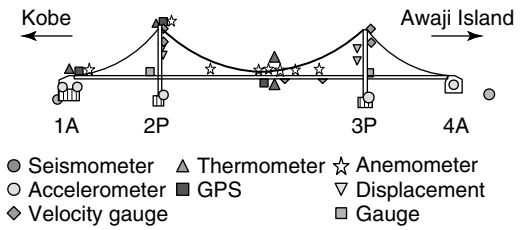

Figure 6. Monitoring system of Akashi–Kaikyo Bridge.

Figure 7. Metropolitan Expressway.

2.2 Stock management

Japanese economy developed rapidly between 1955 and 1975, and a large amount of infrastructure was built in this period. Figure 8 shows a comparison of bridge construction between Japan and the United States [9]. On an average, the US bridges are 10-years older, but the construction of the Japanese bridges took place over a shorter, concentrated period of time. This concentration may induce simultaneous deterioration of a large portion of the stock and would lead to high social cost.

Japanese National Railway (JNR), now divided and privatized, had systematic inspection procedures with data accumulation. Figure 9 shows an example of such data for the period 1963–1971. Annual repair spending and deficient stock are normalized with respect to the total infrastructure stock of JNR. It can be seen that deficient stock is kept at 10–15% of total stock by spending about 1% on repair [10].

Figure 10 shows the total infrastructure stock and GDP from 1955 to 2000 [11, 12]. Because GDP is the flow in economy, while infrastructure is the stock, i.e., integration of flow, a steady increase of stock is observed. As explained by Figure 9, a certain percentage of stock, e.g., 1%, is required each year to maintain the condition of the stock, a larger portion of GDP would be required to in this effort. However, as shown in Figure 11 [13], rehabilitation expenditure with respect to the entire stock is reducing each year, which implies the requirement for more efficient technology to maintain the condition of the stock.

2.3 Risk and safety

Recent finding of severe damage at the Kisogawa Bridge (Figures 12 and 13) on the major trunk highway caused high public awareness on the stock condition and safety of bridges. Because truss structure is theoretically a statically determinant structure, this failure can be considered to near collapse. Detection of this kind of fatal failure would be required to assure safety.

3 MONITORING FOR ENVIRONMENT AND DISASTERS

3.1 Earthquake

Because of the high intensity of seismic activities in Japan, monitoring for seismic response has been widely employed, especially for bridges with special features such as long-span bridges [8], and bridges with new technology such as base-isolated bridges [14].

One such example is the Yokohama Bay Bridge (Figure 14) [15]. A dense seismic measurement system has been installed, as shown in Figure 15. The system identification method based on the system realization using information matrix (SRIM)

Figure 14. Yokohama Bay Bridge.

that utilizes correlations between base motions and bridge accelerations to identify coefficient matrices of a state-space model is applied to several seismic records.

In addition to global behavior such as amplitude dependence of damping ratios, variations of local components were also observed. The identified results of the Yokohama Bay Bridge revealed two types of the first longitudinal mode, where the main difference was the relative modal displacement between the end piers and girder (Figure 16). In design, the end piers and girder are connected by link-bearing connections (LBCs) whose essential function is to prevent the large inertial force of a superstructure from being imparted to substructures during large excitation. For this purpose, the LBC is expected to function as a longitudinal hinge connection to indicate that the girder and pier caps work as separate units in design.

The first type of longitudinal mode exhibited a large relative modal displacement as evidenced by $\varphi = 0.80$ and $\varphi = 0.82$ for the left and right end piers, respectively. The φ factor is defined to express the relative motion between the pier cap and the girder. The shape characteristics and frequency of this mode were very close to that of the analytically obtained the first longitudinal mode. The large relative modal displacement suggested that there might be a hinge mechanism.

The other mode was also identified. The smaller relative modal displacements between the end piers and the girder of this mode (i.e., $\varphi = 0.28$ and $\varphi = 0.25$ for the left and right end piers, respectively) suggested that the LBC had yet to function as full-hinged connections, causing stiffer connection

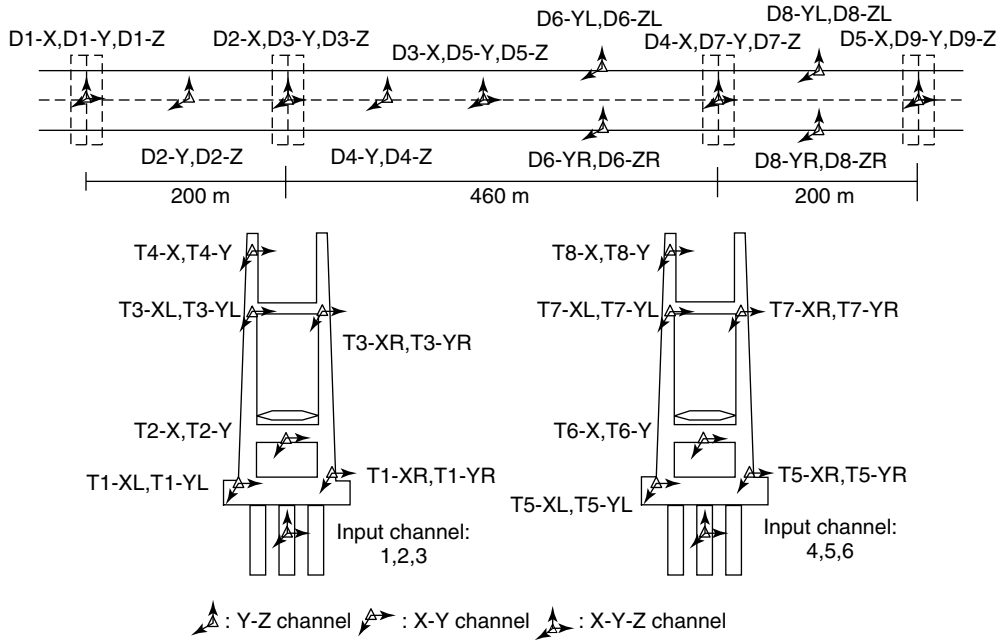

Figure 15. Seismic monitoring at the Yokohama Bay Bridge.

with higher natural frequency. These results indicate that performance of LBC depends on the amplitude of earthquake excitation and does not always follow the analytical prediction.

Although the study is focused on comparison based on design and analysis, the result implies that damage or malfunctioning of the bearing could be detected by the monitoring system. In addition, this result is reflected to on-going seismic retrofit of the bridge, connecting the girder end to the footing by cables (*see* **Design Principles for Civil Structures**; **Soil–Structure Interaction and Seismic Effects**).

3.2 Wind

Wind-induced ambient vibration is measured by dense array at the Hakucho Bridge for a few weeks under various levels of wind speed (Figures 17 and 18) [16]. Ambient vibration measurement is an important tool to evaluate the integrity of in-service structures (*see* **Ambient Vibration Monitoring**; **The Influence of Environmental Factors**). The measured data clearly show the quadratic relationship between wind velocity and response as shown in Figure 19.

The applied structural identification method consists of two steps: identification of vibration modes and inverse analysis of structural properties from the identified modes. For modal identification, the method treats the structure as a multi-input–multioutput system, distinguishing noise from true modes and employing ambient vibration measurement. For the identification of structural properties, assumptions on proportionality of damping, previous estimation of structural damping/stiffness, and numerical iteration are not required. The results verify that the method can precisely determine the characteristics of not only the lower modes, but also the higher modes, and can effectively detect changes in the structural properties. Figure 20 shows the identified aerodynamic stiffness and damping, which are usually measured in wind tunnels, but difficult to obtain *in situ*.

4 MONITORING FOR STOCK MANAGEMENT

Monitoring is expected to improve conventional inspection procedure and rationalize stock management (*see* **Maintenance Principles for Civil Structures**).

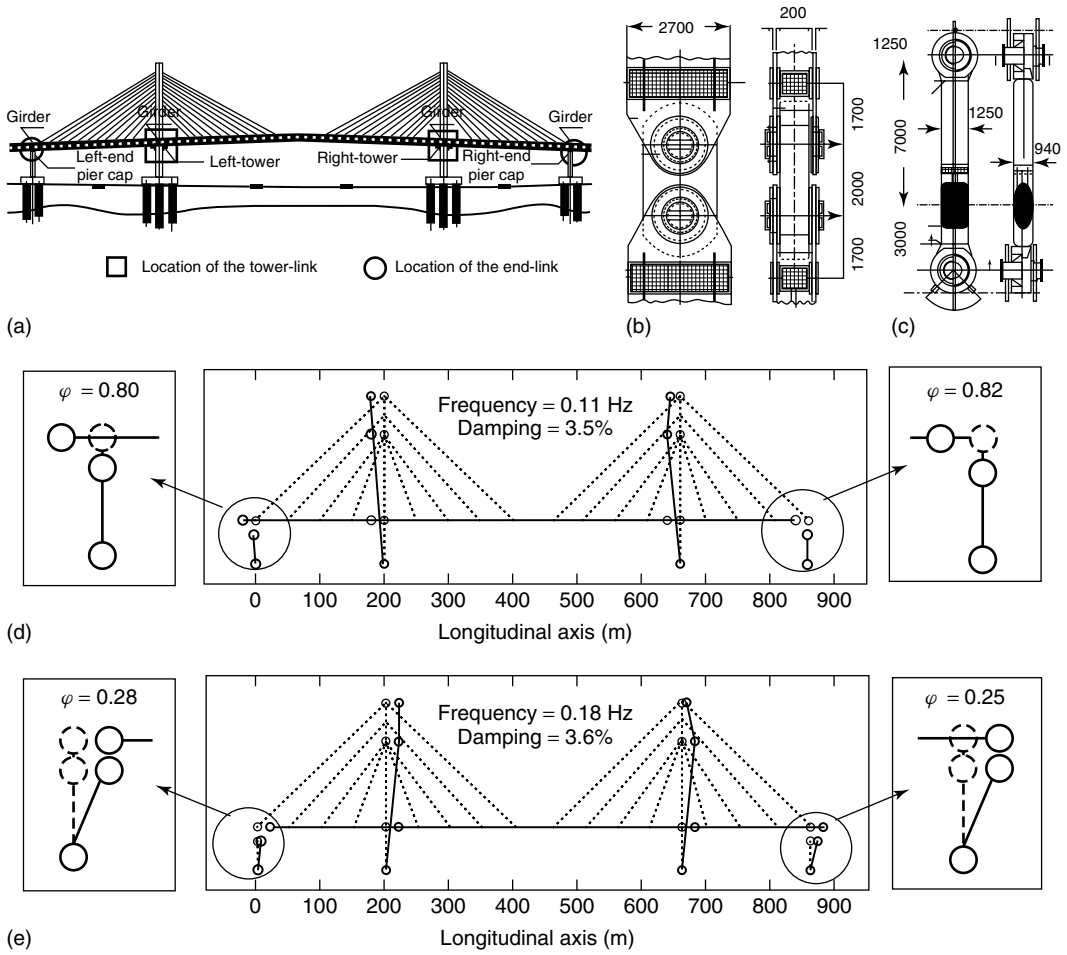

Figure 16. (a) Location of link-bearing connection of the Yokohama Bay Bridge; (b) typical LBC at the tower; (c) typical LBC at end piers; two typical first modes of the Yokohama Bay Bridge identified from the main shock at 17 min 57 sec; (d) hinged–hinged mode: $\varphi_{\text{left}} = 0.80$, $\varphi_{\text{right}} = 0.82$; (e) fixed–fixed mode: $\varphi_{\text{left}} = 0.28$, $\varphi_{\text{right}} = 0.25$.

Figure 17. Hakucho Bridge.

In this context, several examples of monitoring are briefly introduced: (i) workhorse bridges; (ii) preventive maintenance; and (iii) advanced routine inspection.

4.1 Workhorse bridges

For efficient stock management, it is essential to monitor short to medium span bridges, which are the major portion of the stock. Not only the cost associated with sensor hardware, processing and interpreting the large number of data is also a great

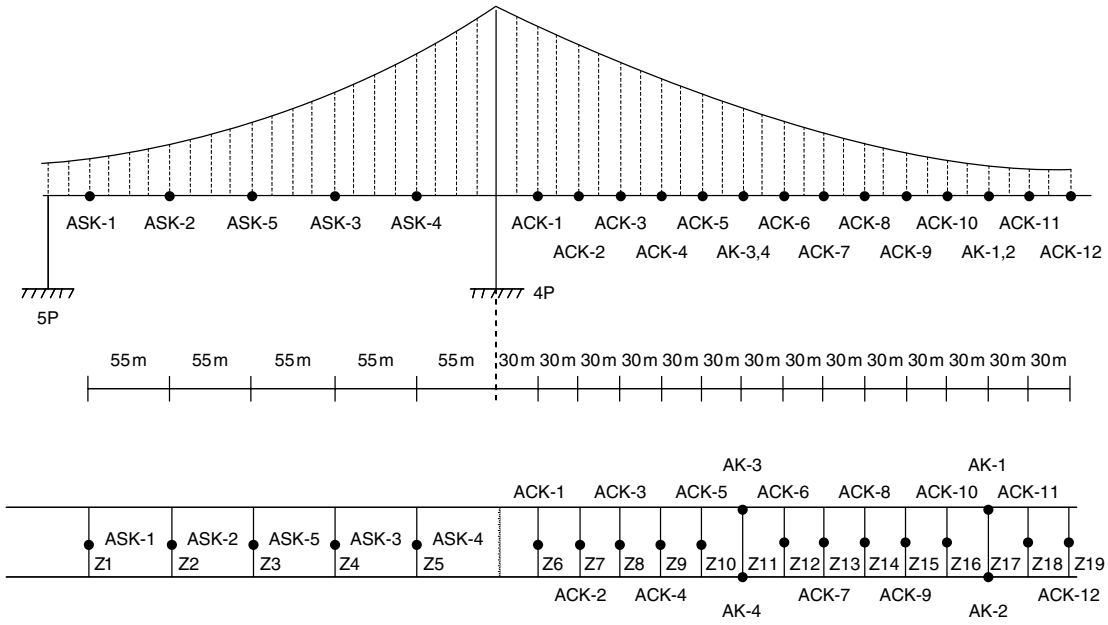

Figure 18. Accelerometer installation.

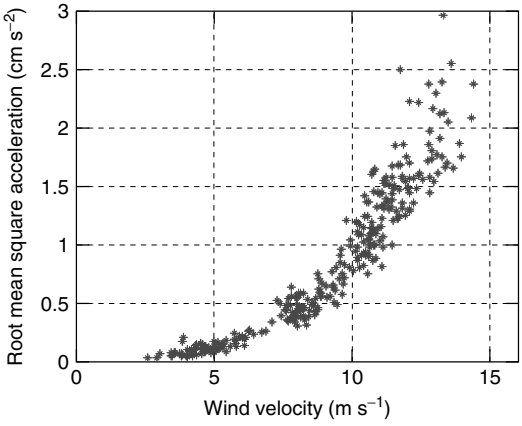

Figure 19. Wind velocity and response.

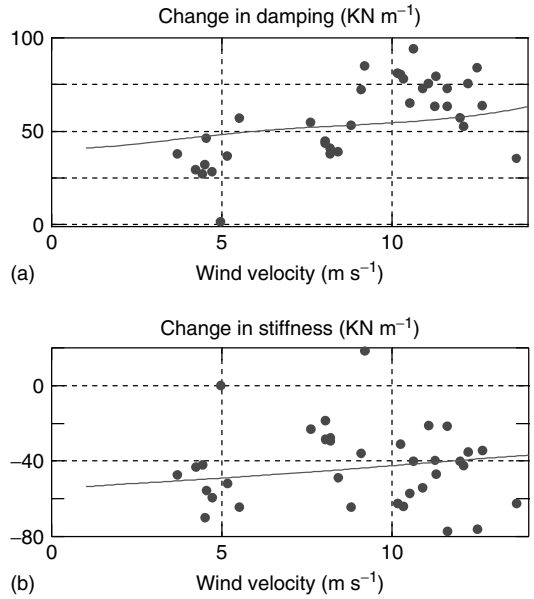

Figure 20. Identified changes in aerodynamic force. (a) Aerodynamic damping, (b) aerodynamic stiffness. ●: Identified value; —: wind-tunnel experiment.

challenge for engineers. The study in [17] demonstrates how to apply some available algorithms to the data measured by a practical structural health monitoring system and how to evaluate the results for the sample ordi- nary medium span bridge of Figure 21. The sensor location at the bridge is shown in Figure 22. Identification of dynamic characteristics, tempe- rature effect, and fatigue damage evaluation (*see* **Fatigue Life Assessment of Structures**) are studied using monitored data. Results indicate that the structural condition is deficient and further special inspection is required at the monitored bridge,

although the structure itself is relatively new, i.e., 12 years old at the time of the study. The deficiency would be related to the skew effect, which may have not been appropriately treated in design. The demonstrated implementation and methodology can be considered as the general basis for monitoring of common workhorse structures.

This field is actively studied and other examples can be found in [18, 19].

4.2 Monitoring for preventive maintenance

Monitoring technology has been applied to improve maintenance at several bridges.

Figure 21. Monitored bridge.

Figure 23. Monitored bridges piers: connecting bridge to Shin–Kitakyushu Airport.

The Shin–Kitakyushu Airport has been constructed on land reclaimed from the sea, 2 km off the east coast of Fukuoka Prefecture, Japan. The airport is connected to the coast by an access bridge having a total of 25 reinforced concrete piers. The bridge is designed taking into consideration 100 years of design service life. However, 22 piers have been constructed in the marine environment as shown in Figure 23, where the piers suffer severe chloride attack, and their durability during the service life is difficult without any maintenance action. Therefore, for constructing a durable bridge, a scheme of durability design of the piers is established on the premise of maintenance action starting from the beginning of the service during its life [20]. The preventive maintenance procedure is shown in Figure 24.

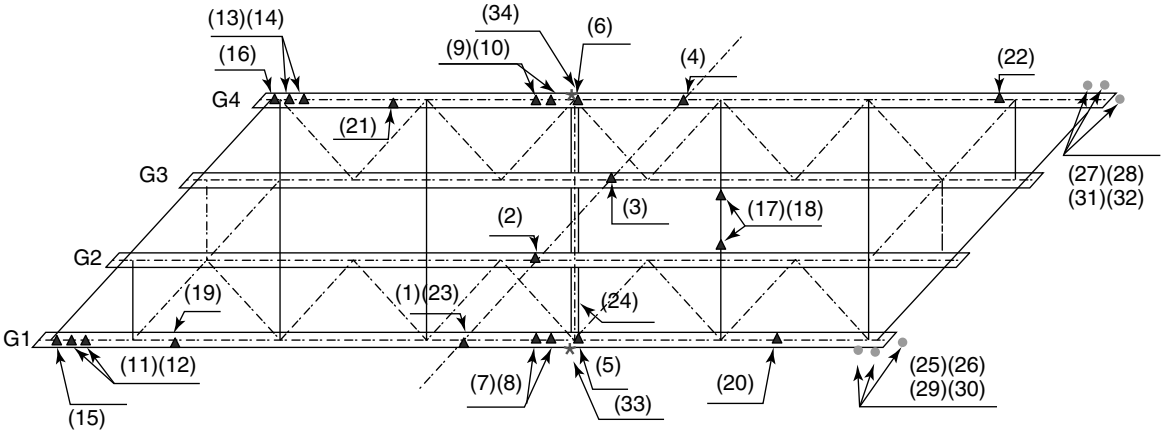

Figure 22. Sensor location. ▲: Strain gauge, 24; ●: displacement sensor, 8; ⋆: thermometer, 2.

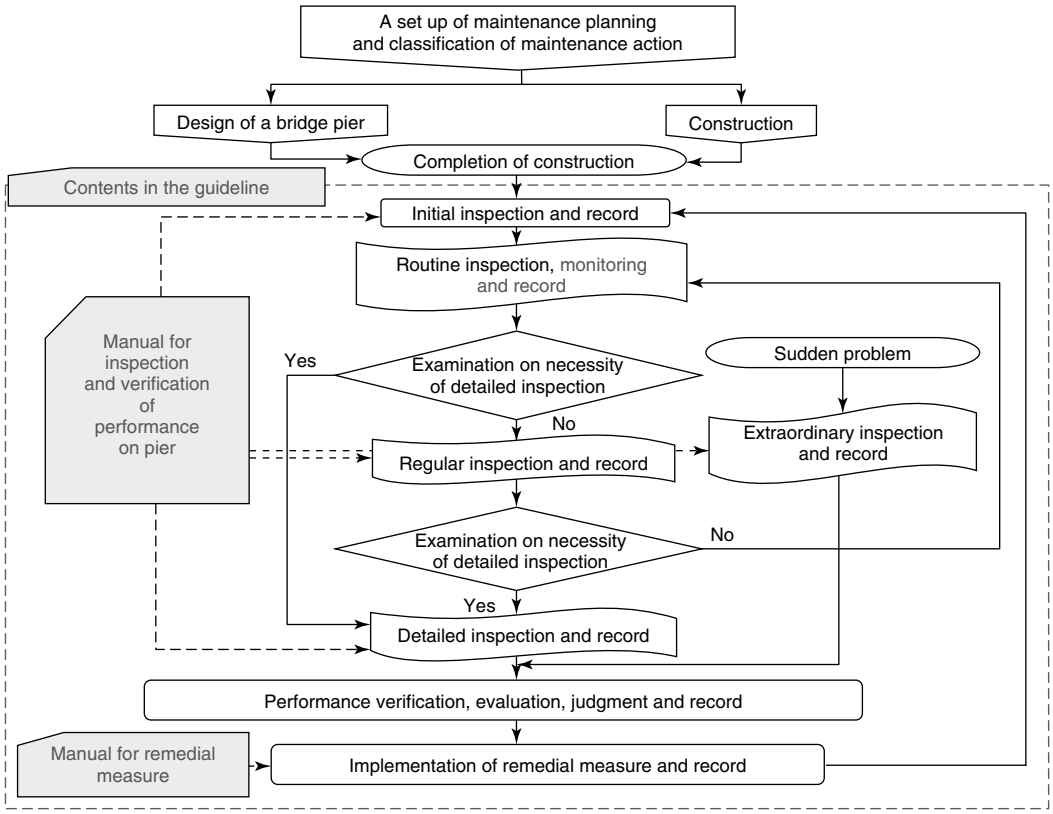

Figure 24. Maintenance procedure.

In the maintenance action, monitoring of chloride penetration into concrete and corrodibility of steel reinforcement is included as continuous inspections for the deterioration of the piers. The outline of the chloride-sensing mechanism is described in Figure 25. The probe body is made of polymer cement mortar cylindrical in shape, around which four thin steel wires are wound over small grooves [21]. Once chloride penetrates into the concrete from the external environment and its content in concrete around the wire reaches the critical value, the wire is depassivated and corrosion starts. After the wire corrodes, it breaks because of its minute cross section.

This chloride-sensing probe utilizes the corrosion of thin wires, which deteriorate faster. A similar sensor is also applied to the fatigue problem. Figure 26 shows the fatigue sensor installed at a railway bridge [22]. The sensor is made of notched thin plate, and by propagation of the crack from the notch, accumulated damage can be estimated.

4.3 Advanced routine inspection

Because transportation infrastructure, such as highways and railways, forms a huge network, bridges are the essential links within. Performance of transportation network relies on the overall performance of these bridges, and efficient inspection is required so that the performance be kept. Conventionally, the structural state is evaluated by qualitative visual inspection. For more efficient inspection for the entire network, and to obtain quantitative information on the infrastructure, vehicle-based monitoring systems are developed for highways and railways. The developed system is called *vehicle intelligent monitoring system* (VIMS), which consists of an accelerometer and a global positioning system (GPS) receiver mounted on a patrol or service vehicle as shown Figure 27 [23]. By using patrol/service vehicles, it is possible to cover the entire network with much higher density and frequency compared with the conventional inspection

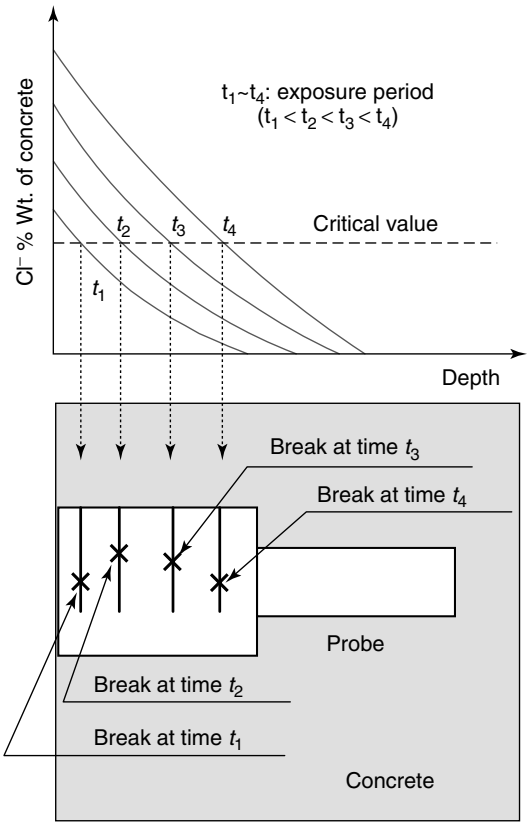

Figure 25. Chloride sensor probe.

with designated personnel and vehicles. Monitoring systems to measure floor vibration of the vehicles are developed so that installation can be made without modification of the vehicles, and to reduce cost of sensors and systems.

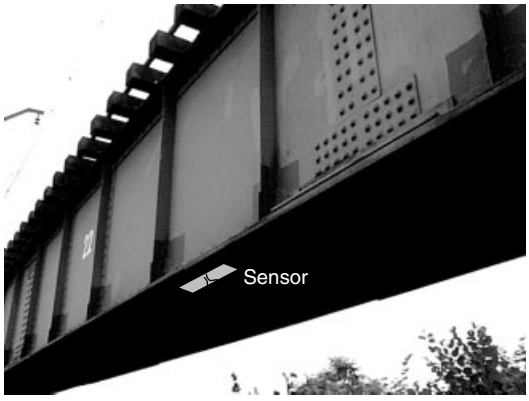

Figure 26. Fatigue sensor installed at a railway bridge.

This system has been applied to Tokyo Metropolitan Expressway, and its effectiveness in road maintenance, i.e., frequent monitoring of the conditions of road pavement and expansion joints, is confirmed [24].

Also, the system is applied to railways, and possibility of utilization of ordinary service vehicles for rail-track monitoring has been studied [25]. The developed system is applied to an actual railway and measurements at different points of time are compared [26]. By looking at the rms acceleration responses, it is found that the responses at the same location are stable with repetitive measurements. It is also observed that repair and deterioration of track beds cause significant change in measurement as shown in Figure 28. Between the two dates indicated in the figure, a major typhoon attacked the area, and the tracks were heavily damaged and repaired.

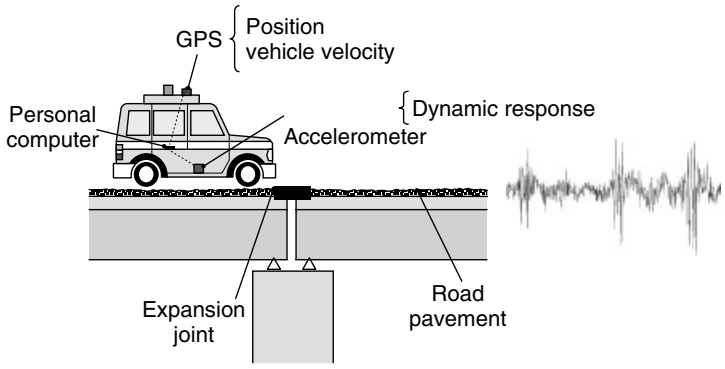

Figure 27. Vehicle intelligent monitoring system.

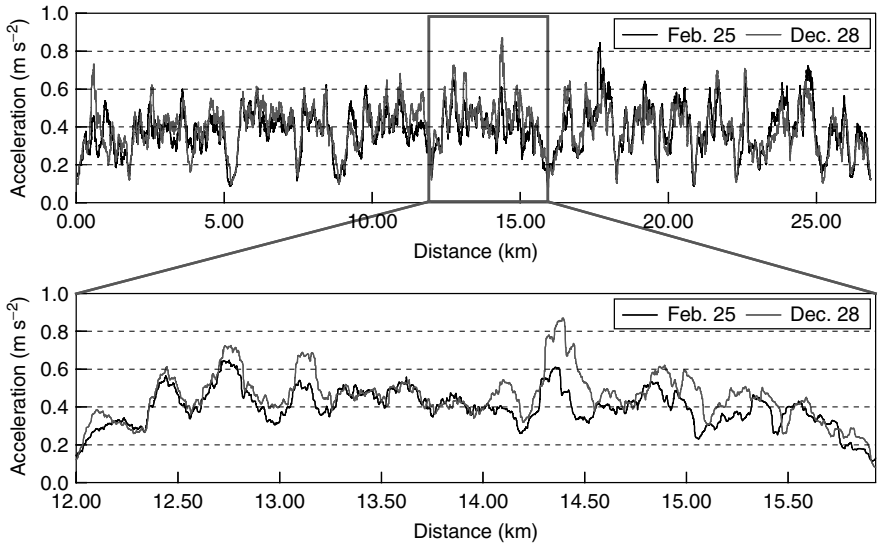

Figure 28. Detected progressive damage.

5 MONITORING FOR RISK AND VULNERABILITY

In this section, monitoring for safety is described from two viewpoints: (i) failure detection; and (ii) vulnerability evaluation (*see* **Risk Monitoring of Civil Structures**).

5.1 Failure detection

When the failure mode of interest is identified or specified, it is not difficult to implement a monitoring system. Several such systems are developed and implemented for safety of railway operations.

Figure 29 shows an unseating sensor. When unseating of a bridge girder occurs, the sensor breaks and an electrical signal is sent to the headquarters to suspend operations. The system is installed to overpass bridges above the highway, where collision risk is supposed to be high. Figure 30 shows clinometers installed at bridges to detect scour-induced collapse

Figure 29. Unseating sensor.

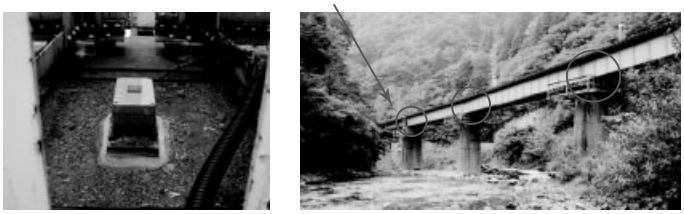

Figure 30. Clinometric type scour-monitoring device. [Reproduced from Ref. 27.

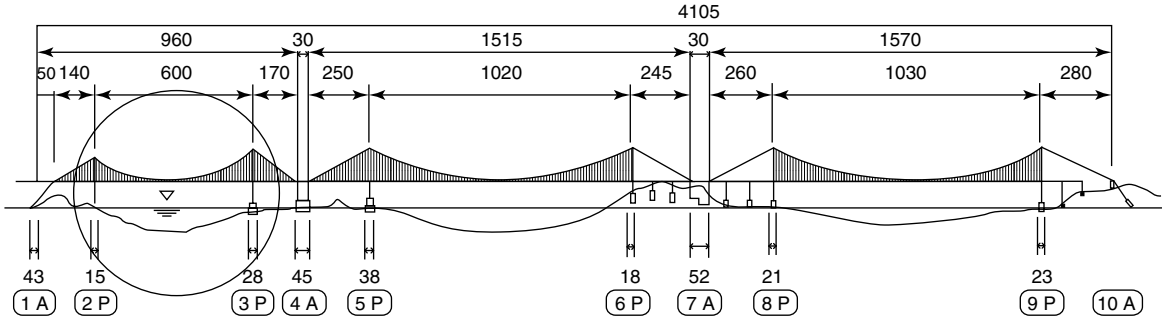

Figure 31. First Kurushima Kaikyo Bridge.

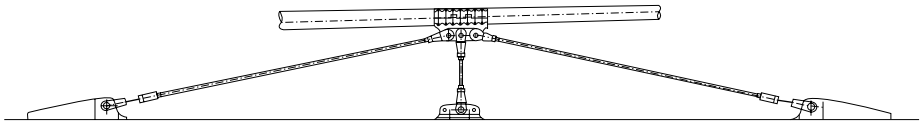

Figure 32. Center stay.

of bridge piers [27]. An alarm is sent when the inclination reaches the maintenance limits of track irregularity. These monitoring systems are developed for specific failure mode and risk, for the purpose of safe operation.

A natural extension of this kind of monitoring system would be the universal sensor system to detect damage and failure, which is the major research area in structural health monitoring.

At the time of the 2001 Geiyo Earthquake, with an intensity of M 6.7 intensity, the center stay rod at the first Kurushima Kaikyo Bridge failed [28]. The outlines of the bridge and the center stay are shown in Figures 31 and 32. Figures 33 and 34 show the failure.

Observed seismic ground motion is applied to dynamic three-dimensional finite element analysis, and it was verified that the failed center stay rods performed as they had been designed to perform. Also, analysis indicates that the failure may have occurred either at 12 or 15 s and other members would not have been damaged. In this way, reanalysis of observed data can provide damage or failure information. Further research and development would be required for damage or failure detection to be made on line in real time.

Figure 33. Observed failure.

5.2 Vulnerability evaluation

Extreme events such as earthquake or scour or accidents due to human error occur in an uncertain manner. Preventive action should be taken in accordance with the probability of the hazard risk and also the extent of vulnerability of the structures. The first step, environmental monitoring, and the next one, vulnerability detection, fall into the core domain of structural health monitoring.

An example of this category of inspection is the impact-testing method, developed by the Railway Technical Research Institute, and is widely used in Japanese railways for the inspection of bridge

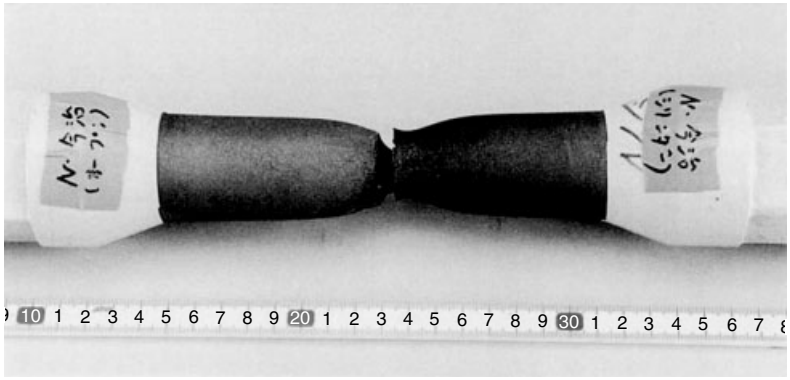

Figure 34. Failed cross section.

substructures [29]. The fundamental procedure is as follows:

1. Measure the free vibration response of the pier excited by impact as shown in Figure 35.
2. Identify the fundamental natural frequency from observed the power spectral density (PSD). This process is manually done by reading the peaks of the PSD.
3. Calculate the integrity index α given by

$$\alpha = \frac{\text{(measured natural frequency)}}{\text{(standard value of natural frequency: } F)} \quad (1)$$

4. Judge the integrity according to the standard given in Table 1. The value of F is provided by regression equations obtained from statistical analysis of the past testing record of railway bridges. For example, the regression equation for a substructure with a pile foundation is given by

$$F = -9.9 \log H_d + 0.005\ W_h + 14.9 \quad (2)$$

where, H_d is the height of the pier from the ground surface (meters), and W_h is the weight of the girder (tonforce), and F, the standard value of natural frequency (Hertz).

The procedure is quantitative, but based purely on heuristic experience. Here, natural frequency is used as the indicator of structural integrity or vulnerability. In design, identical structures have identical natural frequencies, but in reality, natural frequency scatters even for the same design. In this way, the measurement-based index provides at least some information on the relative vulnerability of the structure.

In this direction, trials are being made to use structural response itself as the indicator of vulnerability [30]. A conceptual scheme is shown in Figure 36,

Figure 35. Impact testing.

Table 1. Standard for structural integrity

Integrity index	Integrity criteria	Treatment
Below 0.70	*A* *A*1	Detailed inspection, consideration for countermeasure
Below 0.85	*A*2	Monitor progress of defects such as inclination or scour
Above 0.86	*B*, *C*, *S*	Can be considered sound

*A*1, advanced damage and performance degradation; *A*2, advanced damage, threat to performance degradation; *B*, would reach *A* if progressive; *C*, minor damage; *S*, no damage.

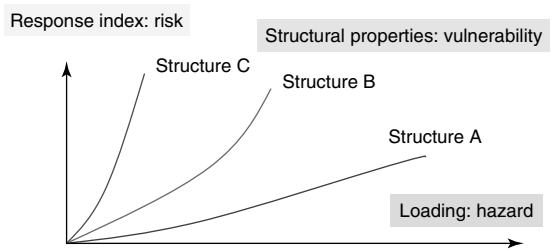

Figure 36. Fundamental concept of vulnerability detection.

where the response index is plotted with respect to loading index, and different response characteristics for a similar structure provides relative vulnerability. The concept is being developed for railway substructures subject to train loading [31] and seismic vulnerability evaluation of buildings [32]. These studies are intended to evaluate overall performance of structures with certain indicators. This approach could be considered "macroscopic" monitoring, in contrast with the "microscopic" monitoring to detect damage or failure. This approach is considered advantageous from a practical point of view since it can readily be related to existing inspection schemes based on visual condition rating.

To date, this approach is based solely on heuristics or statistics. Rationalization and theorization of the method would be the step for its generalization.

6 CONCLUSIONS

In this article, Japanese development of health monitoring of bridges is reviewed from the geographical and socioeconomical background to specific applications. These backgrounds are categorized as (i) environment and natural disasters, (ii) stock management, and (iii) risk and safety. In other words, severe environment, limited resource for maintenance, and increased requirement for safety are the key factors. Structural health monitoring can be considered as a key technology to meet these conflicting demands.

Owing to pronounced natural-disaster risk and severe environment for deterioration, environment and loading have been monitored at various bridges for decades. At several bridges, these measured data are also analyzed in the context of structural monitoring. Although these measurements were intended to measure loading, but not necessarily to measure structural condition, analyses indicate usefulness of these measurements for evaluation of structural integrity.

Structural health monitoring technology is also being developed to improve efficiency of stock management. Monitoring technologies for common workhorse bridges, preventive maintenance, and improvement of routine inspection are being developed and applied to the real world in this domain.

For improved safety, several monitoring technologies for risk and vulnerability are implemented. When the threatening failure mode can be identified, specific monitoring devices, such as unseating sensors or clinometers for scour are installed, and the information is used for operation control. Also, reanalysis of seismic failure implies usefulness of measurement for on-line damage detection, although further research studies would be needed for this purpose. As an example of vulnerability monitoring, the impact vibration testing method to evaluate integrity of structures is introduced. This technique can be used to compare relative safety, and to prioritize the improvement action. Structural health monitoring technologies in this domain can be categorized into (i) microscopic monitoring, where damage detection and localization are main interest; and (ii) macroscopic monitoring, where holistic structural integrity and its comparison are the main focus. The first one is the conventional mainstream of structural health monitoring, while the latter is currently attracting interest especially from practical point of view to connect health monitoring and existing inspection.

Chapter 126

Continuous Vibration Monitoring and Progressive Damage Testing on the Z24 Bridge

Edwin Reynders and Guido De Roeck

Department of Civil Engineering, Katholieke Universiteit Leuven, Leuven, Belgium

1 INTRODUCTION

The Z24 bridge was located in the canton Bern near Solothurn, Switzerland. The bridge was part of the road connection between the villages of Koppigen and Utzenstorf, overpassing the A1 highway between Bern and Zürich. It was a classical post-tensioned concrete two-cell box girder bridge with a main span of 30 m and two side spans of 14 m (Figures 1–2). The bridge was built as a freestanding frame with the approaches backfilled later. Both abutments consisted of triple concrete columns connected with concrete hinges to the girder. Both intermediate supports were concrete piers clamped into the girder. An extension of the bridge girder at the approaches provided a sliding slab. All supports were rotated with respect to the longitudinal axis that yielded a skew bridge. The bridge, which dated from 1963, was demolished at the end of 1998, because a new railway adjacent to the highway required a new bridge with a larger side span.

Before complete demolition, the bridge was subjected to a long-term continuous monitoring test and several progressive damage tests in the framework of the Brite-EuRam project CT96 0277 SIMCES [1]:

- A *long-term continuous monitoring test* took place during the year before demolition. The aim was to quantify the environmental variability of the bridge dynamics.
- *Progressive damage tests* took place over a month, shortly before complete demolition. The aim was to prove experimentally that realistic damage has a measurable influence on bridge dynamics. The

progressive damage tests were alternated with short-term monitoring tests while the continuous monitoring system was still running during these tests.

The Z24 bridge project was unique in the sense that a long-term continuous monitoring test was combined with realistic short-term progressive damage tests. The measurement data have been used for two benchmarks:

- The shaker, ambient, and drop weight vibration data from the third reference measurement on the Z24 bridge (scenario 8, Table 1) were presented as a benchmark study for system identification methods for operational modal analysis at the IMAC XIX conference in 2001 (Section 3).
- The data from the long-term continuous monitoring tests as well as the data from the progressive damage tests were presented as a benchmark study for algorithms for structural health monitoring and damage identification in the framework of the European Cost Action F3 (Sections 4 and 5).

The benchmark data are still publicly available, and some recently developed methods for modal analysis, damage identification, and health monitoring have been tested on the data.

This article is organized as follows. The different tests are described in Section 2. To provide some insight into the dynamic behavior of the bridge, the operational modal analysis results are discussed in Section 3. Sections 4 and 5 contain a literature review of results obtained from the continuous monitoring data and the progressive damage test data, respectively.

2 TEST DESCRIPTIONS

In this section, a brief overview of the performed tests is given. A profound overview is provided by Krämer *et al.* [2].

2.1 Long-term Continuous Monitoring Test

Since the aim of this test was to quantify the environmental variability of the bridge dynamics, all environmental variables that were considered to be of possible importance for the bridge dynamics have been monitored.

Sensors to measure air temperature, air humidity, rain true or false, wind speed, and wind direction were installed at the bridge, resulting in five sensors for the atmospheric conditions.

A sensor consisting of two inductive loops was installed to detect the presence of vehicles on the bridge.

Since temperature was known to have a key influence on the dynamics of civil engineering structures, the bridge's thermal state was monitored in detail. At the middle of the three spans, the temperature was

Table 1. Progressive damage tests: overview of damage scenarios

No.	Date (1998)	Scenario	Description/simulation of real damage cause
1	04.08	First reference measurement	Healthy structure
2	09.08	Second reference measurement	After installation of lowering system
3	10.08	Lowering of pier, 20 mm	Settlement of subsoil, erosion
4	12.08	Lowering of pier, 40 mm	
5	17.08	Lowering of pier, 80 mm	
6	18.08	Lowering of pier, 95 mm	
7	19.08	Tilt of foundation	Settlement of subsoil, erosion
8	20.08	Third reference measurement	After lifting of the bridge to its initial position
9	25.08	Spalling of concrete, 24 m^2	Vehicle impact, carbonization, and subsequent corrosion of reinforcement
10	26.08	Spalling of concrete, 12 m^2	
11	27.08	Landslide at abutment	Heavy rainfall, erosion
12	31.08	Failure of concrete hinge	Chloride attack, corrosion
13	02.09	Failure of anchor heads I	Corrosion, overstress
14	03.09	Failure of anchor heads II	
15	07.09	Rupture of tendons I	Erroneous or forgotten injection of tendon tubes, chloride influence
16	08.09	Rupture of tendons II	
17	09.09	Rupture of tendons III

measured at eight points on the girder: at the center of the north (TWN), central (TWC), and south (TWS) web; below the north (TSWN) and south (TSWS) sidewalk; at the top (TDT) and soffit (TDS) of the deck, and at the soffit (TS) of the girder (Figure 2). Since the girder was a continuous beam with the intermediate piers clamped into it, the angular deflection of the girder at these piers and the elongation of the midspan were measured. The soil temperature near each of the concrete columns at the approaches was monitored, as well as that near the north, central, and south parts of the intermediate piers (12 sensors in total).

Although the original blueprints of the Z24 bridge indicated that the asphalt layer should have a thickness of 5 cm, the drilling of access holes for the installation of the temperature sensors on the girder revealed a cover of 16–18 cm of asphalt. Therefore, the temperature of the pavement (TP) was measured at the middle of the three spans (Figure 2).

To monitor the bridge dynamics, 16 accelerations have been measured on the bridge at different points and in different directions.

Every hour, 10 scans of environmental data, sampled at 48 sensors, and 8 averages of 8192 acceleration samples, taken at 16 sensors, were collected and stored to a hard disk after compression. The construction works at the new bridge that replaced the Z24, caused the loss of six temperature sensors and damage to one accelerometer. Although the type of accelerometers that had been used was specially designed for long-term use, some showed a considerable drift and a few of them failed during operation.

2.2 Progressive Damage Tests

In order for the damage tests to be significant, it was made sure that (i) they were relevant for the safety of the bridge and (ii) the simulated damage occurred frequently, a condition that was checked in the literature [3, 4] and by questioning Swiss bridge owners. Since the A1 highway was never closed to traffic, some damage scenarios that meet these criteria could not be applied without reducing the safety of the traffic, which was considered of paramount importance. The traffic on the Z24 bridge was diverted to the A36 highway. Table 1 gives a complete overview of all progressive damage tests that were performed. Some of them are illustrated in Figure 3.

Before and after each applied damage scenario, the bridge was subjected to a forced and an ambient

(a) (b)

Figure 3. Settlement system used for damage scenarios 3–6 (a) and cutting of tendons for damage scenarios 15–17 (b).

operational vibration test. With a measurement grid consisting of a regular 3×45 grid on top of the bridge deck and a 2×8 grid on each of the two pillars, 291 degrees of freedom have been measured: all displacements on the pillars, and mainly vertical and lateral displacements on the bridge deck. Because of the limited number of accelerometers and acquisition channels, the data were collected in nine setups using five reference channels. The forced excitation was applied by two vertical shakers of EMPA, Switzerland, placed on the bridge deck. A 1-kN shaker was placed on the middle span and a 0.5-kN shaker was placed at the Koppigen side span. The shaker input signals were generated using an inverse fast Fourier transform (FFT) algorithm, resulting in a fairly flat force spectrum between 3 and 30 Hz. After scenario 8, a drop weight test was also performed. The applied shaker and drop weight forces were periodic with eight periods. A total of 65 536 samples was collected at a sampling rate of 100 Hz, using an antialiasing filter with a 30-Hz cutoff frequency.

3 SYSTEM IDENTIFICATION AND OPERATIONAL MODAL ANALYSIS

From recorded force and acceleration or acceleration-only data, the modal parameters can be determined. Since the ambient forces such as wind excitation or traffic under the bridge could not be excluded during the vibration measurements, all modal tests can be considered as operational modal analysis tests, with or without the use of artificial (exogenous) forces. The shaker, ambient, and drop weight vibration data from the third reference measurement (scenario 8, Table 1) were presented as a benchmark study for system-identification methods for operational modal analysis at the IMAC XIX conference in 2001. Peeters and Ventura compare results obtained by seven different research teams [5].

In addition, new modal parameter estimation techniques have been validated on the benchmark data, such as a parametric and nonparametric setup assembly approach followed by maximum likelihood estimation, developed by Parloo *et al.* [6], and an iterative single degree of freedom (SDOF) technique proposed by Allen and Ginsberg [7]. A very complete set of modal parameters was obtained using the reference-based combined deterministic-stochastic subspace identification (CSI/ref) technique on the shaker data [8]. These recent results are briefly summarized to provide insight into the dynamic behavior of the Z24 bridge.

Figures 4 and 5 show the identified bending modes and lateral modes, respectively. The fact that the lateral modes, which are (almost) exclusively excited by the ambient forces, are identified, delivers an experimental proof for the capability of the CSI/ref method to identify modes that are excited by artificial (measured) excitation and those that are excited by ambient (unmeasured) excitation.

The capability of the CSI/ref method to identify closely spaced modes is clearly illustrated in Figure 6. Because of the skewness of the supports of the bridge, these modes are a combination of bending and torsion.

Figure 7 shows the higher torsion modes that were identified. The fact that even mode 14 at 37.25 Hz could be identified, while the cutoff frequency of the analog antialiasing filter had been set to 30 Hz,

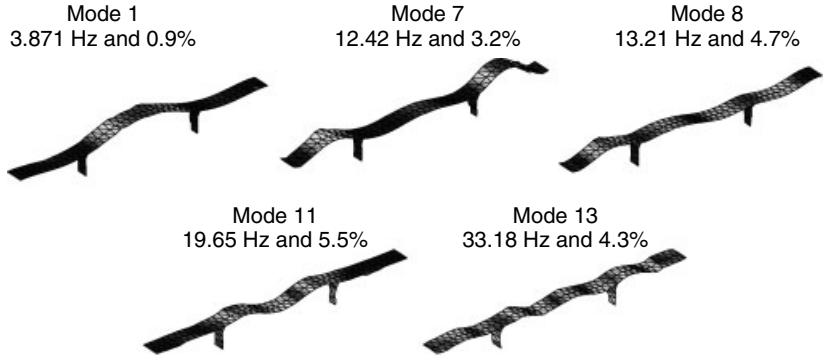

Figure 4. Modal analysis: identified bending modes.

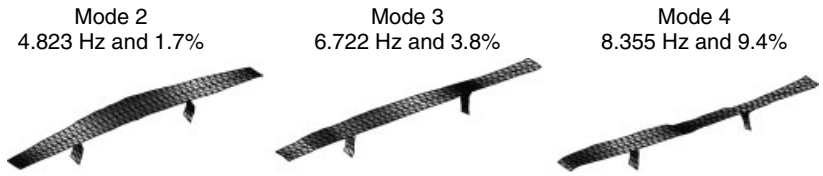

Figure 5. Modal analysis: identified lateral modes.

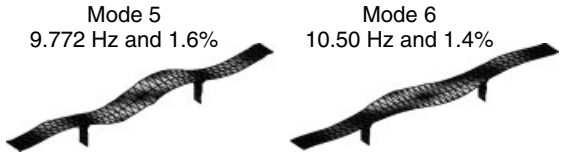

Figure 6. Modal analysis: two closely spaced mixed torsion/bending modes.

indicates that the CSI/ref method is able to identify modes that are very weakly present in the data.

4 CONTINUOUS MONITORING RESULTS

The continuous monitoring data have been investigated by Peeters and De Roeck [9].

First, a modal analysis was performed for each of the 5652 sets of acceleration data recorded every hour. Hereto, the reference-based stochastic subspace identification method was used [10]. Since visual inspection of the stabilization diagram is not an option for continuous monitoring, the selection of modes from the stabilization diagram was automated, resulting in four modes for which the eigenfrequencies could be identified with reasonable accuracy.

Second, the obtained eigenfrequencies were plotted as a function of the recorded environmental variables. Only the temperatures were found to have a clear influence on the eigenfrequencies. As is demonstrated in Figure 8, a plot of the first and second eigenfrequencies versus TP1 and TDS2, respectively, reveals a typical bilinear behavior. This can probably be explained by the change of the Young's modulus

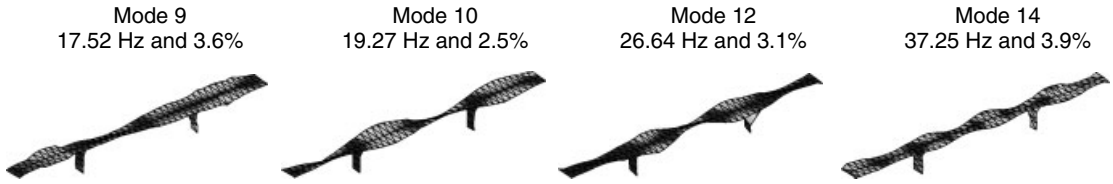

Figure 7. Modal analysis: higher torsion modes.

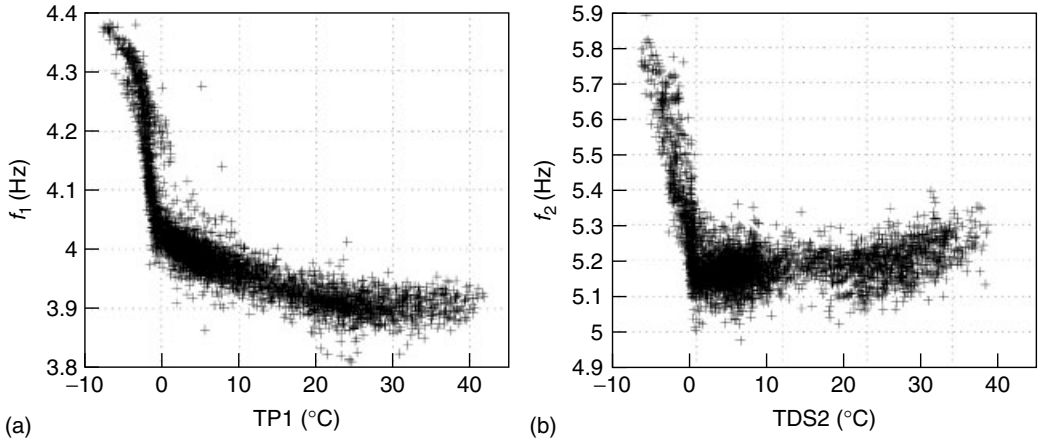

Figure 8. (a) First eigenfrequency versus pavement temperature at the Utzenstorf side span (TP1) and (b) second eigenfrequency versus deck soffit temperature at midspan (TDS2).

of the asphalt layer with temperature. Above 0 °C, the Young's modulus of asphalt is low and varies little with temperature (a constant value of 10 GPa can be taken), whereas below 0 °C, it increases dramatically (to 50 GPa at −10 °C) [11].

Third, a numerical environmental model for the bridge was constructed. The purpose was to remove the environmental influence from the measured eigenfrequencies so as to use them for damage detection (level 1 damage identification [12]). To this end, the number of temperature variables was first reduced from 22 (one variable for each undamaged temperature sensor) to 6 by calculating the correlations between them and grouping variables for which the absolute value of the correlation exceeded 0.99. Because of the lack of a physical model for the temperature influence, a black box ARX model [13] was fitted to each input (temperature) and output (eigenfrequency). A dynamic ARX model performed much better than simple static regression because the thermal inertia of the bridge turned out to be important. It should be mentioned that the ARX model was created with the data for positive temperatures only, since an ARX model is a linear model and so cannot represent the observed bilinear temperature–eigenfrequency behavior. As a consequence, its predictions are only valid for temperatures above 0 °C.

Figure 9 shows the prediction error of the ARX model constructed from the first eigenfrequency as a function of the temperature at the top of the bridge deck at midspan. The vertical line denotes the border between the estimation data that were used to construct the ARX model and the validation data. From day 277 on, the error between the first eigenfrequency as predicted by the ARX model and the measured eigenfrequency becomes significantly large, indicating damage. This date corresponds to damage scenario 5 (pier settlement of 80 mm).

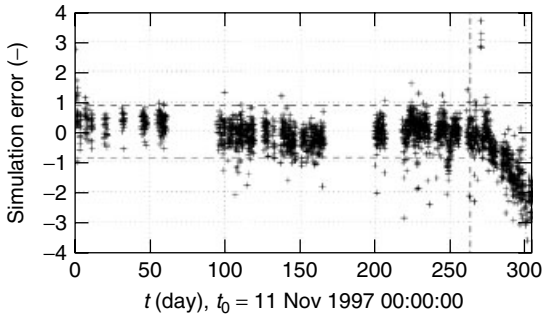

Figure 9. Prediction errors for the first eigenfrequency as a function of TDT2. The horizontal lines denote the 95% confidence bounds.

Mevel *et al.* [14] apply an output-only subspace-based structural damage detection technique to the continuous monitoring data of three accelerometers. Although the environmental influence on the data was denied, damage scenario 5 could be detected. Apparently, the method is more sensitive to damage than to environmental changes.

5 PROGRESSIVE DAMAGE TESTING RESULTS

The data from the progressive damage tests have been investigated by several authors.

Abdel Wahab and De Roeck [15] propose the "curvature damage factor", which is the mean of the absolute differences in measured modal curvatures between a reference state and a damaged state over different modes, for damage detection and localization (level 2 damage identification [12]). Applying it on damage scenarios 2, 5, and 6 (Table 1) using modes 1 and 5 (Figures 4–6), they are able to detect and localize the damage for the 95-mm pier settlement case but not for the 80-mm settlement case. It should be noted that the damage in the immediate vicinity of the settled pier could not be detected because the mode-shape curvature is very small at that location in both damaged and undamaged conditions.

Maeck and De Roeck [16] apply the direct stiffness calculation (DSC) [17] for the detection, localization, and quantification (level 3 damage identification) of damage in beamlike structures on scenarios 2, 4–6, and 8. The DSC is based on the relation that the bending and torsion stiffness in each section of a structure can be written as the quotient of the modal bending and torsion moment, respectively, to the corresponding modal curvature. Although the pier settlement of 40 mm cannot be detected, a maximum bending stiffness decrease of 17 and 30% is detected at midspan near the Koppigen pier for the settlement of 80 and 95 mm, respectively, using mode 1. A torsion stiffness decrease of about 27% is found at the Koppigen pier for the settlement of 80 mm using mode 5. An interesting side result is that for scenario 8, no stiffness decrease is detected, thereby indicating that when the cracks in the concrete closed again due to the lifting of the Koppigen pier, the dynamic stiffness approached its value for the undamaged state.

Mevel *et al.* [14] use a subspace-based damage detection and localization technique to investigate scenarios 2, 3, and 8. While it is claimed that both pier settlements of 20 and 80 mm can be detected (level 1 damage identification), the localization (level 2) fails, because the proposed method is not able to locate damage in symmetric structures and the finite element model that was used for the localization is symmetric.

Kullaa [18] constructs control charts from statistical quality control from eigenfrequencies, eigenfrequencies and reference degree of freedom (DOF) mode shapes, and damping ratios of four modes, obtained from the nine setups for damage scenarios 2, 4, and 5. Using the eigenfrequency and mode-shape data, both pier settlements of 40 and 80 mm can be detected (level 1 damage identification). With the eigenfrequency data, only the settlement of 80 mm can be detected. From the damping ratios, no useful information is extracted.

Parloo [19] considers the analytical sensitivity of the eigenfrequencies of modes 1, 2, 5, 6, and 7 to the stiffness change between two points of the bridge deck. Solving the inverse problem yields the stiffness changes as a function of the observed changes in eigenfrequencies. This method needs mode shapes that are scaled to the mass matrix, but only for the reference configuration, not for the damage configuration. Since the inverse problem is underdetermined, an iteratively weighted pseudoinverse is used, which tries to reduce the identified damage pattern to an as small as possible number of locations. In this way, the method is suitable for identifying local damage. Using a coarse grid, the author is able to locate the pier settlements of 40, 80, and 95 mm correctly and to quantify the damage. Using a denser grid, the localization fails because of the symmetry of the structure, but the detection remains successful. An interesting result obtained with the coarse grid is that, relative to the first reference measurement (scenario 1), damage is localized near the Koppigen pier for the second reference measurement (scenario 2). This indicates that the installation of the settlement system probably caused local damage near the pier, so that the settlement of 20 mm could not be detected with scenario 2 as a reference. However, with scenario 1 as reference, the damage caused by the 20-mm pier settlement could be localized successfully.

Teughels and De Roeck [20] use finite element model updating for detecting, localizing, and quantifying (level 3 damage identification) the damage induced by the pier settlement of 95 mm (scenario 6). An finite element model consisting of three-dimensional beam elements is updated to the reference configuration of scenario 2 using seven damage functions [21] for the bending stiffness, seven damage functions for the torsion stiffness, and two soil

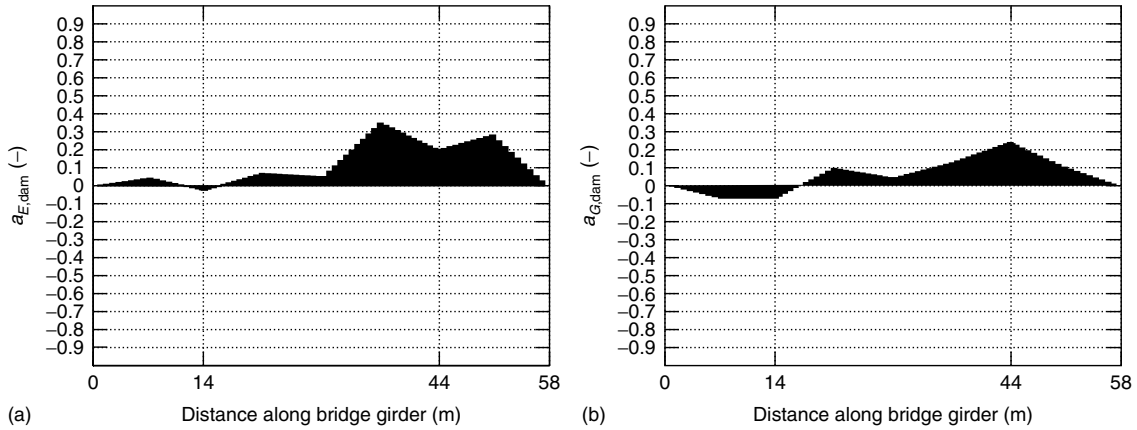

Figure 10. Relative differences in bending stiffness EI (a) and torsion stiffness GI_t (b) for the finite element models updated to scenarios 2 and 6. $\mathrm{EI}_{\mathrm{dam}} = \mathrm{EI}_{\mathrm{ref}}(1 - a_{E,\mathrm{dam}})$ and $\mathrm{GI}_{t,\mathrm{dam}} = \mathrm{GI}_{t,\mathrm{ref}}(1 - a_{G,\mathrm{dam}})$.

springs, resulting in a good match for the eigenfrequencies and mode shapes of modes 1, 2, 5, 6, and 9, for which the updating was performed. Using this updated finite element model for scenario 2, a second updating was performed using the damage functions and the eigenfrequencies and mode shapes of modes 1, 5, 6, and 9, resulting in an updated finite element model for scenario 6. The relative differences in bending and torsion stiffness for both updated finite element models is shown in Figure 10. The maximum bending stiffness decrease of around 35% is in good agreement with the decrease of 30% obtained by Maeck and De Roeck.

6 CONCLUSIONS

One of the goals of the SIMCES project was to deliver a full-scale validation test for the damage-detection methodology based on vibration monitoring. From the tests on the Swiss bridge Z24, the following conclusions can be drawn:

- Reliable modal information can be obtained by output-only dynamic measurements, i.e., accelerations due to ambient influences, e.g., traffic under or on top of the bridge. Closing the bridge to apply controlled force excitation is not necessary.
- The variations between eigenfrequencies obtained by different system identification algorithms are rather small. For the mode shapes, more substantial differences occur. Very good results are obtained by applying the CSI/ref technique.
- Changes in environmental conditions, mainly temperature, lead to changes in eigenfrequencies. With the order of magnitude being similar to that of structural damage, it is important to filter (eliminate) the environmental influence on beforehand. As a consequence, it is advisable to monitor the temperature as well. The relation between eigenfrequencies and temperature can be obtained by monitoring the intact bridge over a period of at least one year. For bridge Z24, the decrease of the first eigenfrequency for an overall temperature increase from $0\,^{\circ}\mathrm{C}$ to $30\,^{\circ}\mathrm{C}$ is about 3%. When the temperature correction is taken into account, the uncertainty interval reduces to $0,7\%$ corresponding to the 95% confidence limits.
- The applied damage scenarios cause eigenfrequency shifts up to 7%. Damage has a selective influence on the eigenmodes: especially those eigenmodes are affected where damage occurs at zones with high modal curvatures. This provides another way to make the distinction between environmental and structural changes.
- Only damage scenarios that produce stiffness reductions could be identified. For instance, this was the case for the support settlement. A loss of prestress will only result in a measurable change in eigenfrequencies if it is accompanied by originating cracks.

- Mode shapes, although less accurately determined than eigenfrequencies, can provide useful information about local changes, e.g., of support stiffness.

Chapter 127

Continuous Monitoring of the Øresund Bridge: Data Acquisition and Operational Modal Analysis

Bart Peeters
LMS International, Leuven, Belgium

1 INTRODUCTION

The number of civil engineering structures that are equipped with monitoring systems is rapidly increasing. Typical examples are long-span cable-stayed and suspension bridges, which represent a large capital investment and where the use of a permanent monitoring system is easily justified and often recommended by insurance companies. Such a monitoring system can serve several purposes [1]:

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

- **Design verification**
It is verified that the structural static and dynamic response does not exceed the design values.

- **Event recording**
Important load (wind, traffic) or response (strains, accelerations) quantities are recorded for archival reasons or to take decisions about the serviceableness of a bridge when preset thresholds are exceeded; for instance, at too large wind speeds, it may be dangerous to use the bridge.

- **Health monitoring**
The recorded data can be used to derive experimental models. Information on the structural health can be obtained by tracking the evolution of these experimental models or by confronting experimental data with analytical models.

Numerous examples of permanently monitored bridges are readily found in the *Proceedings of the International Workshop on Structural Health Monitoring* [2], *Proceedings of the International Operational Modal Analysis Conference* [3], and *Structural Health Monitoring (SHM) related proceedings of SPIE* [4].

This article presents a state-of-the-art monitoring system that was installed on a state-of-the-art bridge. In Section 2, the Øresund Bridge is introduced. Section 3 presents the monitoring system itself and its normal mode of operation. In Section 4, the vibration signals of the cables, deck, and towers are analyzed. These analyses of dynamic data were done off-line, using data captured by the permanent system, but are not part of the standard analysis procedures of the system.

2 THE ØRESUND BRIDGE

Since July 2000, Sweden and Denmark have been connected through the Øresund fixed link consisting of 8 km of bridge and 4 km of tunnel, joined by a 4-km-long artificial island (Figure 1). The bridge has quite a unique two-level design, with a four-lane motorway placed above a two-track railway (Figure 2). The bridge consists of 49 approach spans (7 spans of 120 m, 42 spans of 140 m) and a

cable-stayed component with two side spans on either side (160 and 141 m) and a main span of 490 m over the navigational channel (Figure 3).

Ten pairs of cables on either side connect the pylons of the two H-shaped towers with the bridge deck (Figure 4). The tops of the pylons are 204 m above sea level and the minimum headroom under the main span is 57 m. The monitoring system discussed in next section is installed on the cable-stayed part of the bridge.

3 THE CONTINUOUS MONITORING SYSTEM

The bridge owner was concerned about the stay-cable oscillations under heavy wind conditions, as well as the deformation of the bridge when trains or heavy trucks pass over it. Therefore, GeoSIG installed a new type of monitoring system (called the *CR-4 Central Recorder*) that could acquire both dynamic and static data.

Eighty-five dynamic channels have been installed at the Øresund Bridge; these channels permanently record at a sample rate of 100 Hz signals from 22 triaxial accelerometers and 19 strain gauges. The static-measurement channels are connected to 12 temperature sensors at different points of the bridge and to two weather stations, one at the top of a pylon, and the other, at road level. Static information, such as minimum, maximum, and mean values, is extracted from the dynamic channels for long-term analysis. The CR-4 acquisition system is placed in a technical room at one of the pylons. There is a telephone connection to the general control room of the Øresund link, 3 km away from the pylon, allowing automatic data retrieval.

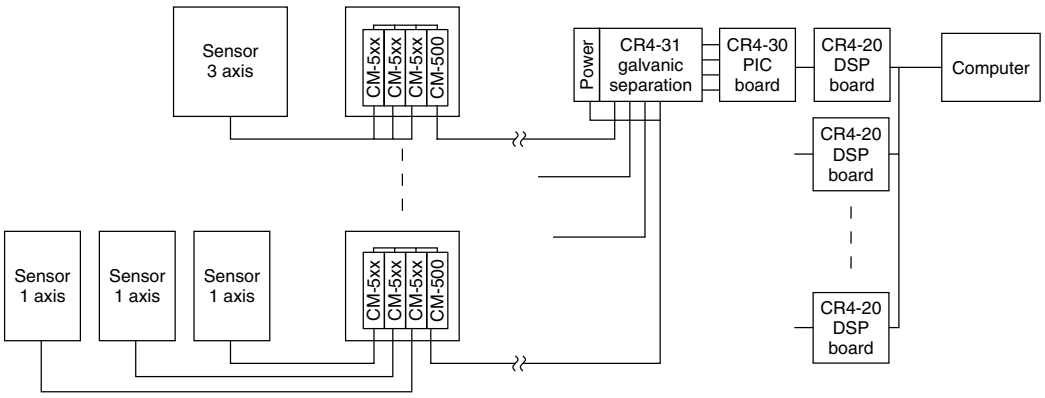

Figure 5. Dynamic data-acquisition architecture.

3.1 Data-acquisition system

The CR-4 system allows different data collection strategies:

- Dynamic acquisition with analog-to-digital (A/D) conversion in the recorder handles up to 33 dynamic channels, with a maximum sample rate of 1000 Hz.
- Dynamic acquisition with A/D conversion near the sensor handles up to 132 dynamic channels, with a maximum sample rate of 200 Hz.
- Static acquisition with A/D conversion near the sensor handles up to 44 chains, each with up to 26 static junction boxes (see below), each of which has up to six channels. So as many as 6864 static channels are possible.

For the Øresund Bridge, a combination of the second and third options has been chosen. The acquisition near the sensor is done by means of a junction box with acquisition modules. Modules differ as a function of the type of sensor that is connected. On the bridge, modules have been used for strain gauges, for voltage inputs like accelerometer and weather station signals, for powering the sensors and generating the sensor test pulse output, and for Pt-100 temperature sensors. Not used in this project, but also available, is a module for linear variable displacement transducers (LVDTs). The junction box is connected to the main cabinet of the CR-4. Power can be supplied locally or, in this case, from the cabinet. The signals from the junction box are digitally transferred to the cabinet through an RS-485 link to avoid any loss of power.

The block diagram of Figure 5 represents the architecture of the dynamic measurement chain: from the sensors on the left to the computer on the right. The analog signal goes from the sensor to the CM-5xx acquisition module where it is converted on request to a digital signal and transferred to the CM-500 module. The CM-500 module makes a package from the collected samples and sends it to the CR4-30 module through the CR4-31 protection board. The CR4-31 is a galvanic separation of the CR-4 and the computer from the external part of the system. The CR4-30 contains four PIC boards, each PIC controlling one CM-500 in dynamic mode and up to 26 chained ones in static mode. The data package of each channel is stored in the PIC and is sent on request to the CR4-20 DSP board where the data is stored in ring buffers. Finally, every second, the computer (CR-4 software) collects 1-s packages of the DSP boards. The computer does signal analysis and treatment, and according to the user-specified trigger mode, the signals are stored in an event file.

The static architecture is different in that several junction boxes can be connected to the same wire. This is not possible in the dynamic mode because of the high baud rate that must be guaranteed. To avoid unnecessary power loss and voltage drops in the powering cables, the CM-500 only powers the sensor if a sample is requested. A start-up routine assures constant values.

A 12-V/115-Ah battery assures power for 15 h in case of power loss. This is sufficient for local conditions, as power failures do not often occur and, if they occur, it would only be for a short period. For

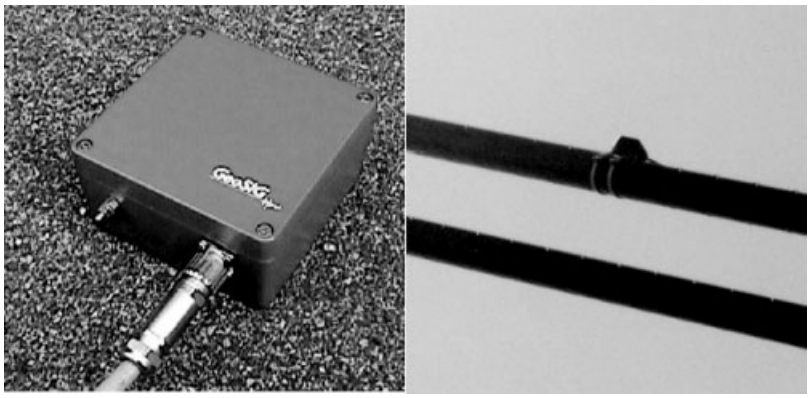

Figure 6. GeoSIG triaxial accelerometer AC-53 mounted on a cable.

accurate timing, a GPS receiver can be connected to the CR-4 that updates the computer time.

3.2 Sensors

The Øresund installation contains four types of sensors. They are specified below together with a description of the type of information that is extracted from the quantities that they measure.

- There are 22 triaxial AC-53, 2*g* full-scale force balance accelerometers (Figure 6). Most of these accelerometers (16) are mounted on the stay cables to measure the cable vibrations. The tops of the two east pylons, as well as four locations along the deck, are also equipped with accelerometers. These sensors allow monitoring the cable vibrations under heavy wind load and the bridge response to railway and road traffic.
- Twelve of the 19 strain gauges LV3400VS0 are mounted on three steel outriggers of the cables, one on either side. Two are mounted on the rail level in the concrete and five are mounted on the lower side of the bridge. These sensors mainly observe torsions due to heavy wind and railway traffic.
- Twelve thermometers Pt-100 are mounted at different locations, most of them at the pylons. These sensors measure temperatures, which are correlated with the strain gauge measurements.
- Of the two weather stations measuring wind speed, wind direction, air humidity, and air temperature, one is mounted on the top of a pylon and the other at road level (Figure 7). The wind measurements serve as a reference for the stay-cable vibrations. The air humidity

Figure 7. Weather station at the deck level of the bridge.

and temperature complete the meteorological information.

4 DATA ANALYSIS

4.1 Standard data analysis procedures

In the daily use of the system, both dynamic and static data are continuously acquired. The dynamic data acquisition is governed by triggering: if the signal of selected data channels exceeds some specified level, the data are logged to an event file, which can be viewed and analyzed later. At the same time, an alarm signal is sent to the traffic control center alerting responsible persons about strong vibrations of the bridge. Static data are logged to another file periodically. There is also a monitoring mode, which indicates the operating status of all dynamic data channels, status of the trigger, and other parameters. The waveform signal of any data channel can be viewed in near real-time mode.

4.2 Detailed dynamic data analysis

In this section, a 5-min recording of the acceleration channels of the CR-4 monitoring system is thoroughly analyzed. Although the type of analysis performed here (operational modal analysis, OMA) is not part of the standard procedures of the Øresund Bridge, it is instrumental in seeing what kind of information can be extracted from the cable, deck, and tower vibrations.

4.2.1 Operational modal analysis

The aim is to identify an experimental dynamic model of the bridge. In laboratory situations, such a model can be obtained by artificially exciting a structure and measuring the responses. Measurement functions (so-called frequency response functions) that relate the input to the output serve as input for *experimental modal analysis* (EMA) methods to achieve this goal. Obviously, the data recorded by the monitoring system are the so-called operational data: bridge responses are measured under dynamic wind or traffic loading without being able to measure all these forces exactly. Nevertheless, it is still possible to derive an experimental dynamic model of the structure from response measurements alone. Hereto, a technique called *operational modal analysis*, OMA, is used. The use of vibration measurements and modal analysis for structural health monitoring (SHM) is also discussed in **Modal–Vibration-based Damage Identification**; **Ambient Vibration Monitoring**.

In the past, OMA in civil engineering was mainly restricted to *peak picking*. The method is named after its key step: the identification of the eigenfrequencies as the peaks of power spectrum plots. However, there exist more advanced methods that better exploit the data and lead to higher-quality models. These methods became accessible through user-friendly commercial software implementations. *Stochastic subspace identification* is, for instance, one such method. In this method, a so-called stochastic state-space model is identified from output correlations [5] or directly from measured output data [6]. The "outputs" in our case are the measured bridge acceleration responses. The first application of stochastic subspace identification to bridge vibration data dates from 1995 [7]. The potential to use stochastic subspace identification for modal analysis applications in general has been described in [8–10]. It is such a stochastic subspace identification method that is used in this article.

Recently, a new frequency-domain method, called *PolyMAX* [11, 12], received considerable attention. Originally developed for use with classical input–output data, it was extended so that it can also cope with output-only data [13, 14]. The main added value of PolyMAX is that it yields very clear stabilization diagrams (Section 4.2.2) so that it has the potential to run autonomously [15]. This is very relevant if the data is almost continuously streaming, as is the case for permanent monitoring systems. PolyMAX is also used in this article.

4.2.2 Cable vibrations

The simplest and least expensive method to measure the cable forces is the measurement of the eigenfrequencies of that cable. Evidently, this is an indirect measurement: the tension force is derived from eigenfrequencies, which are derived from accelerations. Figures 8 and 9 show 5-min recordings of typical accelerations of two-stay cables. The parts (a) of the

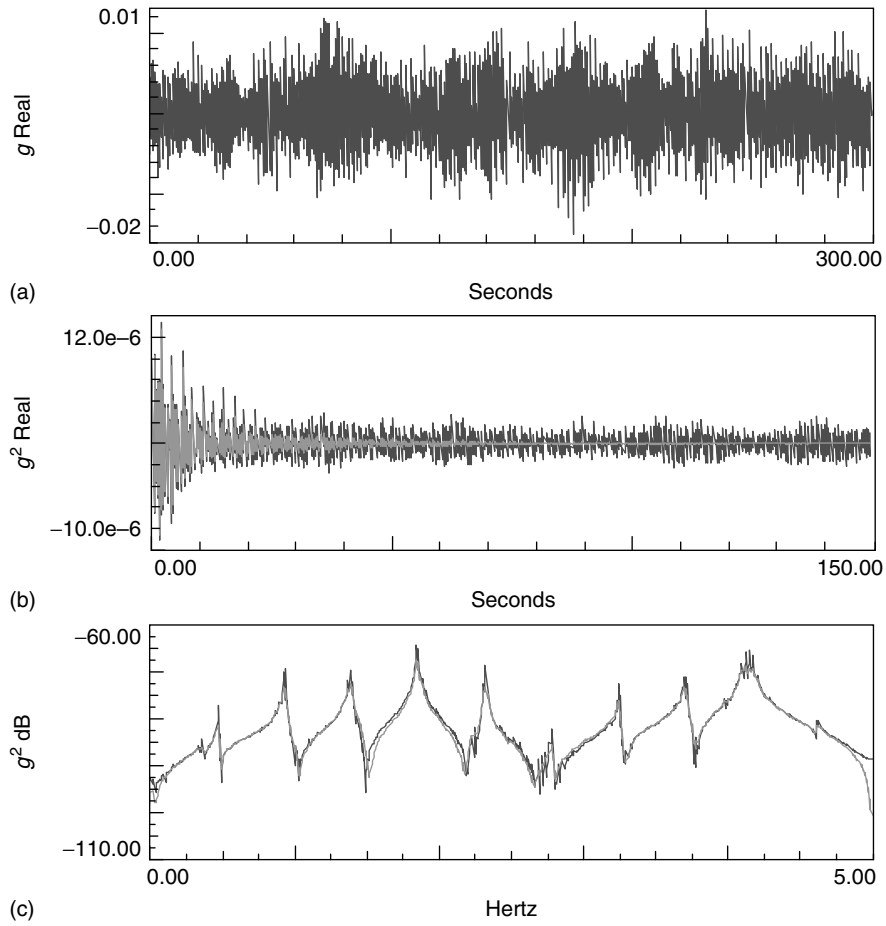

Figure 8. Out-of-plane acceleration of the longest cable from the East–South pylon to mid-span. (a) Time history, (b) output correlations, and (c) half-spectrum magnitude. The effect of the exponential window on the correlations and spectra is clearly visible: no window (black)—exponential window of 1% (gray).

figures show the time histories. The autocorrelations R_i, shown in (b), are estimated from the time data y_k according to

$$R_i = \frac{1}{N} \sum_{k=0}^{N-1} y_{k+i} y_k \qquad (1)$$

where N is the number of time samples used to compute the correlations and k, i both are sample indices. From the plots, it is clear that the correlations have an impulse–response-like behavior. This can also be theoretically proven provided that the structure is excited by white noise. The autocorrelations of the cables are subsequently used as basic functions in stochastic subspace identification to extract the eigenfrequencies. Figures 8(c) and 9(c) show the magnitudes of the discrete Fourier transform of the positive correlation lags. These are estimates of the so-called half spectra, which are the basic functions used in the operational variant of PolyMAX. As in any parametric estimation method, both subspace identification and PolyMAX enable the use of so-called stabilization diagrams that allow for an easy and objective selection of the cable eigenfrequencies. An example of such a diagram is shown in Figure 10.

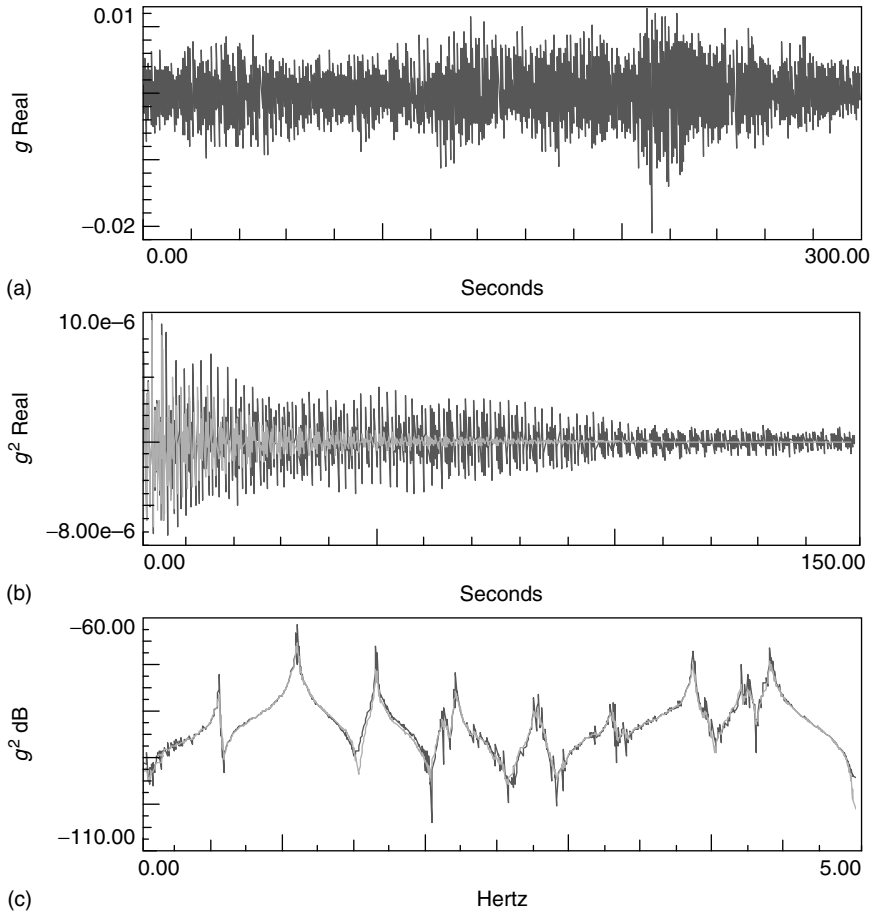

Figure 9. Out-of-plane acceleration of the third longest cable from East–North pylon to side span. (a) Time history, (b) output correlations, and (c) half-spectrum magnitude. The effect of the exponential window on the correlations and spectra is clearly visible: no window (black)—exponential window of 1% (gray).

Finally, Figure 11 compares a measured spectrum with a spectrum that is synthesized from the estimated modal parameters. The good correspondence indicates that all modes were extracted from the data.

By repeating this analysis a number of times, eigenfrequencies are extracted from the accelerations of 10 cables—the 5 longest cables connecting the East–South (ES) pylon to the main span and the 5 longest cables connecting the East–North (EN) pylon to the side span. These frequencies are presented in Table 1. From Figures 8 and 9 and Table 1, the set of cable frequencies seems to be composed of a fundamental frequency f_1 and its higher harmonics $f_n = n\, f_1$. A stay cable is assumed to satisfy the taut string theory with the following relation between frequencies and cable tension forces:

$$f_n^{\mathrm{S}} = n\,\frac{1}{2L}\sqrt{\frac{H}{m}} \tag{2}$$

where f_n^{S} (Hz) is the nth harmonic; L (m) is the cable length; H (N) is the cable force; and m (kg m^{-1}) is the cable mass per unit length. In this article, an estimate of the fundamental frequency is obtained from all harmonics by applying least squares (LS). Following this, the cable forces are

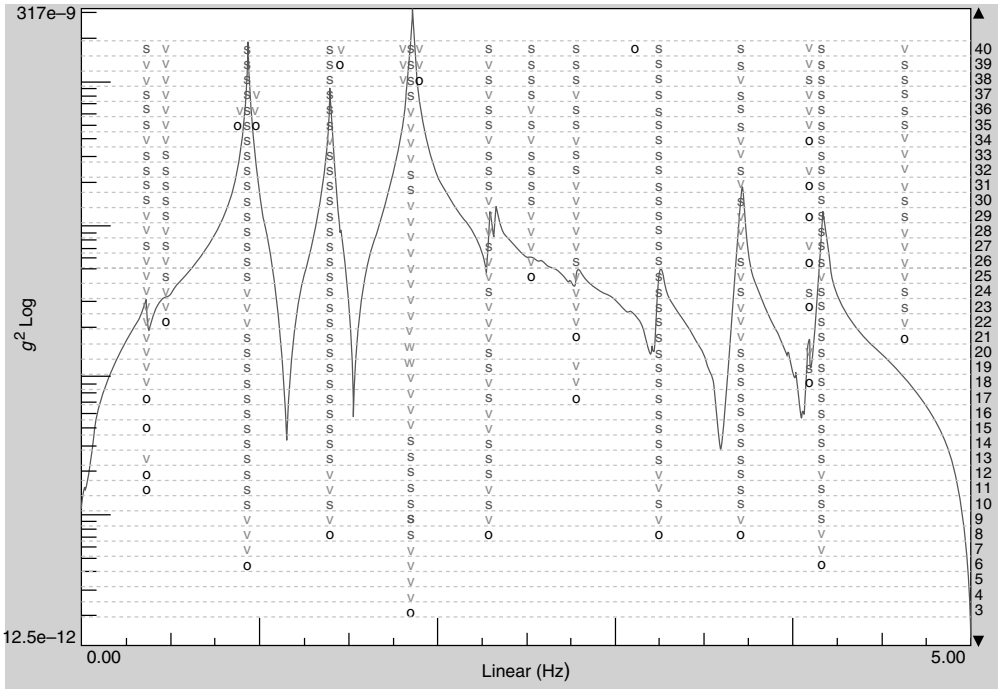

Figure 10. Stabilization diagram obtained by applying operational PolyMAX to the acceleration data of Figure 9.

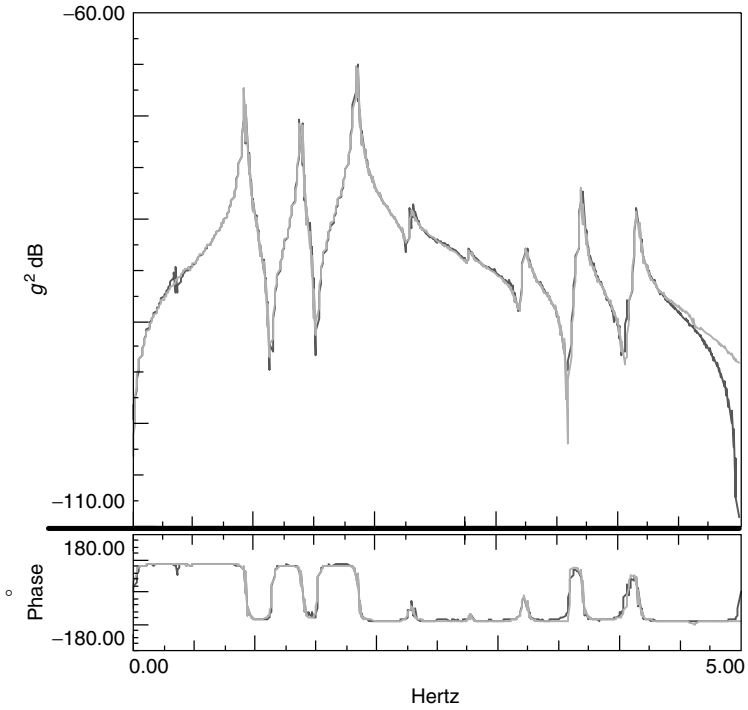

Figure 11. Measured (black) versus synthesized PolyMAX spectra (gray).

Table 1. Determination of cable tension forces from out-of-plane acceleration measurements. Not for all cables it was possible to extract the same number of harmonics

Pylon cable number		ES 1	ES 2	ES 3	ES 4	ES 5	EN 5	EN 4	EN 3	EN 2	EN 1

Cable force difference (%)		2.3	1.9	2.1	1.3	2.0	2.5	1.6	2.0	2.0	3.2

computed according to equation (2) and are as shown in Table 1.

However, the taut string theory does not hold exactly for stay cables, which, inevitably, have a certain bending stiffness, which becomes more important as the cables become shorter. In [16], the following equation has been derived to compute the out-of-plane eigenfrequencies f_n^{EI} of a stay cable:

$$\frac{f_n^{\mathrm{EI}}}{f_n^{\mathrm{S}}} = 1 + \frac{2}{\varepsilon} + \frac{4 + n^2\pi^2/2}{\varepsilon^2} \tag{3}$$

where f_n^{S} are the frequencies if the bending stiffness is zero (the taut string frequencies as given by equation (2)) and ε is a dimensionless parameter related to the bending stiffness EI (Nm^2):

$$\varepsilon = L\sqrt{\frac{H}{\mathrm{EI}}} \tag{4}$$

In [17], it is shown how cable forces and bending stiffness can be estimated from the identified eigenfrequencies by the following procedure:

1. Apply nonlinear LS to estimate f_1^{S} and ε from the measured frequencies f_n, which are assumed to behave like f_n^{EI} in equation (3).
2. From the cable length L and mass per unit length m, and f_1^{S} and ε estimated in the previous step, it is straightforward to estimate the cable force H from equation (2) and the bending stiffness EI from equation (4).

The estimated values are shown in Table 1. One cable consists of 70 tendons, each consisting of seven wires of 5-mm diameter. The mass per unit length is estimated at $91.2\,\mathrm{kg\,m^{-1}}$. From the positions of the anchor points on the tower and the bridge, the lengths of the cables are calculated. As seen from Table 1, the dimensionless bending stiffness parameter ε is about 200–300. This is within the limits for normal stay cables: $70 < \varepsilon < 600$. The frequency f_1^{S}, and so the cable force, is determined more accurately than the dimensionless parameter ε, and so the bending stiffness. The resulting bending stiffnesses have a comparable magnitude, except for cable 1 of the EN pylon (last column of Table 1).

Figure 12 compares the two cable force estimates of the different cables: one estimate according to

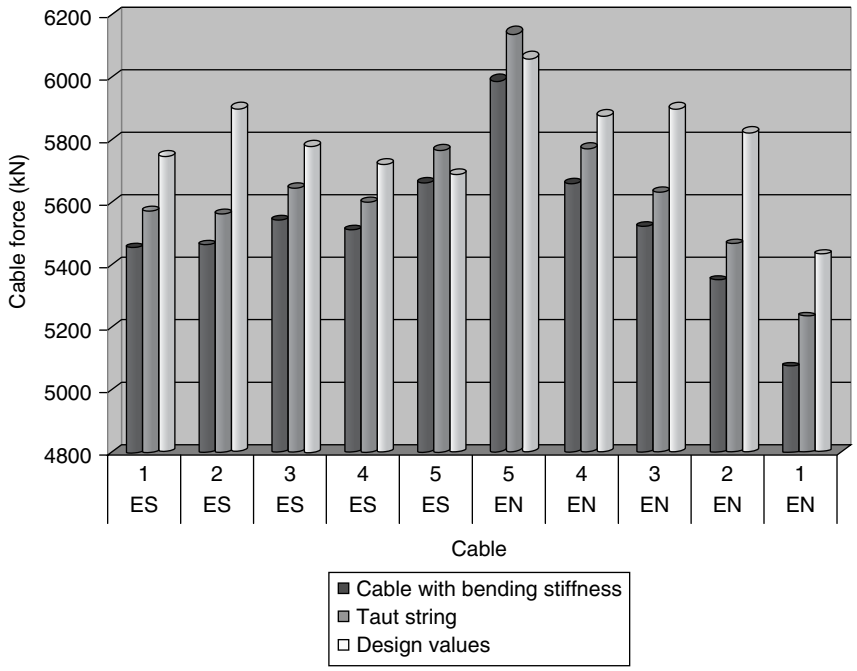

Figure 12. Cable forces estimated from vibration measurements.

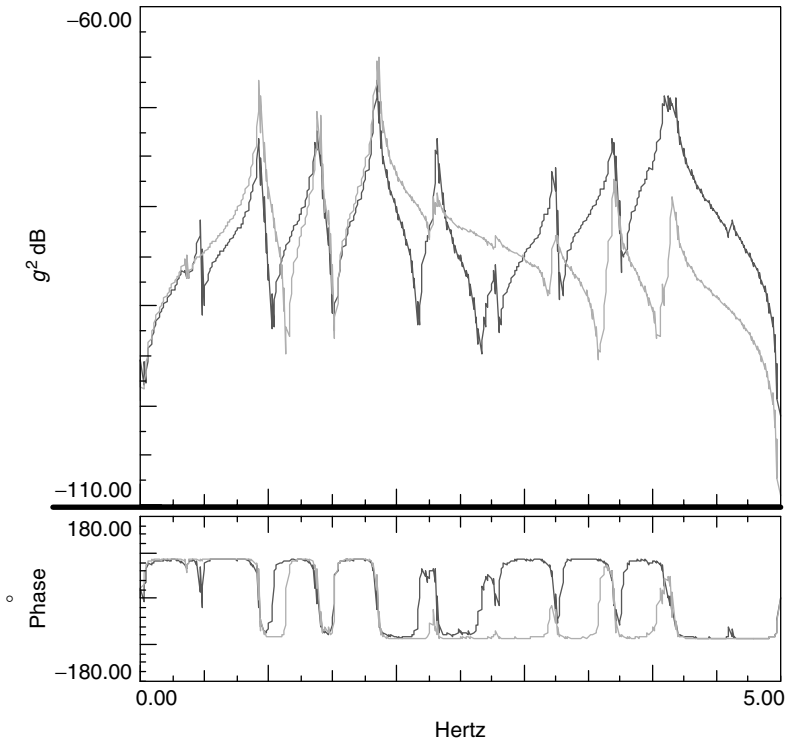

Figure 13. Out-of-plane acceleration of the longest cable from the East–South pylon to midspan. Comparison of two datasets with an interval of more than 1 year.

the taut string theory using an LS estimate of the fundamental frequency; the other taking the bending stiffness into account. The difference between the estimates of the cable forces using the two methods ranges from 1.3 to 3.2%. The tension force differences between cables can go up to 11%, regardless of the estimation method. Also shown on this graph are the design values for the cable forces.

Finally, Figure 13 compares the spectra from the same cable, but using data measured with an interval of more than 1 year (August 2002 vs November 2003). Owing to different excitation conditions (wind speed, direction, distribution), the spectra are not equal, but the location of resonance peaks is still about the same. A more detailed (modal) analysis revealed that the cable frequency differences were in the order of 0.4–0.8%.

The analysis presented in this section shows that it is possible to monitor the cable forces from the accelerations that are recorded by the continuous monitoring system.

4.2.3 Deck and tower vibrations

Figures 14 and 15 show 5-min recordings of a vertical acceleration at the main span deck and a transversal acceleration at the top of the ES pylon. Again, the time histories, the autocorrelations, and the half spectra are shown. The recordings contain the passage of a train, which caused an increase in vibration levels as can be seen from Figure 14. From the pylon accelerations (Figure 15), it becomes difficult to observe the train passage because the pylon vibrations are mainly caused by the wind. The cable vibrations (Figures 8 and 9) are apparently not influenced by the load because of the train. Stochastic subspace identification was applied to determine the deck and tower modal parameters. They are represented in Table 2. As background information and as an assurance that the measured eigenfrequency is plausible, it is interesting to compare these results with the ones obtained from other bridge tests as reported in the literature. For example, in Figure 16 such comparison is made

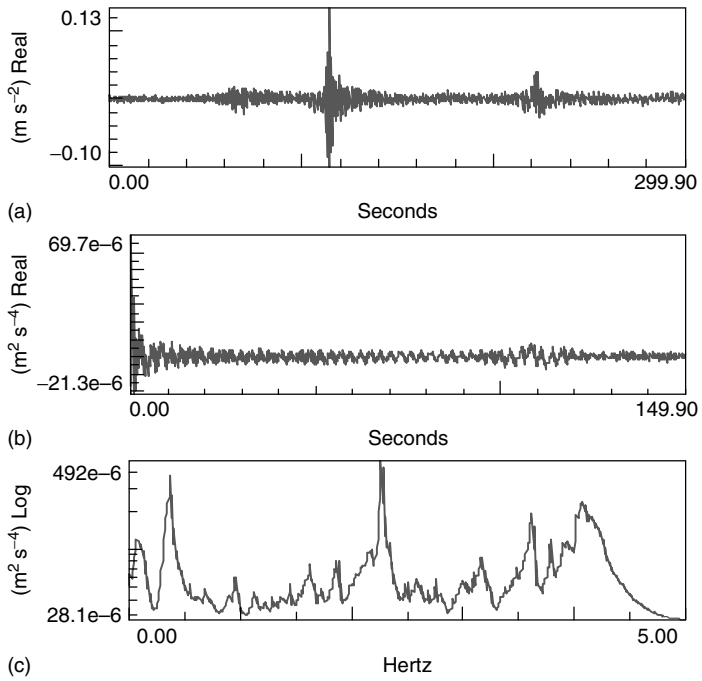

Figure 14. Vertical acceleration at the main span deck. (a) Time history, (b) output correlations, and (c) half-spectrum magnitude.

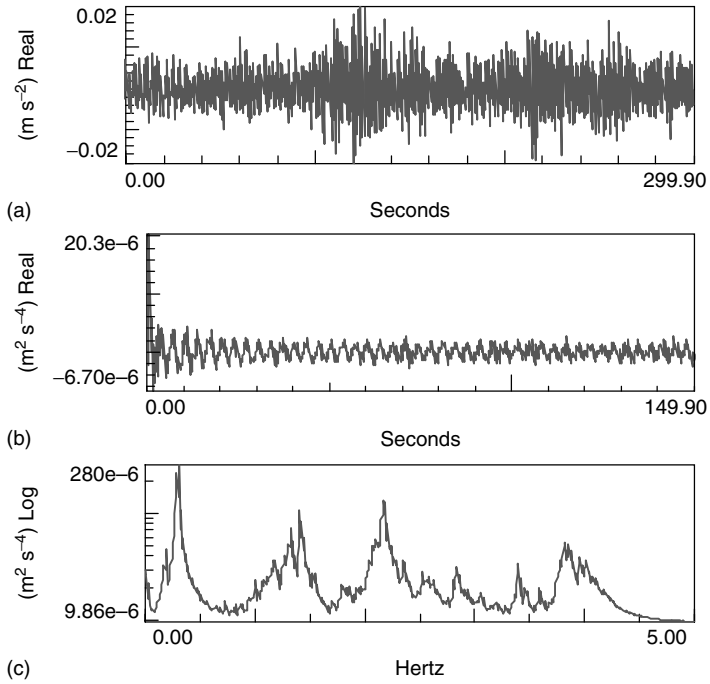

Figure 15. Transversal acceleration at the top of the East−South pylon. (a) Time history, (b) output correlations, and (c) half-spectrum magnitude.

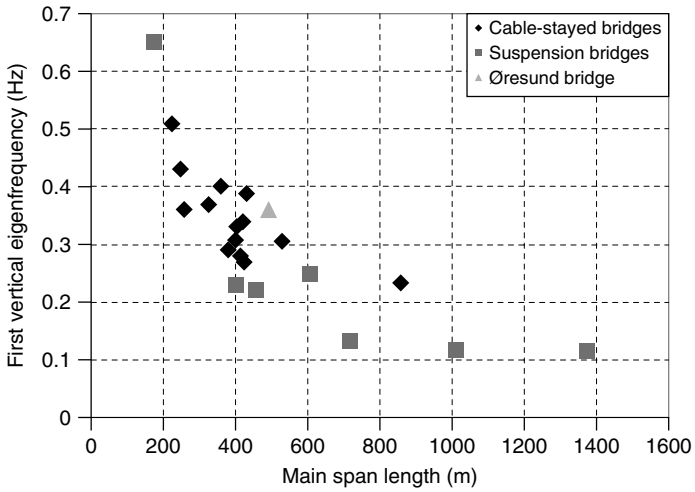

Figure 16. First vertical deck bending eigenfrequency as a function of main span length for cable-stayed and suspension bridges.

Table 2. Deck and tower modal parameters

Description	Frequency (Hz)	Damping ratios (%)
Deck plus tower transversal	0.252	0.74
Tower transversal, pylons in phase	0.294	1.83
Tower transversal, pylons out of phase	0.300	0.82
Deck first vertical bending plus tower longitudinal	0.368	0.65
Tower longitudinal, pylons in phase	0.540	0.40

on the basis of a plot of the first vertical deck bending eigenfrequency as a function of the main span length.

In the present case of the Øresund Bridge, no detailed experimental mode-shape information could be obtained because of the limited amount of accelerometers at the deck and towers. However, OMA methods such as the ones described in Section 4.2.1 are also able to generate accurate mode shapes that can be correlated with numerically predicted mode shapes using, for instance, finite element models. In [18], it is, for instance, demonstrated that detailed mode shapes of a cable-stayed bridge (in this case, the Guadiana Bridge) can be obtained by using ambient vibration data and OMA. In this case, the accelerations at many more deck and tower locations had been measured with nonpermanent equipment. Some of the Guadiana Bridge mode shapes, identified with the PolyMAX method, are represented in Figure 17.

In a continuous monitoring and modal analysis process, the bridge eigenfrequencies could be used to assess the health of the structure. This is, for instance, shown in **Continuous Vibration Monitoring and Progressive Damage Testing on the Z24 Bridge** for the Z24-Bridge in Switzerland. The robustness of vibration-based SHM methods is significantly enhanced by measuring and modeling environmental influences such as temperature on the dynamic properties of the structure (*see* **The Influence of Environmental Factors**) [19], and by using appropriate statistical techniques to interpret the data correctly (*see* **Model-based Statistical Signal Processing for Change and Damage Detection**).

5 CONCLUSIONS

In this article, the continuous monitoring system of the Øresund Bridge was presented. It was also shown how OMA, applied to the dynamic data captured by the system, provides useful information about the health of the bridge. Measuring and analyzing cable vibrations allow monitoring the cable tension.

Figure 17. Guadiana Bridge mode shapes extracted from ambient vibration data using PolyMAX.

Measuring and analyzing deck and tower vibrations allow assessing the health of these structural parts. The analyses of dynamic data presented in this article were performed off-line, using data captured by the permanent system, but which are not part of the standard analysis procedures of the system. The main purpose of the article is to demonstrate the possibilities that advanced data processing techniques offer for SHM.

Condition Compensation in Frequency Analyses—a Basis for Damage Detection

Robert Veit-Egerer

VCE – Vienna Consulting Engineers, Vienna, Austria

1 INTRODUCTION

Recent publications have raised doubts as to whether damage in structures can be detected by the application of frequency analyses. In fact, very often, temperature changes show larger reactions in spectra than any smaller damage. Beside temperature, other environmental influences such as radiation from sunshine create changes in the structural systems that have to be considered.

This article demonstrates the capabilities of new compensation methods in frequency analyses. When the environmental conditions are monitored together with structural response, a proper reaction can be predicted. The described compensation process, in general, deals with the following sources of input:

- temperature (daily and annual cycles)
- compensation of live load (moving vehicles, etc.)
- influence of wind loads
- bearing friction
- restoring forces
- change of boundary conditions
- impact energy
- instrumentation.

After elimination of all operational and environmental factors, stable frequencies are achieved.

$$\boldsymbol{f}_{\text{total}} = \boldsymbol{f}_0 + \sum_{i=\text{factors}} \boldsymbol{f}_i \tag{1}$$

where $\boldsymbol{f}_{\text{total}}$ is the vector of total (measuredlike) frequencies, $\boldsymbol{f}_0$ the vector of structural (ownlike) frequencies, $\boldsymbol{f}_i$ the vector of influenced (measured) frequencies, and i: corresponds to the considered operational and environmental factors.

Any deviation therefrom can be interpreted as damage or extraordinary event. This procedure opens new possibilities for structural management and lifetime prediction. This article describes investigation of two sources (temperature and live load) that are assumed to be the major ones.

2 COMPENSATION OF TEMPERATURE

2.1 Introduction

The following analysis is based on investigations on the Europabrücke—a well-known Austrian steel bridge near Innsbruck, opened in 1963—which is part of one of the main alpine north–south routes for urban and freight traffic (Figure 1).

A long-term preoccupation of VCE with BRIMOS® (*Bri*dge *Mo*nitoring *S*ystem) on the Europabrücke (since 1997) led to the installation of a permanent monitoring system in 2003 [1].

It consists of 24 channels for measuring the accelerations of the main span, the pier, and the cantilever, the dilatation of the abutment, the wind speed and direction, and the temperatures at several locations (Figure 2). The bridge's reference sensor (3-D-forced balance accelerometer) is installed within the main span, at a distance of 0.4 times of the span's length from pier II. At this base point, global stiffness and its dependence to several environmental influences are assessed (sampling rate = 100 Hz, file length = 330 s).

By evaluating the results (frequency spectra) of several measurements, telescoping them together, and viewing them from above (so-called trend cards), the visuals obtained are as shown in Figure 3. These exemplarily show the main span's relevant vertical stiffness patterns of a particular day with a distinctive progression of temperature.

For the sake of completeness, the corresponding frequency spectra themselves are shown in Figure 4, again over a period of this day. An individual procedure has been developed in [2], which contains some measurement preconditioning (offset elimination and bandpass filtering). To enable a more stabilized, automatically performed peak, picking in different ranges of frequency, the response spectra are smoothed in the course of frequency assessment.

The permanent monitoring system exhibits the remarkable loading impact, as the bridge is currently stressed by more than 30 000 motor vehicles per day (approximately 20% of them are freight traffic). By applying the previously described method to the reference sensor's measurement data for the whole day, a progression of stiffness, which consist of 281 single peaks, is obtained (Figure 5a) and represents randomly occurring ambient and forced vibration conditions (scatter).

The complementary relation between stiffness and the air temperature itself (registered at the bridge's base point directly above pier II) is obvious and can be interpreted as a long sinusoidal wave of the main span in the vertical direction. In the course of the described procedure, it should be considered whether to omit the described bandpass filtering and replace it by a further optimized smoothing of the frequency spectra for reasons of stabilizing the accuracy of peak picking.

2.2 Stiffness versus temperature

To describe the verified phenomenon mechanically, attention has to be focused on temperature dependence of the roadbed's asphalt layer, as the change of steel characteristics under varying climate conditions

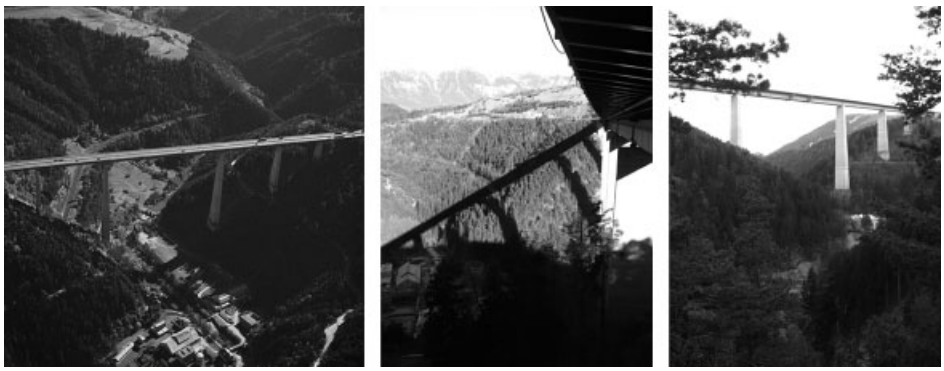

Figure 1. Europabrücke—overview.

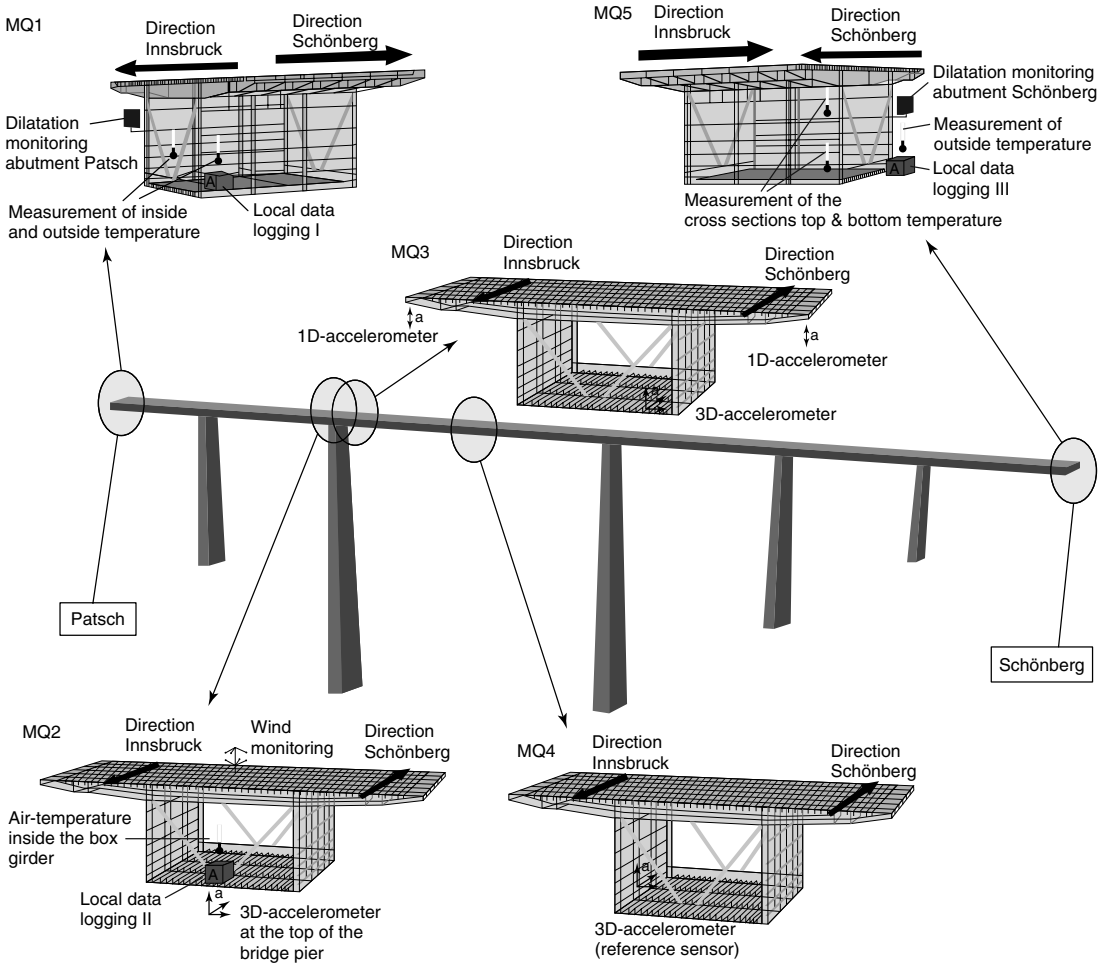

Figure 2. The permanent monitoring system and its several measurement sections.

is negligible. In the first step, the characteristic relationship of the temperature dependence of dynamic Young's modulus is used [3].

Owing to this relation, a temperature-sensitive asphalt layer is implemented into the cross sections of the global structural analysis model, which leads to a distinctive progression of the midspan's flexural rigidity (Figure 6b).

$$f_i = \frac{\lambda_i^2}{2 \cdot \pi \cdot L^2} \left(\frac{EI}{m} \right)^{1/2} \tag{2}$$

According to the widely known equation (2), the frequency of vibration for a bridge beam is proportional to the square root of the moment of inertia [4]. The eigenfrequency f_i is defined as a function depending on the bending stiffness EI of the cross section, the length L of the structural member, the mass m per meter, and the type of the boundary conditions (λ). The utilization of the present equation without considering axial forces is permissible, as the acting forces in the present case are relatively small—furthermore, probable changes of the effective axial forces occur in quite a short timeframe, which minimizes their effect on the dynamic response in the course of frequency analysis.

For further investigations, a curve in terms of frequency needs to be generated (Figure 7b) for the next step, when a temperature-based stiffness path is eliminated from the overall trend (Figure 7a–c).

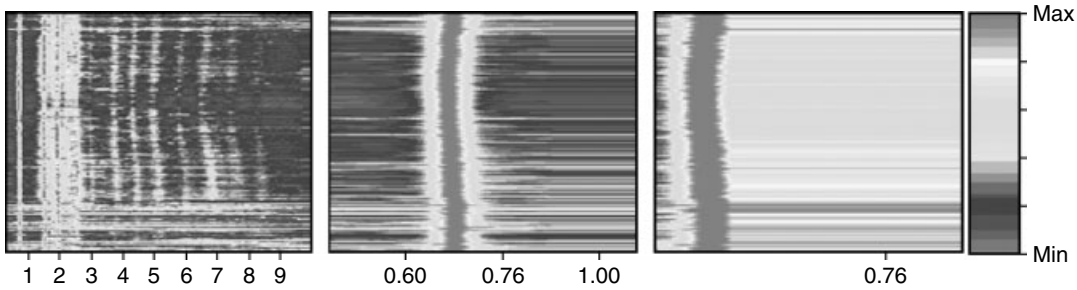

Figure 3. Trend of stiffness during one day: 0.30–10/0.30–1.10/0.60–0.80 Hz.

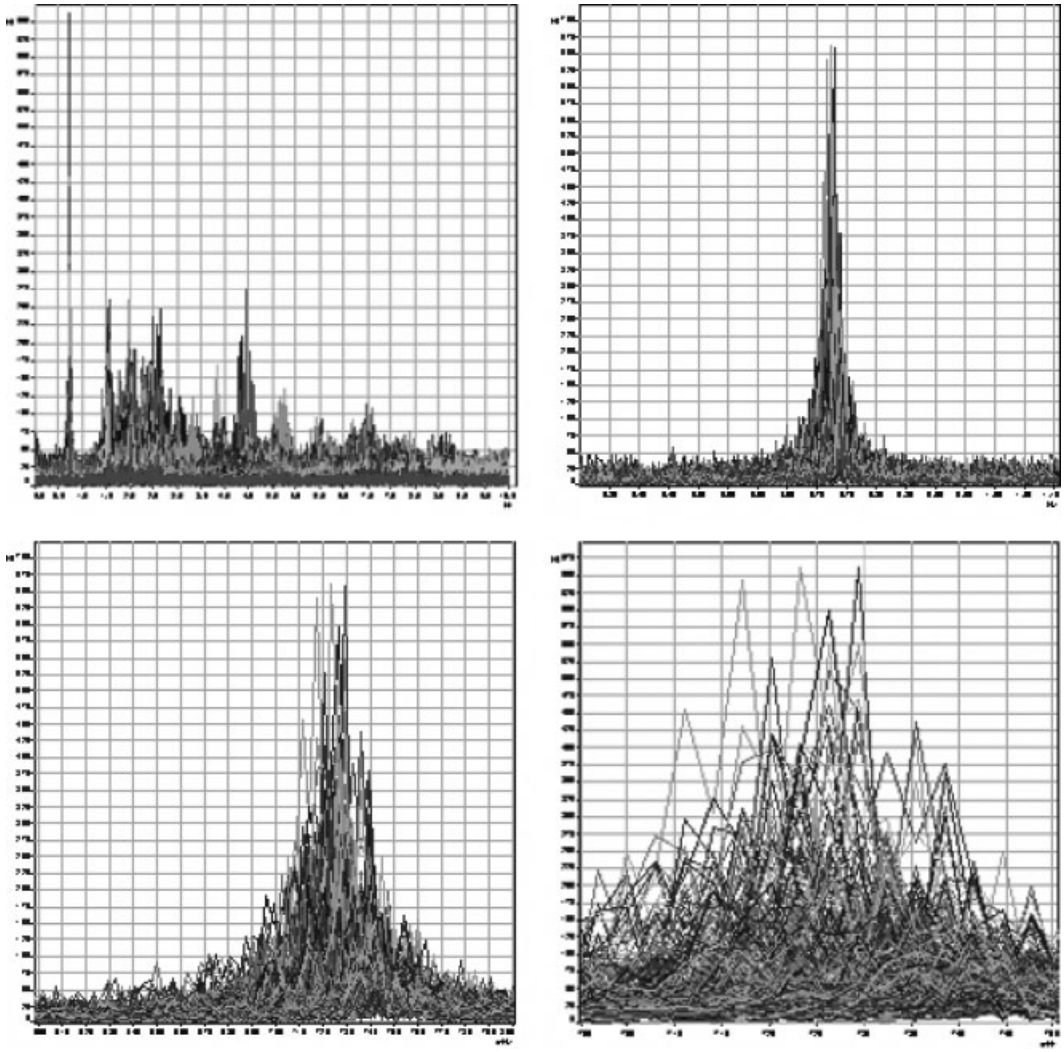

Figure 4. The front views of the trendcard for one day: 0.30–10/0.30–1.10/0.60–0.80/0.68–0.74 Hz.

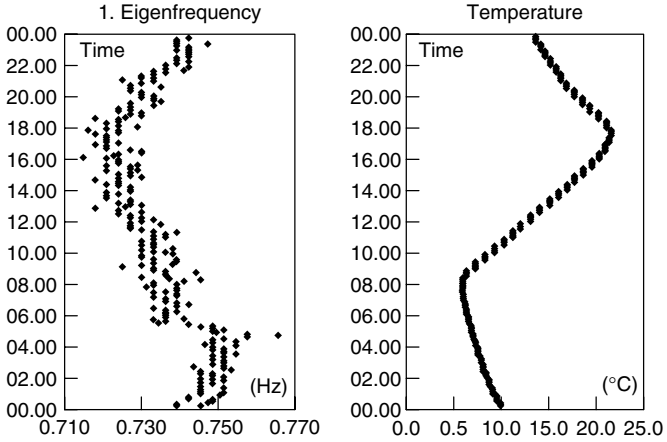

Figure 5. Pattern of first eigenfrequency and its obvious dependency on temperature.

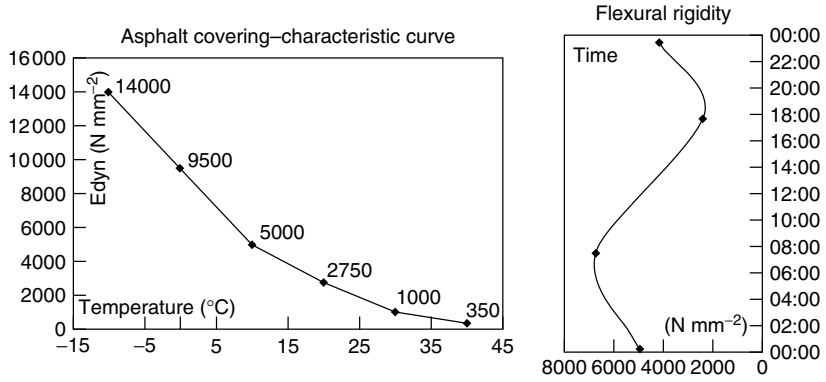

Figure 6. Progression of the asphalt layer's flexural rigidity in dependence of its temperature.

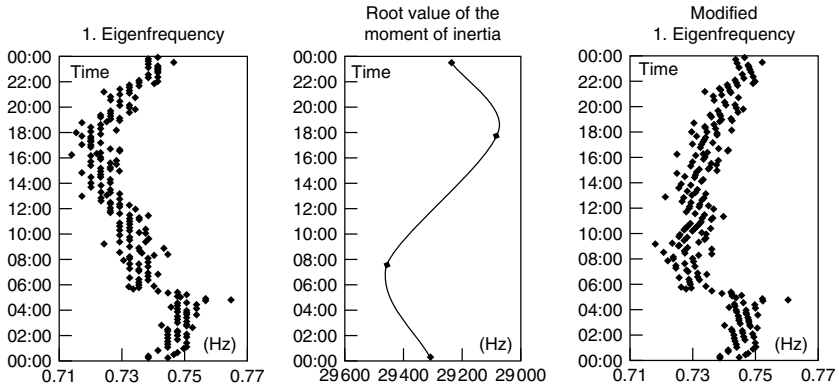

Figure 7. Pattern of first eigenfrequency before and after compensation of temperature.

The obtained trend very clearly shows the remaining impact of freight traffic itself, which strongly affects the timeframe between 5 a.m. and 10 p.m., when trucks are allowed to pass the bridge and cause two characteristic offsets during the course of the day.

3 COMPENSATION OF ADDITIONAL (MOVING) MASSES

The modified trend of the main span's stiffness already includes a number of characteristics of the prevailing freight traffic progression (Figures 8 and 9). Unfortunately, traffic data from the competent authorities are available only per hour. For some introductive exploration on approximate additional mass compensation, further steps need to be undertaken.

The frequency of vibration, based on equation (2) again, is inversely proportional to the square root of the mass. This means that live loads cause increase in effective mass, which leads to hourly calculated factors to modify the fluctuating frequency. Owing to that relation, the scattered trend of frequency is straightened in dependence of modal contribution of trucks per hour (Figure 10).

In fact, the present configuration of the permanent monitoring system provides the possibility to develop a more sophisticated and more reliable, strictly measurement data–based method. Forced balance accelerometers located at a defined distance along the cantilever's outer edges—in both directions of traffic—enable the verification of recurring truck passages and their related velocity and tonnage without any disturbance of traffic. A dynamic freight traffic registration system was developed (a certain pattern-recognition procedure introduced in [5]), which utilizes accelerometer-based, reproduced

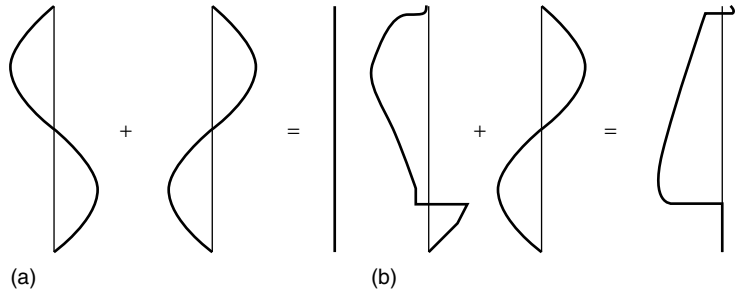

Figure 8. Comparison of expected (a) and actual (b) consequences of temperature-compensated natural frequency patterns.

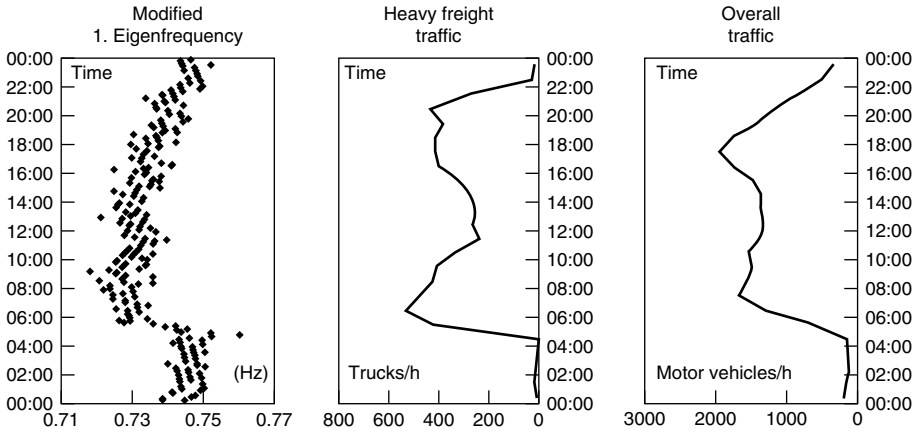

Figure 9. Modified pattern of stiffness—strongly affected by traffic loading (moving additional masses).

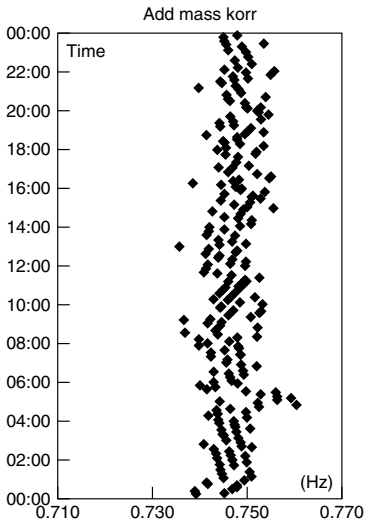

Figure 10. Stiffness pattern after approximate compensation of additional masses.

cantilever deformations. By this method, the moving loads within each measurement file—passing the main span simultaneously—could be identified and would lead to a shifting of the single peak in the frequency-response spectrum, which represents the registered time history in each measurement file.

4 CONCLUSIONS

As permanent monitoring systems produce huge amount of data, they have to be processed systematically to exploit the information fully. For easy handling, it is proposed that statistically based threshold levels are calculated. To do so, continuous monitoring systems—providing information about changed modal parameters under "normal" operational conditions—can be used to trigger warning and alarm levels with regard to damage assessment.

The acquisition and elaboration of the quantities that are provided by the installed instrumentation allow setting up a structural behavior model that is considered as the "regular model" (baseline model). The periodic elaboration of the acquired measurements and the comparison with the baseline model allows to point out indicators of potential structural damages. The availability of periodic surveys of the cause quantities allows, moreover, setting up statistical models of the structural behavior, where

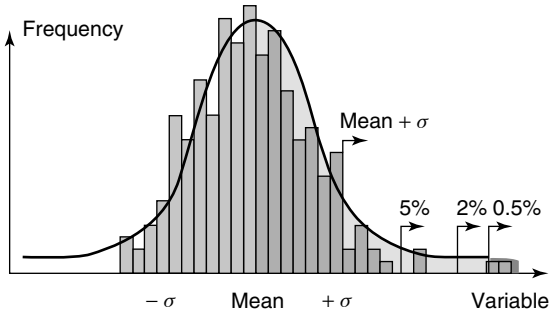

Figure 11. Histogram and best fit distribution-based determination of threshold values.

the structural response is statistically correlated to the trend of the cause quantities. Meanwhile, these models allow a control in time of the structural response by pointing out the "weight" of the cause quantities. The definition of alert threshold levels from analysis of historical database (e.g., extreme-value analysis) may be illustrated as in Figures 11 and 12.

5 OUTLOOK

The discussed approach—benefited by permanent monitoring—allows to reach the conducted goals, even if the experience already gained with the applied methods is still approximate in character. Therefore, the article solves the problem more qualitatively, rather than quantitatively, so far. The main reason is the fact that every condition compensation process based on permanent monitoring has necessarily to be a tailor-made one—depending on the observed bridge object. The polynomial functions—describing the occurring temperature—have always to be derived from measurements for further analysis (implementation of temperature-sensitive asphalt layer into the finite element bridge model—leading to distinctive characteristics of span's flexural rigidity). Although air temperature is used instead of structural elements, the results are very promising. This approach represents an innovation in stiffness assessment appropriate for long-term application. The goal of generating frequency progressions over time, without major environmental and operational impact, has come within reach. The procedure will be optimized in

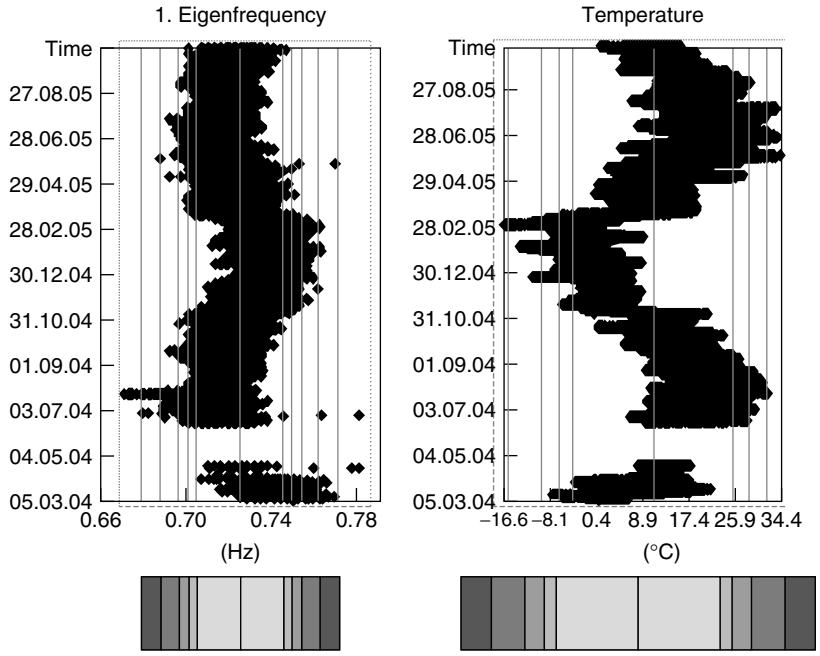

Figure 12. Response for 18 months using threshold levels (statistical time history) with 5/2.75/2.5/1/0.135% probability of exceedance.

progressive stages, as soon as the cantilever-sensor-based approach that has already been introduced is implemented.

Chapter 129

Modal Testing of the Vasco da Gama Bridge, Portugal

Elsa Caetano and Álvaro Cunha
Faculty of Engineering, University of Porto, Porto, Portugal

1 INTRODUCTION

The safety condition of large bridges is normally verified at the end of construction on the basis of static and dynamic tests. Static load tests employ heavy road or railway actions applied in different combinations, reproducing exceptional loading scenarios, in order to ensure that the required strength has been achieved. The structural response is measured in terms of strains or displacements and compared with the results from numerical models. The purpose of dynamic testing is to identify the relevant natural frequencies, vibration modes, and damping ratios in order to calibrate and validate numerical models that have been used during the design to simulate the structural behavior under dynamic excitations such as wind and earthquakes.

The dynamic tests performed on the Vasco da Gama Bridge took place in March 1998 shortly before the opening of the bridge [1]. They comprehended response measurements developed under natural excitation (ambient vibration test (AVT)) and under the releasing of a load applied at the central span of the main cable-stayed bridge (free vibration test (FVT)). The use of high-sensitivity sensors and of an efficient wireless technique allowed the identification of a significant number of vibration modes with high amplitude and spatial resolutions based only on ambient vibration measurements. It also permitted the identification of installed force in some stay cables on the basis of laser measurements and on the indirect evaluation of cable frequencies.

Conventional identification techniques initially employed to extract modal parameters from the recorded time series were subsequently extended to

Figure 1. Vasco da Gama Bridge.

more recent and powerful output-only identification algorithms, which are of interest to improve the quality of model estimates and automatic implementation in the context of long-term monitoring of a structure.

2 THE VASCO DA GAMA BRIDGE

The Vasco da Gama Bridge is a crossing of the river Tagus located in the city of Lisbon, Portugal, and has a total length of 17.3 km (Figure 1), involving three interchanges, a 5-km-long section on land and a continuous 12.3-km-long bridge. This bridge includes a main cable-stayed part over the main navigational channel with a total length of 829.2 m, formed by a central span of 420 m and three lateral spans on each side ($62 + 70.6 + 72$ m) (Figure 2). Two lateral prestressed concrete girders 2.6-m high connected by a cast *in situ* slab 0.25-m thick and by transversal steel I-girders every 4.42 m, form the 31-m-wide deck. The bridge deck is continuous along the total length and is fully suspended at a height of 52.5 m above the river by two vertical planes of 48 stays connected to each tower. The two H-shaped towers are 147 m high,

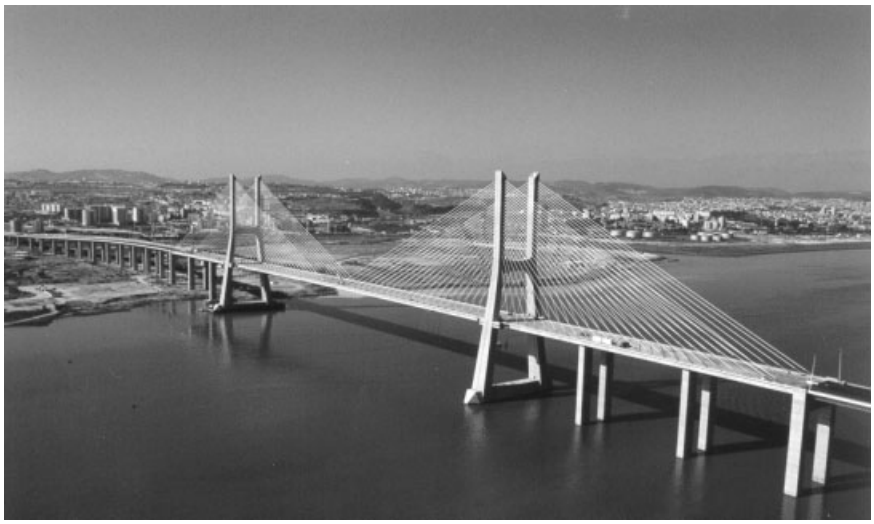

Figure 2. Vasco da Gama Bridge: cable-stayed part.

above a massive zone at their base used as protection against ship collisions.

The stay cables consist of bundles of parallel self-protected strands covered by a high density polyethylene (HDPE) sheath. Specific protection against vibration was adopted, namely, by inclusion of a double helical rib in the cable cover for prevention of rain–wind vibration, and by use of damper devices installed close to the deck anchorage inside the steel guide pipe of the cables. Given the active seismic location of the bridge site, specific measures were taken in the design, namely, the adoption of a full suspension deck from flexible towers to minimize the seismic forces and the introduction of a set of hysteretic steel dampers connecting the pylons and the deck to limit the displacements. Under service loads, the transverse dampers work within the elastic range, acting as elastic supports, whereas the longitudinal dampers allow low-speed displacements. In case of an earthquake, the steel hysteresis is used to dissipate energy.

3 INSTRUMENTATION

The identification of the major natural frequencies and vibration modes of the cable-stayed bridge and viaducts within a very limited time period would be compromised if a conventional acquisition system based on a set of accelerometers and a central unit was employed, due to the limited number of available accelerometers and to the huge requirements in terms of electrical cable length and manipulation to cover a dense mesh of points necessary to characterize higher order vibration modes. An efficient technique was employed instead, which consisted in the performance of the measurements with a total of six triaxial 16-bit strong motion recorders. These devices included force-balance type accelerometers and individual acquisition card and memory units. The operation of these recorders was programmed and synchronized by a laptop, which allowed the performance of measurements without electrical cables (Figure 3). Therefore, it was possible to freely move the sensors along the deck and towers and record the bridge response at a dense mesh of points.

A noncontact measurement system was tested for the instrumentation of the cables, which was based on a laser Doppler velocimeter. Although the purpose of the test was not to identify installed cable force at all stays, such a requirement would be extremely demanding if conventional accelerometers had been employed, due to the need to successively attach the accelerometer to each cable (Figure 4a). Using the laser velocimeter, the sensor head is placed underneath the cable on the deck (Figure 4b) and the relative velocity between the deck and the cable is measured from the analysis of frequency change of the reflected laser beam according to the well-known Doppler effect. The output of this sensor can be processed by a conventional Fourier analyzer. Although the precision of the laser sensor may be lower than that of a conventional accelerometer, the fact that stay cables evidence vibration amplitudes that are typically at least one order of magnitude higher than the deck means that the laser sensor can still provide accurate measurements of cable response. The average power spectrum densities (PSD) represented in Figure 5 obtained for one stay cable using an accelerometer and the laser sensor shows the high quality of the collected signal and the usefulness of this sensor to measure cable frequencies.

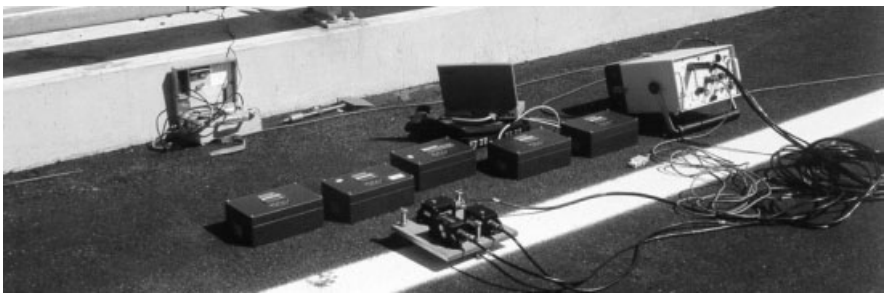

Figure 3. Strong motion recorders used in dynamic testing.

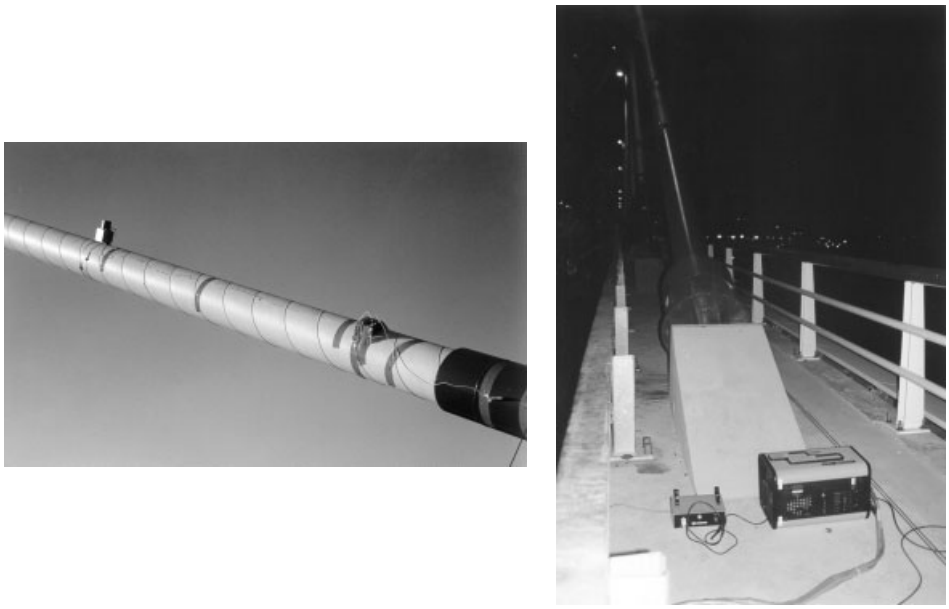

(a) (b)

Figure 4. Stay-cable instrumentation: (a) conventional accelerometer and (b) laser Doppler velocimeter.

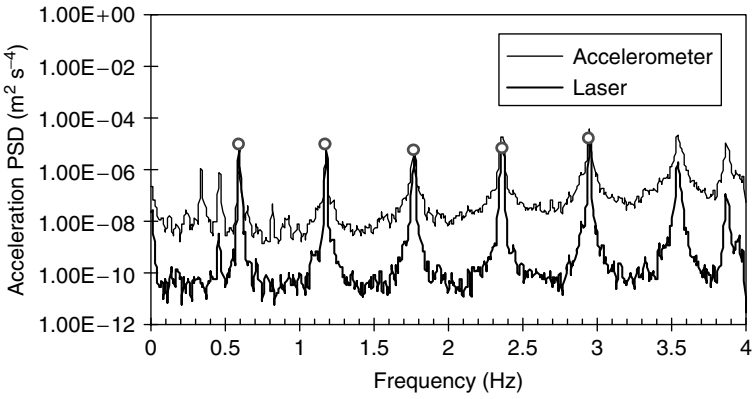

Figure 5. Comparison of acceleration average power spectrum densities (PSD) of the ambient response of a stay cable measured with a conventional accelerometer and a laser sensor.

4 AMBIENT VIBRATION TEST

The AVT was conducted considering two strong motion recorders fixed at reference positions (upstream and downstream), and moving the other four recorders along the successive measurement sections.

For the cable-stayed bridge, the chosen reference sections were located about one-third of the central span on the North side, on marks 10U and 10D of Figure 6. The other four recorders scanned the bridge deck and the towers using a total of 29 measurement sections. The sampling frequency was 50 Hz. The expected interesting frequency range was very low (0–1 Hz). Therefore, a measurement time of 16 min was chosen for each setup, which was sufficiently long to capture various periods of the low-frequency modes. Data recording started every 20 min, meaning

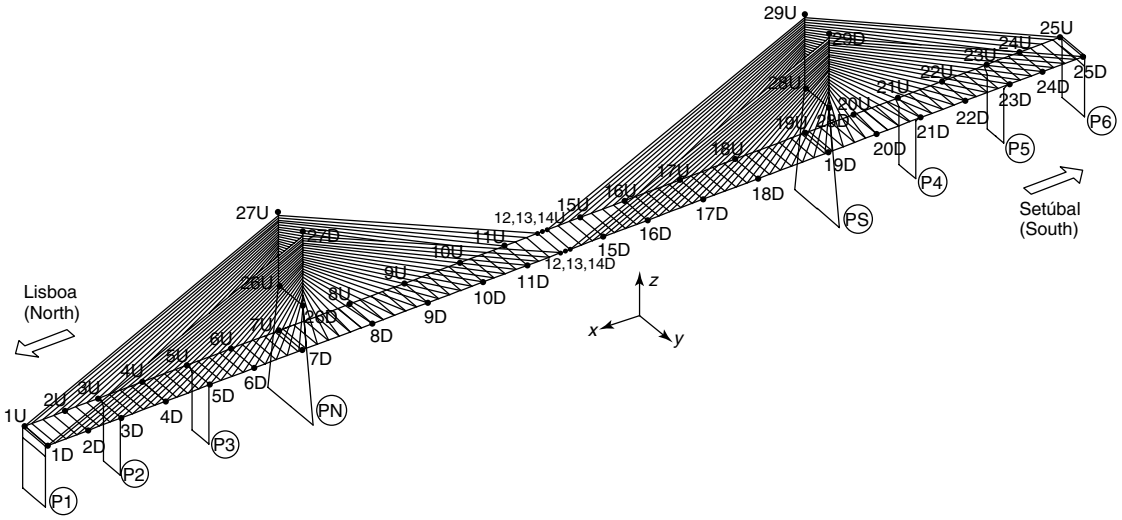

Figure 6. Measurement locations on the Vasco da Gama cable-stayed bridge.

that 4 min were left for moving the four recorders to the adjacent measurement sections. A total of 2.5 days was required to record the triaxial response at the 29 pairs of measurement locations represented in Figure 6.

The excitation source was wind, the speed varying between 1 and 22 $\mathrm{m\,s^{-1}}$ during the complete AVT campaign. This resulted in large differences of bridge acceleration magnitudes, whose root mean square values ranged between 0.03 and 0.4 mg for the horizontal directions, and, between 0.06 and 1.3 mg for the vertical directions, with the consequence of quality differences of the acquired data.

5 FREE VIBRATION TEST

Since there is no reliable analytical model available for the evaluation of damping ratios and, considering the large influence on the bridge response to wind and earthquake excitation, experimental identification of those parameters is extremely important.

Damping-ratio estimates obtained from ambient vibration measurements exhibit a large scatter, as a consequence both of variation of damping with amplitude of vibration and wind speed and of measurement/processing errors. For higher amplitudes of vibration, the scatter reduces and the accuracy of measurements increases. The easiest way of generating higher than ambient vibrations on a full-scale structure is by application of impulsive loads. On the Vasco da Gama Bridge, the impulsive excitation was obtained by suspending a mass of 60 t from a point on the bridge deck, close to location 10U (Figure 6), and suddenly releasing it (Figure 7). The resulting free vibrations were then recorded over 16 min at measurement sections 10, 13, and 16 (Figure 6). This test was performed under low wind speeds (less than 2.5 $\mathrm{m\,s^{-1}}$ were measured), so that the identified damping ratios represented the real structural damping ratios, with no added aerodynamic component.

6 MODAL PARAMETER IDENTIFICATION AND FINITE ELEMENT CORRELATION

6.1 Operational modal analysis

The extraction of modal parameters from the acquired data was initially made on the basis of peak picking method [2]. Subsequently, more powerful output-only modal parameter estimation methods were applied, the stochastic subspace identification (SSI) and the frequency-domain decomposition methods [3, 4], implemented in the software packages MACEC [5] and ARTeMIS [6].

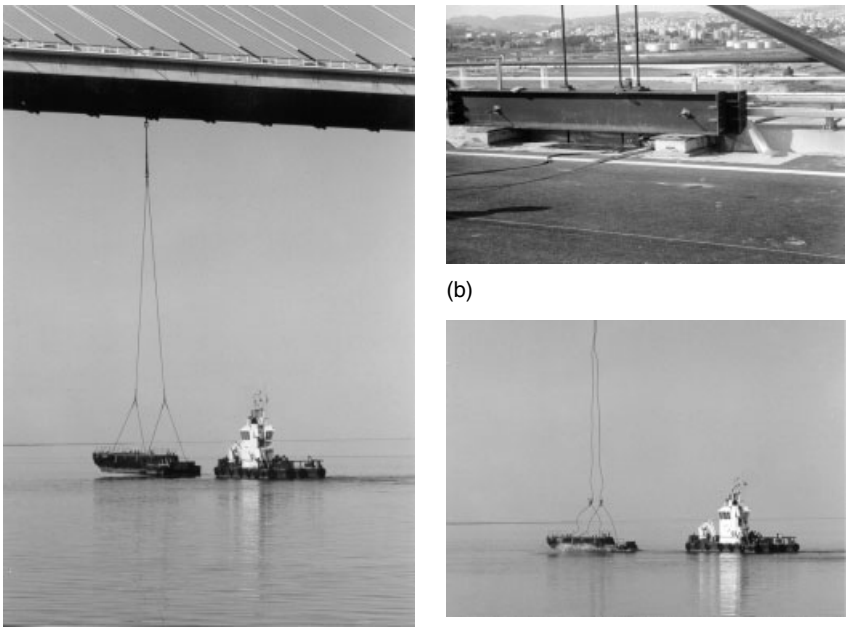

Figure 7. Free vibration test (a) eccentrically suspended 60-t barge, (b) starting cut of hanging Dywidag bar, and (c) release of barge.

Peak picking is the simplest and the most popular method used in civil engineering to estimate the modal parameters of a structure subjected to ambient loading. The method is based on the identification of the natural frequencies from the peaks of power spectra estimates. Mode-shape components are then identified from the analysis of the amplitude and phase of transfer functions relating the ambient response at a reference section with the response at the other measurement points.

Although this method relies on the assumptions of low damping and well-separated eigenfrequencies, some refinements have been introduced [7], which allow more complex applications. The coherence function between two channels tends to go to 1 in the vicinity of the resonance frequencies, because of the high signal-to-noise ratio at these frequencies. Consequently, inspecting the coherence function can assist in selecting the eigenfrequencies. Also, the phase angles of the cross spectra are helpful: if real modes are expected, the phase angles should be either 0° or 180° at the resonance frequencies. An additional improvement consists in separating bending and torsional effects by simple sum/difference of simultaneous records collected at the opposite sides of the deck. However, a violation of the basic assumptions (low damping and well-separated modes) can lead to erroneous results. In fact, the method identifies operational deflection shapes instead of mode shapes and for closely spaced modes such an operational deflection shape will be the superposition of multiple modes. Other disadvantages are that the selection of the eigenfrequencies can become a subjective task if the spectrum peaks are not very clear and that the method does not yield any damping estimates.

The frequency-domain decomposition (FDD) method is an interesting alternative that can be understood as an extension of the peak picking method, enabling the treatment of closely spaced modes and eventually the extraction of damping estimates. This method employs a process of noise reduction of a cross-power matrix of the output measurements based on the singular value decomposition. The obtained singular values are related with the natural frequencies and damping ratios, while singular vectors represent the corresponding mode shapes [8]. Another alternative to the peak picking method is the SSI method, which identifies a so-called stochastic

state space model from measured output data or output covariances. This model is a good representation of a structure excited by unknown forces, which are assumed white-noise signals. After the identification of the state space model, the modal parameters are obtained from corresponding matrices [5]. The three methods referred to above are the most widely used output-only methods in civil engineering applications at the current state of art and were applied to the Vasco da Gama data for comparison of performances.

6.2 Ambient vibration data

The extraction of modal parameters from the ambient vibration data was performed first using the conventional peak picking method. Figure 8 shows average normalized power spectrum density (ANPSD) and average normalized cross power spectrum density (ANCPSD), respectively, associated to vertical and transversal accelerations along the bridge deck, whereas Figure 9 shows normalized cross power spectrum densities (NCPSD) and corresponding coherences relating the ambient response at sections 10 and 16 (Figure 6). The natural frequencies identified on the basis of the peak picking technique are summarized in Table 1, as well as the calculated frequencies obtained at the design stage by EEG (Europe Études Gecti, Villeurbanne, France), using the finite element program Hercules. Figure 10 shows some of the most significant mode shapes of the deck, and the corresponding numerical modes, as well as some modal components identified using the FVT data.

The analysis of Table 1 and Figure 10 shows the excellent correlation between identified and numerical modal parameters, even though the bridge is characterized by a large number of very closely spaced in-frequency vibration modes. The success of the peak picking method in this application stems from the preliminary separation of bending and torsional components of the signal and from the high-frequency resolution of the analysis. The major differences between experimental and numerical data are associated with identified multiple modes, characterized by natural frequencies in the

[(b)] Unknown.

range 0.693–0.755 Hz and with common deck modal configuration, but involving different cable motions. These modes reflect cable–structure interaction [2] and have not been identified numerically, since the cable dynamics was not included in the analysis.

Having the purpose of analyzing and comparing the efficiency of the more powerful identification algorithms based on the FDD and SSI methods, a reanalysis of the ambient vibration data of the Vasco da Gama cable-stayed bridge was done [3, 4], based on the implementations of the SSI in the MACEC software package [5] and on the FDD and SSI implementations in the commercial package ARTeMIS [6]. Tables 2 and 3 show comparisons between natural frequencies identified using both methods and the peak picking method, also summarizing the estimates of modal damping ratios achieved by application of the SSI method. Figure 11 shows a three-dimensional representation of the fundamental identified modes based on the MACEC implementation.

The analysis of Tables 2 and 3 shows that the three methods lead to very consistent estimates, especially in terms of identified natural frequencies. The SSI and FDD methods provide excellent results for closely spaced modes, without special combination (bending/torsion) of the original signals. The identification of multiple modes involving different cables is, however, more difficult. This fact is due to the variable wind speed along the test, responsible for different excitation of cables along the different setups. As for damping estimates, it is seen that similar order of magnitude is obtained using different implementations of the SSI method. The scatter of estimates is, however, very large and is inherent to the identification procedure. It results also from the variation of damping along the test due to aerodynamic variable contribution and amplitude variation of structural damping for very low amplitudes of vibration.

6.3 Free vibration data

The eccentrical release of the 60-t mass from a point in the one-third of the central span of the bridge produced a free decay oscillation with maximum displacement amplitude of 25 mm (30-mg peak acceleration), which attained the ambient oscillation level about 6 min after release of the load.

The identification of natural frequencies from the collected records was made, in a first instance, by inspection of the peaks of fast Fourier transforms (FFTs) of the acceleration time series (Figures 12 and 13). With regard to the mode shapes, these were identified by digital filtering around each of the natural frequencies identified, and by comparing the amplitudes and phases of the filtered signals at different points of measurement. Figure 10 shows the modal components identified by this procedure, which are clearly in good agreement both with the mode shapes obtained by the AVT and with the modal configurations calculated numerically. The identification of the modal damping ratios was done on the

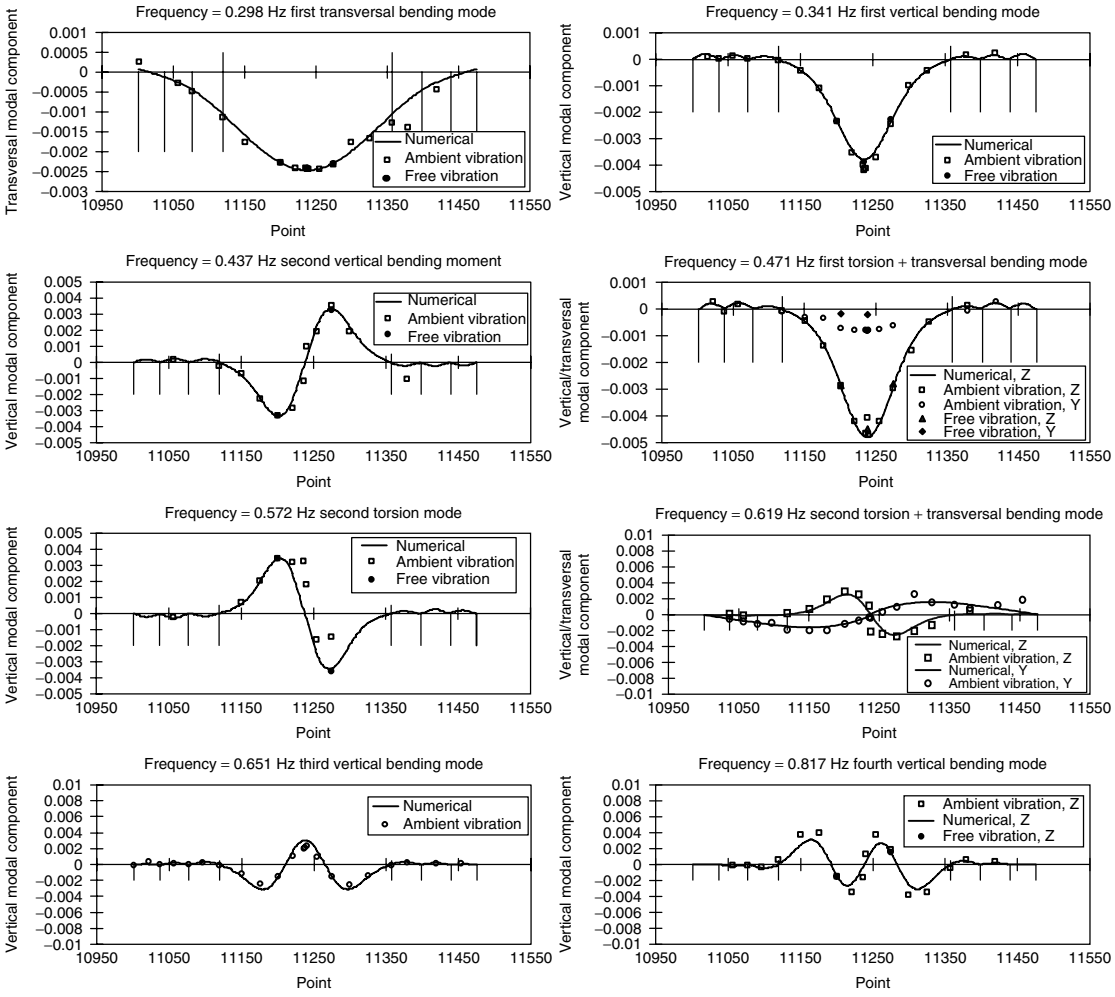

Figure 10. Some of the most relevant identified mode shapes (deck).

basis of the decay of the envelope of the filtered signals obtained as exemplified in Figure 14.

The SSI method was also applied to the set of free vibration records [5]. Table 4 shows a comparison between natural frequencies identified using both the peak picking technique and the SSI method. This table also shows the modal damping ratio estimates achieved. It can be concluded that natural frequency estimates obtained from peak picking method are almost identical to those resulting from the SSI method, except for the third torsional mode (T3), whose peak was unclear for identification with peak picking method. Damping ratios estimated with SSI method are also very similar to the ones estimated from the free decay analysis of the band-pass filtered records.

6.4 Discussion of AVT and FVT results

Considering the different levels of response involved in AVT and FVT, it is of interest to compare the modal parameters obtained from those types of tests. Table 5 systematizes natural frequencies and damping ratios identified for the two situations. The mode shapes are compared by computing the (squared) correlation between the components of the modal vectors, which have been measured in both AVT

Table 2. Ambient vibration modal parameters (AVT) obtained with peak picking (PP) and the MACEC implementation of SSI

and FVT. This squared correlation is called *modal assurance criterion* (*MAC*) in modal analysis and is represented in Figure 15, showing that the AVT and FVT mode shapes are very similar. From Table 5, it is clear that the natural frequencies and damping ratios are also very much alike. In general, damping ratios are identified with larger uncertainty. It is known that they vary with the magnitude of vibrations and that an aerodynamic component may be present in the AVT due to the relatively high wind speeds measured during some of the setups. It appears that the FVT natural frequencies are systematically slightly lower than their AVT counterparts.

7 SURVEILLANCE AND STRUCTURAL MONITORING

As an important infrastructure in the access to the city of Lisbon, the Vasco da Gama Bridge is currently

the object of a surveillance and monitoring program [9]. The purposes are (i) the guarantee of users' safety; (ii) the verification of the variation of structural behavior according to the predicted behavior; (iii) the characterization of the effects associated with exceptional events like earthquakes, ship collision, or high winds; and (iv) the identification of cable retensioning needs according to a predefined plan. To accomplish these objectives, the bridge has been fully instrumented, including, in particular, a set of

electrical sensors for measurement of joint openings, temperatures, wind, strains, and accelerations. All observations are permanently referred to a zero-state condition that corresponds to the measurements performed at the end of construction of the bridge, including the ones referred above. Records are saved in case of exceedance of predefined limits. Otherwise, complete measurement records are obtained every six years. Alert levels have been stipulated, which require different levels of intervention, like closing the bridge to traffic, conducting visual inspections, or developing particular retrofit actions. It is relevant to mention

that until the current moment, no particular threshold has been attained demanding unexpected correction measures.

8 CONCLUSIONS

Experimental modal identification and finite-element correlation of the Vasco da Gama cable-stayed bridge have been conducted on the basis of the performance of AVT and FVT. The high-quality database created was processed using both the conventional peak picking technique and the modern frequency-domain decomposition and SSI methods. The results obtained allow drawing, in particular, the following conclusions:

- The levels of vibration of the cable-stayed bridge under ambient excitation are very low, even for significant wind speeds.
- The measurement system used in the AVT and FVT, based on the use of independent triaxial strong motion recorders conveniently programmed and synchronized by a portable PC, revealed to be a very efficient and comfortable solution, avoiding the use of several hundred meters of electrical cables and permitting the integral data acquisition in a relatively short period of time.
- A large number of modes could be identified in a low-frequency range (0–1 Hz) from low-level ambient vibrations using sensors dedicated to civil engineering applications, collecting long records of response and using appropriate signal processing and modal analysis techniques.
- The FDD and SSI application confirmed earlier results obtained with peak picking.
- The FVT was very useful as a complementary test that permitted not only to check the previous modal identification from ambient data but also to accurately identify modal damping ratios, whose knowledge is particularly relevant in terms of the study of the aerodynamic stability of the bridge.
- The SSI method allows the identification of damping ratios from ambient vibration data. These ratios present a significant scatter and seem to be systematically slightly higher than the corresponding estimates obtained from the FVT, reflecting fluctuations due to aerodynamic variability. Therefore, although it is understood that a lesser accuracy exists in the identification of damping ratios based on ambient vibration data and that this type of tests cannot replace FVTs; information obtained is of extreme usefulness, especially when the latter tests cannot be accomplished.
- There is, in general, an excellent correlation between modal parameters identified and the corresponding parameters calculated on the basis of the 3-D finite element model developed at the

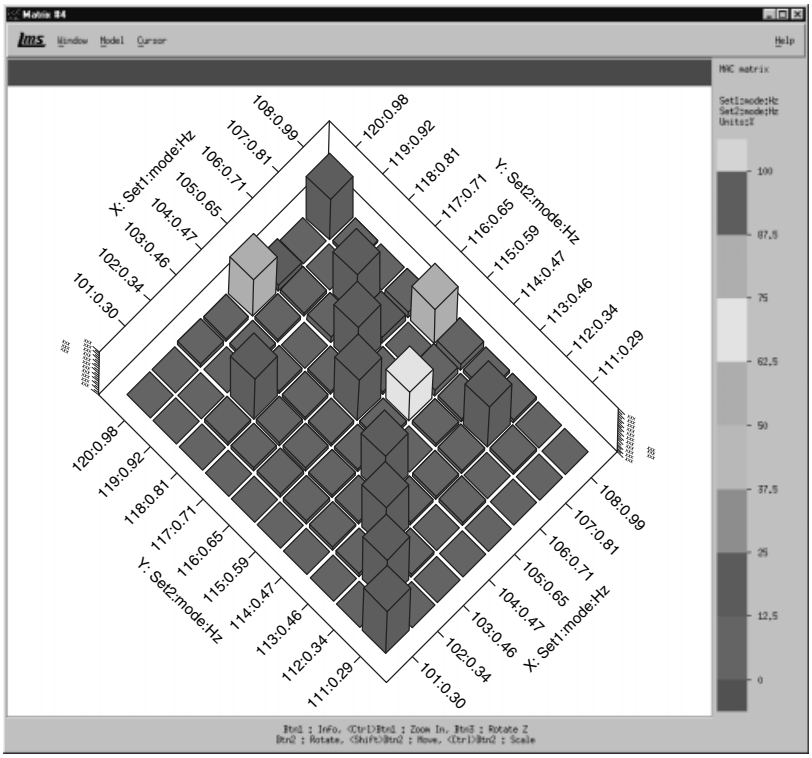

Figure 15. MAC values (mode-shape correlations) between 8 AVT modes and 10 FVT modes.

design stage, though some small differences can be found, as it is the case of the multiple modes identified associated to the second torsion + transversal bending numerical mode, related with local stay-cable frequencies, or the third torsion mode, in which no transversal bending component was experimentally detected.

The Vasco da Gama Bridge has been the object of a surveillance and monitoring program implemented by Lusoponte. This system comprehends extensive instrumentation that permanently collects data that are compared to a zero-state condition, for possible detection of degradation and characterization of the effects of exceptional events. Until the current moment no particular threshold has been attained demanding unexpected correction measures.

Chapter 130
Multiple-model Structural Identification

Ian F. C. Smith
Institute of Structural Engineering, Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

1 INTRODUCTION

While there are other good applications, multiple-model structural identification methods are useful principally for complex civil structures in uncertain environments. In such situations, determining the number of possible causes of anomalous behavior is combinatorial. This aspect has important implications. For example, it is impossible to place sensors so that they can measure directly every type of damage and deterioration at every location on every element. Most measurements are consequently indirect. Behavior models are thus essential to perform diagnoses, to design and plan possible repairs, and then to continue to manage structures throughout the rest of their service lives. Finding good models to support such decision making requires development of appropriate methodologies for structural identification. Such development is one of the most important scientific challenges within the field of structural health monitoring.

Behavior models are rarely accurate. Errors due to factors such as idealizations inherent in models of mechanical principles, numerical errors, inaccurate boundary conditions, and wrong material constants create situations where high model accuracy is unlikely in most practical situations. In addition, measurements have errors. These errors can be several times larger than the accuracies reported by sensor manufacturers owing to factors such as installation difficulties and connection losses. Therefore, engineers cannot assume the same level of accuracy as is observed in laboratory installations.

Service lives of civil infrastructure often exceed 100 years. Monitoring and decision making are thus iterative processes. Once measurements are made and the data is interpreted, additional measurements using new sensors may be warranted. Engineers need to make the most of existing information to

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

plan downstream tasks such as further measurement, preventative maintenance, and structural replacement.

Conditions of indirect measurements, an unavoidable presence of errors in modeling and in measurement, as well as monitoring/interpretation/decision-making cycles over decades create many challenges for structural health monitoring. This article proposes that appropriate selection of the best identification order for the task at hand provides good support for engineers involved in structural management.

2 CURRENT PRACTICE

It is common practice to assume that the service behavior of a structure can be modeled using the same model that was used in design. Since this assumption requires no verification of characteristics such as support conditions, geometry, and damage on the as-built structure, it is clearly the most attractive in terms of time and money. The predictions of this model are then compared with measurements.

When agreement between measurement data and model predictions is bad, measurements are used to "calibrate" the model. This involves selecting a small number of model parameters that may have values that are different from those used in design. Once these parameters are selected, various procedures are used to find their values for which the measurements best match the model predictions. Such a strategy is identification order 0 (Table 1). This approach is commonly used, for example, to interpret measurement data from load tests on concrete bridges where values for the product of Young's modulus and the moment of inertia (EI) are determined [1]. This strategy has also been used to find coefficients of stiffness matrices for vibration model calibration, as described in [2–4], for example.

Approaches more sophisticated than identification order 0 include the determination of more than parameter values within one general design model. Most work to date involves manual selection of a few likely behavior models using engineering experience. Factors such as values of member stiffness, support conditions, and in-span hinges are varied to obtain several models. Again model predictions are compared with measurements to update parameters. The model that best fits all types of measurements at all locations is identified to be the most likely model. An example of this approach is given in [5]. This is identification order 1 in Table 1.

The two approaches described above are the lower two orders of structural identification (Table 1). Order 0 modeling involves the use of the same general model that was used for design; only parameter values are changed. Order 1 modeling includes evaluation of several manually selected models. Order 0 and order 1 modeling involve attempts to match sensor measurements with model predictions directly. If formulated as an optimization problem, the difference between measurement and prediction is minimized.

Recent work has proposed automatic generation of candidate models. This builds on work performed

Table 1. Orders of structural identification

Order	Generation of candidate models	Determination of model parameter values	Criteria for selection of model classes and parameter values	Support for further measurement
0	No generation—engineers use design model only	Calibration with load test	Predictions = measurements	Weak
1	Several models selected manually	Optimization using measurement data	Predictions = measurements	Weak
2	Automatic generation	Optimization using measurement data	(Predictions − measurements) < maximum error threshold	Fair
3	Automatic generation	Optimization using measurement data	(Predictions − measurements) < error threshold that is fixed probabilistically	Fair
4	Automatic generation	Optimization using measurement data with data mining for feature extraction	(Predictions − measurements) < error threshold that is fixed probabilistically	Good

in the field of model-based diagnosis over the past 30 years [6–10]. Several proposals have been developed and tested for applications in areas such as electrical circuits and photocopy machines. A promising approach for automatic model generation is compositional modeling [10, 11]. Compositional modeling is a framework for constructing adequate device models by composing model fragments that are selected from a model fragment library. Model fragments partially describe components and physical phenomena. A complete model is created by combining a set of fragments that are compatible. For modeling the behavior of structures, fragments represent support conditions, material properties, geometric properties, nodes, elements, and loading. Assumptions are explicitly represented in model fragments so that the model composition module only generates valid models that are compatible with the assumptions chosen by the users.

Model composition makes it possible to search for models containing varying numbers of degrees of freedom. There is no need to formulate an optimization problem in which the number of variables is fixed *a priori*. Models are automatically generated by combining model fragments and are analyzed by, for example, the finite element method to compare their predictions with measurements.

An important aspect of the methodology is the use of stochastic global search algorithms for the selection of populations of candidate models whose predictions match measurements [12]. Other optimization techniques that make use of gradients and sensitivity equations are not used because multiple local minima are common in these search spaces. This type of search is common for all identification orders higher than order 1.

3 ERROR THRESHOLDS

Errors play a major role in the structural-identification process. Errors from different sources may compensate each other such that predictions of wrong models match measurements [12, 13]. Rather than search for exact matches, in such situations, it is only possible to identify those models whose predicted values, when subtracted by the measurement data, fall within error thresholds. When absolute values of these differences are taken, models that generate values below these thresholds are taken to be candidate models.

Modeling and measurement errors have been investigated by a small number of researchers in the field of structural identification. Banan *et al.* [14] stated that the selection of an appropriate model is difficult; it is problem dependent, and usually requires the intuition and judgment of an expert in modeling. For example, mathematical models may not be able to exactly capture variations in cross-sectional properties, existing deformations, residual stresses, stress concentrations, and variations in connection stiffness. Sanayei *et al.* [15], and Arya and Sanayei [16] emphasized that errors in parameter estimates may arise from many sources, the most significant of which are measurement errors and modeling errors. Measurement errors can result from equipment as well as on-site installation faults [15]. A statistical evaluation of the performance of a system-identification methodology must account for modeling and measurement errors.

Modeling error (e_{mod}) is the difference between the predicted response of a given model and that of an ideal model that accurately represents behavior. Modeling error propagation is graphically depicted in Figure 1. Modeling error has three constituents: e_1, e_2, and e_3 [17]. The component e_1 is the error due to discrepancy between the behavior of the mathematical model and that of the real structure. Component e_2 is introduced during numerical computation of the solution of partial differential equations. Component e_3 is the error arising from inaccurate assumptions made during simulation. Such a definition of modeling errors by subdividing it into sources is similar to the delineation of errors in physical system modeling [13].

Component e_3 is further separated into two parts: e_{3a} and e_{3b}. The error part, e_{3a}, arises from assumptions made when using the model (typically assumptions related to boundary conditions such as support characteristics and connection stiffness). The error part, e_{3b}, arises from errors in values of model parameters such as moment of inertia and Young's modulus. While it might be impossible to separate the components in practice, it is still important to distinguish between these errors since the only error source that is usually recognized by traditional model-calibration techniques is e_{3b}.

Measurement error (e_{meas}) is the difference between the real and measured quantities in a measurement. Measurement errors result from equipment as well

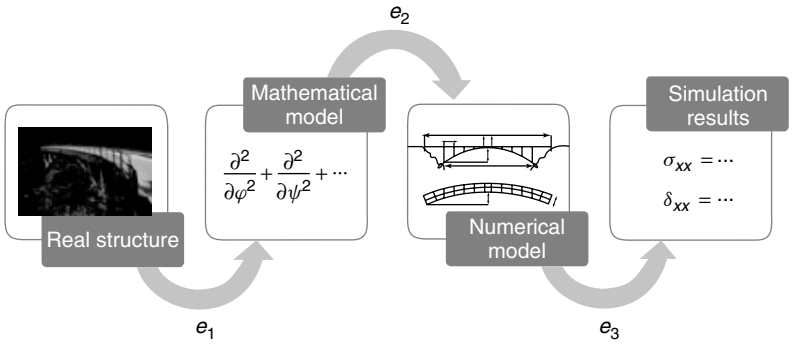

Figure 1. Three sources of modeling errors. e_1, formulation of mathematical models of structure; e_2, representing mathematical models numerically; e_3, simulating numerical models on computers.

as on-site installation faults [15]. In addition to sensor precision values reported by manufacturers, the stability and robustness (for example, with respect to temperature) and the effects of location characteristics (for example, connection losses) also account for measurement error.

The model generation task requires an objective function that accounts for the errors in order to generate a set of candidate models. In Robert-Nicoud *et al.* [12], the objective function is formulated as follows. If x_a is the real value of a behavior quantity such as deflection, x_{meas} is the measured value, and x_c is the value computed using a model, the following relationships have been obtained for a single measurement.

$$x_a = x_{meas} + e_{meas} \tag{1}$$

$$x_a = x_c + e_1 + e_2 + e_3 \tag{2}$$

Model-calibration procedures minimize the absolute value of the difference between x_{meas} and x_c. The difference between x_{meas} and x_c is known as the residue q. Rearranging the terms in equations (1) and (2),

$$q = |x_{meas} - x_c| = |e_1 + e_2 + e_3 - e_{meas}| \tag{3}$$

Thus, model-calibration techniques minimize the quantity $(|e_1 + e_2 + e_3 - e_{meas}|)$. This is equivalent to inaccurately assuming that this quantity is always zero. The objective function that is minimized during the optimization routine is the root mean square error (RMSE), which is calculated as

$$RMSE = \sqrt{\frac{\sum q_i^2}{n}} \tag{4}$$

where $q_i = |x_{i,meas} - x_{i,c}|$ = difference between the value measured at the ith measurement point and the predicted value computed using the model. Any model that gives an *RMSE* value less than a threshold value is considered to be a candidate model. The threshold is computed using an *approximate* estimate of modeling and measurement errors. From equation (3), since errors could be positive or negative,

$$q \le |x_c| + |x_{meas}| \le |e_1| + |e_2| + |e_3| + |e_{meas}| \tag{5}$$

$$\text{Residue, } q \le \text{threshold} = e_{mod}^{est} + e_{meas}^{est} \tag{6}$$

e_{mod}^{est} and e_{meas}^{est} are estimates of the upper bound for modeling errors and measurement errors, respectively. For quantifying threshold, e_{mod}^{est} has been assumed to have a value of $\pm 4\%$ (from finite element simulations) and e_{meas}^{est} was taken (liberally) to be only the precision of the sensor [12]. This is identification order 2 in Table 1. For identification order 2, it is assumed that all candidate models can be generated exhaustively.

4 PROBABILISTIC SUPPORT

While there has been much work on statistics and structural identification [18–20], it is of interest to examine the reliability of structural identification

explicitly. This is done by determining the probability that the correct model is present in the set of candidate models. Absolute reliability (100%) requires that (i) all possible models be considered in the set of models, (ii) there are sufficient measurement data to filter out wrong models, and (iii) all errors are zero.

Estimating the reliability of structural identification involves calculation of a threshold range of errors given a statistical tolerance limit. Many structures can be evaluated using the assumption that, through use of good stochastic search algorithms and high tolerance limits, all possible candidate models are generated. Another assumption made is that enough measurement data is available to filter out wrong models. When these assumptions are not possible, evaluations of reliability that are described in this section provide upper-bound values.

The formulation described earlier for evaluating candidate models is improved by combining errors using statistical methods [21]. In this section, errors are no longer considered to be ranges. Instead, they are values having a statistical distribution. Modeling error e_1 is difficult to quantify. It is problem dependent and can be minimized using intuition and judgment along with modeling expertise [14]. Assuming an ideal situation, $e_1 = 0$. It is assumed that all other errors follow a normal distribution.

Consider x^i_{meas} as the measured value at the ith measurement location and e^i_{meas} as the measurement error at that location. Similarly, x^i_{pred} is the predicted value at the ith measurement location, and ($e^i_{\text{pred}} = e_1 + e_2 + e_3$) is the total modeling error. In the absence of errors, predictions from a candidate model exactly match the measurements. Since errors are present, this is represented in mathematical terms as

$$x^i_{\text{meas}} + e^i_{\text{meas}} = x^i_{\text{pred}} + e^i_{\text{pred}} \tag{7}$$

$$\Delta x^i = x^i_{\text{meas}} - x^i_{\text{pred}} = e^i_{\text{pred}} - e^i_{\text{meas}} \tag{8}$$

Modeling error is defined by a variable e_{pred} with mean μ_{pred} and standard deviation σ_{pred}, and measurement error is defined by a variable e_{meas} with mean μ_{meas} and standard deviation σ_{meas}. Assume that e_{pred} remains the same for one modeling problem. Since values of measurement error depend on sensor type and location characteristics, e_{meas} changes for each measurement location. Many quantities of engineering interest that are not extreme loads generally follow the normal distribution [22]. Assuming both e_{pred} and e_{meas} to be Gaussian distributions, the combined error is defined by a cumulative distribution function Z with mean μ_z and standard deviation σ_z, such that

$$\mu_z = \mu_{\text{pred}} - \mu_{\text{meas}} \tag{9}$$

$$\sigma_z = \sqrt{\sigma^2_{\text{pred}} + \sigma^2_{\text{meas}}} \tag{10}$$

Following from equation (9), the threshold values for a certain reliability of identification (p_{reqd}) are given by

$$r^i_1 \le \left(x^i_{\text{meas}} - x^i_{\text{pred}}\right) \le r^i_2 \tag{11}$$

such that

$$P\left(r^i_1 \le Z \le r^i_2\right) = p_{\text{reqd}} \tag{12}$$

and

$$r_1 = \mu_z - c \quad \text{and} \quad r_2 = \mu_z + c \tag{13}$$

where c is the value that is determined from the required statistical tolerance limit, p_{reqd}.

A function f_i is defined as

$$f_i = \begin{cases} 0 & \text{if} \quad r^i_1 \le \Delta x^i \le r^i_2 \\ \left(\Delta x^i - r^i_1\right)^2 & \text{if} \quad \Delta x^i < r^i_1 \\ \left(\Delta x^i - r^i_2\right)^2 & \text{if} \quad \Delta x^i > r^i_2 \end{cases} \tag{14}$$

where superscript i refers to the ith measurement location.

The new objective function is then defined as

$$E = \sqrt{\sum_1^n \frac{f_i}{n}} = 0 \tag{15}$$

Equation (15) is used to generate candidate models. Differences between measurements and predictions at measurement locations are thus compared with threshold values. The new objective function, E, includes values of errors at each measurement location and provides a probabilistic basis for the reliability of candidate models. This is identification order 3 in Table 1.

5 DATA MINING

Data-mining methods, such as clustering techniques, aid in eliminating incorrect models from candidate model sets and thus they contribute to rapid convergence to the correct model. Integration of data-mining methods is classified as identification order 4 in Table 1. An example of a methodology [23] that combines principal component analysis (PCA) [24] and K-means clustering [25] is used for illustration below.

5.1 Principal component analysis (PCA)

PCA is a method for linearly transforming data in parameter space to a new and uncorrelated feature space [24]. In the machine-learning community, PCA is usually used as a preprocessing technique, for example, before supervised learning. PCA is also used for visualization. It is difficult to visualize clusters when clustering techniques such as K-means are applied to model sets of dimensionality greater than three. PCA finds a set of principal components (PCs) that are sorted such that the first few components explain most of the variability in the model sets. By plotting the first two PCs instead of two randomly chosen parameters, clusters are easier to visualize.

The first step in evaluating the PCs of a data set is the construction of the covariance matrix $\boldsymbol{S}$. The formula for evaluating $\boldsymbol{S}$ is given below.

$$\boldsymbol{S}_{ij} = \mathrm{cov}(x, y) = \sum_{k=1}^{N} \left(x_k - \overline{x}\right)\left(y_k - \overline{y}\right) \qquad (16)$$

$\boldsymbol{S}_{ij}$ represents element at the ith row and jth column of $\boldsymbol{S}$. x and y are the ith and jth parameter and $\overline{x}$ and $\overline{y}$ are their respective means. N is the number of samples. After constructing $\boldsymbol{S}$, its eigenvectors and eigenvalues are found (details are in [24]). The PCs are obtained through sorting eigenvectors in decreasing order of their eigenvalues.

5.2 K-means clustering

K-means [25] is a widely used clustering algorithm that is simple to understand and implement. However, it is useful only when applied and interpreted correctly. The K-means algorithm divides the data into K clusters according to a given distance measure. Although the Euclidean distance is often chosen as the distance measure, other metrics may be more appropriate in certain cases. The algorithm iterates over K clusters to minimize their intracluster distances, shown as the measure J in equation (17):

$$J = \sum_{j=1}^{K} \sum_{x_i \in D_j} \left\| x_i - c_j \right\|^2 \qquad (17)$$

K is the number of clusters, x_i is the ith data point, and c_j is the centroid of jth cluster D_j. The K starting centroids are chosen randomly among all data points. The data set is then partitioned according to the minimum squared distance J. The cluster centers are updated by computing the mean of the points belonging to the clusters. The process of partitioning and updating is repeated until a stopping criterion is reached. The stopping criterion is attained if there is no significant change in the values of c_j or J in equation (17) over two consecutive iterations of the algorithm.

The methodology for grouping models into clusters combines PCA and K-means. Model sets in parameter space are transformed using PCA into an uncorrelated feature space. Next the best number of clusters is estimated using a score function [26]. Once the number of clusters is known, K-means algorithm is applied to the data in feature space.

5.3 Clustering for system identification

The goal of multimodel structural identification is to filter out incorrect candidate models in order to converge to the correct model. Additional measurement locations that produce data, which lead to efficient filtering, are found using cluster information. Figure 2 shows a flowchart with the methodology for system identification assuming that there are several monitoring and interpretation cycles [27]. Engineers provide the structural modeling assumptions that define the parameter set.

The next step, *model generation*, involves creation of a set of candidate models using stochastic search. Measurements, a set of model parameters, and an

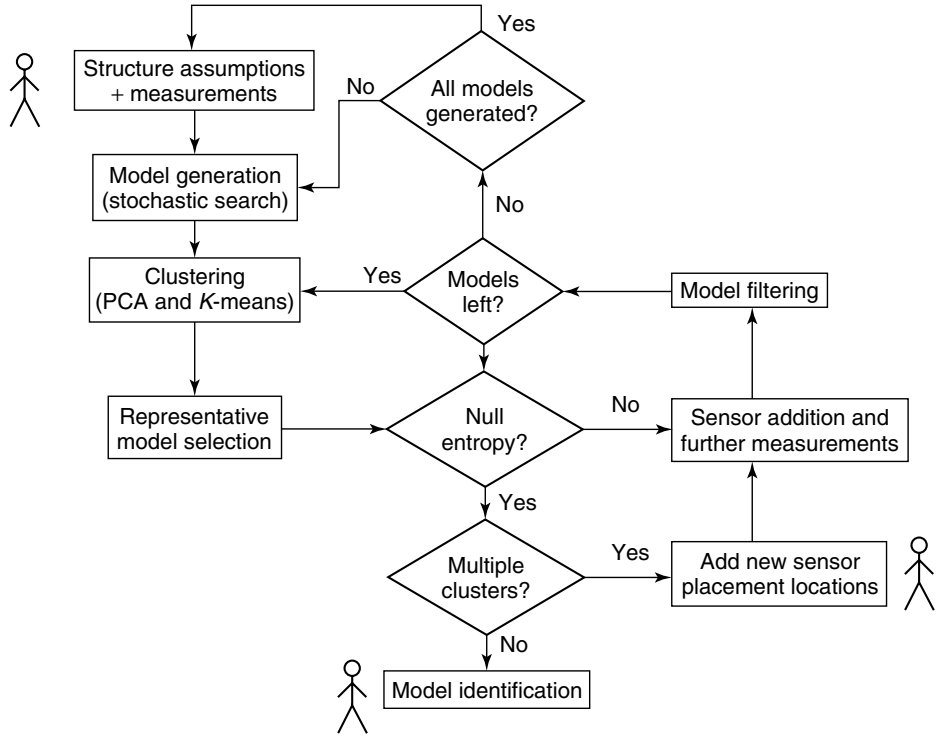

Figure 2. Flowchart showing an example of identification order 4. The human icon means that user interaction is required.

objective function that defines candidate models are needed to generate the set of candidate models.

Once the models have been generated, a clustering algorithm is used to group models through analysis of model predictions. Models are grouped into clusters to (i) facilitate visualization of the model space and (ii) reduce the number of models given to the engineer (the centroid of the cluster is a possible representative model for the entire cluster). Visualization of clusters is improved through the use of PCA. As described earlier, PCA is first applied to models before the K-means algorithm is used.

In the *representative model selection* step, a few models representing each cluster are selected. Only models that are close to the center of the cluster are selected. In this study, 5% of the total number of models in each cluster are taken to be representative models.

After clustering, entropy [28–30] is used as a measure of model separability to identify the next measurement location. Entropy H_s of model sets at measurement location s is given by the following equation:

$$H_s = -\sum_i P_i \cdot \log_2 P_i \tag{18}$$

P_i is the probability of the ith interval in the prediction distribution at location s. P_i is calculated as the ratio between the number of models that have predictions within the ith interval and the total number of models. If model sets have high values of entropy, more candidate models can be filtered.

Additional sensors provide further measurement data. If the entropy of predictions is zero at all measurement locations, data are checked for multiple clusters. If there is evidence of multiple clusters, the current set of measurement locations is incapable of further filtering models. At this point, the engineer needs to provide other measurement types and locations to find the correct model. If there is only one cluster and the entropy is zero, the center of remaining models is given to the engineer as the correct model for the structure (*model identification* step).

During the *sensor addition and further measurements* step, the entropies of predictions of selected representative models are used to find the best position for the next sensor. The location with the highest entropy is chosen. Further measurement of the structure follows.

In the *model filtering step*, sensor measurement at the new location is compared for every candidate model. Candidate models that do not predict the measurement are eliminated from the current set of models. If models are left, then the next step is *clustering*. However, if no models are left, then it is likely that all candidate models are not yet generated by the model generation module. While it may be possible to generate all models for a simple problem at first, it may be difficult to generate all possible candidate models in a complex structure. In this case, the *model generation* phase is revisited. On the other hand, if all models have been generated, then some assumptions related to modeling the structure could be incorrect. Therefore, *structure assumptions* have to be checked and modified by the engineer.

6 SUPPORT FOR DECISIONS RELATED TO FURTHER MEASUREMENT

The activity of filtering candidate models provides opportunities for systematic and rational decision making related to further measurement. In this context, measurement activities can be seen as a way to reduce the number of candidate models to unity. In the last column in Table 1 a qualitative measure of this support is given for each order. If the number of candidate models is small, there is only weak support for choosing what and where to measure next. This support becomes fair when many tens of candidate models are under consideration (orders 2 and 3) [30] and strong when clustering is used in a general framework (order 4) as described in the previous section.

7 CHALLENGES

Technological advances over the past decade have shifted the focus of challenges in structural health monitoring to subfields of structural identification. Challenges have been discussed by Aktan [31] for modal analysis. Taking a more general view, modern challenges related to all types of structural identification are as follows:

- Data management and interpretation (not sensor and computing technologies) have become the dominant causes of the structural-identification bottleneck.
- Measurement interpretation is an inverse engineering task that may have many possible solutions. While models used at the design stage are usually appropriate for design, they are rarely useful for interpreting measurements on existing structures.
- The presence of errors in modeling and in measurements further increases the number of possible solutions. Single-value optimization methods, traditionally used in model updating strategies, are often inappropriate.
- Engineers lack a generally accepted and systematic methodology for selecting sensor type, quantity, accuracy, and position.
- When confronted with decision making related to interpreting and filtering multiple candidate models, engineers can be overwhelmed by the complexity of coping with large decision spaces.

While recent results, such as those reported in the papers listed in the References section, have made progress, these challenges require important long-term multidisciplinary efforts before nonspecialists are able to benefit from the new methodologies that are used in the higher identification orders.

8 CONCLUSIONS

Management of complex civil engineering structures is supported by multiple-model structural identification. Five identification orders classify methodologies. Engineers should select the most appropriate order according to their resources and the levels of decision support that are required for specific infrastructure-management tasks.

Chapter 131

Construction Process Monitoring at the New Berlin Main Station

Rosemarie Helmerich

Division VIII.2 Non-destructive Damage Assessment and Environmental Measurement Methods, BAM Federal Institute for Materials Research and Testing, Berlin, Germany

1 INTRODUCTION

The six dead-end train stations of the first railway concept in Berlin, developed in the nineteenth century, were almost completely destroyed in World War II (Figure 1). The Lehrter Bahnhof, covered by a true arch roof, being one of the six dead-end railway stations, was destroyed too. After the reunification of Germany and the city of Berlin, the German railways (DB AG) developed a new concept with the New Berlin Main Station as a crossing of trans-European high-speed trains. The optimum location for a main station in the city center was found to be near the suburban train station Lehrter Bahnhof, which was rebuilt after the war.

The architects Gerkan, Marg, and partners from Hamburg developed the architectural design for this most modern and large train station. Professor Schlaich, Bergermann, and partners from Stuttgart are responsible for the structural analysis and design.

In the center of Berlin, the new main station with a wide-spanning modern glass roof has been under construction since 2001 (Figure 2). In 2006, the station was taken into service as an important high-speed train crossing of the two international train corridors from Paris to Moscow and from Rome to Stockholm. The German railways, DB Station and Service AG, represented by DB Projektbau, owned the structure during construction.

1.1 Description of the structure

The New Berlin Main Station is a complex structure. The supports of the interesting glass roof do not lead the load directly to foundations and soil, but use other static systems as the viaducts carrying platforms and tracks. The whole bridge viaduct has a length of about 680 m, and the width of the tracks in the station varies between 33 and 68 m [1]. Two of four reinforced concrete viaducts, carrying the east–west

Figure 2. New modern main station Lehrter Bahnhof with flat glass arch roofs during construction in 2003.

directed tracks for the international railway traffic, support the relatively flat glass roof that is up to 60 m wide. The railway station is located in a curve. That is the reason that each of the almost 8000 glass plates has a different geometry.

Partially prestressed concrete bridges in the east–west viaduct are crossing the north–south international passenger train line and have a larger span compared with the other bridges of the station. The prestressed concrete bridges carry the platforms with spans of 18, 21 and 18 meters. The platforms for the north–south and underground line are at about 15 m below the ground level. The partly prestressed, very slender massive concrete bridges of the east–west viaduct are at about 10 m above the ground level. To get sunlight to the underground level, the view through the central station from the top level to the bottom platforms is open, without any through floors. For this reason, 23-m-high steel columns carry the massive prestressed east–west concrete bridges. The steel columns are composed of four single tubes each and form a fork-shaped support for the partly prestressed concrete bridges at their tops.

1.2 Monitoring needs

The steel structure of the glass roof was calculated following the rules of the German national standards DIN 18 800 using partial safety factors according to the modern concept with limit states [1]. During the 1990s, the calculation of the massive concrete bridges followed the rules of the former edition of the German railway standards. The railways still use the concept with allowable stresses and global safety factors. In the level of the supports, a safety factor was applied to compensate for any shortfall in the different safety concepts, the traditional calculation of the concrete superstructure below this level, and the calculation of the glass roof above that followed the new limit states concept. Although additional adapting factors were introduced by the steel specialists at the Technical University Aachen, the Federal supervising authorities for German railways (Eisenbahnbundesamt) required a monitoring system to follow differential displacements between neighboring glass roof supports along the sensitive outer bridges. According to these requirements, the vertical level of the structure must not alter between adjacent glass roof supports by more than 10 mm. A monitoring system should survey the limits of differential vertical displacements. A geometric benchmark system shall be connected to the ends of the monitoring system to have a link between the absolute vertical level and relative displacement data.

2 MONITORING CONCEPT

2.1 State of the art

Monitoring of critical parameters, mainly referred to as *structural health monitoring*, originates from

the airplane and space industries. Continuous data acquisition of critical parameters allows survey of critical areas during changing loading conditions. On-line data availability gives early warning if the data exceed limits to providers of the systems or to the owners. In the late 1990s, it was quite a new concept to apply these ideas to displacements and strains of structures in civil and infrastructure engineering. Furthermore, appropriate long-term stable sensors were not available for all complicated tasks. Sensor development and data acquisition systems are quite cost intensive. Advanced sensor development, but as simple as possible, makes the idea of continuous survey affordable to their application in civil engineering structures. Finally, on-line monitoring for display of data to researchers and owners of the structure was a completely new and higher level of structural survey [2].

2.2 The objective of the monitoring system

A group of scientists at the Federal Institute for Materials Research and Testing, Berlin, BAM, developed a concept for a continuous monitoring system to quickly measure the most relevant data needed for a reliable interpretation of possible changes in the structural condition during construction[2]. The aim was to obtain immediate on-line information about significant differences of displacements and strains in chosen cross sections. The significant period for monitoring was the construction process until the opening of the station in 2006. During the construction process—different load cases from excavation, flooding of the excavated pit, erecting of new structural parts, and dismantling of old structures in the neighborhood—the different load cases cause a continuous change in the structural performance. In some cross sections, the changing loading conditions may cause critical performance scenarios. Therefore, the concrete was cast after the sensor cable tubes were already located in the scaffolding (Figure 3).

The following global load cases were expected:

- loading the steel columns after removing the scaffolding of the concrete bridges;
- surveying the changes during prestressing process in the middle bridges;

Figure 3. The cable tubes for the sensors were fixed in the structure before the concrete (see arrow).

- unloading the immediate vicinity due to dismantling the old suburban train viaduct;
- unloading the surrounding by excavating the north–south tunnel;
- loading the surrounding by flooding the excavation pit with ground water;
- loading the surrounding by casting foundations for the underground track in the north–south tunnel;
- unloading the ground beside the viaducts by removing the ground water;
- completing the track on the bridges and in the underground level;
- completing the framing of buildings.

The function of the chosen measurement system and its long-term stability are contemporarily verified and validated in laboratory monitoring on beams with comparable loading conditions. The information is made available in real time, using the Internet. The Internet collects data of both the sites, at the station and in the laboratory. The software design was specified and developed for this application at BAM.

2.3 Data handling and data transfer

Both the systems, model beams in the laboratory and the sensors at the station, deliver all data also to the central computer, located at the Federal Institute for materials research and testing. Scheme for data acquisition, preprocessing, and transfer is shown in Figure 4. The fiber-optic sensors use the commercial data acquisition amplification and processing. All the other sensors are connected to an amplifier "centipede" (Hottinger) and have a different time basis. Both the systems are connected to the local

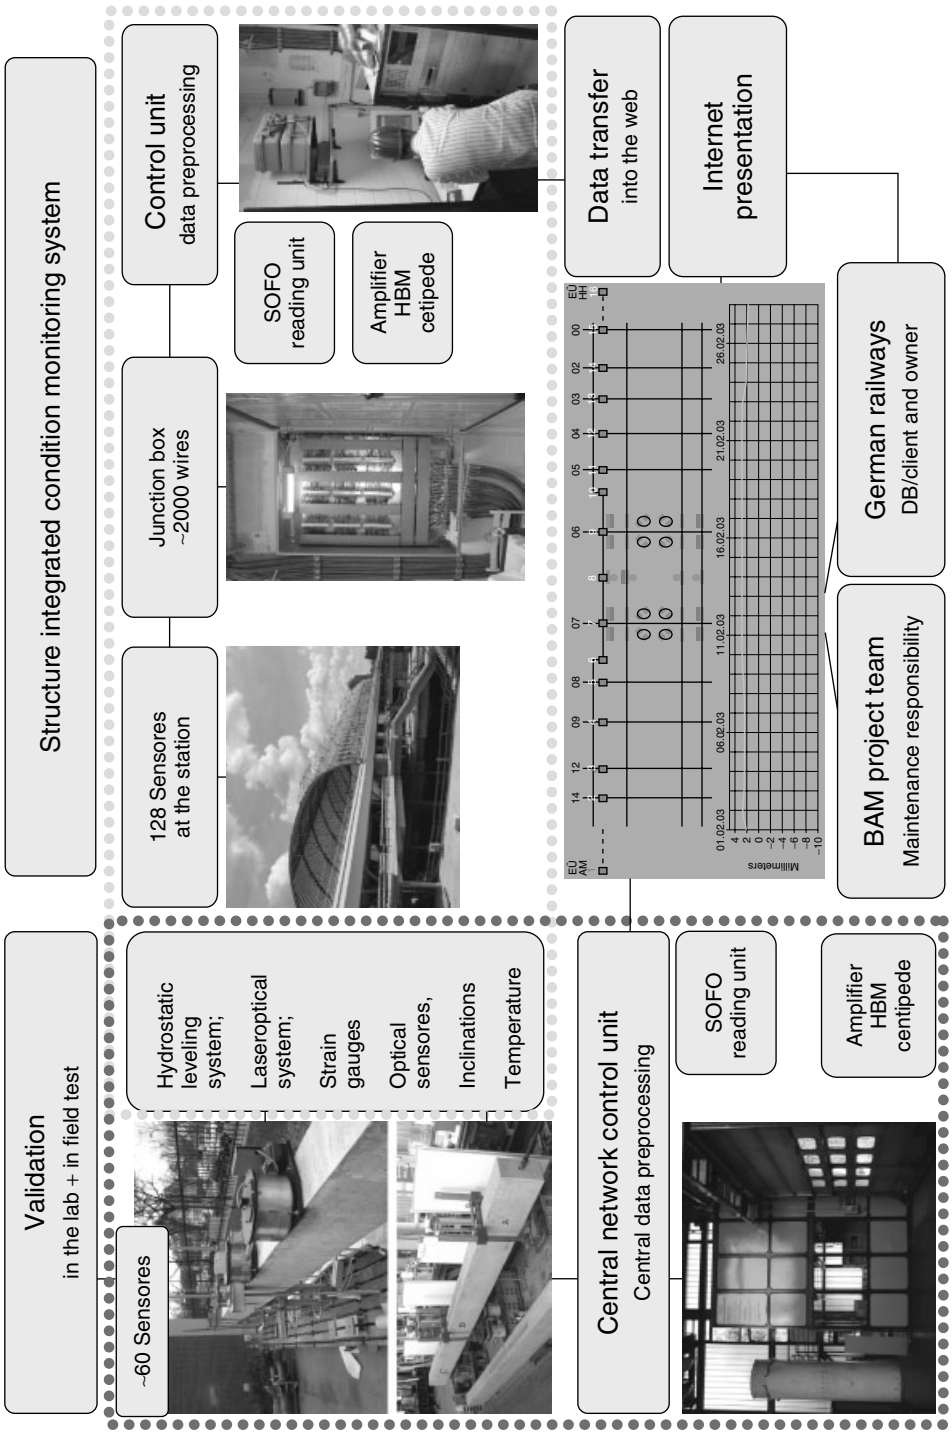

Figure 4. Scheme of the data acquisition, preprocessing, transfer via Internet, and accessibility of the webpage to researchers and end users.

computer and after processing to a unified Internet representation. For central data processing and maintenance of the monitoring system, a central network control unit was arranged at BAM in cooperation with the Engineering laboratory. The central network control unit was the local junction box for the model beams, one located in the laboratory and the other outside the building under environmental conditions. For more information about the model beams, see [3].

2.4 Monitoring system

The continuous survey of vertical movements, strains, inclinations, and temperatures makes it possible to react very fast on early warnings to avoid possible damage. A procedure was proposed to the Federal railway authorities on how to react with corrective decisions and measures in time, i.e., raising or lowering the bridges at supporting points, depending on measurement results. Geodetic measurement of vertical displacements at the supports of the glass roof and at the head of the columns cannot be repeated at sufficiently short intervals owing to the time-consuming procedure and limited accessibility of measurement points [4]. The monitoring system consists of two main elements, installed on both the places, as well at the new main station as in the laboratory beams, to validate the function of the system:

1. monitoring of the vertical displacement at the supports of the glass roof and on the prestressed middle bridge (Figure 5);
2. strain measurement in the partial prestressed outer bridges in the structure of the main crossing (Figure 6).

Figure 5. View of the monitored bridge of the main station during the construction phase. dark: laser displacement sensors; white: hydrostatic leveling system.

As the Federal railway authority required, a redundant strain measurement system, including interference-free fiber-optic sensors, for the monitoring of the partly prestressed bridges at least during the construction period of about 5 years is needed.

The data were collected together with temperature as the environmental parameter, which has an influence on the system. About 2000 single wires in cables are collected in hollow tubes, hidden in the concrete structure, and lead to junction box in a central room at the station. All components of the equipment, such as the electric distributing switchboard and the main computer for data acquisition, are located in the central unit at the station.

The long-term control of changes in the structure was made possible from the beginning of the construction period in 2002. Initially, data were taken manually, before the communication system started working reliably. The positions of sensors in

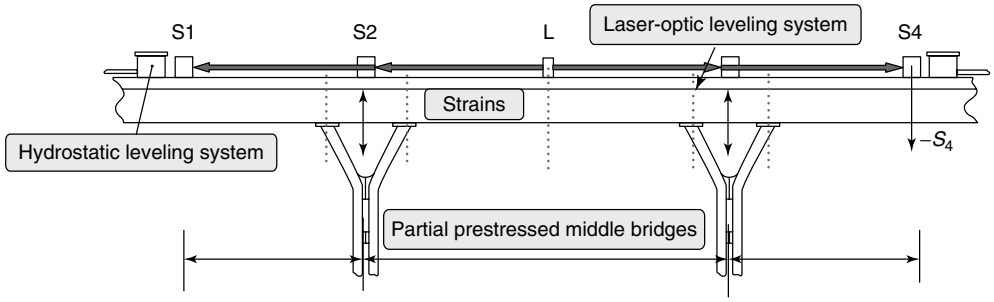

Figure 6. Strain measurement in the partial prestressed bridges and sketch of the measurement system for vertical displacements consisting of laser displacement and hydrostatic leveling components. [Reproduced with permission from Harald Kohlhoff.]

the partial prestressed middle bridges were already prepared during sheeting of the concrete construction to minimize the risk for the structures during construction and demolishing work in the vicinity of the building.

To restrict the number of sensors at the station, it was decided to monitor only the two outer bridges that have additional static loading from the roof structure. To get as much reliable and redundant information as possible, different types of sensors were installed.

2.5 The basic elements and types of sensors

The concept of the field test consists of 128 sensors. Table 1 gives an overview on the sensor types, their location, and measurement uncertainty.

To increase the redundancy of the strain measurement data, different sensor types were installed. The concrete strain measurement—only in the partial prestressed bridges—is performed by means of electric strain gauges, fiber-optic sensors, and mechanic contact strain measurement (type Pfender, BAM). Figure 6 shows the cross sections with strain monitoring in the middle and at the supports.

Contact strain measurement delivered absolute elongation (strain) data in the first phase of monitoring. Unfortunately, the measurement points were removed during the following completion works by sandblasting. Figure 7 shows the cross sections with the strain measurement in the prestressed bridges 12 and 15.

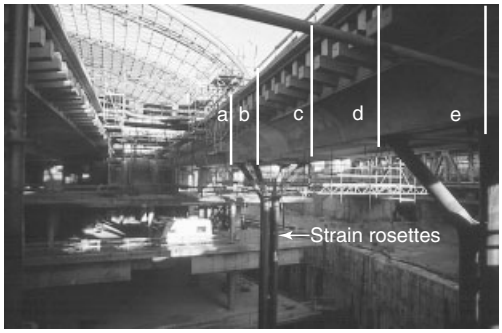

Figure 7. Cross sections with strain measurement points in the prestressed middle bridge and in the upper part of the steel columns. Sensors a–e: fiber-optic sensors and electric strain gauges. [Reproduced with permission from Ref. 5. © IABSE, 2003.]

3 MEASUREMENT SYSTEMS AND ADVANCED SENSORS

3.1 Strain measurement

Strains are measured in

- five cross sections of the partly prestressed middle bridges (north and south) to get information about the near-surface strains, nonsymmetric movement, and/or inclination;

Table 1. Sensors, their location, and measurement uncertainty

Type of sensor	Number	Location	Measurement uncertainty
Strain gauges	40	Bridges 12 and 15	$\pm 3\,\mu m\,m^{-1}$
Fiber-optical sensors		Bridges 12 and 15	
Strain gauge rosettes	16 (+16)	Columns under bridges 12 and 15	$\pm 3\,\mu m\,m^{-1}$
Hydrostatic leveling buoyancy cylinders	30 (+4)	North and south viaduct	Distance: approximately 500 m ±0.3 mm
Laser sensors	10	Bridges 12 and 15	Measurement range ±40 mm ±0.2 mm and add. ±0.1 per 10-m beam length
Temperature sensors	12	North and south viaducts	±0.2 K
Inclination sensors	10	North and south viaducts	Measurement range $\pm 3^{\circ}$ $\pm 0.03^{\circ}$

- the upper part of the steel columns to get information about moments and inclinations.

In the outer concrete bridges, in line with the bridges carrying the roof, fiber-optic sensors, electric strain gauges, and a mechanical strain measurement system (type Pfender) were installed. Since concrete may have local inhomogeneity or cracks, a comparison between locally measured strains by means of electric strain gauges with strain measurement on a longer base line is advisable. For this purpose, fiber-optic sensors are used. For comparability, strain gauges and fiber-optical sensors are located in the same slits and have the same gauging axis.

Like all other data, the strains are measured four times a day. For their near-surface position, the influence of temperature changes is expected to be relatively high compared to other influences as, e.g., symmetric traffic load. The system does not measure the strain distribution inside the massive concrete cross section since the number of sensors was limited.

3.1.1 Electric strain gauges

Prestressed concrete bridges

In five cross sections in the middle of the structure and at the supports of the steel columns, strain gauges (TML) are applied in slits. Electric strain gauges are embedded together with the fiber-optic sensors in slits, relatively close to the upper and lower surface in five cross sections of the prestressed bridges crossing the platforms of the north–south track. All slits were closed after all sensors were installed and the function was validated. Temperature influences the strains very much. In few measurement points, temperature sensors are applied together with the strain gauges.

Steel columns

Two ~25-m high steel columns, each composed of four single columns (see Figure 7), support the prestressed massive concrete bridges. In these cross sections at the supports above the "arms" of the composed steel columns, the maximum strain should occur (Figure 7). The composed steel columns have a hinge bearing on the ground level. Strain rosettes are positioned in the upper part to get information about the loading, inclination, and settlements. For temperature compensation, additional strain sensors were added to each pair of electric strain sensors perpendicular to their axis.

3.1.2 Fiber-optic sensors

Fiber-optic sensors have the advantage of not being sensitive to electromagnetic influences, e.g., from high-voltage cables. The applied, commercially available fiber-optic sensors (SOFO-Smartec) with a length of 0.50–3.50 m work on interferometer principle. In a tube two standard optical fibers are placed and, one of them, the sensing fiber, is fixed at defined points and the other, the interference fiber, is loosely placed in the tube. The second fiber is used to compensate for temperature influences. In real time, the measured data are collected, amplified, stored, and preprocessed by calculation included in the software package. The fiber-optic sensors are connected to a demodulator, which is a one-channel device using a multiplexer for multichannel operation. The fiber-optic sensors have their own time base in a separate receiver [4].

3.2 Vertical displacement measurement

3.2.1 Introduction

The vertical displacement measurement at the outer bridges 12 and 15 consists of 16 sensors each, in a chain of hydrostatic-leveling sensors in the arched sections and the laser-based vertical measurement above prestressed bridges crossing the north-south track. Figures 5 and 8 show the scheme for the location of the measurement points at the supports of the roof on the north and south bridges.

Changes in the vertical level between two neighboring supports should not exceed 1 cm. The relative displacement is measured continuously four times a day. In some places, inclinations perpendicular to the axle of the bridges and the temperature are measured. Geometrical imperfections resulting from displacements and inclinations cause additional loadings in the bridge structures. If the limit value would be attained, then a vertical lifting or lowering of the bridges is needed using the vertical adjustability mechanism.

In the middle part of the bridges between the two roofs, the architects denied installation of the relative huge hydrostatic cylinders for aesthetical reasons. Both the hydrostatic leveling system and the laser-based optical system are installed at the outer bridges and appear in the Internet presentation as one chain.

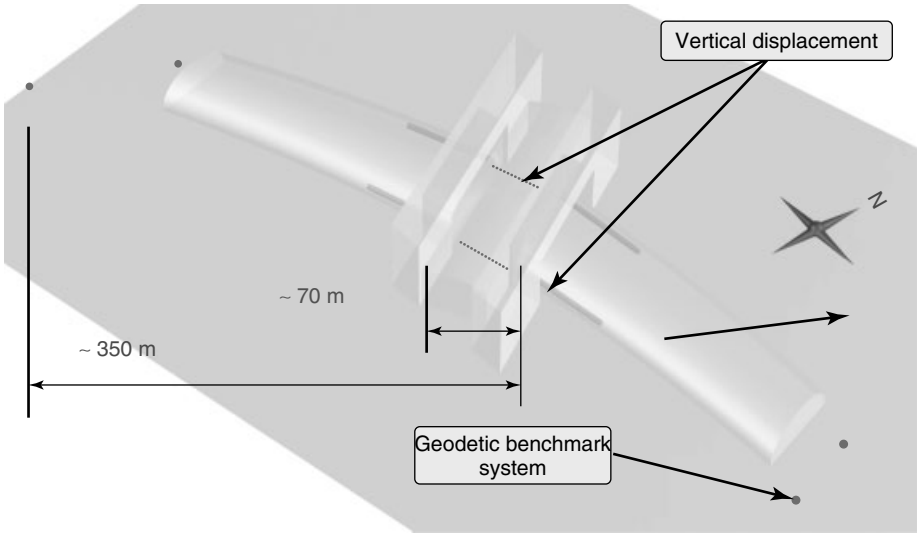

Figure 8. Length of the monitored supports of the outer bridges and connections to the geodetical benchmarks. [Reproduced with permission from Harald Kohlhoff.]

3.2.2 Laser-optic leveling system

On this place, the BAM combines the hydrostatic leveling with an elegant small laser-based sensor system. One laser source emits a vertical laser in the middle of the bridge. Prisms divide and switch the vertical laser beam into horizontal direction to the left and right side along the bridge axis. The widespread lasers meet laterally displaced photodiode chains. Each chain consists of 64 photodiodes; the activated diode is a measure for vertical displacement (Figure 9).

3.2.3 Hydrostatic leveling system

The traditional hydrostatic leveling was improved to obtain a long-term stable chain of sensors to reduce creep and drift of the force transducer. The principle of measuring the displacement of a buoyancy cylinder has been selected for avoiding measurement errors due to influences by partial heating of the sensors, e.g., if exposed to direct sunlight. Raising the liquid level by pumping liquid into the system permits the buoyancy body to separate from the force transducer, as well as checking the operation of the hydraulic system (Figure 10) [6]. This allows to obtain a zero-value in system maintenance. The hydrostatic leveling system automatically records the level of the liquid as a measure about relative vertical displacements. The data is measured as load cell. A benchmark point is connected to the hydrostatic leveling system within the next weeks. The connection to this "fix point" makes it possible to connect the relative settlements with a geodetic measurement, performed on behalf of the German railways (DB AG). The principle of the hydrostatic leveling system was improved to obtain long-term stability with regard to reducing creep and drift of the force transducer.

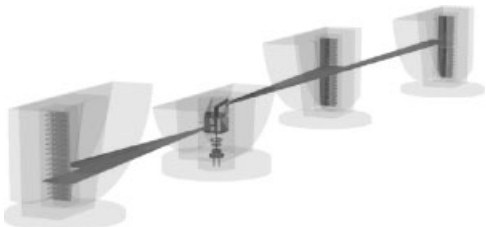

Figure 9. Laser measurement system upgraded by Knapp and Kohlhoff. [Reproduced with permission from Harald Kohlhoff.]

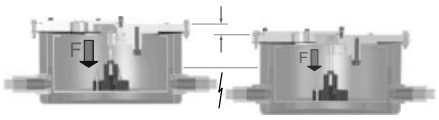

Figure 10. Hydrostatic leveling system type Kohlhoff (patent [7]). [Reproduced with permission from Ref. 7.]

3.3 Maintenance and long-term stability

The chains of hydrostatic sensors on both the bridges have been collecting data since May 2002. During that summer, the data was transferred periodically. Sensors used for construction monitoring must be robust. Construction work and finishing may damage sensors or cables. The ongoing construction work prevented the connection of the measurement points to fixed points. The continuous transfer of data for online presentation on the internet website was available from October 2002 (Figure 11).

During the 5 years of monitoring, the combined system for the vertical displacement, consisting of the hydrostatic leveling and the laser-based leveling system, was maintained several times. The advanced hydrostatic leveling allows to validate the measured data by pumping the fuel into an external pot. This procedure unloads the load cells, after which a real zero-value can be read. Alternatively, mechanical measurement of the fuel level is possible to compare the on-line with real data. In case of dysfunction, some of the sensors can be replaced by new ones. Others may be in non-accessible positions. During harsh conditions of construction processes, accidents can lead to disturbance of the measurement chain. Since the access is limited in the station that is in service, maintenance is almost impossible.

4 RESULTS

The monitoring system was installed before the beginning of the extreme loading conditions, during construction activities in the vicinity of the east–west viaduct.

In 2003, the trains were shifted from the old track to the new track through the new station. Before the first train was shifted, the German Railways made a proof load test, with measurements of displacements. It was possible to increase the data acquisition rate for the BAM monitoring system from only four data per measurement point to about 80 Hz to get information about the strains under traffic. Fiber-optical sensors and the leveling system were not used for these measurements, since the configuration for these systems was appropriate for long-term measurements with only a few data collected per day.

4.1 Relative settlements at the roof supports

The main objective of the monitoring system was controlling the differences between the displacement of neighboring roof supports. During demolition of the old station (Figure 12), excavation of the north–south tunnel, and flooding of the excavation pit (Figure 13), the east–west viaducts carrying the

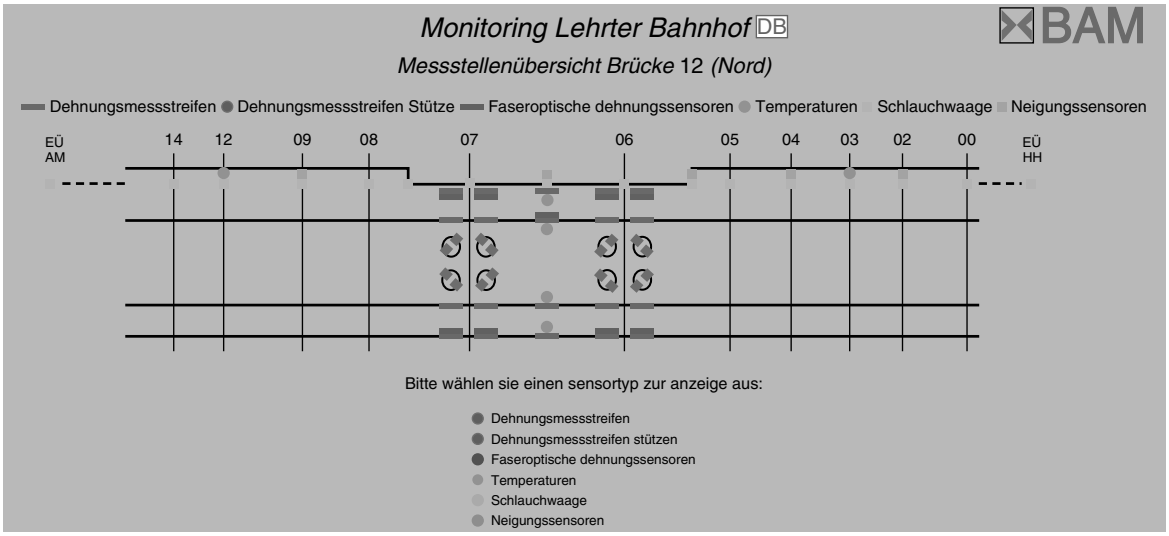

Figure 11. Website with the position of the sensors in the north bridge (bridge number 12).

glass roof were exposed to load differences. Figure 14 shows the differential in settlements and heaving with relative displacements during the loading and unloading phases in the vicinity of the station from May 2002 to July 2003. The positive result was, that over the whole construction, required displacement limits were not exceeded, not even in the year 2003, during the hectic period of dismantling of the old structure and excavating the north-south tunnel (Figure 13).

Figure 12. Load case: demolition of the old station.

Figure 13. Load case: flooding of the excavated pit with ground water.

Figure 15 shows the differences in relative vertical displacements between neighboring roof supports obtained from the chain of the hydrostatic leveling and laser-optic system, for 1 month, as an example. For this purpose, the relative displacement is compared to a mean value of all sensors, including both the leveling systems, by using data displayed from the website.

4.2 Strain measurement

The monitoring of strains is of special interest in partially prestressed bridges. As in the measurement of relative displacements, the measured data have been reliably collected, amplified, stored, and preprocessed by calculation in real time for 5 years. Although both the systems, the electric strain gauges and the fiber-optic sensors, have a different time basis, both the data sets are given in a unified Internet representation.

The analysis of data showed, e.g., in the first year a maximum strain difference of 585 μm. For a maximum temperature difference of 40 K, it results in a mean value of about $10\,\mu\mathrm{m\,m^{-1}\,K^{-1}}$ for the gradient.

The measured values are influenced by many factors, such as shrinking, creeping, nonlinear temperature distribution in the massive concrete cross section, and the fact that a real zero-value cannot be measured again.

The measurement began immediately after the structure was erected, partially prestressed, and the shrinkage was already in process. These values were estimated from calculation and from evaluation of the model beams. Figure 16 shows the course of strains measured with fiber-optic sensors in four points of the prestressed bridge no. 15 for 5 years. The curves with

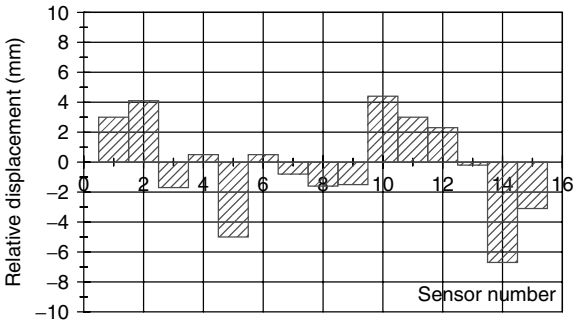

Figure 15. Example for relative displacements for 1 month in March 7, 2003 by means of the hydrostatic and laser measurement at the south bridge.

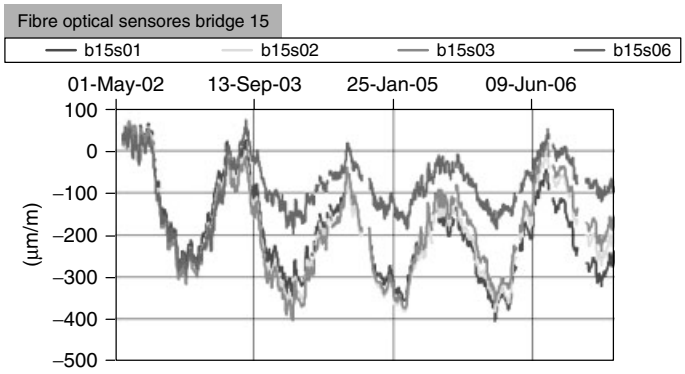

Figure 16. Continuous strain data measured with fiber-optical sensors for 5 years in the partial prestressed bridges. The compression during winter was lower since 2006 because the middle roof was closed and the temperature influence was reduced.

the daily midnight temperatures in three points of the same bridge show that the influence of temperature on the main strain is dominant (see Figure 17). Also it shows, of course, that the temperature and, as a result, also the strains did not reach the negative temperatures, as before. Two reasons are responsible for this result: the warm winter 2006/2007 and the finalizing of the roof. In 2006, the middle roof was built in such a way that the bridges are now located inside and are not exposed to harsh environmental conditions anymore. The strains are lower, which means the structure is safer.

4.3 Long-term stability and maintenance

Continuous control of the stable function of all sensors and the load cells is needed. During first year in service, only three sensors failed (less than 3%), a temperature sensor and two electric strain gauges. Since all slits with the strain sensors are closed, no access is possible anymore.

It can always happen during construction processes that scaffoldings destroy sensors or application of secondary elements hit a cable, e.g., by drilling. Repair and maintenance of systems of this logistic extend require experienced specialists. That is why the access to all sensors, especially to sensors for vertical displacement, is advisable. Reduced maintenance may affect the long-term stability and service of the monitoring system.

5 CONCLUSIONS AND OUTLOOK

The presented monitoring system at the Berlin Main station has been reliably working through all construction phases. The system provided continuous

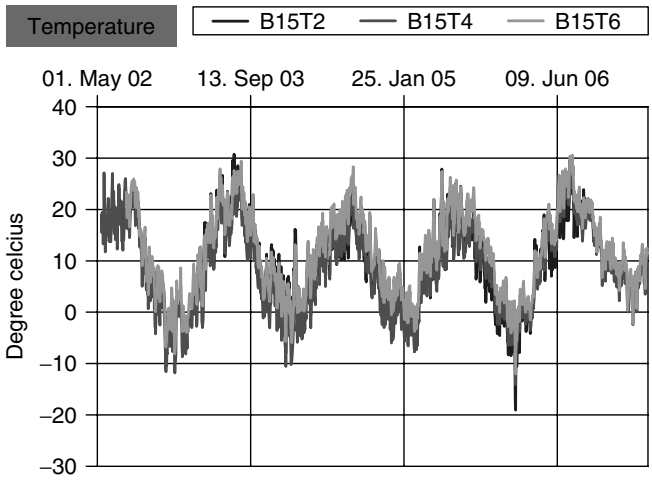

Figure 17. Continuous temperature measurement for 5 years (only midnight values).

on-line data for sensitive parameters of the glass roof. The limits, stated by the railway authorities, as for relative vertical displacements between neighboring glass roof supports, have not been exceeded. The sensors have been working stably for 5 years. The system needs continuous maintenance by experienced specialists.

Measured data are immediately preprocessed and have been presented on line via Internet. Thus, the researchers and the client, the German railways, DB AG, always have the opportunity to identify possible changes of critical parameters at any time.

ACKNOWLEDGMENTS

The German railways (DB) were financing this monitoring system. We thank DB for the confidence in the implementation of advanced techniques and new sensor prototypes, which have never been used before. We thank numerous colleagues from the Federal Institute for Materials Research and Testing, who carried out the research and enabled the realization of the project. We acknowledge especially Klaus Brandes and Wolfgang Habel, who developed the idea and concept to continuously monitor the construction process during all phases. Klaus-Dieter Werner designed and realized the software for the on-line data presentation, and Hans-Joachim Peschke cared for the data preprocessing and transfer. Without the upgraded sensors for the widespread multipoint laser measurement with several lateral displaced measurement points from Juergen Knapp and the patented hydrostatic leveling system by Harald Kohlhoff, the data would not have been so convincing. All systems worked reliably and stably. Joachim Niemann made continuous efforts to keep the system running for over more than 5 years.

Chapter 133
SHM of a Tall Building

James M. W. Brownjohn[1] and Tso-Chien Pan[2]

[1] *Department of Civil and Structural Engineering, University of Sheffield, Sheffield, UK*

1 INTRODUCTION AND CHRONOLOGY

Structural health monitoring (SHM) is frequently associated with damage detection, often using vibration-based techniques. In fact, damage detection represents only a fraction of the spectrum of SHM technologies, which as a whole comprise characterization of structural performance through response measurements, with the aim of learning about the structure *and* the loads that drive it. Misunderstanding the nature of loads on a structure is often a cause of structural "failure"; examples include unstable behavior of bridges due to wind or pedestrian loads, scour of bridge piers, and various forms of seismic-induced structural failure. Hence, SHM focused on characterizing loads is highly relevant, particularly if it can be used to feed information on loading characteristics back into future designs. That is the philosophy of the exercise reported here, in which a new tall building was monitored with the principal aim of providing information on the unknown characteristics of loading.

Singapore is not known for strong winds, nor is it in a seismic area. However, powerful storms have been known to remove aircraft hanger roofs and flip shipping containers over, while the most powerful earthquakes on the planet occur within a few hundred kilometers of a vulnerable financial center that has seen rapid growth in construction of high-rise structures. Local design codes borrowed from the United Kingdom have little relevance yet there is no better guidance, and hence the need to

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

provide information about wind and seismic loads by monitoring performance of a tall building.

In 1993, Shimizu Corporation instrumented the 18th story of a new 65-story 280-m office tower under construction in Singapore with an array of stress and strain gauges and hired Nanyang Technological University researchers to report on the instrument readings. Given the access to the structure, it was also possible to use a simple acceleration recorder to track the parameters of the two lateral fundamental modes of vibration during construction.

When the building was completed but unoccupied at the end of 1995, a full-scale vibration survey with four high-resolution accelerometers was conducted. The results of the operational modal analysis on the data were used to update a finite element model of the structure for interpreting future performance data.

In 1996, a monitoring system was installed, comprising biaxial accelerometers at the basement and roof levels (total of four channels) as well as a pair of anemometers perched on the building parapet.

For several years, the system recorded wind and vibration response, including data on major seismic events in neighboring Indonesia and on the different classes of wind loading. In order to resolve questions about the mixture of static and dynamic response of the building under local wind conditions, a pair of global positioning system (GPS) antennae was installed in order to identify absolute wind-induced displacements.

The system operated until 2005, and since the most useful data obtained concerned seismic response, a simpler four-channel acceleration recording system was installed later. Performance data obtained from the system operation up to 2005 have been useful for preliminary developments of locally oriented design guidance for wind and seismic loads.

2 BUILDING CONFIGURATION

Figure 1 shows a perspective view of the Republic Plaza building, and Figure 2 shows a typical cross section at story 18. The structure is built around a reinforced concrete (RC) central core with almost a square profile of side 22 m that extends for the full height of the building. The perimeter of the building, occupying a 45-m square footprint, comprises 16 steel tube columns around 1-m diameter that connect with the core via a horizontal framing system and are concrete-filled up to the 49th story.

Figure 1. Perspective view of completed building.

Two double-story mechanical equipment floors are located at storys 28 and 47, where the building profile tapers and outriggers are installed for controlling wind-induced drift. Apparent axes of symmetry, labeled A and B in the horizontal and vertical axes of Figure 2, are used for reference in describing the performance measurements.

The whole structure sits on a very rigid foundation system that includes caissons founded up to a depth of 62 m in marine (boulder) clay.

3 TRACKING NATURAL FREQUENCIES DURING CONSTRUCTION AND AMBIENT VIBRATION SURVEY

During the latter period of building construction from June 1994, a portable acceleration recorder was used

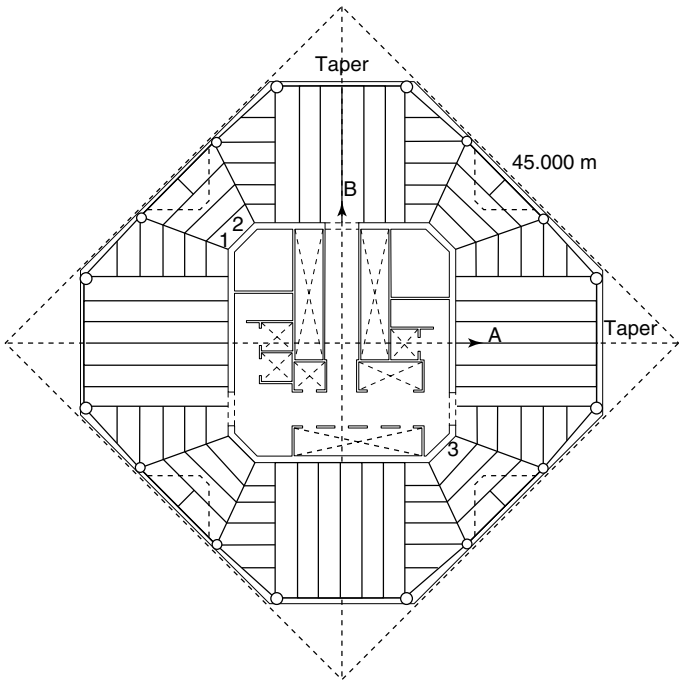

Figure 2. Typical cross section at story 18. Coordinate system for measurements is labeled A and B.

to record horizontal accelerations in the natural A and B axes at the same time as static stress and strain gauges were read. Pairs of first-mode frequency values were obtained from curve fitting to autospectra of the signals showing doubling of both periods up to the point at the end of 1995 when a formal ambient vibration survey (AVS) [1] was undertaken.

The variation, during construction, of period for fundamental modes in each direction, i.e., A1 and B1 is shown in Figure 3 together with mass (above story 18) and construction progress, as indicated by highest story of completed office slab. It is clear that while direction B developed into the stiffer of the two directions, due to structural arrangements inside the core wall, frequencies were originally identical.

The procedure for the AVS in late 1995 involved estimating frequency and damping values by fitting curves of single degree of freedom oscillator response functions around autopower spectral peaks for many data sets acquired over 5 days of measurements at different locations in the building. Then phase angles and amplitudes of cross-power spectra of rooftop response were compared with the response at every second floor level down to the basement at the

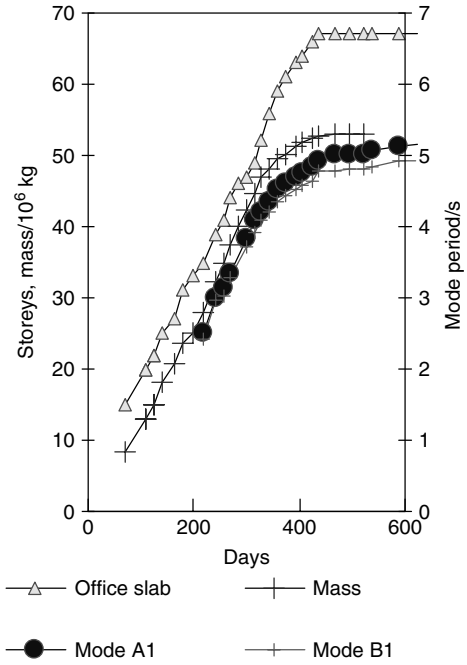

Figure 3. Variation of fundamental mode periods during construction.

estimated modal frequencies to map out mode shapes (in fact operating deflection shapes).

The measurements showed that modes did not divide exactly into the natural A and B directions, rather that the principal axes of movement were rotated unknown angles with respect to these obvious symmetry axes. Also, there was evidence of significant torsional response even in the translational modes, so a set of four measurements were made, one at each of storys 18, 32, 46, and 65, to identify the unknown angles and mode shapes in horizontal planes using an arrangement of the set of four accelerometers.

A complete set of 12 modes was identified. Modes are numbered A1 through A4 for modes aligned closest to the A direction, B1 through B4 for modes aligned closest to the B direction, and T1 through T4 for modes of almost pure torsion. Modes A1, A2, A3, and T1 are illustrated in Figure 4 together with an autospectrum of A-direction story 65 acceleration obtained during the AVS. The modal parameter estimates are given in Table 1 from the AVS as well as from a period in early 1997 when the building was occupied.

The modal survey data were subsequently used for validating a finite element model constructed

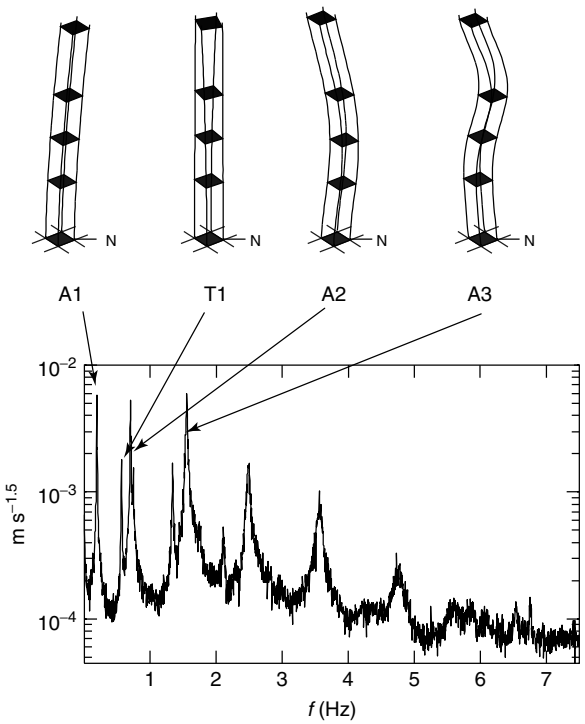

Figure 4. Vibration autospectra at story 65 and measured modes.

Table 1. Modal parameters for Republic Plaza: unoccupied in 1995, occupied in 1997

A mode	Frequency (Hz)		ζ (%)	B mode	Frequency (Hz)		ζ (%)	T mode	Frequency (Hz)		ζ (%)
	1995	1997	1997		1995	1997	1997		1995	1997	1997
A1	0.192	0.184	0.66	B1	0.201	0.194	0.70	T1	0.564	0.528	0.53
A2	0.702	0.676	0.85	B2	0.749	0.726	0.52	T2	1.341	1.258	1.25

using the SAP2000 finite element code [2] by comparing predicted and measured characteristics and carrying out systematic modifications of the model.

4 WIND AND ACCELERATION RECORDING SYSTEM

Long-term monitoring of Republic Plaza followed the experience with a wind and acceleration response recording system installed previously in a 26-story apartment block in Singapore [3] that operated until the end of 1995, when the equipment was removed for use in the Republic Plaza AVS. This preliminary study of the apartment block provided strong evidence that earthquakes occurring in Indonesia were inducing significant and alarming but (so far) nondestructive vibration response in residential structures in Singapore. Because the purpose was to study wind-induced response, the ground motions could only be inferred from the recorded rooftop response. The Republic Plaza study provided the opportunity to record foundation level acceleration measurements using cables installed during construction. Thus, it was intended that over the long term, synchronous roof and foundation level acceleration recordings could be used to capture ground motions and their effects on the building.

Hence, from October 1996 until January 2005, acceleration signals were recorded and analyzed with a few interruptions due to hardware issues. Initially, two accelerometers were used and while a second pair was being procured the two-channel system was left to record continuously for 2 weeks. The aim was to check expected response levels for optimizing system dynamic range, but during the 2 weeks the response due to a strong (Ms6.3) Indonesian earthquake at a relatively close epicentral distance of 700 km was recorded, being the first recorded time series of building structural response in Singapore.

Sensitive quartz-flexure force-balance accelerometers having noise threshold as low as 1 μg were used. Acceleration signals were digitized with a 12-bit analog-to-digital converters and saved in frames of 4096 samples acquired at 7.5 Hz. In fact, signals were oversampled in short frames after analog low-pass filtering and decimated in order to benefit from the sharper cutoff characteristic of digital filters in the acquisition software. The system used double-buffering for simultaneous acquisition (in one buffer) and processing (in the other). The processing involved calculation of FFTs and various statistical properties of the signals so that for every frame of approximately 9-min duration a set of parameters describing mean, variance, and narrow-band root mean square (RMS) corresponding to known vibration modes were stored.

Data frames were saved together with trigger indicators for interesting events. Acceleration trigger conditions, applying only to story 65 accelerometers, included strong broadband response as well as response in lower vibration modes measured using narrow-band RMS.

Trigger levels were also set relative to a moving average of response so that weak signals could be captured against the weaker background of building response to both wind and internal machinery at night. After a short learning period we observed that while wind generated strongest acceleration response in the fundamental vibration mode (A1 and B1), distant earthquakes invariably caused the strongest response in the second mode (A2 and B2). Hence triggering on second-mode RMS was found to be very effective for capturing local effects of distant earthquakes [4].

From almost 5 years of data up to July 2001, daily maximum RMS acceleration values due to wind excluding known earthquake response were obtained and used to obtain statistical distributions of extreme values, presented as Gumbel plots in Figure 5. These plots confirm the relative weakness of A direction and that, even allowing for statistical peak factors (ratio of peak to RMS) around 3.0 for a 10-min record, the serviceability criteria of 98 mm s^{-2} (0.01 g) established for the building by the architect are comfortably higher than the acceleration response expected for a 50-year return period.

Even the strongest ever recorded response to wind, with 15 mm s^{-2}-peak amplitude and peak gusts between 20 and 30 m s^{-1}, was dwarfed by the acceleration response due to the magnitude 8.0 Bengukulu earthquake that occurred in June 2000. Apart from the December 2004 Aceh earthquake, this was the strongest earthquake in the region during the monitoring and it generated the strongest recorded signals, probably clipping at the system range of 50 mm s^{-2}. A summary of characteristics and effects of recorded tremors up to 2000 is given in [4].

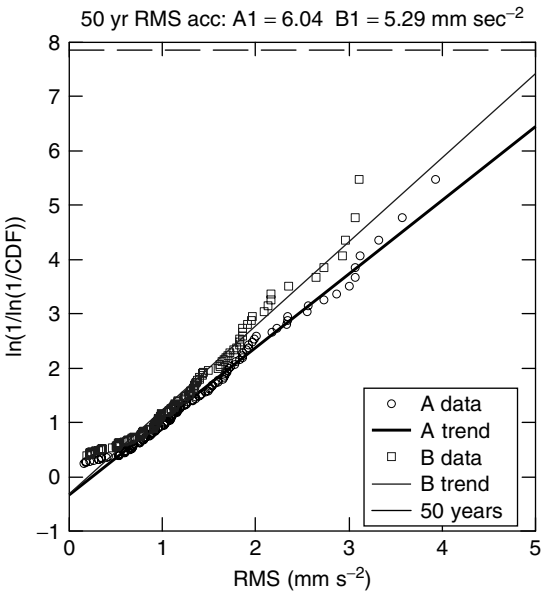

Figure 5. Gumbel plots of story 65 first-mode RMS accelerations.

From an ensemble of large amplitude response time histories collected during strong winds, we established that for unity normalization at the roof, mode-shape amplitudes for the first three modes are 0.006, −0.010, and 0.016, showing the foundation to be extremely rigid. Hence we believe that the recorded basement signals can be taken as representative of local ground movement, with the triggering algorithm working very well to detect weak earthquake events. Moreover, the transmissibility function between basement and roof, (Figure 6) allowed for identification of modal frequency and damping through classical modal analysis procedures such as circle fitting, confirming the results given in Table 1.

Besides discrete events, we tracked modal parameters over the 10 years of monitoring and found a gradual degradation of stiffness; for translational modes A2, B2, A3, and B3 the frequencies drop on average 0.65% per annum.

5 RECOVERY OF DISPLACEMENTS FROM ACCELEROMETER SIGNALS

With the development of a Singapore-specific wind loading code at the time of the project, Republic Plaza provided an opportunity to calibrate the candidate code provisions.

As with a UK exercise [5] in which an empty apartment block was used to study total static and dynamic response to wind load, and the subsequent Chicago Project [6], Republic Plaza provided a convenient form of wind sensor. Wind loading comprises static and dynamic components, and modern wind loading codes deal with the effect via a dynamic magnification factor multiplying the static effect of mean wind and including the effect of both broadband turbulence and response in first-mode resonance. Calculations based on the Australian wind code [7] give a dynamic

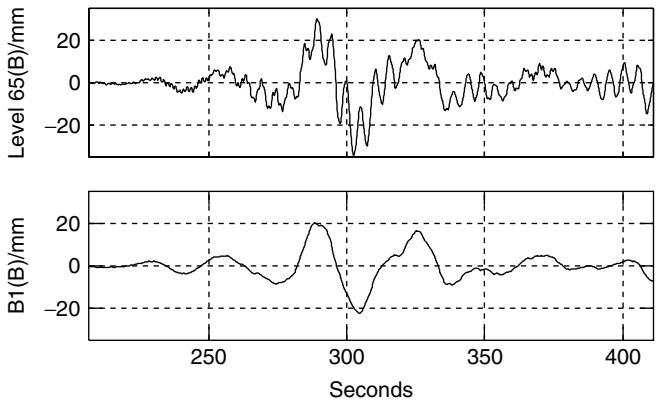

Figure 6. B-direction displacements at basement B1 and story 65 recovered by integrating accelerations resulting from "great earthquake" near Singapore in 2000.

amplification factor close to two, but this depends on the character of the wind, particularly the turbulence, which is relatively high for Singapore.

Apart from issues of occupant comfort during first-mode sway due to wind turbulence, it is the total wind force that concerns designers. The resonant component of base shear can be found by combining known mode shape and mass distribution with the rooftop acceleration signals, but the static component depends on a combination of the stiffness (known from the validated finite element model) with measured absolute mean deflections.

Absolute static displacements cannot be obtained even from the best accelerometers because double-integration of acceleration to displacement is subject to contamination by instrument noise at very low frequencies, translating to high displacements.

Figure 7 shows B-direction displacements obtained by integration of accelerometer signals from the 2004 Bengukulu earthquake and aftershock, using a cutoff frequency of 0.02 Hz. Apart from the obvious first-mode contribution of story 65 response, the two signals are identical indicating a rigid body motion of the entire building. Using a lower cutoff frequency in the integration introduces low-frequency ripples in different channels at different times due to noise, so the result also fixes a reasonable lower cutoff frequency for general application of the integration process and effectively rules it out for the very slow quasi-static wind-induced response.

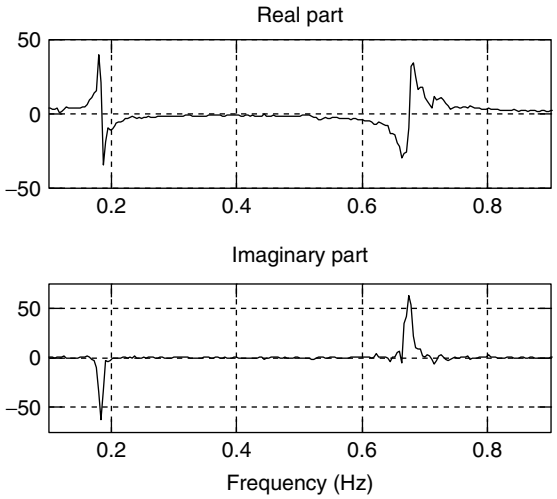

Figure 7. Transmissibility function between level 65 and basement response during an earthquake.

An alternative method was investigated, involving the relationship of tilt to deflection at the roof and interpreting DC acceleration signals as a component of gravity due to rotation of accelerometer sensing axis from horizontal. Even allowing for compensated thermal bias, displacements thus recovered did not correlate with any measured "effects", e.g., wind and differential solar heating, and hence the technique was abandoned.

6 GLOBAL POSITIONING SYSTEM

With a proven track record in recording dynamic structural deflections in suspension bridges [8], the GPS offered possibilities of absolute position measurement for resonant, dynamic nonresonant, and static responses. Hence, in 1999 the acceleration and wind recording system was upgraded to include a dual-rover real-time kinematic (RTK) differential GPS.

For a single GPS antenna/receiver (rover), estimates of position are subject to errors that depend on modification to signal transit time from the satellite due to atmospheric and other effects. If a fixed base or reference (base) station is located nearby, given the known fixed location, the "differential" errors can be identified and used to adjust the rover position estimate. When the errors are transmitted from base station to rover and incorporated in rover position estimates in real time, position fixes accurate to the order of a centimeter or better may be possible. RTK operation uses software embedded in the receivers to correct for the errors. More recent GPS capabilities allow for direct supply of corrections without the need for a base station using corrections supplied over the internet from a collective "virtual" base station.

The system at Republic Plaza used RTK solutions output at 1 Hz for each sample as NMEA (ASCII) text data. Text data is problematic to fuse with signals from analog sensors and hence the NMEA data were converted to analog signals and fed into the existing acquisition system with the analog signals.

The rover antennae were positioned flush with the level of the parapet, and the base station was located on a low-rise building 10 km away. The antenna configuration was not ideal as it was not possible to

use larger, more expensive, and more accurate choke ring antennae.

The initial GPS data appeared very noisy and not to correlate with other signals, and hence we found it hard to believe what the data represented. Validating the GPS data was a major issue, as the signals were subject to various forms of error such as multipath, cycle-slip, random noise, and systematic noise. Also, the total movements of the building, expected to be of the order of ± 0.1 m, would comprise components of dynamic and static response to wind as well as static response to temperature changes in and around the building. We obtained direct evidence that the system was working first by physically moving the antenna during a recording and then by studying the signal during strong winds and/or earthquakes that generated first-mode deflections of at least 1-cm amplitude.

Two periods in early 2003 and early 2004 generated useful GPS data during the relatively strong seasonal monsoon winds. However, the signals were affected by dropouts occurring at slightly irregular intervals of approximately 30 min. A good example of typical data is shown in Figure 8, representing a storm generating first-mode response with an amplitude 10 mm s^{-2}. The RTK data shown were corroborated by the second rover and indicate a steady drift at the roof level of the building with a kind of ratcheting, together with dynamic response.

Surprisingly, the best validation of the GPS performance was provided by the December 26, 2004 earthquake off the coast of Sumatra, Indonesia. Figure 9

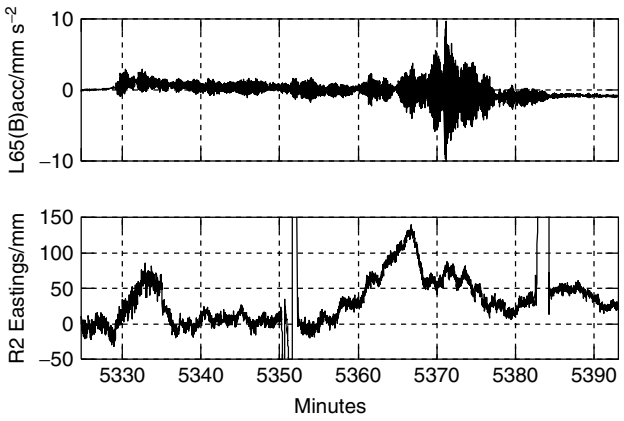

Figure 8. Sampled time series (1 Hz) of story 65 accelerations and RTK displacements during a storm.

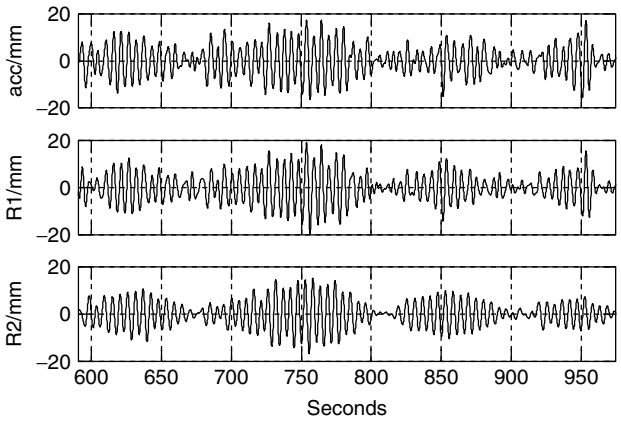

Figure 9. Evidence of GPS performance: correspondence of A-direction relative displacements recovered from accelerometer (acc) compared with RTK-GPS displacements (R1 and R2) during Aceh earthquake on December 26, 2004.

shows story 65 displacement in A direction relative to basement recovered from the acceleration signals, and also displacements obtained directly using RTK from the two rovers. The RTK displacements are the A-direction component of the vector sum of Eastings and Northings, band-pass filtered between 0.1 and 0.3 Hz.

While story 65 acceleration can be integrated to show the type of large low-frequency displacements visible in Figure 7, RTK displacements do not, probably because they were relative to the base station, which moved to the same extent as the ground at Republic Plaza.

7 OBSERVATIONS ON STRUCTURAL AND LOADING MECHANISMS

From the character of the mode shapes as well as the transmissibility function, we deduced that the foundation is extremely stiff, allowing the building to work as an excellent tremor detector, using the second-mode response at roof level as a sensitive trigger. That said, it is not absolutely certain to what extent the building basement movement represents the "free field" motion. Even so, the rigid body motion observed at long periods (20 s to the limit of integration at about 50 s) almost certainly represents a larger scale ground motion in the greater area of Singapore, and the fact that the differential GPS does not show the low-frequency motion supports this.

Over the 10 years of monitoring, the dynamic characteristics in the lower modes changed only slightly, with a detectable gentle downward trend in the higher mode frequencies. The effect is open to interpretation and could result from changes in mass and/or stiffness.

One of the biggest surprises that emerged from the monitoring was that, for Singapore, dynamic loads due to distant tremors are far in excess of the dynamic loads due to wind [9]. It also appears that this also applies when total (dynamic plus static) wind loads are considered. As the basement seismic response spectra show a concentration of energy between 0.5 and 1.0 Hz, there are implications for the majority of tall buildings on Singapore Island having this range of first-mode frequency. The reasoning for this is that Republic Plaza responds in second mode, where (seismic) modal participation factor is relatively low, approximately 25% of first-mode participation factor, depending on the structure. Hence, low-rise buildings will attract proportionally much more seismic load.

It has been possible to draw conclusions about the nature of the loading and response because a validated finite element model has been available. Our recommendation is that dynamic testing and creation of a validated numerical structural model are prerequisites for an effective SHM system.

Chapter 134

Dynamic Response of Buildings of the Cultural Heritage

Paolo Clemente and Giacomo Buffarini

ENEA, Casaccia Research Centre, Rome, Italy

1 INTRODUCTION

The dynamic behavior of historical buildings is quite complex owing to several reasons, such as the complexity of the geometrical characteristics, the nonlinear behavior of the material, and the noneffectiveness of the connection between the masonry walls and the decks. As a result, identification of the dynamic characteristics and the seismic analysis are very hard and we cannot easily generalize the results obtained on a specific building to other structures. Besides, the numerical analysis by means of finite element models, which are usually very helpful to analyze the expected behavior and to interpret the experimental results, contains large uncertainties: the structural size of the various elements (walls, floors, etc.) cannot be evaluated with the needed accuracy; the material characteristics, such as the tension–strain relationship and the strength, are not known; structure and materials often exhibit inelastic behavior; rigid floors are often missing; these are substituted by masonry vaults or by wooden floors, whose effectiveness in connecting walls is uncertain; neither the depth of the foundation nor their geometry and material properties are known; often the depth is variable as well as the soil characteristics; buildings are often connected to other constructions so that their behavior is very complex. Actually, a complete analysis should include clear identification of the structural systems, their dynamic characteristics, and the knowledge of the mechanical properties of the materials used to construct the original buildings. Furthermore, in many cases, the building under investigation may have been altered repeatedly over time. This can be a critical issue because, for example, the building may be founded on older buildings that got buried over. Therefore, for such kind of structures, the experimental analysis is often the only way to improve our understanding about their dynamic behavior.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

Instrumentation of structures to measure their motion under various loading conditions is a widely used practice in engineering. Temporary arrays are generally used for dynamic characterization of structures, which can be excited by means of ambient or forced vibrations, obtained by means of a vibrodine, impulse loading, explosions, etc. In this case, velocimeters are to be preferred, because their deployment is often easier and because they are more sensitive than accelerometers, so also vibrations of very low amplitude, such as ambient vibrations, can be recorded. Accelerometric sensors, which have to be fixed to the structure, are to be preferred in the cases of strong motion recording, due to their larger full-scale value, and long-term monitoring of structures. Obviously, for a fixed instrumentation, the choice of the locations of sensors and the ways for the cables is influenced very much by the interference of the instrumentation with the normal use of the building and the optimization of the ways of the cables and the accessibility of the locations, which must allow the safe installation of sensors. These problems can be often ignored for temporary arrays.

The experimental study of a structure should be organized in two steps. The dynamic characterization should be first performed, in order to have a first glance at the dynamic properties of the structure, such as resonance frequencies, modal shapes, and damping; few sensors can be temporarily deployed in different configurations also to define the optimum deployment. Then the permanent array is designed on the basis of the experimental results obtained from the temporary deployment. A numerical model should accompany both the experimental phases [1, 2].

Two case studies are shown in the following. The first one is a typical masonry bell tower and the second is a historical building. Both of them were damaged by earthquakes.

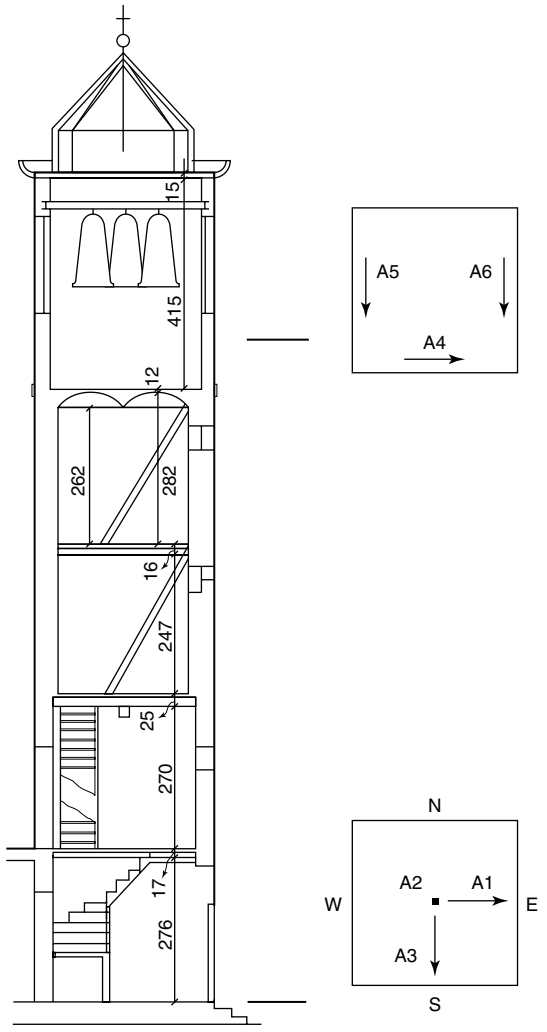

Figure 1. Bell tower at Trignano: accelerometric network.

2 BELL TOWER OF S. GIORGIO CHURCH IN TRIGNANO

The original structure of the medieval Bell Tower of S. Giorgio Church in Trignano, 18.5-m tall and 3.35 m × 3.00 m at the basement (Figure 1), withstood several changes and additions in the past centuries. Four masonry pillars at the corners, about 40-cm thick, compose the main structure. Very poor masonry walls, whose connections with the pillars are not effective, fill the spaces between the pillars. The first three floors are made of timber, the fourth one was substituted by a two-brick little vault floor, supported by a central steel I-beam. The stairs were composed by wooden and steel flights. The tower is connected to the structure of the church and to other masonry buildings on three sides, up to the height between 6 and 7 m.

The tower was seriously damaged by the Reggio Emilia earthquake ($M_L = 4.8$) of October 15, 1996. The most apparent effect of the earthquake was the opening of a near horizontal crack in the freely

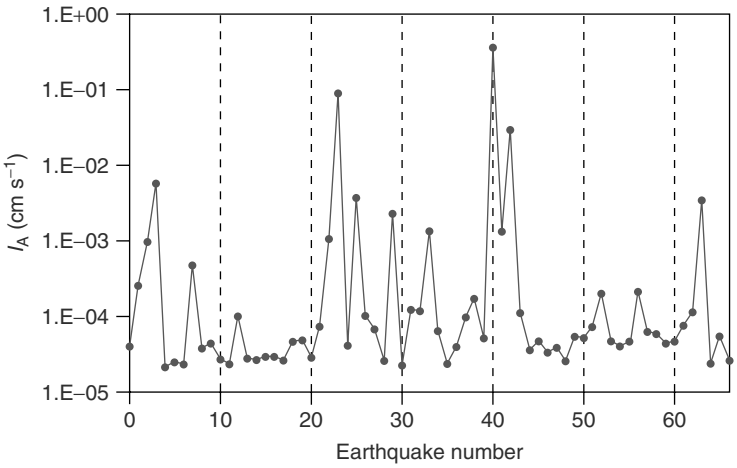

Figure 2. Energy for the recorded earthquakes.

rising part, above the roofs of the adjacent buildings. The crack intersected three of the four sides of the tower. A 3-cm offset was also apparent between the upper and the lower part of east wall, due to a clockwise rotation of the upper part with respect to the lower one.

The dynamic characterization of the tower was performed by means of ambient vibration tests [3]. Forced vibrations were also considered, by recording the vibrations due to the effects of a mass dropped on the ground near the tower. The motion, in terms of modal shapes, was examined by means of the amplitudes of power spectral densities (PSDs). The ambient vibration tests showed a resonant frequency of about 2.7 Hz with prevalent displacements in the N–S direction, and a resonant frequency of about 2.9 Hz with prevalent displacements in the W–E direction. A resonant frequency of 6.9 Hz was associated to a torsional modal shape.

2.1 Analysis of the seismic input at the basement

The fixed instrumentation consisted of a triaxial accelerometric sensor located on the ground floor, which could be assumed as basement, and three uniaxial horizontal accelerometric sensors at the top (Figure 1). Sixty-seven aftershocks were recorded between October and December 1996. The events were classified on the basis of the input energy for the structure, estimated by means of the Arias scalar intensity at the basement $I_A = \pi 2g \cdot \int (a_x^2 + a_y^2 + a_z^2)\,dt$. In Figure 2, I_A is plotted for each earthquake. As one can see, most recorded earthquakes showed values of I_A lower than 1.0E–4 cm s^{-1}; a relevant number of earthquakes had an energy value between 1E–4 and 1E–2 cm s^{-1}. Three events showed energy much higher than the others.

2.2 Dynamic characteristics of the structure

The records obtained under the lower energy earthquakes confirmed the results of the dynamic characterization [4]. Peaks at the already mentioned resonance frequencies are evident. In more detail, the resonance frequency of 2.7 Hz is apparent for CH5 and CH6, while the resonance frequency of 2.9 Hz is present for CH4. The analysis of the phase factor pointed out that the signals at the top and the corresponding ones on the basement are 90° out of phase at these frequencies. The torsional resonant frequency of 6.9 Hz is also present.

The dynamic characteristics, in terms of resonance frequencies, modal shapes, and damping, changed significantly, under earthquakes of higher level energy. In Figure 3, the acceleration time histories relative to strongest event (No. 40) are plotted. The PSDs (Figure 4) show the different frequency content of the top records in comparison to the basement

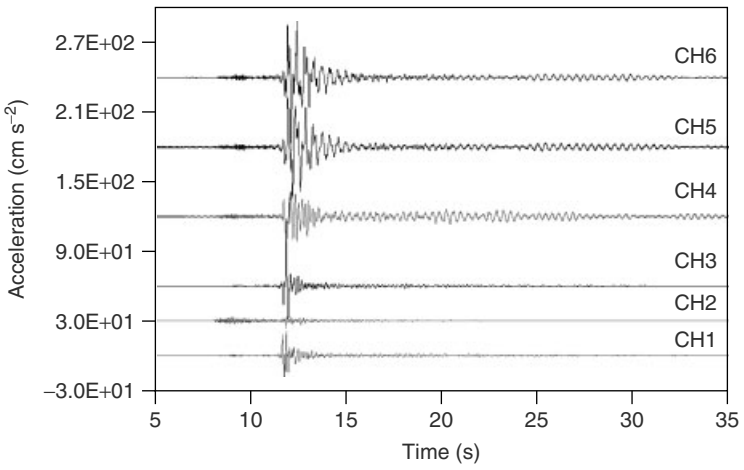

Figure 3. Time histories of the event no. 40.

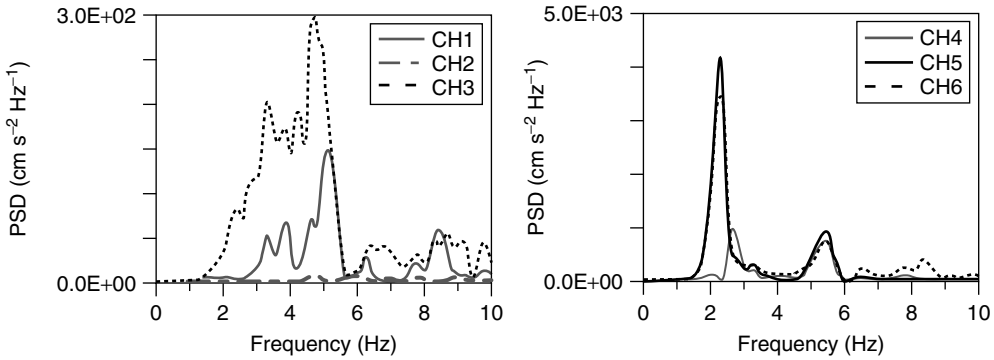

Figure 4. Power spectral densities.

ones, which contain the characteristics of the seismic motion. The reduction of the resonant frequencies is apparent. In fact, the first frequency is equal to 2.25 Hz and is associated to a modal shape with prevalent displacements in the N–S direction. The second frequency is at 2.60 Hz and is relative to a modal shape with prevalent displacements in the W–E direction. It is also evident that, in this case, the energy in the N–S direction is much higher than the energy in the W–E direction. It is also interesting to point out that just the opposite happened in the PSDs of other events. This occurrence is related to the different directivity of the earthquakes.

The resonance frequency of 5.5 Hz is apparent in the cross spectral density (CSD) between sensors CH5 and CH6 (Figure 5). The signals being 180° out of phase, this happens to be the torsional frequency of the tower. The PSD amplitudes of the three records at the top being almost similar, we can conclude that the prevalent motion, associated with this frequency, is a rotation around the vertical center line of the tower.

2.3 Seismic response of the tower

The frequency-domain analysis was performed for all the events. In Figure 6, the resonant frequencies are plotted for each event. Changes in the resonant frequencies for the different earthquakes are apparent. Recalling the classification of the recorded events based on the scalar Arias intensity, I_A, at the basement, we plotted the values of the first three resonance frequencies versus the corresponding I_A (Figure 7). From these plots, the influence of the seismic

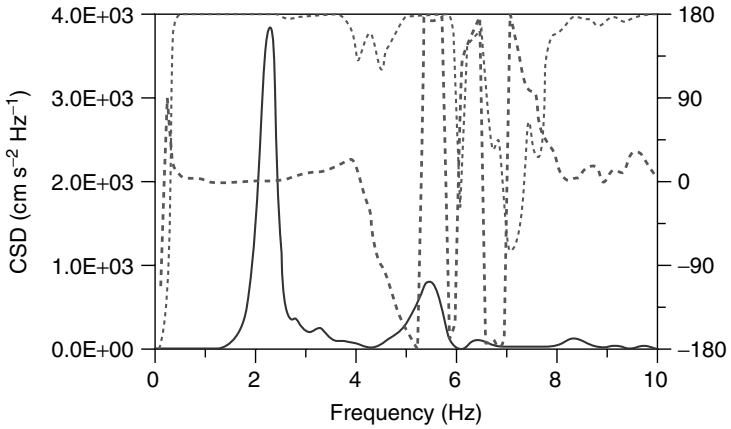

Figure 5. Cross spectrum CH5–CH6.

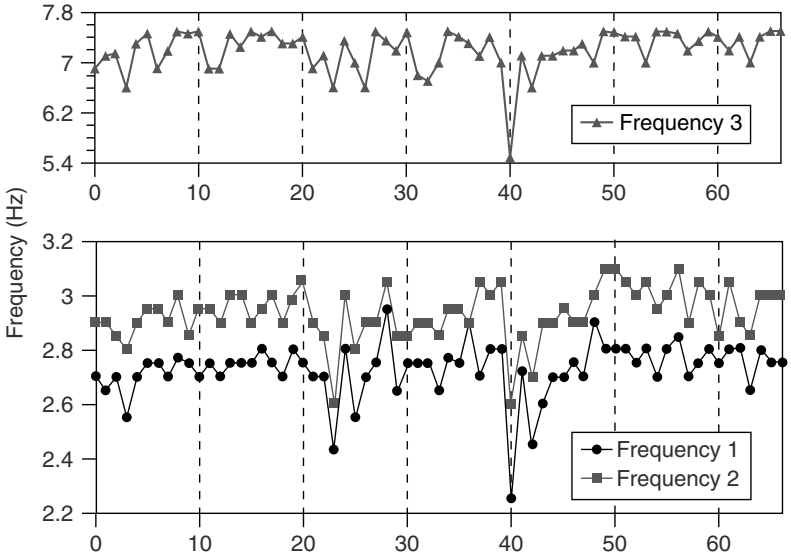

Figure 6. Resonance frequencies for all the recorded events.

input energy on the resonance frequencies is well emphasized. The energy range can be divided into two intervals. In the first one, the resonance frequencies are almost independent of the seismic energy and are very close to those obtained from the characterization tests. In the second one, all the three resonance frequencies decrease almost linearly with $\log(I_A)$. The intersection between the horizontal line, corresponding to the average value of the first resonant frequency found in the lower energy earthquakes, and the straight line that fits the decreasing first frequency values better, gives a numerical evaluation of the boundary between the two intervals. This operation brings the same value $I_{A,0} \approx 5\text{E}{-}4\,\text{cm s}^{-1}$ for the three frequencies, so it can be assumed as the limit value for the seismic energy, which separates the range of the linear behavior of the damaged tower from the nonlinear behavior range. The coherence function assumed lower values for the strongest earthquakes. This occurrence is also a measure of the nonlinearity in the seismic behavior of the tower. It was also noticed that earthquakes of similar intensity

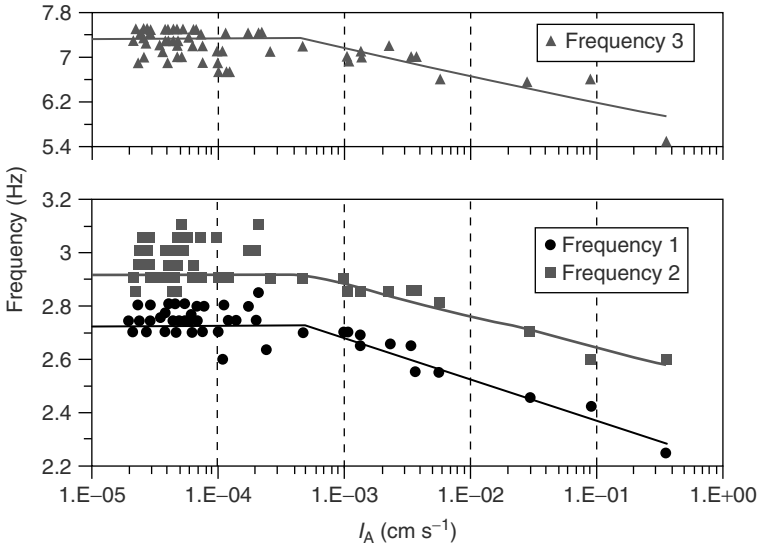

Figure 7. Resonance frequencies against the event energy.

had slightly different effects on the dynamic behavior of the tower. This occurrence demonstrated that even the higher recorded earthquakes did not cause significant additional damages to the tower. In some cases, a different behavior was detected under earthquakes of similar amplitude. This was probably related to the directivity of the earthquakes. In fact, different ratios between the PSDs of the three components were found. Damping was calculated by means of the half-power bandwidth method. It increases with the energy level.

3 CEDRAV BUILDING AT CERRETO DI SPOLETO (ITALY)

The Centre for Anthropological Documentation and Research of Nerina Valley (CEDRAV) was built as a monastery in the fourteenth century on the top of a carbonatic ridge. The building, which is irregular both horizontally and vertically (Figure 8), is composed of a main building and three additional ones connected to it. In the main building, the foundations are not at the same level. The first level is partially embedded into the ground and is mostly founded directly on rock, the second level is partially founded on the rock, and the foundation of the N–W portion of the building is not known in detail. The carrying structure is composed of masonry walls. At the east side, the main building is connected to a small square-shaped structure of three floors, having about half a wall in common. At the north corner, a rectangular building is connected to the main one and at the west side, another rectangular building is connected to the main one by means of a masonry arch. The secondary structures influence the dynamic behavior of the main building very much. In fact, torsional modes with very low damping and coupling with the principal vibration modes of the buildings are generated.

3.1 Experimental tests and data analysis

The building was damaged during the Umbria–Marche seismic sequences of 1997. By observation, it was determined that the building suffered some damage during the two main shocks of September 26 ($M_S = 5.6$ and $M_S = 6.0$, respectively), although the epicenter of the earthquake was 30 km away from the building. Most of the damages were caused by the event of October 14 ($M_S = 5.4$), the epicenter of which was approximately 8–10 km away from the building site.

Following these two earthquakes, the structure was first instrumented using temporary arrays in order

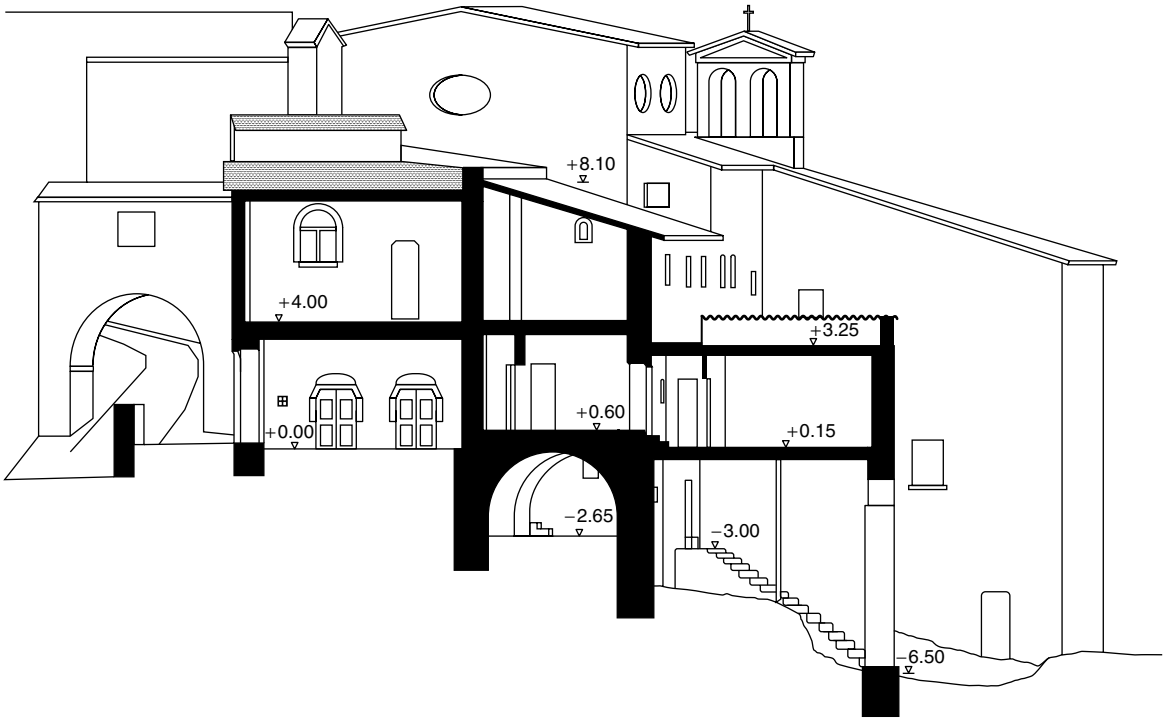

Figure 8. CEDRAV building: vertical section.

to characterize its dynamic properties [5]. Then a permanent accelerometer array was installed. This consisted in three K_2 acquisition systems, each of them having an internal triaxial accelerometric sensor and 27 external FBA11. Schematics showing the locations of the instruments are provided in Figure 9. The permanent deployment recorded several seismic events in about one year.

Collected data were analyzed in the frequency domain. Sample PSDs of the recorded response to a seismic event are provided in Figure 10. Peaks at 9.7 and 10.4 Hz are apparent. The first frequency is associated to a translational mode and the second to a torsional mode. Using system identification, very low damping percentages ($<1\%$) were extracted. The following considerations have to be pointed out: the building behaves like a very complex and rigid system; translational and torsional frequencies are close to one another; mode coupling occurs; and damping percentage is low.

Coupling of the frequencies and low damping are two factors that cause beating effect when shaking is strong enough. In this case, the building is affected by beating effect, even though the shaking level is not high.

3.2 The numerical model

The experimental results were compared with those obtained from a linear finite element analysis, which allowed to interpret the behavior under low energy events very well. Besides, cracks at the test time were very narrow, so no discontinuities were introduced in the model. Walls, floors, and vaults were modeled using four nodes shell elements, having both membrane and bending behavior. The structure is very complex both in plan and in elevation and some uncertainties affected the model. For example, the presence of buried rooms without access was pointed out by the experimental dynamic behavior of the building and the finite element model was consequently modified.

The structure was supposed to be composed by a unique homogeneous and isotropic material, which reproduces the average characteristics of the actual

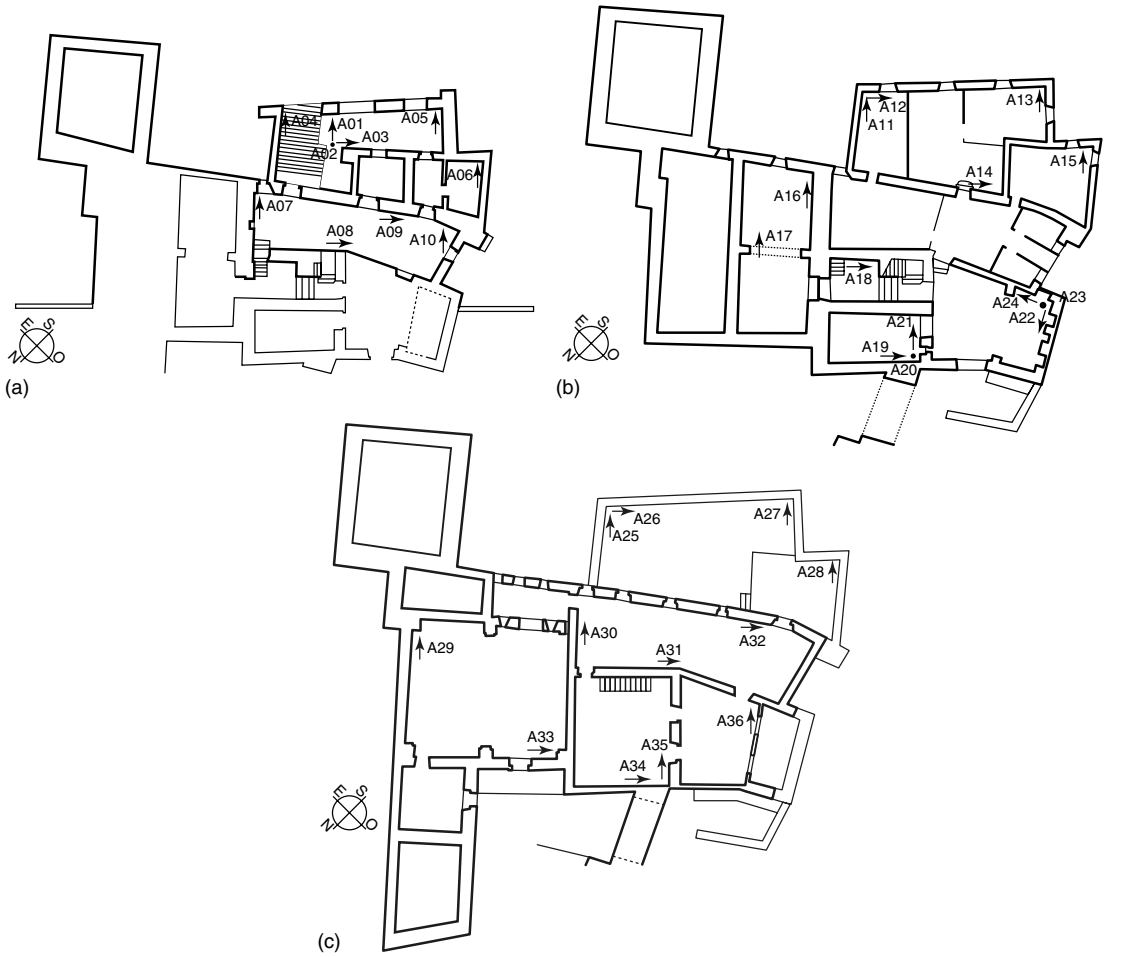

Figure 9. CEDRAV building: plans and sensor locations on the (a) ground floor, (b) first floor, and (c) second floor.

ones. Material characteristics given in the literature were first assumed, and then the Young's modulus was changed so that the first numerical frequency matches the first experimental frequency. In this way, we obtained a quite good correspondence between most of the numerical and experimental frequencies. In the final model $E = 1000\,\mathrm{N\,mm^{-2}}$ for both walls and vaults, while the density was 1800 and $1600\,\mathrm{MNs^2/m^4}$, respectively. The modal analysis gave the frequencies shown in Table 1. As one can see, very close frequencies were found due to the structural complexity. This behavior was shown by the experimental data too. In fact, many substructures behaved also as separated structures, but being linked they influence each other reciprocally. In the following analysis, only the modes

Table 1. Numerical frequencies

No.	1	2	3	4	5	6	7	8	9	10
Hertz	6.35	7.01	7.17	7.61	7.98	8.55	9.26	9.27	9.69	9.71

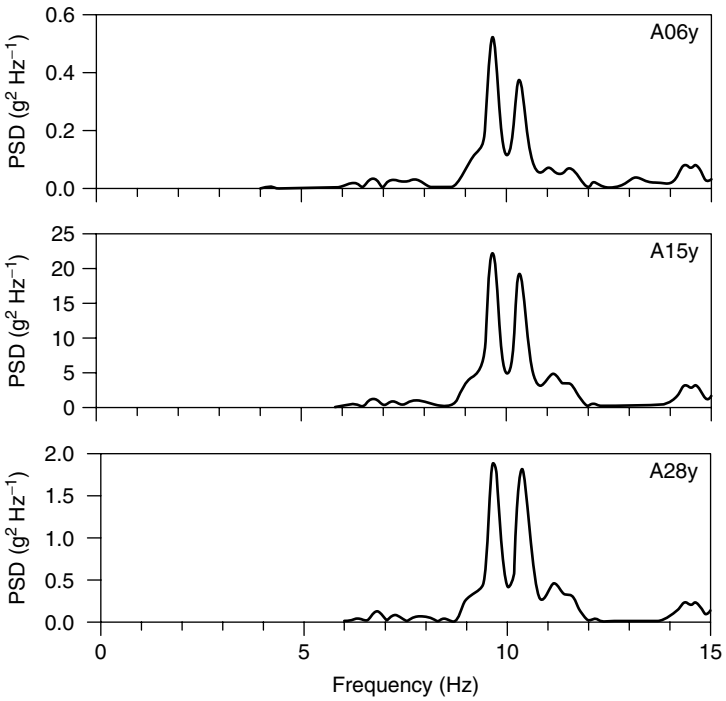

Figure 10. Power spectral densities.

with a significant participation factor were used for validation of the model.

The mathematical model was validated by using the experimental behavior under the higher energy level earthquakes. The time histories recorded on the basement (A01, A02, and A03) were assumed as input accelerations at all the basement joints. The output obtained at sensor locations were compared with those recorded at the same locations, both in time and frequency domain. Modal damping ratio was assumed to be equal to 1% for mode 9 (9.69 Hz) and mode 11 (10.25 Hz), while it was assumed equal to 3% for all the other modes.

In Figure 11, the PSDs of the experimental recorded responses (dashed line) are compared with those from the numerical model (bold line). The correspondence between experimental and numerical graphics is quite good; this occurrence confirms the validity of the hypotheses assumed. In other words, in the frequency range considered (0–10 Hz), the elastic model reproduced the experimental behavior very well. In fact, the same peaks were found in the PDSs, obtained from experimental and numerical

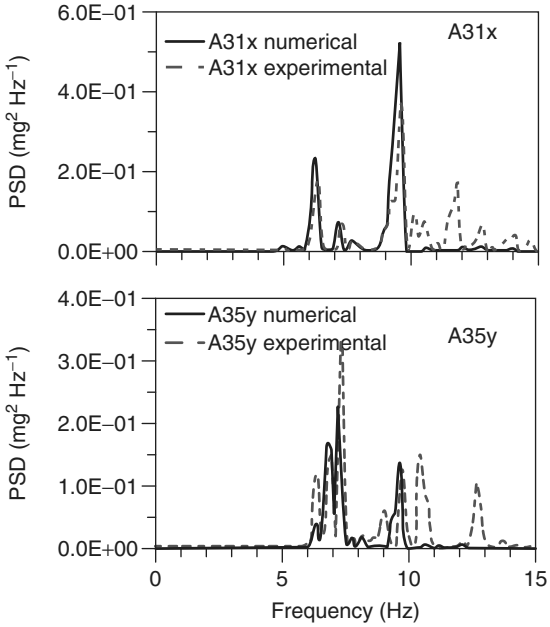

Figure 11. Comparison between numerical and experimental PSDs.

analyses, respectively, often with very similar amplitude.

4 CONCLUSIONS

The dynamic response of buildings of cultural heritage has been investigated in two steps: (i) dynamic characterization tests to evaluate the structural properties and to have preliminary information about the health status of the structure and (ii) strong motion monitoring over a consistent period. The advantage of this second step is that the structure is analyzed under true seismic inputs. The analysis of the experimental results pointed out the main features of the dynamic behavior of the buildings of cultural heritage.

Chapter 135

Suspended Roof of Braga Sports Stadium, Portugal

Álvaro Cunha, Filipe Magalhães and Elsa Caetano
Faculty of Engineering, University of Porto, Porto, Portugal

1 INTRODUCTION

The Braga Municipal Sports Stadium (Figure 1) is one of the stadia that were recently constructed in Portugal to host some of the matches of the 2004 European Football Championship. The stadium, designed by Eduardo Souto Moura in conjunction with the consultancy office Afassociados [1], has been considered a masterpiece of architecture. The roof, suspended by cables, is unique and it presented a particular challenge in terms of conception, structural design, and construction.

The innovative characteristics of this roof structure, as well as the resulting flexibility, have motivated extensive studies developed during the design phase by various independent entities, whose purpose was to adequately define the design wind load, to evaluate the corresponding static and dynamic behavior, and to investigate the susceptibility to aeroelastic instabilities. These studies comprehended the development of different numerical models of the structure, and a series of wind-tunnel tests performed on physical models. The Laboratory of Vibrations and Monitoring (VIBEST, www.fe.up.pt/vibest) of the Faculty of Engineering of the University of Porto (FEUP) was consulted in this context, at an early stage of the project, with the aim of developing a static and dynamic study of the roof structure [2]. The developed numerical models were first used in the definition of the geometric and mechanic characteristics of the cables and slabs, and the calculated dynamic properties were later used in the construction of a physical model for wind-tunnel tests. After the stadium had been constructed, VIBEST/FEUP was also consulted to analyze data provided by forced and free vibration tests developed by the contractor; a complete ambient vibration test of the suspended roof was performed to measure the corresponding dynamic

properties and to use them to validate the developed numerical model.

Under these circumstances, it is the purpose of the current work to describe the research developed for the operational modal analysis and finite element correlation of the suspended roof of the new Braga Sports Stadium on the basis of temporary ambient vibration monitoring. This work allowed the experimental validation of a numerical modeling of the dynamic behavior of the suspended roof, which takes into account the geometric nonlinear structural behavior and the progressive application of loads during the construction phase.

The identification of the modal parameters presented a particular challenge, as the flexibility of the roof is associated with very low and closely spaced natural frequencies. Special attention was given for the identification of modal damping ratios, owing to the necessity of analyzing the susceptibility of the suspended roof to buffeting effects. These coefficients were estimated using data provided by free, forced, and ambient vibration tests, and using an improved implementation of the enhanced frequency domain method and the covariance-driven stochastic subspace identification (SSI-COV) method. The comparison of the estimates achieved by application of output-only identification methods with the ones provided by data collected in artificial excitation tests was important to understand the capabilities of each approach.

2 DESCRIPTION OF THE STRUCTURE

The stadium was constructed on the slopes of Monte Castro, and developed as an amphitheater over a wide rural landscape, formed only by two rows of stands, on either side of the pitch, and by a granite massif (Figure 2). The most noticeable element of the stadium is its roof, which is formed by pairs of full-locked coil cables with diameters varying

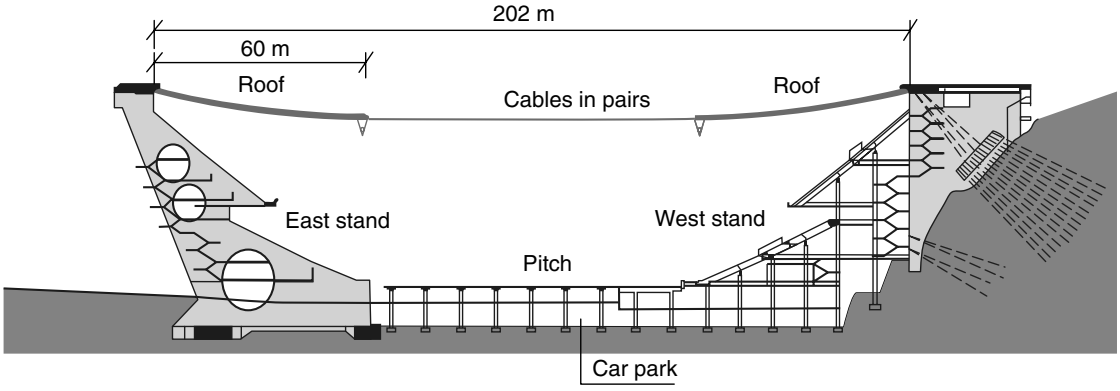

Figure 2. Scheme of the Braga Municipal Sports Stadium.

between 86 and 80 mm, spaced 3.75 m apart from each other, supporting two concrete slabs over the two stands of the stadium. The cables' span is 202 m and the slabs' length is 57.3 m; therefore, the remaining 88.4 m of the central part is free. Rain water is drained from the roof along one side only, the slope being achieved by a variation in the lengths of the cables. The concrete slabs have a thickness of 0.245 m and are connected to the cables only in the normal direction, allowing relative tangential movements. A transversal triangular truss is suspended from the inner border of each slab, acting as a stiffness beam and simultaneously accommodating the floodlights and loudspeakers.

The roof cables are anchored in two large beams at the top of both stands—east and west. The east stand is structurally formed by 50-m-high concrete walls, whose geometry was defined to minimize the unbalanced moments at the level of the foundation, motivated by the combination of the gravitational action of the stand and the high forces transmitted by the roof cables. In the west stand, the concrete walls are anchored in the rock and the roof cables' tension forces are transmitted to the foundation by prestressed tendons embedded in the concrete.

The outstanding characteristics of the structure and the need for a tight control of the corresponding behavior during construction justified the installation of a monitoring system, which comprehends static and dynamic components. The static monitoring system was essential during the construction and is based on a series of load cells installed in the cables anchorages, on embedded instrumentation of the concrete structure (strain gauges, tiltmeters, and thermometers), and on instrumentation of the rock massifs and foundations, with load cells installed in the anchors to the earth and in-place inclinometers. The dynamic monitoring system is important for observing the response of the roof to wind excitation; it is composed of six accelerometers, installed in the inner edges of the concrete slabs, and of cells to measure the wind pressure at various points on the underside and top of the roof slabs.

3 AMBIENT VIBRATION MONITORING AND STRUCTURAL IDENTIFICATION

3.1 Ambient vibration measurements

The temporary ambient vibration monitoring comprehended the measurement of the vertical acceleration at 42 points of the roof, using three strong-motion recorders (Figure 3a), synchronized by GPS and programmed using a laptop. The use of these recorders was very practical, as no electrical cabling was required. In the present test, the use of cables connecting equipment placed on both sides of the suspended roof would have made the test preparation very complicated.

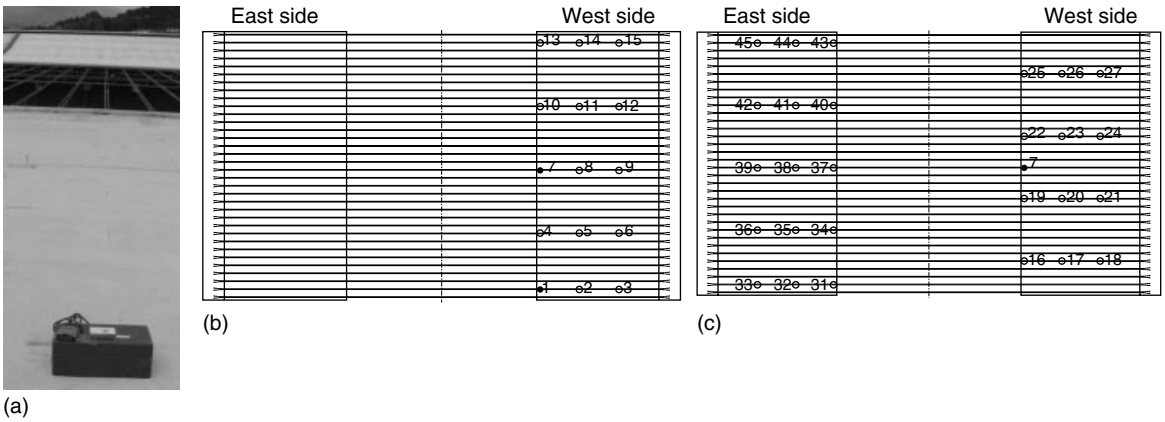

Figure 3. Placement of one of the used seismographs (a) and measurement points of the ambient vibration test: (b) first day (test 1 layout), and (c) second day (test 2 layout). ●, reference points; ○, points measured with moving sensors.

The test was performed over two days. On the first day, the measurements were taken at the points of the west slab represented in Figure 3(b), using 13 setups, while on the second day, the measurements were carried out at the points of the west and east slabs represented in Figure 3(c), using 15 setups.

On the first day of measurements, two reference points were considered (two recorders were permanently placed at points 1 and 7 during all setups). After a preliminary analysis of the data, it was concluded that, for the frequency range of interest (0–1 Hz), all the modes were detected by the reference sensor placed at point 7. Thus, to reduce the duration of the test, it was decided to use just this reference point for the remaining measurement sections. The test developed on the second day provided a set of new responses on the east slab and more response measurements on the west side slab that allowed the improvement of the spatial resolution used in the characterization of the mode shapes.

For each setup, time series of 16 min were collected with a sampling frequency of 100 Hz (minimum sampling frequency allowed by the acquisition system). Figure 4 represents one of the time series collected at point 7 (reference point) and shows the variation of the standard deviation of the time series measured at point 7 during the 28 setups. The amplitude of vibration is essentially dependent on wind, as this was the only significant dynamic excitation of the roof during the test. Therefore, the graph shows that, during the first day of the test (a rainy and windy day), the wind speed was higher and had greater fluctuations than on the second day (a sunny and calm day).

During the tests, the maximum value of recorded vertical acceleration was of about 5 mg, denoting a very low level of oscillation of the roof structure.

3.2 Operational modal identification

3.2.1 Frequency-domain decomposition

The ambient vibration response was initially processed by the Artemis software [3] using the frequency domain decomposition (FDD) method [4]. In this method, the natural frequencies are identified from the peaks of the singular values of the spectral matrices. The mode shapes are identified from the singular vectors of the spectral matrices evaluated at the identified resonance frequencies and associated with the singular values that contain the peaks.

In the present application, the spectral matrices were calculated with a resolution of 0.00488 Hz, which allowed sufficient accuracy in the identification of the natural frequencies. Figure 5 represents the configurations of the most relevant identified mode shapes, showing the good quality of the results and the existence of pairs of closely spaced modes. These are justified by the slope of the roof to drain the rain water, which breaks the symmetry of the structure with respect to the middle axis parallel to the cables. The lower spatial resolution of the measurements performed in the east slab explains the lower quality of the estimates of the last three mode shapes in this slab.

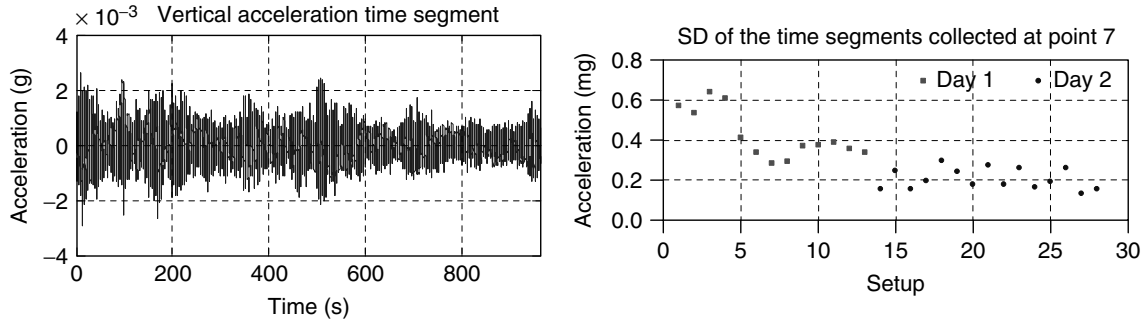

Figure 4. Vertical acceleration time series measured at point 7 during the first setup and variation of the standard deviation of the time series measured at point 7 along the 28 setups.

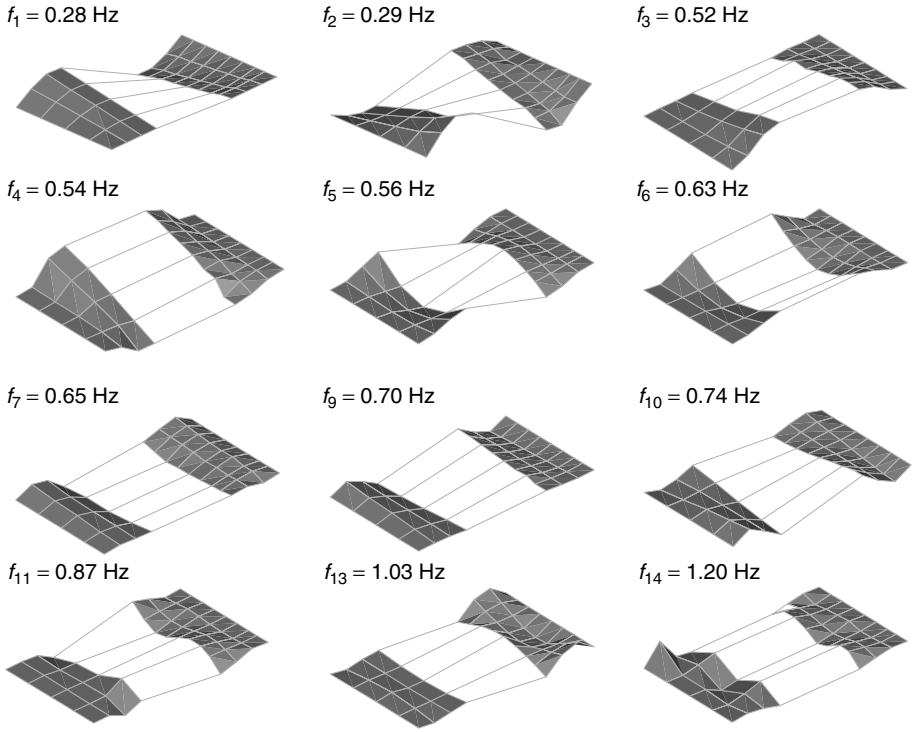

Figure 5. Mode shapes estimated by the FDD method.

The modal damping ratios can be estimated using an enhanced version of the FDD method, the enhanced frequency-domain decomposition (EFDD) method [5]. Usually, when the ambient vibration test is performed using several setups, the modal damping ratios, as well as the natural frequencies, are estimated using independently the spectral matrix of each setup; the final estimates are then obtained, averaging the estimates provided by all the setups.

In the present case, the duration of each setup time series is not sufficiently long to accurately estimate modal damping ratios of modes with such low natural frequencies, especially because very small values of damping are expected.

However, on the first day of tests, the vertical accelerations at points 1 and 7 (points defined as references in Figure 3b) were measured simultaneously during 13 setups, which means that these 13 time series with 16 min were a good basis to evaluate the modal damping ratios.

Beyond that, to increase the accuracy of the estimates, the autocorrelation functions were calculated using an alternative procedure to the one presented in [5] to avoid the circular error (the calculated autocorrelation is a superposition of the desired function and its mirror image [6]). These were obtained using an adaptation of the procedure described in [7], which is also based on a fast Fourier transform (FFT) approach [8].

In the processing of the available data collected at points 1 and 7, time series with 11 min were selected using an overlap of 54%, allowing the accomplishment of averages over 26 record estimates. The singular values calculated from the spectral matrix, with dimension 2×2, are represented in Figure 6. In the same graph, the points chosen to estimate the autospectra (Spi) associated with six different modes are selected (points with modal assurance criterion (MAC) > 0.8). For the other modes, identified in the plot by the peaks, it is not possible to select well-defined autospectra, because of the proximity between resonance peaks. The natural frequencies identified in the graph and summarized in Table 1 are more accurate than the ones presented in Figure 5

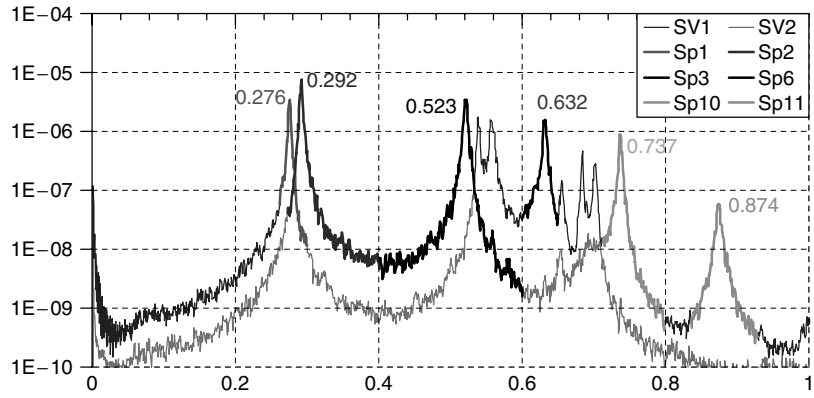

Figure 6. Singular values of the spectral matrix calculated using the time series collected at the reference points (1 and 7) and selection of the autospectra of each mode.

Table 1. Natural frequencies (f.) and modal damping ratios (damp.) identified with the ambient vibration test

Mode	EFDD		SSI-COV			
	f. (Hz)	damp. (%)	f. (Hz)	SD f. (Hz)	damp. (%)	SD damp. (%)

10	0.737	0.25	0.737	0.0009	0.26	0.13
11	0.874	0.36	0.874	0.0016	0.41	0.10

because the frequency resolution is higher in this analysis (0.000763 Hz).

Figure 7 shows two of the autocorrelation functions calculated from the identified autospectra. The envelopes of these functions were fitted by exponential decays to estimate the modal damping ratios presented in Table 1.

3.2.2 Stochastic subspace identification

Despite the very good quality of the estimates of natural frequencies and mode shapes obtained by the FDD method, a stochastic subspace identification (SSI) method was also applied with the main objective of comparing estimates of modal damping ratios using different output-only modal identification techniques. For this purpose, the data collected on the first day of tests was used. To reduce the influence of the aerodynamic damping, it would have been better to use data collected during the second day (very low wind velocities). However, the data of the first day has the advantage of having two reference points.

In the present research, the SSI-COV method was applied using MatLab routines developed at the University of Porto [9]. Before application of the identification algorithm, the measured signals were filtered by a low-pass filter with a cutoff frequency of 1 Hz and the application of a decimation of order 20 (reducing the sampling frequency from 100 to 5 Hz).

The correlation functions are the basis of this identification method. These can be estimated using three different procedures: the direct definition (summation

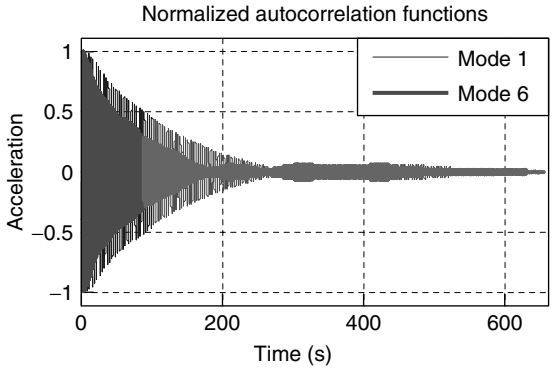

Figure 7. Normalized autocorrelation functions associated with modes 1 and 6.

formula), the FFT, or the random decrement. In the present application, the first alternative was used, which is not very computationally efficient, but does not introduce bias and is easy to program.

The data of the 13 setups was processed independently using the three collected time series and consequently, 13 stabilization diagrams, like the one presented in Figure 8, were constructed. This diagram shows that the dynamic behavior of the structure is well represented by state-space models of order between 20 and 40. The use of models of this relatively low order was only possible because a low-pass filter was applied, which eliminated the contribution of modes with frequencies greater than 1 Hz.

The most suitable model order was selected for each of the 13 stabilization diagrams, and the corresponding natural frequencies and modal damping ratios were calculated. Table 1 presents the mean and standard deviation (SD) of the identified modal parameters. The standard deviations show that the dispersion of the estimates of natural frequencies for the various setups is very low, whereas the estimates of modal damping ratios present significantly higher scatter. This dispersion shows the difficulty of getting reliable damping estimates, which stems not only from the uncertainties of the method but also from the variation of damping with the level of oscillation and with the wind characteristics.

4 FORCED AND FREE VIBRATION TESTS

The identification of modal damping ratios on the prototype structure was developed, in the first instance, at the request of the design office Afassociados [10], on the basis of a set of data collected by the instrumentation installed at the roof structure, during the forced and free vibration tests developed at the commissioning phase. In this section, the corresponding estimated modal damping factors are compared with the ones provided by the output-only identification techniques.

The free vibration test was based on the sudden release of a 5-t mass from a point located close to mark 1 (represented in Figure 3b). The response was collected by the six triaxial force-balance accelerometers of the dynamic monitoring system, which are located at marks 1, 7, 13, 31, 37, and 43 (Figure 3).

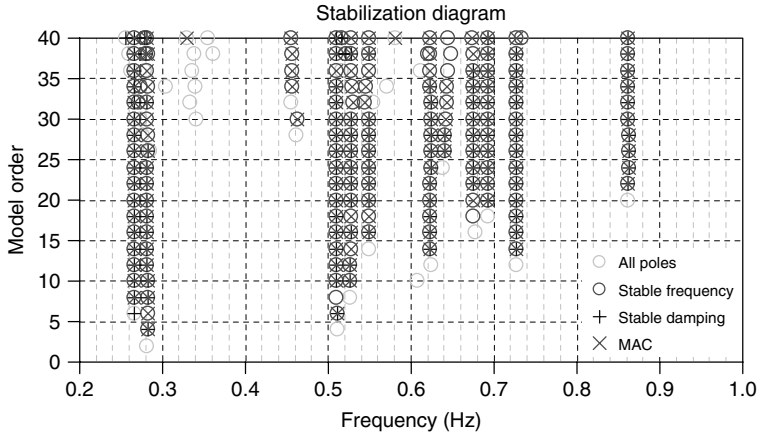

Figure 8. SSI-COV method stabilization diagrams of setup 4.

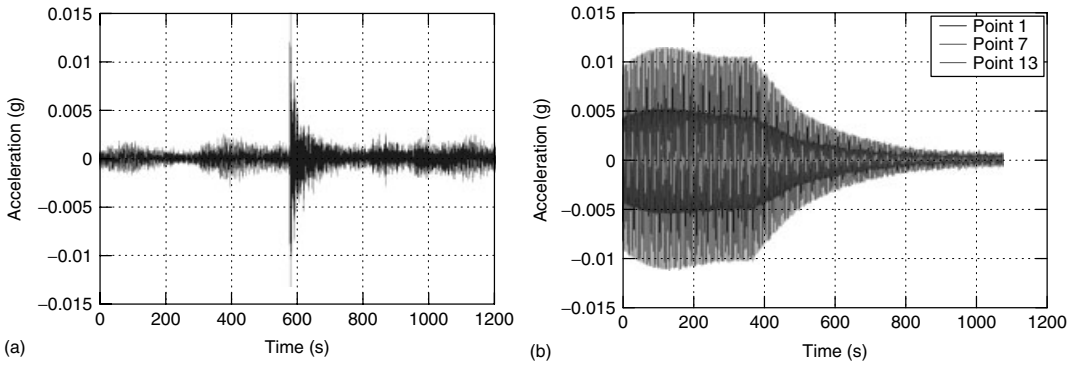

Figure 9. Free decays measured after the application of an impulse (a) and after harmonic excitation of the second mode (b).

Figure 9(a) represents the response measured at point 31. The application of band-pass filters to the measured signals enables the evaluation of modal free vibration responses, which were used to estimate the modal damping ratios presented in the second column of Table 2. This procedure faces two problems that explain the missing values in the table: the low level of excitation of some modes and the difficulty in isolating the contribution of modes with very close natural frequencies. An alternative to this procedure consists in using the measured response to the impulse as input to the SSI-COV method, as responses motivated by impulses are proportional to correlations of responses to white-noise excitations. This technique was used after application of a low-pass filter with a cutoff frequency of 1 Hz, and a decimation to reduce the sampling frequency to 5 Hz. The results obtained are presented in the third column of Table 2. It is relevant to observe that the new estimates are very consistent with the previous ones for the modes where both techniques provided results.

Forced vibration tests were further conducted, based on a harmonic excitation of the roof at resonance, by means of a cable pulled by an electric engine from mark 1 or 7 (Figure 3b). After resonance was attained, the excitation was suppressed and the free vibration response measured by the same six accelerometers. Using this procedure, five modes were excited and so five free decays were measured, like the one represented in Figure 9(b). The fourth column of Table 2 shows the values of the corresponding identified modal damping ratios, which show consistency with previously described estimates.

Table 2. Modal damping coefficients (%) identified with the free vibration tests

Mode	Free vibration filter	Free vibration SSI-COV	Harmonic excitation
1	—	0.29	0.28

The comparison between modal damping coefficients identified using artificial and ambient excitation shows the existence of satisfactory correlation. However, one can notice that relative differences tend to increase at lower frequencies. In effect, the difficulty in identifying modal damping ratios is well known, since they are dependent on the amplitude of vibration and also on the wind characteristics, which can introduce a significant component of aerodynamic damping, as experimentally observed in [11]. The very low damping values of this structure make the comparison even more difficult because very small differences are expressed by significant relative errors.

As for the quality of the estimates provided by the various identification methods, it is relevant to stress that in the present case, the results provided by the FDD method are close to the ones obtained by the SSI

methods, as very long-time series were used and an alternative procedure to estimate the autocorrelation function was introduced. It is still worth mentioning that the application of the standard EFDD method, using independently the time series of each setup (with 16 min.), led to values of modal damping ratios for the first modes of about 1%.

5 FINITE ELEMENT CORRELATION

5.1 Finite element modeling

The analysis of the static and dynamic behavior of the suspended roof was based on a three-dimensional finite element model [12]. This model was formed by a total of 34 cables spaced at 3.75-m intervals, which were idealized as 89 truss elements each. These were linked by shell elements, simulating the slabs, which were only activated after full application of the corresponding weight, and were linked also by transversal truss girders at the ends of the slabs, simulating the lattice structures used to accommodate the floodlights and loudspeakers. An overall slab thickness of 0.245 m was considered. To accommodate thermal deformations without further stressing the cables, sliding between the cables and slabs was allowed. This effect was achieved by definition of different layers of nodes for the cables and slabs, which were constrained to identical vertical displacements. A 1% slope was created along the transversal direction by gradual modification of the lengths of successive cables, for the purpose of water draining.

Considering the structure deformed under permanent loads, natural frequencies and vibration modes were calculated. Table 3 summarizes the first 11 calculated natural frequencies, while the first six mode shapes are represented in Figure 10.

Table 3. Calculated versus identified (SSI-COV) natural frequencies and MAC values

5.2 Correlation between experimental and numerical frequencies and mode shapes

The numerical and experimental assessment of the dynamic behavior of the Braga Stadium suspended roof permitted to achieve an excellent correlation between calculated and identified modal parameters (natural frequencies and mode shapes), which evidences the high quality of the complex finite element modeling developed, as well as the accurate and reliable nature of the sophisticated output-only modal identification techniques employed.

The very good agreement obtained in terms of natural frequencies and mode shapes is shown by Table 3. The mode shapes are compared using the (MAC) [13] that present values close to those when the modes are similar.

6 CONCLUSIONS

The most relevant dynamic properties of the new Braga Sports Stadium suspended roof have been assessed experimentally, on the basis of the application of different output-only modal identification techniques, allowing the subsequent validation of the finite element modeling developed to investigate the static and dynamic behavior of this complex structure.

It is shown that, despite the low levels of signal captured during the ambient vibration test and the existence of a large number of modes of vibration in the frequency range 0–1 Hz, the available stochastic modal identification methods can provide very accurate estimates of natural frequencies and mode shapes, which present an excellent correlation with the corresponding calculated values. This agreement validates the sophisticated finite element modeling, which takes into account the geometric nonlinear structural behavior and the progressive application of the loads.

Because of the major importance of damping in the aerodynamic behavior of the suspended roof, special attention was dedicated to the estimation of modal damping ratios either from free vibration or ambient vibration tests. Results achieved show that, even in this challenging structure, with extremely low natural frequencies and damping factors and with closely spaced modes, operational modal analysis can provide reliable estimates of the order of magnitude of modal damping ratios (absolute differences inferior to 0.25%), constituting therefore an interesting alternative to the more costly, but certainly more accurate, procedures based on artificial excitation. An essential aspect in the application of the operational modal analysis is the use of very long-time records, preferably collected over a period of very low and steady wind velocity condition. However, further research is still needed to improve the potential of operational modal analysis in the estimation of modal damping ratios.

rci dynamics, Duebendorf, Switzerland

1 INTRODUCTION

1.1 Health monitoring of dams

Standard procedures to monitor dams include visual inspection, monitoring of the static deformation behavior using geodetic instruments, plumb lines and clinometers, checking for pore and uplift pressures using piezometers, measuring drainage water as well as measuring temperature and water level. In addition, some dams are equipped with vibration sensors and a local data acquisition facility that can be accessed remotely. In Switzerland, five dams are part of the Swiss National Strong Motion Network [1]. Signals are acquired upon the trigger level of, depending on the local conditions, $0.001, \ldots, 0.005\,\mathrm{g}$, being crossed. From the installation of the system in 1992 until the end of 2004, 502 acceleration time signals from 161 events have been recorded [2]. This yielded insight into the dynamic behavior of the dams in a limited number of points under earthquake excitation. However, to the knowledge of this author, no real attempt to monitor a dam's structural health based on its dynamic characteristics has been realized up to now. There are several reasons for this.

Firstly, the dynamic characteristics of a civil engineering structure are determined through its mass and stiffness. Before being able to relate changes in these characteristics to changes in structural health, any other source of changes in the dynamic characteristics has to be identified and its influence eliminated. For bridges, these "other sources" predominantly include temperature, because this may influence the stiffness of (asphalt) pavement and (flat) foundations. For dams, the situation is worse. Here, the main "other source" is the level of water in the reservoir. This simultaneously influences the mass and stiffness of the dam structure. This is discussed in a later section.

Second, determination of a dam's dynamic characteristics is not easy. Large dams tend to be located in remote areas where accessibility might be a problem. Performing a dynamic test on such a structure usually becomes an expensive challenge.

Although no real health monitoring system making use of changes in dynamic characteristics has been installed in a dam up to now, several steps in this direction have been undertaken in the last 20–30 years.

Step 1. Achieving a set of experimental data reflecting the real behavior of the structure and hence

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

becoming able to update an existing finite element (FE) model of the structure. Within the limits of linearity, further analyses can then be performed on a model known to be as close to reality as possible. This article presents two examples of this kind. Attempts to extend the boundaries of the problem to the surrounding rock and to the reservoir and to study dam–reservoir–soil interaction effects are discussed in [3–6]. Then, the challenge from the view of experimental side is the simultaneous measurement of dam vibrations and hydrodynamic pressure oscillations.

Step 2. Determining the influence of changes in the reservoir water level on the dynamic characteristics of a dam [5, 6]. This article presents one example of this kind.

1.2 Dynamic (dam) testing methods

Today, two basically different test procedures are available: forced vibration testing (FVT) and ambient vibration testing (AVT). FVT is also called *experimental modal analysis* or *traditional modal analysis* in the literature. For AVT, there are even more expressions used: "output-only modal analysis", "natural input modal analysis", and "operational modal analysis". For the sake of simplicity, we will stay with the expressions FVT and AVT here.

With FVT, the structure is excited dynamically using a vibration generator (shaker) and the resulting structural vibrations are measured. The dynamic excitation force is either measured with a load cell or calculated through determination of the inertial forces involved. The structure's vibrations are measured using accelerometers. The number of measurement points usually being much larger than the number of sensors disposable, the measurement is divided into several setups. One setup being finished, the sensors are moved to new positions and the next setup is measured. The force signal acts as a reference, which all response signals are related to. It is then possible to put together, e.g., the mode shapes determined to cover all the measured points. Data processing, i.e., determination of the structure's dynamic characteristics is based on the assumption that the artificial force produced by the vibration generator is the only source of the dam vibrations measured. We see that this assumption is not valid in cases where, e.g., machinery is operating close to the dam. We also see that this is not always a serious problem. With dams, problems might arise when the excitation through wind and/or waves is of the same order of magnitude as the shaker-induced vibrations.

With AVT, the structural vibrations excited by unknown ambient sources are measured. In the case of dams, these ambient forces can be wind, waves, and/or microtremors. Instead of using the force input signal as a reference signal, the response signal measured in (one or more) so-called reference points is used for this purpose. The reference points have to be measured in all setups. Data processing, i.e., determination of the structure's dynamic characteristics, is based on the assumption that the frequency content of the exciting forces is flat, i.e., more or less of the white noise type.

Besides being much cheaper than FVT, AVT has the advantage of being a multiple input multiple output (MIMO) procedure. This means that the ambient forces exciting the structure are simultaneously acting on many points of the structure. Especially for civil engineering structures, FVT is usually a single input multiple output (SIMO) procedure. It can be seen from the examples, discussed later, that using more than one shaker on a structure is not the standard procedure. Choosing the proper position of the driving point, where the vibration generator is located is hence always one of the crucial problems to be solved. The shaker should not sit in a node of the shape of one of the modes of concern. The same problem arises with AVT tests when only one reference point is used. This can, however, be solved easily through using more than one reference point. Performing a preliminary FE analysis is also a good means to prevent problems with the placement of shaker and reference points.

1.3 Short history of dynamic testing of structures

Historically, efficient FVT procedures have been developed much earlier than AVT procedures. The first important step was development of the fast Fourier transform (FFT) algorithm, which allowed easy calculation of a frequency spectrum from a measured time signal in 1965 [8]. Subsequently, further signal processing routines were developed by mechanical engineers dealing with "small" structures easily fitting into a laboratory. In such cases, artificial

excitation, e.g., using a hammer or a small electrodynamic shaker was not a problem. The first International Modal Analysis Conference (IMAC) 1, held in 1982, and its successors reflected the respective development. In the late 1970s, when civil engineers started to make use of the methods developed in the "mechanical world" they tried to apply the well-developed FVT methods as far as possible.

However, there are civil structures like, e.g., suspension bridges or dams, which are not easy to excite artificially to a sufficient degree. This is why AVT soon became a topic for civil engineering structures. Of course, "manual signal processing" using a two-channel frequency analyzer and determining the amplitude and phase relationships between two time signals has been possible since about 1975. However, in the mid 1990s, the time had come for civil engineers to develop the procedures necessary for the efficient processing of an AVT test with a large number of degrees of freedom involved [9]. Today, even more efficient methods operating in the frequency and/or the time domains are available to process the signals of an ambient test [10–12].

1.4 Short history of dynamic dam testing

Probably, first attempts to experimentally determine a dam's dynamic characteristics were undertaken in the late 1970s. In a book edited by Graham Tilly [13], Calciati is cited having tested 10 dams in Italy [14], and a British team of the University of Bristol and the British Research Establishment (BRE), is cited to have tested 6 dams in the United Kingdom and in Switzerland [15, 16]. Flesch of Austrian Arsenal is cited to have performed tests on a dam with the reservoir being full and empty [17, 18]. Fanelli and his colleagues report on extensive tests performed during three years on Talvacchia Dam in Italy [5, 6]. All these tests were performed between 1978 and 1988.

As a consequence of the historical development described earlier, the FVT method using vibration generators was applied in all the above-mentioned cases. Since hammer is not really a well-suited instrument to excite a dam, vibration generators of the unbalanced mass type were built. These are relatively easy to install and they can be operated with a comparatively small amount of energy. The inertial force produced is concentrated into one simply harmonic vibration. However, performing a test covering the typical frequency band $f = 2, \ldots, 20\,\text{Hz}$ was a very time-consuming procedure. Assuming a frequency resolution of $\Delta f = 0.1\,\text{Hz}$, the test consisted of 180 individual tests using a different frequency of excitation (and keeping the response measurement points always in the same place). To keep the amplitude of the dynamic force generated in certain limits, the position of the unbalanced masses had to be adapted from time to time. Usually, this force could not be measured directly. Therefore, modern modal analysis methods could not be applied. It was, however, possible to determine natural frequencies, mode shapes, and damping of earth dams, gravity dams, and arch dams like the Emosson dam in Switzerland with a height of 180 m. With the latter, some problems arose with the wind influencing the dam vibrations [16]. For strong wind conditions, the vibrations excited through wind were of the same order of magnitude as those excited with the shaker.

As a next step, servohydraulic vibration generators were built e.g., in Switzerland by the Swiss Federal Laboratories for Material Testing and Research, EMPA. (A similar device was also built by Arsenal in Austria.) Besides a simply harmonic vibration's these could produce a broadband random-type force signal covering the whole frequency band of concern. The energy available was distributed over a larger frequency band, but the tests were much less time consuming. This allowed increasing the number of measurement points significantly. Instead of using the time slot available for testing with sweeping through the frequency band of interest, it was used for roving the sensors available over the structure in several test setups. As a result, the measurement point grid density and hence the resolution of the mode shapes could be increased significantly. As is shown with the three tests described here, respective limits are dictated by the accessibility of points to be measured only. Tests performed by EMPA on two dams using servohydraulic shakers are described, in more detail, later.

The AVT signal-processing routines having become available in the mid 1990s, ambient tests were subsequently performed on dams. Such a test, again performed by EMPA, is also described later.

Today, dynamic tests on dams are performed relying either on the AVT method [7] or, again, on

the FVT method using unbalanced mass exciters [4]. These two methods are much cheaper to be applied than FVT using servohydraulic vibration generators.

2 VIEUX EMOSSON DAM

2.1 The dam

Vieux Emosson dam is a curved concrete gravity structure located close to the border between Switzerland and France in the Mont Blanc region at a height of 2200 m above sea level. With a length at the crest of 175 m, a maximum height of 42 m, and a concrete volume of 62 500 m^3, it is of moderate size (Figures 1 and 2). The dam consists of 13 monolithic blocks of roughly 13.5 m length each. The block width varies between 4 and 7 m at the dam crest and reaches 20 m at the foundation (Figure 3).

No machinery is located close to the dam. Vieux Emosson dam is simply collecting water throughout the summer and the reservoir is emptied in autumn through letting the water flow freely in the reservoir of Emosson dam, which is located downstream of Vieux Emosson dam. This means that no disturbing dam vibrations generated by machinery occur.

Figure 1. Vieux Emosson dam as seen from the air side.

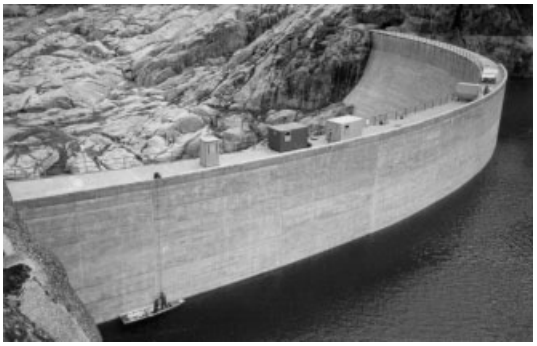

Figure 2. Vieux Emosson dam as seen from the water side.

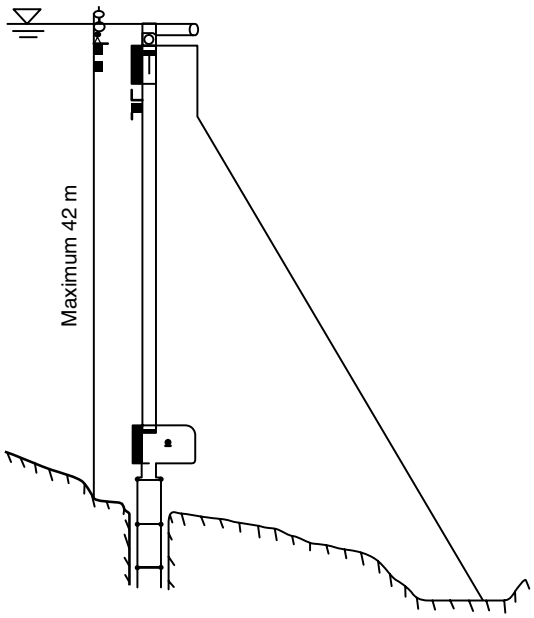

Figure 3. Vieux Emosson dam cross section.

As the dam site is accessible with cars but not with trucks, all the equipment discussed here had to be flown to the dam crest using helicopters of the Swiss Army (Figure 4).

The dam is owned by the Swiss Federal Railways, SBB. The tests were financed as an EMPA research project [19–21].

Figure 4. Helicopter taking over equipment at the base station.

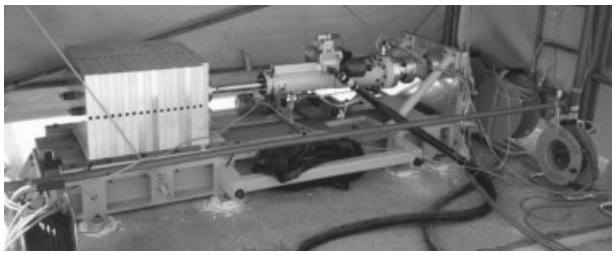

Figure 5. Servohydraulic vibration generator fixed to the crest of Vieux Emosson dam.

2.2 The excitation

The main part of the vibration generator is a 32-kN cylinder with a 1000 kg mass fixed to the piston rod (Figure 5). A load cell is located between the cylinder and its supporting device. The 250-mm-stroke cylinder is equipped with a $63\,l\,min^{-1}$ servo-valve and controlled through an electronic circuitry. The hydraulic power pack driving the cylinder produced $40\,l\,min^{-1}$ of 280 bar oil (Figure 6). In order not to disturb the measurements, the power pack was supported by air springs. A 60-kW diesel generator drove the hydraulic power pack (Figure 7).

Points 10 and 17 were chosen as driving points (where the vibration generator was located). The influence of the shaker location on the results is discussed in [20]. Here, results for only the shaker position 10 are presented.

The driving signal of band-limited burst random type was provided by the modal analysis software package. To achieve a force spectrum being flat in the region of interest, $f = 5, \ldots, 40$ Hz, the signal driving the cylinder in the displacement-controlled mode had to be fine-tuned on site. The peak force amplitude was chosen to 28 kN.

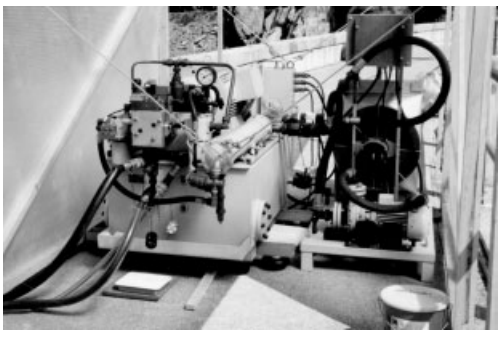

Figure 6. Hydraulic power pack (to the left) and air cooler (to the right).

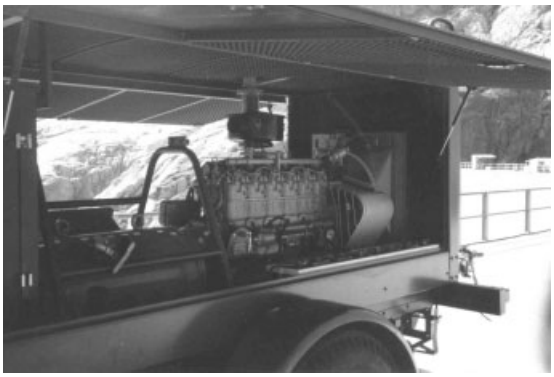

Figure 7. Sixty kilowatt diesel power generator.

2.3 The response

Three accelerometers Brüel&Kjær 8306 mounted orthogonally to each other on a supporting steel plate were used to measure the structural response (*see* **Microelectromechanical Systems (MEMS)**). The sensitivity of this type of instruments is $10\,V\,g^{-1}$ and the resolution is $10^{-6}\,m\,s^{-2}$. As Vieux Emosson dam has an inspection gallery close to the foundation only, the measurement points were located on the dam crest and above the water line (Figures 8 and 9). One of the questions that should have been answered through the tests was, is there any relative movement between two adjacent blocks? As a consequence, measurement points were located on both sides of the joints. The measurement point grid consisted of a total of 53 points (Figure 10).

2.4 Signal acquisition and processing

The forcing signal and six response signals were acquired simultaneously using an 8-channel front

Figure 8. 3-D accelerometer response measurement point fixed to the dam crest.

Figure 9. 3-D accelerometer response measurement point fixed to the dam water face.

end, a computer, and dedicated software. From this, frequency response functions (FRFs) were calculated and the modal parameters subsequently extracted. Figure 11 shows the modal indicator function (MIF), indicating the existence of nine physical modes with a maximum modal participation at mode 2, $f = 9.90$ Hz. Table 1 gives the frequency and damping in percent of critical for the first six modes.

The test revealed that there is some relative movement between two adjacent blocks and that the movement at the dam foundation is not equal to zero. The latter indicates the existence of soil–structure interaction. These facts are discussed in more detail in [19] and [21].

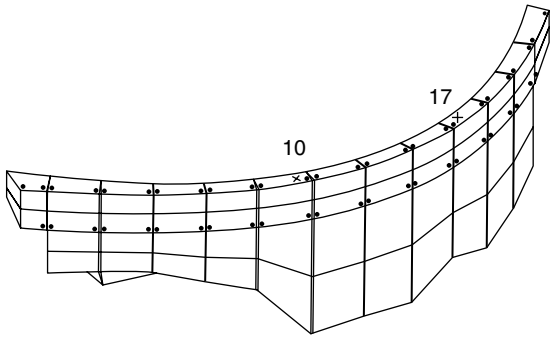

Figure 10. Measurement point grid (dots) and location of the driving points 10 and 17 (crosses).

2.5 Finite element modeling and updating

After completion of the tests, a preliminary FE model was updated using a dedicated software package [21]. Updating included the introduction of a soft layer between the blocks and optimizing the stiffness of the springs reflecting soil–structure interaction. The modal assurance criterion (MAC) value is used to compare the coincidence of two mode shapes. $MAC = 1$ (also given as $MAC = 100\%$) means that two shapes are identical, $MAC = 0$ means that two shapes are orthogonal (completely different from each other). For the final model, MAC values comparing the mode shapes as determined experimentally and as calculated from the FE model are higher than 0.92 for the first five modes. This can be rated as "very good". Figure 12 shows a comparison between the frequencies and shapes of the first four modes as extracted from the experiment and as calculated using the FE model.

3 NORSJÖ DAM

3.1 The dam

Norsjö dam is located in northern Sweden, west of Skellefteå. The dam is a cylindrically shaped reinforced concrete structure with a length at the crest of 169 m, a maximum height of roughly 46 m, and a radius of curvature of $R = 110$ m (Figures 13 and 14). The dam width is 2.5 m at the crest and 5.5 m at the foundation (Figure 15). At the dam downstream side, a reinforced concrete wall of 150 mm width is located at a 0.8 m distance of the main

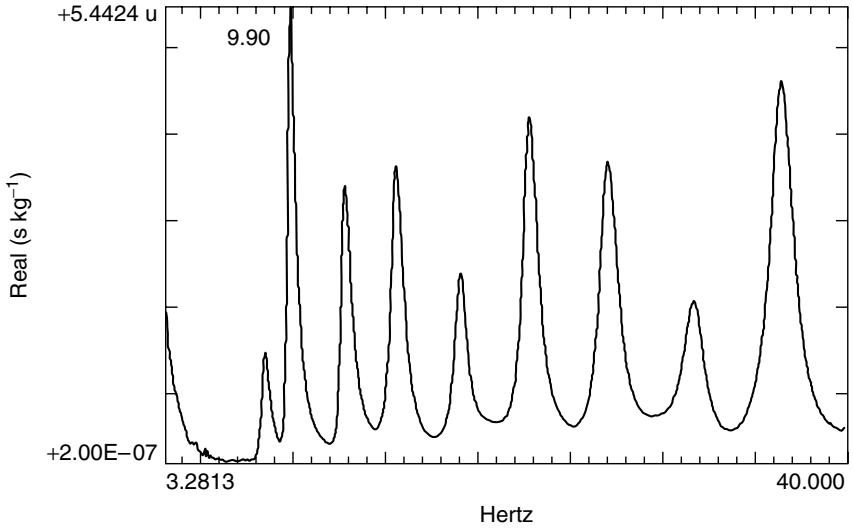

Figure 11. Modal indicator function (MIF) for Vieux Emosson dam.

Table 1. Frequency and damping of the first six modes of Vieux Emosson dam

Mode number	Frequency (Hz)	Damping (%)
1	8.42	3.5
2	9.90	2.6
3	12.80	2.8
4	15.62	2.7
5	19.10	2.4
6	22.86	2.5

structure. This wall and the dam's main structure are connected through a large number of reinforced concrete bars of 150 mm × 150 mm cross section positioned in a grid with a mesh width of 2.88 m. Wooden planks are located on every second row of these concrete bars, which makes the downstream face of the main structure easily accessible over the whole dam height (Figure 16). This wall prevents the downstream face of the dam from freezing and hence from locking the water flow. Norsjö dam is part of a river exploitation system with the turbines and generators located at the dam footing. Although the reservoir surface freezes in winter, the production of electricity continues throughout the year.

Norsjö dam is owned by Vattenfall Utveckling AB. The tests were jointly financed by Vattenfall and an EMPA research project [22, 23].

3.2 The problem

A preliminary FE analysis performed at the Royal Institute of Technology, KTH, Stockholm [24], had shown that the behavior of the structure was strongly dependent on the real state of the boundary conditions: Where is the connection to the surroundings pinned, where is it elastic, and where is it clamped? Having a look at the cross section shown in Figure 15, it becomes clear that it is, e.g., not easy to predict the behavior of the connection between the footing of the dam and the rock. It was, therefore, the major goal of the tests described here to determine an FE model being as close to reality as possible.

3.3 Preliminary ambient test

To get an idea of the dam fundamental natural mode a preliminary test was performed. Two facts resulted from this: (i) the dam fundamental frequency is $f \approx 3.2$ Hz and (ii) operation of the turbines and generators located at the powerhouse at the dam bottom resulted in disturbing peaks in the dam vibration spectra (Figure 17). The very narrow peaks in the spectrum could all be related to either the Kaplan or the Francis turbine located at the powerhouse. This meant that testing was reasonable at times when

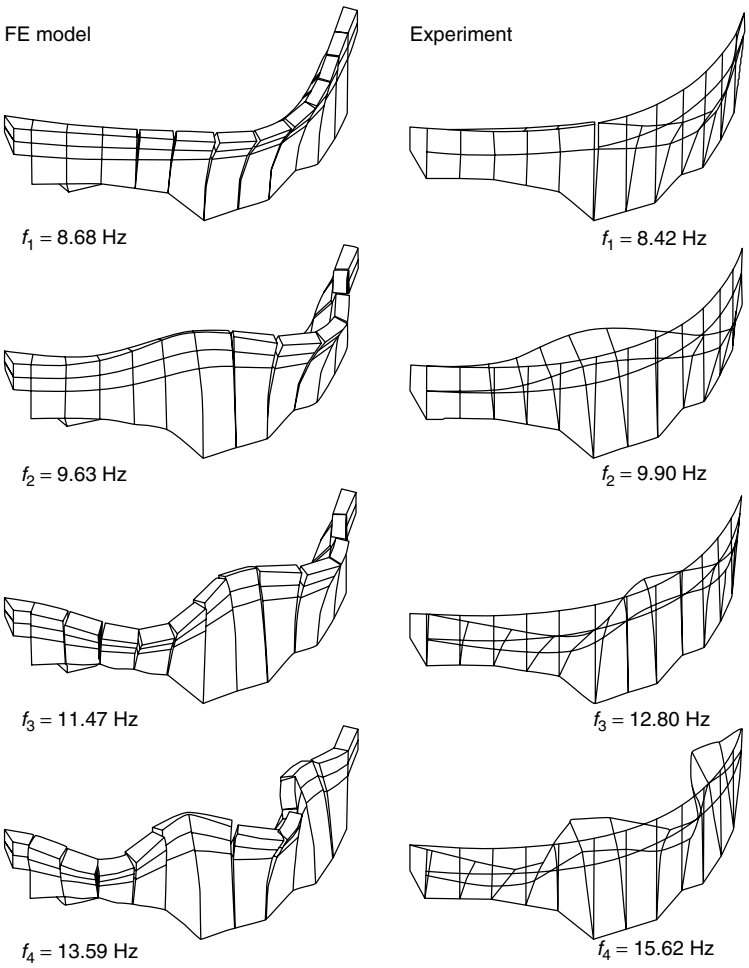

Figure 12. Natural frequencies and mode shapes of the first four Vieux Emosson dam modes.

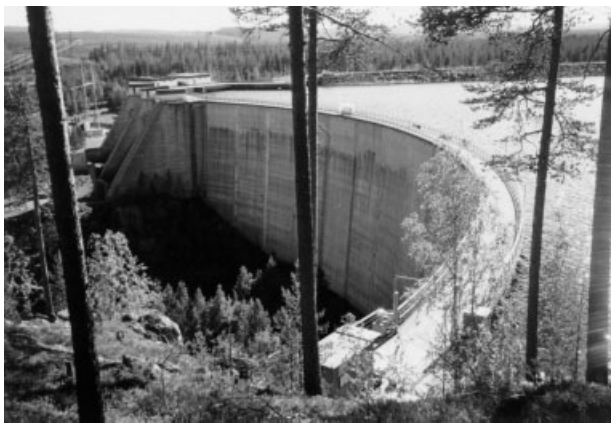

Figure 13. Norsjö dam. To the left, spillways and powerhouse.

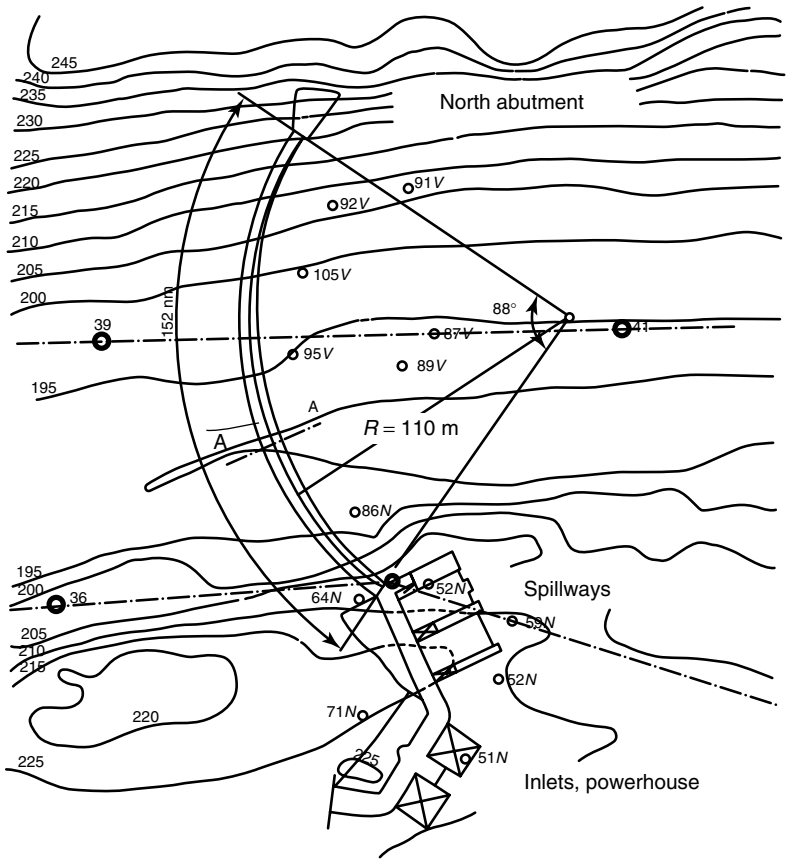

Figure 14. Plan view of the Norsjö Dam and the adjacent structures.

the powerhouse was shut off only. As a consequence, tests were performed during the night and during weekends only and close cooperation with the powerhouse control center was necessary. The consequences of the dam natural frequency being $f \approx 3\,\mathrm{Hz}$ are discussed below.

3.4 The excitation

A similar servohydraulic shaker as for the Vieux Emosson tests was used (Figures 18 and 19). However, as there were no insurmountable problems with the accessibility of the dam here, a hydraulic power pack with an $80\,\mathrm{l\,min^{-1}}$ capacity was chosen instead of the $40\,\mathrm{l\,min^{-1}}$ power pack used for Vieux Emosson. The reason for this was the fact that the Norsjö dam fundamental frequency, $f \approx 3.2\,\mathrm{Hz}$, lies significantly lower than the $f = 8.42\,\mathrm{Hz}$ of Vieux Emosson dam.

The basic problem with any kind of vibration generator using inertial forces is the force produced being directly proportional to the acceleration of the moving mass and hence to the square of the frequency of excitation. This means that it is difficult to generate high forces at low frequencies. Whereas it was acceptable for Vieux Emosson dam to have an excitation spectrum being flat for $f = 5, \ldots, 40\,\mathrm{Hz}$, it was preferred for Norsjö dam to dispose of a force spectrum being flat for $f = 2, \ldots, 40\,\mathrm{Hz}$. This could be achieved using the larger power pack because this allowed to make use of the full capacity of the $63\,\mathrm{l\ min^{-1}}$ servovalve and of the 250-mm-cylinder stroke for low frequencies. The forcing signal was of the continuous random type with a maximum force amplitude of 32 kN (Figure 20).

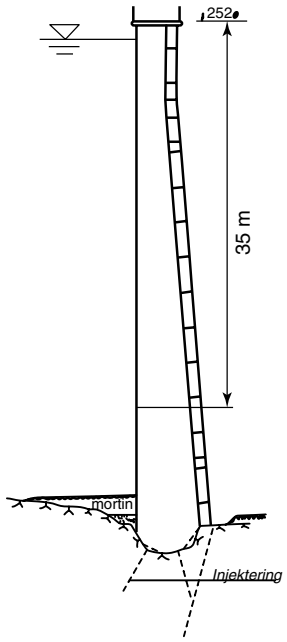

Figure 15. Norsjö dam cross section.

Figure 16. Between water (to the right) and air (to the left).

The standard problem with having enough electric power available to drive the power pack could be solved in a very elegant way here. If we need a 90-kW connection, we can simply plug into the local network (Figure 21).

On the basis of the results of the preliminary FE analysis performed at KTH earlier [24], point 6 was chosen as the driving point (Figure 22). At the end of the first day of testing, this choice was confirmed through analyzing the results for the measurement points on the dam crest. The shaker was obviously not sitting in a node of the shape of a mode of concern.

3.5 The response

The measurement point grid consisted of 227 three-dimensional measurement points distributed over the dam crest and the downstream face (Figure 22). This grid was subsequently extended to the rock foundations and to the spillway and inlet/powerhouse structures, where accessible. The number of measurement points thus increased to 270. The full measurement point grid is reflected in the graphics shown in Figures 30–33.

Three sensor units consisting of three Brüel&Kjær 8306 accelerometers (Figure 23) and a fourth unit consisting of three PCB 393B31 accelerometers (Figure 24) were used simultaneously. Both sensor types have similar specifications (Section 2.3).

3.6 Signal acquisition and processing

The forcing signal and 12 response signals were acquired simultaneously using a 16-channel front end, a computer, and dedicated software (Figure 25). The sampling rate was $s = 100\,\text{Hz}$, the length of a time window was roughly $T = 41\,\text{s}$. No disturbing effects due to nonstationary environmental conditions leading to system nonlinearities were to be observed. Water-level variations in the reservoir were less than 100 mm for the whole week of testing. From the time signals, FRFs averaged over eight times windows were calculated and the modal parameters extracted. Both, the driving point FRF (Figure 26) and the MIF (Figure 27), indicate the existence of 12 natural modes in the frequency range $f = 3, \ldots, 13.5\,\text{Hz}$.

The shape at the crest, the deformation type, the frequency, and the percentage of critical damping of

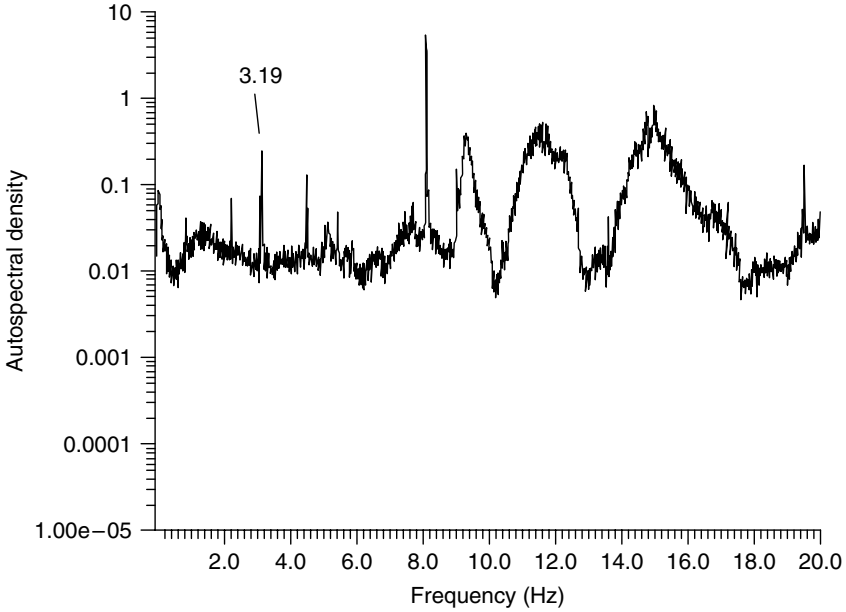

Figure 17. Spectrum of the Norsjö dam vibrations measured with the powerhouse under operating conditions.

Figure 18. The servohydraulic shaker fixed to the Norsjö dam crest. In the background, the air-sprung hydraulic power pack to the left and the air cooler to the right.

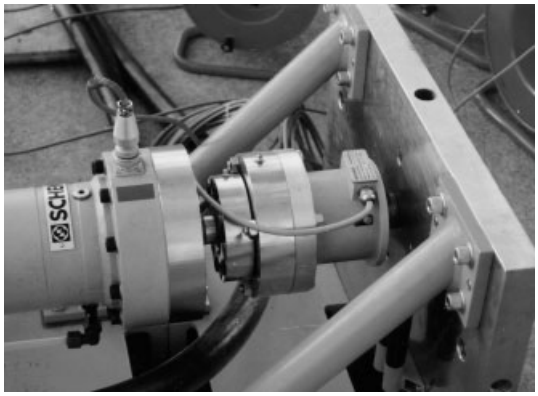

Figure 19. Load cell between the cylinder and the supporting structure.

the 12 modes identified are given in Figure 28. Three basically different shape types can be distinguished: antimetric horizontal bending (AHB), symmetric horizontal bending (SHB), and vertical bending (VB). The horizontal bending modes follow the well-known schedule of an arch-type structure. There is no horizontal bending mode without a node in the crest shape. However, the respective crest shape appears at mode 6, which turns out to be a VB mode (Figure 28).

Unfortunately, it is not possible to discuss all details concerning modes shapes here, in detail. However, to summarize, for all modes, the crest shape indicates the dam being simply supported at the spillway side and completely clamped in at the rock side (Figure 28). The vertical shape of the modes indicates the boundary condition rock/structure at the dam bottom-line to be elastic with being closer to simply supported than to fully clamped in (Figures 30–33).

Figure 21. Swedish–Swiss 90-kW power connection.

3.7 Finite element modeling and updating

The FE model for Norsjö dam consisted of roughly 1000 solid elements representing the dam's main structure, 1500 plate elements representing the secondary wall on the downstream side, and 500 beam elements for the connections "main structure—secondary wall". The boundary conditions in the structure/rock contact area were modeled using three-dimensional elastic springs. Upon updating using a dedicated software package, a quite nice correlation between the experimental and analytical modes could be achieved (Table 2 and Figure 29). This applies, above all, for the first five modes where not only MAC is between 0.8 (80%) and 0.95 (95%) but also the sequence of the modes is the same for experiment and modeling. For the higher modes, there is some disorder in the mode sequence and MAC is between 0.58 and 0.86. Further discussion in this matter can be found in [22]. In Figures 30–33, the experimental and the analytical mode shapes are displayed overlaid; the wire-framed shape shows the experimental results.

4 MAUVOISIN DAM

4.1 Introduction

The goal of the tests discussed here was to prove that it is also possible to determine the dynamic properties of a large dam using ambient methods. To investigate into the effect of the reservoir water level on the dam dynamic characteristics, the dam was tested seven times. Subsequent continuous monitoring of the dam

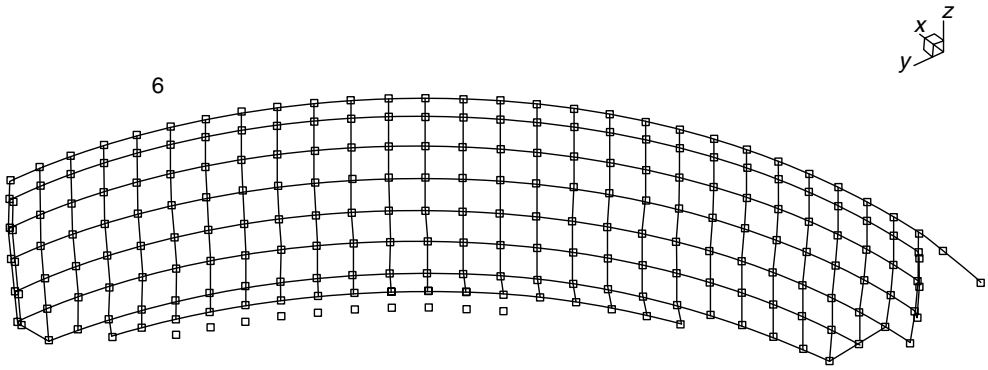

Figure 22. Norsjö Dam: primary measurement point grid as seen from the downstream side. Later on this was extended to also cover the spillways and powerhouse. Point 6 indicates the driving point where the shaker was located.

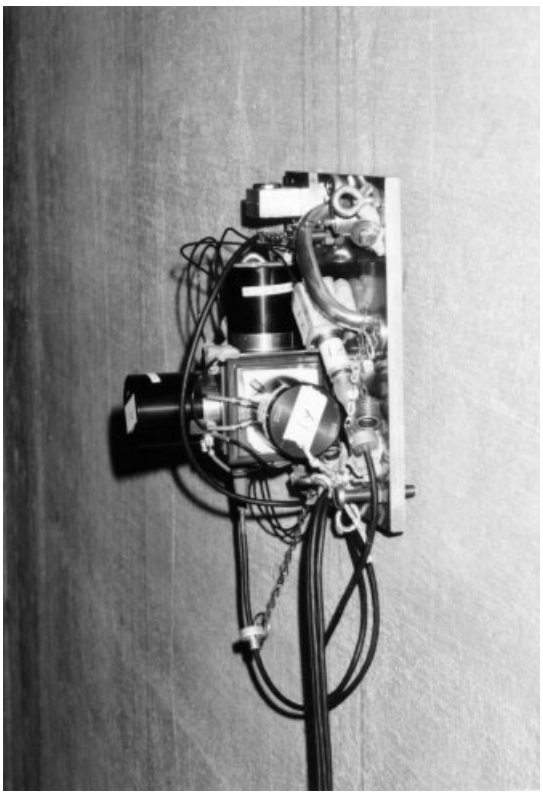

Figure 23. Norsjö Dam: 3-D measurement point with Brüel & Kjær sensors.

during 180 days in 1998/1999 as well as comparison of ambient dam vibrations and vibrations induced by an earthquake occurring during this time is discussed in detail in [25].

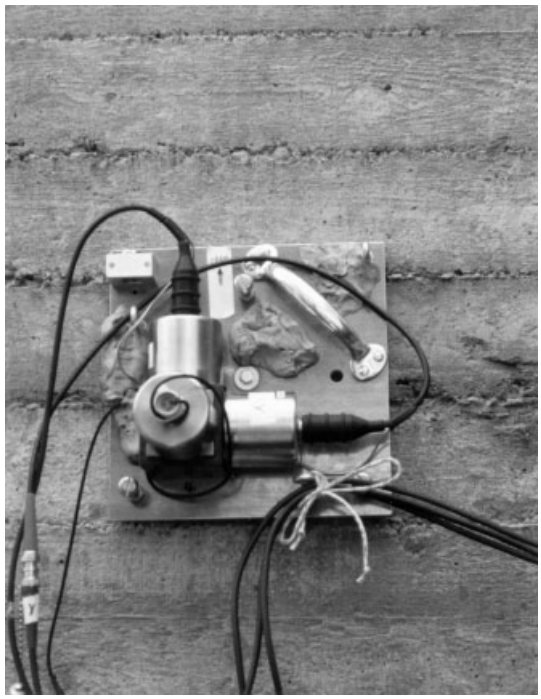

Figure 24. Norsjö Dam: 3-D measurement point with PCB sensors.

4.2 The dam

Mauvoisin dam is a double-curved concrete arch dam with a height of 250 m and a crest length of 520 m (Figure 34). The dam width is 12 m at the crest and 53 m at the foundation. The crest lies at 1976 m above sea level. The dam consists of 2.1 million cubic

Figure 25. The measurement center on Norsjö dam crest.

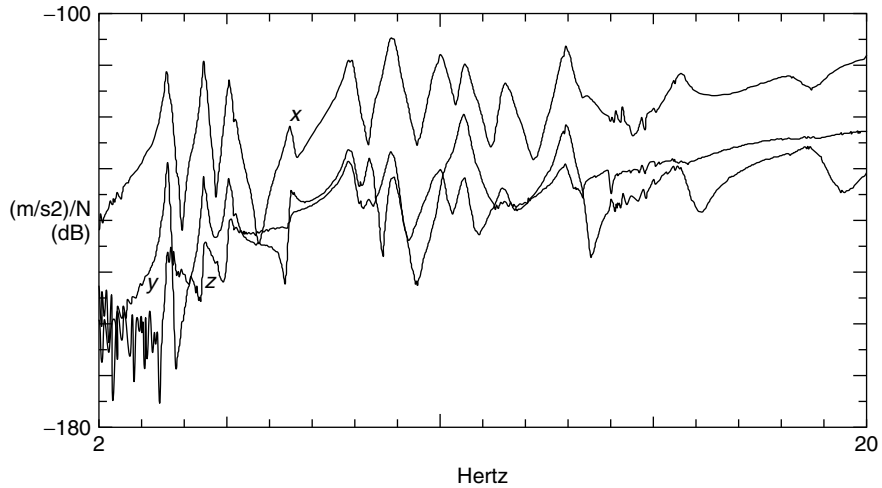

Figure 26. Norsjö Dam: driving point 6 FRF for the x, y, and z directions.

meters of concrete; the reservoir has a volume of 204 million cubic meters. Mauvoisin dam is owned by the Forces Motrices de Mauvoisin SA, Sion, Switzerland. The tests described here were financed through an EMPA research project [26, 27].

When it comes to planning a dynamic test on a dam, one of the first problems to deal with is the accessibility of the measurement points. Usually, small and medium-sized dams like Vieux Emosson dam do not have horizontal inspection galleries between the crest and the foundation. A gallery at the foundation is not very interesting from the point of view of dam dynamics. It is used to connect vertical galleries allowing for checking of the dam static deformations and to check for possible incoming water. The conditions at Norsjö dam were very fortunate allowing installing a very tight grid of measurement points and hence determining the mode shapes

with an extraordinary high resolution. In this respect, Mauvoisin dam is somehow in-between the two.

The nice thing with Mauvoisin dam is that, as a consequence of the dam height having been increased in 1990, there is very large gallery at the old crest level, 1961 m above sea level (Figure 35). In the snow-free seasons, this gallery is accessible with trucks and provides a very nice sheltered area at an interesting dam level. Further galleries are at 1957, 1885, 1837, and 1789 m and at the foundation, 1728 m above sea level. With the exception of the 1837-m gallery, all the galleries are accessible through an elevator at the east side of the dam.

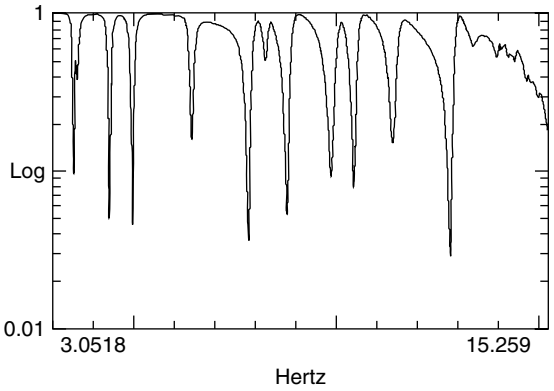

Figure 27. Norsjö Dam: modal indicator function, MIF.

4.3 The test program

Figure 36 shows the relationship between the seven tests performed (phase 1–7) and the reservoir water level.

4.4 The excitation

Although ambient tests were planned, excitation has to be a topic here. Taking a look at the Mauvoisin installation scheme, it becomes clear that several "disturbing vibration generators" exist (Figure 37). Operation of the Chanrion powerhouse located close to the dam crest was easy to identify and to work

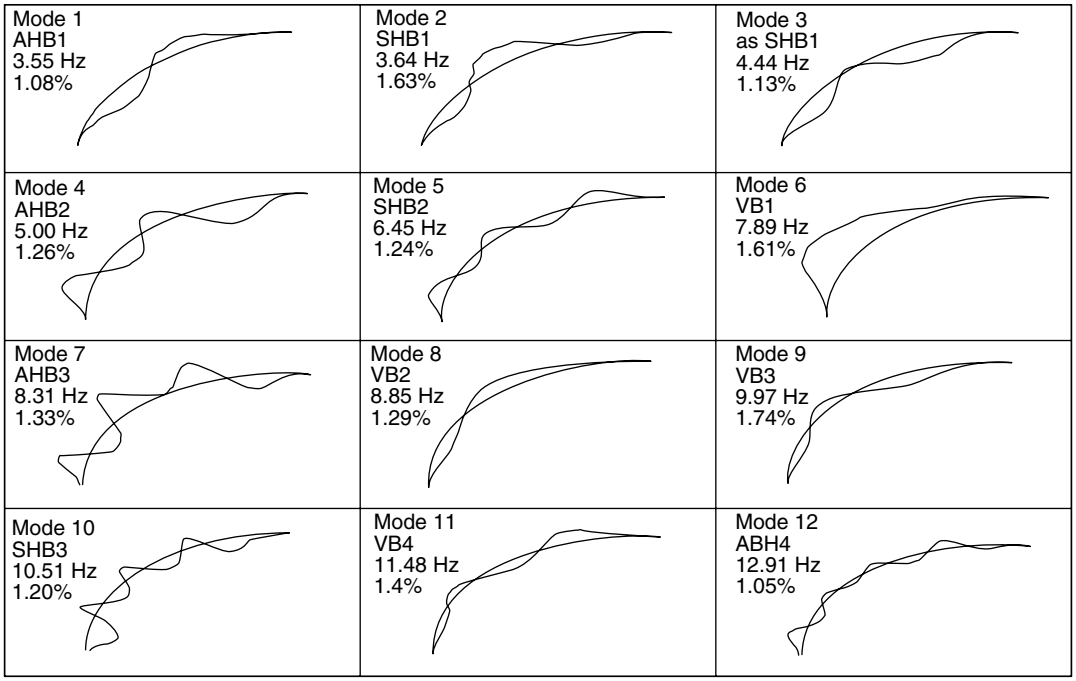

Figure 28. Frequency, damping in percent of critical and crest mode shape for the 12 first modes of Norsjö dam. AHB = antimetric horizontal bending, SHB = symmetric horizontal bending, and VB = vertical bending. The spillway side is to the left, the "rock side" to the right of the shape.

Table 2. Norsjö dam natural frequencies as calculated finite element analysis (FEA) and as measured experimental modal analysis (EMA) and MAC values comparing the mode shapes

Mode pair	FEA number	Frequency (Hz)	EMA number	Frequency (Hz)	MAC (%)
1	1	3.66	1	3.55	87.4
2	2	3.71	2	3.64	79.5
3	3	4.64	3	4.44	95.8
4	4	4.92	4	5.00	94.7
5	5	6.16	5	6.45	89.2
6	6	7.70	7	8.31	58.6

8	10	8.85	8	8.85	86.1
9	11	9.48	10	10.51	72.8
10	12	9.75	9	9.97	77.2
11	13	10.81	11	11.48	74.6
12	14	11.58	12	12.91	69.4

around (Figure 38). This "work around" is discussed in more detail in Section 4.6.

It took some time to find out that operation of the Fionnay power station had quite bad effects on the signals measured. Opening and closing of the valves controlling the water flow to the turbines produced shock waves traveling back to the dam and significantly disturbing the dam's natural vibrations. As these processes could not be easily controlled, tests were performed with the Fionnay power station being out of operation for phases 2–7.

Furthermore, problems arose with changing wind conditions. This is discussed in detail in [26, 27]. Summarizing here, the level of the dam vibrations was significantly influenced by the wind conditions. Therefore, not all the maximum 16 dam natural modes could be identified for all seven tests performed (Section 4.8).

4.5 The response

The dam vibrations were measured using three-dimensional force balanced accelerometers, Kinemetrics FBA-23, and one-dimensional FBA-11. These have a full-scale range of $\pm 0.5\,\mathrm{g}$, a sensitivity of $5\,\mathrm{V\,g^{-1}}$ and a dynamic range of 140 dB for frequencies $f = 0, \ldots, 10\,\mathrm{Hz}$. The 16-channel signal-conditioning hardware consisting of amplifiers and filters is described in detail in [26].

Seven tests were performed between June 1995 and October 1996 (Figure 36). All the measurement points shown in Figure 39 were covered in one of these tests only. For the other tests, the measurement points were located on the "old crest" level only.

This is quite easy to understand, because distributing the cables from the "old crest" level, where the measurement center was located, to the lower galleries was very difficult and very time consuming. It can be seen from Figure 34 that from two of the lower galleries access to a device mounted on the dam air side was possible. Let us call this device an "air ladder". Here, the cables could be led

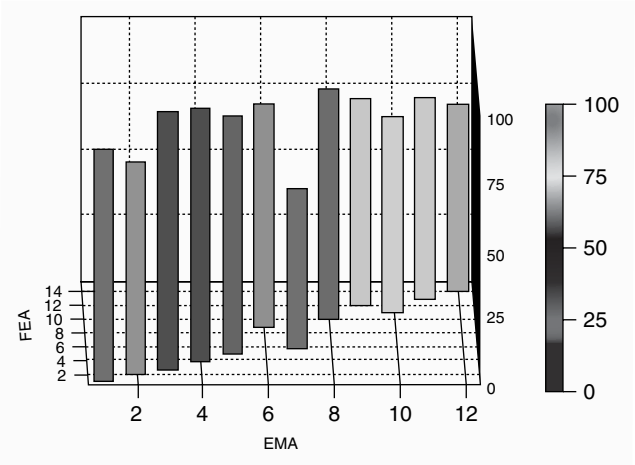

Figure 29. Norsjö Dam: graphical representation of the MAC values comparing the mode shapes as calculated (FEA) and as measured (EMA).

down to a lower gallery through the air. Access to the gallery without this air ladder was possible through a vertical tunnel only. This was quite a bad experience. Another bad experience was the fact that Mauvoisin dam is one of the favorite places for base jumpers to practice. The opening of their parachutes sounds very much like an explosion and if we are situated on one of these air ladders and do not hear them coming, and their parachutes open some meters from us, we are in for a shock.

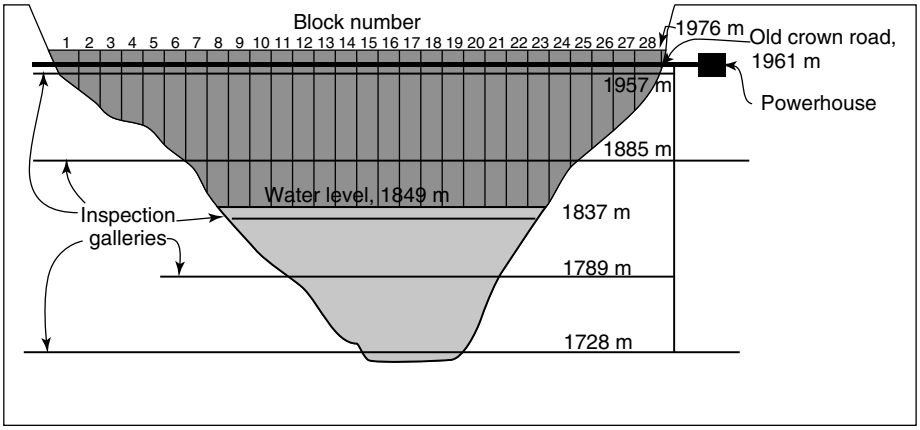

Figure 35. Mauvoisin dam. Topology of blocks and galleries as seen from downstream. The elevator is indicated to the right.

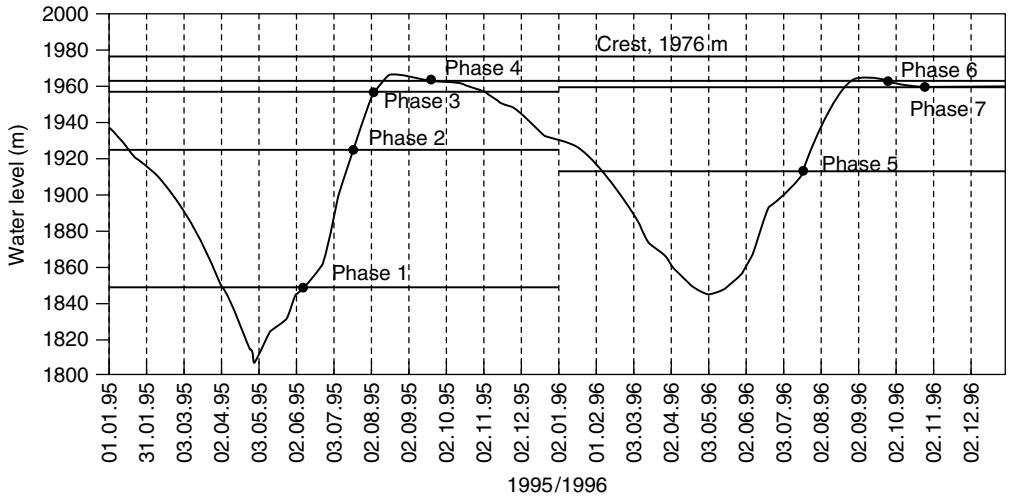

Figure 36. The seven test phases and the respective reservoir water level.

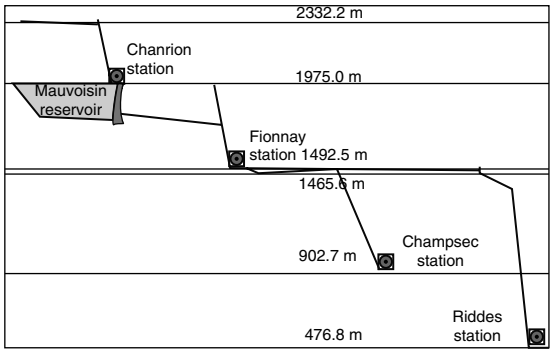

Figure 37. The Mauvoisin exploitation system.

4.6 Signal acquisition and processing

The sampling frequency was $s = 40\,\text{Hz}$, the length of the time window acquired per setup was either $T = 54\,\text{s}$ or $T = 108\,\text{s}$. Figure 40 shows a typical time signal for both a low-level and a high-level ambient excitation state. The amplitude ratio is about 1 : 30.

The signals were processed by Andreas Felber using the software package that he had developed [9]. Today, his method is called *peak picking*. This means that the amplitude and phase relationships

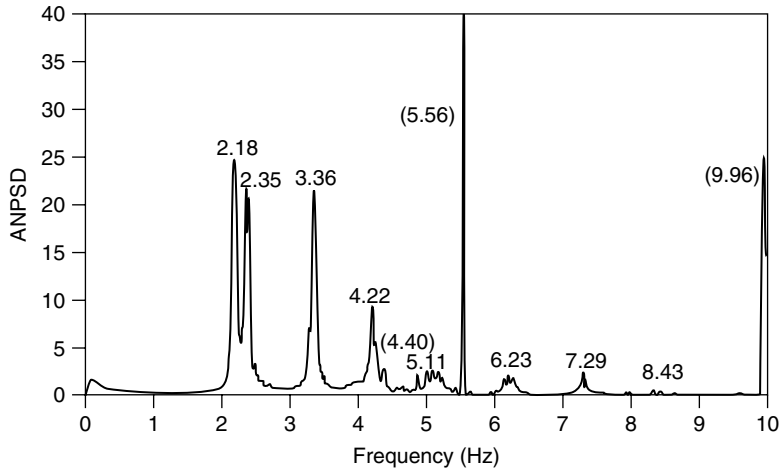

Figure 38. Typical frequency spectrum for the upstream/downstream direction with the Chanrion powerhouse in operation. ANPSD = averaged normalized power spectral density. Frequency values in parentheses are machine-excited harmonic vibrations.

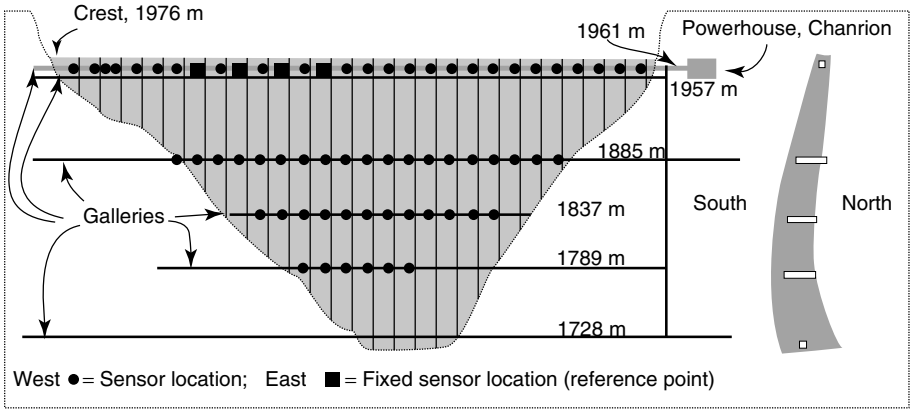

Figure 39. Mauvoisin dam measurement point grid as seen from downstream.

between the signals of a reference sensor, degree of freedom (DOF), and a roving sensor DOF is calculated for the frequency line manually picked from the spectrum. The advantage of this procedure is that peaks representing machine-induced harmonic vibrations can easily be kept out of the signal processing (Figure 38). This is not the case for traditional modal analysis procedures used for FVT tests where signal processing is automated. The same would also apply to modern stochastic subspace identification (SSI) techniques [11], used to process ambient tests in the time domain. In the last two years, the problem of automatically removing "disturbing" peaks related to machine-induced, purely harmonic vibrations from automated signal-processing algorithms, has been successfully dealt with in [12]. These algorithms consider the fact that the kurtosis of a natural structural vibration and of machine-excited purely harmonic vibration is not the same. Hence, the algorithm checks the kurtosis for every peak in the frequency spectrum (transferred back to time domain) and takes out the "bad" ones.

Finally, Felber's software packages did not deal with damping. Therefore, damping is not a topic here. Helmut Wenzel later on extended the Felber software packages with a routine to estimate damping.

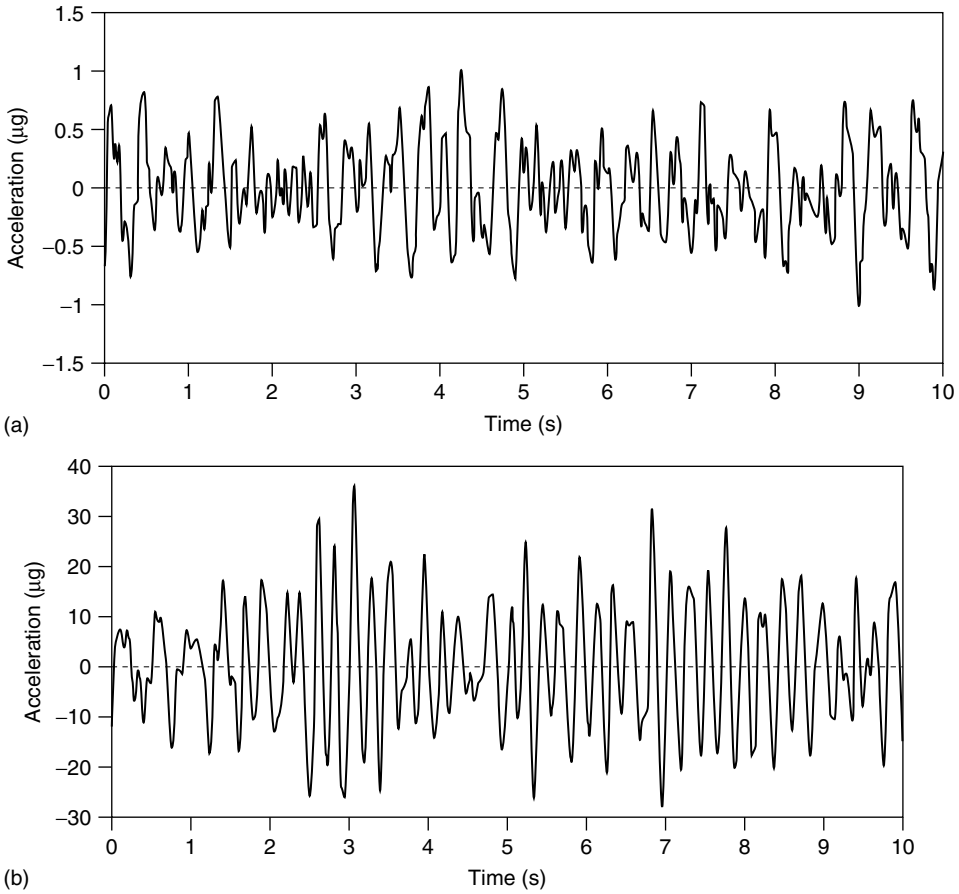

Figure 40. Typical acceleration time signal as acquired at block 7 of Mauvoisin dam for phase 1, water level 1849 m (a) and for phase 2, water level 1924 m (b).

Estimation of damping coefficients from ambient tests is included in modern commercial signal-processing software packages.

4.7 Modal parameters

Figure 41 shows the Mauvoisin dam crest shape for the first eight modes determined for a water level of 1.849 m. As for Norsjö dam, there is no node-free mode shape for horizontal bending.

4.8 Influence of the reservoir water level

Figure 42 shows the natural frequencies of the first 16 modes of Mauvoisin dam as a function of the

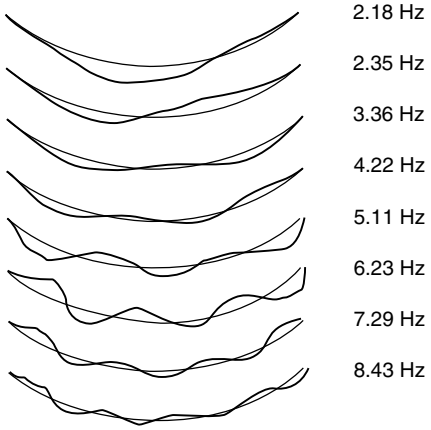

Figure 41. Mode shapes of Mauvoisin dam crest as determined for phase 1, water level 1849 m.

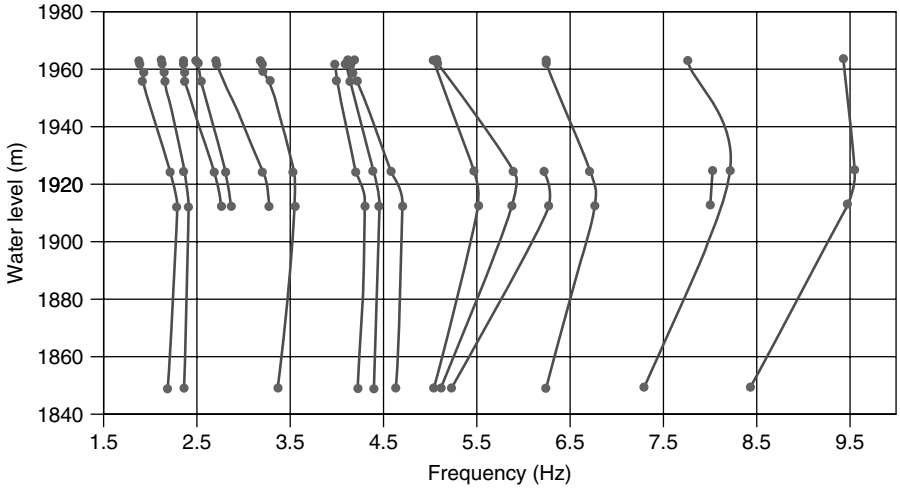

Figure 42. Frequencies of modes 1–16 of Mauvoisin dam as identified for different reservoir water levels.

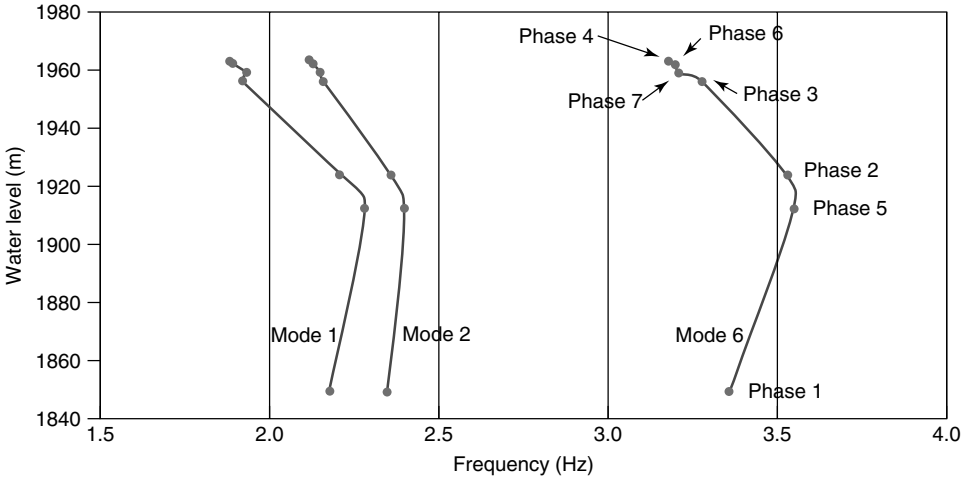

Figure 43. Frequencies of modes 1, 2, and 6 of Mauvoisin dam as identified for different reservoir water levels.

reservoir water level. Missing points indicate that it was not possible to identify the respective mode. This was mainly due to a bad signal-to-noise ratio for the respective frequency.

The results for the "best identified" modes 1, 2, and 6 are shown in Figure 43 and the phases 1–7 are identified.

Citing from the conclusions given in [25]: "The stiffening of the dam due to increasing hydrostatic pressure is more important than the added hydrodynamic masses for lower water levels. This trend is reversed for higher water levels."

Chapter 137
Condamine Floating Dock, Monaco

Luis M. Ortega and Manuel A. Floriano
GEOCISA, Madrid, Spain

1 INTRODUCTION—DESCRIPTION OF THE DOCK

The surface area of the Condamine Marina in Monaco was enlarged by 60 000 m^2 by building a semifloating dock. This floating dock is a double hull structure 352.72-m long, 28-m wide (44 m at the bottom slab level) and 19-m high (24.5 m with building superstructures included). This 167 000-t caisson was built in a dry dock prepared for this purpose in Algeciras Bay (Cádiz) (Figure 1) and was towed to Monaco in August 2002 (Figure 2). Detailed description of the work and its transport process can be found in [1–7].

A four-level car park with a capacity of 380 vehicles occupies 192 m of the dock, and another 136 m is used for storing cargo and small boats in two levels, 6-m high each. There are 12 cells, distributed on both sides of the structure (zones X and Z), which contain the liquid ballast (water) needed to control the floating level of the caisson (Figure 3).

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

2 MONITORING OBJECTIVES

The idea of monitoring the dock enables to meet the owner's requirement to check that the structure had not suffered any damage during its transportation to Monaco and its installation over there [1, 4].

The main objective of the monitoring was, therefore, to provide the necessary information for assessing the flexural forces produced during these phases and to verify that they did not exceed those established for the project.

Given this basic objective, the design of the instrumentation developed by GEOCISA was carried out in permanent collaboration with INTECSA-INARSA, the engineering consultant, commissioned with the design and supervision of floating dock and the control of the bending forces during the launching and transport phases to the Port of Monaco.

The installation of the instrumentation was carried out when the caisson was dry in the Crinavis dock. Preliminary tests for checking the monitoring system were performed during the floating phases of the

Figure 1. The caisson during the controlled flooding of the basin.

Figure 2. The caisson during the transport to Monaco.

dock and when changing the ballasts from the floating phase to the transport phase.

3 DESCRIPTION OF THE MONITORING SYSTEM

In order to meet the above-mentioned basic objective, an automated monitoring system was installed and designed to accomplish the following:

- recording the movements produced in the dock by measuring the longitudinal and transverse rotations using six servoclinometers;
- assessing the flexural forces in the dock as a box beam, from the longitudinal strains measured using 39 fiber-optic sensors;
- checking that no problems arose in the ballast cells by permanently controlling the water level in those cells using 12 pressure sensors;

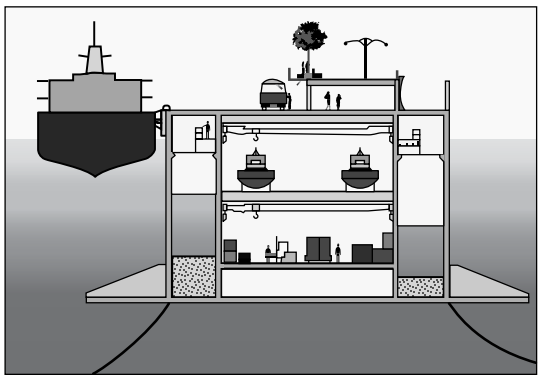

Figure 3. Typical cross section of the caisson.

- registering the overpressures, which could be produced on the upper slab or the port and starboard side walls of the caisson, in the areas next to forward and astern due to the swell. To do so, 18 sensors were used for the control of these potential hydrodynamic overpressures and 6 sensors for the control of the draught level.

All the above was completed with 16 sensors for temperature control on the external and internal concrete surface areas. There were a total of 97 sensors, 61 of which (those corresponding to rotations, strains, and temperatures) were concentrated in the three sections indicated as A, B, and C in Figure 4.

3.1 Strains

The deformations were measured using long-base (2 m) fiber-optic extensometers, with a silicon cover by *OSMOS* (Figure 5). Thirteen sensors were installed in each section in the positions indicated in Figure 6.

Each extensometer was connected using a multimode fiber-optic cable to an optoelectronic device called an *Opto-Box* (Figure 7), which generates an infrared light beam that is propagated through the extensometer. The light intensity of the optic signal from the extensometer, related to the unit deformation between its ends, returns to the Opto-Box and is converted into an electric signal, which is subsequently sampled by the data-acquisition system (DAS).

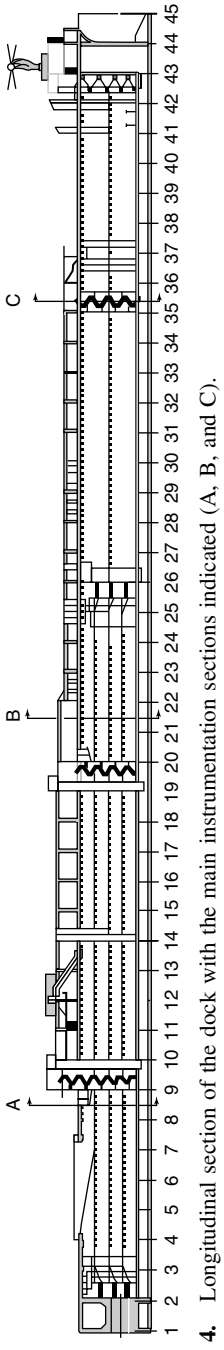

Figure 4. Longitudinal section of the dock with the main instrumentation sections indicated (A, B, and C).

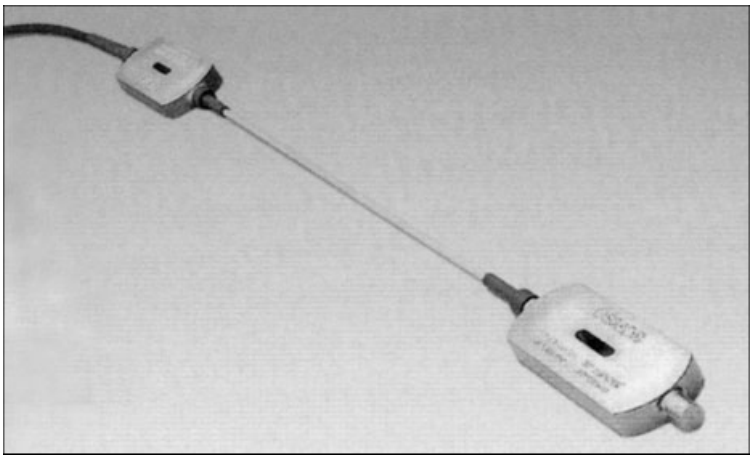

Figure 5. Long-base fiber-optic extensometers.

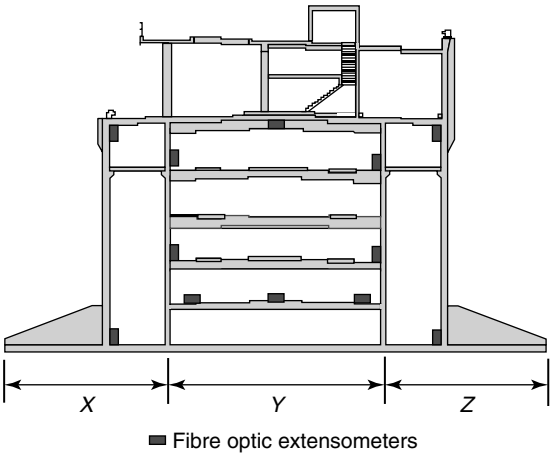

Figure 6. Cross section of the dock, showing the typical location of the fiber-optic extensometers in each instrumented section.

The sensors were installed by fixing their ends to the brass plates anchored to the concrete face. As a lot of work continued to be performed on the dock while installing the monitoring equipment, the extensometers were protected from possible mechanical impacts by using a polyvinyl chloride (PVC), semi-tube (Figure 8).

3.2 Rotations

For knowing the swell-induced movements produced during transport, both pitching (rotation in the vertical plane according to the longitudinal axis of the dock) and rocking (rotation in the vertical plane normal to the longitudinal axis of the dock) were measured in various points on the structure.

To do so, six inertial servoclinometers by *Jewell Instruments* were installed on metal supports with leveling screws. Their output signal was proportional to the pitch or rock angle with regard to the vertical line, and thus a resolution of 0.1 s was obtained.

Two sensors were installed in each of the three main measurement sections: one for measuring the pitching and another for the rocking. As the expected rotations in the event of a storm during transport could be considerable, it was decided that four of them should have a range of $\pm 14.5^{\circ}$ in order to avoid saturation, even in extreme conditions. The range of the other two was considerably lower ($\pm 3^{\circ}$) in order to try to accurately measure the rotations if, as expected, the movements were far less than such maxima. The installation of the clinometers was carried out in watertight boxes fitted to vertical faces on the deck (Figure 9).

3.3 Ballast and draught levels

One of the situations that had to be controlled during the transport was that of a possible break of the ballast cell walls. If such a break occurs, for any accidental circumstances, it could cause an alteration in the liquid ballast (outlet/inlet of water or even its flow

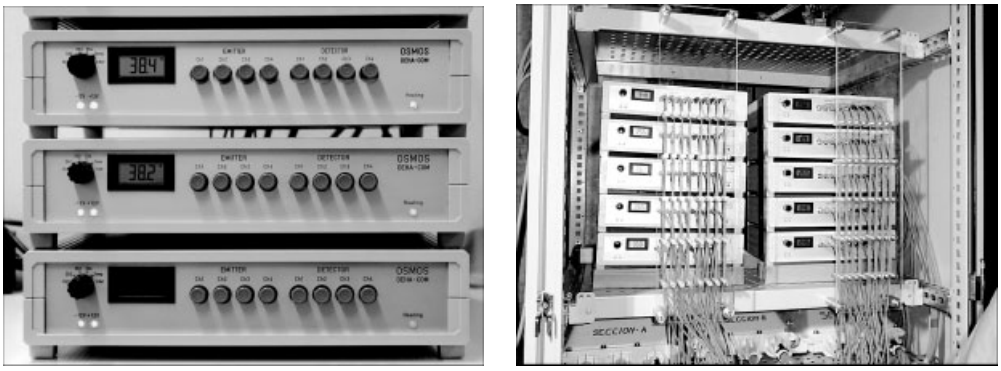

Figure 7. Opto-Box *units*. On the right are the 10 units used, arranged in the measurement centralization cabinet and with the sensors connected.

(a) (b)

(a) (b)

Figure 9. Servoclinometer Jewell LSOC (a) and cabinet with the two clinometers installed in section C (b).

from some cells to others, as not all of them would have the same water level), which could compromise the dock's stability. As such, it was decided to control the water level in the 12 watertight cells fitted to both sides of the structure (Figure 10, zones *X* and *Z*) by installing a relative pressure transmitter in each of them, *DRUCK* PTX-1730, with a measurement range equivalent to a water column of 20 m.

Identical transducers were installed outside on the lower part of the dock, both in each of its four corners and on both sides of its central section B, to measure the dock draught at different points at any time. This was a complementary measurement to that of the rotations, which would allow to detect and characterize strong swell periods.

3.4 Hydrodynamic pressures

In order to determine the hydrodynamic pressures produced by swell during the transport, 18 hydrodynamic pressure transmitters *DRUCK* PTX-530 with a range of 0.15 Mpa were installed: 10 were distributed on the deck slab along the 50 m nearest to forward and astern; and the other 8 were placed on the external face of the caisson side walls at a level corresponding to the theoretical floating level during transport (4 in each of the port and starboard faces, in the zones near to forward and astern) (Figure 11).

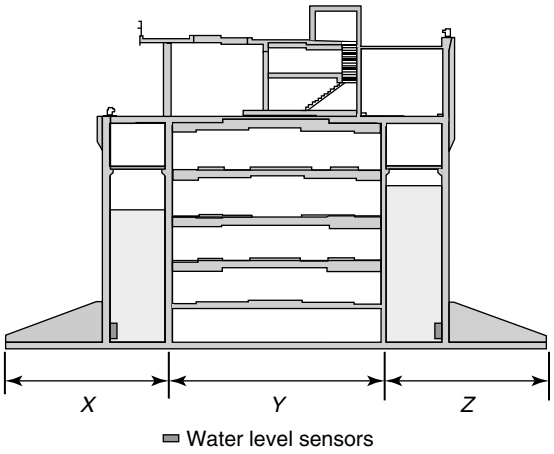

Figure 10. Location of level transmitters in the liquid ballast cells.

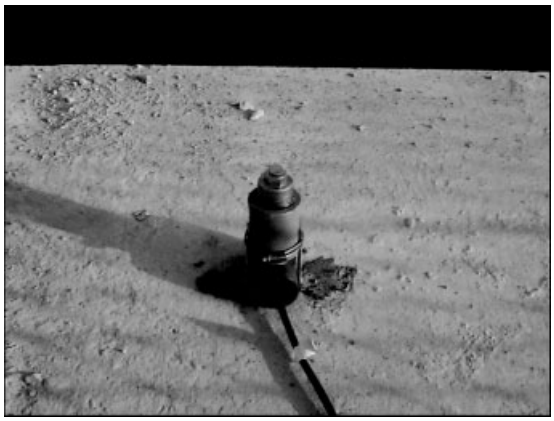

Figure 11. Hydrodynamic pressure sensors arranged on deck.

3.5 Temperatures

In order to make the interpretation of the strain measurements easier (fundamentally during the floating and ballasting operations), it was also decided to register the temperatures on the surface of the concrete using 16 PT-100-type sensors with galvanically isolated outputs.

3.6 Data-acquisition system

A data acquisition system (DAS) captured the information from the 97 sensors. It was located in an air-conditioned cabinet inside the dock (the central process unit (CPU), the Opto-Box units, the power sources, the galvanic isolation converters and connection boxes were also installed in such cabinet) (Figure 12).

The controlled magnitudes were of different nature; some of them (strain, hydrodynamic pressure, and rotations) could vary dynamically, while the others (temperature, ballast, and draught level) would only show slow variations with time. Accordingly, it was decided to record each of the measurement channels corresponding to the dynamic ones at a rate of 10 samples per second, while the other sensors were measured at a rate of 1 sample per second.

The system continuously took recordings lasting for 10 min of the signals from all sensors at the sampling speeds indicated. The real-time status of each sensor could be displayed both in numerical and graphical forms.

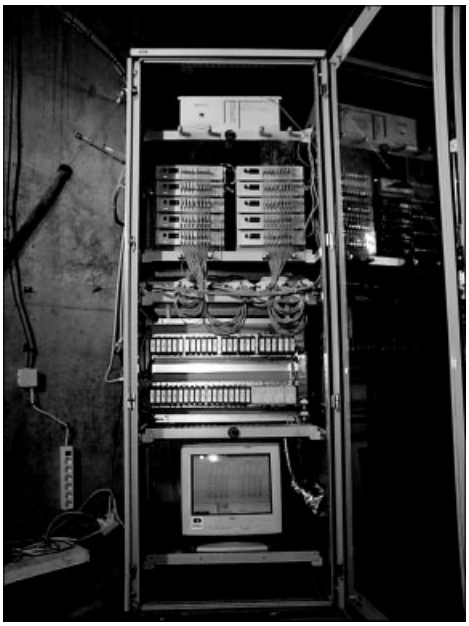

Figure 12. System centralization cabinet.

The owner demands to verify that the bending forces caused during the crossing were below the maximums in the project, called for saving all the 10-min recordings obtained throughout the complete monitoring period, regardless of nothing significant having been detected initially. By saving all records, an analysis could be made at a later date if needed. On the other hand, the number of recordings to be performed over various months (if the floating process was included) would be very large and the calculation of bending forces from the measured strain deformations required a certain amount of time. Taking into account all these circumstances, it was not logical to carry out a detailed analysis, systematically, of each and every one of the recordings, whether in real time or at a later date.

There was a secondary objective of the monitoring: the control of the transport process in real time. This would allow detecting any anomalous situation that could require urgent decisions to be taken (within the limited possibilities for action, which existed in the event of an emergency). This secondary objective was required to perform a rapid analysis of the large volume of data provided by the system and to summarize it into basic information, which could be transmitted to land for the monitoring of the transport.

To do so, it was decided to establish a preliminary processing of the data to help review and transmit them to land and to rapidly take decisions if necessary. This preliminary processing also made it easier to identify the periods during which more significant phenomena had been detected and to concentrate on the detailed analysis of the recordings obtained, and this led to the calculation of the flexural forces from the strain measurements only in these significant periods.

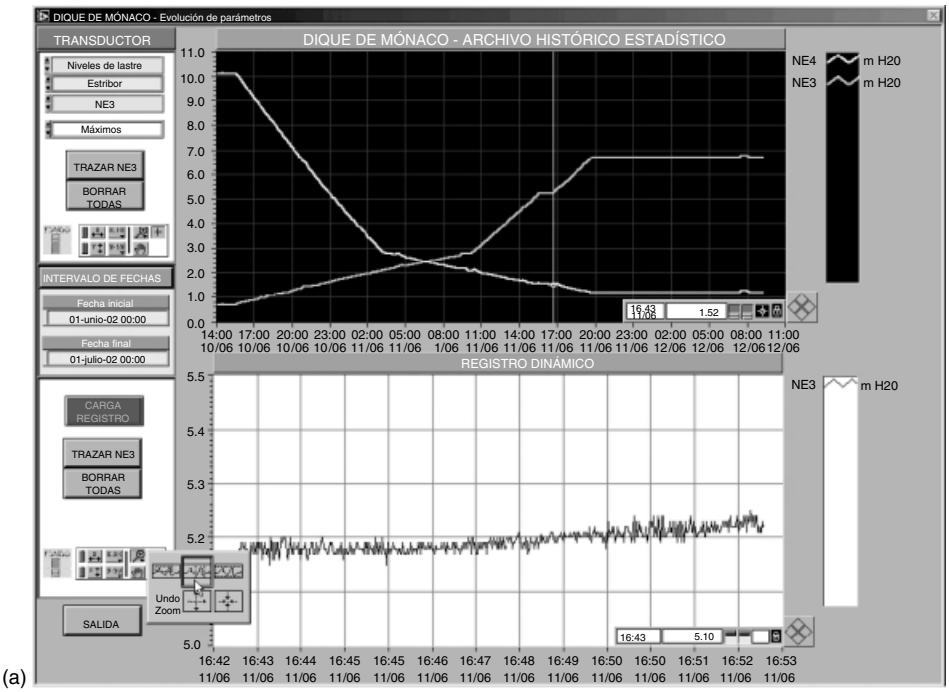
This preliminary processing determined the maximum, minimum, and mean values, and the corresponding deviations of each of the 10-min dynamic recordings for each of the channels were measured. These values characterized each 10-min dynamic recording and they were stored, along with the corresponding start time, on a historical log of the statistical values, which allowed following the evolution of all the channels easily.

A special purpose software developed by GEOCISA facilitated the consultation, on various synoptic panels, of either the time evolution of the statistical values of any sensor and of any of the dynamic recordings carried out, or the visualization of the statistical values of various sensors at the same time, corresponding to a specific period of 10 min (Figure 13).

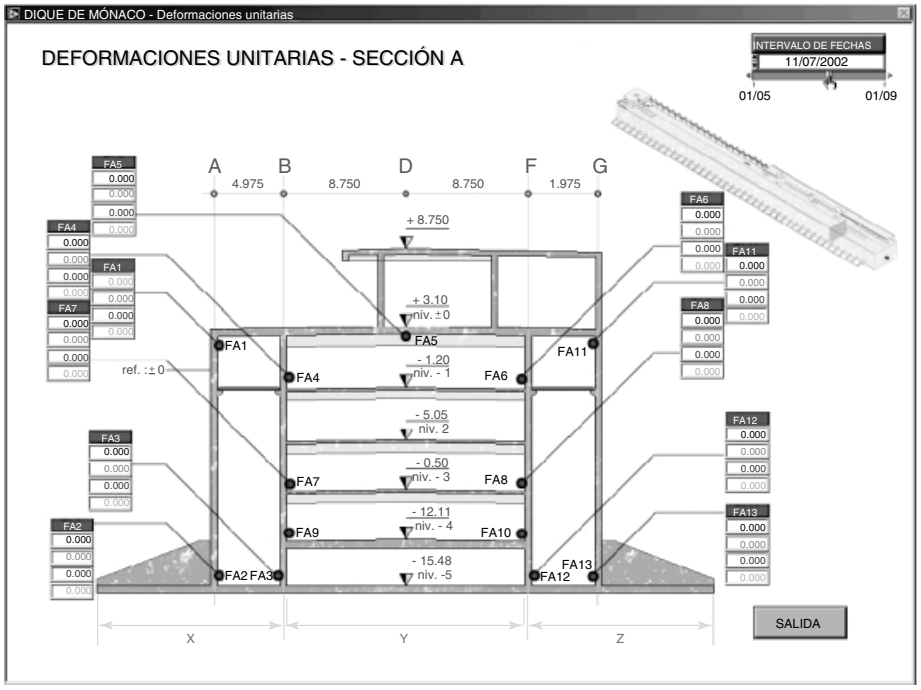
Additionally, upper and lower warning and alarm limits were established for each of the sensors to highlight their status if they exceeded the limits and to facilitate the task of supervising the monitoring by making the operator aware of the occurrence of the most significant situation.

For safety reasons, the physical presence of persons on the dock during the crossing was prohibited except in specific situations. This is the reason a radio link was established between the main computer of the monitoring system, located on the dock, and a second computer for the follow-up and analysis of data, located on one of the tugs. Through this *RadioLink* at 2.4 GHz, which provided a data transmission speed of approximately 4–5 mbps and the use of *PCAnywhere 10.0*, by *SYMANTEC*, both the transfer of files from the main computer, fitted in the caisson, and its remote operation from the remote computer was possible.

The application for displaying the historic files of the aforementioned statistical data, as well as the one for calculating bending forces from the measured



(a)



(b)

Figure 13. (a) Historic evolution of the statistical value of two channels and visualization of a 10-min dynamic register of one of them. (b) Synoptic panel of statistical values of various channels for a period of 10 min.

strains (which is commented on below), was installed on this remote computer. The use of these software applications made it necessary to keep also an up-to-date copy of the historic files of statistical parameters as well as—at least—of those dynamic registers, which could be most significant or of greatest interest on this remote computer. This task was carried out through occasional communication between both computers in order to transfer different files from their initial location in the main computer to the remote computer, installed on board the support tug "*Typhoon*", which accompanied the dock during its crossing to Monaco (Figure 14) [4, 5].

The information was permanently examined and reviewed in the remote computer by two operators taking it in turns. They transmitted it once a day, by e-mail, according to a protocol previously defined, to the follow-up team on land, in order to cover the event of any critical situation that would require extraordinary decisions to be taken.

3.7 Estimating bending forces

Two different phases were considered for estimating the bending forces from the strain measurements. The first corresponded to the floating procedure and the subsequent operations (ballasting with water, tests for the water tightness of the ballast cells, caisson exit maneuvering from the basin to the bay and changing the ballast to the transport situation) until the dock was ready for crossing to Monaco. The second corresponded to the transport itself until completion of the connection operation of the ball-and-socket joint.

3.7.1 Floating phase

During this first phase, the possible bending forces caused in the dock corresponded to very slow processes and the strains had to be calculated by the difference between the measurement at any time and the initial "zero" reading. As the period involved was quite long (various weeks), thermal variations could occur, which would affect both the dock itself and the sensors, as well as the measurement system. As such, it was recommendable to control the temperatures, which could help in interpreting the measurements.

Furthermore, as these quasi-static loads varied very slowly, the measurements over a measurement period of 10 min would have to be noticeably constant. Accordingly, the bending forces during this phase were calculated on the basis of the mean values of the effective strains for each 10-min period. These effective strains were obtained as the difference between the mean readings of each sensor during this period and the period that was considered as origin or zero situation (which was normally the initial point of measurement before starting to flood the dock to float it).

For each measurement section, the program calculated the deformation plane. From this and the geometric and mechanical characteristics of the transversal caisson section, it also estimated the bending forces. The calculation program allowed obtaining the bending moments in two different cases: assuming that the axial strain is nil (forcing the deformation plane to give strain zero in the center of gravity of the section) or not adopting such an assumption (and calculating also the axial

(a) (b)

Figure 14. Remote computer (a) installed on the support tug (b).

strain). Depending on the hypothesis, two or three values were obtained (the bending moments M_y, M_z according to two perpendicular planes and axial force N, in the event of not assuming it as zero) for each 10-min period studied, in each of the sections A, B, and C.

3.7.2 Crossing phase

During the second phase, interest centered exclusively on the bending forces that could be caused by swell. As this was a dynamic phenomenon with a nil average, it was decided to set the average of the readings obtained during each 10-min period to zero and thus only the dynamic variations produced by the swell remained. Any slow variation process was thus eliminated (sensor drift, if it were to exist, influence of the temperature changes on the sensors or on the structure, creep), which would have given a spurious result for the purposes pursued (estimation of the bending moments caused exclusively by swell).

As during the floating phase, the deformation planes were calculated from the effective strains and, based on each of these, the bending moments M_y and M_z were obtained in the three instrumented sections A, B, and C. Similar to a previous hypothesis, it was assumed that the swell did not cause significant axial forces. Therefore, it was always ensured that the deformation plane corresponded to zero strain in the section's center of gravity. As the strain did vary dynamically in this phase, the calculation of the moments was carried out for all the instants measured (at a rate of 10 times per second), providing 6000 values of each bending moment (M_y and M_z) for each 10-min period studied in each of the sections A, B, and C.

Both during the floating phase and the crossing, the program allowed the user to eliminate the values of one (or various) sensor, in order not to take them into account, if it was suspected that, for any reason, this sensor or sensors were not operating correctly.

4 RESULTS OBTAINED

Discussion of results obtained by the monitoring instrumentation is made separately for the two phases mentioned above:

- **Phase 1**

Work performed in Algeciras Bay (flooding of the dock, floating of the caisson, exit of the dock from the basin, and change of ballast in order to have the dock ready for transport) from June 10 to August 13, 2002.

- **Phase 2**

Check during the crossing from Algeciras to Monaco (from August 14 to 26, 2002) and the subsequent operations for connection of the ball-and-socket joint (until September 6, 2003).

4.1 Phase 1—Algeciras

Two curious sets of circumstances are worth highlighting with regard to the analysis of the results of this phase, both related with the actual analysis of the data.

Figure 15 shows the evolution graphs for two strain sensors in section B, located on the lower face of the caisson's upper slab (Figure 2) throughout the whole of August 13. On the one hand, it shows a slow variation over the day (13–15 $\mu\varepsilon$ peak to peak), which responds to the daily cyclical temperature change. A ripple with a much smaller amplitude (2–3 $\mu\varepsilon$) is superimposed onto this daily variation wave. After a careful analysis, it was concluded that this ripple corresponded to the warm-up/cooling cycles of the Opto-Boxes, caused by the operation inputs and shutdowns of the actual cabinet air-conditioning system. This emphasized the importance of maintaining the operating temperature of these Opto-Boxes under a specific threshold, as recommended by the manufacturer. At the same time, the result highlighted the magnificent stability and sensitivity of these fiber-optic sensors.

Figure 16 shows the evolution of two strain sensors (FB-4/FB-6) in section A throughout August 11. A sudden jump in the measurement ($\approx$100 $\mu\varepsilon$) can be observed, which did not correspond to similar situations in the other sensors of the section nor with possible real strain caused in the structure. As both sensors were placed in the bottom area of one of the liquid ballast cells, the graph depicting the evolution of the water level in this cell (NB-2) was examined. It was noted that the jump coincided with the moment in which the water level in the

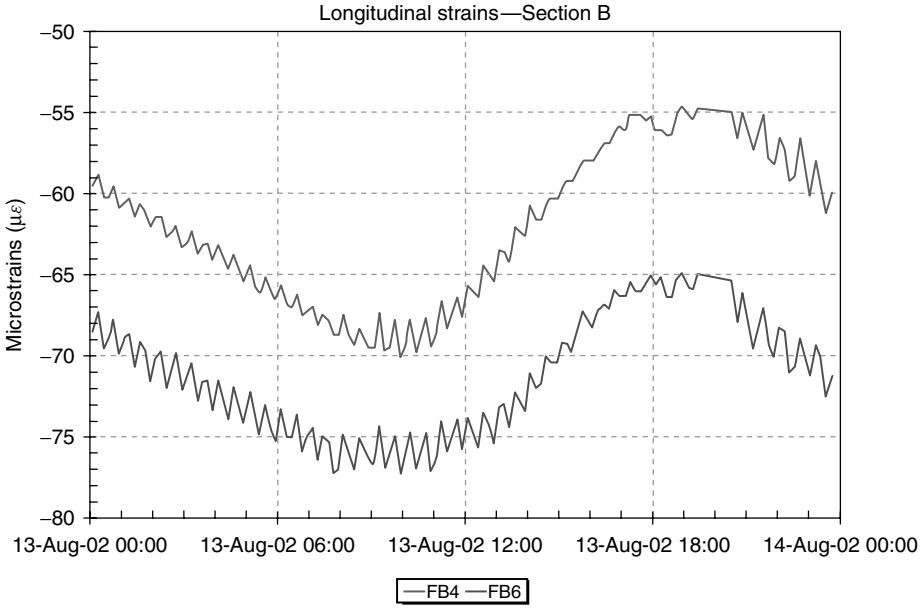


Figure 15. Evolution of unit deformations over one day.

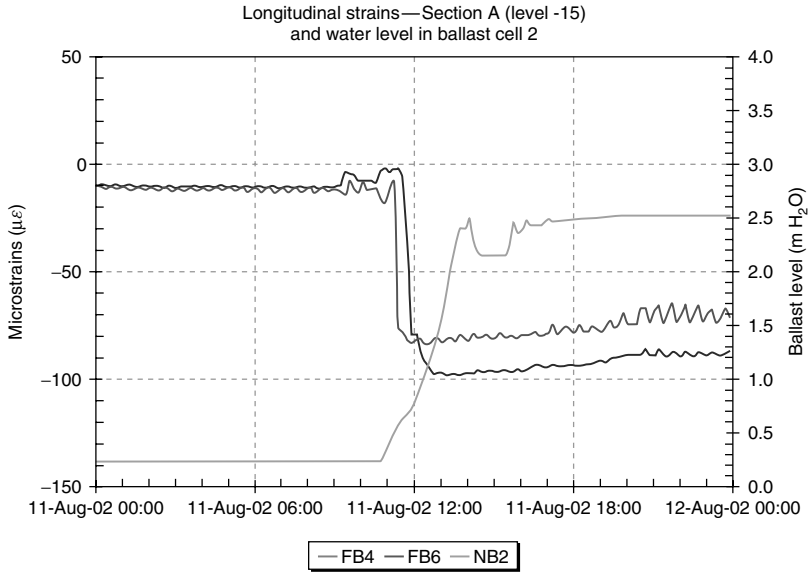

Figure 16. Effect of the hydrostatic thrust on the deformation sensor.

cell passed the level at which these sensors were positioned.

It was checked that the effect was produced when the water level was rising (and, accordingly, the sensor changes from being dry to being submerged) and that the opposite process was produced when the water level was going down.

These apparent strains were mainly caused by the effect of the hydrostatic thrust acting on the actual fiber optic anchored at its ends and, to a far lesser

extent, by the effect of the sudden change of the sensor temperature (and of that of the concrete) when coming into contact with the cold water. This effect was produced in all of the sensors located in the lower section of ballast cells when, as a result of the filling and emptying tests on the cells, there was a change from being submerged to dry or vice versa. Fortunately, once detected, this was easy to correct.

Concerning the bending moment calculation, the main objective of its evaluation during this phase was the possible contrast or calibration of the entire process. In this sense, the fact that various tasks were being carried out on the structure during almost the whole of this phase (water tightness tests, ballast transfer from one cell to another, etc., and even the continuation of works on the dock itself) made it practically impossible to perform a reference theoretical assessment. This difficulty in assessing the actions, actually applied to the caisson, prevented from obtaining a reference to compare the experimental measurements. Nevertheless, an attempt was made to experimentally contrast the flexural forces produced by the change of ballast level performed just before transporting to Monaco and after the exit of the dock from the basin. In that process, there was a relatively good control of the actions (the ballast levels in the cells and, therefore, draught of the dock) on the caisson, except for thermal effects, and a reasonable estimation of the theoretical bending moments caused by them was possible.

The effective strains were obtained as a difference between measurements taken just before the exit of the dock from the basin (August 6 at 9 p.m.—floating ballast situation) and on August 13 at 9 p.m. (transport ballast situation). The bending moments estimated experimentally, both under the assumption of zero and nonzero axial forces, were quite similar in both hypotheses (differences less than 10%) and clearly less than those estimated theoretically (differences of approximately 30%).

An analysis of the sensitivity of the estimated bending moments with regard to small variations in the strains measured by the sensors furthest away from the center of gravity was performed. It showed that relatively small variations of these measurements ($15-20\,\mu\varepsilon$), due to temperature changes or any other effect (impossible to prevent in a process lasting for various days), could lead to variations in the estimated bending moments of the same order of magnitude as the differences detected with regard to the theoretical values.

4.2 Phase 2—crossing Algeciras—Monaco

During the 12-day crossing, the weather was pleasant and no episodes of significant swell occurred. The liquid ballast levels, a fundamental parameter for control as already commented, maintained good stability throughout the crossing.

The evolution graphs corresponding to the maximum or minimum rotations every 10 min, both transversally and longitudinally, enable a quick detection of episodes of greatest caisson movements due to swell. These most significant movements started at noon on August 18 and were increasing until reaching their greatest value at noon on August 19. The greatest maximum movements were detected at approximately 11 a.m., with maximum transversal and longitudinal tilts of 0.66° and 0.14°, respectively (Figure 17). The hydrodynamic pressures recorded on the caisson side walls are in good agreement with the measurements of the rotations, with the greatest pressure also being detected on August 19. In any case, their values were very small, not exceeding 0.019 Mpa.

The maximum bending moments (in kilonewton meters) produced by the swell, corresponding to those moments of greatest movements during the transport are shown in Table 1. Even in those moments of greatest movements, such bending moments were below 5% of the design theoretically estimated maximums in the event of a storm. The evolution graphs of the experimentally estimated bending moments show very small values, which would have to be considered as practically nil.

The follow-up of the instrumentation was continued until finalizing the ball-and-socket joint connection process [1, 5]. The evolution graphs of the rotations show, perfectly well, the final setting of the first phase of this connection (dock approach until inserting the outside cone of the ball-and-socket joint into its seating in the abutment [1]) (Figure 18). This operation was performed on September 3. Between

Figure 18. Views of the approach process for the final installation of the dock in Monaco.

10:30 and 11:00 a.m., a rotation of approximately 0.1° was observed corresponding to the lifting of 40 cm, using jacks, required for aligning the ball-and-socket joint as referred to in [1]. Later, at approximately 1:00 p.m., an isolated peak of 0.2° was recorded. With a detailed analysis of the dynamic records of the 10-min period between 1:07 and 1:17 p.m., it can be seen that it corresponds to the precise moment when the ball-and-socket joint was connected (Figure 19).

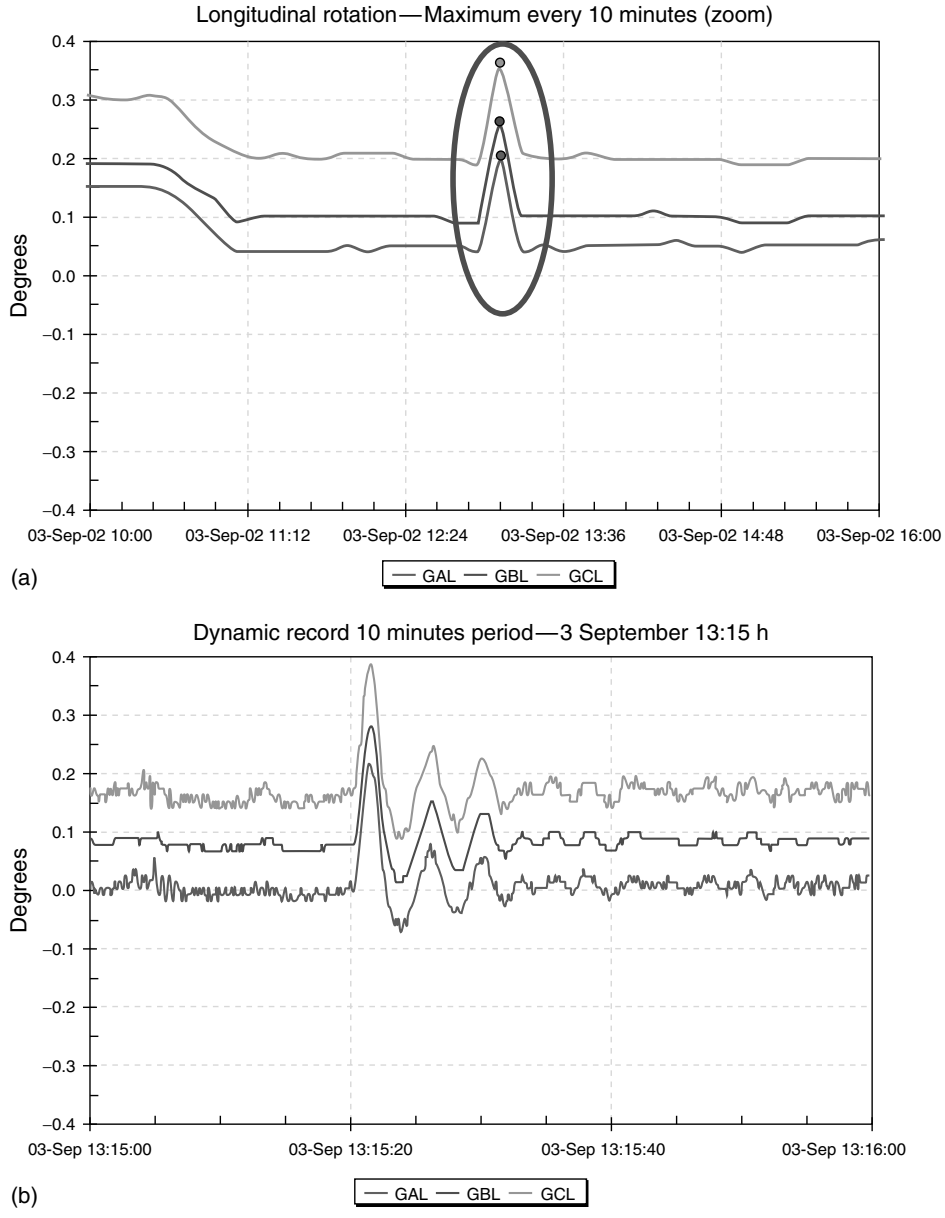

Figure 19. Longitudinal rotations during the connection operations of the knuckle joint (September 3, 2002). (a) Registered maxima every 10 min. (b) Extract of the dynamic register of the rotations corresponding to the period of 10 min between 1:07 p.m. and 1:17.

5 CONCLUSIONS

The monitoring of the floating dock for the enlargement of Port Condamine, carried out during the sea crossing from Algeciras to its definitive location in Monaco, allowed to experimentally check that the flexural forces induced on it during this transport operation was, at all times, under the maximum limits outlined in the project.

The control of the water levels in the liquid ballast cells confirmed its perfect water tightness and the good behavior of their walls and slabs.

The movements (rotations) showed values that were far below the pre-established warning levels. This is in accordance with the favorable weather conditions that prevailed throughout the crossing. In line with this almost calm-sea situation, no episode of swell over the deck was recorded, and the pressure cells installed in port and starboard in the areas close to forward and astern recorded reduced pressure values, far lower than those that could have been withstood by the outer walls.

The bending moments caused by the swell in the caisson, estimated from the strain data experimentally measured, gave values well below those estimated in the various design calculations.

Chapter 138

Soil–Structure Interaction and Seismic Effects

Günther Achs
VCE – Vienna Consulting Engineers, Vienna, Austria

1 INTRODUCTION

In the last few centuries, the seismic risk of many countries was redefined due to several new findings of seismologists and geologists. This has brought considerable changes in civil engineering, concerning the development of new structures as well as the assessment of the seismic bearing capacity of existing structures. As there are various structures that have not been constructed against horizontal loading in previous times, the big challenge of today's engineers is the reassessment of those existing structures.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

Among others (material aging, damages, etc.) there are two main aspects, soil–structure interaction and the realistic system identification, which should be considered within this context. In Section 2 of this article, the effect of soil–structure interaction is described and a brief overview of the existing methods is given. The problem of a realistic identification of the dynamic behavior of existing structures and the benefit of experimental methods are described in Section 3. The main attention is attached to the measurement techniques and signal processing. Finally, in the last section of this article, an overview of seismic effects is given in general.

2 SOIL–STRUCTURE INTERACTION

2.1 Basic information

In seismic hazard analysis of building structures, two main foundation types have to be distinguished. In case of a structure founded on rock, the ground motion on the base can be considered as identical to the ground motion on the same point before the erection of the building. However, if the subsurface consists of soft soil sediments, then there will be

change in the dynamic system. In this case, the structure interacts with the surrounding subsoil, leading to a change in the seismic motion at the base.

In general, the effect of soil–structure interaction due to earthquake loading cannot be neglected and thus appropriate analysis techniques have to be used.

2.2 Theoretical background

For the seismic analysis of structures, it is necessary to apply the earthquake design loads to the foundation. The design loads arise from the inertia forces developed in the superstructure and from the subsoil deformations, which are generated by the passage of seismic waves. As mentioned in the technical literature [1], these two effects are referred to as *inertial* and *kinematic loading*. The influence of both effects depends on the characteristics of the investigated structure, the geometric parameters of the foundations, and the nature of incoming waves. Soil–structure interaction therefore covers both effects.

Most of the design engineers refer to inertial loading as soil–structure interaction, ignoring the kinematic component [1], which can be interpreted from the fact that

- in some situations kinematic interaction has negligible influences;
- kinematic interaction is often not mentioned in seismic building codes; and
- the evaluation of kinematic interaction effects is more difficult than inertial interaction effects.

In Figure 1, the key features of the soil–structure interaction problem are represented [2]. The general situation of an embedded foundation supported on

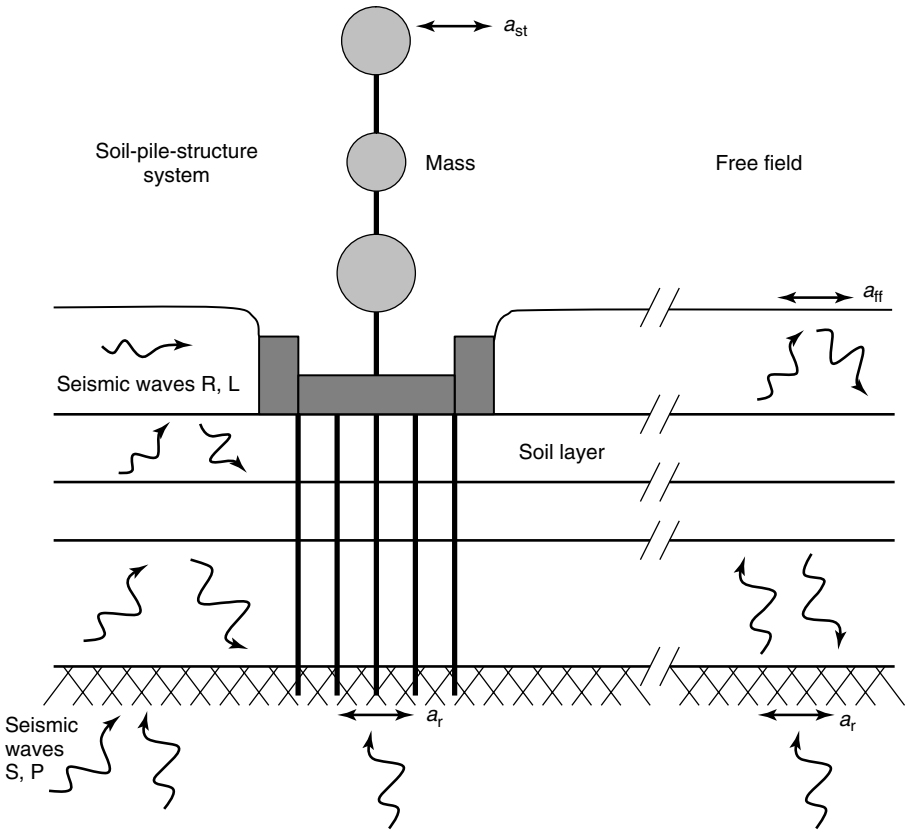

Figure 1. Illustration of soil–structure interaction on the structure response; structural acceleration a_{st}, free-field acceleration a_{ff}, and rock acceleration a_r.

piles is presented. The conclusions given in Figure 1 are also valid for any other foundation type. The subsoil layers around the structure are subjected to seismic excitation, consisting of numerous incident waves such as shear waves (S waves), dilatational waves (P waves), and surface waves (R or L waves).

In national building codes, the nature of the incoming waves is more or less given based on the global seismological conditions of the area. Nevertheless, the geometry, stiffness, and damping of the local soil deposits modify the characteristics of the free-field motion. The modified free-field motion can then be considered as the seismic input on the foundation of the structure. The determination of the free-field motion itself can be very difficult [3]. As mentioned in the technical literature [1], the design motion is usually specified at only one location (ground surface) and the complete wave field cannot be calculated back from this incomplete information. Therefore, assumptions have to be made regarding the exact composition of the free-field motion and it can be stated that no satisfactory solution is available so far.

Owing to the seismic motion around the structure and its foundation, the subsoil forces the piles and the embedded foundation to move. Even without the existence of any superstructure, the motion of the foundation will be different from the free-field motion. This can be explained by the differences in rigidity between the soil on one hand and the piles and foundations on the other hand. The incident waves are reflected and scattered by the foundation and piles. Thus, displacements and forces are imposed on the structure. This phenomenon is called *kinematic interaction*. Owing to the displacements induced at the foundation level, oscillations in the superstructure are generated, which develop inertia forces and overturning moments at its base. Hence, the foundation and the surrounding soil are exposed to additional dynamic forces and displacement; this phenomenon is generally called *inertial interaction*. It is therefore necessary to analyze the foundation of a structure for combined inertial and kinematic soil–structure interaction.

To evaluate the effects of soil–structure interaction of linear systems, it is most appropriate to use linear elastic constitutive or equivalent viscoelastic linear models for the soil. In many cases, soil nonlinearities can often be considered using an approximation by choosing appropriate values for the soil parameters.

2.3 Methods

For practical applications of soil–structure analysis, it is beneficial to use either so-called direct methods or substructure methods.

2.3.1 Direct methods

In general, the easiest way to analyze the soil–structure interaction for seismic excitation is to model a meaningful geometric section of the subsoil around the embedded building structure and to apply the free-field motion to the boundary layer of the subsoil [4]. With this approach, nonlinear behavior of the soil can also be considered. As the number of dynamic degrees of freedom can be very high, according to the geometric extension of the model and the complexity of the parameters, large computational resources are necessary.

2.3.2 Substructure methods

For big and complex models, it is more beneficial to use the substructure method, which implicitly assumes that the method of superposition has to be valid in a soil–structure interaction analysis.

The substructure method is roughly explained in Figure 2. Initially, the free-field vibration needs to be evaluated in the foundation nodes (white nodes). Afterward the interaction part is investigated in two steps, whereas the unbounded soil is analyzed as a dynamic subsystem.

To evaluate the seismic vulnerability of an existing structure based on structural health monitoring, it is indispensable to have information on the local soil parameters. The local soil parameters can be identified using laboratory tests or *in situ* measurements. As laboratory testing always points out only the parameters of a single borehole, it is generally more informative to use *in situ* experiments.

3 EXPERIMENTALLY BASED SEISMIC ASSESSMENT OF STRUCTURES

3.1 Basic information

Seismic analyses of building structures are based on the dynamic parameters of the considered object

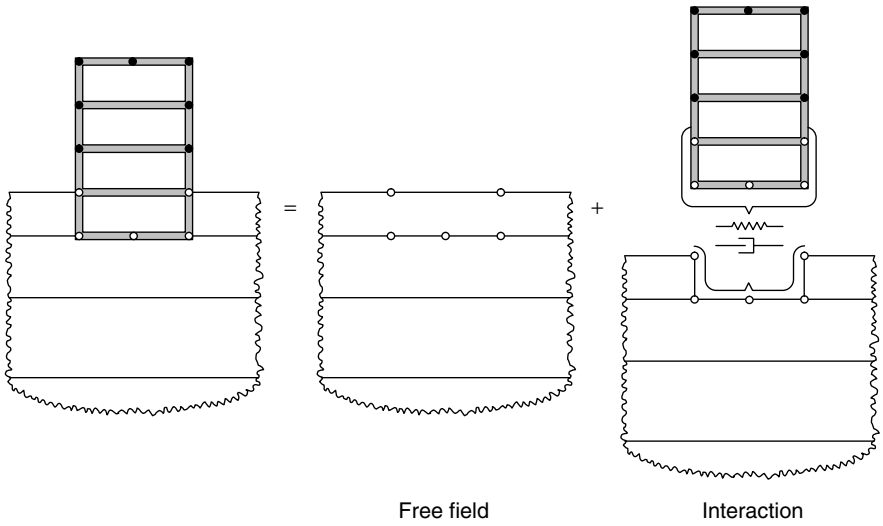

Figure 2. Illustration of the substructure method.

such as natural frequencies and the corresponding mode shapes. For existing buildings, these parameters are determined beneficially from data recorded by *in situ* measurements, in particular, when the structural system and utilized materials are unknown.

3.2 *In situ* measurements

To identify the dynamic parameters of a building structure, it is proposed to utilize accelerometers, which are distributed on the story levels on top of each other. As an example, Figure 3 shows the position of accelerometers in an investigated residential building. The sensors are placed next to the staircase because the flats are occupied, and therefore cannot be entered without additional logistic effort. It would be best to perform the measurements at night when pedestrian traffic is low and excitation from engines such as washing machines is very unlikely.

In tall buildings, measurements cannot be conducted simultaneously because the number of available sensors is customarily limited. For such objects a reference sensor is located in a story, where it remains during the entire measurement period. After each measurement, a second accelerometer is moved to a further measuring point at a different story level until the entire building is surveyed. The response of the sensor to be moved is related to the response measured with the reference sensor.

Depending on the type of building and measurement equipment, two different analysis techniques may be utilized to evaluate the dynamic parameters:

- the ambient vibrations response (ambient excitation); and
- the free vibration response after an impulsive-like load applied with a hammer (transient excitation).

It is noted that the location of excitation must remain the same when measurements are performed with a reference sensor.

3.3 Signal processing

The dynamic time–history response is recorded in three directions. However, if reasonable, the evaluation of the data is confined to one building axis, where the structure is most vulnerable, i.e., effects such as torsion or coupled-bending torsional vibrations are negligible.

The natural frequencies of the building structure are determined by transforming the time–history signals of each sensor into the frequency domain by fast Fourier transformation (FFT). Depending on the recorded data, the mode shapes are evaluated in the time domain (transient excitation) or in the frequency domain (ambient excitation).

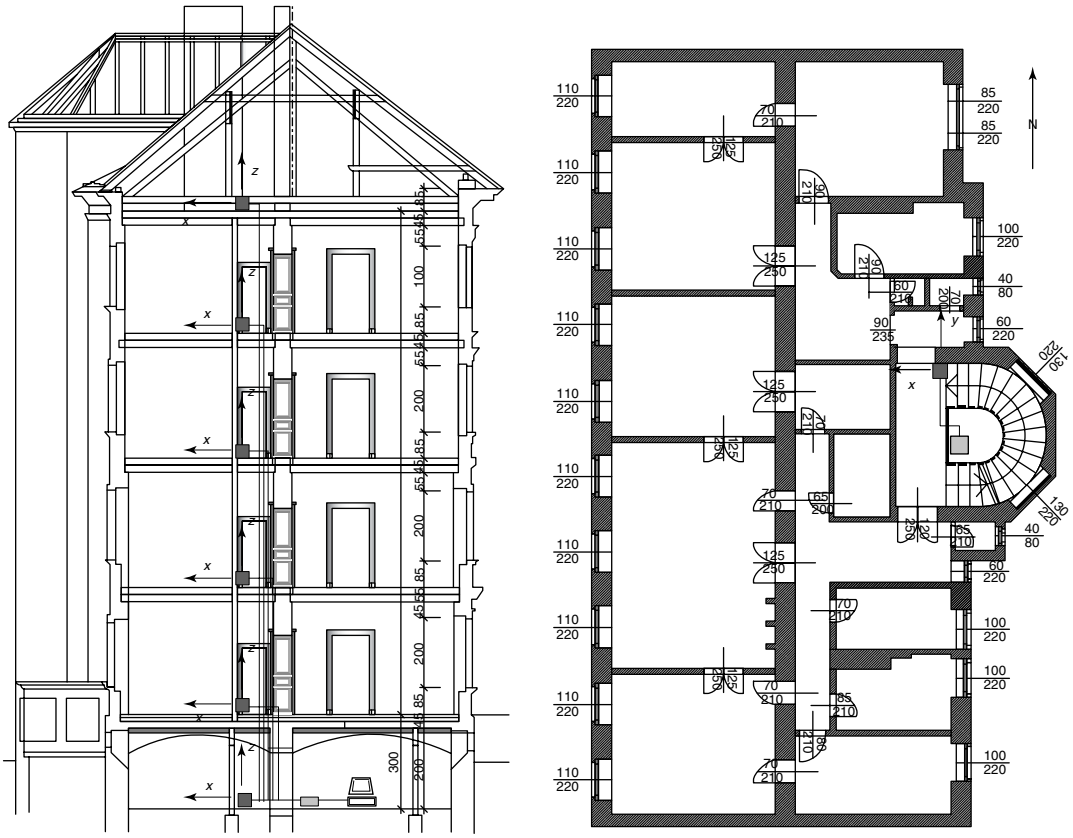

Figure 3. Sensor instrumentation of a residential building.

3.4 Transient excitation—time domain

If the building can be excited transiently by means of a hammer, the induced free vibration response is utilized to identify the dynamic parameters. The procedure of data processing in the time domain is shown in Figure 4.

The nth modal component of the undamped free displacement and acceleration response $\vec{w}_n$ and $\ddot{\vec{w}}_n$, respectively, of a multidegree-of-freedom (MDOF) system vary by the square of the nth natural circular frequency ${\omega_n}^2$ [5]:

$$\vec{w}_n = \vec{\phi}_n \cos \omega_n t, \quad \ddot{\vec{w}}_n = -{\omega_n}^2 \, \vec{\phi}_n \cos \omega_n t \quad (1)$$

In equation (1), $\vec{\phi}_n$ denotes the nth mode shape. Since the maximum amplitude of a mode shape is arbitrary, the mode shape can be extracted directly from the acceleration response.

The fractions of the response, which vibrate in the natural frequencies of interest, are extracted by filtering the raw signal. Therefore, the raw acceleration response is edited by a band-pass filter of the fourth order. The frequency band around the considered natural frequency f_n is very narrow, i.e., the upper and lower boundaries of the frequency $f_\mathrm{u,l}$ are selected according to

$$f_\mathrm{u,l} = f_\mathrm{n} \pm \frac{f_\mathrm{n}}{100} \quad (2)$$

This procedure is performed for each identified natural frequency f_n. Subsequently, the extracted time–history responses of each story is plotted on top of each other, and at certain time instants the amplitudes are read and combined to the vector $\vec{\phi}_{n,i}$. Note that the floor response must be related to the response recorded with the reference sensor

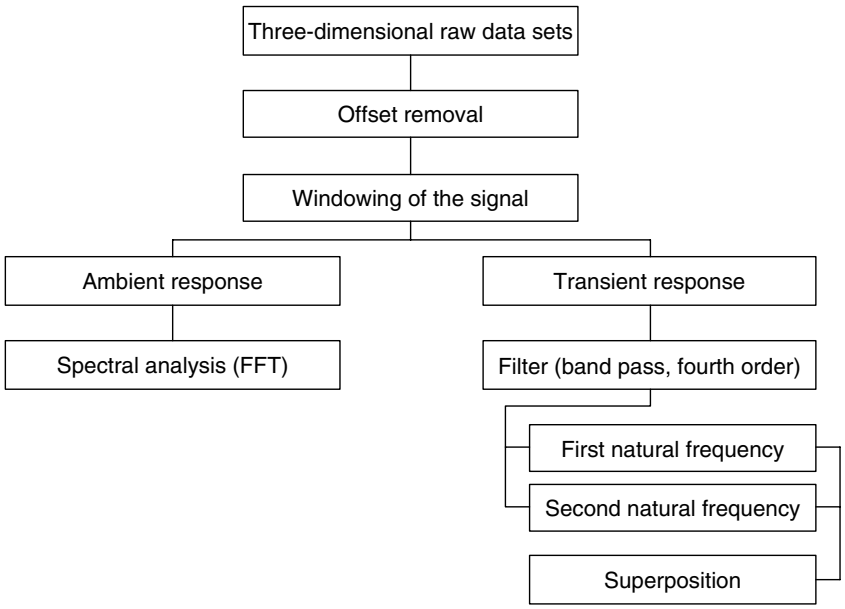

Figure 4. Evaluation of natural frequencies and mode shapes based on transient excitation. [Reproduced with permission from Ref. 5. © Prentice Hall, 2006.]

when the measurements of the floor accelerations are conducted at different time instants. Finally, the estimate of the nth mode shape $\vec{\phi}_n$ is determined by averaging

$$\vec{\phi}_n = \frac{1}{m} \sum_{i=1}^{m} \vec{\phi}_{n,i} \tag{3}$$

In Figure 5 the evaluation of the first bending mode $\vec{\phi}_1$ of an investigated building structure according to the described procedure is shown.

3.5 Ambient excitation—frequency domain

If the frequency domain is used to analyze the mode shapes, it is necessary to evaluate the phase of the acceleration response. Therefore, the phasing of the response signal in each floor of the building needs to be investigated. To increase the reliability of the results, this should be done simultaneously for each obtained record. The mode shapes are finally averaged for the different recorded signals [6]. The evaluation of the fundamental natural frequency of a structure is shown in Figure 6.

3.6 System identification—results of some investigated structures

Several existing objects were tested in order to verify the applicability and reliability of the proposed method. The *in situ* measurements were preferably performed using transient excitation. In Table 1, the investigated structures, their dimension, and employed building material are listed. Furthermore, the first and second natural frequencies f_1 and f_2, respectively, in two directions (E–W, east–west and N–S, north–south) of the objects are given in the same table.

In the following object 1 of Table 1, (Riglergasse 10, Vienna) is examined. Both ambiently and transiently excited building responses are utilized for the evaluation of this building. Measurements were performed during a long period with a sampling rate of 500 Hz. This large sampling rate was selected to window the signal with small time steps. A part of a record and the windowing of the signal are shown in Figure 7.

The structural mass was estimated consulting design documents, and lumped to the story levels. The first and second mode shapes, the story masses, and the story stiffnesses are specified in Figure 8. The

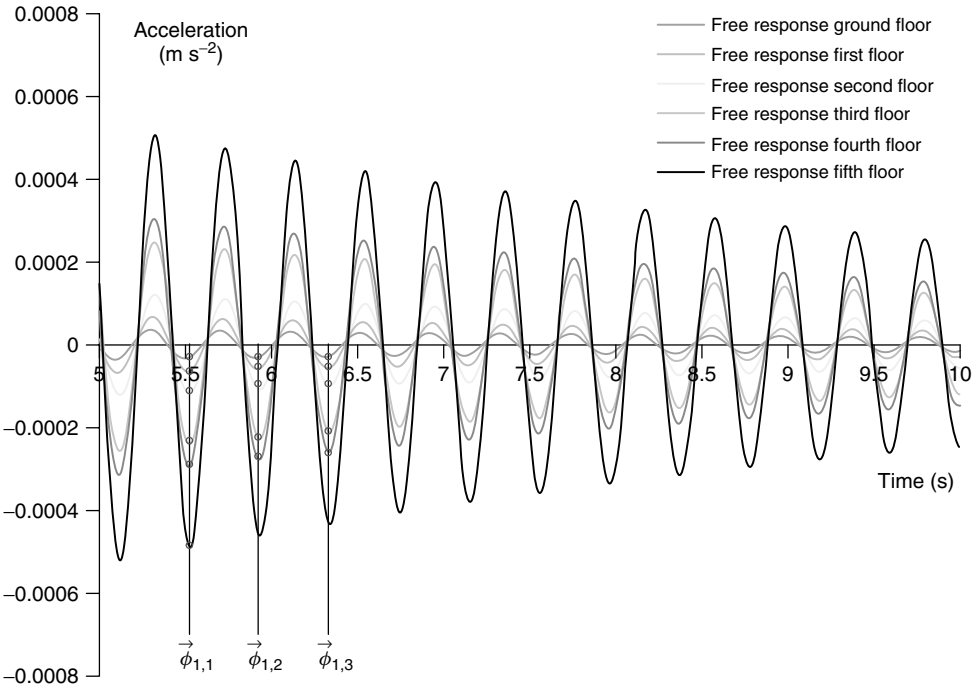

Figure 5. Evaluation of the fundamental mode of a building structure (time domain).

stiffness of the mechanical model was determined by application of the mentioned indirect finite element update procedure [7].

These results constitute the structural input values for the capacity design method. Therefore, the structural model shown in Figure 8 is subjected to a static pushover analysis [8].

To consider the global nonlinear behavior of the building structures, it is advantageous to perform large-scale *in situ* pushover tests on real structures. The outcomes of these tests can be utilized to calibrate the numerical pushover analysis. The nonlinear material parameters can be verified using several laboratory tests on specimens.

3.7 Finite element model update

An estimate of the distributed stiffness of the investigated building is calculated utilizing the equations of motion for a simplified mechanical model. Therefore, the structure is considered as an MDOF system with lumped masses at each story level. The model of the MDOF system is thus created as an approximation with several assumptions and can lead to differences in the real structure. To improve the accuracy of the system, the dynamic parameters are calibrated with the outcomes from *in situ* measurements. Therefore, a numerical updating procedure is utilized [7].

In general, finite element model updating can be performed using direct or iterative methods [9]. The former has advantages because no iteration is required and measured data are exactly reproduced. However, if the measured data are inaccurate or correspond to a highly nonlinear system, a model with no physical meaning may be obtained. In contrast, iterative methods are based on a nonlinear penalty function, which is minimized through subsequent linear steps, and more computational time is required.

4 SEISMIC EFFECTS

Earthquakes can cause tremendous damages on nature and structures. Owing to numerous different parameters (fault mechanism, epicentral depth, source and site parameters, soil conditions, etc.), the effects on the surface can have large discrepancies for every

earthquake event. The mechanism of the environment during an earthquake event is illustrated in Figure 9.

4.1 Local amplification—site effects

Local soil amplification has become a major topic in seismic hazard analysis in the last few decades. The influence of the local subsoil conditions on the intensity of earthquakes was well investigated. Especially in areas with high population density, the effects of different conditions can have major effects on the damage distribution of building structures.

The effects of local amplification can have an influence on all important characteristics of an earthquake,

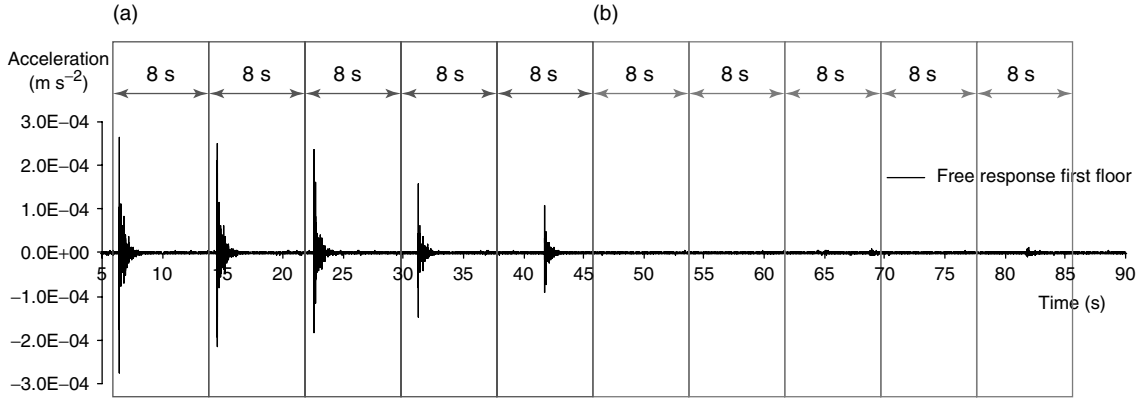

Figure 7. Transient (a) and ambient (b) windows with a length of 8 s for the acceleration record at the first floor of an investigated residential building.

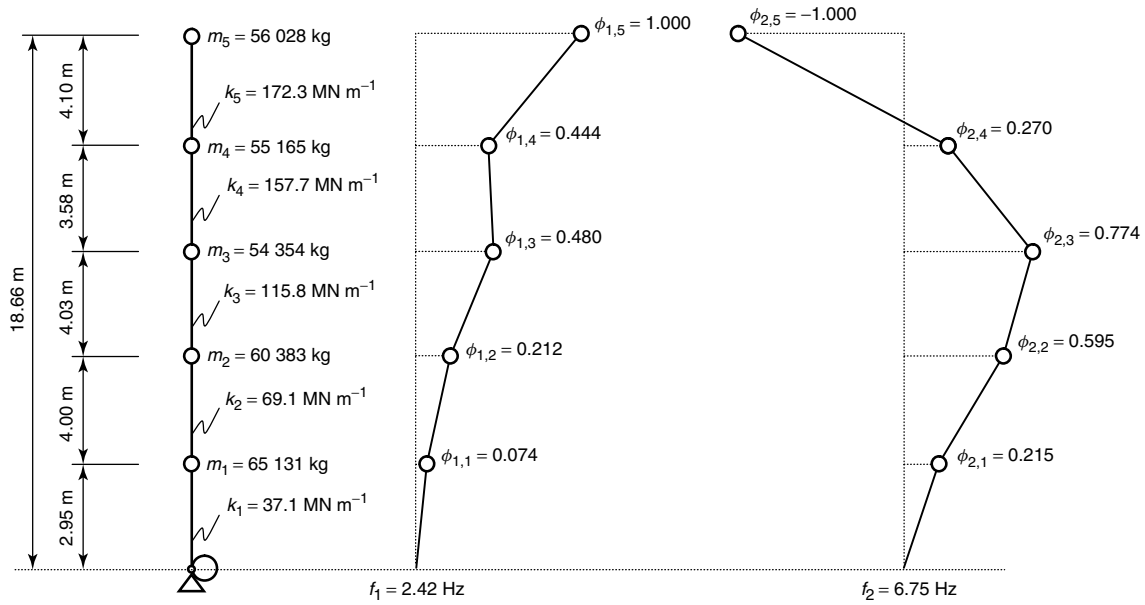

Figure 8. Final model of the investigated residential building—mode shapes (east–west direction) for the corresponding frequencies.

such as the amplitude, frequency content, and duration. Depending on the geometric extension and the material parameter of the subsoil layers, this influence is quite different.

4.1.1 Basic information

Local soil conditions have a large influence on the intensity of ground motion and earthquake damage [10]. The effects of the local soil conditions on ground motions have been demonstrated in many earthquakes that have occurred around the world. Since the use of strong motion instruments has increased over recent years, it was also possible to measure those effects. In the design of building structures, local site effects play a very important role and have to be considered as the cases arise. This can be done using site-specific design

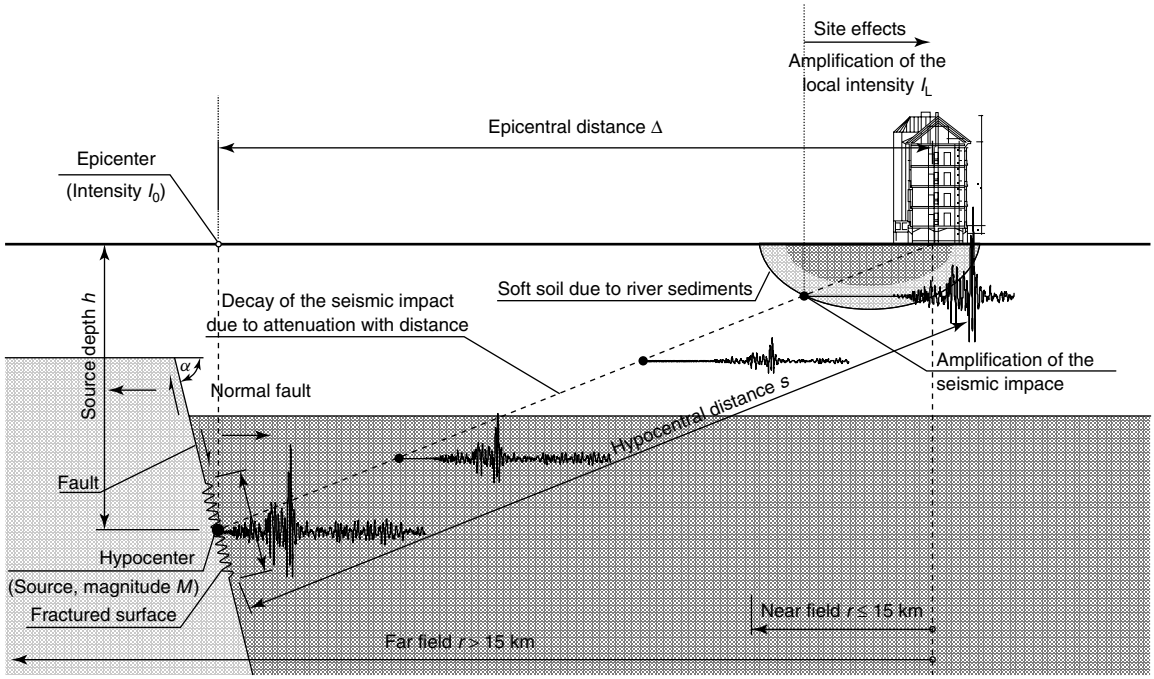

Figure 9. Schematic illustration of the seismic wave attenuation from the earthquake source to the investigated site: fault geometry, normal fault; hypocenter (source); epicenter (epicentral intensity I_0); epicentral distance Δ; hypocentral distance s; dip angle α; width of the fractured surface B.

ground motions. Nevertheless, in many cases local soil effects have been neglected during design previously. Therefore, the vulnerability of the existing buildings due to site effects needs to be evaluated subsequently.

4.1.2 Theoretical background

All important characteristics and parameters of the ground motion such as duration, frequency content, and amplitude are significantly influenced by local soil conditions. Therefore, the incoming ground motion on equal building structures founded on different subsoil can have rigorous differences. The elongation of local site effects is also dependent on the soil geometry (mainly the layer thickness), site topography, the material properties of the subsurface materials, and on the characteristics of the input motion.

In most of the cases, the S-wave velocities of materials near the surface are smaller than at greater depths [10]. The conservation of elastic wave energy under negligence of the scattering and material damping requires that the energy flow $\rho v_s \dot{u}^2$ from the depth is constant. As the density ρ and the S-wave velocity v_s decreases with ascending waves, the particle velocity $\dot{u}^2$ has to increase and leads to a higher ground motion amplitude on the surface.

The parameters of local soil effects can be evaluated theoretically using existing information about the subsoil conditions or experimentally by means of surface measurements.

4.1.3 Evaluation of site effects using theoretical investigations

Amplifications of soil site responses were simulated using several computer programs that assume simplified soil deposit conditions such as horizontal soil layers of infinite extent. One of the first computer programs developed for this purpose is SHAKE [11]. More than 25 years after its release, it is still commonly used in geotechnical earthquake engineering.

4.1.4 Measurement-based investigations of local site effects

Ambient vibration testing is a very attractive method for measurements in urban areas with moderate seismicity, because on one hand the low ambient vibration amplitudes indicate better correlation with moderate seismic events (approximately linear elastic constitutive material behavior) and on the other hand seismic cross-hole tests are complicated in urban areas because of the disturbance of building occupants and induced damages on the building structure.

A very common method to determine local site effects is the evaluation of the amplification factor using the H/V ratio according to Nakamura [12]. The method was successfully accomplished in countries with moderate seismicity where no strong motion data was available. It is therefore convenient for almost every region. In general, the input for the H/V computation can also consist of transiently or even ambiently excited signals.

In case of the evaluation of the amplification factor in urban areas, it is more beneficial to use ambient excitation because the large number of samples, which are needed for statistical evaluation would, in case of transient excitation, lead to unacceptable disturbance of the occupants.

4.1.5 Implementation in seismic hazard maps

The results of the evaluation of amplification factors can be used to generate seismic hazard maps. According to the high resolution of the measurement grid, this procedure is often called *microzonation*. The results of those microzonation studies should be implemented in existing catastrophe management plans to identify the most vulnerable parts of an urban area. This is primarily useful to organize the rescue teams in case of a tremendous earthquake event. In addition, the identification of the most vulnerable seismic zones within the city can have a direct influence on urban planning. In case of existing public utilities and infrastructure in very vulnerable areas, it may have an influence on the ongoing safety precautions. Therefore, the main utilizations of a seismic hazard map can be listed as follows:

- additional tool for the catastrophe management;
- implementation on urban and regional planning;
- attachment for national building regulations; and
- decision support for insurance companies.

4.2 Liquefaction

Nonlinear material behavior of the subsoil may have an important influence on the damage potential of earthquakes. In the last few years, numerous examples of this influence occurred, e.g., the Loma Prieta earthquake in California 1989, the Kobe earthquake in Japan 1995, and the Ismit earthquake in Turkey 1999. In the following, the nonlinear effects (mainly related to liquefaction) of the soil during an earthquake are explained.

According to technical literature [10], liquefaction is one of the most important, interesting, complex, and controversial topics in geotechnical earthquake engineering. The destructive effects of liquefaction were first recognized in 1964 during the Good Friday earthquake in Alaska and the Niigata earthquake in Japan. During both earthquakes, the phenomenon of liquefaction caused some tremendous damages, including slope failures, foundation failures, and flotation of buried structures. As liquefaction describes different phenomena, some of the most important are described, following the specification in the literature [10].

Liquefaction was first described [13] in conjunction with some phenomena that involve soil deformations caused by monotonic, transient, or repeated disturbance of saturated cohesionless soils under undrained conditions. The generation of excess pore pressure under drained loading conditions is a hallmark of all liquefaction phenomena. The tendency for dry cohesionless soils to densify under both static and cyclic loading is well known. When cohesionless soils are saturated, however, rapid loading occurs under undrained conditions, so the tendency for densification causes excess pore pressures to increase and the effective stresses to decrease. The liquefaction phenomena resulting from this process can be divided into flow liquefaction and cyclic mobility.

4.3 Earthquake-induced landslides

Landslides induced by earthquakes can be a common phenomena in mountainous regions [14]. The number

of landslides is dependent on the intensity of the earthquake and the geometric conditions of the surface (slope angles) as well as on the properties of the soil.

Multiple landslides occur almost simultaneously when slopes are shaken by an earthquake or over a period of hours or days when failures are triggered by intense rainfall or snow melting. The 1964 Great Alaska Earthquake caused widespread landsliding and other ground failure, which caused most of the monetary loss due to the earthquake. Other areas of the United States, such as California and the Puget Sound region in Washington, have experienced slides, lateral spreading, and other types of ground failure due to moderate to large earthquakes. Another phenomenon of earthquakes is widespread rockfalls caused by loosening of rocks.

Some significant examples of earthquake-triggered landslides in the past are as follows [15]:

- In May 1960, one of the world's strongest earthquakes ($M_w = 9.2$) [16] struck the coast of south-central Chile causing numerous major landslides and hundreds of surficial slides [17, 18]. The largest individual mass movements were three contiguous landslides with a total volume of 40 million m^3.
- The $M = 9.2$ Alaska earthquake in 1964 dislodged landslides from slopes over an area of about 260 000 km^2 [19].
- The 1987 Reventador earthquakes ($M = 6.1$ and 6.9) in northeastern Ecuador occurred after about 1 month of heavy rain, causing thousands of small landslides, which began as small slips on steep slopes [15, 20]. These thin slides liquefied and turned into major debris flows in the region's tributaries and main streams. Hundreds of square kilometers of the Earth's surface were modified by the landslides, which had a total volume estimated at 110–120 million m^3 [21].
- An event similar to that in Ecuador occurred in southwestern Colombia in 1994. The $M = 6.4$ Paez earthquake caused thousands of thin residual slides on steep slopes; these thin slides liquefied and turned into damaging debris avalanches and debris flows [22]. A total of 250 km^2 of the ground surface of the area was affected.

Geomorphological inventory maps can be used to study the relationships between the lithological and structural settings and the landslide types and pattern. Despite the fact that this information can prove extremely valuable for landslide hazards assessment, review of the literature shows that such studies are rare, mostly because geographical databases containing landslides, lithological, and structural information with the required accuracy are not readily available. Landslide inventory maps should be prepared after each landslide-triggering event (e.g., a rainstorm, a snowmelt event, or an earthquake), thereby covering the entire territory affected by the event. Such maps allow determining the full extent of landslide events on the structures and the infrastructure. They can also provide valuable information for evaluating the types, extent, and severity of damage caused by slope failures [23].

4.4 Surface faults and cracks

Surface faults and cracks can occur if the fracture path of the earthquake reaches the surface. This phenomenon is therefore dependent on the magnitude of earthquakes, the hypocentral depth, and the orientation of the fracture mechanism and more or less independent of the type of the subsoil. For the identification of zones with high vulnerability for surface faults and cracks, it is therefore necessary to have knowledge about active faults. These data are available in most of the cases; nevertheless, zones with active faulting are rather broad. Therefore, the influence of surface faulting and cracks can hardly be included into microzonation studies.

5 CONCLUSION

Monitoring of soil–structure interaction effects is something that needs to be intensified in the future. The topics mentioned in this article should indicate a perspective view on possible applications.

The seismic assessment of existing structures has become much more important during the last decades, as the seismic risk of many countries is redefined and increased. Within this article, the importance of the influence of the subsoil, the realistic assessment of the dynamic parameters, and local seismic effects are described. This should give the engineers a

brief overview of the complexity of a comprehensive seismic investigation of building structures.

Chapter 139

System Identification for Soil–structure Interaction

Erdal Safak

Department of Earthquake Engineering, Kandilli Observatory and Earthquake Research Institute, Bogazici University, Istanbul, Turkey

1 INTRODUCTION

The term *soil–structure interaction* (*SSI*) refers to the influence of the deformations of the ground on the dynamic response of a structure. It is an important phenomenon of the seismic response of structures. If a structure is founded on rock, it is reasonable to assume that the ground does not deform and the structure is rigidly fixed at the base. If it is founded on soil, however, the flexibility of soil will cause the foundation of the structure to have translational and rotational motions when it is vibrating. SSI can have a major influence on the seismic response of structures founded on soft soils. It can significantly alter the vibration characteristics and, consequently, the characteristics of recorded motions. If it is not accounted for in the analysis, SSI can cause erroneous interpretation of recordings from structures.

Although SSI is always present to some degree, it is generally assumed that when SSI is small, the recorded motions at the foundation level are not influenced by the motions of the superstructure. Therefore, the structure can be assumed to be fixed-based and the foundation level recordings can be taken as the base excitation. When SSI is significant, this assumption is not valid because of the feedback from the structure to the foundation and the surrounding soil medium. The feedback makes the structure a closed-loop dynamic system, where the input (i.e., the foundation motion) and the output (i.e., the motion of the superstructure) are coupled.

The identification of SSI is relatively easy if, in addition to the records from the building, there are also records available from downhole or nearby free-field stations that are not influenced by the structure's vibrations. In most cases, such records are not available.

The common approach to identify structures that are subjected to SSI has been to develop finite element models of the structure with soil springs, and then determine the characteristics of the springs

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

by trial and error until the recorded superstructure motions are matched. This approach, however, does not lead to a unique solution, since a large number of soil and structural system combinations can match the recorded motions.

There are very few studies on direct identification of SSI from recorded motions, the most notable being [1, 2], Safak [3] and [4]. This article reviews the effects of SSI on the response of structures to seismic excitations by using simple models. It presents two criteria to detect the presence of SSI in a structure, and introduces a methodology to identify the fundamental frequencies of the fixed-base building, and the characteristics of the translational and rocking motions of the structure due to SSI.

2 EFFECTS OF SSI ON RECORDED MOTIONS

We can investigate the effects of SSI on the frequency content of the vibrations of a structure by employing the simplest model available for SSI, the 2-DOF (two degrees-of-freedom) model. The model accounts for the relative translational motions of the foundation with respect to soil. The rigid-body vibrations with respect to foundation, known as *rocking motions*, will be considered later. There are more complicated and realistic models of SSI available in a number of references in the literature (e.g., [5, 6]). In spite of its simplicity, the 2-DOF model is sufficient to expose the fundamental characteristics of SSI and is widely used in practice.

A schematic of the 2-DOF model is shown in Figure 1. The lower and upper mass-spring-dashpots represent the foundation and the structure, respectively. The model is based on the assumptions that both the superstructure and the soil are linear, their motions are dominated by fundamental modes, the soil stiffness is frequency independent, and the rocking motions are negligible.

The model given in Figure 1 can be considered to represent a structure whose vibrations are dominated by its first-mode response, such as a multistory building. Let x_f, x_b, and x_0 denote the absolute displacements of the foundation, building, and the free field, respectively, and $y_f = x_f - x_0$ and $y_b = x_b - x_f$ the relative displacements of the foundation with respect to the free field and of the building with respect to the foundation. With these, we can write the following equations for the motion of the 2-DOF system subjected to base acceleration $\ddot{x}_0$

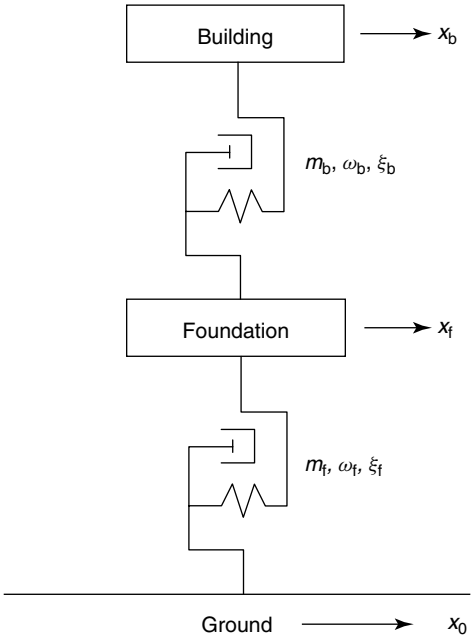

Figure 1. Two-degrees-of-freedom system representing soil–structure interaction.

$$m_f\ddot{y}_f + c_f\dot{y}_f + k_f y_f - c_b\dot{y}_b - k_b y_b = -m_f\ddot{x}_0$$
$$m_b(\ddot{y}_f + \ddot{y}_b) + c_b\dot{y}_b + k_b y_b = -m_b\ddot{x}_0 \quad (1)$$

where a dot over a variable denotes the derivative with respect to time. The standard notation used in the equations represent the mass (m), stiffness (k), and damping (c) of the fixed-base building (subscript b), and of the foundation when no building is present (subscript f), respectively. The two natural frequencies of this coupled system are

$$\omega_{1,2}^2 = \frac{1}{2}\cdot\left[\omega_f^2 + (1+\mu)\omega_b^2 \pm \sqrt{[\omega_f^2 + (1+\mu)\omega_b^2]^2 - 4\omega_f^2\omega_b^2}\right] \quad (2)$$

where $\mu = m_b/m_f$, the mass ratio, and $\omega_f = \sqrt{k_f/m_f}$ and $\omega_f = \sqrt{k_f/m_f}$ are the natural frequencies of the foundation when no building is present, and of the building when it is fixed-based, respectively.

The ratios of the natural frequencies of the coupled system to the frequency of the fixed-base building, and the frequency of the foundation when no building is present, can be expressed by the following equations:

$$\left(\frac{\omega_{1,2}}{\omega_b}\right)^2 = \frac{1}{2\eta^2}\left[1 + (1+\mu)\eta^2 \pm \sqrt{[1+(1+\mu)\eta^2]^2 - 4\eta^2}\right]$$

$$\left(\frac{\omega_{1,2}}{\omega_f}\right)^2 = \eta^2 \cdot \left(\frac{\omega_{1,2}}{\omega_b}\right)^2 \tag{3}$$

where $\eta = \omega_b/\omega_f$.

Note that the ratios depend only on μ and η, the mass, and the frequency ratios. The variation of ω_1/ω_b for η varying from 0.1 to 10, and three values of μ are plotted in Figure 2. The figure shows that for the lowest natural frequency, ω_1, the ratios are always less than one. In other words, the fundamental frequency with SSI is always lower than the frequencies of the fixed-base building and the foundation with no building. It can be shown similarly that for the second natural frequency, ω_2, the ratios are always greater than one.

By studying the limits of equation (3), we find that

$$\text{If } \eta \ll 1 : \omega_1 \approx \omega_b \text{ and } \omega_2 \approx \omega_f$$
$$\text{If } \eta \gg 1 : \omega_1 \approx \frac{\omega_f}{\sqrt{1+\mu}} \text{ and } \omega_2 \approx \sqrt{1+\mu}\cdot\omega_b \tag{4}$$

The first expression in the above equations corresponds to flexible buildings and stiff soil conditions, where SSI is negligible, and shows that the frequencies of the coupled system converge to those of the fixed-base building and the foundation, respectively, for all values of μ. The second expression corresponds to rigid buildings and soft soil conditions, where SSI is significant, and shows that the frequencies of the coupled system converge to two values, one smaller than the frequency of the foundation and the other larger than the frequency of the fixed-base building.

In general, the recorded responses in buildings are accelerations. The effects of SSI on the frequency content of recorded accelerations can be investigated by studying the frequency response functions, $H_f(\omega)$ and $H_b(\omega)$, of $\ddot{x}_f$ and $\ddot{x}_b$. To calculate frequency response functions, we take $\ddot{x}_0 = e^{i\omega t}$ in equation (1) and let $\ddot{x}_f = H_f(\omega)\cdot e^{i\omega t}$ and $\ddot{x}_b = H_b(\omega)\cdot e^{i\omega t}$. Solving

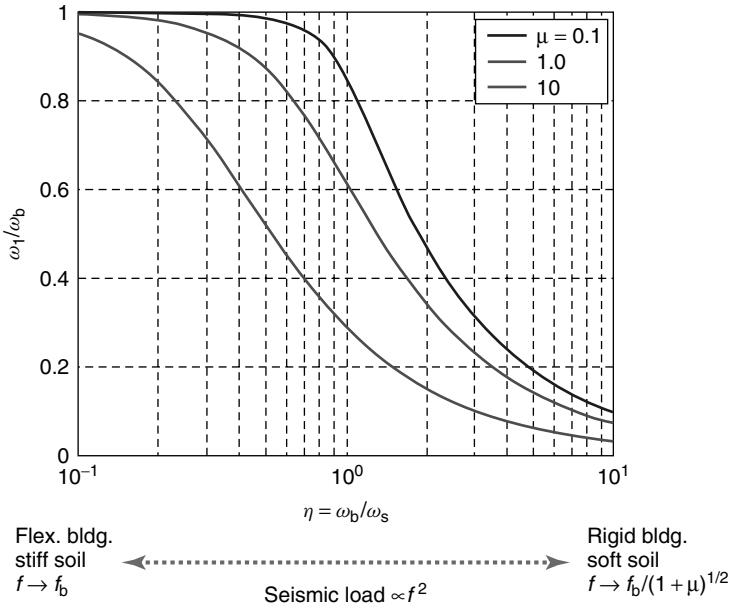

Figure 2. Effects of SSI on the natural frequency of the structure.

for $H_f(\omega)$ and $H_b(\omega)$ gives [7]

$$H_f = \frac{1}{\Delta}\cdot\left[-i\omega^3 2\xi_f\omega_f - \omega^2(\omega_f^2 + 4\xi_f\xi_b\omega_f\omega_b) + i\omega(2\xi_f\omega_f\omega_b^2 + 2\xi_b\omega_b\omega_f^2) + \omega_f^2\omega_b^2\right]$$

$$H_b = \frac{1}{\Delta}\cdot\left[-\omega^2 4\xi_f\xi_b\omega_f\omega_b + i\omega\left(2\xi_f\omega_f\omega_b^2 + 2\xi_b\omega_b\omega_f^2\right) + \omega_f^2\omega_b^2\right]$$

where

$$\Delta = \omega^4 - i\omega^3\cdot\left[2\xi_f\omega_f + 2(1+\mu)\xi_b\omega_b\right] - \omega^2\cdot\left[\omega_f^2 + (1+\mu)\omega_b^2 + 4\xi_f\xi_b\omega_f\omega_b\right] + \cdots + i\omega\cdot\left(2\xi_f\omega_f\omega_b^2 + 2\xi_b\omega_b\omega_f^2\right) + \omega_f^2\omega_b^2 \qquad (5)$$

where $\xi_b = c_b/(2m_b\omega_b)$ and $\xi_f = c_f/(2m_f\omega_f)$, the viscous damping ratios for the building and the foundation, respectively, and $i = \sqrt{-1}$.

The investigation of the changes in the transfer functions with various soil and structural parameters is given in [2]. The results clearly confirm that SSI has significant influence on the frequency content of the motions recorded at the foundation and the superstructure. Depending on the magnitude of SSI, the dominant frequencies of the recorded motions can be completely different from those of the fixed-base building, or the foundation when no building is present. The observed narrowband characteristics of the foundation transfer function for soft soils and large buildings suggest that recordings from the basements of such buildings cannot be taken as the free-field ground motions.

3 DETECTION AND IDENTIFICATION OF SSI

Since SSI alters the frequency characteristics of the recorded motions, it is important to determine if the building is subjected to SSI, prior to any identification. Normally, the motion of the building is recorded at the foundation level, top story, and several intermediate stories. If there is no SSI, we can identify the building by taking the recordings at the foundation level as the input and the recordings at upper stories as the output. A building with no SSI represents a causal system, because the input at time t_i can only influence the output at times $t > t_i$. Since there is no coupling (i.e., feedback) between the input and the output, such systems are termed *open-loop systems*. When the building is subjected to SSI, the motions of upper stories influence the motion of the foundation, i.e., the input and the output of the system are coupled. Such systems are termed *closed-loop systems*. It can be shown that the impulse response function of closed-loop systems are noncausal [8].

The causality condition provides a convenient tool to detect the SSI. For causal systems, the impulse response of the system is zero for $t < 0$, whereas for noncausal systems it is not. Therefore, we investigate the impulse response of the building from the records of the foundation and the upper stories. If the impulse response shows significant amplitudes at negative times in comparison to those at positive times, we conclude that there is SSI. Impulse response functions can be calculated by taking the foundation accelerations as the input, and the top-story accelerations as the output, and using the method given in [9]. In this method, a prewhitening filter is applied to the input so that it becomes as close to a white noise as possible. The same filter is also applied to the output. The impulse response function is obtained by scaling the cross-correlation function of the filtered input and output. A more straightforward approachto calculate the impulse response function is to find the transfer function by taking the ratio of the Fourier transforms and then to take the inverse Fourier transform of the transfer function. However, this method does not give a correct and stable impulse response because of the noise in the records. The method suggested by Ljung is more robust and mathematically more accurate for noisy signals.

An alternative to the above procedure is to first identify the building as if there were no SSI and then investigate the cross correlation of the input with the residuals (i.e., the difference between the recorded output and the output of the identified model) of the identification. If there is SSI, the cross correlation would show large amplitudes at negative time lags. A more detailed discussion of this method can be found in [10].

A less sophisticated, but a much simpler, way to detect SSI is to compare the dominant frequency of the vibration records from the roof (or, one of the upper stories) of the building to the dominant

frequency of the foundation-to-roof transfer function. The former is the frequency with SSI, whereas the latter is the frequency if the building were fixed-based (i.e., no SSI). If these two frequencies are equal or close, there is no SSI, otherwise there is SSI. We prove this by using the simple 2-DOF model of the SSI given in Figure 1. Let us first calculate the ratio $R = H_b/H_f$ of the transfer functions for accelerations $\ddot{x}_b$ and $\ddot{x}_f$. From equation (5), and by defining the nondimensional frequency ratios $r_f = \omega_f/\omega$ and $r_b = \omega_b/\omega$, we can write

$$R(\omega) = \frac{H_b(\omega)}{H_h(\omega)} = \frac{4\xi_f\xi_b r_f r_b - i(2\xi_f r_f r_b^2 + 2\xi_b r_b r_f^2) - r_f^2 r_b^2}{r_f^2 + i2\xi_f r_f + 4\xi_f\xi_b r_f r_b - i(2\xi_f r_f r_b^2 + 2\xi_b r_b r_f^2) - r_f^2 r_b^2} \tag{6}$$

Note that R is independent of $\mu = m_b/m_f$. From equation (6), we can further derive the following equations for the squared amplitude R^2 of R:

$$|R(\omega)|^2 = \frac{r_b^2(r_b^2 + 4\xi_b^2)}{1 - 2r_b^2 + r_b^2(r_b^2 + 4\xi_b^2)}$$

or

$$|R(\omega)|^2 = \frac{1 + \left(2\xi_b \frac{\omega}{\omega_b}\right)^2}{\left[1 - \left(\frac{\omega}{\omega_b}\right)^2\right]^2 + \left(2\xi_b \frac{\omega}{\omega_b}\right)^2} \tag{7}$$

By making the derivative of $R(\omega)$ with respect to ω equal to zero, we can determine the frequency ω_{max} where $R(\omega)$ has its peak as

$$\omega_{max} = \frac{\left(-1 + \sqrt{1 + 8\xi_b^2}\right)^{1/2}}{2\xi_b} \cdot \omega_b \tag{8}$$

There are two important observations that can be made from equations (7) and (8). First, equation (7) shows that $|R(\omega)|$ is independent of μ, ω_f, and ξ_f. In other words, $|R(\omega)|$ is not influenced by the dynamic characteristics of the foundation. Second, equation (8), when the coefficient of ω_b on the right-hand side is evaluated numerically, shows that $|R(\omega)|$ has its peak at or near $r_b = 1$, or $\omega = \omega_b$. For example, for $\xi_b = 0.02$, 0.05, 0.10, 0.20, and 0.50 the corresponding values of the coefficient of ω_b are 1.00, 1.00, 0.99, 0.97, and 0.85, respectively. Note that, even at $\xi_b = 0.50$, the shift of the peak frequency from the frequency of the fixed-base building is only 15%. From these two observations, we conclude that $|R(\omega)|$ describes the characteristics of the fixed-base building, and always peaks at or near the fixed-base building frequency for buildings with small damping.

The statements we have just made regarding $|R(\omega)|$ being independent of the foundation characteristics may seem contradictory to our earlier statements, where we claim that SSI causes coupling of building and foundation motions. In fact, this was used to detect the existence of SSI by showing that the coupling results in noncausal impulse response function. There is no contradiction. As clearly seen in equation (6), the real transfer function $R(\omega)$ is a complex-valued quantity, and incorporates the coupling, because the parameters of both the building and the foundation are in the equation. Since the impulse response function is merely the inverse Fourier transform of $R(\omega)$, it also incorporates the coupling, and therefore is appropriate to be used for detection. It is the amplitude of the transfer function, $|R(\omega)|$, which is independent of the foundation characteristics. In other words, the coupling between the foundation and the building motions alters the phase of the transfer function, but not the amplitude. More details on this can be found in the discussion by Zhao and closure by Safak in [3].

Considering the definitions of $H_f(\omega)$ and $H_b(\omega)$, $R(\omega)$ can be calculated as the ratio of the Fourier amplitude spectrum (FAS) of the top-story accelerations to that of the foundation accelerations. The dominant peak of this ratio gives the fundamental frequency of the building for the fixed-base case. The fundamental frequency of the foundation can be estimated from equation (3). For this, we first determine ω_1, the dominant frequency of the top-story records, and make an assumption for the value of μ based on the design specifications for the building. We then put the values of ω_1, ω_b, and μ in equation (3), and solve it for ω_b.

The damping ratios ξ_b and ξ_f corresponding to ω_b and ω_f can be estimated by first filtering the accelerations by narrowband filters centered at ω_b and

ω_f, and then calculating the displacements and the rate of decay of the amplitudes.

If, in addition to recordings from the building, there were recordings from a nearby free-field site (i.e., a site whose motion is not influenced by the vibrations of the building), the identification of SSI would be fairly straightforward. We take the free-field recordings as the input, and foundation and upper-story recordings as the output, and identify the soil–foundation–structure system as a whole using open-loop identification techniques.

4 ROCKING MOTIONS

Rocking motions are the rotational rigid-body vibrations of structures with respect to their foundations. Rocking motions are frequently encountered in tall buildings founded on soft soils and mat foundations. It is less common in structures with pile foundations.

The 2-DOF model used above can be expanded to include rocking motions by allowing the foundation mass to rotate as well as translate. This requires adding a rotational spring (to represent the rocking stiffness) and a dashpot (to represent the rocking damping) in Figure 1, which results in a 3-DOF model for SSI. The equations of vibration for this model can be found in [4]. By writing the transfer functions for the superstructure and foundation, it can be shown that the apparent frequency, f_a, and the damping, ξ_a, of the structure, with translational and rocking SSI, are

$$f_a^2 = \frac{1}{1/f_b^2 + 1/f_f^2 + 1/f_\theta^2}$$

$$\xi_a = \left(\frac{f_a}{f_b}\right)^3 \xi_b + \left(\frac{f_a}{f_f}\right)^3 \xi_f + \left(\frac{f_a}{f_\theta}\right)^3 \xi_\theta \quad (9)$$

where f_θ and ξ_θ denote the frequency and the damping ratio for the rocking.

Rotational vibrations are commonly identified from the measurements of the vertical motions of the foundation mat. For a building with a rectangular cross section and a rigid foundation mat, we need at least three vertical sensors located near the corners of the foundation. If the foundation mat is not rigid (i.e., it can deform in shear or bending), we would need more vertical sensors to separate the rigid-body rocking motions from the mat deformations. Time history, and the frequency and the damping, of the rocking motions are determined by taking the differences of the vertical motions recorded by the sensors. Typically, for building-type structures, the recorded amplitudes of vertical vibrations at the foundation level are much smaller than those of horizontal vibrations. The amplitudes of the calculated rocking motions are even smaller. Therefore, the signal-to-noise ratios in the recorded vertical motions are usually very low. Taking the difference of two noisy signals gives a signal with a noise level much worse than the original signals [11]. It is strongly recommended that first the rocking frequency is identified from the spectral analysis of vertical records before taking the difference. Next, to improve signal-to-noise ratios, the records should be band-pass filtered around the rocking frequency, and then the rocking signal should be calculated by taking the difference of the filtered records. This process would improve the accuracy of the identified rocking characteristics. To further confirm that the calculated values are those of the rocking but not the deformations of the foundation mat, the amplitude and the phase of the rocking displacements at the foundation level should be compared with those of horizontal displacements (calculated after the records are band-pass filtered around rocking frequency) at upper stories.

5 CONCLUSIONS

SSI can significantly alter the characteristics of seismic records from structures, particularly when they are founded on soft soil. It can be shown that the dominant frequency of a structure with SSI is always smaller than that of the fixed-base structure and of the foundation with no superstructure.

If there are recordings from a nearby free-field site (i.e., a site whose motions are not influenced by the vibrations of the structure), a structure with SSI can be identified by using the standard open-loop system identification techniques, i.e., by taking the free-field records as the input and the foundation and upper-story records as the output. However, if the foundation records are taken as the input, the standard identification techniques may not work because the coupling between the input and the output makes the system a closed-loop system. The impulse response function of a close-loop system is noncausal.

The causality condition provides a convenient tool to detect the existence of SSI. For this, we calculate the impulse response function from the foundation and upper-story accelerations. If the amplitudes of the impulse response function at negative times are comparable to those at positive times, we conclude that the building is affected by SSI.

The study of transfer functions of a simple 2- or 3-DOF model for SSI shows that the ratio of the FAS of an upper-story acceleration to that of the foundation acceleration gives the dominant frequency of the fixed-base building. Once this frequency is determined, the dominant frequencies of the translational and rotational SSI effects can be estimated from simple analytical relations.

1 INTRODUCTION

This contribution is concerned with natural environmental factors, especially with improving the understanding of the influence of environmental factors and of natural hazards on civil infrastructure and on damage-accumulation prognostics. It addresses problems caused by extreme geologic processes and hazards such as earthquakes, flooding, and volcanic eruptions. The use of geographic information systems (GIS) integrated remote sensing data in the scope of environmental studies has been a continuous process taking place over the last decades [1]. Data from earth-observing satellites have become a valuable supporting tool for natural hazard damage detection in Indonesia, especially during the aftermath of earthquake and tsunami disasters as in December 2004 and July 2006. Earth observation satellites as LANDSAT, SPOT, IKONOS, QUICKBIRD, ERS, or ENVISAT with increasing capabilities in terms of spatial, temporal, and spectral resolution allow a more efficient, reliable, and affordable monitoring over time. Thus, remote sensing technology has become a fundamental input for GIS, especially for natural hazard information systems. The design of a common GIS database structure—always open to new data—can greatly contribute to the homogenization of methodologies and procedures of natural hazard risk management requiring an approach by integrating remote

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

sensing data, geologic, geophysical, seismotectonic, and topographic data and catalogs of historical hazardous events. This can be demonstrated by the example of Java/Indonesia.

2 METHODS

In order to establish a cost-effective method for getting a quick overview of the determining factors influencing environment and potential damage intensity in hazard-prone areas, it is recommended to start analyzing those causal factors and their complex interactions first based on remote sensing and GIS methodologies and later, step by step, going into details. The goal is to develop a multisensor and multirisk approach in a GIS environment to assess the potential for natural hazard on a regional basis. The various data sets as LANDSAT thematic mapper (TM) data, topographic, geological, and geophysical data from the investigation areas are integrated as layers into GIS using the software ArcGIS 9.2 of ESRI. The GIS-integrated evaluation of the georeferenced satellite imageries allows the storage of the results in a standard form such as vector formats (point-, line-, or polygon shapefiles). Various digital image processing tools delivered by ENVI Software/CREASO were tested, as for finding the best-suited LANDSAT enhanced thematic mapper (ETM) band combinations or contrast stretching parameters. The imageries were merged with the panchromatic band 8 of LANDSAT ETM to get the spatial resolution of 15 m. Standard approaches of digital image processing with regard to the extraction of natural hazard relevant information used for this study are methods like classification for land use and vegetation information, and processing of the thermal band 6 for deriving surface-temperature information. For the investigation of vegetation anomalies related

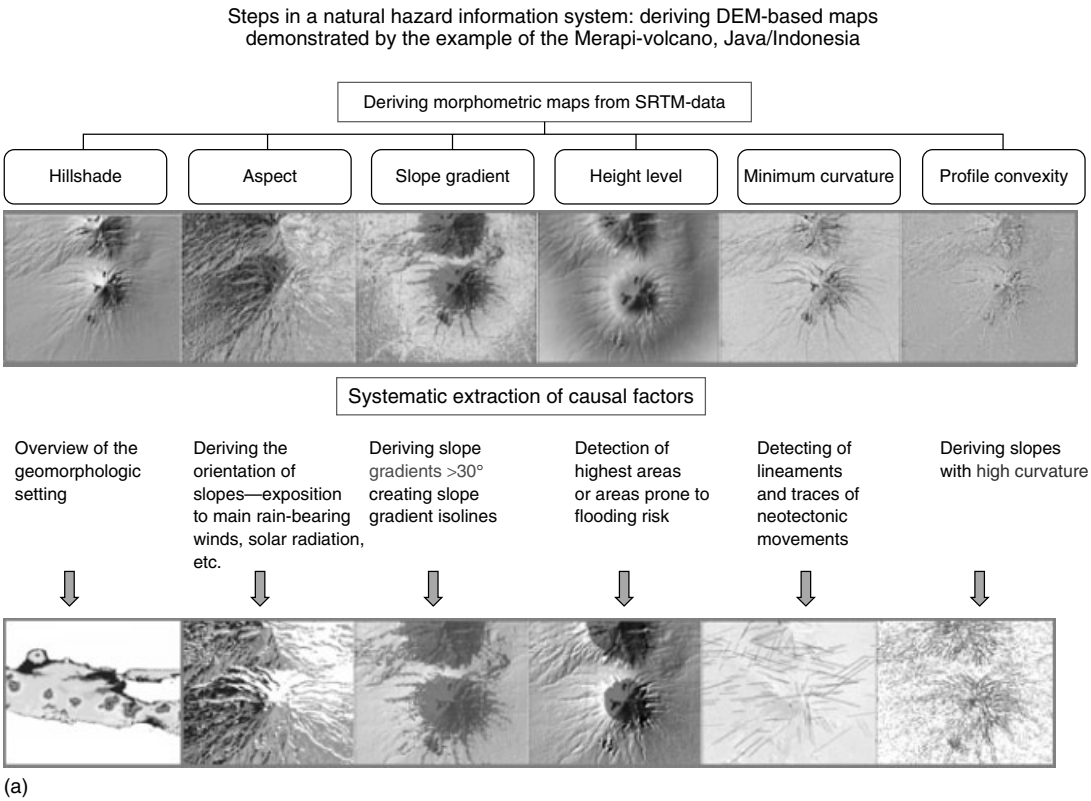

Figure 1. (a,b) Extraction of critical geomorphometric and hydromorphologic parameters based on SRTM and LANDSAT data demonstrated by the example of the Merapi volcano in Java/Indonesia.

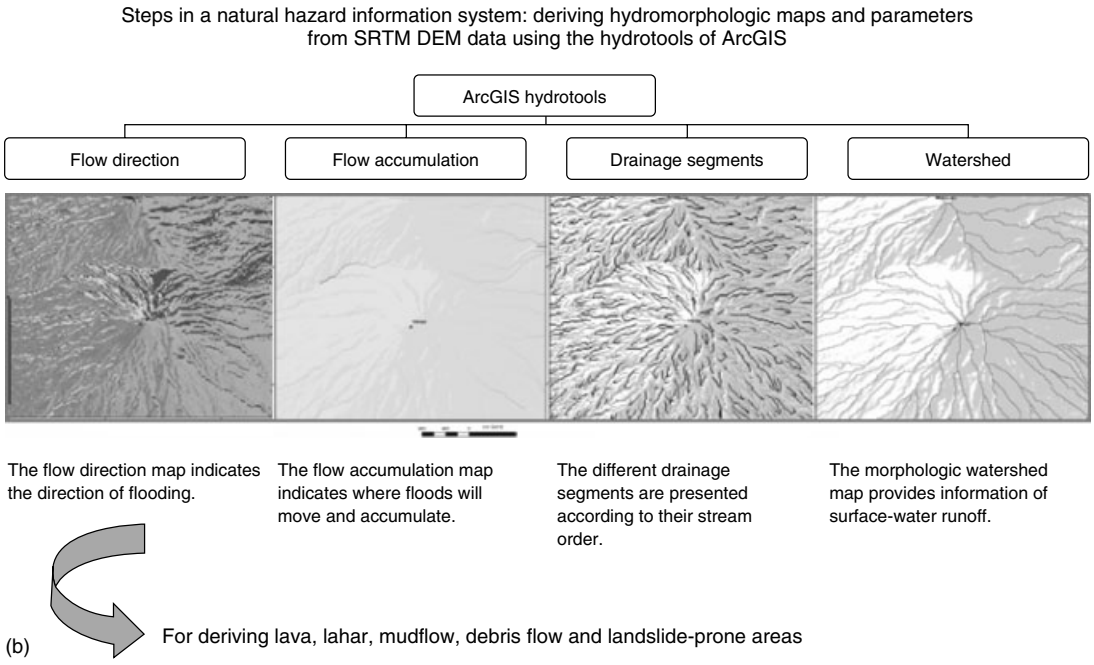

Figure 1. (*Continued*)

to subsurface structures and landslides, the NDVI (normalized difference vegetation index) was calculated on the basis of the available LANDSAT ETM bands 3 and 4. The evaluation of digital topographic data is of great importance as it contributes to the detection of the specific geomorphologic/topographic settings of hazard-prone areas. Data of the shuttle radar topography mission (SRTM, February 2000) are used to provide accurate digital elevation information. A systematic GIS approach is recommended extracting geomorphometric parameters based on digital elevation model (DEM) data as part of a multihazard information system. Figure 1(a) and (b) shows how the causal factors for natural hazards in Java are extracted systematically. From slope gradient maps, the areas with the steepest slopes are extracted, from curvature maps the areas with the highest curvature that are susceptible to landslides are extracted, from height maps the low-lying areas susceptible to flooding are extracted, and from flow accumulations maps the areas with the highest flow accumulations are extracted. Height maps help to search for topographic depressions, which are often linked with water accumulations and wetlands. Linear morphologic features (lineaments) visible on hillshade maps and LANDSAT imageries are often related to traces of faults and fractures in the subsurface.

3 EVALUATIONS OF LANDSAT AND SRTM DATA FOR DETECTING AREAS PRONE TO NATURAL HAZARDS

3.1 Earthquake damage amplification due to local site conditions

The most important geodynamic process, which determines all the tectonic and geomorphologic features of the Java Island, is the subduction of plates. Indonesia is a country where four of the earth's main plates contribute to the seismic activities in the region. Other earthquake sources are interplate and intraplate subduction seismic source zone [2]. One important factor that must be accounted for in local hazard studies is the site response caused by the surface conditions. Earthquake damage may vary locally, being a function of the type of structures in

the subsurface and/or soil mechanical ground conditions, for example, of faults and fractures, lithology or groundwater table [1] (*see* **Soil–Structure Interaction and Seismic Effects**; **System Identification for Soil–structure Interaction**). Evaluations of remote sensing data can help considerably to identify those vulnerable areas, to enhance mapping, and to improve evacuation planning. Remote sensing data can be used to map factors that are related to the occurrence of higher earthquake shocks and/or earthquake-induced secondary effects such as liquefaction or landslides (*see* **The Influence of Environmental Factors**). Previous earthquakes have indicated that the damage and loss of life are mostly concentrated in areas underlain by deposits of soft soil and high groundwater tables, for example, the Mexico City earthquake in 1985 [3]. Soft soils amplify shear waves and, thus, amplify ground shaking. The growth of Jakarta has been documented by earth observation satellites since 1972. Figures 2 and 3 illustrate the development of the Indonesian capital from 1976 to 2001 based on LANDSAT scenes. The urban areas show an enlargement of more than 2/3 in this time period. This monitoring of the urban development is of great importance for disaster preparedness as buildings constructed on former lakes and wetlands have a higher damage potential during earthquakes due to longer and higher vibrations. Most of the city of Jakarta is built on loose sedimentary covers [4] with potential risk of soil amplification, compaction, and liquefaction in case of stronger earthquakes. Therefore, it is necessary to carefully map the hydrologic and geomorphologic situation before the large spread of urban settlement. The change of urban coverage is visualized by Figure 3 showing the difference map calculated on the basis of the LANDSAT imageries from 1976 to 2001 of Jakarta. It is clearly visible where buildings were constructed on areas of former lakes and wetlands.

Another approach to detect the influence of local site conditions on earthquake damage intensity is the lineament analysis based on SRTM-derived morphometric maps and on LANDSAT data. Lineament analysis based on satellite imageries can help to delineate local fracture systems and faults that might influence seismic wave propagation and influence the intensity of seismic shock (as by causing constructive interference of multiple reflections of seismic waves at the boundaries between fault zones and surrounding rocks). Seismic waves traveling in the subsurface might be refracted at sharply outlined discontinuities as faults, and, thus, arrive at a summation effect that influences the damage intensity. Fault segments, their bends, and intersection are more apt to concentrate stress. The highest risk must be anticipated in junctions of differently oriented ruptures, especially where one intersects the other. Therefore, special attention is focused on precise mapping of traces of faults on remote sensing data, predominantly on areas with distinct expressed lineaments, as well as on areas with intersecting/overlapping lineaments. As ground movements such as liquefaction, lateral spreading, soil amplification, and compaction are important with regard to extended lifeline systems of Jakarta, a more detailed study of subsurface structures is necessary. South of Jakarta SW–NE-oriented lineaments can be detected on SRTM-derived morphometric maps and on LANDSAT imageries by the analysis of the drainage pattern, of linear valleys and hills, and of linear, tonal anomalies (Figure 4).

In the case of a stronger earthquake in this area, the highest shock can be assumed in areas with intersecting larger fault zones. The lineament density map provides an impression of such case.

3.2 Flooding susceptibility of Jakarta

The lowland area of Jakarta has always been naturally subject to regular flooding by the waterways cutting through the plain, such as the Cisadane, Ciliwung, Bekasi, and Citarum Rivers. During the wet season, when these rivers carry down the largest part of their sediment, which in the course of time has grown in quantity because of upstream human-induced eroding developments, the risk of flooding becomes paramount and has large impact [5]. Prolonged periods of rainfall can lead to plain floods that build up over days and can affect large areas of Jakarta, whereas short-lasting, very intensive rainfalls often cause flash-floods. The probability, frequency, intensity, and duration of extreme weather events will increase in Indonesia due to global climate change and due to seawater level rise and will become more common in future. This will require an efficient water management. Flood reservoir management, water steering, and retention systems for the area are necessary. One of the

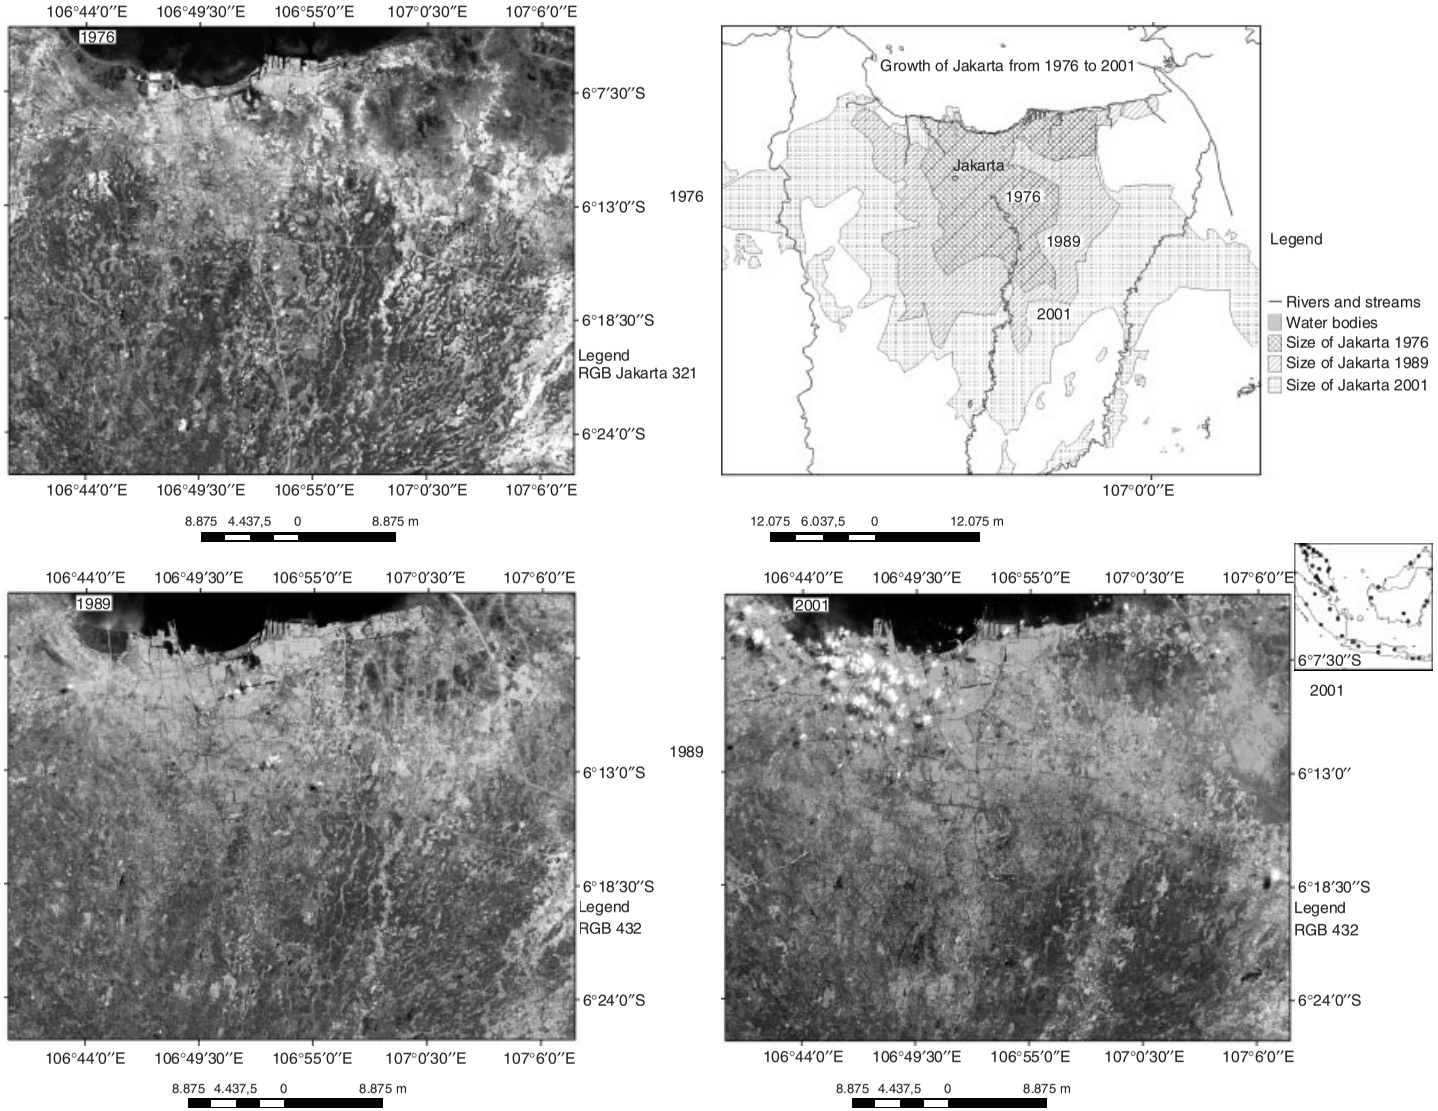

Figure 2. Development of Jakarta from 1976 to 2001 as visible on LANDSAT multispectral scanner (MSS), LANDSAT thematic mapper (TM) and LANDSAT enhanced thematic mapper (ETM) imageries. [Reproduced from LANDSAT, NASA, 1976–2001.]

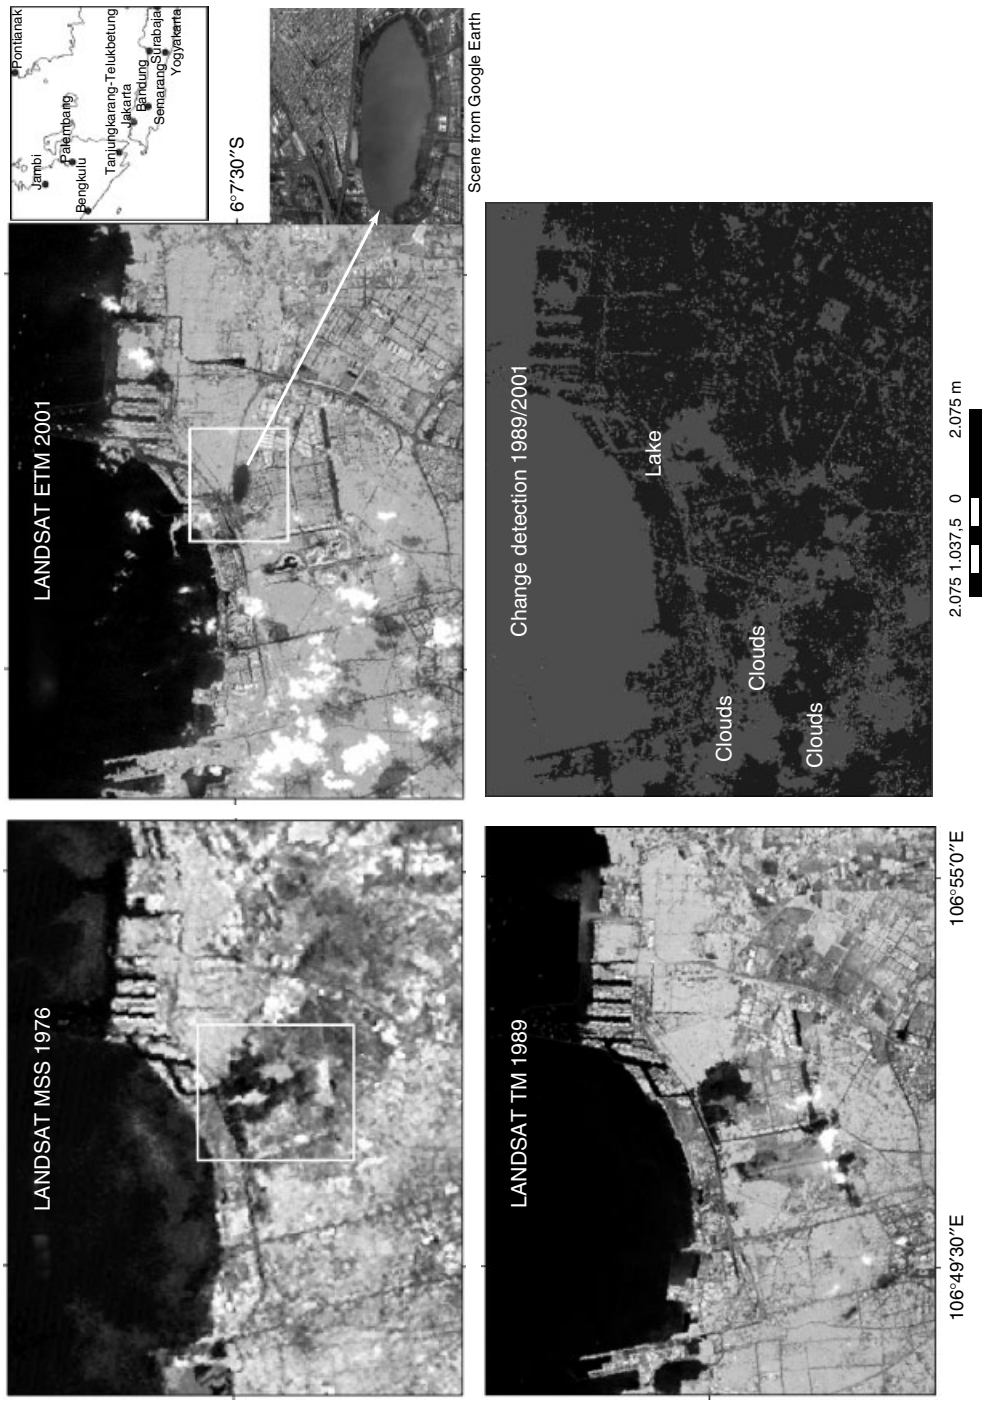

Figure 3. Change detection in Jakarta between 1976 and 2001.

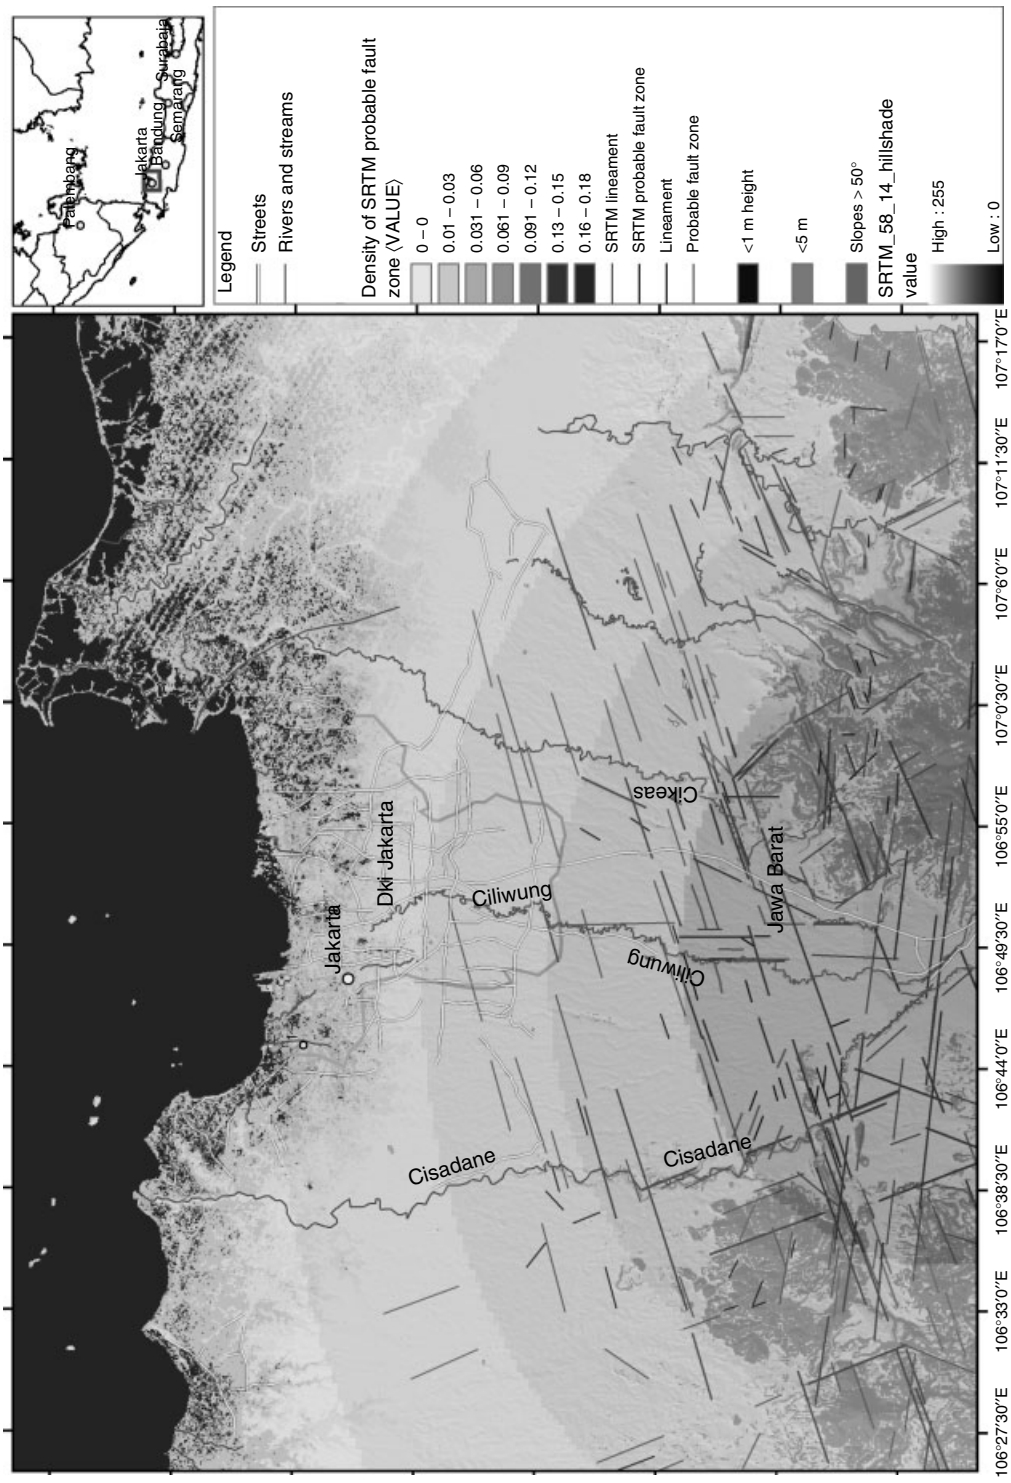

Figure 4. Lineament analysis and lineament density map—detection of linear features in the surface morphology and the drainage pattern, detection of linear tonal anomalies.

problems during these emergencies is to obtain an overall view of the phenomenon, with a clear idea of the extent of the flooded area, and, to predict the likely developments. Height maps derived from the digital elevation data of the SRTM mission indicate the lowest areas. Flow-accumulation maps calculated on the basis of SRTM data help to detect those areas, which are most susceptible to the effects of these events. The flow-accumulation map indicates, by high flow-accumulation values, that Jakarta has a very high susceptibility of being prone to flood in case of intense precipitations (Figure 5).

The GIS-implemented flow-accumulation function is applied to calculate surface runoff and lateral flow toward streams using a two-compartment distributed delay function. The flow-accumulation function routes the flow of water finding a flow direction for every cell of the elevation grid following the steepest paths. Flows from cell to cell on the same flowpath result in a flow-accumulation map in which the value for each cell represents the accumulated flow along a particular path.

The lowlands can be considered to have higher groundwater tables and to be more susceptible to flooding. It is obvious that the city of Jakarta is situated unfavorably, as it gets most of the surface runoff and groundwater flow from the southern hills. Flood-control reservoirs and flood ways retaining and focusing surface runoff are proposed for the area at the foothills and hill forelands as shown in Figure 5. The areas recommended for water-retention measurements as flood reservoirs were chosen on the basis of LANDSAT ETM imageries. However, Jakarta suffers not only seasonal flooding but is also prone to storm surge and tsunami waves. The lowlands prone to storm surge, tsunami flooding, and the consequences of rising seawater level due to global climate warming (Figure 5) need further protection measurements.

3.3 Volcanic activity in Java

One of the many natural disasters that has caused suffering and damage to human lives and nature in Indonesia is the eruption of volcanoes. Indonesia has the largest number of historically active volcanoes (76), and a total of 1171 dated eruptions. Indonesian authorities often need data of volcanic areas, not only to monitor eruptions but also to produce maps and thematic diagrams predicting the potential risk to the surrounding areas. In this field, remote sensing data is used to detect lithological differences, vegetation changes, landuse classification, variations after volcanic events, and the extent and growth of urban areas into endangered areas. One of the most dangerous, well-known Indonesian volcanoes is Merapi in Central Java. It has a height of 2911 m above mean sea level, lying on the boundary of special district of Yogyakarta Province and Central Java Province. Its distance from the capital city Yogyakarta is about 35 km. Merapi volcano is characterized by periodic, dangerous, big eruptions in the range of three to seven years. The Merapi eruptions, i.e., the explosions of the lava dome, consist of hot volcano debris and gases of 900–1200 °C temperature. More than 1.5 million people are working and living in the near surroundings of this volcano, where the danger is even extended to people living along the rivers draining the lower lands. This specific danger is caused by mudflow containing debris and rocks of volcanic origin and transported by rainwater of the often-heavy monsoon rainfall from November through April, which can amount to 40 mm within 2 h. Another danger, which could also threaten the people and nature in the relevant area, is pyroclastic flow that exists in two types. The first type results from the collapse of lava domes in the crater of the volcano. Occasionally, a dome might grow so large that it becomes unstable and collapses into several drainage catchments. The distance traveled by the flow at its extent strongly depends upon the volume of the destroyed lava, gas, pressure, and the slope angle of the flank. The second type results from the collapse of debris that is erupted vertically. Most of the eruptions have low explosivity and the pyroclastic flow usually reaches up to 6 or 7 km from the summit. The velocity of pyroclastic flow can reach up to 110 km h^{-1}. Various data set on past eruptions, administrative data, landuse data, topographical data, geological data, and the satellite images acquired from LANDSAT TM 2001 for the months of April and July have been assembled and provided by GFZ, Potsdam, a German partner institution in a joint Indonesian–German research project, not to mention the meteorological data, i.e., rainfall intensity and topographic map of the study area that is provided from Indonesian authorities. The task is

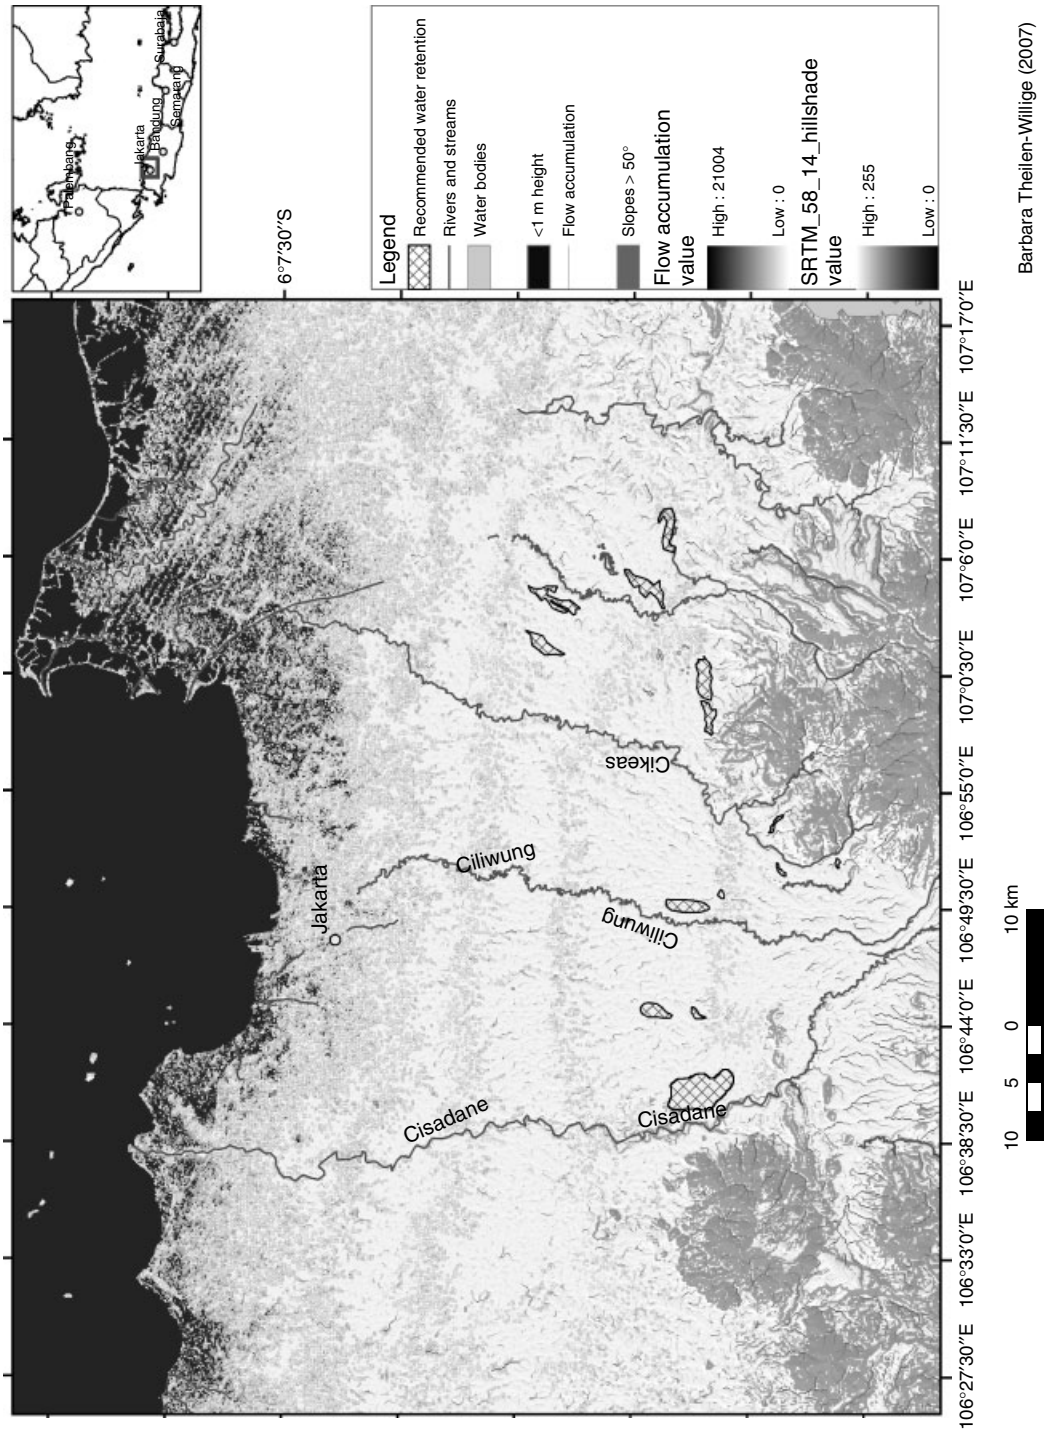

Figure 5. Flow-accumulation map indicating, in Darker grey tones, those areas with the highest flow accumulation.

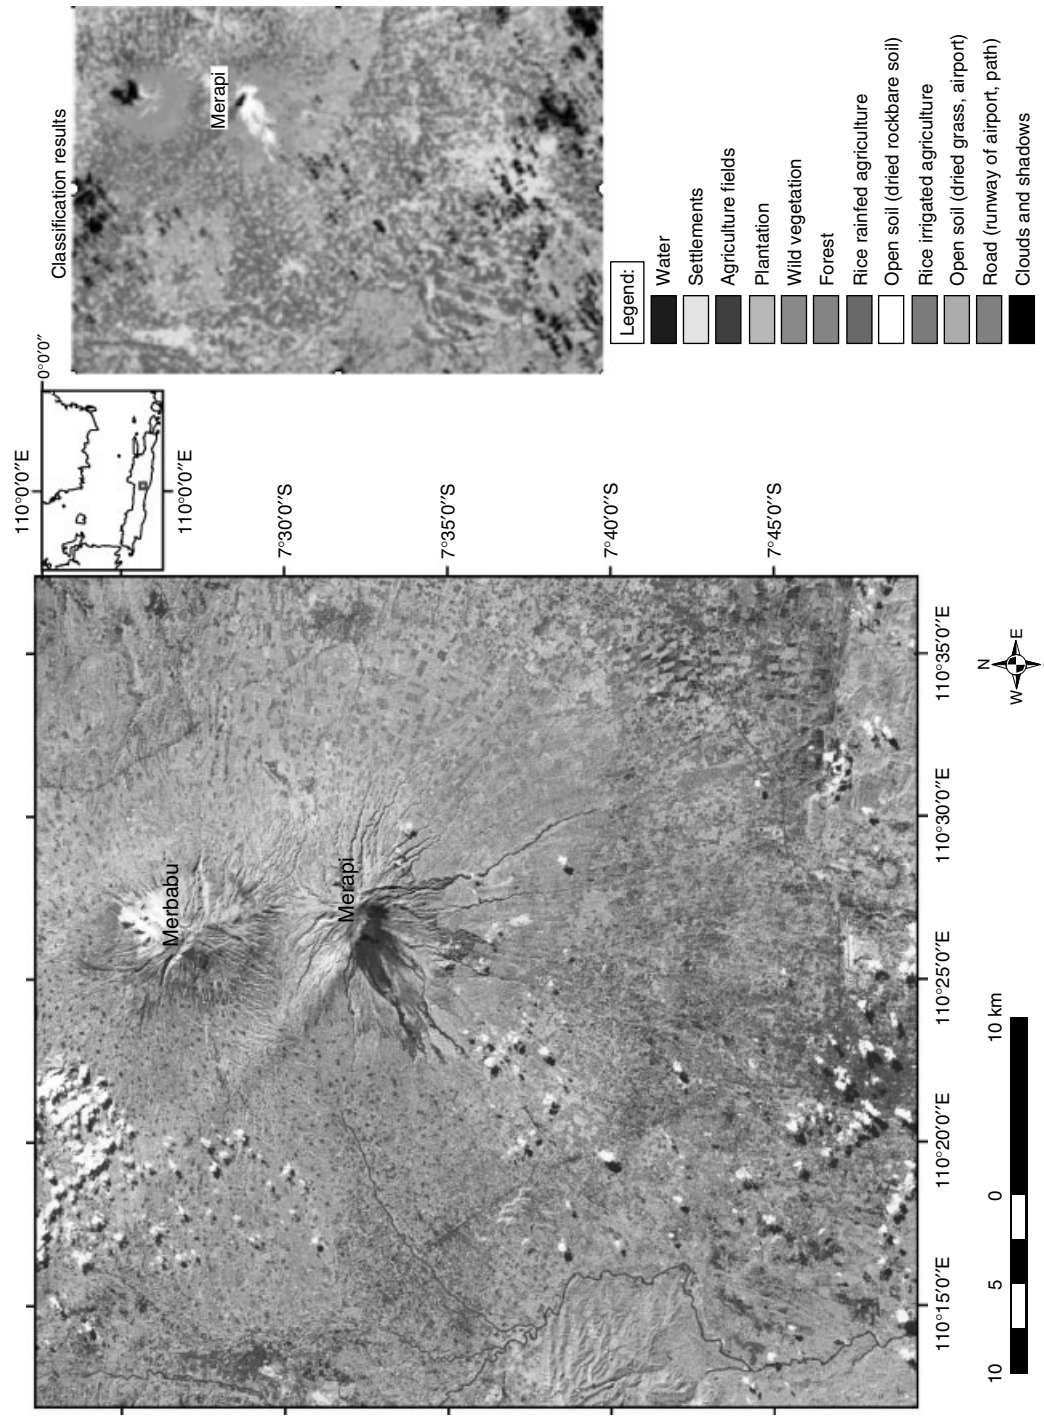

Figure 6. LANDSAT TM 2001 (TM band combination: 5, 4, 3) and classification result [6]. [Reproduced from LANDSAT, NASA, 2001.]

divided into three stages: in the first stage, remote sensing techniques are used in order to process and analyze the satellite images, classify them into several main classes as landuse classification. In the second stage, numerical model of a pyroclastic flow (typical of Merapi volcano eruption) is used, where several parameters are set in the frame of case studies, to stimulate the possible damages that affect the types of landuse within the hazard area. Finally, in the third stage, Arc View GIS technique is used for further analyzing and processing of types of landuse that are affected from the eruption, where hazard damage calculation could be produced (Figure 6). Hence, the estimated degree of damage due to the (assumed) eruption can be derived [6]. The accuracy of the total hazard damage calculation gives an overall impression as to how huge the loss (human lives and properties) will be, if the eruption occurs.

4 CONCLUSIONS

All the above-mentioned issues are important for the understanding of natural hazards, especially when located in very densely populated areas, where the welfare of human lives should be taken into consideration in the first place. The presented methods contribute to the improvement of the risk mitigation efforts at the local level, by applying theoretical knowledge, together with the relevant technology in the reduction of natural disasters that mostly occur in developing nations [6]. The design of a common GIS database structure—always open to new data—can greatly contribute to the homogenization of methodologies and procedures of natural hazard risk management. Meanwhile, the so-called Free GIS software fulfilling the basic GIS requirements, for example, DIVA-GIS, Map Window GIS, SAGA GIS, etc., can be used without costs. Additional Free GIS software is also available for the spatial analysis of DEM data. Basic LANDSAT ETM and SRTM data are provided free of charge for scientific research purposes, for example, by the University of Maryland, USA. Therefore, the use of the remote sensing and GIS technology for natural hazard site assessment and for the elaboration of hazard maps, according to the presented approach, can be recommended as low-cost approach that could be achieved by local communities in every country as a contribution to a GIS database for disaster preparedness [7, 8].

Chapter 149
Gas Turbine Engines

Michael J. Roemer
Impact Technologies, Rochester, NY, USA

1 INTRODUCTION

The history of structural health monitoring for gas turbine engines by most accounts began with the engine original equipment manufacturers (OEM's) in the 1970s and their utilization of engine component design models for tracking critical life-limited components of the engine. Models for components such as turbine inlet vanes/blades based on thermomechanical fatigue were used to track and trend life usage based on calculated stress/strain histories formed using onboard sensor readings that could be correlated (using gas path models) with turbine inlet temperature (*see* **Health and Usage Monitoring Systems (HUM Systems) for Helicopters: Architecture and Performance**). On the basis of the estimated turbine inlet temperatures and appropriate heat transfer models, estimates of actual metal temperatures and associated stress/strain achieved during operation could be determined. This was used as input to associated fatigue calculations, and eventually damage accumulation trending using Minor's rule was performed off-line and used as an initial process of structural health management for life-limited components.

During a similar time frame, aerothermal performance models were also being used with the gas path measurements being monitored on the engine to perform estimates of its efficiency. In many cases, only the performance margins (e.g., exhaust gas temperature—EGT) were used to infer a performance-based health indicator and determine when an engine was due for an overhaul. Hence, tracking and trending of an individual engine's performance margins became part of the off-line procedures used to manage the health of many engines. Hence, from both a mechanical and performance perspective, the current state of this technology was structured as isolated, independent health management approaches based on trending the damage and performance margins of the engine separately, relying upon physics-based models, simple

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

trending, historical information, or inspection and maintenance results in a fragmented approach.

Later in the 1980s, as information and data coming from the engine became more available based on regular downloads from engine controllers, it became more plausible to perform automated trending and analysis that could enable more consistent results for their respective applications. With the wide-scale application of digital computers and commercial products that allow for data monitoring and analysis of various types, advanced fault detection and prediction technologies became more easily implemented and cost-effectively linked to the necessary data for providing real-time assessments of engine health. Technologies such as advanced signal processing, probabilistic component life analysis, neural network classifiers, fuzzy logic decision support analysis, and Bayesian networks were just a few of the algorithmic approaches being implemented to provide for better automated equipment health state awareness and prediction (*see* **Aerospace Applications of SMART Layer Technology**).

As such technologies are currently being implemented today, we now have the data and information necessary to eliminate many of the engine faults and failures that contribute most significantly to downtime and prolonged maintenance activities. Hence, these assets are now becoming more economically viable over their life cycle and providing operators with increased profits and/or output. Therefore, increased applications of enhanced diagnostic and prognostic algorithms that can detect and predict, within a specified confidence bound, time-to-failure of critical engine faults and components have the potential to provide many benefits including.

- improved safety associated with operating and maintaining gas turbine engines;
- reduced overall life cycle costs (LCC) of engines from installation to retirement;
- ability to optimize maintenance intervals for specific engines or fleets of engines and prioritization of tasks to be performed during the planned maintenance events;
- increased uptime/availability of all engines within a fleet;
- provides engineering justification for scheduling maintenance actions with corresponding economic benefits clearly identifiable.

2 INTEGRATED ENGINE HEALTH MONITORING OVERVIEW

Figure 1 provides an illustration describing how fault detection, isolation, and prognostic technologies are

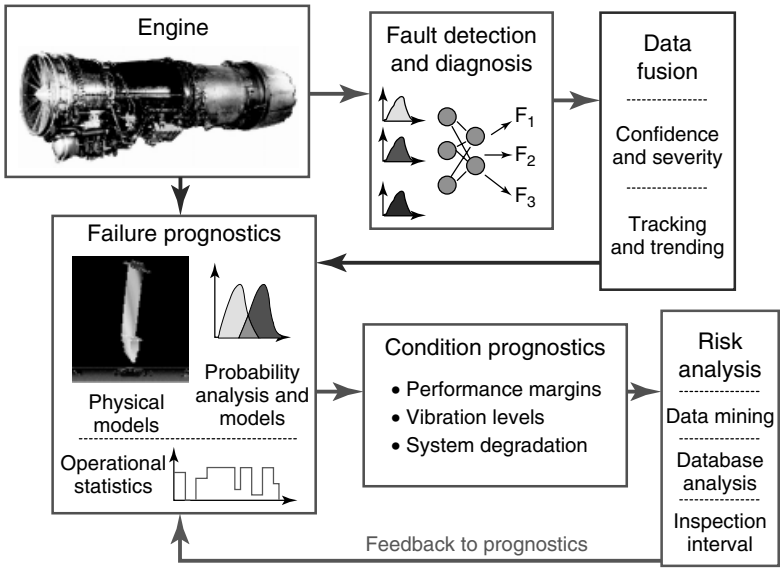

Figure 1. Integrated engine health monitoring.

currently being implemented within many military engine health monitoring programs. The integration of such technologies typically begins with validated sensor information currently measured on the engine being fed directly into the diagnostic algorithms for fault detection/isolation and classification. The ability of a diagnostic system to fuse information from multiple diagnostic sources together to provide a more confident fault assessment is emphasized along with a system's ability to estimate confidence and severity levels associated with a particular diagnosis. In a parallel mode, the validated sensor data and real-time current/past diagnostic information are utilized by prognostic modules to predict future time-to-failure, failure rates and/or degraded engine condition (i.e., vibration alarm limits, performance margins, etc.). The prognostic modules typically utilize physics of failure, stochastic models taking into account randomness in operation profiles, extreme operating events, and component forcing. In addition, the diagnostic results can be combined with past history information to train real-time algorithms (such as neural networks or real-time probabilistic models) to continuously update the projections on remaining life. A few selected and relevant approaches and algorithms for performing component prognostics are described in this article.

Once predictions of time-to-failure or degraded condition are determined with associated confidence bounds, the prognostic failure distribution projections can be used in a risk-based analysis to optimize the time for performing specific maintenance tasks. A process that examines the expected value between performing maintenance on an engine or component at the next opportunity (therefore reducing risk but at a cost of doing the maintenance) versus delaying maintenance action (potential continued increased risk but delaying maintenance cost) can be used for this purpose. The difference in risk between the two maintenance or operating scenarios and associated consequential and fixed costs can then be used to optimize the maintenance intervals or alter operational plans.

3 SENSOR VALIDATION

Sensor malfunctions have traditionally plagued many engine health monitoring systems with false alarms and an inability to distinguish between real engine-based faults and sensor faults. Hence, a necessary "front end" of any engine health monitoring system should have the capability to detect and classify specific sensor failure modes and distinguish them from actual engine faults. One particular approach that has been implemented within several gas turbine engine test cells is based on utilizing generic signal-processing techniques such as digital filtering, cross-correlation, and coherence coupled with an intelligent classifiers including a fuzzy logic rulebase to diagnose malfunctioning sensors.

The generic, signal-processing-based approaches are capable of detecting signal anomalies such as spiking, intermittent signal loss, cross talk, and clipping using modified signal correlation and coherence algorithms. Digital filtering is used to aid in the detection of spikes, noise, intermittent loss of the signal, and other anomalies, which manifest themselves by a rapid change in signal magnitude. The high degree of overlap between the two methods in detecting the most common signal faults provides a higher degree of confidence when an anomaly is flagged and will therefore minimize false alarms.

The digital filter algorithm utilizesa high-pass Butterworth or similar filter with a 3-Hz minimum cutoff frequency that is selected based on the physical response of the engine sensors themselves. Figure 2 shows how the standard deviation of a filtered signal is used to detect an anomalous signal. The top left window shows a noisy, time-domain thermocouple signal and the top right shows a "normal" thermocouple signal. The filtered version of both these signals is shown below with the variance of the filtered signal used as the feature, which will flag a signal anomaly. Although this technique is a simple one, its effectiveness and generic implementation capability makes it a practical choice for instrumentation validation.

The cross-correlation and coherence algorithms attempt to find statistically significant shifts in the quantitative relationships between signals in both the time and frequency domains. These techniques are implemented utilizing a moving time-domain window that continuously computes the correlation and coherence functions of each of the measured signal pairs. Therefore, any signal whose previous $(t - n)$ window of time-domain data becomes consistently less correlated with the current (t) windows can be identified

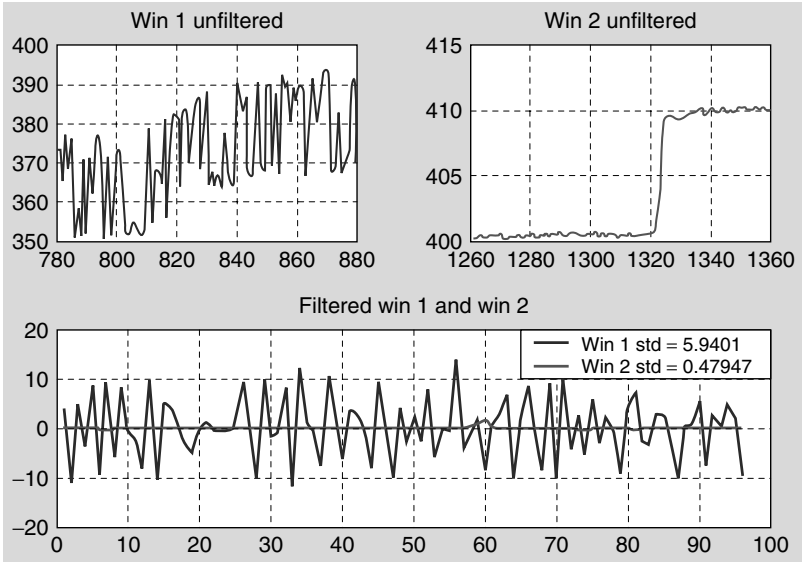

Figure 2. Digital filter detecting thermocouple noise.

as a sensor-related issue and not engine performance driven. The cross-correlation and coherence functions are as calculated as follows:

$$R_{x_1x_2}(0) = \frac{\sum x_1(n)x_2(n)}{\sqrt{\sum x_1^2(n)\sum x_2^2(n)}}$$

normalized zero-lag correlation (1)

$$\gamma^2_{X_1X_2}(\omega) = \frac{\left|\sum R_{x_1x_2}(\tau)\mathrm{e}^{-i\omega\tau}\right|^2}{\left(\sum R_{x_1x_1}(\tau)\mathrm{e}^{-i\omega\tau}\right)\left(\sum R_{x_2x_2}(\tau)\mathrm{e}^{-i\omega\tau}\right)}$$

coherence function (2)

Though only two signals are represented in equations (1) and (2), the correlation and coherence functions can be applied to any number of signals at once. The data samples utilized within these generic techniques are typically small and dependent upon the sampling frequency and the amount of time over which data is gathered. This may require the use of the "small sampling theory". In gas turbine engine monitoring applications, statistics are typically obtained from the coherence and correlation functions a priori and then the level of significance is determined by utilizing a t-test on the statistic of interest, as shown in equations (3) and (4). In many cases, the mean value of the samples is used to determine if a significant shift in the statistic has occurred.

$$t = \frac{\bar{X}_1 - \bar{X}_2}{\sigma\sqrt{\frac{1}{N_1} + \frac{1}{N_2}}} \tag{3}$$

where

$$\sigma = \sqrt{\frac{N_1 s_1^2 + N_2 s_2^2}{\nu}} \tag{4}$$

$\bar{X}_1$ the mean value of the first sample

$\bar{X}_2$ the mean value of the second sample

N_1 the size of the first sample

N_2 the size of the second sample

s_1 the standard deviation of the first sample

s_2 the standard deviation of the second sample

$\nu = N_1 + N_2 - 2$ the degrees of freedom

Figure 3 shows some selected results from two of the signal-processing techniques that were used to detect sensor faults on data taken from an engine test cell. Note that multiple sensor spikes, signal noise, and a signal "drop out" are all present within

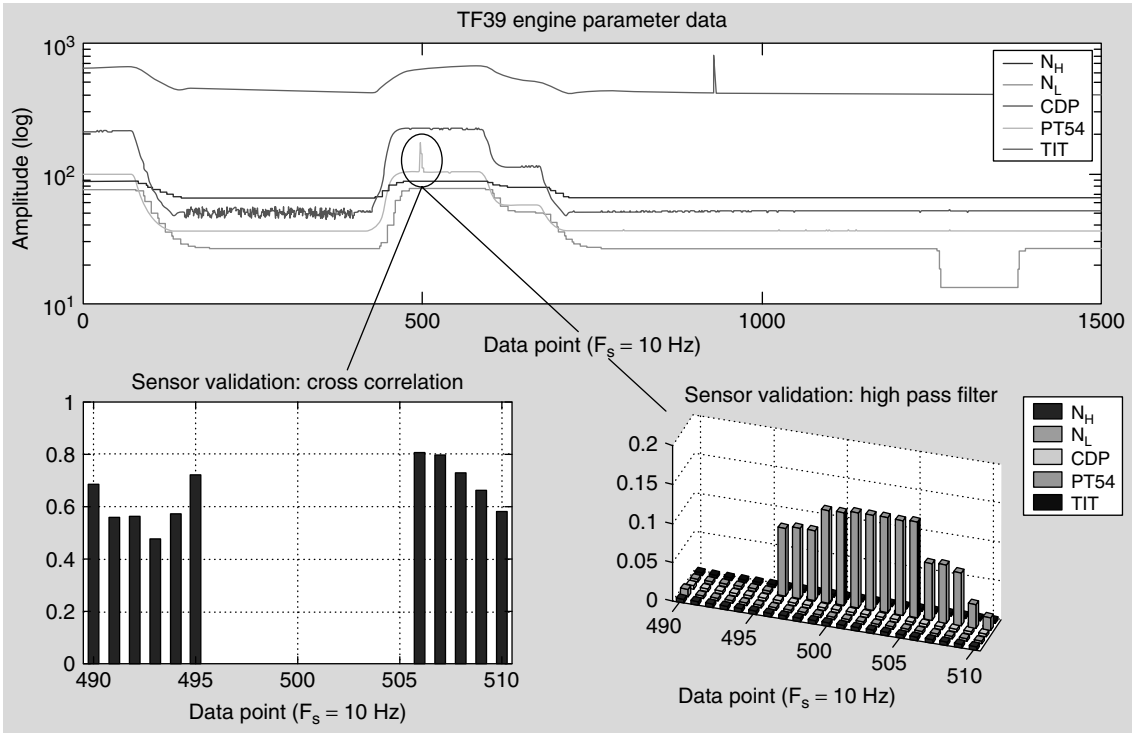

Figure 3. Results of cross-correlation and digital filtering.

this data set. As illustrated, the cross-correlation approach, shown on the bottom left, identifies an anomaly when its value drops to zero. The digital filter approach triggers an anomaly when the signal's standard deviation is high (coherence results are not shown). Both approaches indicate that the anomaly occurred and then returned to normal.

Finally, when the engine sensor data is processed by both the generic filtering and correlation techniques, the individual algorithm outputs can be fused together in a postprocessing stage to provide a more confident sensor fault detection. A Dempster–Shafer fusion algorithm can be implemented for this purpose, which accounts for uncertainty in the conditional probabilities derived by the various techniques being processed. The Dempster–Shafer methodology hinges on the construction of a statistical set, called the *frame of discernment*, in which a set size will contain every possible hypothesis. Every hypothesis (A) has a belief (lower bound) denoted by a mass probability $(m(A))$ and a plausibility (upper bound) denoted by $1 - m(A')$. Beliefs and plausibilities are combined in the following manner. A full example of the Dempster–Shafer fusion technique is provided in [1].

$$\text{Belief}(Hn) = \frac{\sum_{A \cap B = Hn} m_i(A) \cdot m_j(B)}{1 - \sum_{A \cap B = 0} m_i(A) \cdot m_j(B)} \tag{5}$$

4 ENGINE THERMODYNAMIC PERFORMANCE DIAGNOSTICS

The sensed parameters associated with the engine gas path and corresponding ambient conditions are required by performance analysis algorithms to detect and isolate performance faults. Pressure, temperature, and flow readings at different points within the gas path are required, as are any bleed flows, fuel flow, rotor speeds, and any other engine conditions that must be accounted for in performance calculations. Figure 4 shows the locations and their

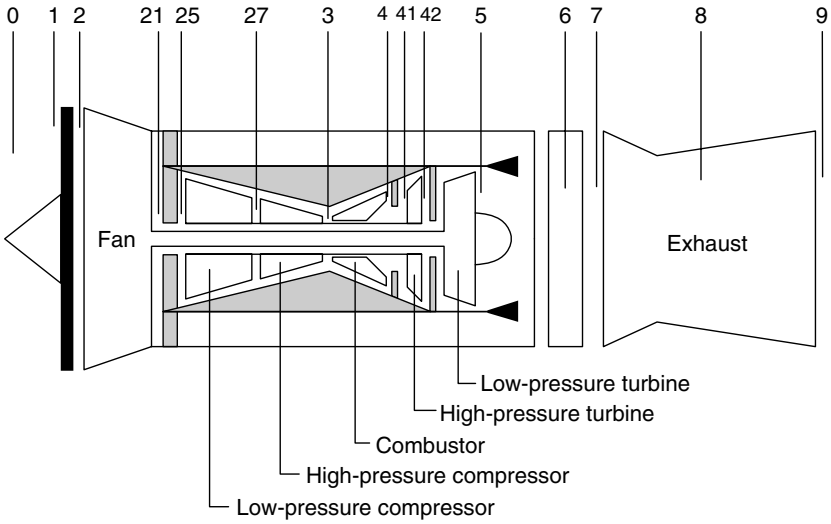

Figure 4. Engine gas path designations.

associated designations for jet engine pressure and temperature measurements. A specific engine gas path analysis model is typically run off-line under off-design conditions to develop a matrix of "diagnostic error patterns" expected under ideal engine degraded conditions. Measurement and modeling uncertainties are developed based on the variances in the modeling and measurement acquisition processes.

Using the gas path performance measurements, statistical engine parameter curves can be developed for specific engines so that comparisons can be made between current conditions and some baseline or normal condition. Measurement uncertainties can be calculated based on this recorded data. The middle plot shown in Figure 5 illustrates the corrected performance curve of the compressor discharge pressure as a function of N2 speed at pseudo-steady-state conditions. The "bands" around the curve represent the 1-sigma distribution (1 SD) levels. The left side of Figure 5 shows a 3D representation of how the percent deviation in compressor delivery pressure (CDPC) changes with speed.

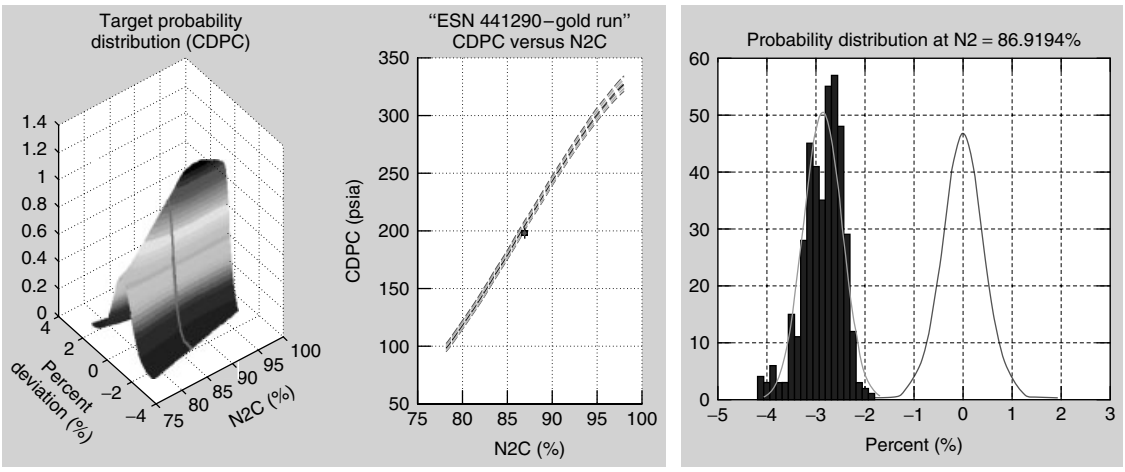

Figure 5. Statistical engine signature curves and shift detection.

Utilizing confidence intervals for the discovery of a statistically significant trend away from "normal" engine operation is a rigorous way to assess engine anomalous events. Utilizing a full set of engine signature curves described above is well suited for this type of analysis. The detection of an anomalous event will trigger the start of a more comprehensive diagnostic treatment of the detected error pattern. The key is to be capable of determining whether the mean measured parameter values have shifted with a high degree of confidence. The confidence interval approach is a well-proven statistical method for performing this calculation. The t-test is another commonly used technique to determine if a parameter has shifted appreciably from its performance curve.

In the right side of Figure 5, the distribution centered about 0% deviation is the compressor discharge pressure associated with specific engine. The histogram, with a distribution centered about -3% deviation, was acquired from a degraded engine. Clearly, this distribution is different with a high level of statistical significance, over 99% in fact. As a result, it can be confidently stated that the current engine condition has a lower compressor delivery pressure (CDP) than the baseline engine data. This type of analysis, combined with all of the other relevant parameters, is used to determine if the overall compressor efficiency of the current engine condition was lower than that of the baseline.

Next, the performance diagnostic approach relies on gauging the proximity of ALL the current system deviations to known performance faults based on the gas path analysis (GPA) model. A multiparameter, probabilistic classifier technique has been shown to be capable of identifying degraded performance in propulsion systems [2]. This approach requires that sufficient sensor information be available to assess the current condition of the system in terms of shifted trends in parameters from a baseline condition. Modeling and measurement uncertainty is accounted for with this technique utilizing the distributions on the current parameter shifts and model-based fault conditions. While a physical model, such as a gas path analysis or control system simulation, is beneficial, it is not a requirement for this approach to work. An alternative to the physical model is built-in "expert" knowledge of the fault condition.

This generic, probabilistic-based diagnostic classifier involves assigning non-normal or normal probability density functions (PDFs) to performance error patterns associated to known faults in N-dimensional space. Similarly, the current error exists as a PDF in the parameter space as well. The probability that the current condition (C, measured parameter shifts) may be attributed to a given fault (F, identified known fault conditions) is determined by the "overlap" (i.e., multidimensional integration) of their respective joint probability density functions. Figure 6 shows how this is done in two-dimensional parameter space. If C and F can be assumed to be normally distributed (not a necessary assumption, however), the probability of association (p_a) with a given fault condition F can

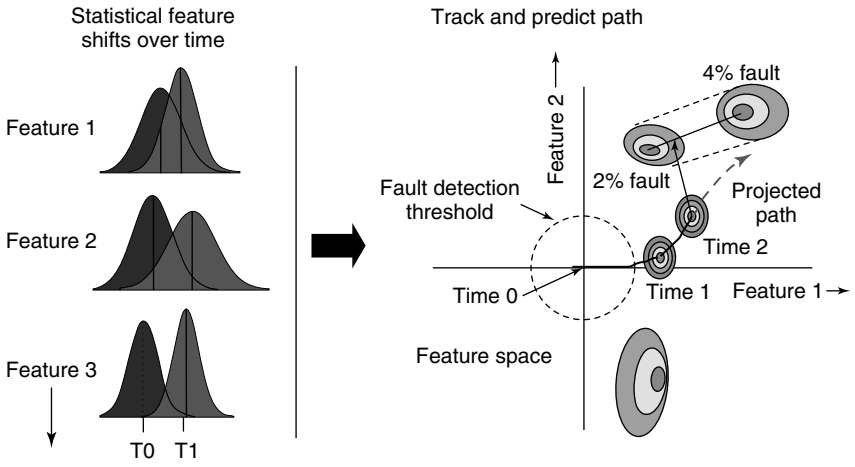

Figure 6. Multiparameter diagnostic technique.

be found using

$$p_a = 2\Phi\left(-\frac{\overline{F-C}}{\sqrt{\sigma_f^2+\sigma_c^2}}\right) = 2\Phi(-\beta) \qquad (6)$$

where:

$\bar{F}, \bar{C}$ = the mean of the distributions F and C, respectively

σ_f, σ_c = the standard deviation of the F and C distributions

The function $\Phi(\,)$ is the standard normal cumulative distribution and the β is denoted as the reliability index. The β represents the Euclidean distance between the current conditional distribution (C) and a given fault distribution (F). Hence, this approach performs diagnostics by evaluating the likelihood of the current conditions to known fault conditions and prognostics by extrapolating a fault-weighted, evolutionary path.

Figures 7 and 8 provide an example of the evolution of a performance error pattern as an engine's performance degrades over time. In the scenario shown in Figure 7, the PDF of the current error pattern initially evolves toward a 2% high-pressure compressor (HPC) efficiency fault. This is also shown in Figure 8 from the fact that from $T = 0$ to $T = 3$ the Euclidean distance between the current PDF and the HPC fault gets smaller. However, as time goes by, the current condition evolves toward, and eventually past, the HPC fault. From Figure 8, at $T = 5$ the current PDF is closest to the 2% high-pressure turbine (HPT) efficiency fault. Figure 7 illustrates that the engine's degradation has indeed evolved beyond association with the HPC fault to high association with the HPT fault. In this example, the final position rests at 9.98% association with the HPC fault and 22.8% association with the HPT fault.

The final step in the performance diagnostic process involves mapping the measured parameter deviations to the modeled engine faults. Hence, this performance model or alternatively an OEM DEC model is used to generate performance error patterns or diagnostic scalars used for fault isolation. As illustrated in Figure 9, the diagnostic scalars are simply the differences between the model estimate and the measured values of key performance parameters shifts (Wf,N2,T45,P25,T25,T3,P3) at referred conditions. When these error patterns are generated,

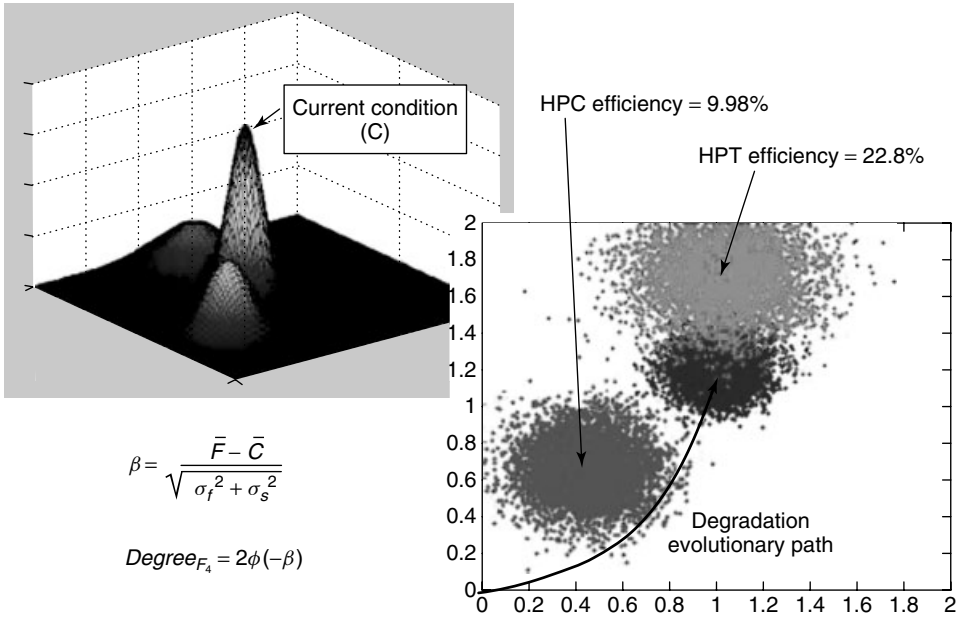

Figure 7. Degree of fault association.

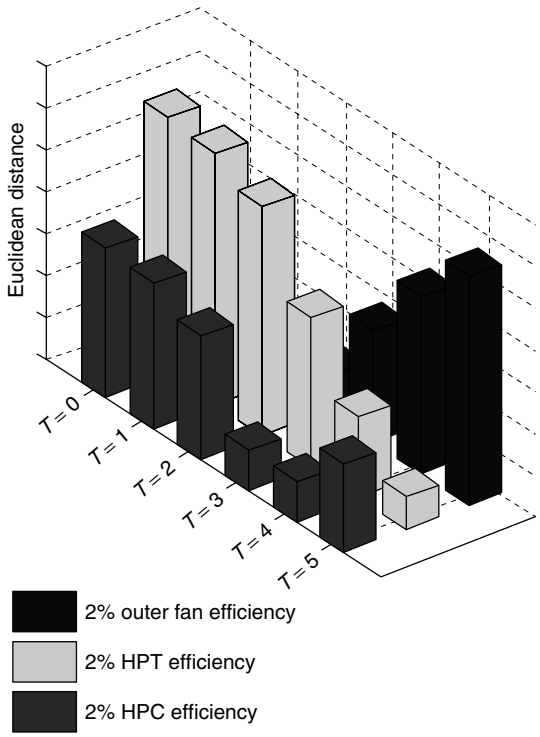

Figure 8. Performance fault evolution.

the next step is to consider the influence of root cause performance faults on the key performance parameters. A set of root cause performance faults for typical engines are fan efficiency degradation, low-pressure compressor (LPC) efficiency, HPC efficiency, HPT efficiency, low-pressure turbine (LPT) efficiency, 2.5 bleed flow, 2.9 bleed flow, discharge area, and stator vane misrigging.

Different severities of these faults will create different performance parameter error patterns that must be contained in an "engine-specific baseline characteristics" database. Although actual engine faults would be ideal for producing the fault error patterns, simulating them with the engine model a priori is typically done. With the error pattern calculated, the database of known faults must be autonomously compared with the current delta scalar pattern to enable real-time performance assessments. In reality, the data-driven error pattern will not exactly match any of the calculated (ideal) error patterns, so the most likely root causes must be determined. There are potentially many methods for performing this classification task. A few of these include least squares pattern match algorithms, Kohonen map/neural network classification and the previously described probabilistic classifier technique, shown in Figure 9. These error pattern classification techniques have already been shown to be capable of identifying degraded performance in propulsion systems [3]. Modeling and measurement uncertainty is accounted for with this technique utilizing the distributions on the current parameter shifts and model-based fault conditions.

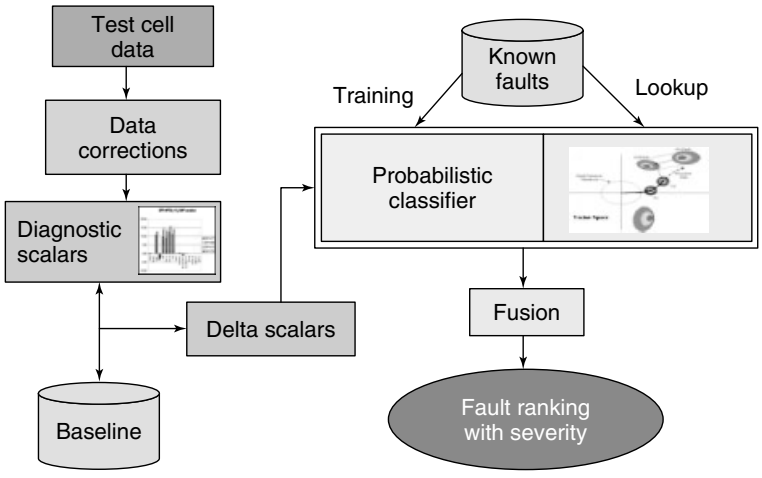

Figure 9. Performance diagnostic process.

5 ENGINE VIBRATION DIAGNOSTICS

Typical engine vibration monitoring systems utilizes piezoelectric-based accelerometers to measure the dynamic response of the engine. One of these accelerometers is often located on the compressor rear frame, while another is typically on the turbine rear frame. Vibrations from various sources, such as engine core rotor, fan rotor, hydraulic pump, etc., are detected by the transducers and converted into electrical signals. The signals are then routed to a vibration signal conditioning analyzer where the signals are amplified and antialiased filtered. If the system is functioning properly, the signal is typically modulated by primarily two components that are proportional to the fan and core speeds.

Real-time assessment of mechanical faults (i.e., bearing, rotordynamic, and structural) based on analysis of the vibration signatures at specified locations on the engine has been developed using feature-based diagnostic techniques. Domain knowledge associated with particular vibration fault frequencies, fixed frequency ranges, per-rev excitations, and structural resonances are extracted from the vibration spectrums acquired from the engine. These spectrums are used to develop a knowledge base from which fuzzy logic membership functions and an associated rulebase are developed. An example of a generic fault matrix and feature extraction process is illustrated in Figure 10 for a typical waterfall vibration plot.

The functionality associated with a feature-based vibration diagnostics capability is primarily based on the development of two particular analysis approaches. These approaches can best be described using the two plots in Figure 11, which illustrate the following: (i) waterfall plot of vibration spectrums (0–1000 Hz, typically) over several different core engine speeds and (ii) tracked-order plots of 1XRev through 2XRev amplitudes for all engine rotors plotted as a function of core speed. Examples of these two plots are shown for a large military engine.

The amplitude associated with the waterfall plot is typically in mils (Pk–Pk), but can also be given in velocity units of (cm/s Pk). Once these measurements are obtained, plots of the transient vibration waterfall are stored and analyzed for rotordynamic health. Using the data set of vibration measurements from a specific engine or group of engines, a table of spectral features and corresponding "normal" amplitude bands are developed for detecting anomalous

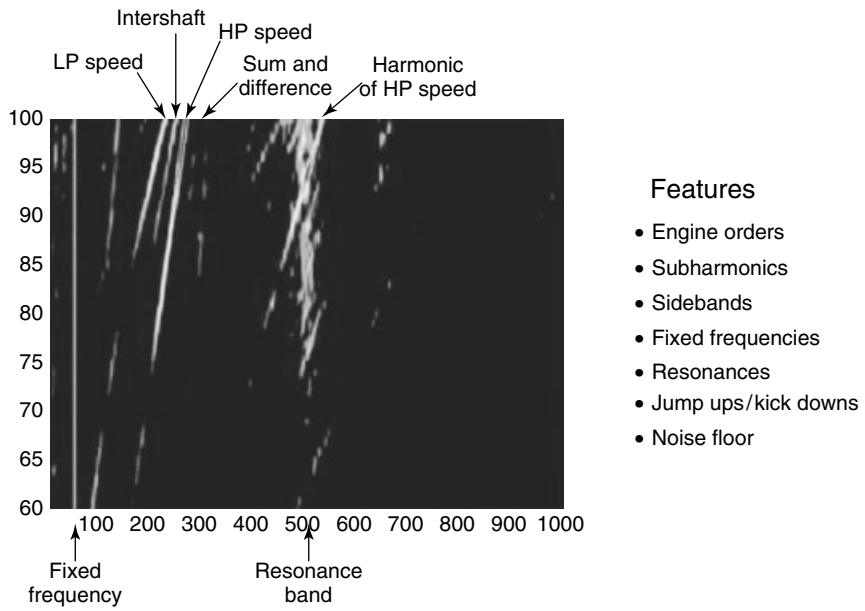

Figure 10. Feature extraction from vibration analysis.

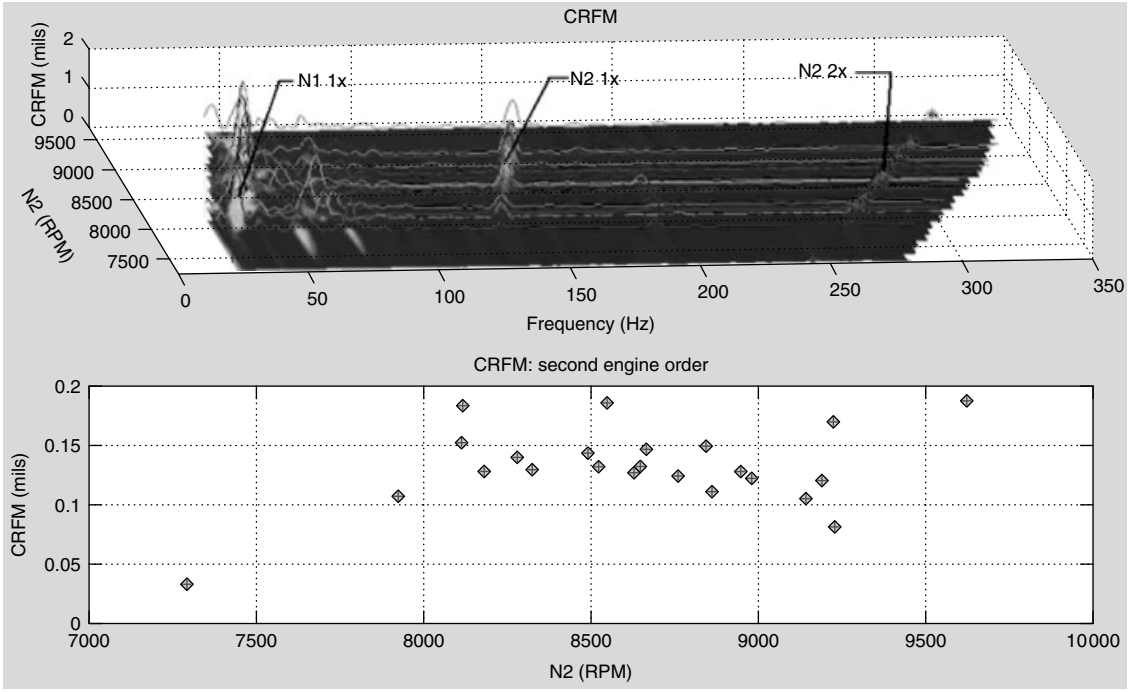

Figure 11. Waterfall and tracked-order plots for TF39 engine.

vibration signatures and associating them with particular diagnostics where applicable. In Figure 11, one can easily see that vibration peaks are associated with the core engine and fan speeds.

The vibration analysis schemes also utilize a shape-based statistical analysis of the tracked orders to detect and diagnose mechanical faults. The combination of these techniques allows for a more robust and sensitive diagnostic capability. Figure 12 shows a particular shape of a high-pressure (HP) shaft tracked-order and ± 2 SD determined from testing of multiple engines. The bold line in Figure 12 shows a simulated tracked order of an engine with a different structural resonance. In this example, which is for illustration purposes, an amplitude level band on the tracked order would not detect a problem; however, a statistical analysis of the shape of the tracked order would be able to detect a fault.

Owing to the varying amount of data and diagnostic information that exists in regard to vibration anomalies that occur on particular engines, many programs propose to use a master database to collect these vibration signature features associated with the waterfall plot and tracked-order statistics. The engine-specific vibration signatures will be used to develop a statistical description of engine shaft tracked-order amplitudes, broadband amplitudes, and nonsynchronous vibration amplitudes. The statistical description can then be utilized directly in the vibration anomaly detector algorithms using normal distribution membership functions within the fuzzy logic decision process.

6 ENGINE LIFE-LIMITED COMPONENT PROGNOSTICS

A prognostic model for an engine's life-limited component such as a hot section blade and nozzle must have ability to predict or forecast the future condition or risk of failure given the past operating environment and some prediction on how the engine will be operated in the future. To be clear, oftentimes the term prognostics is further defined by either failure or condition prognostics. Failure prognostics often refers to the continuous accumulation

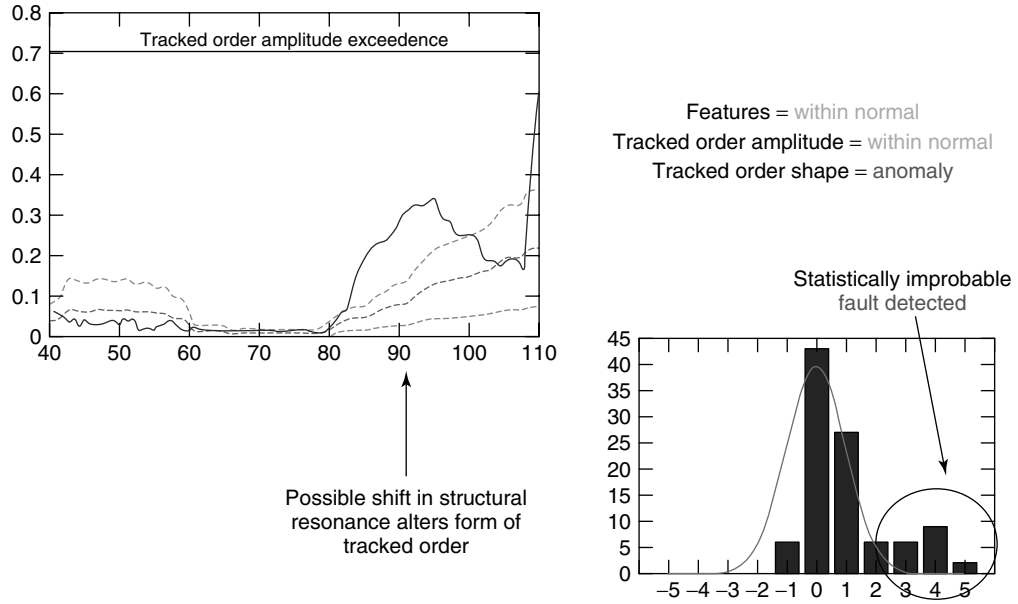

Figure 12. Tracked-order analysis.

of damage and/or life on components or systems of components, with or without the presence of any identified faults. Components governed by mechanical wear and failure often fit into this category (i.e., prediction of crack initiation without the presence of a fault detected). In contrast, condition prognostics is most often associated with a fault being diagnosed prior to a vibration or performance-related limit being exceeded. A detected fault must be isolated and assessed for severity so that the remaining useful life can be determined. This useful life is defined by the operating time between detection and an unacceptable level of degradation.

For life-limited components, failure prognostics is applied using a physics-based stochastic model that typically incorporates mechanical (finite element) or thermodynamic (through-flow model) deterministic models as their basis. The probabilistic procedure for addressing inherent modeling uncertainties must be built into these models using statistical distributions of the parameters that most directly affect the component life-limiting factors. Some of these factors include the material properties, dynamic forcing, and process variability. The distribution on the current remaining life in a component life prediction may be determined by calculating all possible combinations of these life-limiting factors in a stochastic process given past operating conditions. Operating hours can be statistically analyzed, trended and projected into the future to provide the prognosis of remaining life. More advanced stochastic models that represent failure-mode uncertainties, projected operational parameters, and rare/random events can be used to help predict failure-mode propagation. This physics-based model should be calibrated using in-service data to clearly reflect the root cause of the in-service failure-mode experiences. In the case where a finite element model can be used (gearing, blading, impellers, or rotors, for example), crack initiation regions should agree with any in-field experience and inspection data. More empirically analyzed components such as bearings should have clearly identified relationships between diagnosed fault severity and life consumption.

6.1 Example of a stochastic physics-based model

Sophisticated fracture mechanics and damage accumulation analysis have shown that accelerated crack nucleation and microcrack formation in components

can occur due to start-ups and shutdowns, transient load swings, higher than expected intermittent loads, or defective component materials. More commonly, normal wear causes configuration changes (loose fit of assembled parts, work-hardened surfaces, and reduced structural section areas) that contribute to increased or unexpected dynamic loading conditions. High cycle dynamic and transmission loads can lead to micro-crack incubation and formation of micro-cracks at the material grain boundaries in stress concentrated regions (especially between hardened surfaces and softer subsurface material interfaces, and at acute changes in component material geometry). The majority of crack growth evolves in a subcritical propagation process of crack tip blunting, unstable crack formation, and crack elongation. As supercritical loading in the cracked material region is approached, growth accelerates resulting in material dislocation and detachment. Subcritical crack evolution is highly dependent on a component's material, geometry, loading conditions, and the particulars of the unique component crack growth cycle. This kind of failure-mode knowledge is often times overlooked in determining the potential usefulness of a particular prognostic or diagnostic algorithm.

The available time to take corrective or compensatory actions during specific periods of microcrack incubation, formation, and subcritical propagation in the material of a faulted component must be considered. On the basis of this understanding, either of two beneficial actions could be taken: a corrective one to perform maintenance to repair or replace the part, or a compensatory one to reduce system operational loads to extend the life of the faulted part. The informed decision exists only if the diagnostic/prognostic system has the ability to detect that the fault exists, isolate it to the specific component, and assess its severity in a timely manner.

A stochastic physics-based model of a turbine blade is used to describe the modeling approach described above and is shown below in Figure 13. Although each component prognostic modeling procedure is different based on the failure modes being predicted, a process that utilizes the raw, database and processed diagnostic data through a physical-based model is still applicable.

The factors and associated level of uncertainty that most directly affect the remaining useful life on a component must be identified in this physical model. One of these factors specific to a turbine blade is

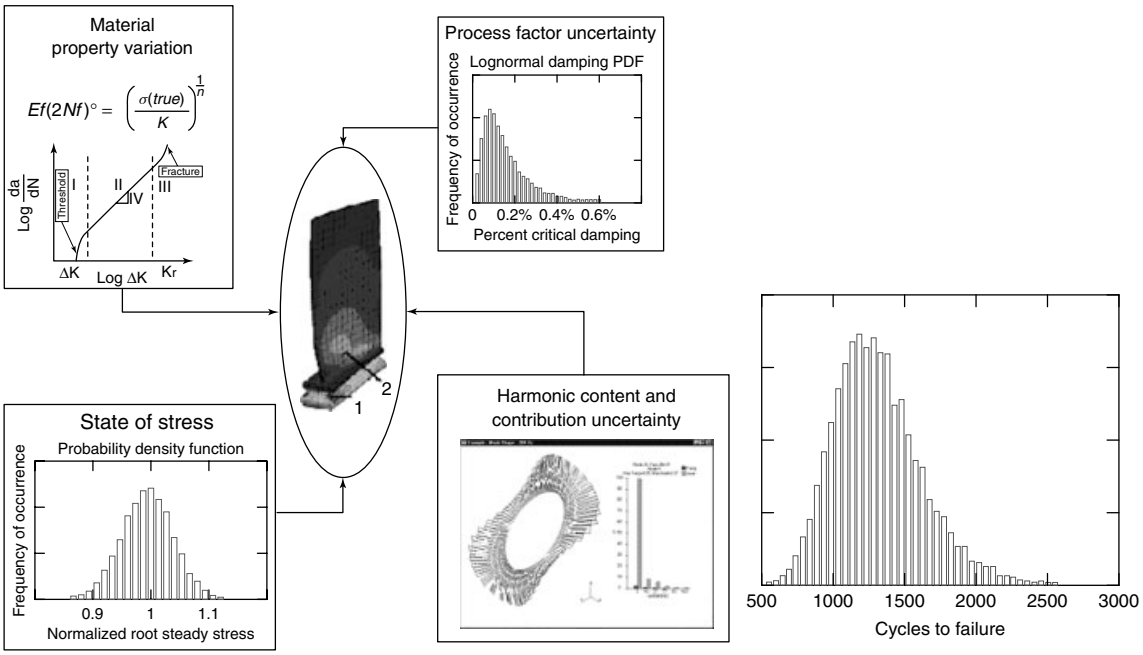

Figure 13. Physics-based stochastic model.

the steady stress at the critical locations in the root region. The uncertainty associated with this steady stress due to variations in the operating environment, temperatures, manufacturing tolerances, etc., must be accounted for with a statistical distribution computed by testing and field service data. Another factor critical in predicting turbine blade life is the dynamic stress as a function of the uncertainty in harmonic excitation and response characteristics. The strength or resistance capability of the material must also be considered as a function of the uncertainty in material properties.

In an effort to describe the process of prognostic modeling for a specific component failure mode (only one aspect of this turbine blade model), the low-cycle fatigue (LCF) fatigue life for the root location that experiences stress cycling in excess of the material's yield strength is described in equation (7):

$$Nf1_L = \frac{1}{2}\cdot\sigma_L(\text{true})^{\left[\frac{1}{(n-c)}\right]}\cdot K^{\left[\frac{1}{(n-c)}\right]}\cdot Ef^{\left(\frac{-1}{c}\right)} \quad (7)$$

All of the parameters involved in calculating LCF life have levels of uncertainty associated with them and are therefore given as probability distributions that may or may not be Gaussian. The distributions are combined using a Monte-Carlo simulation. The Monte-Carlo simulation is an automatic process that randomly selects thousands of different values from each of the life-limiting factor distributions. Over the entire simulation, the randomly chosen values are combined to generate the distribution of a parameter that may have been very difficult or impossible to calculate in a strict analytical sense. The result of the simulation is also shown in Figure 13.

The damage due to the LCF may be given by a nonlinear damage accumulation rule proposed by Halford at NASA Langley [4]:

$$\text{Damage} = \left(\frac{n_1}{Nf1_L}\right)^{r_1} \quad (8)$$

The complete turbine blade prognostic model must further account for the other failure modes at other critical locations on the blade; however, this is outside the illustrative scope of this article. The net result, however, is the path that has been taken to determine the current component life consumption as shown in Figure 14.

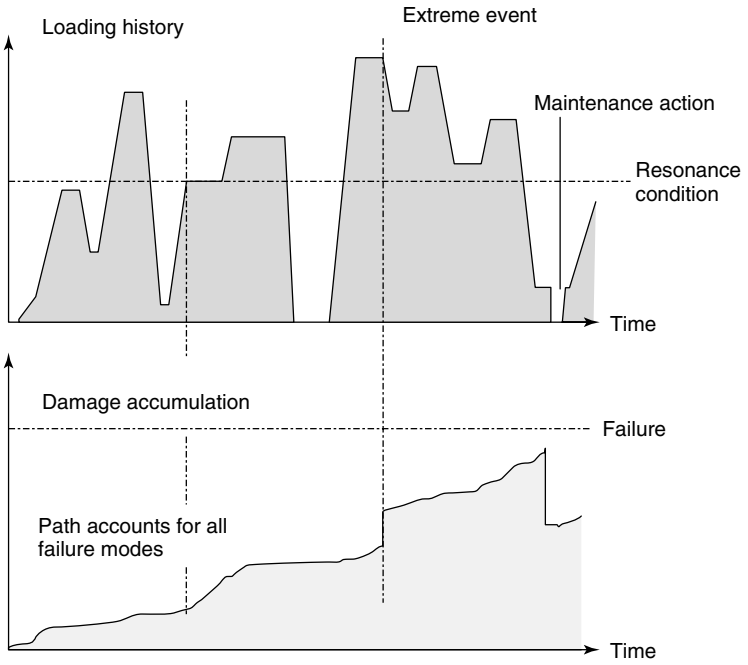

Figure 14. Damage accumulation and projected remaining useful life.

When statistics on the past operating profile of the machine are tracked, projected future operating conditions and maintenance actions can be estimated and utilized by the prognostic model in order to forecast the remaining life in the blade.

7 CONCLUSIONS

A cross section of the current state of the art in applying integrated gas turbine engine health monitoring, and diagnostic and prognostic technologies has been presented, which can offer significant potential for reducing current engine LCC. These technologies can be implemented across the entire spectrum of both military and industrial engines from land-based gas turbines to aircraft engines. Implementation of these technologies is advantageous in nearly eliminating sensor problems, improving maintenance decision effectiveness by providing early warning of incipient performance and vibration faults, and gauging remaining life and predicting future usage associated with critical components.

This article has also introduced specific methods currently being implemented for automated sensor, vibration and performance diagnostics for engine health management. Specifically, the techniques have been developed and implemented for various military engine test cells and industrial gas turbines. Initial results on implementing these technologies has been encouraging, with several sensor faults and vibration-related fault frequency being detected. The capabilities of the engine health monitoring approaches will satisfy system requirements of reduced support costs and improved engine testing and accountability. The initial findings are favorable in the quality of the signals, capabilities to store and network data, and implement diagnostics and intelligent troubleshooting.

Chapter 156
Integrated Sensor Durability and Reliability

James L. Blackshire and Kumar V. Jata
Air Force Research Laboratory, Wright Patterson Air Force Base, Dayton, OH, USA

1 INTRODUCTION

A significant amount of interest currently exists in the area of integrated systems health management (ISHM). Although this basic concept can take on many different functional forms, for civil, mechanical, and aerospace systems, the use of structural health monitoring (SHM) as part of a larger ISHM strategy offers the potential for monitoring the structural health of a system with far-reaching consequences and benefits [1–3]. Improved fleet management using condition-based maintenance (CBM) strategies, for example, would use ISHM and SHM to provide critical diagnostic information for assessing the health of an aircraft system. In a CBM framework, aircraft would be maintained more efficiently and effectively using critical health status indicators, which would be provided by an integrated health diagnostic system (*see* **Usage Management of Military Aircraft Structures**).

A critical aspect of the ISHM and SHM concepts involves the use of integrated sensing systems to interrogate, inspect, and diagnose the structural systems. In practice, the inspection system uses distributed sensors, which are attached to an existing structure or integrated directly within a newly fabricated structure [4–8]. In either case, the integrated sensors become a part of the structure, and are subjected to similar or identical environmental conditions (*see* **The Influence of Environmental Factors**). This places additional requirements on the performance of the sensor system with regard to long-term durability, reliability, and operational performance over extended time periods, and in a wide variety of varying environmental conditions. These environmental conditions would likely include variations in moisture, chemical attack, vibration, temperature, and mechanical loading of the structural components [1, 3–7, 9]. In addition, the sensors would need to behave in a consistent and reliable manner throughout the duration of the inspection process, which for most applications could span several years to decades.

1.1 Historical background

The durability of onboard sensing systems has been an important and long-standing problem for more

 ISBN: 978-0-470-05822-0.

than a century. Much of the early development and use of sensor technologies involved wired sensing systems in the manufacturing industries for process control in the form of temperature, humidity, pressure, displacement, force, fluid flow, acceleration, and proximity sensors [10, 11]. Significant advances in sensor system design, speed, accuracy, miniaturization, packaging, and overall performance were made in the 1970s, which enabled the development and growth of whole new manufacturing industries. At the heart of these advances were efforts to improve sensor system durability, reliability, and survivability using newly developed sensor materials, improved sensor system designs, and robust sensor packaging methods. As a result, unprecedented sensing capabilities became available with extended dynamic ranges, sensitivities, and useful sensor lives [10–14].

The development of miniature electronic circuitry and portable battery technologies in the mid-twentieth century provided an additional opportunity for developing onboard sensing systems for remote locations and mobile systems [15–20]. The transportation and civil industries, in particular, have benefited significantly from sensors for monitoring performance and load states in automobiles, railway systems, aircraft, and civil structures. In addition to increased demands on sensor system performance, durability and reliability issues became much more prevalent and demanding for these remote/mobile sensors, which were required to operate in dynamic and sometimes unpredictable operational environments. Unlike the earlier manufacturing and processing sensors, which were used in controlled environments, the sensors used in transportation and civil applications were often subjected to uncontrolled environments, which affected their performance, reliability, and durability. The use of onboard power and control circuitry also required strategies for improving battery and circuit durability [21–23]. By the mid-1990s, rugged sensor systems had become available with advanced heat sink, vibration isolation, and connector designs, which provided virtually trouble-free sensor performance capabilities in remote locations for extended times of up to 5–10 years [10, 11, 24, 25].

Within the past decade, the concept of SHM has advanced to a state where onboard sensing systems are becoming available for assessing the structural integrity of numerous civil, mechanical, and aerospace systems [1–8, 25–29]. In general, the sensing of structural integrity involves the use of sensors that are intimately coupled to the host structure. As far as the sensor system durability and reliability are concerned, this places additional demands on the sensor with regard to its ability to withstand usage and environmental conditions that would normally be subjected to the host structure alone. As a result, new challenges and opportunities exist for advanced SHM sensor systems, which have yet to be fully addressed.

1.2 State of the art

SHM represents a wide, multidisciplinary field of engineering where integrated sensing systems are used to diagnose/monitor a structure's operational status and damage state. A large number of integrated sensing methods are currently being developed for many different structural applications [30–35]. Table 1 provides an abbreviated listing of the major types of sensors used in SHM applications along with the measurement types, physical principles involved, and reliability issues for each major sensing method.

With regard to SHM system durability and reliability, a number of technologies have advanced to a level where they are being applied to realistic structures for long-term assessment and use [36–40, 43, 48]. Traditional sensing technologies utilizing commercial-off-the-shelf (COTS) sensors, for example, have been used for more than a decade in civil and aerospace applications [4, 37, 38]. Building on flight recorder data collection systems originally developed in the 1950s–1960s, the health and usage monitoring system (HUMS) represents one of the most mature onboard sensing technologies in use today [38, 49, 50] (*see* **Experience with Health and Usage Monitoring Systems in Helicopters**). Originally developed in the early 1990s for monitoring structural vibrations (and anomalies) in helicopter rotor and gearbox assemblies, the HUMS system constitutes a complete onboard SHM system, which has had a nearly 100% reliability rate during extensive trials over the past decade. This high reliability rate has been attributed largely to the use of a variety of proven COTS technologies (accelerometer sensors, electronics, and wiring, communication elements). Only limited premature sensor failures,

attributed primarily to electronic faults and inadequate mounting of the sensors, have been observed. Similar sensing approaches are beginning to appear for SHM aerospace [37], automotive [4], and train/rail system [51] applications.

The use of thin-film strain gauge and corrosivity sensors for structural assessment is also noteworthy with regard to SHM sensor reliability testing on a large scale (*see* **Loads Monitoring in Aerospace Structures**; **Aircraft Structural Diagnostic and Prognostic Health Monitoring for Corrosion Prevention and Control**). An ongoing US Air Force program for C-17 cargo aircraft is currently utilizing a suite of strain gauges on a portion of the fleet in key structural locations to compare actual usage data against design assumptions [43]. In that program, the durability of the strain gauge sensors was tracked for 22 aircraft from 1992 to the present. An important result of that program was an observation of infant mortality rate of 23%, where sensors failed very close to their installation time. Of the 160 sensors installed, 58% were still operational as of March 2003. A similar large-scale flight test program involving the evaluation of thin-film galvanic corrosivity sensors was begun in 2003, where more than 600 sensors were attached to 100+ commercial and military aircraft [44]. Roughly, 10–15% of the sensors were reported as being lost due to neglect during periodic depot maintenance (PDM) activities, where physical damage to the sensor and electronics had occurred. Environmental exposure had also caused the degradation of an additional 1–2% of the sensors within 2–3 years for internally mounted sensors and ~5% for externally mounted sensors.

The development of custom and more nontraditional sensing approaches has also progressed in recent years. To a large degree, many of the leading SHM methods have completed laboratory proof-of-concept evaluations and are being considered for transition opportunities in real-world applications. Six technologies in particular (fiber-optic, piezoelectric, thin-film, electromagnetic, microelectromechanical sensors (MEMS), and vacuum sensors) have matured to a level where initial reliability testing has been completed, and real-world testing trials have begun [41, 42, 52–54]. Building on two decades of research and development, fiber-optic

sensors are being used in load and strain monitoring applications for bridges [54] (*see* **Fiber-optic Sensor Principles**; **Fiber Bragg Grating Sensors**; **Hybrid PZT/FBG Sensor System**; **Fiber-optic Sensors** and **Reliable Use of Fiber-optic Sensors**) and for damage detection in composite aerospace structural components [41]. Miniature piezoelectric sensors arrays have also been installed on commercial and military aircraft recently, where preliminary flight testing has demonstrated 1151 flight hours over 246 take-off/landing cycles with only minor problems being reported [42] (*see* **Stanford Multiactuator–Receiver Transduction (SMART) Layer Technology and Its Applications**). Additional operational testing programs have been reported recently for comparative vacuum monitoring (CVM) crack sensors [55] (*see* **Comparative Vacuum Monitoring (CVM™)**), meandering winding magnetometer (MWM) damage sensors [47], (*see* **Electric and Electromagnetic Properties Sensing**) and MEMS sensors [46] (*see* **Microelectromechanical Systems (MEMS)**).

2 TECHNICAL BACKGROUND

At a fundamental level, the reliability of an SHM sensing system involves the durability of the materials that make it up. Both individually and collectively, the long-term effectiveness of an onboard sensing system relies on how the various component materials of an SHM system perform/degrade with time and usage. In this section, the various degradation mechanisms that can affect an SHM system are briefly described, where the influence of environmental factors is highlighted (*see* **The Influence of Environmental Factors**).

2.1 Environmental effects on SHM system performance

The environmental effects on an SHM sensor system can be loosely categorized into four basic areas: (i) mechanical effects, (ii) thermal effects, (iii) chemical effects, and (iv) electrical effects. Mechanical effects include structural loading, vibration, and acceleration, which can range from small, long-duration stresses to large dynamic 'shock' events (e.g., a quick acceleration event) (*see* **Civil Infrastructure Load Models for Structural Health Monitoring**; **Static Damage Phenomena and Models**; **Damage Evolution Phenomena and Models**; **Failure Modes of Aerospace Materials** and **Principles of Structural Degradation Monitoring**). Thermal effects include direct/indirect heating, natural environmental temperature variations, high/low temperature extremes, and thermally induced mechanical loading (*see* **Thermomechanical Models**). Chemical effects include corrosion, moisture, and fluid susceptibility, which can selectively attack the various parts of an SHM system through chemical interactions. Electrical effects include electrical conduction/insulation loss, electrical short circuits, and electromagnetic field interactions (e.g., electromagnetic interference (EMI)) (*see* **Electric and Electromagnetic Properties Sensing**).

2.1.1 Mechanical loading, vibration, and acceleration effects

With regard to SHM reliability, mechanical effects involve the ability of an SHM material or system to resist applied forces, where the strength of a material or system determines whether degradation or damage will occur (*see* **Damage Evolution Phenomena and Models**; **Fatigue Life Assessment of Structures**). Material strength is usually categorized in terms of compressive strength, tensile strength, bending strength, and shear strength, depending on the direction of the applied force relative to the material response. The strength is also affected by how the force is applied in time, that is, static (i.e., constant) or dynamic. In general, the yield strength of a material becomes important for static loading, while dynamic loading involves fatigue and wear processes.

One of the simplest expressions used in strength assessments involves uniaxial stress:

$$\sigma = \frac{F}{A} \tag{1}$$

where F is the force (in newton) acting on an area A (in square meter). Compressive stress involves loading where the material tends to compact, while tensile stress results in a stretching of a material by pulling forces [45, 56, 57]. Materials such as metals, which can tolerate nominal tensile stresses of $\sim$100 Mpa or more, are termed elastic/linear, while materials such as ceramics, which can be susceptible to failure at low nominal tensile stress levels, are considered to be inelastic/nonlinear. Bending stresses

typically involve combinations of compressive and tensile stresses, while shear stresses result in the sliding of a material along planes that are parallel to the direction of the applied force.

The durability and reliability of an SHM material or system is directly related to its strength limits. If a material is stressed beyond its limits, it will fail on the basis of its yield strength or yield point, where a fundamental transition from elastic behavior to plastic behavior occurs. Knowledge of the yield point is vital when designing a material, component, or system because it generally represents an upper limit to the load that can be applied [45, 56, 57]. In general, yield will occur when the largest principal stress exceeds the uniaxial tensile yield strength [45]:

$$\sigma_{\text{applied}} \geq \sigma_{\text{YS}} \tag{2}$$

In many materials, the relation between applied stress and the material's elastic deformation response (i.e., strain) is directly proportional, where the "modulus" of a material can be used to determine stress–strain relationships [45]. In particular, Young's modulus (E) describes the material's response to linear strain, the bulk modulus (K) describes the material's response to uniform pressure, and the shear modulus (G) describes the material's response to shearing strains.

Mathematically, Young's modulus is related to the tensile stress and tensile strain by [45]

$$E \equiv \frac{\sigma}{\varepsilon} = \frac{F/A_0}{\Delta L/L_0} = \frac{FL_0}{A_0 \Delta L} \tag{3}$$

where σ is the tensile stress, ε is the tensile strain, F is force, A_0 is the original cross-sectional area, L_0 is the original length, and ΔL is the change in length. Using equation (3) and Hooke's law, the force exerted by a material under a specific strain can be calculated [45]:

$$F = \frac{EA_0\Delta L}{L_0} = \left(\frac{EA_0}{L_0}\right)\Delta L = kx;$$
$$k = \frac{EA_0}{L_0}; \quad x = \Delta L \tag{4}$$

where again F is the force exerted by a material when it is compressed/extended by length ΔL.

The shear modulus, G, is important for material interfaces (e.g., a sensor bond interface), and is defined as the ratio of shear stress to the shear strain [45]:

$$G = \frac{F/A}{\Delta x/h} = \frac{Fh}{\Delta x A} \tag{5}$$

where F is the shearing force, A is area, F/A is the shear stress, h is the initial length, Δx is the transverse displacement, and $\Delta x/h$ is the shear strain.

2.1.2 Thermal effects

Temperature is an important aspect of most SHM applications, affecting both sensing performance and system reliability (*see* **Thermomechanical Models** and **Loads and Temperature Effects on a Bridge**). The temperature of a system is related to the average energy of microscopic motions in the materials that make up the system. In a solid material, the microscopic motions are primarily due to vibrations of the constituent atoms and molecules in the solid. A closely related principle to temperature is the concept of heat (symbolized by Q), which determines how thermal energy is transferred within a material/system [58]. With regard to SHM reliability, temperature and heat transfer cause three basic degradation or damage effects in a sensing system: (i) thermal effects on sensing performance, (ii) thermal changes in material structure/phase, and (iii) thermal expansion/contraction of materials.

Thermal effects on sensing performance are largely dependent on the sensor type and the materials used in the sensing system. Electronic circuitry, metallic wires, sensor channels, and connections suffer from reliability issues due to the generation of heat when they are used. This is primarily due to the fact that freely moving valence electrons in a metal transfer both electric current and heat energy efficiently. Most electrical components generate heat and can malfunction if they are overheated, or in extreme cases the SHM system can become permanently damaged.

With regard to sensor material properties, temperature and heat transfer can also impact performance, reliability, and durability by permanently changing

the chemical phase and physical response characteristics of a sensor material. The index of refraction in fiber-optic sensors, piezoelectric properties in elastic wave/vibration sensors, and electrical resistance properties of semiconductor strain gauges can all be altered because of high–low temperature extremes. The *Curie temperature* (T_C), for example, refers to a characteristic property of ferromagnetic and piezoelectric materials where sensing performance can be reduced or lost completely if reached [59]. At temperatures below T_C, the magnetic moments of ferroelectric materials and net dipole moments of piezoelectric materials provide the needed sensing characteristics. As the temperature is increased, however, thermal fluctuations destroy preferred alignments in the materials, resulting in the loss of net magnetization and spontaneous polarization when T_c is reached.

Perhaps, the most common temperature-related factor that can affect SHM system reliability involves the thermal expansion/contraction of a material. Thermal expansion is the tendency of matter to increase its volume/size in response to an increase in temperature. The degree of expansion divided by the change in temperature is called *the material's coefficient of thermal expansion*, α, which in one-dimensional form can be written as [58]

$$\alpha = \frac{\Delta L/L_o}{\Delta T}; \quad \Delta L = L_o \alpha \Delta T; \quad L = L_o(1 + \alpha \Delta T) \tag{6}$$

where L_o is the original material length, ΔL is the length change, and ΔT is the temperature change. Figure 1 provides a schematic diagram of the thermal expansion process for an increase in temperature in a 1D solid, and also a schematic of the resulting tension/compression stresses for a rigidly bonded PZT sensor on aluminum substrate material, which has been subjected to a temperature increase and differential material expansion.

For solid materials, the coefficient of thermal expansion is positive, which means that the solid will expand on heating, and contract on cooling [58]. For coefficient of thermal expansion values of $4 \times 10^{-6}/^{\circ}\mathrm{C}$ and $23 \times 10^{-6}/^{\circ}\mathrm{C}$ in piezoelectric and aluminum materials, respectively, a thermal expansion of 22.5 and 131 $\mu\mathrm{m\,m^{-1}}$ would be expected in each respective material for a $+100\,^{\circ}\mathrm{F}$ ($+55.5\,^{\circ}\mathrm{C}$) increase in temperature. This fivefold difference in expansion level results in compressive stresses in the substrate material and tensile stresses in the piezoelectric sensor, which can cause physical damage to the sensor material [60–62].

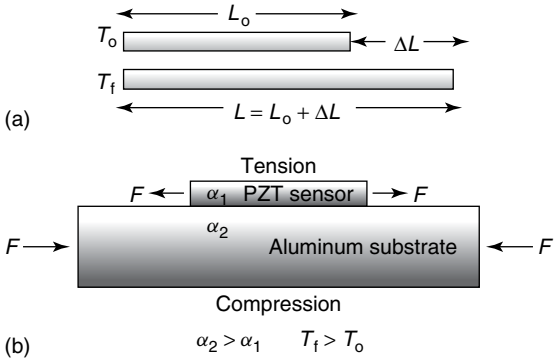

Figure 1. Schematic representation of thermal expansion due to temperature increase (a) and resulting tension/compression stresses in bonded PZT sensor on aluminum substrate (b).

2.1.3 *Moisture and fluid susceptibility effects*

There are two primary types of chemically induced damage that can impact the reliability of an SHM system—moisture and chemical attack. Moisture, acting as an electrolyte, can cause corrosion and electrical shorting problems, while chemical attack can occur from a wide variety of solvents, lubricants, cleaning solutions, fuels, and other fluids used in SHM sensing environments. In general, almost every material used in an SHM sensing system is susceptible to chemical attack, where protective coatings or encapsulation provide the best protection.

2.1.4 *Electrical, magnetic, and electromagnetic radiation effects*

The major electrical effects that can impact the reliability of an SHM system include electrical conduction/insulation loss, electrical short, and EMI. Electrical shorting and the loss of electrical connections for transmitting sensor/signal information, in particular, represent two of the most common reliability and durability issues for most SHM applications. Electrical shorts can take place because of a number of reasons including mechanical, thermal, and chemical breakdown of the wiring as described above.

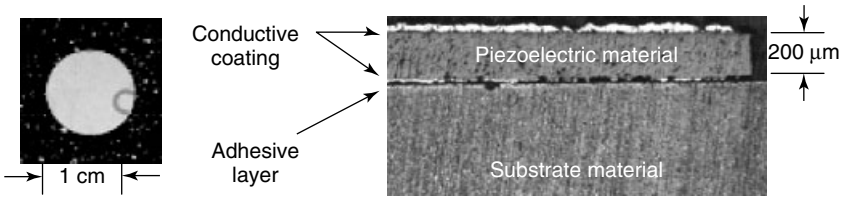

Figure 2. Digital image and cross-sectional cut through piezoelectric sensor disk.

In addition to causing reliability issues, a short circuit can also cause circuit damage, overheating, fire, and battery explosions.

3 EXAMPLES OF SHM SENSING SYSTEM RELIABILITY

Previously published work has shown that the reliability of an SHM system can be compromised by environmental stresses, resulting in system performance loss, sensor degradation, and sensor damage [9, 40, 43, 60]. Both gradual and abrupt performance losses have been reported, being attributed to a number of factors including undesired load transfer [9, 60, 61], thermal assisted fracture, and simple electrical/electronic failures. In this chapter, four examples are provided for SHM sensor reliability, including (i) a study of damage introduced in surface-bonded piezoelectric sensors, (ii) a study of the reliability of thermocouple sensor arrays, (iii) durability testing for CVM sensors, and (iv) performance testing results for layered piezoelectric actuator/sensor networks.

3.1 Reliability of surface-bonded piezoelectric sensors

Surface-bonded piezoelectric sensors are considered to be one of the most attractive integrated sensor concepts for SHM (*see* **Piezoceramic Materials—Phenomena and Modeling**; **Piezoelectricity Principles and Materials**; **Piezoelectric Wafer Active Sensors**). By converting mechanical energy into electrical energy, piezoelectric materials provide an effective means for monitoring structural vibrations and for probing structures with elastic waves. Damage is typically characterized through elastic wave scattering, where the amplitude, phase, and frequency content of the waves is used to understand the damage state of a structure. Surface-bonded piezoelectric sensors provide an inexpensive, lightweight, and minimally intrusive sensing solution for SHM.

For most applications, single-crystal or polycrystalline ceramic piezoelectric materials are used, where miniature disks are engineered for a specific application. A typical piezoelectric sensor disk consists of a layer of piezoelectric material coated on the top and bottom with a thin conductive layer (Figure 2). A very thin adhesive bond layer is then used to attach the sensor to a substrate material, which consists of an approximate 10-μm-thick layer of Vishay's M-Bond 200 cyanoacrylate adhesive and catalyst as shown in Figure 2.

Previous work has shown that static load transfer between the host structure and an attached piezoelectric sensor disk can have a significant impact on the sensor's durability and its performance characteristics [9, 60, 61]. In particular, the partitioning of load between the substrate and sensor was found to be dependent on the relative stiffness between the two materials, which can result in premature failure of the adhesive or the sensor due to high stress levels. This situation is depicted schematically in Figure 3, where a cross-sectional representation of the problem is depicted, along with key material properties: elastic modulus E_r and E_p; layer thicknesses t_r, t_a, and t_p; adhesive shear modulus G_a, and sensor dimensions y and L.

Following the analysis of Martin and Blackshire [61], the piezoelectric sensor stress, σ_r, can be expressed in terms of the stiffness ratio, $S = (E_r t_r / E_p t_p)$, as follows:

$$\sigma_r(y) = \left[\frac{FS}{((1+S)t_r)}\right]\left\{1 - \left[\frac{\cosh(\beta y)}{\cosh(\beta L)}\right]\right\} = \sigma_r(sp)\left\{1 - \left[\frac{\cosh(\beta y)}{\cosh(\beta L)}\right]\right\} \quad (7)$$

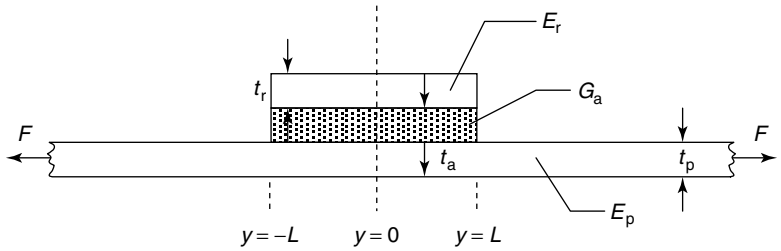

Figure 3. Schematic representation of bonded piezoelectric sensor disk (cross-sectional view).

where F is the load per unit length and β^2 is given by the expression:

$$\beta^2 = \left(\frac{G_a}{t_a}\right)\left[\left(\frac{1}{E_p t_p}\right) + \left(\frac{1}{E_r t_r}\right)\right] \tag{8}$$

The corresponding shear stress distribution in the adhesive layer is given by the expression:

$$\tau_a(y) = -t_r \sigma_r'(y) = \beta\left[\frac{FS}{((1+S)\cosh(\beta L))}\right][\sinh(\beta y)] \tag{9}$$

Using equation (7), the stress conditions in a surface-bonded sensor for compliant, rigid, and infinitely rigid bonds can be calculated (Figure 4a), with parameters of $E_p = 7.31 \times 10^{10}$ Pa, $E_r = 8.40 \times 10^{10}$ Pa, $G_a = 7.00 \times 10^6$ Pa (for compliant) and 7.00×10^8 Pa (for rigid, and infinite), $t_p = 0.001$ m, $t_r = 0.0001$ m, $t_a = 0.0001$ m, $L = 0.005$ m. To lower stress transfer between the substrate and the sensor, the size of the sensor or adhesive shear modulus must be decreased, the adhesive layer thickness must be increased, or the stiffness ratio must be decreased.

Using equation (9), the adhesive shear stress for a compliant and rigid bond can be calculated (Figure 4b). From Figure 4, it is clear that the use of a compliant bond helps with load/stress transfer to the sensor, and also with shear stress levels in the adhesive layer, both of which help enhance sensor durability and bond integrity. Thus, to lower the stress transfer to the reinforcement, the size of the reinforcement or adhesive shear modulus must be decreased or the adhesive layer thickness must be increased. Decreasing the stiffness ratio will also decrease the stress transfer.

Blackshire *et al.* experimentally studied SHM environmental usage effects and demonstrated that these

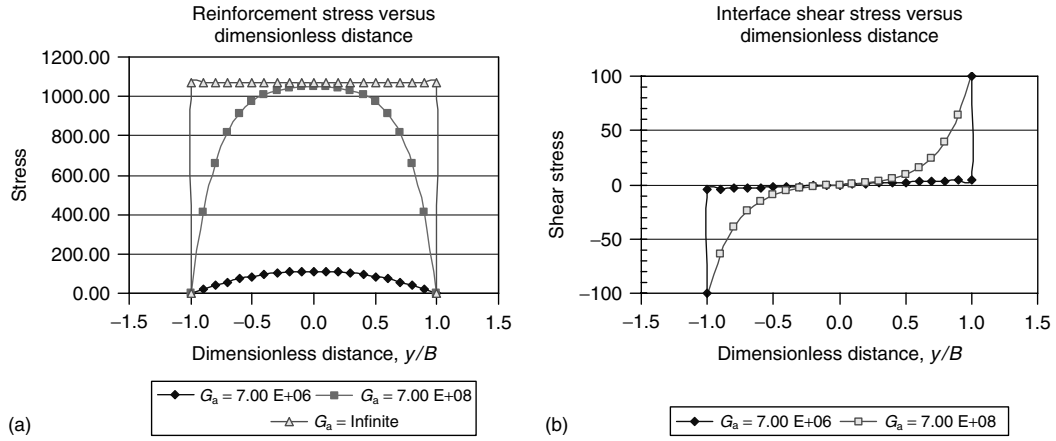

Figure 4. (a) Piezoelectric sensor disk stress distribution for compliant, rigid, and infinitely rigid bonds and (b) interface shear stress distribution for compliant and rigid bonds.

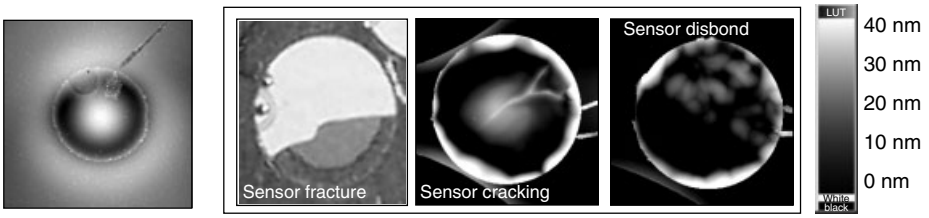

Figure 5. Examples of (a) undamaged piezoelectric sensor and (b) piezoelectric sensors damaged by mechanical and thermal loading of the substrate material.

factors can cause degradation and damage to surface-bonded piezoelectric sensor systems [9, 60–62]. Figure 5 shows typical examples of their observations, which included sensor fracture, cracking, and disbonding. The damage was attributed to induced stresses in the bonded sensors arising from biaxial bending, and thermal loading of the substrate material. The effects of static biaxial stress in the substrate, and the influence of adhesive bond, was also modeled and studied by Martin and Blackshire [61]. These studies pointed to the need for mechanically decoupling the bonded sensor from the stresses present in the structure due to static and low-frequency (i.e., vibration) loading.

In an attempt to understand the thermal expansion damage effects observed in Figure 5(b), Martin *et al.* used an equivalent spring analysis [60–62] to determine the stress levels within the piezoelectric and bond material for a 37.8 °C (+100 °F) thermal loading event. In their analysis, the initial (unloaded) spring heights corresponded to the lengths of the piezoelectric sensor and aluminum substrate after free thermal expansion had occurred in the materials. The springs were then coupled in parallel to determine the equilibrium spring height that would occur when the force of compression on the taller spring (aluminum, in the case shown) equaled the force of elongation on the shorter spring (piezoelectric sensor) so that their deformed lengths were equal. An equivalent spring stiffness per unit depth could then be calculated by

$$k_i = \frac{E_i t_i d}{l_i} \tag{10}$$

where $l_i \sim l_j$. The difference in spring heights was then found to be

$$\Delta h = \Delta l_i - \Delta l_j = \Delta x_i - \Delta x_j \tag{11}$$

where the force equation could be written as follows:

$$F_i = k_i \Delta x_i \tag{12}$$

and where, from equilibrium considerations, $F_i = -F_j$. Substituting and solving for Δx_i gives

$$\Delta x_i = \frac{\Delta h}{(1 + k_i/k_2)} = \frac{\Delta h}{\left(\dfrac{k_j + k_i}{k_j}\right)} \tag{13}$$

The relationship between force per unit length and stress is then given by

$$\sigma_i = \frac{F_i}{t_i} = \frac{k_i \Delta x_i}{t_i} \tag{14}$$

which results in a stress level of 53 MPa in the piezoelectric sensor for $E_1 = 7.31 \times 10^{10}$ Pa, $E_2 = 8.40 \times 10^{10}$ Pa, $t_1 = 0.001$ m, $t_2 = 0.0002$ m, and $L = 0.01$ m. This analysis ignores the axial symmetry of the sensor, the bending stresses, and transient thermal effects, which would tend to increase stress levels within the piezoelectric sensor material. For failure stress levels estimated at 70–80 MPa for the piezoelectric materials used, the possibility of fracture of the sensor is a real possibility for a +100 °F increase in temperature and the resulting thermal expansion mismatch conditions.

The effects of piezoelectric sensor disbond on the generation and reception of elastic wave energy were also studied. Figure 6(a) depicts the received signals from a pair of surface-bonded piezoelectric sensors spaced at 2.5″ (63.5 mm) for two different measurement cases: (i) a pair of fully bonded piezoelectric sensor disks and (ii) a 33% disbonded transducer sending a signal to a fully bonded sensor [62]. The

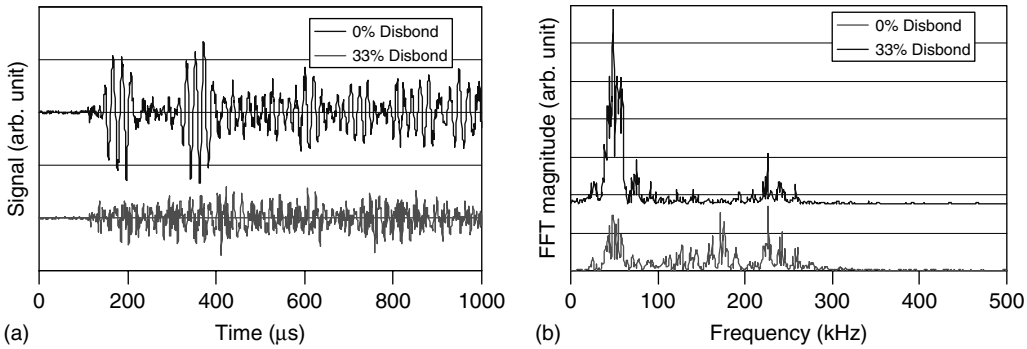

Figure 6. (a) Pitch–catch signals between two fully bonded sensors and one good and one 33% disbonded sensor and (b) frequency content of received signals.

drive signals in this case were at 50 kHz for a five-cycle toneburst at ±5 V. The received signal for the two fully bonded sensors (top) shows the distinct five-cycle waveform for the various expected Lamb modes, while the signals for the bonded and 33% disbonded pair shows a reduced signal level and loss of drive frequency fidelity in the received signal. The frequency content of the signals is depicted in Figure 6(b), which shows this basic effect, with an increase in frequency content for the 100–300 kHz band, which is likely because of the modal vibration effects in the disbonded sensor. A noticeable degradation in sensor system response was, therefore, observed for disbonded piezoelectric sensors in this case.

With regard to surface-bonded piezoelectric sensor durability, the use of advanced silicon, polymer, and epoxy adhesives has recently shown promise for improved sensor bonding compared to rigid cyanoacrylate adhesives [63]. Research involving electroactive polymer (EAP), electroactive paper (EAPap), and piezoelectric polymer materials has also progressed recently, where flexible/conformable sensor concepts are becoming available and more common [64–66], improving piezoelectric sensor system ruggedness and durability.

3.2 Reliability of direct-write thermocouple sensor array

The reliability of thermocouple sensors integrated onto the surface of a titanium plate by direct-write plasma spray methods was recently studied by Ackers *et al.* [67]. In that study, the direct-written sensors were subjected to various thermal soak conditions at elevated temperatures, where the modal frequency response characteristics of the plate–sensor combination were monitored to assess changes in SHM system reliability. Figure 7 provides a schematic depiction of the titanium plate, sensor locations, and modal impact point locations used in the study.

The modal impact testing used four reference accelerometers to measure vibration frequency response functions (FRFs) of the instrumented plate up to 4 kHz for the 109 impact locations depicted in Figure 7. Three baseline measurements were first collected before any thermal soaks were conducted, followed by two sets of data collected after each thermal soak. The Ti 6242 titanium plate was subjected to thermal soaks of increasingly higher temperature loads, at 400 °C for 24 h, 450 °C for 24 h, 475 °C for 48 h, and a final 2-h period cyclical soak ranging from 450 to 525 °C over 48 h, simulating operational conditions.

Figure 8 provides examples of the major results for the study, where an upward shift in the FRFs of the plate–sensor combination was observed owing to the elevated temperature soak conditions. The results were consistent with analytic considerations, mode-shape curvature effects, and transmissibility function analysis, each of which provides information on global parameter changes in a system based on stiffness, density, and inertial properties [67]. In particular, the upward shift in FRF frequency depicted in Figure 8 was attributed to a mass change resulting from oxidation at high-temperature exposure of the plate–sensor system [67].

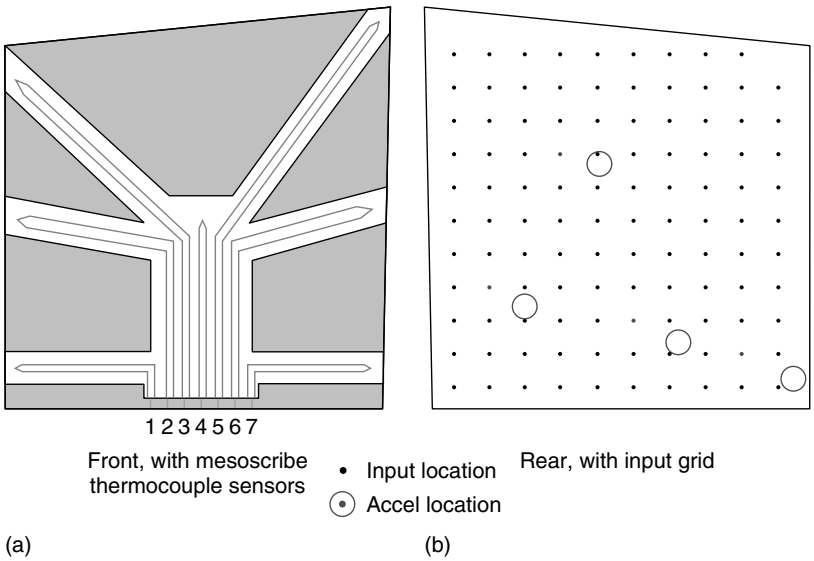

Figure 7. Schematic of titanium plate with positions of direct-write thermocouple sensors depicted (a) and modal impact grid pattern (b). [Reproduced from Ref. 67.]

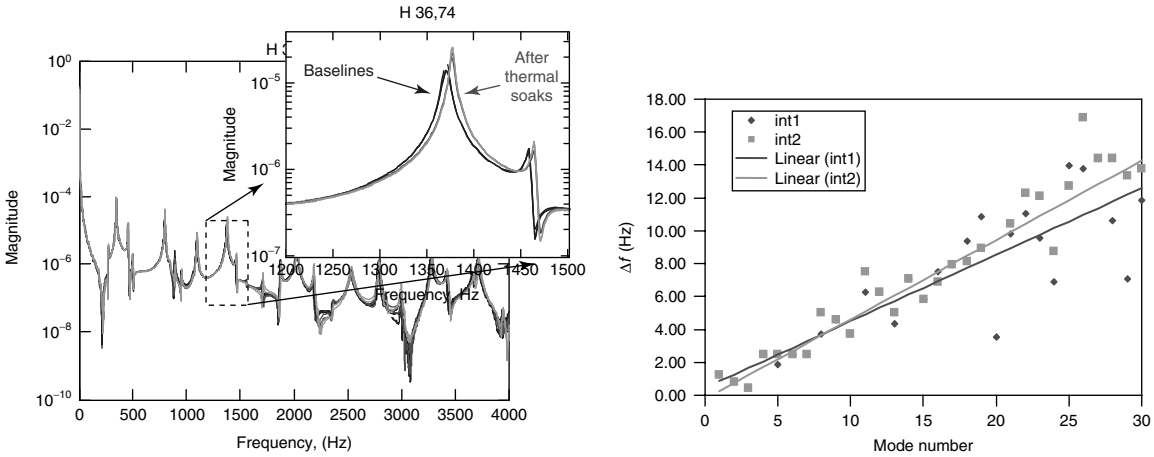

Figure 8. Frequency response function data taken before and after thermal soaks showing frequency shifts in modal frequency response after elevated temperature exposures. [Reproduced from Ref. 67.]

Figure 9 provides representative measurement results for the direct-write thermocouple output readings for the 400 °C (752 °F) and 450 °C (842 °F) thermal soak cases. In both cases, the thermal soak lasted for a 24-h period. The measurement results showed consistency between all of the channels with a nominal standard deviation of ∼1.5 °C (2.5 °F) during the 24-h period for each measurement. The measurements also showed a reliable and accurate measurement output between consecutive thermal soak cycling events.

From these results, it was concluded that the thermocouple sensors were reliable under the thermal loads examined. The results from the FRF analysis did show changes occurring in the global properties of the plate, which were attributed to minor changes in mass or stiffness. Modal curvature and transmissibility analyses, however, indicated that there was

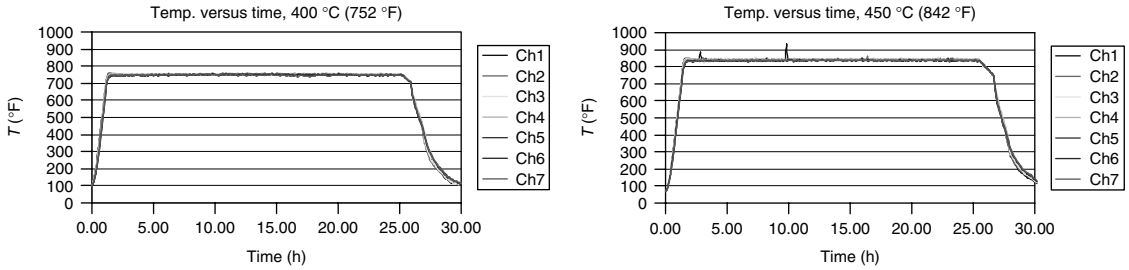

Figure 9. Direct-write thermocouple readings for 400 and 450 °C thermal soak cases. [Reproduced from Ref. 67.].

no localized damage or disbonding of the thermocouples themselves. Additionally, the thermocouples continued to output thermal data with reasonable accuracy throughout the experiments. Further studies are currently being carried out to understand the reliability of direct-write thermocouple sensors to withstand other types of loads (e.g., mechanical load and thermal shock).

3.3 Reliability of comparative vacuum monitoring (CVM) sensors

The reliability of CVM sensors was recently studied by Roach *et al.* [68, 69]. In that effort, the performance and reliability of CVM sensors for crack detection in thin and thick metallic structures was evaluated under controlled laboratory conditions and during a long-term flight testing program (*see* **Comparative Vacuum Monitoring (CVM™)**). As part of a performance validation effort, a series of 26 sensors were installed in four different DC-9, 757, and 767 aircraft in the Northwest Airlines and Delta Airlines fleet [68]. The testing was used to study the long-term operation of the sensors in actual operating environments, where complementary laboratory flaw detection testing was undertaken as part of an overall CVM certification effort. Additional CVM sensor durability testing was also conducted by the Australian Defense Science and Technology Organization (DSTO) and Airbus, where temperature, chemical, and ultraviolet (UV) exposure studies showed no loss in sensor functionality for long-term testing up to 36 months.

A typical CVM sensor bonded to an aircraft component is depicted in Figure 10 along with vacuum tube connections and SHM's PM200 portable data collection module. The sensor includes a self-adhesive, elastomeric material, which has had fine channels laser machined along the bottom surface to form alternating pressurized (atmospheric) and vacuum galleries or channels. When a surface-breaking crack occurs under the CVM sensor, a leakage path forms between the atmospheric and vacuum channels, producing a measurable change in

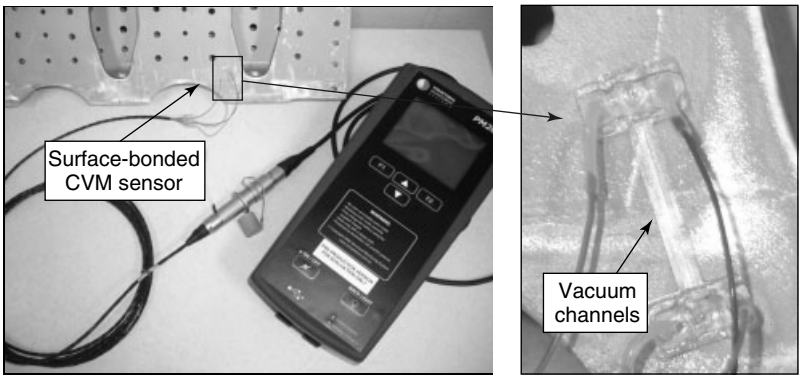

Figure 10. Comparative vacuum monitoring (CVM) sensor bonded to aircraft component.

the vacuum state, which is a positive indication that a crack exists under the sensor.

Regarding CVM sensor durability and reliability, the use of load-bearing elastomer materials and flexible/compliant adhesives enables the sensor to withstand high loading stresses and temperature changes in the aircraft environment. The use of self-test procedures also provides fail-safe conditions, which ensure that the sensor is attached to the structure and working properly. Because the sensor physics relies on pressure measurements, the inherent reliability issues related to electrical wire connections and interference signals are minimized, improving overall system reliability. The use of a protective sealant (e.g., PR1440 sealant) over the sensor and its connection points, and durable Teflon tube attachments to the sensor has also helped to ensure good reliability under operational use in aircraft environments.

3.4 Reliability of layered piezoelectric actuator/sensor networks

The performance and reliability of layered piezoelectric actuator/sensor networks was recently evaluated by Kusaka and Qing [70] and Beard *et al.* [71, 72] (*see* **Stanford Multiactuator–Receiver Transduction (SMART) Layer Technology and Its Applications**). In those efforts, the mechanical loading durability, environmental reliability, and overall system reliability of Acellent's Stanford multiactuator receiver transduction (SMART) layer technology [73] were studied, respectively. Kusaka *et al.*, for example, studied the performance and degradation of layered piezoelectric actuator/sensor networks under monotonic and fatigue loading conditions. Both surface-bonded (metallic and composite substrates) and fully embedded (within composites) sensor networks were investigated, where the piezoelectric sensor performance remained unchanged for strain levels below the static failure limit of the sensor material (lead zirconate titanate (PZT)). For strain levels above the static PZT failure strain limit, reductions in electromechanical coupling efficiency were observed at ∼20% for both monotonic and cyclic loads [70]. The measurement results were consistent with previously published work by Mall and Hsu [74], Mall and Coleman [75], and Paget *et al.* [76] for isolated piezoelectric sensors embedded within composite materials.

The work of Beard *et al.* considered practical issues in the real-world implementation of an SHM system, where sensor integration, calibration, reliability, and environmental compensation were identified as key issues that need to be considered. Testing results for the SMART Layer system were highlighted in that effort, where environmental conditions (temperature, moisture, chemical attack) were considered as well as mechanical shock/loading, and intense fatigue testing. In general, the results indicated that the layered piezoelectric actuator/sensor networks did not lose functionality for most realistic operational conditions [71]. The need for self-diagnosis, sensor redundancy, and environmental compensation was also discussed with regard to improving overall system reliability [72].

Regarding sensor durability and reliability, the use of sealed electrical connectors, sensor system encapsulation/coating, optimized adhesive bonding, and sensor networks integrated on a flexible thin-film material (polyamide) provided for a rugged SMART Layer design [71–73]. The use of multiple distributed sensors also provided the system with sensor redundancy and opportunities for implementing self-test procedures. Ongoing systematic test and evaluation of the technology is taking place, where standardized test procedures (e.g., MIL-STD-810F) are being used to maximize sensor system performance, durability, and reliability.

4 CONCLUSIONS

The long-term reliability, durability, and survivability of integrated sensor systems and their associated hardware represent a critical aspect of any SHM system. Although significant improvements in SHM system reliability and durability have been made in recent years, much more work is needed to help ensure the long-term performance of SHM systems in fielded, operational environments. In general, an SHM sensing system's design must include hardening against mechanical, thermal, chemical, and electrical environmental effects, where intelligent choices in component materials and packaging are needed to maximize system reliability. Standardized testing and evaluation, calibration procedures, and self-test diagnosis can also provide additional means for ensuring

long-term reliability for SHM systems. The interested reader is encouraged to explore the numerous references provided, and particularly the books by Rao [1], Inman [2], Adams [4], Giurgiutiu [25], Holnicki-Szulc and Rodellar [26], Staszewski *et al.* [30], and the SHM Workshop series edited by Chang [31–34].

1 INTRODUCTION

1.1 The need for novelty detection

The complexity of modern high-integrity systems is such that only a limited understanding of the relationships between the various system components can be obtained. An inevitable consequence of this high degree of system complexity is the large number of possible failure modes, the effects of which on observable (sensor) data are often poorly defined. To compound this, examples of abnormal behavior in high-integrity systems are few and far between; usually, there are insufficient examples of failure to construct accurate fault-detection systems. As a result, conventional fault-specific failure-detection schemes are usually limited to identifying a small subset of known, well-understood modes of failure.

An alternative to identifying rare and unexpected modes of failure is the *novelty detection* paradigm [1–5], in which a model of normality is constructed from normal system data. Departures from normal behavior are classified as novel events. Novelty detection is alternatively known as *one-class classification* [6] or *outlier detection* [7].

1.2 Overview of novelty detection methods

The concept of "novelty" can be related to the probability of observing data that do not belong to the distribution characterizing normal data. Fundamental to this approach is the assumption that normal data are generated from an underlying data distribution, which may be estimated from example data. The classical approach to this estimation problem is based on the

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

use of density-estimation techniques to determine the underlying data distribution [8]. The resultant distribution may then be thresholded to define the boundaries of "normal" areas of data space [3].

With *parametric* techniques, assumptions are made about the form of the underlying data distribution, and the parameters of the distribution are estimated from observed data. The most commonly used form of distribution for continuous variables is the Gaussian distribution, which is defined by its mean and variance parameters. These parameters are estimated from the data using the *maximum likelihood* method, which has a closed-form analytical solution for a Gaussian distribution. More complex forms of data distribution may be modeled by using Gaussian mixture models [9, 10] or other mixtures of different types of distributions such as the gamma distribution [11, 12]. Model parameters are again estimated from data by maximizing the likelihood, but this now requires the use of numerical techniques such as the expectation-maximization algorithm [13]. Mixture models, however, can suffer from the requirement of large numbers of training examples to estimate model parameters accurately [5].

A further limitation of parametric techniques is that the chosen functional form for the data distribution may not be a good model of the distribution that generates the data. *Nonparametric* approaches, which make as few assumptions as possible about the form of the distribution, include kernel density estimators and neural networks. With kernel estimators, the probability density is estimated using large numbers of kernels distributed over the data space. The estimate of the probability density at each location in data space relies on the data points that lie within a *localized* neighborhood of the kernel [10]. The kernel density estimator used in this article, Parzen windows, places a Gaussian kernel on *each* data point and then sums the local contributions from each kernel over the entire dataset. Hence there is no computation required while "training" the model, other than for storage of the dataset. This implies that the cost of estimating the data density grows with the size of the dataset, but this shortcoming is addressed in Section 4 below.

Neural networks are an alternative nonparametric method, although their main use is not in density estimation but in *multiclass* classification problems [14]. However, neural networks can also be used for novelty detection by generating artificial data around the normal data to simulate the patterns from an "abnormal" class [15]. This approach is fraught with danger, however, as it requires the use of strong assumptions about the distribution of abnormal data beyond the boundaries of normal data. Furthermore, any approach that depends on the generation of artificial data is plagued by the curse of dimensionality: a very large number of artificial patterns are required to populate high-dimensional spaces.

The self-organizing map (SOM), initially proposed for the clustering and visualization of high-dimensional data [16], provides an unsupervised representation of training data using a neural network. Various applications of the SOM to novelty detection have been proposed [17, 18]. In this article, we present results from our use of the Sammon map and its parameterized version, NeuroScale, to visualize high-dimensional feature vectors, but this is purely for data understanding prior to the design of an appropriate density estimator for novelty detection.

Another type of classifier that has been adapted for novelty detection is the support vector machine (SVM), in which a number of hyperplanes are found that best separate data from different classes, after their transformation by a kernel function [19]. In the application of an SVM to one-class classification or novelty detection, two main approaches have been taken. The first finds (in the transformed space) a hypersphere of minimum radius that best surrounds most of the normal data [20]. The second approach separates the normal data from the origin with maximum margin [21]. In work related to that described in this article, we have extended this latter approach to novelty detection in jet-engine vibration data [22].

Hidden Markov models (HMMs), which include temporal dependence through the use of a state-based representation updated at every time step, are ideal for novelty detection in a sampled *time series*. While the features are directly observable, the underlying system states are not, and hence they are "hidden". The transitions between the hidden states of the model are governed by a stochastic process [23]. Each state is associated with a set of probability distributions describing the likelihood of generating observable "emission" events. These distributions may be thresholded to perform novelty detection [24]. Novelty detection with HMMs may also be achieved by constructing an "abnormal" state, a transition into

which implies abnormal system behavior [25]. A related state-based approach to novelty detection in time-series data relies on factorial switching Kalman filters [26]. This is a dynamic extension of the switched Kalman filter [27], which models time-series data by assuming that a continuous, hidden state is responsible for data generation, the effects of which are observed through a modeled noise process. Again, an explicit "abnormal" mode of behavior is included within the model, which is used to identify departures from normality. The weakness of this approach is that it requires assumptions to be made about the distribution of features for the "abnormal" state.

In this article, rather than using dynamic models such as HMMs or Kalman filters, we focus instead on *static* novelty detection, in which each pattern is treated independently. Our overall approach is outlined in Section 1.3.

1.3 A framework for novelty detection

The first step in the process of novelty detection, as with any other pattern-recognition technique, is *feature extraction* (Section 2). The aim here is to derive features that characterize normality but which are also likely to be affected by the occurrence of abnormal events. This usually requires some prior knowledge of the system under study.

We next make use of *data visualization* techniques (Section 3) for increasing our understanding of the data. In particular, we are interested in how the D-dimensional feature vectors (where D is the number of features) are distributed over the space of normal data, especially near the boundaries of normality.

Normality is then characterized by learning the probability density function (pdf) $p(x)$ of normal feature vectors using a nonparametric method, as it is best to make as few assumptions as possible about the distribution of normal data. In Section 4, we describe how we use Parzen windows as a nonparametric density estimator, and show how we deal with the problem of having very large numbers of feature vectors in the training dataset.

To classify new examples of vibration spectra as either "normal" or "abnormal", a *novelty threshold* has to be placed on the value of $p(\mathbf{x})$ for the new feature vector. We address the question of how to set the novelty threshold in principled fashion by introducing extreme value statistics in Section 5. These are methods that allow us to explicitly model the abnormal areas at the boundaries of normal feature space given the normal data.

1.4 Application of novelty detection to jet-engine vibration data

Throughout this article, we illustrate our approach to novelty detection in the context of jet-engine health monitoring, using vibration data from the development program for a three-shaft Rolls-Royce aerospace gas-turbine engine. The dataset covers 135 test flights, spanning a period of six months. The data were acquired over a wide range of operating conditions, and the behavior of the engine is characterized by three distinct periods:

- period A: normal, consistent operation of the engine from flights 1–127;
- period B: a change in engine condition, as a component from one of the three engine shafts works its way loose and moves freely inside the engine between flights 128 and 133;
- period C: a final engine event during flight 134, as the component is ejected through another one of the engine shaft stages and the engine surges. A subsequent engine test ("flight 135") is undertaken on the ground for experimental purposes.

We show that, by modeling normality using vibration parameters acquired at the start of period A, it is possible to detect both the initial shift in engine behavior due to the loose component (period B) and the transient event associated with the final component ejection during period C.

2 PREPROCESSING AND FEATURE EXTRACTION

2.1 Introduction

To prepare a real-world dataset for analysis, *preprocessing* is invariably performed. This is necessary because the analysis of sensor signals in their original form usually yields poor results. The main issues to consider are as follows:

- **Data quality**

The acquisition of data for novelty detection is susceptible to noise, both from the environment in which the system is operating and from the characteristics of the sensor. To facilitate analysis, noise-reduction techniques are applied. Typically, this involves filtering of the acquired data according to prior knowledge (or estimation) of the noise process.

In the example of the gas-turbine engine introduced in Section 1, analog measurements of the amplitude of engine vibration are made, using sensors mounted on the engine casing. These signals are initially low-pass filtered to remove high-frequency noise. Prior to quantizing these analog signals into digital signals for computerized analysis, antialiasing filtering is applied to the time-domain waveform to prevent errors in digitization.

- **Suitability of the data domain**

The domain in which the data are acquired may not be best suited for characterizing differences between "normal" and "abnormal" behavior of the monitored system. Transforming the data into a new domain can often allow more effective novelty detection.

For example, a gas-turbine engine contains rotating shafts and clearly exhibits peaks in vibration amplitude at the fundamental rotational frequency of those shafts when observed in the frequency domain. These vibration amplitudes can be used (as described later) to characterize the condition of the engine. However, as data are acquired in the time domain, these characteristics are not easy to identify. In this case, acquired data are transformed into the frequency domain using short-time fast Fourier transforms (FFTs).

- **Tractability**

Novelty detection problems can involve large datasets that are intractable to analyze in terms of both computing time and memory storage requirements. This is typical for datasets in which samples are obtained at a high sampling rate, and for datasets that consist of channels of data obtained from many sensors. To make such analysis tractable, some form of data compression must be performed to reduce the size of the dataset. In most cases, data compression involves the loss of information. The challenge is to ensure that sufficient information is retained such that "normal" and "abnormal" behavior may be characterized.

Techniques such as down-sampling or data averaging can be applied to reduce the size of datasets for which the sampling rate is particularly high, though it is critical to retain sufficient information to allow novelty detection.

The process of *feature extraction*, described in the next subsection, provides a means of reducing data size, while still retaining sufficient information to separate "normal" and "abnormal" behavior, provided that appropriate features are chosen.

2.2 Feature extraction

Feature extraction is the representation of signals using a smaller set of quantities, termed *features*. Prior knowledge of the system for which novelty detection is to be performed can often be used for *feature selection*. For example, if an engine shaft rotates at 50 Hz, a peak in vibration energy occurs at 50 Hz, with corresponding harmonics occurring at multiples of 50 Hz. Engine manufacturers use the values of vibration amplitude at the fundamental frequency and its harmonics (termed *tracked orders*) as features deemed suitable for characterizing the condition of the engine.

The gas-turbine engine used as an exemplar within this article contains three shafts that rotate concentrically, termed the *low-pressure* (LP), *intermediate-pressure* (IP), and *high-pressure* (HP) shafts. Air at atmospheric pressure enters the engine at the LP shaft, is then forced into the smaller IP shaft, and then into the yet smaller HP shaft, increasing in pressure at each stage. The HP shaft forces the air into the combustion chamber at many times atmospheric pressure, where it is mixed with fuel and ignited to generate thrust.

The tracked order corresponding to the fundamental rotational frequency of the LP shaft is termed $1LP$, and its harmonics are termed $2LP, 3LP, 4LP$, etc. Harmonics also occur at $0.5 \times$ fundamental frequency ($0.5LP$), and at $1.5 \times$ fundamental frequency ($1.5LP$). In practice, harmonics above $4LP$ are not usually considered owing to their low amplitude. Similarly, tracked orders for the IP and HP shafts are termed $1IP, 1HP, 2IP, 2HP$, etc.

2.3 Features for in-flight novelty detection

For the example dataset considered in this article, analog vibration measurements recorded by sensors mounted on the engine casing are used to compute 1024-point FFTs every 0.2 s. Using measurements of the shaft speeds recorded by tachometers mounted on the shafts, the various tracked orders are located as peaks in the 1024-point FFT. Each vibration spectrum is reduced to a small number of extracted features (the vibration amplitudes at the fundamental frequency and its harmonics), for each of the three shafts, thereby removing the need to store the original spectra.

Thus, feature extraction here results in a time series of tracked order amplitudes at 0.2 s intervals. To remove spurious transients in the data, these time series of features are smoothed using a three- or five-point median filter.

2.3.1 Constructing a feature vector

After feature extraction, a single *feature vector,* $\mathbf{x}_i$, is constructed for each shaft. For example, the feature vector for the IP shaft is

$$\mathbf{x}_i = [0.5IP, 1IP, 1.5IP, 2IP, 3IP, 4IP, RE] \tag{1}$$

which is a 7-D feature vector formed from six of the IP-shaft tracked orders and the *residual energy RE*, defined to be

$$RE = E - T_{\mathrm{LP}} - T_{\mathrm{IP}} - T_{\mathrm{HP}} \tag{2}$$

where E is the total signal energy in the vibration spectrum (the sum of all the energy values in the first 512 values of the 1024-point spectrum), and T_{S} is the total energy in all the tracked orders related to shaft S. T_{S} is calculated by summing the energy values around the spectral peaks corresponding to the six tracked orders. Typically, this is performed over a very small number of frequency bins (three or five) around each peak. The residual energy is included as a seventh feature to detect gross changes in vibration energy not captured by the tracked orders.

The feature vector $\mathbf{x}_i$ for the IP shaft is used for the remainder of this article to illustrate in-flight novelty detection. (The LP or HP shaft feature vectors could equally well have been chosen.) A feature vector is computed every 0.2 s, allowing novelty detection to occur in real time, the aim being to provide early warning of abnormal engine operation during a flight.

2.3.2 Utilizing system expertise

We have considered the use of prior system knowledge for selecting features to extract from original data, in this case, the vibration tracked order values for a shaft concatenated into a single feature vector. It is known, however, that engine condition varies throughout the phases of a typical flight, from takeoff, through climbing, to cruising, and then landing, and the levels of vibration for each shaft are different for each flight regime or phase. It is not a trivial exercise to partition the time series of feature vectors according to flight regime automatically because of the speed overlap between the different regimes. Instead, the total speed range for each shaft is divided into four speed bands of equal width, $\{\mathrm{S1}, \ldots, \mathrm{S4}\}$, with a separate model constructed for each speed band.

2.3.3 Acquiring a balanced dataset

When building a dataset for training a data-driven model, it is important that data are acquired as uniformly as possible over the system's entire *operating range*. A jet engine spends much of its time operating at "cruise" conditions, with much less time spent operating under takeoff or landing conditions. If training data were drawn randomly from the entire *flight*, then this would result in a strong bias toward cruise conditions, simply because there would be many more feature vectors derived from periods of cruise operation.

A balanced dataset is constructed by rejecting feature vectors during steady-state conditions if the change in engine speed with respect to that associated with the previous feature vector is below a given threshold. The effect of this is shown in Figure 1, in which a histogram of feature vector speeds from the original dataset shows a very dominant peak in the range from 80 to 85% of maximum shaft speed, corresponding to cruise conditions. After rejection of consecutive feature vectors with similar speeds, the distribution is much more uniform across the whole speed range. This type of approach is used

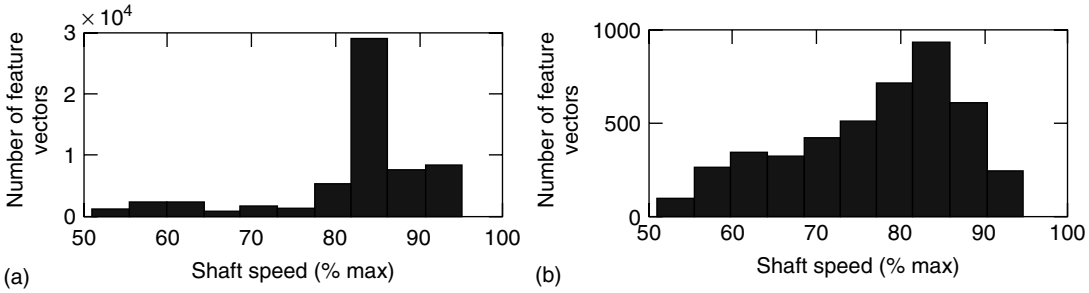

Figure 1. Histograms showing the effect of introducing a criterion for rejecting feature vectors that are too similar to each other during steady-state conditions. The histogram corresponding to the original dataset is shown in (a), with a predominance of speeds between 80 and 95% of maximum shaft speed. Speed-based rejection gives the more uniformly distributed histogram (b). Note the change in scale on the y axis from 30 000 (a) to 1000 (b).

to construct a balanced dataset of 7-D feature vectors acquired during a number of consecutive flights. The use of this balanced dataset for training in-flight models of normality is described in Sections 4 and 5 of this article.

2.4 Features for flight-by-flight novelty detection

As a complement to the real-time on-the-engine monitoring described in Section 2.3, there is also a need to perform novelty detection on a flight-by-flight basis. The latter approach is adopted for ground-based analysis of summaries of engine condition throughout an entire flight. A *vibration signature* for the entire flight can be constructed for each tracked order, using a speed-based representation in which the complete range of shaft speeds is divided into subintervals (*speed bins*) of equal width. Within each speed bin, the vibration amplitude of the corresponding tracked order is averaged across the entire flight.

An example of this is shown in Figure 2, in which a flight summary of 1*IP* vibration amplitude is shown,

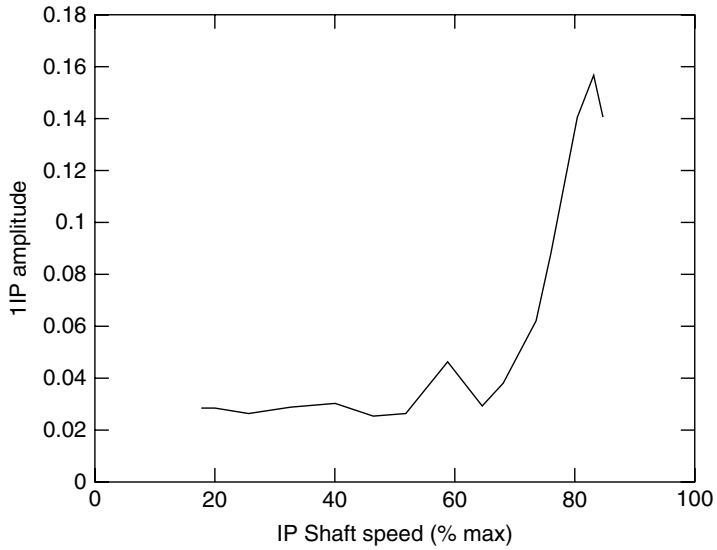

Figure 2. The 1*IP* vibration signature, summarizing 1*IP* vibration amplitude throughout a flight, using a 20-D feature vector.

displayed against IP-shaft speed. The range of shaft speeds has been divided into 20 speed bins, resulting in a 20-D feature vector.

2.5 Normalization

In general, we cannot assume that each feature in the vector has the same dynamic range. It is therefore desirable to normalize feature vectors such that their individual elements may be compared, regardless of their absolute values, while preserving information necessary for novelty detection. Though many normalization schemes exist for normalizing a D-dimensional feature vector $\mathbf{x}_n = [x_n^1, \ldots, x_n^D]$ from a set of N feature vectors $\{\mathbf{x}_1, \ldots, \mathbf{x}_N\}$ [28], the most appropriate, in practice, is *component-wise normalization*, defined to be

$$\mathbf{x}'_n = \left[\frac{x_n^1 - \mu_1}{\sigma_1}, \frac{x_n^2 - \mu_2}{\sigma_2}, \ldots, \frac{x_n^D - \mu_D}{\sigma_D}\right] \tag{3}$$

where μ_d and σ_d are the mean and standard deviation of element d across the whole dataset:

$$\mu_d = \frac{1}{N}\sum_{i=1}^{N} x_i^d \quad \sigma_d = \sqrt{\frac{1}{N-1}\sum_{i=1}^{N}(x_i^d - \mu_d)^2} \tag{4}$$

3 VISUALIZATION

3.1 Introduction

The process of feature extraction leads to feature vectors $\mathbf{x}$ that combine D features extracted from original data. Typically, D is large; for example, feature vectors from the in-flight engine dataset have $D = 7$ dimensions, and feature vectors from the flight summary dataset have $D = 20$ dimensions. The initial analysis of datasets containing high-dimensional feature vectors is performed using *visualization* techniques that allow us to explore the structure of the datasets.

In visualization, feature vectors are mapped from their original D dimensions into a 2- (or 3-) D space such that each vector is mapped onto a corresponding single point in this visualization space. Feature vectors similar to one another in D-dimensional space map to points that are close to one another in the 2D space, while feature vectors that are significantly far apart in D-dimensional space should map to points that are far apart in the 2D space. As a result, groups of similar feature vectors form clusters in the visualization space.

In datasets suitable for the application of novelty detection techniques, feature vectors that correspond to "normal" data (which are often similar) form clusters. Feature vectors that correspond to "abnormal" data (which are dissimilar to "normal" feature vectors) appear as outlying points, separated from the normal clusters. Thus, we can determine the effect of selecting various features for inclusion in the feature vectors by examining the separation of "normal" and "abnormal" data in the visualization, with the goal of selecting features that result in maximum separation.

Similarly, the effects of various methods of normalizing the feature vectors can be determined using visualization, again with the goal of choosing a normalization method that maximizes separation between "normal" and "abnormal" data, such that abnormal data may be clearly identified.

3.2 Mapping with NeuroScale

To map N feature vectors $\{\mathbf{x}_1, \ldots, \mathbf{x}_N\}$ from their original D-dimensional space (the *data space*) into 2-D space (the *visualization* or *latent space*), we consider the distance $d_{i,j}$ between two feature vectors $(\mathbf{x}_i, \mathbf{x}_j)$ in data space and the distance $d^*_{i,j}$ between the corresponding pair of mapped points (y_i, y_j) in latent space. The *Sammon stress metric* is defined to be the difference between the Euclidean distance $d_{i,j}$ in the high-dimensional space and the Euclidean distance $d^*_{i,j}$ in the low-dimensional space, summed over all N feature vectors:

$$E_{\text{sam}} = \sum_{i=1}^{N}\sum_{j>i}^{N}(d_{i,j} - d^*_{i,j})^2 \tag{5}$$

The NeuroScale training algorithm seeks to minimize the error function E_{sam} to best preserve the original interpoint distances $d_{i,j}$ after mapping the points into latent space [29]. The mapping is learnt,

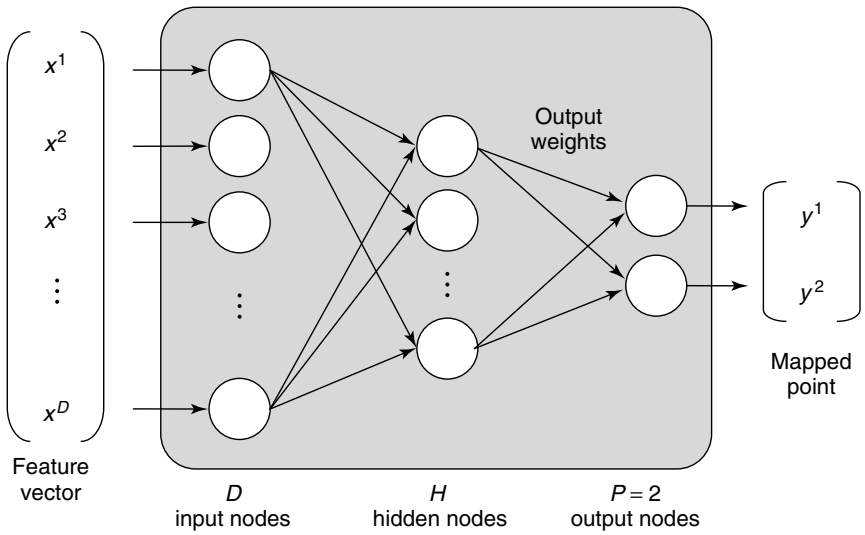

Figure 3. Mapping a D-dimensional feature vector into two dimensions using a NeuroScale neural network.

using a radial basis function (RBF) neural network with D inputs, $P = 2$ output nodes, and a single hidden layer of H hidden nodes, as shown in Figure 3.

Each of the H nodes in the hidden layer corresponds to a basis function in D-dimensional data space. H is typically selected to be an order of magnitude greater than the dimensionality, D, of the feature vectors, and an order of magnitude smaller than the number, N, of feature vectors. For example, if $D = 10$ and $N = 1000$, an appropriate number of hidden nodes would be $H = 100$.

To construct the NeuroScale mapping, the parameters of the H basis functions and the values of the output weights (i.e., those from the hidden layer to the output layer) must be determined. To achieve this, the neural network is first initialized, and then trained using the *training set* of N feature vectors as described below:

1. Initialization

The initial centres of the H radial basis functions are set to be the D-dimensional co-ordinates of H feature vectors randomly selected from the training set. There are a number of algorithms which may be used for setting the initial width of the H radial basis functions. Typically, the width is set to be the distance between the two centers that are furthest apart to achieve good coverage of input space.

The output weights from the H hidden nodes to the P output nodes are initialized using principal component analysis (PCA). The eigenvectors of the training set covariance matrix with the largest eigenvalues are found. These *principal components* are the P vectors in data space that account for maximum variance in the data, and they are used as the *initial* values for the target outputs from which the initial values of the output weights are computed [14].

2. Training

Training the RBF network is a two-stage process. In the first stage, the parameters of the basis functions are set so that they approximately model the unconditional data density of the training set. In the second stage, the output weights are learnt by optimizing the Sammon stress metric using methods from linear algebra [30].

Once training is complete, feature vectors may be visualized by presenting them at the input layer of the NeuroScale network, which then gives the corresponding 2-D coordinates of the mapped feature vector at its output.

3.3 Application to in-flight engine data

3.3.1 Selecting a "normal" training set of feature vectors

To examine how the 7-D feature vectors extracted from in-flight vibration data vary from flight to flight, a NeuroScale network was trained for each of the speed bands $\{S1, \ldots, S4\}$ using the process described above. The training set in each speed band consisted of feature vectors acquired during a set of "normal" flights, as explained below.

Flights 1–30 corresponded to recordings during which the engine did not exceed takeoff speed. Thus, these flights could not be used for training NeuroScale networks for each of the speed bands. Flights 31–79 were the first "normal" flights to cover the full range of shaft speeds, of which 14 flights contained full 7-D data. These 14 flights were therefore selected to provide the feature vectors used to train the NeuroScale network for each speed band.

3.3.2 Training the NeuroScale network

The optimization of the NeuroScale network requires the minimization of E_{sam}. There are $N(N-1)/2$ distances to consider for a training set of N feature vectors, and so the computational demands of the training process increase as $O(N^2)$. The set of 14 flights selected in the training set contains $N1 = 8770$, $N2 = 14\,295$, $N3 = 28\,232$, and $N4 = 4603$ feature vectors in speed bands S1 to S4, respectively. For the training time and computational requirements to be manageable, each of the four training sets is first reduced to a smaller representative set of feature vectors, using k-means clustering.

The k-means clustering algorithm [23] is an iterative method for producing a set of cluster centers μ_j (for $j = 1, \ldots, k$) that represents the distribution of a (typically much larger) set of feature vectors $\mathbf{x}_i$. For the purposes of training NeuroScale networks for the speed bands S1 to S4, we reduce the training set of N1 to N4 feature vectors to $k = 500$ cluster centers in each case, as shown in Figure 4.

After application of the k-means algorithm, each original training set with $\{N1, \ldots, N4\}$ feature vectors is reduced to a new training set consisting of the $k = 500$ cluster centers. Using the rule of thumb that the number of nodes H in the hidden layer of the NeuroScale network should be an order of magnitude smaller than the size of the training set, we set $H = 50$. The network is then trained as described above.

To confirm the appropriateness of the $k = 500$ cluster centers, we can compare the visualization of the cluster centers with that of the original feature vectors.

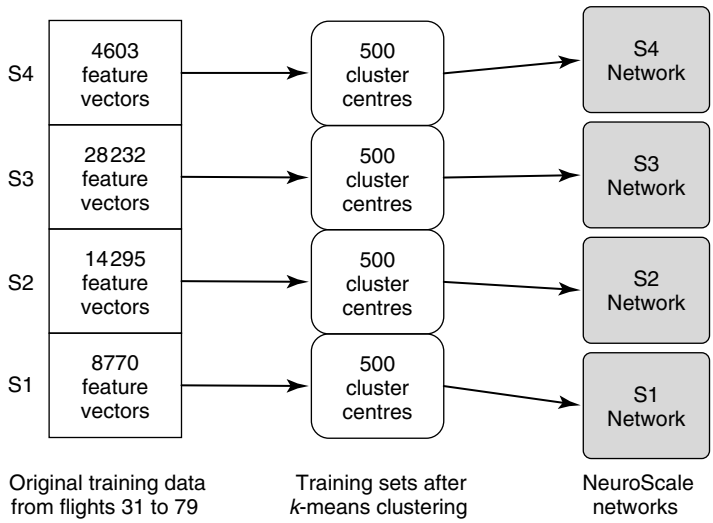

Figure 4. Training NeuroScale visualization networks for each of the four speed bands $\{S1, \ldots, S4\}$, using training sets of $k = 500$ cluster centers derived from the $\{N1, \ldots, N4\}$ feature vectors.

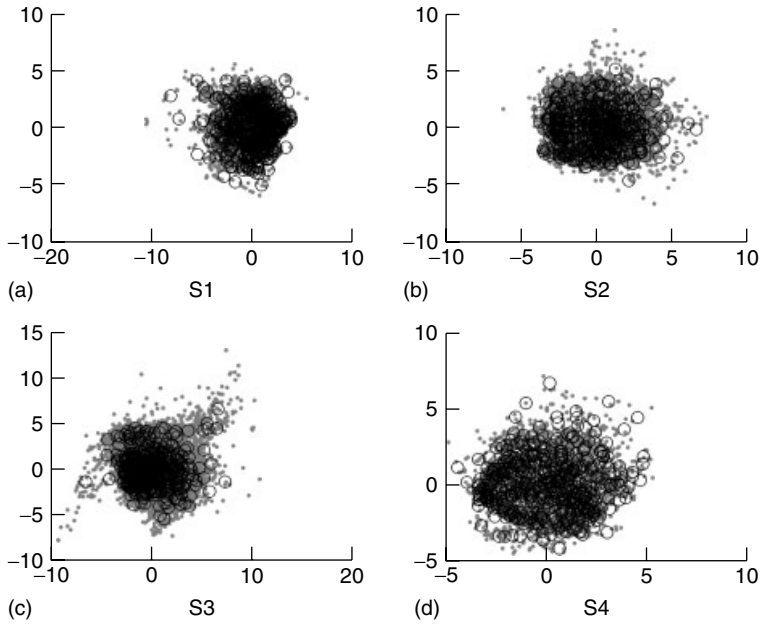

Figure 5. Visualization of 7D in-flight feature vectors in 2D, using NeuroScale. Data for the four speed subranges $\{S1, \ldots, S4\}$ are shown in (a–d), respectively. 7D cluster centers are shown as circles in the visualization. The projections of the original 7-D feature vectors from which the cluster centers were generated are shown as gray dots. In each case, the cluster centers are seen to be a valid representation of the original feature vectors.

Figure 5 shows visualizations of the $k = 500$ cluster centers, and the original data, for each of the four speed bands $\{S1, \ldots, S4\}$. In each plot, it can be seen that the 7-D feature vectors generally overlay the 7-D cluster centers (shown by circles) when visualized in two dimensions.

In any dimensionality-reduction mapping, the $N(N-1)/2$ intervector distances are not perfectly preserved. A small number of the original feature vectors lie slightly outside the main distribution of cluster centers, as may be seen in the bottom left of Figure 5(c), for example. As seen later, however, these distances from "normal" feature vectors to the nearest cluster centers are small compared to the distances from mapped "abnormal" feature vectors to the nearest cluster centers.

3.3.3 Visualizing test data

Figure 6 shows a visualization of the 7-D feature vectors from flight 131 within period B, in which a previously undetected change in engine condition occurred. The NeuroScale networks trained previously using data from "normal" flights are used to map the feature vectors from flight 131 into two dimensions.

Figure 6(a) shows feature vectors from speed band S2, with the cluster centers from the "normal" flights shown for comparison. It can be seen that some of the feature vectors within this speed band are not closely aligned with the cluster centers. A few are well separated, appearing in the lower left of the plot.

Figure 6(b) shows test data from speed band S3. Here, a large proportion of the test data is well separated from the "normal" cluster centers, indicating that majority of the feature vectors in this speed band appear to be considerably "abnormal". Speed band S3 includes that part of the flight in which the airplane is climbing, which engine experts describe as being a period during which evidence of any abnormal engine behavior is likely to become apparent.

Figure 7 shows the visualization of the 7-D feature vectors from flight 134 from period C, during which an engine event occurred. The same NeuroScale networks are used to map the feature vectors from the test flight into two dimensions.

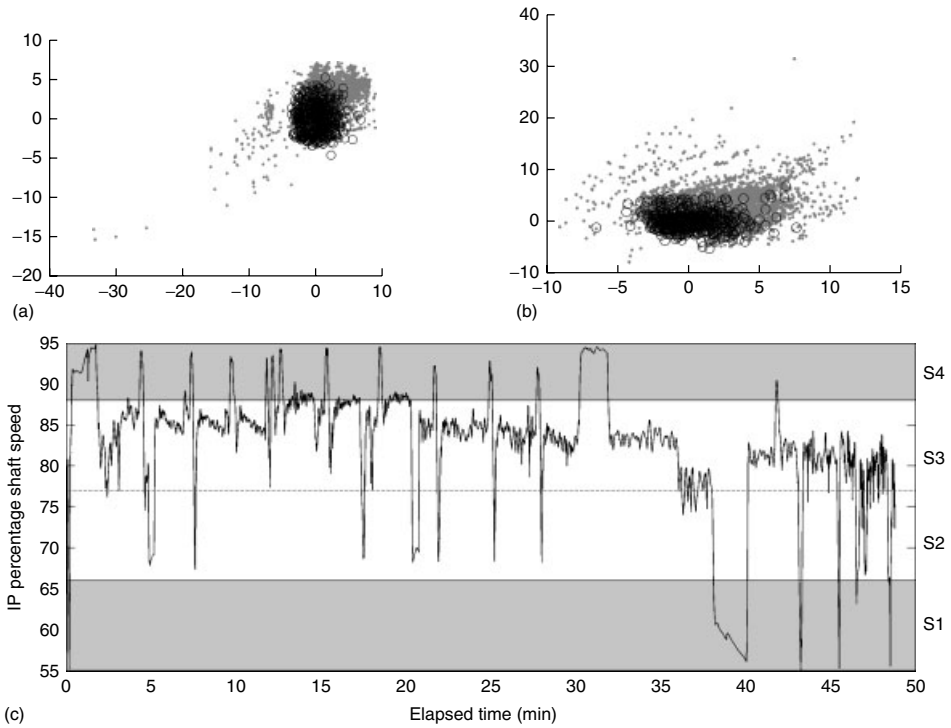

Figure 6. Visualization of in-flight feature vectors from flight 131 (shown as gray dots). 7-D cluster centers from "normal" flights are shown in the visualization as circles. (a) Feature vectors from speed band S2 do not lie close to the "normal" cluster centers, with a few extending out to the lower left of the plot. (b) Feature vectors from speed band S3 lie mostly away from the "normal" cluster centers. (c) Engine speeds throughout flight 131, showing speed bands $\{S1, \ldots, S4\}$.

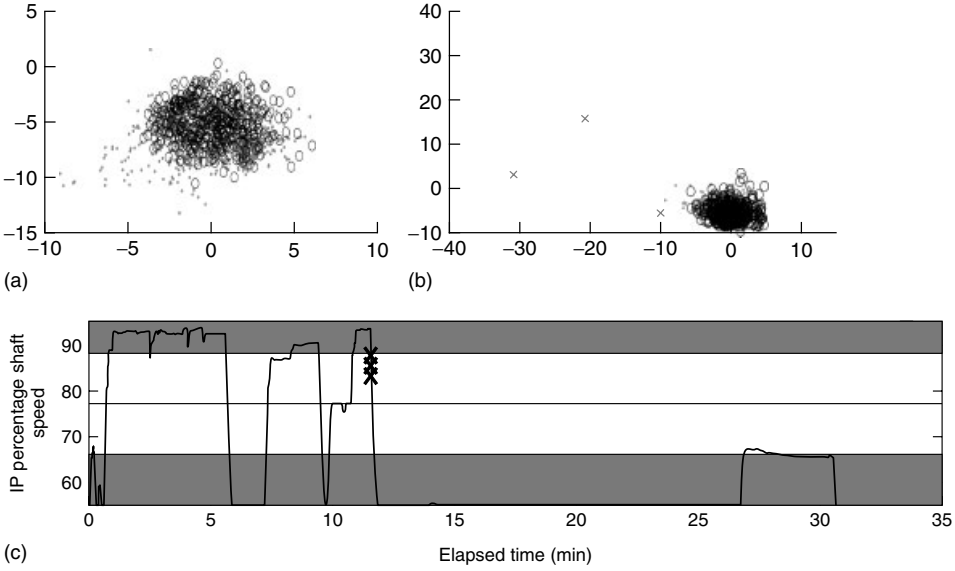

Figure 7. Visualization of in-flight feature vectors from flight 134 (shown as gray dots). 7-D cluster centers from "normal" flights are shown in the visualization as circles. (a) Feature vectors from speed band S2 extend significantly from the main cluster of "normal" centers. (b) Three of the feature vectors from speed band S3 (marked by gray crosses) lie even further from the "normal" cluster centers. (c) Engine speeds throughout flight 134, showing speed bands $\{S1, \ldots, S4\}$.

Figure 7(a) shows the visualization of the feature vectors from speed band S2 with respect to the "normal" cluster centers. Again, feature vectors within this speed band are separated from the normal cluster centers, extending into the lower left of the plot.

Figure 7(b) shows the visualization of the feature vectors from speed band S3. Retrospective analysis of the original IP-shaft vibration data by engine experts showed that the damage caused by the loose component led to an engine surge early in the flight (after about 11 min). The engine deceleration that follows shortly afterward—marked by three crosses on (c)—gives rise to a highly abnormal vibration pattern—also marked by three crosses on (b).

3.3.4 Visualizing flight-by-flight summaries using 7-D vectors

We have so far described the visualization of feature vectors from individual flights, comparing them with the set of cluster centers previously derived from "normal" flights. We describe here how the same visualization method can also be used for the direct comparison of flights.

Given N 7-D feature vectors $\mathbf{x}_n = [x_n^1, \ldots, x_n^7]$ from a flight, we can obtain a summary representation for that flight, a single vector $\hat{\boldsymbol{\mu}}$, which we define as follows:

1. For the N feature vectors in the flight, compute the component-wise mean vector $\boldsymbol{\mu}$:

$$\boldsymbol{\mu} = \frac{1}{N}\left[\sum_{n=1}^{N} x_n^1, \sum_{n=1}^{N} x_n^2, \ldots, \sum_{n=1}^{N} x_n^7\right] \quad (6)$$

2. The mean $\boldsymbol{\mu}$ is a "synthetic" feature vector. The best equivalent representation for the flight data is the feature vector $\hat{\boldsymbol{\mu}}$ from $\{\mathbf{x}_1, \ldots, \mathbf{x}_N\}$ that is closest to $\boldsymbol{\mu}$, using Euclidean distance inversely weighted by the variance in each dimension as the distance metric.

Figure 8 shows a visualization of the $\hat{\boldsymbol{\mu}}$ vectors from speed band S3, for all flights. The $\hat{\boldsymbol{\mu}}$ vectors from the "normal" period A form a cluster to the left of the plot, while the $\hat{\boldsymbol{\mu}}$ vectors from periods B and C lie to the right of this cluster, indicative of the abnormal vibration behavior of the IP shaft in these latter flights.

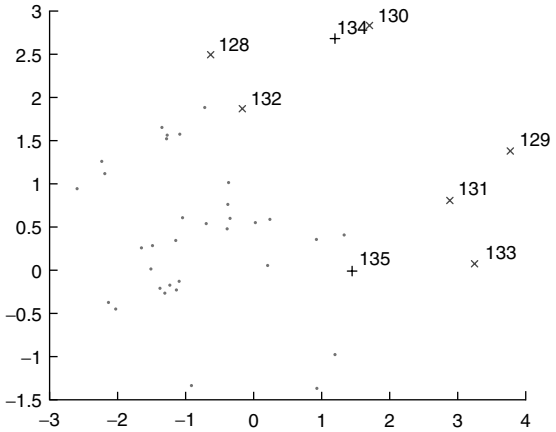

Figure 8. Visualization of $\hat{\boldsymbol{\mu}}$ vectors for each flight. Vectors from periods A, B, and C are shown as dots, crosses, and plus symbols, respectively. It can be seen that the $\hat{\boldsymbol{\mu}}$ vectors from period A form a cluster to the left, while vectors from periods B and C lie to the right of this cluster, corresponding to the abnormal IP-shaft vibration behavior observed during these flights.

The NeuroScale visualization shown here is only an approximate summary of the "average" behavior of IP-shaft vibration in one speed band. The optimal summary representation of a flight is the 20-D vibration signature for each shaft across the entire speed range, and the NeuroScale visualization techniques are applied to this representation in the next subsection.

3.4 Visualization of 20-D flight summary signatures

A 20-H-2 NeuroScale network was trained to map the 20-D vibration summary signatures for the IP shaft into a 2-D visualization space. As with the in-flight data in Section 3.3, the network was trained using "normal" flights $\{31, \ldots, 79\}$ from period A, and thus the number of examples in the training set is 49. The number of nodes in the hidden layer of the network was set to $H = 30$.

Note that the rule of thumb given in Section 3.2, in which the value of H is set to be an order of magnitude greater than the number of input nodes and an order of magnitude less than the number of

examples in the training set, cannot be met in this case. The best practice is to train several networks using different values of H, and compare the resultant visualizations to ensure that an appropriate value of H is selected for use. In practice, NeuroScale visualizations are robust to changes in H, and it is often possible to construct useful visualization maps despite the number of available training examples being not much greater than the number of inputs.

Figure 9 shows the result of using the trained NeuroScale network to visualize the 20-D vibration signatures for the IP shaft from all flights. It can be seen that signatures from "normal" flights (in period A, plotted with dots) form a cluster in the upper right quadrant of the visualization map, close to the (0, 0) point in the map. This indicates that the signatures are similar in 20-D space, and thus the behavior of the IP shaft during these "normal" flights is consistent.

Signatures in which a change of engine condition took place (in period B, plotted with crosses) are seen to be well separated from the cluster of signatures from "normal" flights, highlighting departure from normality in the IP-shaft vibration signature.

The signature corresponding to the engine event (flight 134 in period C) is the furthest away from the cluster of "normal" signatures, confirming that the highly abnormal vibration behavior of the IP shaft during this flight was captured in this summary signature.

4 CONSTRUCTING MODELS FOR NOVELTY DETECTION

The objective of a novelty detection system is the generation of reliable and robust alerts if the condition of the system being monitored is deemed to have deteriorated. The techniques described in the previous section allow us to visualize the data to be used to construct the model of normality.

4.1 Parzen window model of normality

The Parzen window kernel density estimator method [31] is the model adopted here to estimate the pdf, $p(\mathbf{x})$, for the training (normal) data. With this method [10], $p(\mathbf{x})$ is estimated using the following steps:

1. Locate a hyperspherical Gaussian window, or kernel, with width σ, on *each* of the D-dimensional feature vectors in the training

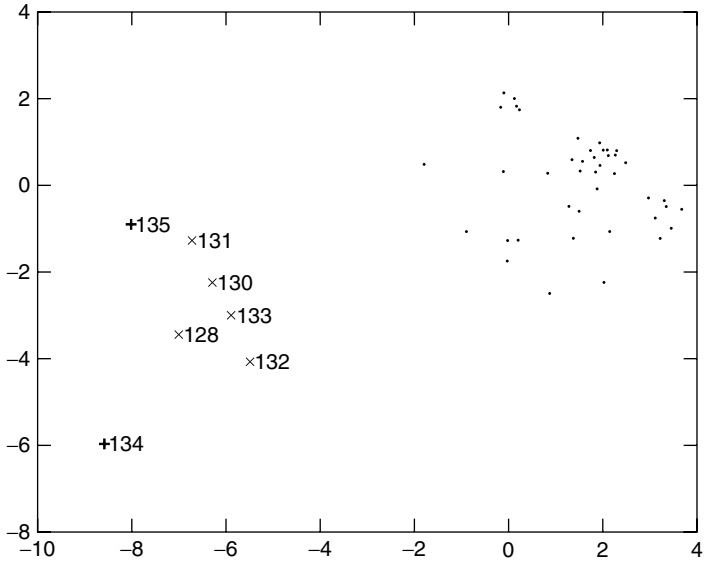

Figure 9. Visualization of 20-D flight summary signatures. Signatures from periods A, B, and C are shown by dots, crosses, and plus symbols, respectively. Signatures from periods B and C are clearly separated from the signatures from "normal" period A.

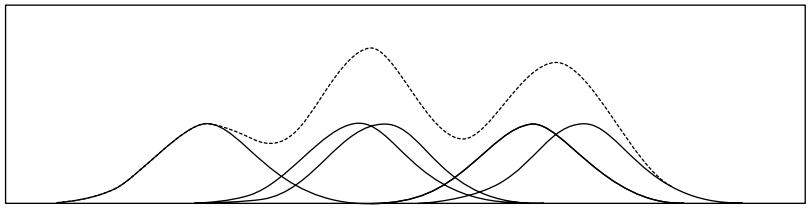

Figure 10. A simple 1-D example of the Parzen windows method of estimating a probability density function. Five Gaussians (solid lines) of uniform width, centered on five observations of a random variable x, are shown along with their sum (dashed line). Wherever the data density is highest, the probability density function (pdf) estimate takes a higher value.

dataset, $\mathbf{x}_i$, where $i = 1, \ldots, N$; (a one-step "training phase").

2. Evaluate the sum of the Gaussian distributions using the squared Euclidean distances between the test feature vector $\mathbf{x}$ and the training vectors $\mathbf{x}_i$, normalized by a factor that ensures $p(x)$ integrates to 1.

This gives the following formula for the estimate of $p(\mathbf{x})$:

$$p(\mathbf{x}) = \frac{1}{N(2\pi)^{D/2}\sigma^D} \sum_{i=1}^{N} \exp\left\{\frac{-\|\mathbf{x} - \mathbf{x}_i\|^2}{2\sigma^2}\right\} \tag{7}$$

By placing a Gaussian kernel over each feature vector $\mathbf{x}_i$ in our training dataset, we construct a probability density estimate of $p(\mathbf{x})$ that will have a higher value of p where the concentration of training data is greatest. This is illustrated in the simple 1-D example shown in Figure 10.

There are two parameters that must be carefully chosen for an accurate estimation of the pdf of the training (normal) data according to the above equation: the number N of training vectors and the width parameter σ. N must not be too large to avoid undue computational complexity. Hence the number of training patterns is reduced to 500 by using the k-means clustering algorithm as described in Section 3.3 and illustrated in Figure 4. Thus the 500 cluster centers used for training the NeuroScale network for speed band S3 (as shown in Figure 4) are also the N feature vectors $\mathbf{x}_i$, where $i = 1, \ldots, N$, used in the Parzen windows model of normality.

If desired, some of the outliers in the visualization map can be removed from the set of N Gaussian kernels used in the Parzen windows model of normality, so that only the "most normal" feature vectors are used to define normality. This strategy was not adopted here and all 500 cluster centers were retained for defining normality.

The width parameter σ acts as a smoothing parameter for the estimator. If its value is too large, local variation in the D-dimensional space is not captured. If the value is too small, the estimate of the pdf is too noisy and follows the data too closely (overfitting). There are a number of methods for setting the value of σ; for example, by using a validation set. Here, we use a simple heuristic method whereby σ is set to be the average distance of the 10 nearest neighbors from each vector in the (normal) training dataset, averaged across all 500 feature vectors [2].

Novelty increases as $p(\mathbf{x})$ decreases; we define the *novelty score* as $\log_e 1/p(\mathbf{x})$ which is equivalent to $-\log_e p(\mathbf{x})$. Thus feature vectors a long distance away from the Gaussian kernels centered on the normal training vectors will have a low value of $p(\mathbf{x})$ and hence a high novelty score.

4.2 Application to in-flight vibration data (7-D feature vectors)

A Parzen window model of normality is first constructed for the 7-D vibration feature vectors introduced in Section 2.3 (IP-shaft tracked orders in speed band S3, plus residual energy, to which component-wise normalization is applied). The 500 cluster centers are selected, using the k-means clustering algorithm, from the 28 232 feature vectors available in speed band S3 in the data from flights 31–79 (Figure 4) and visualized in 2-D in Figure 5(c). The width σ is set using the 10 nearest-neighbor heuristic described above.

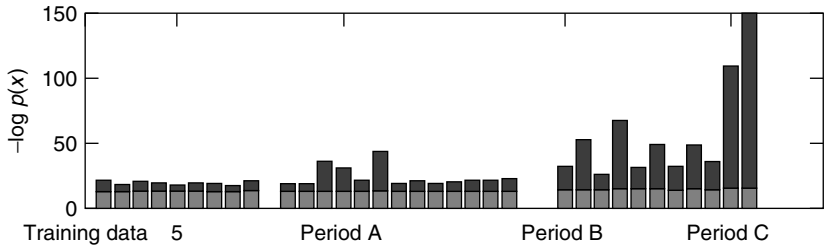

Figure 11. Novelty scores (mean shown in light gray and max in dark gray) for 7-D vibration feature vectors, computed using a Parzen windows model of normality for the IP shaft based on 500 cluster centers. The model was constructed using the same 500 prototype vectors as in the visualization studies of Section 3.3. These vectors were extracted from the IP-shaft vibration data in speed band S3 between flights 31 and 79 (shown as training data in the above figure).

The mean and maximum novelty scores for each flight are calculated using the Parzen window estimate of $p(x)$. These scores are shown in Figure 11 for the training data (flights 31–79), the rest of period A (up to flight 127), the eight flights from period B (flights 128–133), and finally the two "flights" from period C (flights 134 and 135). The deterioration at the start of period B is evident from the increase in maximum novelty score. The final event, which causes the engine to surge in flight 134 (penultimate flight on Figure 11) has an even greater effect on this parameter.

Figure 12 shows the novelty scores computed every 0.2 s during two flights (flight 80 from period A and flight 134 from period C), using the same 500-center Parzen window model of normality for the 7-D vibration feature vectors for the IP shaft.

The consistently low novelty scores throughout flight 80 (apart from one noise transient) are evidence of the normal condition of the engine at this point in the test flight program. The novelty scores recorded for a short period of time during flight 134, after which an engine shutdown was carried out, are far in excess of the scores seen in earlier flights.

4.3 Application to flight summary data (20-D vibration signatures)

A Parzen window model of normality can also be constructed for the 20-D vibration signatures that provide a flight summary for each shaft. The fundamental tracked order data for the IP shaft from flights 30–79, previously used to train the NeuroScale network of Section 3.4, are now used to construct a Parzen window model of normality for IP-shaft vibration, using the 49 available training signatures (i.e., $N = 49$, for this Parzen window model) and the same heuristic for setting the width σ for each of the 49 Gaussian kernels.

The resulting novelty scores for the 20-D vibration signatures shown in Figure 13 are significantly higher for the flights in periods B and C (flight 128 onward) than during period A when the engine was known to be operating at normal condition.

Thus the 20-D vibration signature model confirms the results obtained with the in-flight 7-D vibration model, with both novelty detection models detecting increased abnormality in the engine's vibration patterns for the IP shaft. The 20-D vibration model, which is based on a vibration signature averaged across the entire flight, provides a clearer distinction between normality (period A) and the onset of deterioration at the start of period B. Methods for setting the novelty threshold for the automatic detection of abnormality are considered in Section 5 of this article.

5 SETTING NOVELTY THRESHOLDS

5.1 Introduction

To decide whether a feature vector $\mathbf{x}$ is "normal" or "abnormal", we require a decision boundary, termed the *novelty threshold*. This threshold p_H can be defined using the unconditional probability distribution $p(\mathbf{x}) < p_H$. However, because $p(\mathbf{x})$ is a *distribution* function, it is necessary to integrate to give the cumulative probability $P(\mathbf{x})$. This is then used to

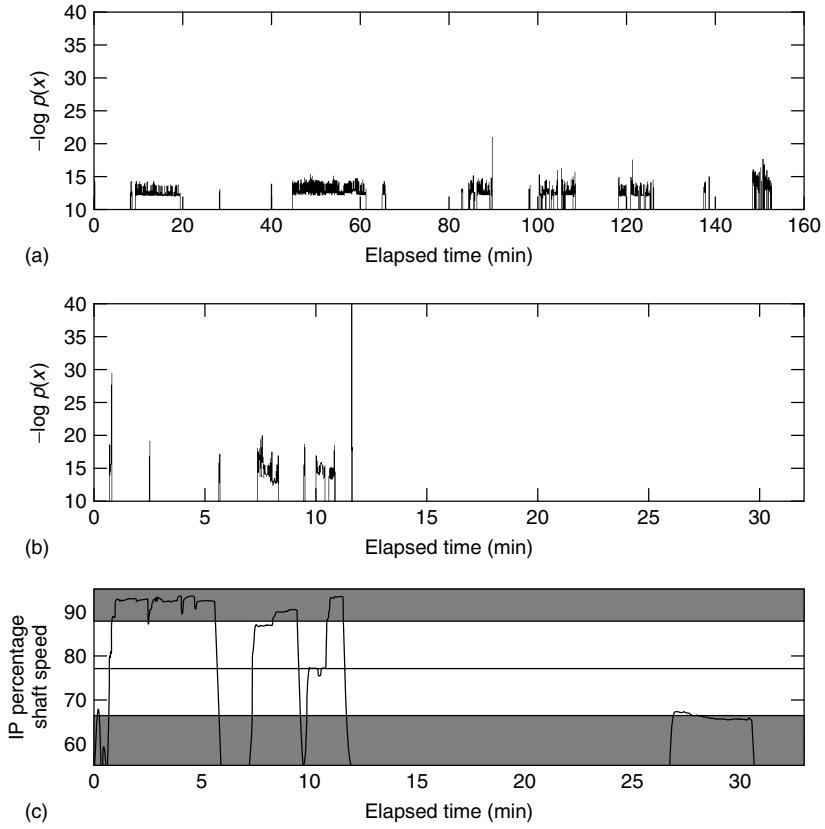

Figure 12. Novelty scores for the 7-D vibration feature vectors, computed using a Parzen window model of normality based on 500 cluster centers. Flight data from speed band S3 of the IP shaft acquired from flight 80 at the beginning of period A (a) produces low (albeit noisy) novelty scores. The acceleration during the climb at the beginning of flight 134 gives rise to a high novelty score for a short time at the beginning of plot (b), and an even higher score at the end (deceleration after surge). Plot (c) shows the engine speeds throughout flight 134, showing speed bands {S1, . . . , S4}.

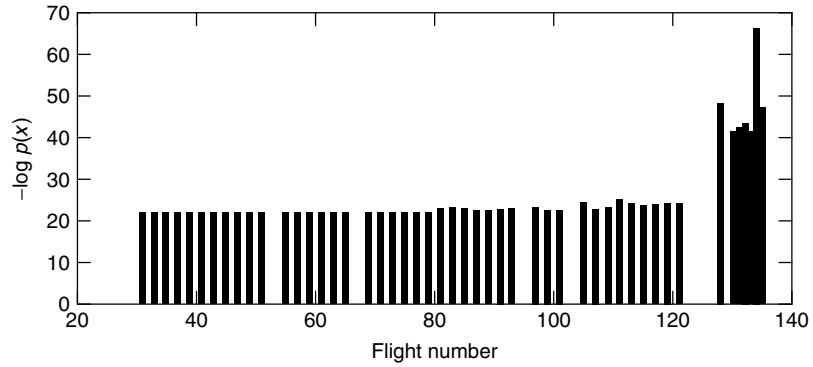

Figure 13. Novelty scores for the 20-D vibration signatures from each flight, computed using a Parzen window model of normality with $N = 49$. The model was trained using signatures from flights 31–79. Only those flights that had a sufficiently broad coverage of the speed range to create a valid 20-point summary signature are included.

set thresholds in relation to the actual probability of observing an abnormal event (e.g., $P(\mathbf{x}) = 10^{-6}$).

This section discusses the disadvantages of using conventional methods for setting novelty thresholds, and then describes a principled probabilistic approach suitable for novelty detection, illustrated using the models described in Section 4.

5.2 Disadvantages of conventional methods

Conventional methods of creating a probabilistic model of normality, as described in Section 4, are well suited for estimating the distribution of *normal* data. However, vectors close to the boundary of normality, which is defined by the novelty threshold, lie in regions of input space with very low data density (the tails of the $p(\mathbf{x})$ distribution). Conventional density-estimation methods may not accurately model the boundary of normality in input space.

5.3 Extreme value statistics

Extreme value theory (EVT) is a branch of statistics that provides a probabilistic method of directly estimating the boundaries of normality in input space. Given a set of normal training data $\mathbf{X} = \{\mathbf{x}_1 \ldots \mathbf{x}_m\}$, EVT estimates the probability distribution of the *maximum* of that set, $\max(\mathbf{X})$. The threshold is set according to where we believe the maximum of the normal data will occur, and thus provides a principled method of setting novelty thresholds.

The case studies described in this article focus on the detection of novelty in multidimensional data: the analysis of 7-D feature vectors of in-flight data and that of 20-D vibration signatures summarizing an entire flight. For the purposes of explanation, this section first considers the setting of thresholds with EVT using 1-D data.

Extreme value statistics originated in the field of civil engineering, used for modeling the likelihood of observing extreme loads in structures [32]. Here, we focus on "classical" EVT as previously used in novelty detection [33, 34] for biomedical applications.

According to the Fisher and Tippett theorem [35] upon which classical EVT is based, the distribution H describing the location of $\max(\mathbf{X})$ must belong to one of the following three families of extreme value distributions:

Type I (Gumbel):

$$H(y_m) = \exp\left(-\exp(-y_m)\right) \tag{8}$$

Type II (Fréchet):

$$H(y_m) = \begin{cases} 0 & \text{if} \quad y_m \leq 0 \\ \exp\left(-y_m^{-\alpha}\right) & \text{if} \quad y_m > 0 \end{cases} \tag{9}$$

Type III (Weibull):

$$H(y_m) = \begin{cases} \exp\left(-(-y_m)^{\alpha}\right) & \text{if} \quad y_m \leq 0 \\ 1 & \text{if} \quad y_m > 0 \end{cases} \tag{10}$$

where the Fréchet and Weibull distributions have a shape parameter α, and y_m is termed the *reduced variate*, being a linear transformation of the normal data x.

For novelty detection purposes, we have described the modeling of normal data using Parzen window density estimators in Section 4, which consist of a mixture of Gaussian kernels. Maxima from these Gaussian components are modeled using a Gumbel distribution [32, 33].

5.4 Setting novelty thresholds in univariate models

We first illustrate threshold setting for novelty detection using EVT with a univariate (1-D) example. Figure 14(a) shows a histogram of the maximum vibration levels for each flight observed within one of the speed bins in the 20-D vibration signature. A conventional density-estimation process is used to construct a model of normality, in which a distribution is fitted to the data. If we assume that the distribution of vibration levels in this speed bin is approximately Gaussian, the most likely distribution, given the data (the *maximum likelihood* distribution), is shown by the curved line.

A novelty threshold can then be set in the tails of this distribution. A typical threshold for this application is $P(x) = 1 \times 10^{-6}$ [36], which corresponds to $x = 0.018$. As can be observed from Figure 14(a), the gradient of the fitted distribution

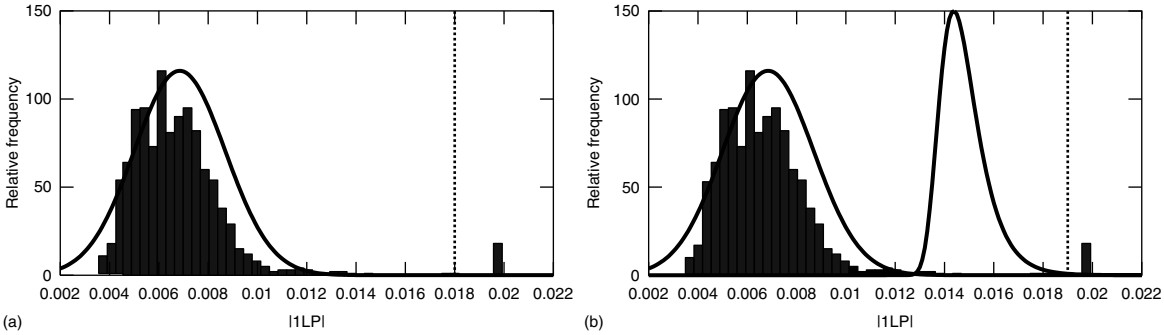

Figure 14. (a) Normal data are used to fit an estimated data distribution (curved line). A novelty threshold (dashed line) is set in the tail of this distribution. (b) An EVT distribution is estimated from the normal data (second curved line), which is then used to set a novelty threshold (dashed line).

is approximately zero when $x = 0.018$, making the position of the threshold sensitive to small changes in normal data around the mean of the distribution if the data are modeled with this single Gaussian distribution.

Assuming that the normal data are normally distributed $x \sim N(\mu, \sigma^2)$, we can set a novelty threshold using the expanded form of the Gumbel distribution, given that extreme values of the Gaussian distribution are described by the Gumbel:

$$p_E(x) = \frac{1}{\sigma d} \exp\{-y_m - \exp(-y_m)\} \qquad (11)$$

where the reduced variate is $y_m = (x' - c)/d$, with location c and scale d parameters:

$$c = \sqrt{2 \ln m} - \frac{\ln \ln m + \ln 4\pi}{2\sqrt{2 \ln m}}$$
$$d = (\sqrt{2 \ln m})^{-1} \qquad (12)$$

using normalized data $x' = (x - \mu)/\sigma$, and where m is the number of data in $\mathbf{X}$. Thus, the value of $\max(\mathbf{X})$ has distribution $p_E(x)$, shown by the second curve in Figure 14(b). A novelty threshold is then set at $P_E(x) \leq 1 \times 10^{-6}$ using the cumulative Gumbel distribution

$$P_E(x) = \exp\{-\exp(-y_m)\} \qquad (13)$$

corresponding to $x = 0.019$, shown by the vertical line in Figure 14(b). Unlike the threshold found using conventional density-estimation techniques, the novelty threshold found using EVT is robust to small changes in normal data. It is based on the EVT distribution $P_E(x)$, and is thus only dependent on m, μ, and σ, which are insensitive to small changes in normal data.

5.5 Setting novelty thresholds in multivariate models

Section 4 described the Parzen window method of constructing a model of normality for multivariate data, in which the probability density of normal data $p(\mathbf{x})$ is estimated using a mixture of Gaussian kernels, with a kernel centered on each normal training example. In multivariate data space, the novelty threshold will form a contour. Data falling within the region contained by the contour are classified "normal", while data falling outside it are classified "abnormal".

To illustrate some of the difficulties encountered when setting a novelty threshold with multivariate data, we first consider using the cumulative probability $P(\mathbf{x})$ associated with the data density $p(\mathbf{x})$ from the Parzen window model. We then show how EVT can be used to set the novelty threshold in multivariate data.

5.5.1 Multivariate novelty thresholds using P(x)

As before, we may wish to set the novelty threshold using $P(\mathbf{x})$, yet no cumulative distribution is defined for multivariate Gaussian distributions in closed form.

Instead, we define the cumulative distribution $P(\mathbf{x})$ at a certain contour on the data density $p(\mathbf{x}) = C$ to be

$$P(\mathbf{x}) = \int_C p(\mathbf{x})\, d\mathbf{x} \tag{14}$$

i.e., $P(\mathbf{x})$ is the volume contained by integrating $p(\mathbf{x})$ around contour C. Thus, we recast the problem of setting the multivariate novelty threshold into finding that contour $p(\mathbf{x}) = C$ which contains the desired probability volume; e.g., $P(\mathbf{x}) \leq 1 \times 10^{-6}$.

In order to find this contour C that contains some probability volume $P(\mathbf{x}) = H$, we can draw a large number of samples N from the Parzen window model, and compute the values of $p(\mathbf{x})$ with respect to that model. The novelty threshold $p(\mathbf{x}) = C$ can then be set such that the proportion H of the total number of samples N is contained by that contour C i.e., for $H \times N$ samples, $p(\mathbf{x}) < C$.

For example, if $H = 1 - 10^{-6}$ and we draw $N = 10^8$ samples from the Parzen window model, the novelty threshold C can be set such that $H \times N = 100$ samples are contained by the contour C i.e., 100 of the 10^8 samples have $p(\mathbf{x}) < C$.

Thus, we could use this method to set a novelty threshold as a contour of $p(\mathbf{x})$ that contains the desired probability volume $P(\mathbf{x})$. However, this method is based on a stochastic sampling process, and we can use EVT to set the multivariate novelty threshold in a more principled manner.

5.5.2 *Multivariate novelty thresholds using EVT*

As before, our goal is to find a contour $p(\mathbf{x}) = C$ such that the desired probability volume is contained within it, this time using the cumulative Gumbel distribution $P_E(\mathbf{x})$ instead of the cumulative distribution $P(\mathbf{x})$; e.g., $P_E(\mathbf{x}) \leq 1 \times 10^{-6}$.

In a Parzen window model, probabilities $p(\mathbf{x})$ along the radius of each kernel vary with the distance from the kernel center according to a single-sided Gaussian distribution $|N(\mu_n, \sigma)|$, and so tend to the Gumbel distribution for extreme values along that radius. This is illustrated in Figure 15, in which an example density $p(\mathbf{x})$ is formed from two Gaussian kernels, $N(\mu_1, \sigma)$ and $N(\mu_2, \sigma)$. Along the radius shown by the solid line, the Gumbel distribution $p_E(\mathbf{x})$ quantifies our belief in where extreme values generated from the kernel should lie.

Thus, we can use the cumulative Gumbel distribution $P_E(\mathbf{x})$ to determine where extreme values should

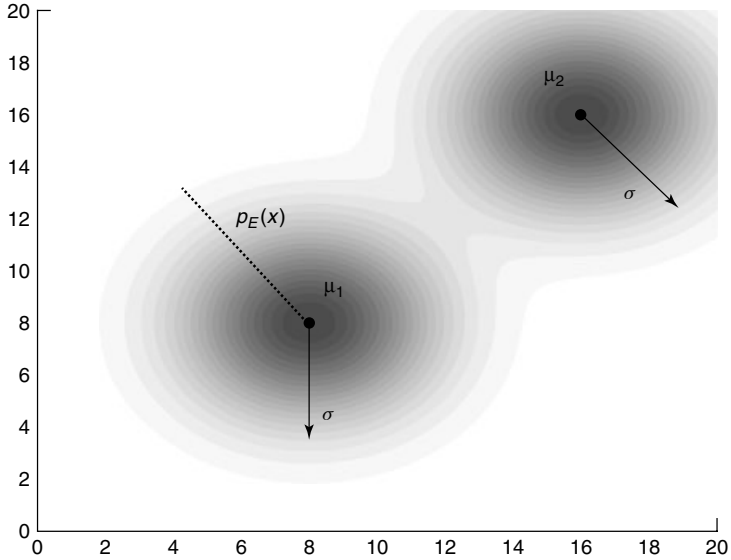

Figure 15. An example bivariate Parzen window model, where $p(\mathbf{x})$ is formed by two kernels $N(\mu_1, \sigma)$ and $N(\mu_2, \sigma)$. Probabilities $p(\mathbf{x})$ along the radius of each kernel vary with distance from its center according to the single-sided distribution $|N(\mu_1, \sigma)|$, and so tend to the Gumbel distribution $p_E(\mathbf{x})$ as shown.

lie along that radius. Rearranging (13) and using the definition of the reduced variate y_m in terms of (12), we find the radius x where $P_E(x) \leq H$:

$$x = \frac{\sigma}{\sqrt{2\ln m}}\left[2\ln m - \ln(-\ln H) - \frac{\ln\ln m + \ln(4\pi)}{2}\right] \quad (15)$$

This radius x occurs at some multiple of the kernel width $x = K\sigma$, and has an associated kernel probability $p(K\sigma)$. The contour $p(\mathbf{x}) = C$ that corresponds to $P_E(\mathbf{x}) \leq 1 \times 10^{-6}$ is thus given by $p(\mathbf{x}) = p(K\sigma)$, and defines the desired EVT novelty threshold.

This is illustrated in Figure 16, in which the novelty threshold that corresponds to $P_E(\mathbf{x}) \leq 1 \times 10^{-6}$ is shown as a black contour, $p(\mathbf{x}) = p(K\sigma)$.

5.6 EVT novelty thresholds for in-flight vibration models

Figures 17 and 18 show the result of using the above method to set an EVT-based novelty threshold in the 7-D models constructed using in-flight engine data. Using equation (15) with $m = 500$ and $H = 1 \times 10^{-6}$, the novelty threshold for this model that contains probability volume $P_E(\mathbf{x}) \leq 1 \times 10^{-6}$ occurs at the contour $p(\mathbf{x}) = 1.2 \times 10^{-13}$, or $-\log_e p(\mathbf{x}) = 29.7$.

Flight 80 from period A is shown in Figure 17(a), in which $p(\mathbf{x})$ is well below the novelty threshold, as expected for "normal" data. Flight 134 from period C, in which the engine surge occurs at the beginning of the flight, is shown in Figure 17(b). Here, $p(\mathbf{x})$ exceeds the novelty threshold shortly after takeoff and again very clearly at the time of the deceleration after the engine surge.

5.7 EVT novelty thresholds for flight summary models

We can also set novelty thresholds using the same EVT methods for the 20-D model of vibration signatures summarizing entire flights. As before, we consider only those 49 signatures deemed to be valid, which covered over 50% of the total speed range.

Using equation (15) with $m = 49$ and $H = 1 \times 10^{-6}$, the novelty threshold for this model that contains the probability volume $P_E(\mathbf{x}) \leq 1 \times 10^{-6}$ occurs at the contour $p(\mathbf{x}) = 7.4 \times 10^{-18}$.

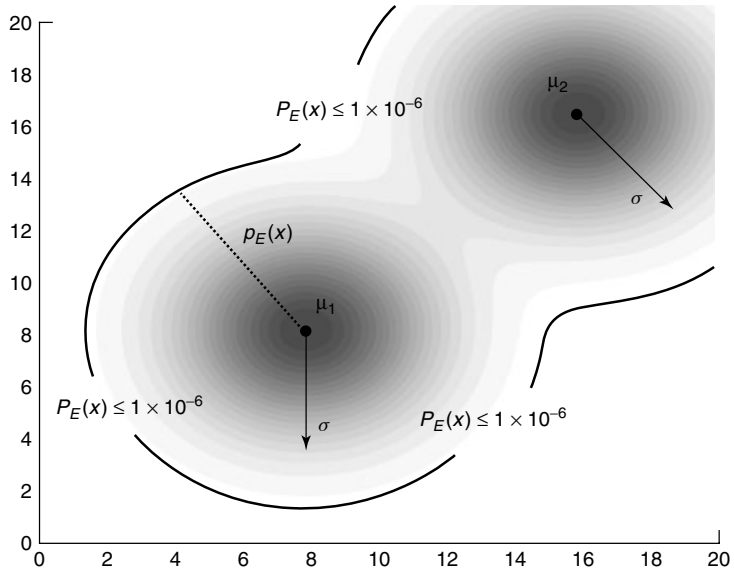

Figure 16. The EVT novelty threshold at $P_E(\mathbf{x}) \leq 1 \times 10^{-6}$ is shown as a contour line in this 2-D example. In 3-D, the novelty boundary would be described by a plane, and a hyperplane in higher dimensions.

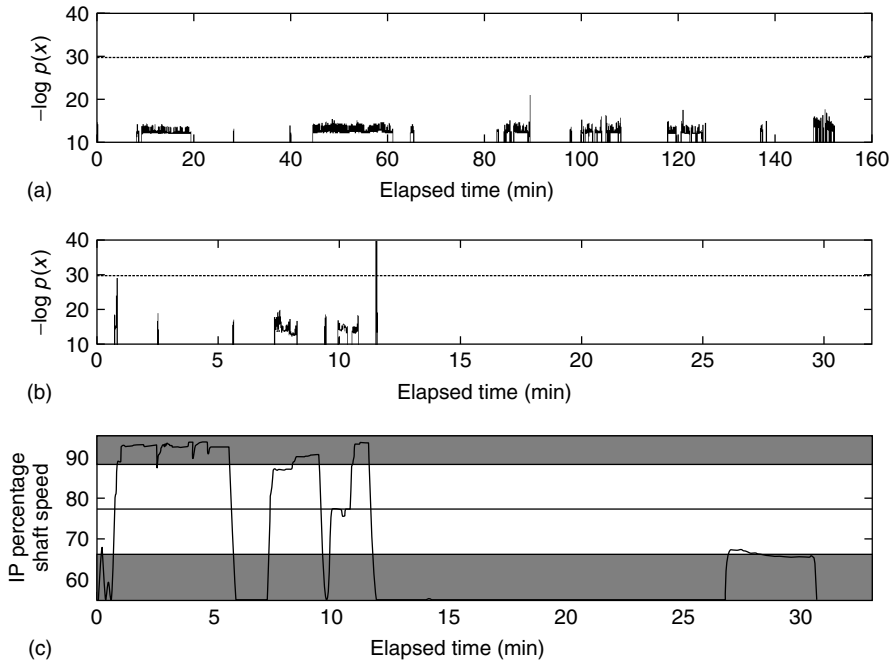

Figure 17. Plot (a) figure shows the novelty scores for flight 80, which all lie well below the novelty threshold computed using EVT, shown as the horizontal line at $-\log_e p(\mathbf{x}) = 29.7$. For flight 134, plot (b), the EVT novelty threshold is exceeded at the beginning (during climbing) and again at the end (deceleration after surge). Plot (c) shows the engine speeds throughout flight 134, showing speed bands $\{S1, \ldots, S4\}$.

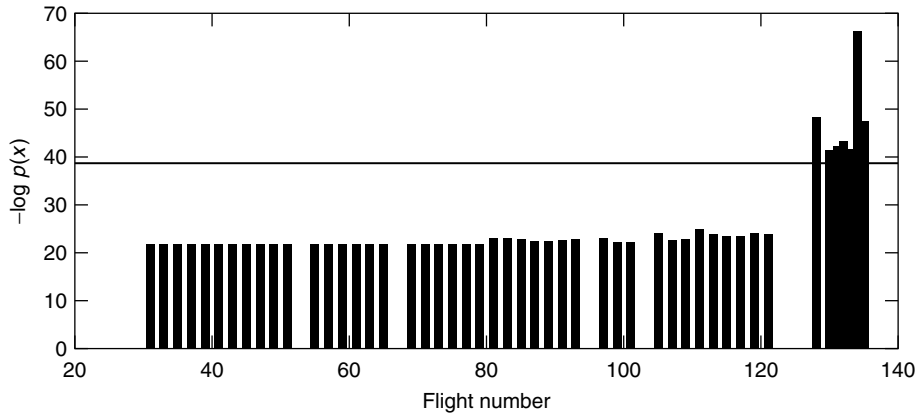

Figure 18. Novelty scores $-\log_e p(\mathbf{x})$ for flight summary vibration signatures, computed using a 20-D Parzen window model of normality. The novelty threshold (shown as a horizontal line) was determined using EVT, and takes the value $-\log_e p(\mathbf{x}) = 39.4$.

Figure 18 shows the novelty threshold compared with $p(\mathbf{x})$ for each of the 49 valid flight signatures. For all signatures in period A (the normal flights), $p(\mathbf{x})$ is significantly below the novelty threshold. It can be observed from the figure that even the "normal" flights of period A have novelty scores of $-\log_e p(\mathbf{x}) \approx 22$. This is because the model is 20-D and so even the peaks of the probability distribution

$p(\mathbf{x})$ will take small values. Assuming that the peak of $p(\mathbf{x})$ occurs at the mean of a Gaussian kernel, $\boldsymbol{\mu}$, the associated maximum probability $p(\boldsymbol{\mu})$ can be determined from the Gaussian distribution:

$$p(\mathbf{x} = \boldsymbol{\mu}) = \frac{1}{(2\pi\sigma^2)^{20/2}} \exp\left(-\frac{\|\mathbf{x} - \boldsymbol{\mu}\|^2}{2\sigma}\right) = 3.6 \times 10^{-10} \quad (16)$$

and so the lowest possible novelty score, corresponding to this peak in $p(x)$, is $-\log_e p(x) = 21.7$.

It may also be seen from the figure that the novelty scores for all flights during periods B and C exceed the novelty threshold. Flight 134 has the highest novelty score ($-\log_e p(\mathbf{x}) = 68.0$), which corresponds to the occurrence of the major engine problem.

6 CONCLUSION

In this article, we have presented results showing how abnormal behavior during an early flight test of a new three-shaft jet engine may be identified using novelty detection. Two types of vibration feature detectors have been investigated: one, which consists of the vibration levels at harmonically related frequencies and can be computed in real time during a flight; the other, which is a speed-based vibration signature, summarizing the entire flight. Models of normality have been constructed for both representations, following the application of the k-means clustering algorithm to reduce the number of training vectors. Results presented in Section 4 of this article show how the novelty score increased for both the real-time and the end-of-flight summary models, for a test flight during which the development engine surged following the ejection of a loose component. We have also demonstrated how extreme value statistics, which models the tails of the normal data distribution, can be adapted to set a robust novelty threshold for the reliable detection of unexpected events such as the one highlighted in this article.

Chapter 31
Machine Learning Techniques

Fulei Chu, Shengfa Yuan and Zhike Peng
Department of Precision Instruments and Mechanology, Tsinghua University, Beijing, China

1 INTRODUCTION

Condition monitoring and fault diagnosis (CMFD) is a process usually being implemented in aerospace, civil and mechanical structures, etc., to ensure their safe performance [1]. Many researchers in both academia and industry have been engaged in the development of these techniques. In a CMFD system, three basic units are necessary: a signal acquisition unit, a signal analysis unit for fault feature extraction, and a fault classification unit. Recent advances in both hardware and sensor technology mean that signal acquisition with high accuracy and high sampling frequencies is now possible. Attention was therefore turned to the study of how to extract fault features and classify faults from the observed signals. The feature extraction and fault classification are essentially an object-orientated knowledge-acquisition process, and the performances of the CMFD systems are crucially determined by the quantity and quality of the obtained knowledge. Owing to the complexity of modern structures and machines and the continuous emergence of new knowledge, it is hard for the conventional knowledge-acquisition methods (KAMs), where the knowledge is usually gained through the knowledge of engineers, to meet the demand of health monitoring for the modern structures. The deficiencies of the conventional KAMs have promoted the application of machine learning in condition monitoring and fault diagnosis.

Machine learning simulates the learning ability of human by using computers to gain knowledge and skills automatically, and by learning to improve performances continuously and to realize self-improvement. The objective of machine learning is to design some methods that can effectively find the inherent relations in data by learning from the known data, thus predicting the unknown data or judging their characteristics. Therefore, generalization is the most concerned issue for machine learning.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

It is sometimes stated that learning theory is designed to address three main problems [2]:

1. classification, i.e., the association of a class or set label with a set or vector of measured quantities;
2. regression, i.e., the construction of a map between a group of continuous input variables and a continuous output variable based on a set of samples;
3. density estimation, i.e., the estimation of probability density functions from the samples of measured data.

The excellent capability of machine learning in classification makes it to be of great potential in the development of condition monitoring and fault diagnosis. Since direct engagement between machine learning and the fault diagnosis system is the classification, the article is mainly focused on the introduction of implementing machine learning in the fault diagnosis studies as classifier.

2 A BRIEF INTRODUCTION OF MACHINE LEARNING

2.1 The idea of machine learning

From the view of the theory of knowledge, machine learning is very similar to human learning [3]. First, the purposes of both machine learning and human learning are to become intelligent. Secondly, both of them are a knowledge-increasing process. Thirdly, their aims are to understand the objective things and this is also the most essential common ground between machine learning and human learning.

The differences between machine learning and human learning [4] are as follows:

1. Human learning is a long-term process, while machine learning is usually fast and short.
2. Humans are forgetful and can only remember some knowledge but machines can remember all knowledge that it has learned.
3. For human learning, knowledge is untransportable, namely, one person's knowledge cannot be directly copied to another person, but machine learning can copy the learned knowledge to any other system.
4. A distinct characteristic of human learning is generating ideas in a best way, while the ideas obtained by machine learning are usually not the best.
5. The connection and inspiration of humans are hard to be simulated by a machine. Human learning can be of jumping style, while machines always follow rules docilely. This is caused by the different logics followed by human learning and machine learning, respectively.

The essential differences between machine learning and human learning make it impracticable to directly introduce the mechanism of human learning to machine learning. Designing the mechanism of machine learning must take into account the computer specialty and it is necessary to study algorithms for machine learning.

When computers are applied to solve a practical problem, the methods used to derive the desired outputs from a set of inputs usually are required to be able to be described explicitly. However, for solving complex problems, the situations in which there is no method available to compute the desired output from a set of inputs can arise, or the computation may be very expensive [5]. Examples of such situations could be found while modeling a complex chemical reaction, where the precise interactions of the different reactants are generally not known. An effective strategy to solve the problems is to learn the input/output functionality from examples in the similar way of children learning what cars are sport cars simply by being told which cars are sporty rather than by being given a precise specification of sportiness. The approach of using examples to synthesize programs is known as the *learning methodology* and, in the particular case, where the examples are input/output pairs it is called the *supervised learning* [6]. The examples of input/output functionality are referred to as the *training data*.

When an underlying function from inputs to outputs exists, it is referred to as the *target function* [6]. The estimation of the target function learnt by the learning algorithm is known as the *solution of the learning problem*. In the case of the classification, the target function is sometimes referred to as *the decision function.* The solution is chosen from a set of candidate functions that build a map from the input space to the output domain. Usually, a set of candidate functions known as *hypotheses* is chosen before

trying to learn the correct function. Hence, the choice of the set of hypotheses (hypotheses space) [7] is the first important part of the learning strategy. The next important part is the learning algorithm [8], which takes the training data as input and selects a hypothesis from the hypotheses space. When a hypothesis that is consistent with the training data is found, it may not make correct classifications for the unseen data. The ability of a hypothesis to correctly classify the data not in the training set is known as its *generalization* [9]. The learning algorithm is actually a kind of optimization algorithm that can be described in geometric ways or in algebraic ways.

2.2 The key elements of machine learning

Machine learning constitutes of four key elements [9] including the environment, the learning segment, the knowledge base, and the implement segment, as shown in Figure 1.

2.2.1 Environment

The environment is the outside source from which the machine gains knowledge. It includes working objects of the system and their external conditions, such as the diagnosed objects and fault symptoms in the intelligent fault diagnosis systems.

2.2.2 Knowledge base

The knowledge base stores or remembers various kinds of knowledge gained by learning. The knowledge includes

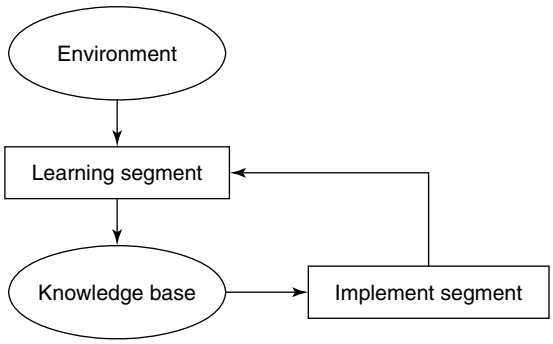

Figure 1. Key elements of machine learning.

1. the object's basic concepts, definitions, theorems, and axioms;
2. laws, rules, and special information of the concrete objects in various conditions;
3. data, information, intermediate result and so on, which can reflect the change in the environments.

2.2.3 Implement segment

The implement segment is also called *working segment* or *decision-making segment*. Using the knowledge stored in the knowledge base, it makes decision or action to complete various work such as the pattern recognition and the expert consultation, and reports the operation results to the learning segment.

2.2.4 Learning segment

The learning segment does searching, control, and logical thinking, such as abstraction, comparison, summarization, synthesizing, and reasoning, to produce, amend, and update the knowledge.

3 REVIEW OF LEARNING METHODS

Machine learning is applied in a wide range of fields and each field has its own characteristics and therefore machine learning methods vary for different fields. Learning methods can be sorted from various aspects or on the basis of different ways. A relatively reasonable way to categorize the machine learning methods is based on the systematicness [3, 9]. Using the systematicness-based way, the machine learning methods can be classified into following categories.

3.1 Inductive learning

Inductive learning [3, 9] is a learning method that derives general rules from the particular cases. Environment provides a series of positive cases and negative cases to the system, and the system conducts the generalization operation with these cases by induction learning and engenders a series of conceptual descriptions. Inductive learning algorithms fall into

two categories: learning from examples and learning from observations and discoveries.

3.2 Analytic learning

Analytic learning [3, 9] applies the domain knowledge to do analysis and learns with one or a few examples. Its main features are as follows: (i) Its inference strategy is deduction rather than induction; (ii) The experiences gained by solving past problems are used to solve new problems or to produce control rules of searching that enables the applications of the domain knowledge to be more effective. The goal of analytic learning is to improve the efficiency of the system rather than to enlarge the range of the concept descriptions. Analytic learning mainly includes the explanation-based learning, the analogy-based learning, and the case-based learning.

3.3 Genetic algorithm and classifier system

Classifier system [3, 9] is a kind of high parallel message-passing rule based systems. It learns by means of the trust-allot and the rule discovering. The genetic algorithms (GAs) [3], which were motivated by the analogy to the biological evolution, provide an effective rule discovering method. Rather than searching from the general-to-specific hypotheses or from the simple-to-complex, GAs generate successor hypotheses by repeatedly mutating and recombining parts of the best-so-far hypotheses. Hypotheses are often described using bit strings whose interpretation depends on the application and, sometimes, may also be described by symbolic expressions or even computer programs. GAs have been applied successfully to a variety of learning tasks and optimization problems.

3.4 Connectionist learning (or neural net)

A connectionist model [3, 9] (neural net) consists of some simple cells similar to the nerve cells and the weighted connections between these cells. Each cell has a state determined by the inputs of other cells to which the cell links. The connectionist model trains the net with different categories of examples and produces internal representations for the net. With the obtained internal representations, other input examples can be identified. Learning is mainly the adjustment of the connection weights. The connectionist learning is nonsymbolic and possesses the ability of the high parallel distributed processing. Neural networks have some disadvantages such as the local optimal solution, the low convergence rate, and the "over-fitting". The neural network methods are based on the empirical risk minimization principle that assumes the sample number is infinite. However, in practice, the sample number is always finite, and the insufficiency of fault samples can make the neural network poor in generalization and, therefore, is a bottleneck problem for the fault diagnosis applications.

4 SUPPORT VECTOR MACHINES

As a principled and very powerful learning method that is based on statistical learning theory, the support vector machines (SVMs) were developed by Vapnik and coworkers [6, 10]. It has already outperformed most other methods in a wide variety of applications in the few years since its introduction. SVMs are especially suitable for the small-sample cases and their aim is to find the optimal solution in the finite available information rather than in the infinite large samples. SVM can satisfactorily overcome the problems of "over-fitting", local optimal solution, and low convergence rate and, moreover, has good generalizations even when the samples are few [11–14].

The basic idea of the pattern recognition with SVM is to project the sample space into a high-dimension *eigenspace*. In the eigenspace, the optimal separating hyperplanes of the original sample set can be found, but the calculation complexity will not increase significantly. In this section, the SVM algorithm and its motivation are briefly described, and the more detailed description of the SVM can be found in [6].

For the typical binary pattern recognition, given a training set $\{(x_1, y_1), \ldots, (x_l, y_l)\}$ where $x_i \in X$ and X is an input vector of l dimension, and $y_i \in \{0, 1\}$ is called *target* or *label*. Symbol H represents the set of all possible hypotheses that may be considered as classification functions by a learning machine.

The notion of shattering is defined as a *set of instances*. Consider a subset of instances $S \subseteq X$. Each hypothesis h from H can impose dichotomy on S by partitioning S into two subsets: $\{x \in S | h(x) = 1\}$ and $\{x \in S | h(x) = 0\}$. Given an instance set S of size $|S|$, there are $2^{|S|}$ possible dichotomies but, however, H may be unable to represent all of them. It is said that H shatters S if every possible dichotomy of S can be represented by the hypothesis from H. Therefore, a set of instances S is shattered by hypothesis space H if and only if for every dichotomy of S there exists some hypothesis in H consistent with it.

The Vapnik–Chervonenkis (VC) dimension d of hypothesis space H defined over instance space X is the size of the largest finite subset of X shattered by H. If arbitrarily large finite sets of X can be shattered by H, then $d \equiv \infty$. The larger the subset of X that can be shattered, the more expressive H is. The VC dimension of H is precisely this measure [3]. VC dimension of the class H measures the richness or flexibility of the function class, which is also often referred to as its *capacity*. Controlling the capacity of a learning system is one way of improving its generalization accuracy [10].

Theorem: Let H be a hypothesis space of VC dimension d. For any probability distribution $\Im$ on $X \times \{-1, 1\}$, with probability $1 - \delta$ over random examples S, any hypothesis $h \in H$ that makes k errors on the training set S has error no more than

$$\underset{\Im}{\text{err}}(h) \leq \varepsilon(l, H, \delta) = \frac{2k}{l} + \frac{4}{l}\left(d \log \frac{2el}{d} + \log \frac{4}{\delta}\right) \tag{1}$$

provided $d \leq l$.

The theorem suggests that a learning algorithm for hypothesis class H should seek to minimize the number of training errors, since everything else in the bound has been fixed by the choice of H. In inductive principle this is known as *empirical risk minimization*, since it seeks to minimize the empirically measured value of the risk functional. The theorem can also be applied to a nested sequence of hypothesis classes

$$H_1 \subset H_2 \subset \cdots \subset H_i \subset \cdots \subset H_M \tag{2}$$

By using δ/M, the probability of any one of the bounds failing to hold would be less than δ. If a hypothesis h_i with minimum training error is sought in each class H_i, then the number of errors k_i that it makes on the fixed training set S will satisfy

$$k_1 \geq k_2 \geq \cdots \geq k_i \geq \cdots \geq k_M \tag{3}$$

while the VC dimension $d_i = \text{VC dim}(H_i)$ is from a nondecreasing sequence. The bound of the above theorem can be used to choose the hypothesis h_i for which the bound is minimal, that is, the reduction in the number of errors (first term) outweighs the increase in the capacity (second term). This induction strategy is known as *structural risk minimization* [10].

The introduction of SVM can start with a simple case of two classes that is linearly separable. Assume a data set

$$D = \{(\mathbf{x}_i, y_i)\}, \quad (i = 1, \ldots, l), \quad y_i \in \{-1, +1\} \tag{4}$$

where $\mathbf{x}_i$ is the input sample and y_i is the output class, y has two values (-1 or $+1$) that stand for two classes, l is the sample number. It is required to determine, among all linear separating planes that can separate the input samples into two classes, which one will have the smallest generalization error. In Figure 2, rings and diamonds stand for the two classes of sample points respectively and H is a separating plane. H_1 and H_2 are the planes that are parallel to H and pass through the sample points closest to H in the two classes. Define the distance between H_1 and H_2 as *margin*. The optimal separating plane that has the smallest generalization error is the one that not only correctly classifies all sample points into the

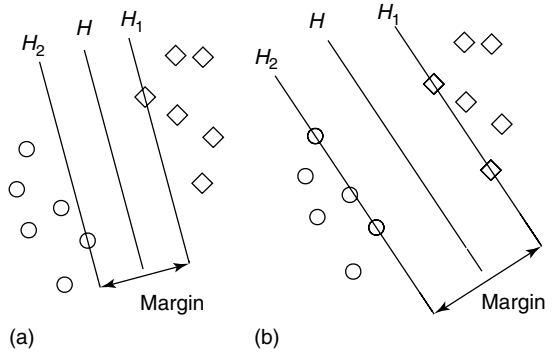

Figure 2. Separating plane with different *margin* (a) and (b). [Reproduced from Ref. 21. © Elsevier, 2006.]

two classes but also has the maximal *margin* between H_1 and H_2.

As a starting point for the analysis and construction of more sophisticated SVMs, the maximal margin classifier is an important concept but, however, it cannot be used in many real-world problems. For example, in the case where the data are noisy, there will in general be no linear separation in the feature space unless very powerful kernels are used. In order to overcome the defect, Vapnik proposed a *soft margin* algorithm to allow some data points misclassified by using the margin slack variables. In the *soft margin* algorithm, the optimal separating plane is a linear classifier that has the classification function as follows [15]:

$$f(\mathbf{x}) = \operatorname{sgn}\left\{\sum_{i=1}^{l} \lambda_i y_i \mathbf{x}^{\mathrm{T}} \mathbf{x}_i + b\right\}, \quad (i = 1, \ldots, l) \tag{5}$$

where sgn( ) is the sign function. If $u > 0$, then $\operatorname{sgn}(u) = 1$; if $u \leq 0$, then $\operatorname{sgn}(u) = -1$. The Lagrange coefficient λ_i is the solution of the following quadratic programming (QP) problem:

$$\begin{aligned} \underset{\mathbf{\Lambda}}{\text{Maximize}}\ W\ (\mathbf{\Lambda}) &= -\mathbf{\Lambda}^{\mathrm{T}}\mathbf{1} + \frac{1}{2}\mathbf{\Lambda}^{\mathrm{T}} D \mathbf{\Lambda} \\ \text{subject to} \quad \mathbf{\Lambda}^{\mathrm{T}} y &= 0 \\ \mathbf{\Lambda} - C &\leq 0 \\ -\mathbf{\Lambda} &\leq 0 \end{aligned} \tag{6}$$

where $(\mathbf{\Lambda})_i = \lambda_i$, $\mathbf{1}_i = 1$ and $D_{ij} = y_i y_j \mathbf{x}_i^{\mathrm{T}} \mathbf{x}_j$, C is a penalty constant for the sample points misclassified by the optimal separating plane. Its role is to strike a proper balance between the calculation complexity and the classifying error. When $C \to +\infty$, it is the ideal case in which all samples are theoretically correctly separated by the optimal separating plane and there is no classifying error at all, but the calculation complexity could be the biggest. It is found that only a few coefficients λ_i are not zero, and since every coefficient λ_i corresponds to a particular sample point, this means that only the sample points with nonzero λ_i determine the optimal separating plane, and only these few sample points called *support vectors* can affect the classification result while other sample points could be removed from the sample set and the optimal separating plane would be almost unaltered. The *support vectors* are usually few in the sample set, and Vapnik has shown that the sample number is proportional to the generalization error of the classifier.

Since there are certain problems in practice that are not linearly separable, SVM has to be developed for the classification of nonlinear problems. By projecting the original sample space into a high-dimension *eigenspace* with a kernel function $K(\mathbf{x}, \mathbf{x}_i)$, the nonlinear separable problem becomes linearly separable in the *eigenspace*. The classification function for the SVM classifier in the eigenspace is shown as follows:

$$f(\mathbf{x}) = \operatorname{sgn}\left\{\sum_{i=1}^{l} \lambda_i y_i K(\mathbf{x}, \mathbf{x}_i) + b\right\} \tag{7}$$

In Table 1 some kernel functions $K(\mathbf{x}, \mathbf{x}_i)$ proposed by Vapnik are listed together with the associated classifiers, which are known to have good properties.

The SVM initially proposed for the two-class pattern recognition is often called as *two-class SVM classifiers*, which can be generalized to the multiclass pattern recognition by some methods. These methods can be summarized into two kinds.

The first one is the multioutput SVM algorithm, which has only one SVM classifier but many outputs. When constructing the classification function, all classes are considered, and the classification function is constructed by revising the optimization functions and constraint conditions used in two-class SVM classifiers. This algorithm has only one SVM classifier but its classification function is very complex and, accordingly, the calculation is very complex as well and the training and recognition is very time-consuming, and therefore the classifying error is big when the number of samples is large [16].

Another kind is to combine some two-class SVM classifiers for the purpose of multiclass pattern

Table 1. Some kernel functions and the type of classifiers defined by them

Kernel function	Type of classifier
$K(\mathbf{x}, \mathbf{x}_i) = (\mathbf{x}^{\mathrm{T}}\mathbf{x}_i + 1)^d$	Polynomial of degree d
$K(\mathbf{x}, \mathbf{x}_i) = \exp(-\lVert\mathbf{x} - \mathbf{x}\rVert^2/2\sigma^2)$	Gaussian radial basis function (RBF)
$K(\mathbf{x}, \mathbf{x}_i) = \tanh(\mathbf{x}^{\mathrm{T}}\mathbf{x}_i + \theta)$	Multilayer perceptron

recognition. This method mainly consists of two submethods as follows.

One is the "one to one" algorithm. This algorithm constructs all two-class SVM classifiers between any two classes; therefore, $k(k-1)/2$ two-class SVM classifiers can be constructed in all for the case of k classes. At the recognition stage, new coming sample $\mathbf{x}$ is input to the established classifier [17]:

$$f^{mn}(\mathbf{x}) = \operatorname{sgn}\left\{\sum_{i=1}^{l} \lambda_i^{mn} y^{mn}{}_i K(\mathbf{x}, \mathbf{x}_i) + b^{mn}\right\} \quad (8)$$

If the classifier shows that $\mathbf{x}$ belongs to the m class, then a ballot is cast for class m. After recognized by all these $k(k-1)/2$ classifiers, $\mathbf{x}$ is then judged to belong to the class that has the most ballots.

Some disadvantages of this algorithm are as follows: (i) the number $k(k-1)/2$ of two-class SVM classifiers increases greatly with the class number k and, consequently, the calculation increases greatly and, moreover, the rates of training and recognition are very slow; (ii) when two or more classes have the same ballots, it is hard to judge which class the new sample $\mathbf{x}$ belongs to; (iii) there is at least a class that has the most ballots; therefore, a new sample $\mathbf{x}$ that does not belong to any of the k classes would be misjudged to belong to them and therefore the wrong classification rises.

The other submethod is the "one to rest" algorithm. This algorithm takes each class, e.g., class m of these k classes as a separate category and the rest $k-1$ classes as another category and then constructs a two-class SVM classifier and names it as SVM m. In this way, k two-class SVM classifiers can be constructed in all. The classification function of SVM m is as follows:

$$f^{m}(\mathbf{x}) = \operatorname{sgn}\left\{\sum_{i=1}^{l} \lambda_i^{m} y^{m}{}_i K(\mathbf{x}, \mathbf{x}_i) + b^{m}\right\} \quad (9)$$

At the recognition stage, the new sample $\mathbf{x}$ is input to all the obtained k classifiers SVM m ($m = 1, \ldots, k$). There are k outputs in all. The new sample $\mathbf{x}$ is judged to belong to the class whose corresponding classifier has the largest output [18].

The disadvantages of this algorithm are as follows: (i) all samples have to be taken into the training of the k classifiers and, in the recognition stage, the classification result can be obtained only after the new sample $\mathbf{x}$ has been recognized by all these k classifiers. Therefore the calculation is very time consuming and the rate of training and recognition is slow as well; (ii) it also shares the disadvantages (ii) and (iii) of the above algorithm [11, 14, 19, 20].

5 THE MACHINE-LEARNING-BASED FAULT DIAGNOSIS SYSTEM

For many kinds of complicated machines like turbopump rotors [21], it is difficult to use the mathematical model to describe their faults. Artificial intelligence methods [3–5], which do not involve mathematical models, have been widely used in the fault diagnosis in the recent years, especially in the fault diagnosis for dynamic procedures such as the starting, the stopping, and the changing of working mode. Knowledge is the foundation of artificial intelligence. Generally, there are two ways to obtain knowledge. One is that knowledge is induced and sorted by human, and is input to the computer in acceptable and processible forms. Expert systems usually adopt this way. The other is that computers are endowed with the ability of self-learning, called *machine learning*. For many complicated machines, knowledge sources are not rich and, therefore, knowledge acquisition is very difficult but extremely necessary. Machine learning can acquire knowledge beyond human ability, learn new knowledge with the changing of environment, and improve itself automatically with experience.

5.1 The framework of the machine-learning-based fault diagnosis system

The framework [21] of the machine-learning-based fault diagnosis system is shown in Figure 3. Four modules are used: the signal preprocessing module, the feature extraction module, the training module, and the recognition module.

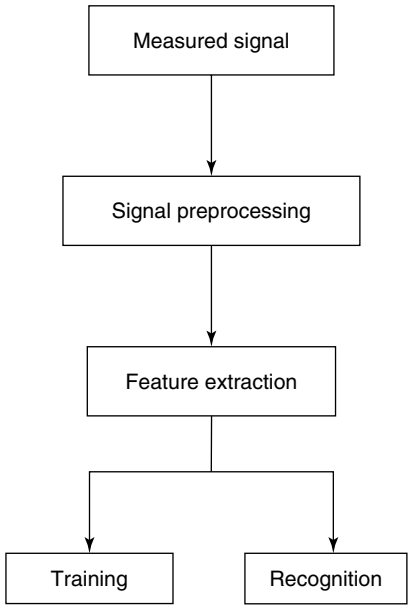

Figure 3. Pattern-recognition-based fault diagnosis system. [Reproduced from Ref. 21. © Elsevier, 2006.]

5.2 Signal preprocessing

Signal processing is important for condition monitoring and fault diagnostics, which aims at finding a simple and effective transform to the original signals. Therefore, the important information contained in the signals can be seen and then the dominant features of signals can be extracted for fault diagnostics. Various signal processing methods are available including the most popular method—Fourier transform [4], and the wavelet transform [5] and so on.

5.3 Feature extraction

Fault feature vectors often are of multiple dimensions and consist of a number of variables, between which there exist correlations and redundancies. To eliminate the redundancies and to be convenient for the classification, feature selection methods are often employed, such as principal component analysis (PCA) [4]. By these methods, the fault feature vectors with high dimension can be transformed to the low dimension vectors that preserve enough information in the raw fault feature vectors and, therefore they should be adequate to present the system.

5.4 Training

After obtained the fault features, the next step is the pattern classification (or training). For many complicated machines like the turbo-pump rotor, it is difficult to use the mathematical model to explicitly describe the faults. On the other hand, the machine learning does not involve the mathematical models and it can learn the input (fault features)/output (fault types) functionality from examples.

5.5 Recognition

When a machine learning system has been trained, it obtains the knowledge related to the faults. When a new coming fault feature is inputted to this machine learning system, the machine learning system can recognize the fault type of this fault feature. It is called *diagnosis process*. In addition, to avoid the situation that a normal state is recognized as a fault by the machine learning system, normal features are required to be used to train the machine learning system together with the fault features; therefore, the machine learning system can judge whether the object is normal or not.

6 APPLICATION OF SVMs IN TURBO-PUMP FAULT DIAGNOSTICS

Turbo-pump rotors are complicated machines whose working condition is special. Faults frequently occur on the turbo-pump rotors, and some of them are quite dangerous. Fault diagnosis technique for the turbo-pump rotor is therefore very important. Table 2 shows 14 familiar fault patterns of the turbo-pump rotors, based on which the "one to others" SVM algorithm is used to construct 13 two-class SVM classifiers. These 13 two-class SVM classifiers are ranged as a binary tree in terms of the fault priority where more common or more dangerous faults are placed with precedence, and then they form a multiclass fault diagnosis system as shown in Figure 4. The Gaussian function $K(\mathbf{x}, \mathbf{x}_i) = \exp(-\|\mathbf{x} - \mathbf{x}_i\|^2/2\sigma^2)$ is chosen as the kernel function. Vapnik has shown that different kernel functions used make only slight differences to the classification results.

Table 2. Fault patterns of turbo-pump rotor and vibration energy distribution

	Fault pattern	Frequency band (f_r is the frequency of rotor rotation)								
		$<0.4f_r$	$0.4-0.49f_r$	$0.5f_r$	$0.51-0.99f_r$	$1.0f_r$	$2.0f_r$	$3.0-5.0f_r$	$>5.0f_r$	Mesh frequency
1	Gear damage	—	—	—	—	0.22	—	—	—	0.82
2	Structure resonance	0.21	0.27	—	—	0.51	0.11	—	—	—
3	Rotor radial touch friction	0.13	0.04	0.04	0.12	0.31	0.11	0.11	0.11	—
4	Rotor axial touch friction	0.04	0.04	0.04	0.11	0.32	0.22	0.15	0.16	—

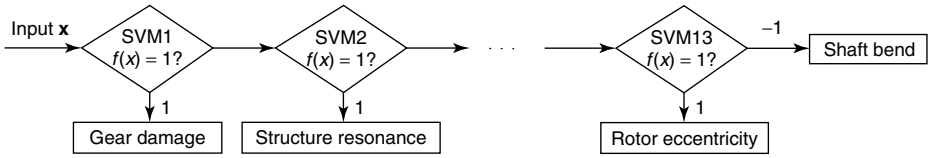

Figure 4. "One to others" multiclass fault diagnosis system. [Reproduced from Ref. 21. © Elsevier, 2006.]

By PCA, nine-dimensional fault feature vectors are transformed to two-dimensional fault feature vectors. Some of the obtained two-dimensional fault feature vectors are shown in Figure 5, where rings, triangles, diamonds and several other graphics denote the feature data for different faults. It is evident that they are classifiable. The two-dimensional vectors possess more than 80% information contained by the original nine-dimensional fault feature vectors. Therefore, they are adequate to present the system.

After the training procedure, the obtained 13 two-class SVM classifiers produce 13 optimal separating planes. The area I, II, III, ..., XIV are associated to the 14 kinds of faults respectively. The classification results in Figure 6 show that "one to others" SVM algorithm has classified 240 data into 14 kinds of faults accurately, and there are no reject regions.

When a new coming fault sample **x** is to be recognized by the "one to others" multiclass fault diagnosis system, its two-dimension feature data is first input to SVM1 in Figure 4; if the output of SVM1 is 1, then the new sample **x** is recognized as the fault "gear damage" and the recognition is finished; or if the output of SVM1 is −1, then

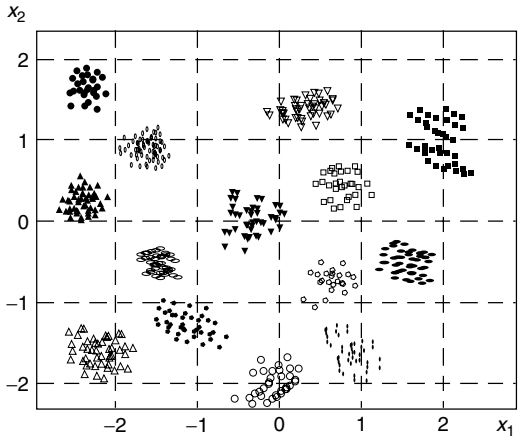

Figure 5. Two-dimensional fault feature vectors. [Reproduced from Ref. 21. © Elsevier, 2006.]

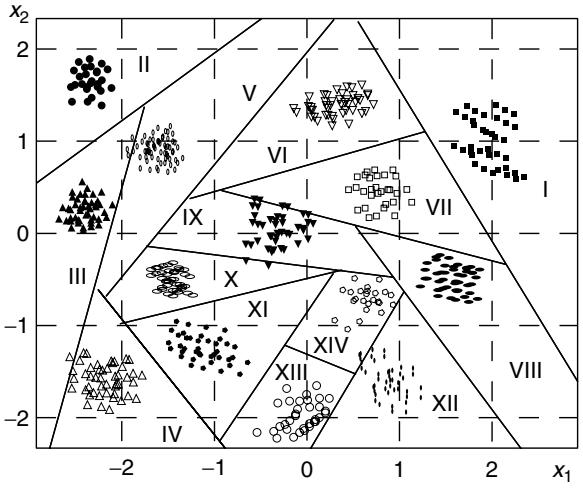

Figure 6. Optimal separating hyperplane of SVM. [Reproduced from Ref. 21. © Elsevier, 2006.]

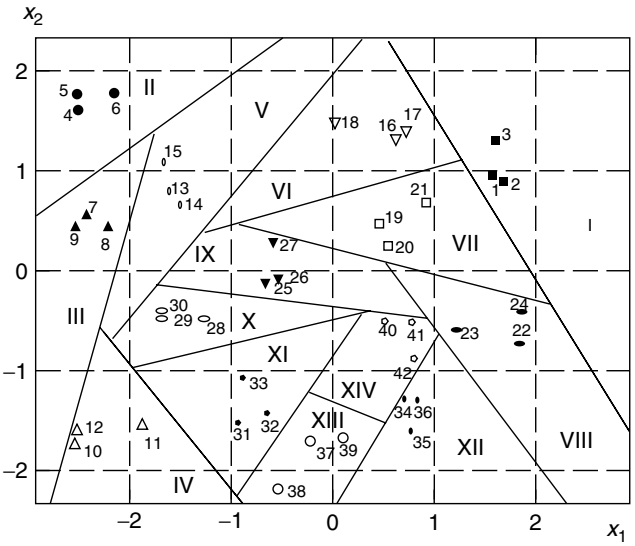

Figure 7. Recognition results. [Reproduced from Ref. 21. © Elsevier, 2006.]

the feature data of **x** is automatically transferred to SVM2; and so on.

To test the generalization ability, 42 samples that have not been used in the training stage have been input to the "one to others" multiclass fault diagnosis system. The nine-dimension data of the 42 samples have been transformed to two-dimension data by PCA method. Since they are testing samples, their fault types are known as *prior*. Figure 7 shows the recognition results of the "one to others" multiclass fault diagnosis system.

The positions of the 42 testing samples in Figure 7 clearly tell which type of faults they belong to, and the recognition results are consistent with the actual

fault types. This verifies that the "one to others" SVM algorithm can correctly recognize the fault samples.

To compare the "one to others" SVM algorithm with other algorithms, five different algorithms including one to rest SVM, one to one SVM, one to others SVM, RBF neural net, and back propagation (BP) neural net are used to diagnose 14 kinds of faults in Table 2 using the exact same fault samples. By averaging 10 best results for each algorithm, average diagnosis accuracies are 93, 96, 88, 83%, respectively, for the methods of one to rest SVM, one to one SVM, RBF neural net and BP neural net, and the average relative diagnosis time is 82, 100, 70, 65%, respectively, for the above four different methods, while the average diagnosis accuracy is 97% and the average relative diagnosis time is 54% for the method of "one to others" SVM. Therefore, the "one to others" SVM algorithm turns out to be the most effective one as it has the shortest diagnosis time and the highest accuracy.

A problem in the practical application of SVM is how to select some SVM parameters so that the performance of SVM can be the best. These SVM parameters mainly include the penalty constant C, the relaxation factor ξ, and the parameters in the kernel function, for instance, the width parameter σ in RBF kernel function. These parameters affect the SVM performance more or less. Up to now, there is no effective method to determine these SVM parameters. Generally, the cross verification trial or the gradient step-down operation is used to select them, but these methods depend on human experiences too much or require the kernel function to be continuously differentiable and, therefore, the resulted SVM classifier is likely to fall into the local minimum. These problems present an obstacle to the more effective application of the SVM.

Moreover, in the real fault diagnosis application, the use of dimensionality-reducing methods such as PCA to extract the fault features might lead to the loss of useful information while discarding some redundant variables. In addition, when there are many fault-correlated variables, the number of principal components gained by PCA could be still large if enough fault messages are to be retained. The great number of principal components would equally bring in many irrelevant messages and consequently reduce the efficiency of the fault diagnosis system. Therefore, more efficient feature selection methods must be developed. In order to overcome the shortcomings mentioned above, an attempt is made to jointly optimize the feature selection and the SVM parameters with GAs to improve the SVM performance that is taken as the target function in the optimization.

The performance of SVM is mainly referred to its generalization capability, namely the capability of recognizing new data that mainly consists of three indexes: error ratio $E_{\xi\alpha}$, recall ratio $R_{\xi\alpha}$, and accuracy ratio $P_{\xi\alpha}$. Here, a correct ratio $E = 1 - E_{\xi\alpha}$ is suggested to estimate the performance of the SVM [22, 23].

In the training of SVM, the proper choice of the kernel function is very important, which is closely related to the complexity of the classification functions set and can affect the performance of SVM. Two most commonly used kernel function in SVM is the Gaussian function $K_{\mathrm{RBF}}(x_i, x_j) = \exp\left(-\|x_i - x_j\|^2/\sigma^2\right)$ and the polynomial function $K_{\mathrm{poly}}(x_i, x_j) = (x_i{}^{\mathrm{T}} x_j + 1)^d$, where x_i and x_j are vectors in the input space, σ and d are the parameters of the Gauss function and the polynomial function, respectively. The ability of a single kernel function to improve the performance of SVM is limited, and a parameter λ is introduced to construct a mixture kernel function:

$$K_{\mathrm{mix}}(x_i, x_j) = \lambda K_{\mathrm{RBF}}(x_i, x_j) + (1 - \lambda) K_{\mathrm{poly}}(x_i, x_j), \quad 0 \le \lambda \le 1 \tag{10}$$

The penalty constant C in SVM makes a considerable influence on the performance of SVM, and it decides the complexity of the SVM model and the penalty degree to those sample points misclassified by the optimal separating plane. When C is too big or too small, the generalization capability of SVM can be weakened [24, 25]. For unevenly distributed data, using different penalty constants for each class could reduce the real risk. For the binary classification, the penalty constants for each class are used as C_+ and C_-.

The relaxation factor ξ in SVM indicates the error expectation in the classification process. The value of ξ affects the number of *support vectors* generated by the SVM classifier. When ξ is too big, the number is small, but the classification error is high, and vice versa [26–28].

Combining the above parameters, the training model of SVM can be established as

$$\begin{aligned} \boldsymbol{M} &= \{\lambda, \sigma, d, C_+, C_-, \xi\} \\ & 0 \le \lambda \le 1, \sigma, d, C_+, C_- \ge 0 \end{aligned} \tag{11}$$

The SVM performance E is taken as the target function in the optimization of the training model of SVM, which can be described as

$$\begin{aligned} &\max_{M} E(\boldsymbol{M}) \\ \text{s.t.} \quad &\boldsymbol{M} = \{\lambda, \sigma, d, C_+, C_-, \xi\} \\ & 0 \le \lambda \ge 1, \sigma, d, C_+, C_-, \xi \ge 0 \end{aligned} \tag{12}$$

For a feature set $F = \{f_1, f_2, \ldots, f_i \ldots, f_N\}$, where N is the size of the feature set and f_i is a feature. The following binary vector is introduced to denote the feature selection: $\boldsymbol{S} = \{s_1, s_2, \ldots, s_i, \ldots, s_N\}$, $s_i \in \{0, 1\}, i = 1, \ldots, N$. The values 0 and 1 for s_i stand for whether the corresponding feature f_i in $\boldsymbol{F}$ is selected or not. Considering the SVM performance E as the target function, the optimization problem of the feature selection can be expressed as

$$\begin{aligned} &\max_{S} E(\boldsymbol{S}) \\ \text{s.t.} \quad &\boldsymbol{S} = \{s_1, s_2, \ldots, s_i \ldots, s_N\} \\ & s_i \in \{0, 1\}, i = 1, \ldots, N \end{aligned} \tag{13}$$

The training model $\boldsymbol{M}$ of SVM must be given in advance before optimizing the feature selection $\boldsymbol{S}$, and the feature selection $\boldsymbol{S}$ must be done before optimizing the training model $\boldsymbol{M}$. Since the optimization targets in formulas (11) and (13) are all to improve the SVM performance E, the feature selection $\boldsymbol{S}$ and the training model $\boldsymbol{M}$ can be jointly optimized at the same time, which can be expressed as follows:

$$\begin{aligned} &\max_{M} E(\boldsymbol{S}, \boldsymbol{M}) \\ \text{s.t.} \quad &\boldsymbol{S} = \{s_1, s_2, \ldots, s_N\}, s_i \in \{0, 1\}, \ i = 1, \ldots, N \\ &\boldsymbol{M} = \{\lambda, \sigma, d, C_+, C_-, \xi\} \\ & 0 \le \lambda \ge 1, \sigma, d, C_+, C_-, \xi \ge 0 \end{aligned} \tag{14}$$

where $(\boldsymbol{S}, \boldsymbol{M})$ is a hybrid vector that jointly describes the feature selection and the training model of SVM. This joint optimization problem can be solved by GAs. The optimization of $\boldsymbol{S}$ and $\boldsymbol{M}$ are mutually correlated.

With the above experimental data, the feature selection and SVM are first optimized separately and then optimized jointly. The comparison results of the diagnosis of fault 1 (gear damage) are shown in Figure 8. Cases 1–4 are the results obtained using the optimized SVM and the nonoptimized feature selection, the optimized feature selection and the nonoptimized SVM, the jointly optimized feature selection and SVM and no further optimization, respectively. It can be seen that both the separate optimization and the joint optimization on the feature selection and the SVM can improve the SVM performance E. The joint optimization improves the E most and has the fastest convergence and, in addition, solely optimizing the feature selection can improve the E better than solely optimizing the SVM [29, 30].

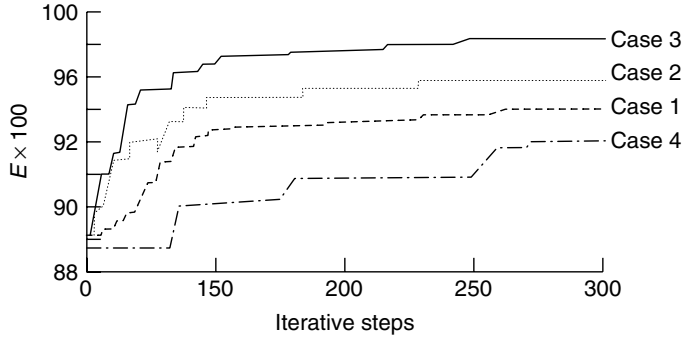

Figure 8. Optimization results with GAs.

7 CONCLUSIONS AND REMARKS

Owing to the complexity of modern structures and machines, the conventional knowledge engineer based knowledge-acquisition methods are no longer able to meet the demands of the condition monitoring and fault diagnosis for modern structures and machines. More sophisticated knowledge-acquisition methods are therefore expected. Machine learning, which is a significant development in the artificial intelligence in recent years, has already shown excellent capability in discovering knowledge from observed data through constructing computational relationships between quantities on the basis of observed data and rules. Especially, it is expected that the machine learning can greatly promote the development of the condition monitoring and fault diagnosis as it has the excellent capability of classification, and the performances of classifier play a crucial role in the condition monitoring and fault diagnosis system. This article has given an outline to machine learning including the background and some key algorithms and theories that form the core of machine learning. More efforts have been made to the introduction of SVM and an application example of using SVM to successfully conduct fault diagnosis on a turbo-pump rotor, with which the great potential of the machine learning in fault diagnosis has been validated.

Risk Monitoring of Aircraft Fatigue Damage Evolution at Critical Locations

Michael Shiao

Airport and Aircraft Safety Group, Aviation Research & Development Office, Federal Aviation Administration, Atlantic City International Airport, NJ, USA

1 INTRODUCTION

Traditionally, structural health of aircraft is monitored by scheduled or unscheduled inspections using nondestructive inspection (NDI) methods. However, human error, cost of inspections, reliability of crack detection, damage inspectability, etc., motivate the development of automated inspection techniques. Recent development in structural health monitoring (SHM) via on-board surface or embedded sensor systems allows continual NDIs for aircraft airworthiness. One key element for risk monitoring of aircraft fatigue damage is to characterize the damage evolution due to fatigue. In the Encylopedia, there are several articles also discuss the damage evolutionary process in a structure (*see* **Damage Evolution Phenomena and Models** and **Fatigue Life Assessment of Structures**). For metallic structures, damage tolerance (DT) analysis has been developed. The DT approach recognizes the existence of initial anomalies or flaws and incorporates inspection and repair/replacement as an important method to sustain structural reliability and safety.

The DT approach complements SHM and provides updated damage information for proper maintenance actions. It also provides SHM with the ability to forecast and update the risk using the information from damage monitoring.

For fatigue damage risk management, probabilistic DT analysis is one of the methods to predict the risk and to characterize the uncertain damage state of structures associated with damage initiation, accumulation, inspection, detection, and other maintenance

ISBN: 978-0-470-05822-0.

effects. However, there are several difficult issues in the DT approach that need to be addressed.

- **Assumptions of initial flaw sizes and other uncertainties in the DT models**

Assuming a deterministic flaw size is not realistic and the reliability of the design cannot be quantified. On the other hand, the initial flaw sizes are often too small to be detected by NDI tools or on-board SHM systems, and it is practically impossible to develop initial flaw-size probability distributions with confidence. To address the issue, a common approach is to use measurable defects at a later time, such as from a teardown inspection, and apply fracture mechanics crack growth models to back-extrapolate the defect sizes to develop the equivalent initial flaw size (EIFS). However, it is well known that the EIFS derived under a specific condition is not suitable for different geometries or loading conditions.

- **Uncertainties and sensitivities of NDI methods and advanced on-board SHM systems**

Characterizing NDI capability and sensitivity using probability of detection (PoD) is a well-accepted approach for conventional off-board NDI methods. PoD obtained for conventional off-board NDI methods represents the inspection reliability due to device sensitivity and variability; inspectors' physical and mental conditions; detection variability due to component geometry, defect shape, size, location, orientation, effect of operating environments, etc. To improve the inspection reliability, one can use on-board sensors for automated inspection on the fatigue hot spot and to eliminate human error.

The concept of a PoD curve is still viable for on-board sensors. The PoD curve for a particular on-board sensor of a specific manufacturing and application process needs to be developed. A PoD curve for a sensor indicates that not all sensors are manufactured and operated identically; there is variation in the detectability between sensors. For example, the PoD for an on-board sensor would be developed on the basis of the manufacturing process of the sensor, the corresponding electronics, and the *in situ* environment of application. Development of the PoD would involve a test article with multiple sensors and a series of cracks of various sizes. Multiple test articles would be used to determine the PoD as a function of crack sizes. Potentially, in the future, computational methods incorporating the physics of the sensor mechanics, structural mechanics, and probabilistic methods will be used to develop computational PoD curves [1].

- **Inspection schedule and frequency**

The simplest approach to select inspection intervals is to divide the service time by an integer and use equal intervals for conventional NDI methods. Clearly, this would not be optimal, as the best inspection intervals should reflect the fact that the defect growth rate is nonlinear, and it is also more effective to detect defects when they are easily detectable, but before they are near critical sizes. For on-board sensors, owing to their continual inspection feature, the question will be when to assess the data obtained from the continued monitoring. When an on-board sensor is installed, inspection frequency can be drastically increased, since cost incurred for manual inspection is of no concern. However, inspection dependency needs to be carefully investigated. Using conventional NDI methods, inspections are assumed to be independent of one another since the inspection process is a result of many independent probabilistic events. However, the continual inspections become highly correlated for advanced SHM systems since a specific SHM system, with known detection sensitivity, is used repeatedly throughout the aircraft life.

- **Maintenance-induced damage and quality of repairs and replacements**

When damage is detected, repair should follow immediately. It has been recognized that poor repair quality may cause future aircraft failure. In addition, there have been reports regarding maintenance-induced damage. Although in many risk analyses repair quality is assumed to be perfect for computational simplicity, repair quality may play an important role in probabilistic risk assessment when inspection and repair frequency increase.

In this article, a probabilistic framework for the risk forecasting and updating and associated methodologies are described. The framework includes risk forecasting probabilistic algorithms considering the uncertainties in inspection sensitivity, repair quality, fatigue crack growth characterization, and risk updating using updated uncertainties by Bayesian updating approach. Risk forecasting is based on the integration

of damage accumulation methodology, simulation-based probabilistic methods for uninspected structures, and special probabilistic algorithms to account for uncertainties associated with materials, structures, and loadings/environments, as well as uncertainties related to maintenance practices, such as inspection scheduling and techniques, replacement and retirement decisions, and repair quality (including maintenance-induced damage). The measured damage information through scheduled, nonscheduled, or continual inspection is used to update prior knowledge of uncertainties and hence improve the risk prediction.

2 PROBABILISTIC FRAMEWORK FOR RISK FORECASTING

The framework, illustrated in Figure 1, includes a wide range of uncertainties including:

- random or uncertain parameters in material (e.g., crack growth threshold, modulus of elasticity, fracture toughness);
- defect or flaw (including size, shape, and location, and the frequency of occurrence);
- loading, type of usage (with frequency of occurrence);
- finite-element model (including modeling error);
- crack growth model (including modeling error);
- maintenance (including inspection schedules, frequency of inspections, PoD curves, repair/replacement methods, and effects).

In the following, we discuss the maintenance event tree and repair quality modeling first, since they are the main reason risk forecasting using SHM is computationally challenging. It is followed by the discussion of probabilistic methods for risk prediction.

2.1 Maintenance event tree

In the case of damage accumulation processes, it may be uneconomical to design a structure in such a way that the reliability is sufficient for an entire design life. A more economical solution can be obtained by establishing a maintenance scheme. In

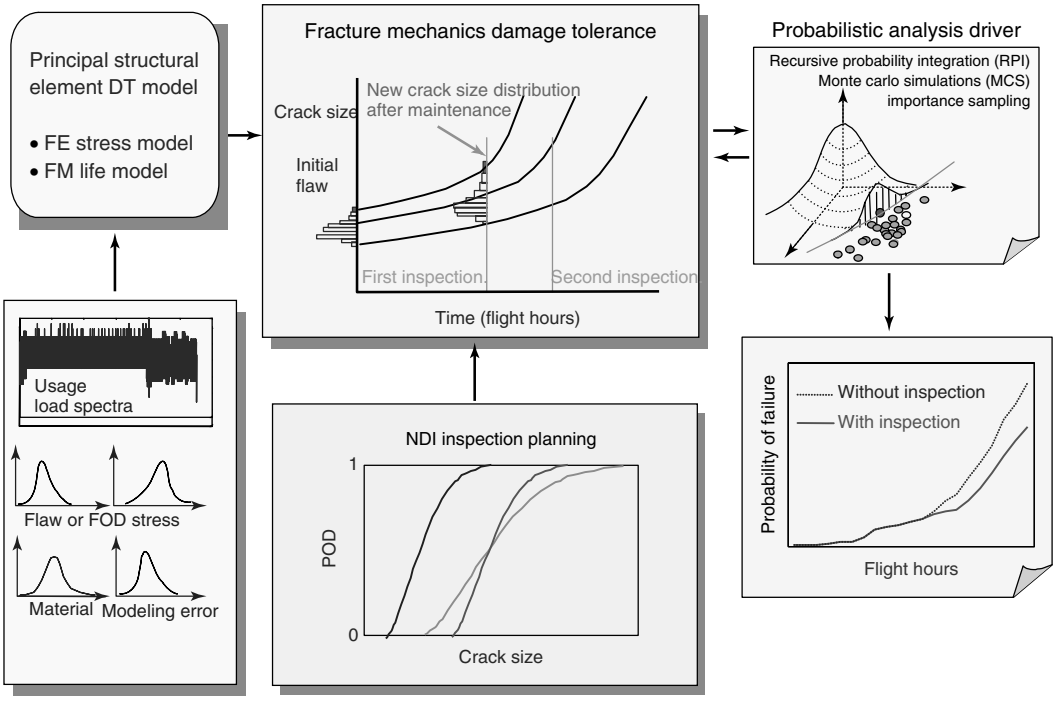

Figure 1. Probabilistic framework for risk forecasting.

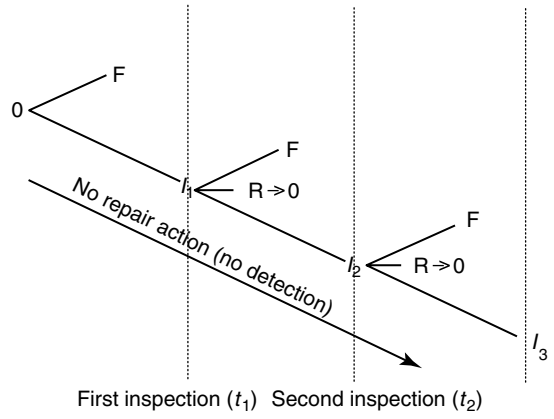

Figure 2. Maintenance event tree.

these cases, failures will not occur if the inspection detects damages and repair action is taken immediately. The sequence of inspection and repair events can be represented in an event tree, as shown in Figure 2.

Let the first inspection I_1 be planned at time t_1. At this node, there exists a branch with three possible events: (i) event of failure F—a failure occurs before t_2, (ii) event of repair R—the inspection detects a serious defect and repair is conducted, and (iii) event of no-finding I_2—no serious defect is detected and the next inspection at $t = t_2$ is planned. When a detected defect has been repaired, a new sequence is started and a new branch is generated at the next inspection.

2.2 Repair quality modeling

Perfect repair is unlikely. Often, field repair may produce inferior quality owing to insufficient equipment, inability to acquire high-quality materials on time, poor repair skills, etc. In addition, repair most often removes the crack tip of the propagating crack, yet it often leaves behind potential initiation sites for cracks to grow during future operation. For these reasons, assuming a perfectly repaired structure may be unconservative.

In general, a postrepair crack size distribution that is worse than that of the original parts has to be estimated. Berens *et al.* [2] used the equivalent repair quality to quantify the possible repair flaws inherited in the structure after repair. Although the effect of repair quality on the failure probability is not immediate, it can have a major effect on aging structures. In addition, the effect of the potential maintenance-induced damage should be modeled by further adjusting the postrepair crack size distribution.

2.3 Probabilistic methods for SHM using conventional NDI methods

In the last decade, several probabilistic methods and associated software have been developed for DT applications, considering uncertainties and inspection planning. While each of the methods works well for the damage scenario considered and the uncertainty model adopted, these methods are limited in their ability to solve general problems. Therefore, general and accurate methods are needed for DT analysis with maintenance planning under various uncertainties, including EIFS and location, material properties, loads and environmental effects, inspection scheduling, PoD, and repair quality and frequency.

Monte Carlo simulation (MCS) offers the most robust and reliable solution framework for general problems. The major issue is that MCS is usually time consuming. For maintenance planning and risk monitoring, the computational issue is further amplified because the conventional approach requires an MCS for each different maintenance plan. As a result, many sets of MCSs are required to search for the optimal solution by exploring the design space that consists of many possible combinations of inspection scheduling, techniques, and repair/replacement/retirement strategies.

To relieve the computational burden of traditional MCS methods and to further reduce the computational time for generating many sets of crack growth histories for maintenance planning, this article describes an efficient method that combines the generality of MCS with the efficiency of analytical probabilistic methods. The core of the method is a recursive probability integration (RPI) method that allows repeated use of baseline MCS-based crack growth histories for various maintenance plans. The fundamental concept of RPI is based on branching out the probable events after each maintenance action following an inspection where the PoD is applied. The probability of occurrence of each branched event is then determined on the basis of the probability of crack detection. In addition to allowing the reuse of

crack growth histories, RPI has an additional benefit of improving the MCS sampling efficiency, especially when a maintenance plan significantly reduces the probability of failure. When the RPI algorithm is used, inspections are assumed to be independent. This assumption is appropriate for the traditional NDIs, i.e., different operators, equipment, and locations, and widely separated by the time of inspections, but may not be so for on-board sensors.

The MCS-based RPI method randomizes non-inspection-related random variables only and has been demonstrated to be several orders of magnitude faster than traditional MCS methods, which randomize all uncertain random variables [3, 4]. The computational efficiency can be further improved by a combination of the RPI method and the conditional expectation method (CEM) [5, 6]. Both methods, as well as the proposed analysis procedure, are described in detail in the following sections.

2.3.1 MCS-based recursive probability integration method

Figure 3 shows the possible fatigue crack growth paths from an MCS without inspections. Failure of each fatigue path is indicated by the cross symbol for any failure requirement, such as net section yield, reaching critical crack size, or fracture. To illustrate the RPI concept using a graphical presentation for clarity, Figure 4 shows fatigue life simulations without inspections. In the figure, the horizontal line indicates the beginning and end of fatigue life of a simulation without inspection. This line is called the *fatigue path*, since it implicitly represents the fatigue crack growth path from the beginning to the end.

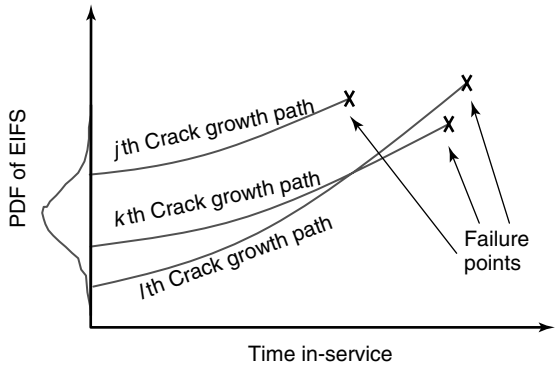

Figure 3. Fatigue life and fatigue crack growth paths without inspection.

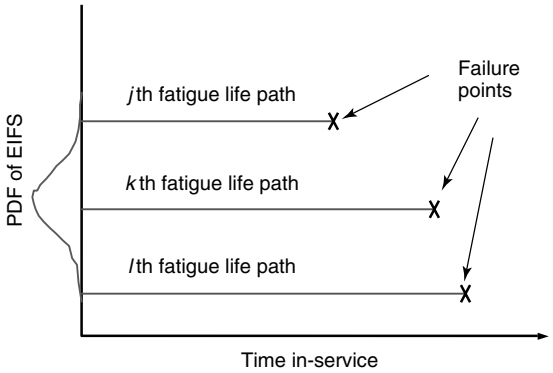

Figure 4. Fatigue life paths without inspection.

Now let us investigate the probability calculation. When n simulations are conducted in an MCS, the probability of occurrence of each path (simulation) is $1/n$. The conditional probability of failure of jth fatigue (simulation) path, given the occurrence of this path, ${P_f}^c(j)$, is defined by equation (1), where c stands for conditional.

$$\begin{aligned} {P_f}^c(j) &= 0 \quad j\text{th fatigue life} > \text{design life} \\ {P_f}^c(j) &= 1 \quad j\text{th fatigue life} < \text{design life} \end{aligned} \tag{1}$$

The probability of failure for an MCS without inspection can be obtained by equation (2).

$$P_f = \frac{1}{n}\sum_{j=1}^{n} {P_f}^c(j) \tag{2}$$

Now let us add one inspection to the analysis. Figure 5 shows an inspection at time t that is conducted on the jth fatigue path.

The crack size at the time of inspection is denoted as $a(j,t)$. Owing to the inspection, the jth fatigue path will branch out to two possible paths. If the crack is not detected, the jth fatigue path will continue its original fatigue path as indicated by path 1 in Figure 5. When a crack is detected and repaired immediately, the following path can be either one of the multiple repair paths, indicated by path 2 in Figure 5. As a result of probability branching, ${P_f}^c(j)$ in equation (2) needs to be updated accordingly by equation (3).

$$\begin{aligned} P_f^c(j) = {} & PoD(a(j,t)) \times P_f(\text{path 1}) \\ & + (1 - PoD(a(j,t))) \times P_f(\text{path 2}) \end{aligned} \tag{3}$$

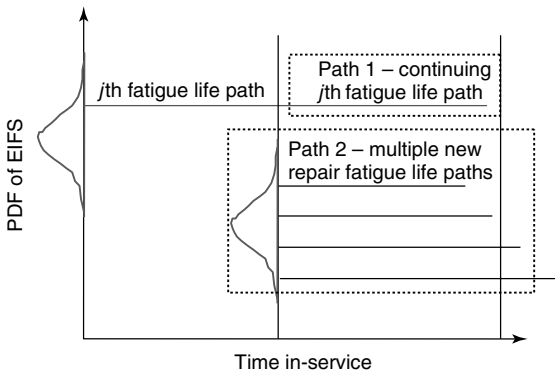

Figure 5. Probabilistic branching due to inspection and repair.

$PoD(a(j,t))$ is the PoD of crack size $a(j,t)$. P_f(path 1) is the conditional probability of failure of the original (jth) fatigue path, as defined in equation (1). P_f(path 2) is the probability of failure of repair paths, which can be determined by an MCS without inspection starting at the time of inspection using equations (1) and (2). Once $P_f{}^c(j)$ is updated by equation (3), the probability of failure with one inspection can be computed by equation (2). Using the same analogy, probability of failure for multiple inspections can be derived. Several key parameters used for RPI are defined below and illustrated in Figure 6.

t_s: service life (or design life);
m: number of inspections;
$MCS(k)$: an MCS without inspections starting at the kth inspection, where $k = 0$ to m; $k = 0$, representing simulations with original parts; and $k > 0$, representing simulations with repair parts;
n_k: number of simulations for $MCS(k)$;
$t_f(k, j)$: fatigue life of the jth simulation of $MCS(k)$;
$a(k, j, i)$: the crack size at the ith inspection of the jth fatigue path of $MCS(k)$; $k = 0$ to m; $j = 1$ to n_k; for each k, $i = k + 1$ to m;
Full Path i: a probability event consists of complete fatigue paths of an MCS considering subsequent inspections starting at the ith inspection, $i = 0$ to m;
$Br(k, j, i)$: a branched probability event consists of all possible fatigue paths of an MCS considering subsequent inspections starting at the ith inspection with the following conditions.

The initial condition of the fatigue branch $Br(k, j, i)$ is inherent from the condition at the ith inspection of the jth fatigue path of $MCS(k)$ where $k = 0$ to m; for each $k, i = k$ to $m - 1$; for a pair of k and i, $Br(k, j, i)$ consists of fatigue branch $Br(k, j, i + 1)$ and *Full Path*$(i + 1)$

Figure 6 shows a full repair path starting at the $(m - 2)$th inspection. The dashed line represents the jth fatigue path of $MCS(m - 2)$, and the circle indicates that an inspection has been conducted along this path. A diamond indicates that a repair action has been taken after detecting a crack. The solid line with a diamond at the beginning and an arrow at the end represents an MCS considering subsequent inspections. It also represents a Full Path starting at the time indicated by the diamond.

Figure 6 also shows that $Br(m - 2, j, m - 2)$ consists of a single (jth) realization of $MCS(m - 2)$ and two possible branched probability events, *Full Path*$(m - 1)$ and *Full Path*(m), after subsequent inspections along this realization. From the definition of Full Path, *Full Path*$(m - 2)$ is also represented

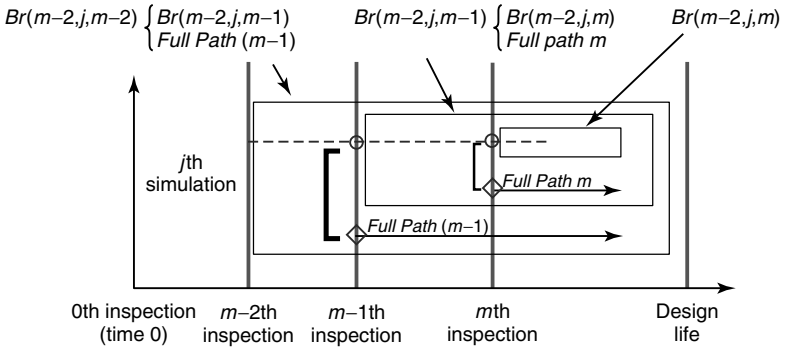

Figure 6. *Full Path*$(m - 2)$ with two subsequent inspections.

by the probability events $Br(m-2, j, m-2)$, where $j = 1, n_{m-2}$. The following are also shown in Figure 6: $Br(m-2, j, m-2)$ consists of $Br(m-2, j, m-1)$ and the *Full Path*$(m-1)$, $Br(m-2, j, m-1)$ consists of $Br(m-2, j, m)$ and the *Full Path* m, and $Br(m-2, j, m)$ represents the last segment of the jth fatigue path of $MCS(m-2)$.

Now let us follow the jth simulation path to investigate the probability of occurrence of each probability event. At the $(m-1)$th inspection, if a crack is detected and a repair action is taken, the probability of occurrence of a repair action (or *Full Path*$(m-1)$) is equal to the PoD for the crack size $a(m-2, j, m-1)$. If no crack is detected, the probability of occurrence of a fatigue branch $Br(m-2, j, m-1)$ is equal to $1 - PoD$. As defined before, *Full Path*(i), where $i > 0$, represents the probability event after a repair action is taken at the ith inspection. It is noted that *Full Path*(i) depends upon index i but is independent of indices k and j (same indices for $a(k, j, i)$ and $Br(k, j, i)$), which means that this event can be used repeatedly for any k and j index. In other words, the probability of failure of this probability event just needs to be calculated once. However, the probability of occurrence of this event will be the PoD of crack size $a(k, j, i)$, which is a function of indices k and j.

The basic concept described above leads to the development of the RPI algorithm, as shown in equations (4) and (5).

$$P_f^{\,Full\,Path\ k} = \frac{1}{n_k}\sum_{j=1}^{n_k} P_f^{\,Br(k,j,k)} \tag{4}$$

where $k = m$ to 0

In equation (4), $P_f^{\,Br(k,j,k)}$ for $k < m$ is calculated recursively by equation (5).

$$\begin{aligned} P_f^{\,Br(k,j,i)} &= (1 - PoD(a(k, j, i+1))) \\ &\quad \times P_f^{\,Br(k,j,i+1)} + PoD(a(k, j, i+1)) \\ &\quad \times P_f^{\,Full\,Path(i+1)} \end{aligned} \tag{5}$$

where $i = m-1$ to k

The P_f of the structure, considering all the uncertainties, as well as a maintenance plan, is equal to the failure probability of the *Full Path* 0 found at the end of the computation by recursive equations.

2.3.2 CEM-based RPI method

This method, referred as *RPI/CEM*, is a two-stage numerical procedure. The first stage computes the crack growth history using non-inspection-related random variables that were randomly simulated using CEM. The second stage accounts for maintenance-related uncertainties by the RPI method together with the crack growth histories generated from stage 1. In the following, we discuss the CEM first and then discuss the integration of RPI and CEM for risk assessment.

Let $\underline{Z}$ be a set of random variables and g be a performance function. The probability of failure given probability event, $g(\underline{Z}) < 0$, can always be determined using MCSs by generating random samples for all random variables as shown in the following equation.

$$P_f = \int \cdots \int P[g(\underline{Z}) < 0]\ f_{\underline{Z}}\ \mathrm{d}\underline{z} \tag{6}$$

where

$$\begin{aligned} P[g(\underline{Z}) < 0] &= 0 \quad \text{if} \quad g(\underline{Z}) > 0 \\ P[g(\underline{Z}) < 0] &= 1 \quad \text{if} \quad g(\underline{Z}) < 0 \end{aligned}$$

In equations (6) and (7), f represents the probability density function (PDF), g represents performance function, other lowercase symbols represent realizations (randomly selected real values), P represents probability, E represents expectation, superscript c represents conditional, and other uppercase symbols represent random variables. As shown, equation (6) determines the average of n values from simulations; most of them are 0 and very few are 1. As a result, it is well known that MCS is time consuming and often computationally impossible for complex engineering systems. Therefore, the CEM approach was adopted to circumvent the computational demand of the MCS approach. The fundamental of CEM is described next. If one can group the random variables $\underline{Z}$ into two sets, $\underline{X}$ and $\underline{Y}$, equation (6) can be rewritten as shown in equation (7).

$$\begin{aligned} P_f &= \int \cdots \int P[g(\underline{x}, \underline{y}) < 0] f_{\underline{X}} f_{\underline{Y}}\ \mathrm{d}\underline{x}\ \mathrm{d}\underline{y} \\ &= \int \cdots \int P[g^c(\underline{X}|\underline{y}) < 0] f_{\underline{Y}}\ \mathrm{d}\underline{y} \\ &= \int \cdots \int P_f^c(\underline{X}|\underline{y}) f_{\underline{Y}}\ \mathrm{d}\underline{y} \\ &= E[P_f^c] \end{aligned} \tag{7}$$

As can be seen, equation (7) determines the average value of $P[g^c(\underline{X}|\underline{y}) < 0]$. In each simulation, a set of realizations $\underline{y}$, for random variables $\underline{Y}$, is randomly generated. $P[g^c(\underline{X}|\underline{y}) < 0]$ can be determined by a numerical method such as numerical integration or other fast probability integrators. With proper selection of $\underline{X}$, the variation of $P[g^c(\underline{X}|\underline{y}) < 0]$ can be well behaved, where fewer samples are needed to determine its mean value.

Combining the RPI with the CEM, equation (5) is modified, as shown in equation (8).

$$\begin{aligned} {P_f}^{Br(k,j,i)} &= (1 - PoD(a(k, j, i+1))) \\ &\quad \times {P_f}^{Br(k,j,i+1)} \\ &\quad + (1 - {P_f}^{\text{acc}}(j, i+1)) \\ &\quad \times PoD(a(k, j, i+1)) \times {P_f}^{FullPath(i+1)} \\ &\quad + {P_f}^{\text{int}}(j, i) \end{aligned} \tag{8}$$

where $i = m - 1$ to k

${P_f}^{\text{acc}}(j, i)$ in equation (8) is the cumulative probability of failure in the jth simulation at the $(i + 1)$th inspection time considering inspection effect, which is 0 using MCS. ${P_f}^{\text{int}}(j, i)$ represents the cumulative probability of failure (POF) between the ith and the $(i + 1)$th inspections without inspection effect, which is either 0 or 1 when MCS is used. ${P_f}^{\text{int}}(j, i)$ in equation (8) is calculated by the following equation.

$$\begin{aligned} {P_f}^{\text{int}}(j, i) &= {P_f}^{c}(\underline{X}|\underline{y_j} \text{ at } i+1^{\text{th}} \text{ inspection}) \\ &\quad - {P_f}^{c}(\underline{X}|\underline{y_j} \text{ at } i^{\text{th}} \text{ inspection}) \end{aligned} \tag{9}$$

In equation (9), $\underline{X}$ represent random variables not randomly generated, and $\underline{y_j}$ are the realizations randomly generated for the random variables $\underline{Y}$ in the jth simulation. $P_f^c(\underline{X}|\underline{y_j})$ can be determined by any numerical methods, such as numerical integration or advanced probability algorithms, for a given failure function $g(\underline{X}|\underline{y_j}) < 0$.

This procedure reduces the computational burden of using MCS alone (randomly simulates all uncertainties) or using RPI/MCS (randomly simulates non-inspection-related uncertainties). In addition, it maintains the unique capability of the reuse of stored crack growth histories without inspections to compute risk as a function of inspection time and/or inspection techniques without additional stress and life analyses.

Maintenance optimization can be achieved by repeated stage-2 analysis using the same set of crack growth histories considering various maintenance strategies. Since the RPI method uses the probabilistic results of inspection-free structures, advanced probabilistic methods for inspection-free structures, such as importance sampling methods, can be used to generate crack growth history. This particular feature results in additional computational time reduction.

As mentioned earlier, repeated risk assessments can be achieved for different maintenance strategies using the same set of random crack growth histories generated using non-inspection-related random variables. As a result, more computational time can be saved for maintenance optimization.

2.3.3 Sampling-based RPI method

For MCS or importance sampling (IS)-based RPI method, all non-inspection-related random variables are randomly generated to compute crack growth histories without inspection. As a result, equation (9) for RPI/CEM can be simplified to equation (10) for MCS or IS-based RPI.

$$\begin{aligned} {P_f}^{\text{int}}(j, i) &= 0 \quad \text{no failure between } i\text{th and } i+1\text{th inspection} \\ {P_f}^{\text{int}}(j, i) &= 1 \quad \text{one failure between } i\text{th and } i+1\text{th inspection} \end{aligned} \tag{10}$$

In addition,

$${P_f}^{\text{acc}}(j, i+1) = 0 \tag{11}$$

2.3.4 Special RPI algorithms for perfect repairs

In cases where the failure contribution of repair components is known to be secondary, equations (10) and (11) can be simplified, as shown in equations (12) and (13).

$$P_f = P_0 \frac{1}{n} \sum_{j=1}^{n} P_f^{Br(0,j,0)} \tag{12}$$

$$P_f{}^{Br(0,j,i)} = (1 - PoD(a(0, j, i+1))) \times P_f{}^{Br(0,j,i+1)} + P_f{}^{\text{int}}(j, i) \quad (13)$$

where $i = m - 1$ to 0 ; $j = 1, n$

2.4 Probabilistic methods for SHM system with on-board sensors

SHM with on-board sensors minimizes human error through automation. However, other factors that affect the sensor sensitivity and variability still exist. Therefore, the concept of PoD curves is still valid to characterize the performance of sensors, as done for traditional inspections and for risk assessment. When on-board sensors are installed in a structural component, the same sensor is performing subsequent inspections. As a result, the variation of sensor sensitivity from one inspection to the other on the same component is reduced. Inspection dependency has been studied extensively by Shook *et al.* [7–9]. If there are no other factors that may affect the sensor sensitivity, inspections on the same structural component are considered fully dependent. However, the operational condition at each inspection time may be different. In addition, it is known that on-board sensors are sensitive to surrounding operating environments such as temperature, moisture, and loads. As a result, multiple inspections of on-board SHM systems will not be completely repeatable and they are not truly fully dependent. However, as shown by Shook *et al.* [7], modeling the inspection as independent leads to unrealistic over optimistic inspection efficiency and modeling the inspections as dependent is conservative.

Clearly, there is an underlying mechanism for variations in the sensor sensitivity. The degree of dependency can be accounted for by a physics-based stochastic modeling of those random factors, such as operational temperature, moisture, and load condition, if data is available. If not, risk should be bounded by results with independent and fully dependent inspections. In this section, only dependent inspection will be addressed. Further study is required to investigate risk forecasting with partially correlated inspections. Another issue that will not be addressed here is the effect of repair quality on the risk forecasting. The reason is that, other than MCSs methods, efficient probabilistic algorithms considering repair quality and correlated inspections have not yet been developed.

Assumption of dependent inspection assumes that damage detectability of a sensor is developed at a fixed testing environment or effects on its variability by other factors are negligible. Figure 7 illustrates the inspection sequence in jth simulation. Let E_i be the probability event of damage detection at ith inspection. As shown in Figure 8, E_i is a subset of E_{i+1} when dependent inspection is assumed. The reason is that the sensor sensitivity does not change during the damage evolution process. The probability event E_i becomes a subset of E_{i+1} is due to an increase in the crack size only since there is no additional contribution from other sources of randomness to the probability space of E_{i+1}. In Figure 7, F_j is the conditional failure event for the jth simulation conditional on the jth set of realizations. The joint failure event A_j for the jth simulation can be expressed by equation (14).

$$A_j = \left(\bigcap_{i=1}^{m} \overline{E_i}\right) \bigcap F_j \quad (14)$$

where $\overline{E_i}$ is the complement of E_i, and m is the number of inspections. When failure occurs at a given time in service in the jth simulation, the conditional probability of failure $P(F_i)$ is equal to 1. If the jth simulation survives at a given time in service, $P(F_i)$ is equal 0. As can be seen from Figure 8, the joint event of $\overline{E_i}$ is the complement of E_m, as shown in equation (15).

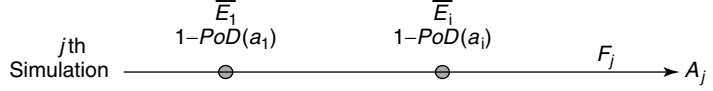

Figure 7. Inspection sequence in a given simulation. E_i: probabilistic event that crack was detected at ith inspection. $\overline{E_i}$: probabilistic event that crack was not detected at ith inspection. F_j: probabilistic event that failure occurs at time in service. A_j: probabilistic event that jth simulation has failed at time in service.

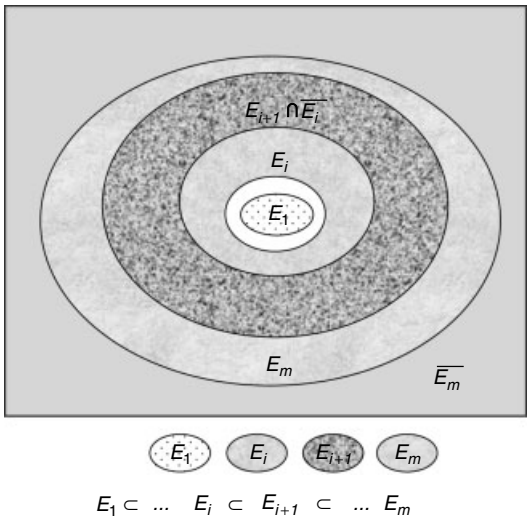

Figure 8. Dependency of continual inspection events.

$$\bigcap_{i=1}^{m} \overline{E_i} = \overline{E_m} \tag{15}$$

By substituting equation (15) in equation (14), we obtain equation (16).

$$A_j = \left(\bigcap_{i=1}^{m} \overline{E_i} \right) \bigcap F_j = \overline{E_m} \bigcap F_j \tag{16}$$

We also know that $\overline{E_m}$ and F_j are independent probability events. Therefore, the conditional probability of failure for each simulation conditional on a set of realizations is shown in equation (17).

$$\begin{aligned} P(A_j) &= P(\overline{E_m} \bigcap F_j) \\ &= P(\overline{E_m}) P(F_j) \\ &= (1 - PoD(a_m)) P(F_j) \end{aligned} \tag{17}$$

Probability of failure is then determined by equation (18).

$$P_f = \frac{1}{n} \sum_{j=1}^{n} P(A_j) = \frac{1}{n} \sum_{j=1}^{n} (1 - PoD(a_m)) P(F_j) \tag{18}$$

where n is the number of simulations.

3 PROBABILISTIC FRAMEWORK FOR RISK UPDATING

SHM is a way to assess the airworthiness of aircraft structural systems. One of the major elements of the SHM is the ability to update the risk using the information provided by either the on-board sensors or off-board scheduled or unscheduled NDIs. For fatigue damage management, probabilistic DT analysis is one of the methods to predict the risk and to characterize the uncertain damage state of structures associated with damage initiation, accumulation, inspection, detection, and other maintenance effects. However, probabilistic analysis relies on proper selection of the input parameters of uncertain variables, which are typically difficult to define.

During the design phase and early operational life, some of the input parameters for probabilistic DT analysis were quantified on the basis of expert opinions from previous experience, or were extracted from laboratory experiments. Although experiments and analyses can be performed to help characterize uncertainties, realistic conditions are often difficult to model. As a result, the risk forecasting may require further attention owing to questionable parameters that may be used in the prediction. This dilemma can be alleviated by using the new information in structural damage state found in later structural life. The measured damage information can be used to update prior knowledge of uncertainties by Bayesian updating approach, as described in the following section.

3.1 Bayesian updating formulation

Structural applications using Bayesian updating approach to improve the accuracy of risk prediction have been studied in the past [10, 11]. The Bayesian updating framework discussed in this section is illustrated using damage accumulation processes modeled through a probabilistic DT analysis with a set of random variables. The random variables include EIFS, fracture toughness, parameters for crack growth equation, extreme load, yield strength, and plate thickness. For illustration purposes, a simple example is used that assumes EIFS follows the two-parameter (α, β) Weibull distribution and α and β are quantified by random variables α_0 and β_0,

respectively. Using the example, Bayesian updating formation is described to determine the optimal values of α_0 and β_0 based on the latest crack information.

In Figure 9, $\underline{a}_{i,}(t_i)$ represents the crack found in the ith component at the inspection time t_i. The solid circle indicates the time and crack size at detection. Figure 9 also shows the PoD curve of the NDI technique used for the crack detection. The dashed line represents real crack growth history of each operational component, which is normally unknown. Baye's theorem allows an update of prior knowledge using new evidence. With this theorem, updated probability distribution function of α_0 and β_0 based on the observed crack sizes $\underline{a}_{i,}(t_i)$ is obtained, as shown in equation (19).

$$\begin{aligned} & f_U(\alpha, \beta | \underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n)) \\ &= \frac{q_D(\underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n), \alpha, \beta)}{\iint q_D(\underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n), \alpha, \beta)\ \mathrm{d}\alpha\ \mathrm{d}\beta} \\ &= \frac{g_D(\underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n) | \alpha, \beta) f_0(\alpha, \beta)}{\iint g_D(\underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n) | \alpha, \beta) f_0(\alpha, \beta)\ \mathrm{d}\alpha\ \mathrm{d}\beta} \end{aligned} \tag{19}$$

In equation (19), n is the total number of components. If a crack is not found in component j, $\underline{a}_{i,}(t_i)$ should be removed from the formulation. f_0 represents the prior joint PDF of α_0 and β_0. f_U represents the updated joint PDF of α_0 and β_0, given a detected crack size at each component. It is also referred to as the *posterior joint PDF* of α_0 and β_0. q_D represents the joint PDF of detected crack sizes, α_0 and β_0. g_D represents the joint PDF of detected crack sizes, given the realizations α and β of random variables α_0 and β_0, respectively. It can be computed using various probabilistic methods; however, joint PDF is extremely difficult to obtain. To address this problem, the following approach is proposed.

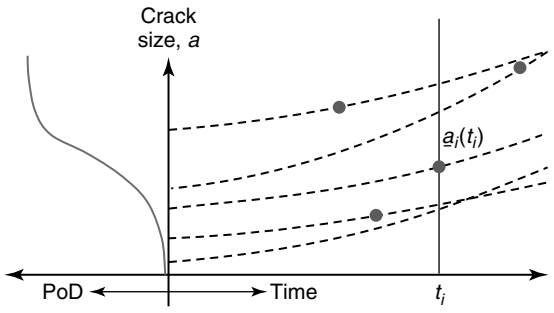

Figure 9. PoD curve and crack growth histories and detected crack sizes.

For many fatigue problems, $\underline{a}_{i,}(t_i)$ can be considered to be statistically independent events. For those cases, g_D can be simplified, as shown in equation (20).

$$\begin{aligned} & g_D(\underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n) | \alpha, \beta) \\ &= \prod_{i=1}^{n} h_D(\underline{a}_i(t_i) | \alpha, \beta) \end{aligned} \tag{20}$$

h_D represents PDF of detected crack size in the ith component at inspection time t_i and is determined by equation (21).

$$\begin{aligned} h_D(\underline{a}_i(t_i) | \alpha, \beta) = c_i \times h_0(\underline{a}_i(t_i) | \alpha, \beta) \\ \times PoD(\underline{a}_i(t_i)) \end{aligned} \tag{21}$$

In the equation, $PoD(\underline{a}_i(t_i))$ is the PoD of crack size $\underline{a}_{i,}(t_i)$ for a NDI method used at time t_i. c_i is the normalization constant. h_0 represents PDF of a crack size in the ith component found at inspection time t_i, given α and β. It can be determined by various physics-based probabilistic methods. By substituting equation (20) in equation (19), equation (22) is obtained.

$$\begin{aligned} & f_U(\alpha, \beta | \underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n)) \\ &= \frac{\left[\prod_{i=1}^{n} h_D(\underline{a}_i(t_i) | \alpha, \beta)\right] f_0(\alpha, \beta)}{\iint \left[\prod_{i=1}^{n} h_D(\underline{a}_i(t_i) | \alpha, \beta)\right] f_0(\alpha, \beta)\ \mathrm{d}\alpha\ \mathrm{d}\beta} \end{aligned} \tag{22}$$

In equation (22), f_U is the posterior joint PDF of α_0 and β_0 with observed crack sizes $\underline{a}_i(t_i)$. f_0 is called the *prior probability* and represents prior knowledge of input parameters, and $\prod_{i=1}^{n} h_D(\underline{a}_i(t_i) | \alpha, \beta)$ is the "likelihood function", which reflects the likelihood that the observed event could indeed take place.

The optimal estimations of random variables α_0 and β_0 are the values where the posterior joint

PDF is maximized. In many practical applications, such as parameter estimation, the denominator in equation (22) can be considered as a normalization constant. Therefore, a proportional relation can be shown in equation (23).

$$f_U(\alpha, \beta|\underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n)) \propto \left[\prod_{i=1}^{n} h_D(\underline{a}_i(t_i)|\alpha, \beta)\right] f_0(\alpha, \beta) \tag{23}$$

Therefore, a better alternative is to maximize the function G defined in equation (24) for the optimal parameter estimation.

$$G = \left[\prod_{i=1}^{n} h_D(\underline{a}_i(t_i)|\alpha, \beta)\right] f_0(\alpha, \beta) \tag{24}$$

Owing to the complexity of the function G, it is not a trivial task to find the maximum value. An alternative in Bayesian estimation is to compute the posterior means for respective parameters, as shown in equations (25) and (26).

$$E[\alpha|\underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n)] = \int_0^\infty \int_0^\infty \alpha f_U(\alpha, \beta|\underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n)) \times \mathrm{d}\alpha \ \mathrm{d}\beta \tag{25}$$

$$E[\beta|\underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n)] = \int_0^\infty \int_0^\infty \beta f_U(\alpha, \beta|\underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n)) \times \mathrm{d}\alpha \ \mathrm{d}\beta \tag{26}$$

Since it is hard to compute the posterior joint PDF, an importance sampling scheme is introduced [12], as shown in equations (27) and (28). In the equations, k is the joint PDF to be selected for importance sampling.

$$E[\alpha|\underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n)] = \int_0^\infty \int_0^\infty \frac{\alpha f_U(\alpha, \beta|\underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n))k(\alpha, \beta)}{k(\alpha, \beta)} \times \mathrm{d}\alpha \ \mathrm{d}\beta \tag{27}$$

$$E[\beta|\underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n)] = \int_0^\infty \int_0^\infty \frac{\beta f_U(\alpha, \beta|\underline{a}_1(t_1), \ldots, \underline{a}_i(t_i), \ldots, \underline{a}_n(t_n))k(\alpha, \beta)}{k(\alpha, \beta)} \times \mathrm{d}\alpha \ \mathrm{d}\beta \tag{28}$$

The Bayesian updating formulations derived in this section can be applied to any damage accumulation processes not just to aircraft fatigue damage evolution, that observations of damage states can be obtained. With the new estimates, designers or analysts can proceed to forecast and update the potential risk as discussed in the previous section.

4 SUMMARY

A probabilistic framework was described for risk monitoring of aircraft fatigue damage evolution at critical locations when SHM concepts are used. The risk monitoring framework includes probabilistic risk forecasting and updating of damage accumulation processes with inspections and maintenance. Four main features of this framework are (i) modeling the damage accumulation process by a fatigue crack analysis, (ii) modeling inspection dependency within an SHM system, (iii) forecasting risk using special probabilistic algorithms to account inspection and maintenance-related uncertainties, and (iv) enabling Bayesian updating using measured data from multiple components with different inspection times and NDI methods or advanced SHM systems. The fast probability integration method was described for the probabilistic risk forecasting, including failure contribution from repaired structural components for independent inspections. Probabilistic formulas for fully dependent inspection assuming perfect repair are also provided. The risk prediction of correlated inspection should be bounded by results of risk assessments from independent and fully dependent inspections. Mathematical formulations for risk updating were described. Risk updating is accomplished by the updating of uncertain statistical parameters. The updating approach consists of (i) probabilistic DT analysis without inspection-related uncertainties, (ii) damage information obtained by SHM, and (iii) Bayesian updating approach.

Chapter 87
Risk Monitoring of Civil Structures

Narito Kurata
Kobori Research Complex, Kajima Corporation, Tokyo, Japan

1 INTRODUCTION

Risk of buildings and civil engineering structures from natural and man-made hazards is large and growing. Natural hazards include earthquake, tsunami, floods, and hurricane. The 1995 Kobe earthquake in Japan killed over 6400 people and the number of completely destroyed buildings and houses was over 100 000. The 2004 and 2007 Niigata earthquake in Japan, the tsunami due to the 2004 Indian Ocean earthquake, and the 2005 Hurricane Katrina in New Orleans caused heavy damage. Man-made hazards include fires, crime, and terrorist attack. The 110-floor twin towers of the World Trade Center and numerous other buildings at the World Trade Center site were destroyed by the September 11, 2001 terrorist attacks. The 2007 Minneapolis bridge disaster was not a natural disaster, but an important issue of structural damage. The Interstate 35W bridge collapsed into the Mississippi River during rush hour on August 1, 2007. It was pointed out that a quarter of the nation's major bridges in the United States carried more traffic than they were designed to bear. Risk monitoring is one of the most promising emerging technologies for mitigation of these hazards [1].

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

2 CONCEPT OF RISK MONITORING

The word "risk" is used in a number of different ways and contexts. For example, in [2], it is defined as the chance of loss, the possibility of loss, uncertainty, the dispersion of actual from expected results, the probability of any outcome different from the one expected, or a condition in which a possibility of loss exists. Also, it is often used alongside the term *hazard*. This term is used to describe the potential of a compound to cause damage or harm.

Buildings are subjected to natural hazards such as severe earthquakes, tsunamis, floods, and hurricanes,

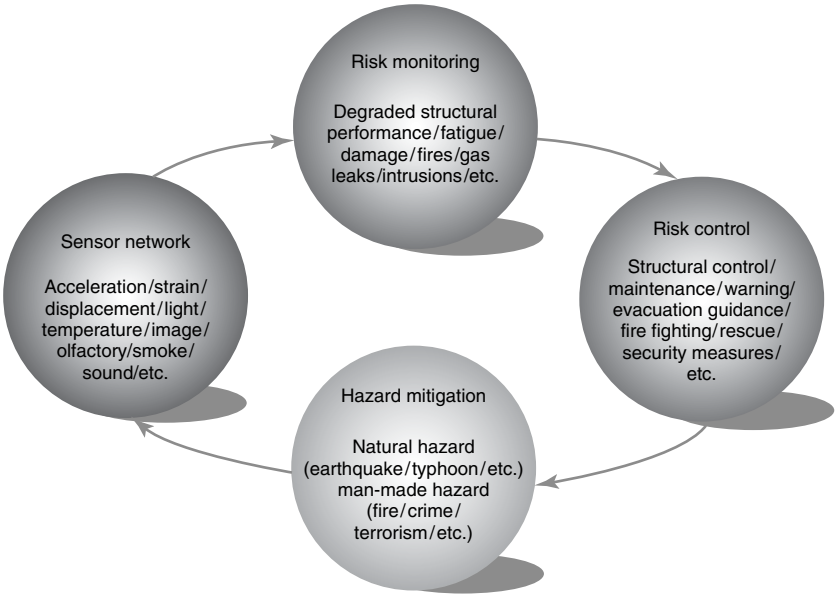

Figure 1. Risk monitoring and hazard mitigation.

as well as man-made hazards such as fires, crime, and terrorist attacks, during their long-term use. To mitigate these hazards, monitoring various risks in a building employing structural health monitoring (SHM) technologies is necessary. Figure 1 indicates a concept of risk monitoring and hazard mitigation, and Table 1 shows various kinds of hazards and possible applications/combination of sensors. The risks to buildings are defined as follows.

2.1 Risks for natural hazards

Risks for natural hazards are related to structural performance of buildings. Structural deterioration is a risk that should be monitored for maintenance of buildings for long-term use (*see* **Maintenance Principles for Civil Structures**; **Usage Management of Civil Structures**). It can be evaluated by inspection of crack, corrosion, and fatigue of structural members. Nondestructive evaluation and strain-based sensing technologies are effective (*see* **Nondestructive Evaluation/Nondestructive Testing/Nondestructive Inspection (NDE/NDT/NDI) Sensors—Eddy Current, Ultrasonic, and Acoustic Emission Sensors**). Structural damage is an important risk that should be monitored for postdisaster mitigation. It can be evaluated by sensing of floor acceleration and story deformation of buildings. Information from risk monitoring of structural

Table 1. Sensor applications

Hazard	Application	Sensor
	Observation	Acceleration, wind speed
Earthquake/ tsunami/flood/ hurricane	Experiment	Acceleration, strain
	Structural control	Acceleration
	Structural deterioration	Crack, corrosion, fatigue, strain
	Structural damage	Acceleration, story deformation
	Fire detection	Temperature, smoke, acoustic, acceleration, olfactory
Fire	Gas leak detection	Olfactory
	Alarm, warning	Sounder
	Evacuation control	Temperature, smoke, acoustic, light, olfactory
Crime/terrorist attack	Surveillance	Camera, acceleration, acoustic, light
	Security alert	Sounder

damage can be used for risk control measures such as warning, alarms, and evacuation guidance.

2.2 Risks for man-made hazards

Influence on buildings by man-made hazards such as fires, crimes, and terrorist attacks is growing in recent years. Especially, there are points in common between terrorist attack and natural disaster. They are unexpected and unpredictable, and happen during short term. Early detection just after the event is required. Risks for man-made hazards, which should be monitored, include small fire, gas leaks, intrusions, an explosive substance, etc. Temperature, smoke, acoustics, acceleration, and olfaction are sensing items that are required for detection of fires, gas leaks, etc. Camera, acceleration, acoustics, and light are effective for surveillance for avoiding crimes and terrorist attacks. According to the risk monitoring results, appropriate risk control measures such as fire alarms and fire fighting, rescue, and security measures can be applied.

3 SENSING TECHNOLOGIES FOR RISK MONITORING

The general purpose of SHM includes hazard mitigation, improvement of safety and reliability of the structural system, sustainability, and life-cycle cost reduction. The SHM technology consists of sensing, signal processing, health evaluation, and system integration. In recent years, a number of conferences have been held in which SHM techniques for buildings and civil engineering structures has been presented [3–12]. Some of this work has focused on wireless sensing technology. Researchers at Stanford University have developed a wireless sensing unit for real-time structural response measurements and conducted a series of validation tests [13, 14].

"Ubiquitous computing/networking/sensing" is expected to be realized over the next 10 years. The interest in sensing technology for various uses has been growing, and new kinds of sensors have been developed by microelectromechanical systems (MEMS) technology (*see* **Microelectromechanical Systems (MEMS)**). Environmental information, such as brightness, temperature, sound, vibration, and a picture of a certain place in a building, is evaluated by the network to which a huge number of microcomputer chips with sensors are connected [15]. Figure 2 shows the flow toward a ubiquitous sensing/computing/networked society. A wireless sensor network plays an important role in such strategies and can be connected to the internet so that this information can be used to monitor future risks. Wireless sensors are easy to install, remove, and replace at any location, and are expected to become increasingly smaller (i.e., "smart dust" [16]) by using MEMS technology. They provide a ubiquitous, networked sensing environment in building and civil engineering structures. For example, the acceleration and strain at numerous locations on each structural member, temperature and light in each space, as well as images and sounds in desired regions can be obtained by the "smart dust" sensors, as illustrated in Figure 3.

The requirements of a dense array of smart sensors using wireless technology for SHM have been investigated by using the Mote platform [1, 17–21]. It is an open hardware and software platform for smart sensing and supports large-scale, self-configuring sensor networks as shown in Figure 4 (*see* **Wireless Sensor Network Platforms**; **Sensor Network Paradigms**). Ruiz-Sandoval developed an

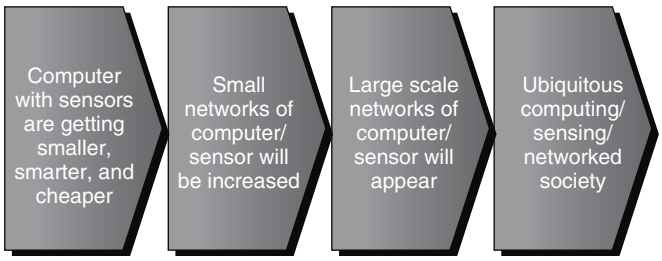

Figure 2. Toward a ubiquitous computing/sensing/networked society.

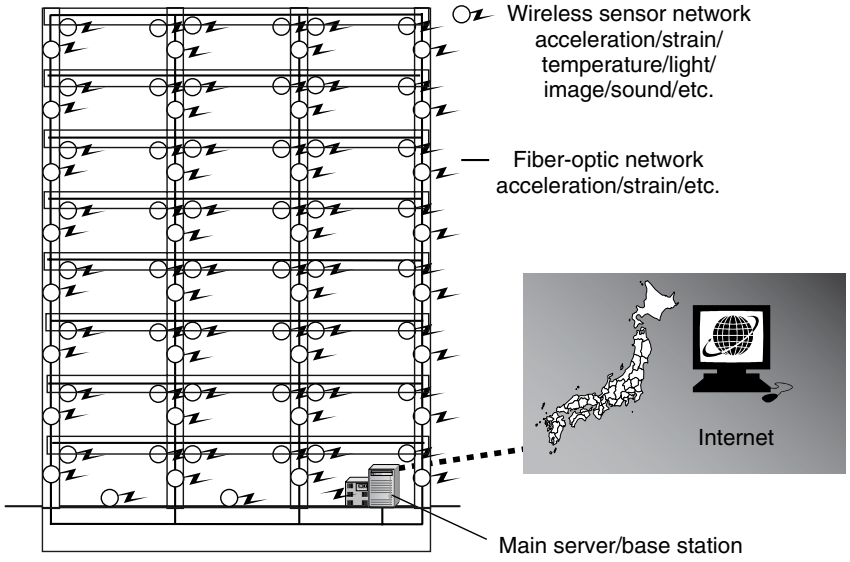

Figure 3. Example of risk monitoring system.

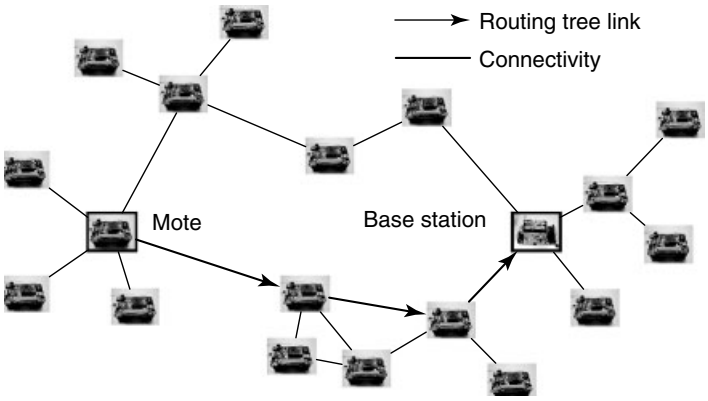

Figure 4. *Ad hoc* and multihop sensing.

agent-based framework, a hardware- or software-based computer system, which enjoys the properties of autonomy, social ability, reactivity, and proactiveness for SHM [18]. A distributed computing strategy for SHM was proposed, which is suitable for implementation on a network of densely distributed smart sensors [19]. A scalable and autonomous SHM system using smart sensors was developed and the damage detection capability and autonomous operation of the developed system were experimentally verified [20]. Tenet architecture that simplifies application development for tiered sensor networks without significantly sacrificing performance was proposed [21]. Its collection of tasklets support data acquisition, processing, monitoring, and measurement functionality. A wireless sensor system using the Mote platform with a developed sensor board was tested on the 4200-ft-long main span and the south tower of the Golden Gate Bridge [22]. Reference 23 provides a summary review of the collective experience the structural engineering community has gained from the use of wireless sensors and sensor networks for monitoring structural performance and health.

4 APPLICATIONS

4.1 Ubiquitous structural monitoring system using wireless sensor networks

One of the main purposes of SHM is for damage detection of the structure [24] (*see* **Signal Processing for Damage Detection**; **Damage Detection Using Piezoceramic and Magnetostrictive Sensors and Actuators**; **Damage Measures**). Since structural damage is a local phenomenon, a ubiquitous structural monitoring (USM), i.e., high-density distributed structural monitoring, is needed. From this point of view, a laboratory experiment has been devised to assess the performance of the "smart dust" Mote, the platform of wireless sensor networks (*see* **Wireless Sensor Network Platforms**), for SHM. Through shaking table experiments, it was recognized that the Mote was useful for the damage detection of the structure [1]. To increase the performance of structural monitoring, a high-sensitivity acceleration sensor board for the Mote has been developed and tested [17, 18]. On the basis of these activities, research on wireless sensor network architecture for USM in the next generation, which includes a design of hardware and development of communication software, has been conducted [6, 7]. Figure 5 shows an example of the concept of the USM system. Wireless sensor nodes are distributed in the room to measure the acceleration during the earthquake. By using the double integration scheme, displacement of each sensing point is evaluated. After the earthquake, information of risk monitoring by space deformation is obtained.

The authors have developed a sensor module for USM consisting of a sensor board and wireless network module as shown in Figure 6. There are several test beds for wireless network module

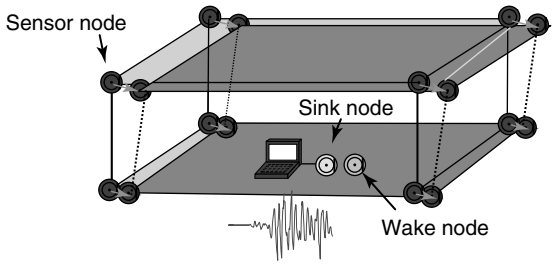

Figure 5. Example of ubiquitous structural monitoring system.

[16, 20, 25, 26]. The MEMS acceleration sensor was examined for the development of the acceleration sensor board that can be connected with such a wireless network module. Required specifications for the acceleration sensor board for the USM are shown in Table 2. It shows the performance necessary for general seismic observation and vibration measurement of buildings from a moderate earthquake to a large earthquake. Performance of various MEMS sensors is usually confirmed only in the frequency range of 10 Hz or more, though the performance in the low-frequency range from 0.1 Hz is important for the vibration measurement of high-rise building and the observation of long-period ground motion.

The developed sensor board consists of MEMS acceleration sensor, which was selected by the benchmark tests, low-pass filter, and 16-bit A/D converter (Figure 7). The sleep function of the MEMS acceleration sensor and the low-pass filter can be used to achieve low power consumption. The module for the

wireless sensor network was connected to the developed sensor board for the test as shown in Figure 6. The developed sensor module for the USM and USM system is shown in Figures 8 and 9, respectively. A shaking table test was carried out to recognize the performance of the developed sensor module for the USM. Eight sensor nodes, a wake node, a sink node connected to the PC, and the reference sensor were fixed on the shaking table as shown in Figure 10. The shaking table is 1.8 m $\times$ 1.5 m and can shake at 0.1–100 Hz using external input waves. The input wave was the Japan Meteorological Agency (JMA) Kobe North-South direction (NS), which was observed at the Great Hanshin–Awaji disaster that occurred in 1995. Figure 11 shows the measurement acceleration time histories of the eight sensor nodes and the reference sensor. The eight sensor nodes were synchronized within 1 ms by a protocol proposed by the authors [27]. According to the packet from the wake node, sensor nodes started to measure the acceleration. After the measurement, stored acceleration data in the memory on the sensor board was transmitted to the PC through the sink node by wireless communication. The measurement result by the eight sensor nodes corresponds well to the result by the reference sensor. It was confirmed that the developed sensor module had enough basic performance for the USM.

4.2 Risk information delivery system using wireless sensor networks

A safe evacuation is expected as a countermeasure for a large earthquake [28]. There is the first disaster such as structural damage of a building and the secondary disaster such as fire. It is required

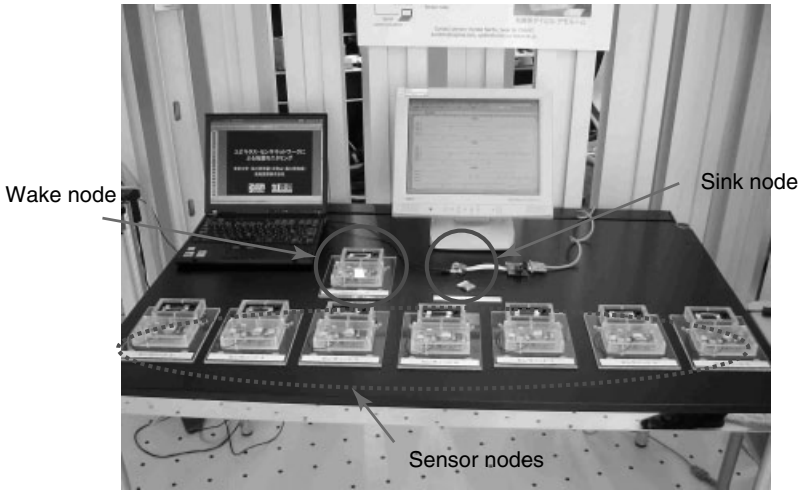

Figure 9. Ubiquitous structural monitoring system.

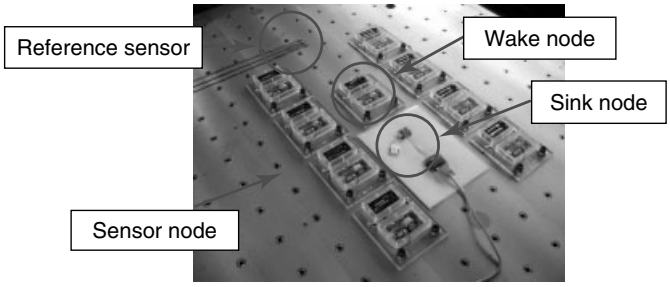

Figure 10. Developed USM system and reference sensor on the shaking table.

to offer users adequate information more immediately after earthquakes occur. From this point of view, a risk information delivery (RID) system using wireless sensor networks was proposed [28]. RID detects dangerous areas by using a sensor network constructed in the structure and judges the degree of risk by calculating the risk of dangerous areas.

The RID system is based on a client–server model and composed of RID_Client, RID_Server, stationary node (SN), and emergency node (EN) as shown in Figure 12. An accelerometer and a temperature sensor are used. The accelerometer detects earthquakes and the temperature sensor detects fire.

An SN with an accelerometer always observes the state. When SNs detect an acceleration more than constancy, SNs judge the occurrence of earthquakes and send wake-up messages to the EN. In addition, SNs aggregate risk information that ENs calculated and also calculate risk of an area where SNs belong. An EN is equipped with sensors that detect various dangers. ENs start by receiving wake-up messages from SNs through the occurrence of earthquakes. Starting ENs send SNs risk information calculated from sensors data. RID_Servers are equipped with SNs and save risk information on an area that SNs calculated in a database. Moreover, a risk map is constructed by adding risk information to map information. This map is offered to the RID_Client. The RID_Client assumes personal digital assistant (PDAs) and mobile phones are carried by people who then view risk maps (viewer) that the RID_Server constructed. Figure 13 shows the example of node arrangement.

The degree of risk is decided by making some thresholds in the value of sensors. The maximum value of degree of risk is 100, and the value

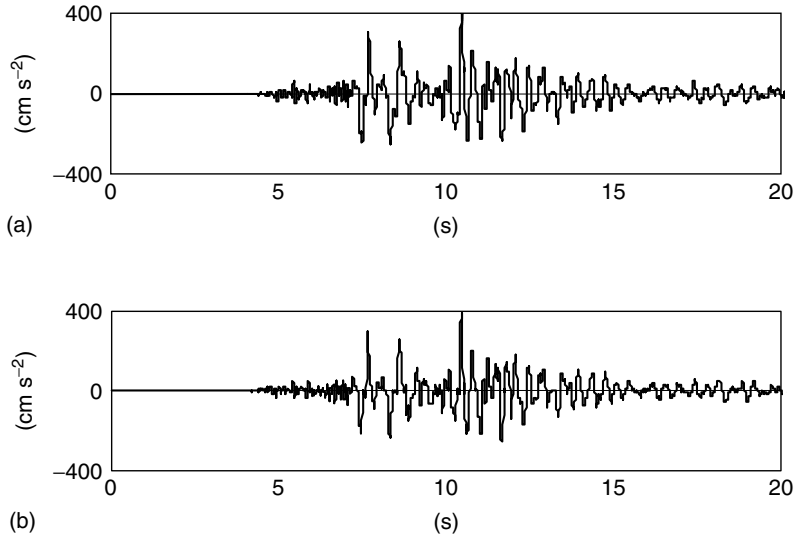

Figure 11. Measured and transmitted time histories. (a) Eight sensor modules and (b) Reference sensor.

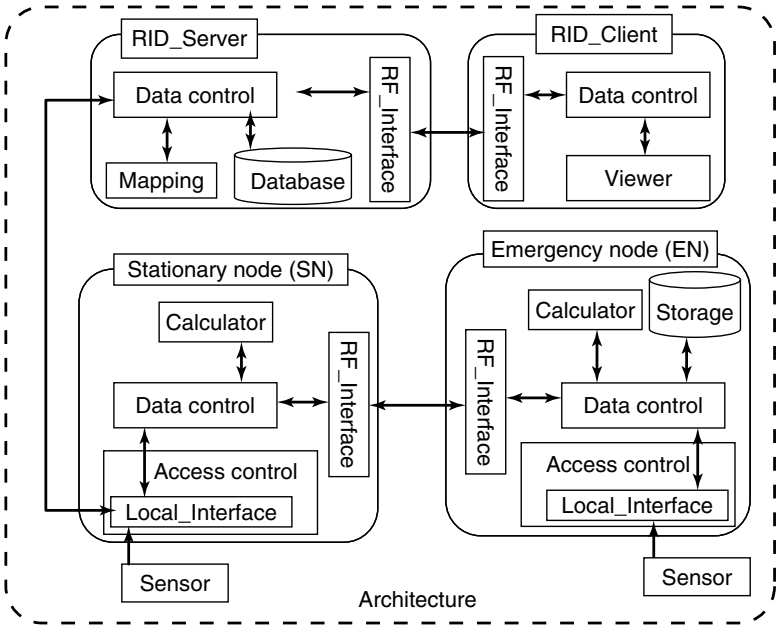

Figure 12. Risk information delivery (RID) system architecture.

changes based on the threshold. Tables 3 and 4 show examples of the degree of risk for temperature and maximum acceleration, respectively. A judgment of the degree of risk is defined by three stages. Users can stand ready to evacuate at the first phase from 0 to less than 20, need to evacuate at the second stage from 20 to less than 60, and must not act and keep themselves in safe at the third stage of 60 or more. An SN calculates the degree of risk of areas. First, an SN aggregates risk information on all the sensors of

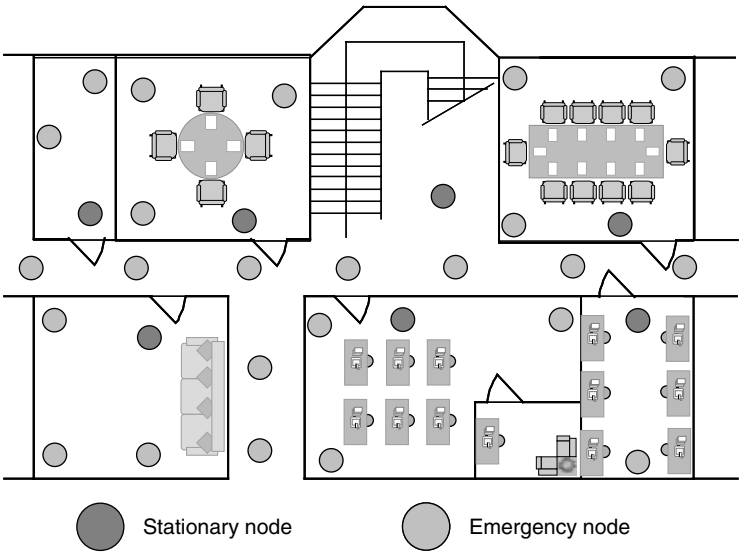

Figure 13. Example of ubiquitous structural monitoring system.

ENs. Next, the SN averages the degree of risk information on each sensor and reflects the degree of risk of the sensor with the highest risk.

Table 3. Relation between temperature and degree of risk

Temperature	Degree of risk
Below standard temperature	0
From 20 to less than 30 °C against standard temperature	50
From 30 to less than 50 °C against standard temperature	75
50 °C or more from standard temperature	100

Table 4. Relation among maximum seismic intensity and degree of risk

Maximum acceleration (Gal)	Seismic intensity	Degree of risk
0–40	∼3	0
40–110	4	10
110–240	5 lower	20
240–520	5 upper	40
520–830	6 lower	60
830–1500	6 upper	80
1500 ∼	7 ∼	100

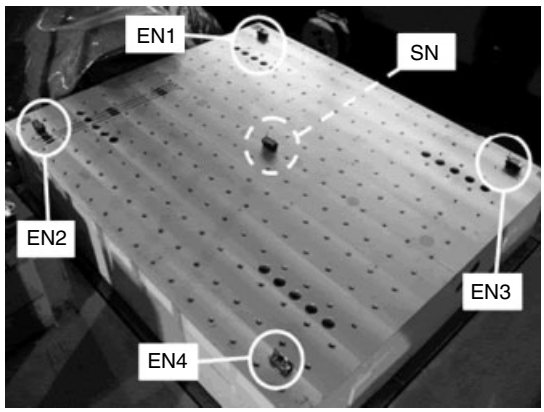

Figure 14. Arrangement of ENs and SNs.

A shaking table test was carried out to recognize the performance of the developed RID system. Both SN and EN were installed on a shaking table as shown in Figure 14. The SNs and ENs are Mica Z Motes. The sensor nodes utilize an accelerometer and a temperature sensor, respectively, to measure the degree of risk. The sampling frequency of these sensors is 100 Hz. The ENs are quaked on the shaking table and heated by a drier. All of the data, i.e., temperature, acceleration, and risk degrees of temperature and acceleration, which ENs sensed during 40 s are collected. The maximal value of accelerations is

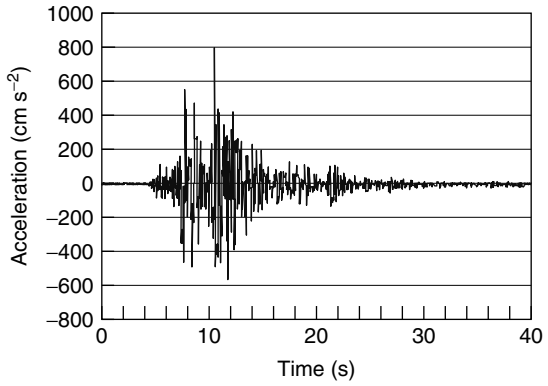

Figure 15. Result of reference sensor.

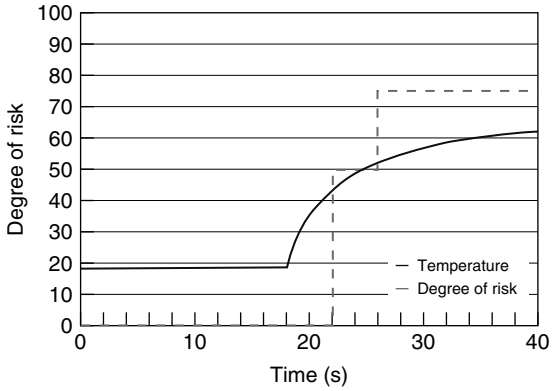

Figure 17. Result of temperature sensor of ENs.

averaged per 10 samples and assigns the risk corresponding to Table 4 using the average. On the other hand, sensed temperature data are averaged per 100 samples every 1 s. Then the RID system subtracts averaged temperature from the standard temperature that was measured when the system started and assigns the risk corresponding to Table 3 using the averaged temperature. Figure 15 shows measured data of the reference acceleration sensor for comparison. Figures 16 and 17 show measured data of acceleration and temperature on ENs, respectively. As a result of this experiment, it was recognized that the RID system could measure each degree of risk accurately. The RID system detects a dangerous part in the structure and offers risk information after an earthquake. Users can get risk information on a detailed area such as rooms and the passages by the RID.

5 CONCLUSIONS

This article provides a concept for the risk monitoring of buildings for disaster mitigation and reviewed related sensing technology. An USM system and an RID system using wireless sensor networks were introduced as applications. Risk monitoring is expected as one of the most promising and emerging

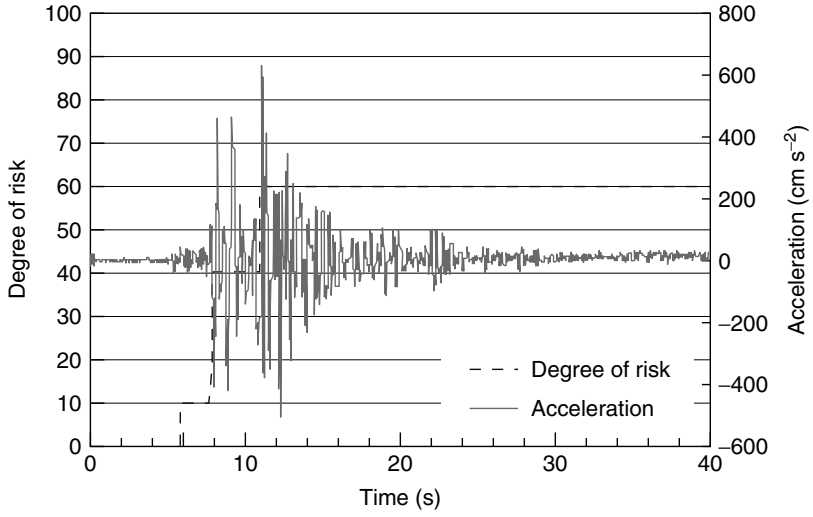

Figure 16. Result of acceleration of ENs.

technologies for the mitigation of natural and man-made hazards.

1 INTRODUCTION

Managing the life-cycle costs (LCCs) of an aircraft structure has become a critical challenge for engineers and managers of aircraft fleets. The importance of controlling sustainment costs is epitomized by the reality that many old aircraft in the US Air Force fleet are expected to remain in service for another 25 years. Even today, many of these aircraft exhibit aging problems such as fatigue cracking, stress corrosion cracking, corrosion, and wear [1]. For example, the annual costs of maintenance due to corrosion alone are already many hundreds of millions of dollars, and these costs are steadily increasing [2]. To address these challenges, condition-based maintenance (CBM) approaches are being implemented to perform inspections and repairs only when necessary. In the case of aircraft structures, CBM employs nondestructive evaluation (NDE) through external tests and structural health monitoring (SHM) using embedded sensors as part of maintenance plans that are based on system condition diagnostics and prognostics.

NDE consists of test methods used to examine the material integrity of an object or system of objects without impairing its future usefulness. It is utilized for detecting and characterizing discontinuities such as cracks, porosity, and corrosion in materials and structures to ensure their reliability and extend their service life. The reliability of NDE techniques is critical for aircraft maintenance programs. Issues in NDE discovered through probability of detection (POD) studies have generated an interest in determining the impact of inspection performance on total service life [3]. For inspection problems that include manual

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

scanning, complex procedures, and low frequencies of finding critical flaws, there is a potential for some critical sites to not be inspected effectively owing to the requirements of the inspection process, or there are inconsistent requirements for identifying marginal defects [4]. Although methods have been proposed to help address NDE reliability issues, the application of SHM systems with *in situ* sensors also has the potential to improve health assessment reliability by eliminating problematic human factors.

The application of *in situ* sensors for SHM has been extensively explored in recent years [5–9]. Two classes of SHM systems are considered here. The first approach is based on the acquisition of data for life prediction models. During in-service periods, distributed sensors can be used to measure the loading and environmental conditions experienced by the structure (*see* **Loads Monitoring in Aerospace Structures**; **Environmental Monitoring of Aircraft**; **Agile Military Aircraft**; **Loads and Temperature Effects on a Bridge**). Subsequently, these data can be used to improve fracture mechanics models to better predict the flaw state. This approach can be considered "indirect", since the damage state in the future is estimated using a model prediction based on input measurement data. The most significant benefit of "indirect" SHM schemes is a reduction in the uncertainty of the fracture mechanics model predictions. The second approach is based on the acquisition of NDE data using *in situ* sensors to quantify the damage state of a structure (*see* **Signal Processing for Damage Detection**; **Model-based Statistical Signal Processing for Change and Damage Detection**; **Nondestructive Evaluation/Nondestructive Testing/Nondestructive Inspection (NDE/NDT/NDI) Sensors—Eddy Current, Ultrasonic, and Acoustic Emission Sensors**; **Damage Presence/Growth Monitoring Sensors**). This approach is classified as a "direct" method, requiring that the damage state be observable in distributed sensor data. There are two subclasses of SHM damage characterization systems: global health monitoring systems incorporate distributed sensors such as strain gauges and acoustic emission transducers to detect the presence and general location of damage in a structure, while local health monitoring systems detect damage in critical structural locations by using ultrasonic and eddy-current sensors.

In practice, there is a continuum of potential scenarios using NDE and *in situ* sensors to ensure structure reliability and mitigate maintenance costs. These scenarios include hybrid NDE and SHM strategies, such that SHM can be used to identify the presence of a critical damage state, while NDE can be used for final verification before an expensive teardown or repair is performed. Examples of the array of maintenance approaches for management of critical damage locations include the following:

1. fail-safe design (using life prediction based on model only);
2. scheduled NDE maintenance (NDE);
3. load monitoring with life prediction model refinement (indirect SHM);
4. damage state monitoring with *in situ* sensors (direct SHM);
5. load monitoring with CBM (indirect SHM and NDE);
6. damage state monitoring with follow-up NDE inspection (direct SHM and NDE).

This hybrid approach for fleet management is proposed through the careful selection and pairing of reliable SHM and NDE systems for a given critical location. The theme of this article is a value assessment methodology incorporating cost–benefit analysis (CBA) and probabilistic risk assessment into NDE and/or SHM system design to maintain acceptable structural health assessment reliability and minimize total service life cost.

2 VALUE ASSESSMENT PROBLEM FOR SHM

At the center of the fleet management problem exists a compromise between aircraft availability, reliability, and cost: (i) maximizing availability and total life of an aircraft may require higher costs for maintenance systems (such as SHM) or may adversely impact reliability; (ii) minimizing cost of a maintenance program for a critical location may require limiting availability (such as reducing overall life) or sacrificing reliability; and (iii) improving reliability may reduce availability owing to longer depot

maintenance periods, or may require more expensive SHM systems. An approach is needed to evaluate and establish the optimal trade-offs between these factors for several maintenance approaches including SHM. CBA provides a framework for this evaluation.

2.1 Overview of SHM benefits and costs

The primary benefit of SHM concerns integration with prognostics, where the management of high-value assets such as military aircraft is improved through the quantitative prediction of future operating capability and accurate determination of remaining life. Potential cost benefits for SHM include (i) reduction in labor cost and time for unnecessary NDE inspections, (ii) management of locations of limited accessibility to minimize costly teardowns, and (iii) availability of robust indications of impending failure of the structure to trigger safe retirement. Improvements in availability of aircraft can also be addressed using SHM, by limiting time in maintenance to only when absolutely necessary. In addition, when considered during the aircraft design phase, SHM has the potential to provide engineers with the means to reduce structure weight by avoiding conservative designs, reduce the need for costly assessments of fatigue-critical locations [5], and improve aircraft dynamic performance. Additional benefits may also be realized through the use of *in situ* sensor data to indirectly detect unsafe conditions of interest such as excessive loading or icing conditions, and to support accident investigation, potentially leading to a safer fleet over the long term.

Recent work has also explored the significant costs and challenges of SHM implementation [10, 11]. The costs associated with SHM systems can be categorized as development costs, implementation costs, in-service costs, and end-of-life costs. Development costs include any initial research and system development work for a particular application. Implementation costs are associated with the fixed initial cost for purchasing and installing the on-board SHM system and for performing validation studies to satisfy reliability requirements. Both development and implementation costs are expected to be much higher for SHM systems with respect to those of NDE techniques, given the increasingly difficult system requirements concerning inspection and reliability. In-service costs can include the additional cost of fuel due to added SHM system weight, data interpretation labor costs, SHM maintenance costs, and the cost of secondary inspection and unnecessary repair due to false calls or unnecessary calls when flaws are very small. While in-service costs of SHM systems are expected to be low in relation to those of NDE procedures, design-time consideration must be given for the possibility of such costs being significant to minimize their impact on total LCC.

Given the potential benefits and costs of SHM, a key issue for the success of any SHM implementation is the ability to establish how the SHM technology affects figures of merit such as cost, safety, and availability of aerospace structures. Without reliable value assessment studies that take into account all impacts of the technology on these figures of merit, it will likely be impossible to justify the initial investment in SHM technology to financial decision makers and, more importantly, it will be impossible to predict whether the SHM implementation will improve or degrade the ability to efficiently manage the aerospace structure.

2.2 Basic principles of value assessment methods

In this section, we review several methods for value assessment. We describe the cost–benefit analysis, cost–effectiveness analysis (CEA), and cost–utility analysis (CUA) methods, which have been widely used for economic analysis in many fields. We also describe multiobjective optimization methods, which are not yet as widely used, but can be quite useful when the diversity of the multiple objectives makes it difficult to aggregate objectives for comparing alternatives.

CBA is based on representing in monetary units all consequences of the proposed technology as either costs or benefits. The net benefit of a proposed solution, which equals the difference between its benefits and costs, is used as the sole basis for comparing alternate solutions. CBA or other types of value analyses can be costly themselves, and enough care and diligence must be exercised to obtain the intended insight for decision making. The major steps in CBA, as adapted for the SHM case from those listed in [12], are as follows:

1. Specify the set of alternative SHM technologies, including the complementary NDE processes if existent and not fixed, and the alternate parameters of the combined SHM-NDE (structural health monitoring—nondestructive evaluation) system. This can also include the alternative consisting of not using SHM.
2. Decide whose benefits and costs count. For example, the use of SHM may eventually reduce the need for inspection labor. This would be detrimental to an inspection business, and the loss of revenue and expertise could be considered a cost.
3. Catalog the impacts and select measurement units. This would include, for example, the impact on reliability, safety, development costs, and labor over the system's life.
4. Predict the impacts (benefits and costs) quantitatively over the life of the system.
5. Assign monetary values to all impacts (benefits and costs).
6. Apply interest and/or discount rates to obtain the present value of each impact.
7. Compute the net present value (NPV) of each alternative SHM-NDE combination. This should be equivalent to the LCC of each SHM-NDE alternative [13].
8. Perform sensitivity analyses. These determine how changes in the estimated impacts, the interest rate, or other parameters can affect the NPV of the various alternatives.
9. Make a recommendation based on the NPV and sensitivity analyses. Normally, the recommended alternative is that with the largest NPV.

It is sometimes impossible or inappropriate to assign monetary value to the most important benefit expected from a technology. In CEA, this nonmonetary benefit is called the *effectiveness*. The ratio of the effectiveness and the cost for a given alternative is referred to as the *cost–effectiveness criterion*, and it is used instead of the monetary NPV as a basis for comparing alternatives. For example, the number of lives saved can be considered the effectiveness of a particular SHM implementation. In CUA, alternatives are compared on the basis of the ratio of their utility and their cost, where the utility is a number that combines at least two benefits. The difficulty in appropriately combining benefits makes CUA less appealing for SHM technology value analysis.

The value analysis problem can also be posed as a multiobjective optimization problem are constraints functions [14],

$$\begin{aligned} &\text{Maximize } f(\mathbf{x}) = [f_1(\mathbf{x}), f_2(\mathbf{x}), \ldots, f_p(\mathbf{x})] \\ &\text{Subject to } g_j(\mathbf{x}) \leq 0 \quad j = 1, 2, \ldots, m \end{aligned} \tag{1}$$

where $\mathbf{x}$ is a vector of independent variables, the f_i are objective functions, and the g_j are constraint functions. Usually, the objective functions are competing and cannot be simultaneously optimized. A candidate solution $\mathbf{x}$ in the decision space is called *feasible* if it satisfies all the constraints. Consider two feasible solutions $\mathbf{x}_a$ and $\mathbf{x}_b$. If $f_i(\mathbf{x}_a) \geq f_i(\mathbf{x}_b)$ for all i and there exists an i for which $f_i(\mathbf{x}_a) > f_i(\mathbf{x}_b)$, then the solution $\mathbf{x}_b$ is said to be dominated by the solution $\mathbf{x}_a$, and $\mathbf{x}_b$ can be eliminated from further consideration. Eliminating all dominated solutions results in a set of *nondominated, Pareto efficient*, or *efficient* solutions from which the decision maker must choose [14]. For a solution that is efficient, it is not possible to improve any objective without making one or more of the other objectives worse.

There exist methods that can process multiple alternate solutions to yield nondominated solutions, and others that can even help the decision maker select among a set of nondominated solutions, while preserving each objective's variable type without the need to transform all impacts to financial values. These methods are generally known as *multicriteria optimization*, and can enable effective trade-off analysis when the number and types of impacts make it difficult to aggregate them. Good reviews of existing evolutionary and nonevolutionary methods for solution of multicriteria optimization problems can be found in [14] and [15], respectively. The software used in the examples of Section 4 utilizes multicriteria optimization methods for trade-off analysis.

2.3 Prior applications

Related to the value assessment problem for SHM, prior work has discussed the need to evaluate the costs and benefits of NDE technology. Hagemaier describes the uses of NDE in the *cradle-to-grave* product cycle at a large aircraft manufacturing company [16, 17]. That description starts to address how NDE capabilities, requirements, methods, and

parameters affect decisions across stages of the life cycle, but does not address the methods by which this decision making process can be systematically improved by the use of a systems and optimization approach and corresponding numerical tools. Given this need, specific methods have been developed to estimate the economic value of NDE techniques. In the area of technology value assessment, a technology benefit estimator (T/BEST) was developed by NASA (National Aeronautics and Space Administration) to quantitatively assess the value of advanced aerospace technologies and quantify the benefits for prioritization [18]. Brechling developed a methodology for the economic assessment of NDE research and development in terms of NPV, including direct and indirect benefits to society [19]. Papadakis outlined three practical financial methods for making decisions in NDE: the Deming inspection criterion (DIC), the internal rate of return (IRR), and the productivity and profit methodology [20, 21]. Wall and Wedgwood also developed a quantitative inspection value method (IVM) for application to NDE focusing on the major costs and benefits of a particular technique by evaluating the impact of sensitivity, speed, and reliability [22].

A few studies have been presented to date concerning the cost justification for SHM applications [6–9]. Kent and Murphy performed a technology assessment of health monitoring system technology including a CBA [23]. In prior work, Aldrin *et al.* have also explored the problem of cost–benefit assessment of SHM incorporating probabilistic models [10]. Kapoor, Goh, and Boller perform SHM cost estimation as part of their proposed procedures for assessment of SHM potentials [24]. Boller and Staszewski provide an example of how to estimate LCCs for a new damage monitoring technique in [[6], pp. 36–43] and the references therein. The integration of cost models with probabilistic risk assessment tools incorporating NDE and SHM is presented in the next section.

3 COMPONENTS OF STRUCTURAL LIFE MANAGEMENT

Experience has demonstrated the need to develop lifelong plans for evaluating and maintaining a structure, to avoid excessive future costs for maintenance and repairs. The concept of a systems-level approach is necessary to develop the most economical sustainment of future weapon systems throughout their lifetime. The systems-level approach implies that tasks are accomplished in teams that bring together all interested and affected personnel. For instance, a new repair to a specific location on an aircraft must take into account larger structural considerations.

A strategy for component life-cycle optimization incorporating NDE and SHM is presented first in terms of the necessary components. Refined system components are models, characteristics, and functions that are necessary for constructing the component life model. To achieve optimal component life management, the following refined system components must be well understood and integrated within a complete system approach: (i) identification of critical locations to inspect, failure analysis, and loss assessment; (ii) initial quality and flaw initiation models (including material, geometry, and process models); (iii) flaw growth models; (iv) load and environmental monitoring, which evaluates the conditions under which the component will operate; (v) maintenance scheduling and repair tracking; (vi) value analysis methodology; and (vii) inspection technique capability, which is normally measured by POD of a certain flaw type and size. Figure 1 presents a diagram of a component life management approach incorporating NDE and SHM. The refined system components have been broken up into two categories: those that specifically address modeling the inspection technique and those that indirectly impact the inspection technique design, defined as *economic service life management resources*.

3.1 Models and software tools for system life management

Several software packages incorporating modeling tools have been proposed over the years to address various aspects of the system management problem. In [9], Kacprzynksi, Roemer, and Hess propose an approach for design of health management systems that is based on extending failure modes effects and criticality analysis (FMECA) with system modeling, LCC modeling, CBA, trade-off analysis, and sensitivity analysis. The proposed result is a prognostic

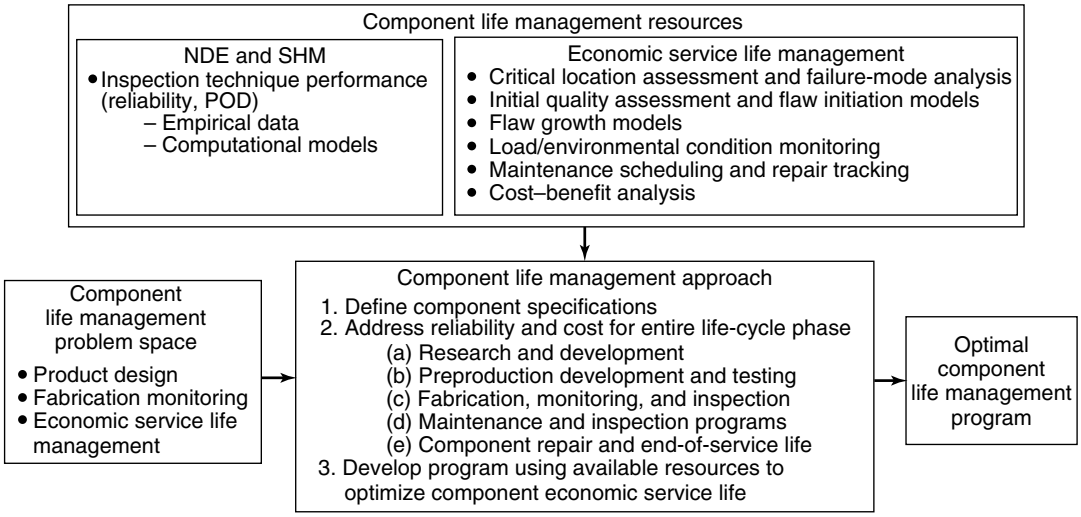

Figure 1. Component life management approach incorporating NDE and SHM.

and health management (PHM) system design tool that can enable analysis of alternative sensors, algorithms, and other health management technology, can use interactive databases, and can operate in a collaborative, web-based fashion. They present an example of an electromechanical valve of an aircraft. Related work by the same authors has focused on aircraft propulsion, industrial power generation, and other systems with rotating components. FMECA and aggregated modeling of component and system reliability are an important part of health management for that type of system because of the number of components involved and the complexity of the functions performed by the subsystem. Two of the most common functions of aerospace structures are (i) carrying of mechanical load and (ii) protection from the environment. In such applications, failure modes are often related to fatigue cracking and corrosion in multilayered metallic structures with stiffeners, and delamination and other types of damage in structures manufactured from composites. Accessing the areas of the structure where critical damage can occur can be difficult, labor intensive, and risky in terms of the possibility of damaging the structure during teardown or reassembly. One common important challenge in health monitoring of structures is the selection, placement, and installation of sensors that can reliably provide the necessary data and the design of algorithms that can process these data to detect damage trends in the presence of environmental disturbances and variations in the operational loads of the structure.

3.2 Probabilistic models for risk assessment incorporating NDE and SHM

Probabilistic models are another key component to successfully represent SHM systems with life prediction models for risk assessment and CBA (*see* **Risk Monitoring of Aircraft Fatigue Damage Evolution at Critical Locations**). This approach builds upon prior work comprising the development of a strategy and software framework for integrating NDE design and product life management tools [10, 25–27]. The model is based on prior work by Berens *et al.*, who developed a software tool (PROF) for probabilistic risk assessment of fatigue crack growth and fracture incorporating NDE [28, 29]. This model primarily addresses direct SHM systems capable of acquiring NDE-type data using embedded sensors to quantify the damage state of a structure. To model an indirect SHM system, the SHM measurement data would simply be used to refine the life prediction model.

Figure 2 depicts a diagram of a generic SHM process. First, there are two time intervals to consider: one associated with each opportunity for decision on maintenance (indexed by i) to be performed in

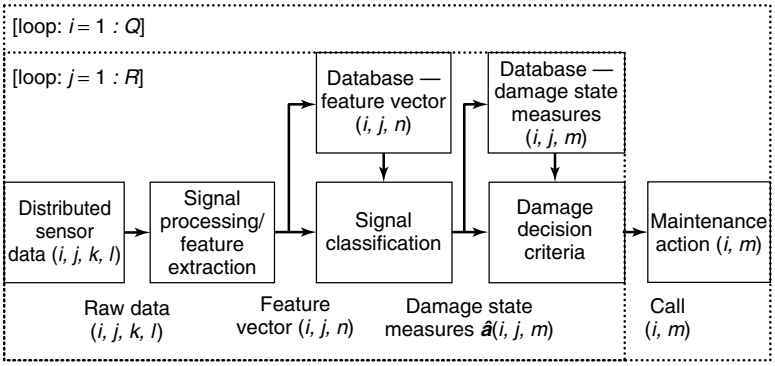

Figure 2. Flow diagram representation of an SHM system model identifying the steps of analysis from sensor data to decision on a maintenance action.

the field, and the other, an in-service SHM data-acquisition time interval (indexed by j) at which an assessment of the damage state can be performed. It is important to distinguish between these two time intervals, since data may be acquired and a damage state estimate may be obtained at a rate different from the rate corresponding to the opportunity for decisions on performing in-field maintenance in the form of secondary inspections and/or repairs. For each data-acquisition time interval (j), data can be acquired from each sensor (indexed by k) in the array for a given number of samples (indexed by l). For example, the number of samples (l) may be large for the case of acoustic emission measurements for impact damage estimation or quite small for humidity sensors for corrosion monitoring. Starting with the raw data, signal-processing and feature-extraction algorithms are applied to filter and extract features as a set of scalar values (indexed by n). Signal classification can subsequently be applied to a database of feature vectors collected over time to estimate the damage state ($\hat{\boldsymbol{a}}$) for each critical location (indexed by m). To assess the damage state and perform maintenance for each opportunity, a damage decision criterion, is applied on the basis of a maximum acceptable critical flaw size (a_{cr}). A database of damage state estimates ($\hat{\boldsymbol{a}}$) from prior decision intervals and data-acquisition periods (i, j) may be used in the decision process. The final step is the decision to perform a maintenance action such as a secondary inspection or repair.

From the perspective of quantifying the reliability of an SHM system, there is an underlying relationship that must be evaluated between the damage state estimate ($\hat{\boldsymbol{a}}$) and the actual damage state ($\boldsymbol{a}$), with special interest placed on the critical flaw size (a_{cr}) that prompts a maintenance action. This POD assessment is no different from the "$\hat{\boldsymbol{a}}$ versus $\boldsymbol{a}$" analysis procedure previously devised for NDE systems [30]. Although a model-based approach including each analysis step for the SHM process shown in Figure 2 would be ideal, it is proposed, as a first approximation, to represent the relationship between the flaw size and the POD, false call rate, and random missed flaw rate directly using a four-parameter POD model [31] given by

$$POD(a,t) = \alpha(t) + (\beta(t) - \alpha(t)) \times \left\{1 + \exp\left[-\frac{\pi}{\sqrt{3}}\left(\frac{\ln a - \ln \mu(t)}{\sigma(t)}\right)\right]\right\}^{-1} \quad (2)$$

where a is the flaw size, t is time, α corresponds to the false call rate, β is defined as one minus a random miss rate, σ controls the steepness of the POD curve, and μ is the flaw size for which the POD is 50%. Use of this four-parameter POD model has been recommended to address the fact that both hits and misses are often made for reasons that are independent of crack length. Note that α, β, σ, and μ can be functions of time to represent changes in the characteristics of the SHM system during its service life. One commonly proposed advantage of SHM systems is that they can be installed at locations of difficult access. This makes it necessary to model and evaluate the effects of time-dependent variations on the response of the SHM system.

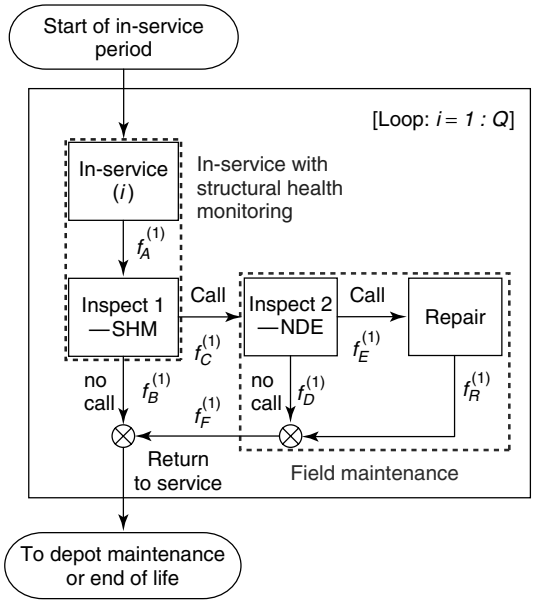

Figure 3. Flow diagram representing a model of an in-service period with SHM and an optional in-field maintenance.

Figure 3 presents a flow diagram for a basic SHM system integrated with an in-service period, with the opportunity for in-field maintenance incorporating a secondary inspection and repair process (with $j = 1$). A probabilistic analysis methodology is utilized for evaluating the model component blocks "Inspect 1—SHM", "Inspect 2—NDE", and "Repair" found in the figure.

In this formulation, $F\mathrm{p}^{(1)}$ and $f\mathrm{p}^{(1)}$ are defined as the cumulative density function (CDF) and probability density function (PDF) respectively, representing the flaw size distribution for feature type 1 (given by the superscript) at stage p (given by the subscript) in the inspect–repair subprocess. The subscripts A, B, and C are associated with flaw size distributions for the start of the SHM process, the portion associated with no call made (flaws not found), and the portion associated with a call made (flaws detected). ${P_{\mathrm{SHM}}}^{(1)}$ is defined as *the fraction of the PDF called (flaws detected) by the SHM process*, and is given by

$$ {P_{\mathrm{SHM}}}^{(1)} = \int_0^\infty POD_{\mathrm{SHM}}(a)\, f_A^{(1)}(a)\, \mathrm{d}a \tag{3} $$

where a is associated with flaw size and $POD_{\mathrm{SHM}}(a)$ is the POD function for the SHM process. The corresponding "no call" and "called" distributions resulting from SHM are respectively given by

$$ f_B^{(1)}(a) = (1 - POD_{\mathrm{SHM}}(a)) \times f_A^{(1)}(a) \tag{4} $$

$$ f_C^{(1)}(a) = POD_{\mathrm{SHM}}(a) \times f_A^{(1)}(a) \tag{5} $$

A secondary inspection given in block "Inspect 2—NDE" can also be evaluated in a similar fashion, where ${P_{\mathrm{NDE}}}^{(1)}$ is defined as *the fraction of the PDF called (flaws detected) by the NDE procedure*, and is given by

$$ \begin{aligned} {P_{\mathrm{NDE}}}^{(1)} &= \int_0^\infty POD_{\mathrm{NDE}}(a)\, f_C^{(1)}(a)\, \mathrm{d}a \\ &= \int_0^\infty POD_{\mathrm{NDE}}(a) POD_{\mathrm{SHM}}(a) \\ &\quad \times f_A^{(1)}(a)\, \mathrm{d}a \end{aligned} \tag{6} $$

The corresponding "no call" and "called" distributions resulting from the secondary NDE procedure are respectively given by

$$ \begin{aligned} f_D^{(1)}(a) &= (1 - POD_{\mathrm{NDE}}(a)) \times f_C^{(1)}(a) \\ &= (1 - POD_{\mathrm{NDE}}(a)) POD_{\mathrm{SHM}}(a) \\ &\quad \times f_A^{(1)}(a) \end{aligned} \tag{7} $$

$$ \begin{aligned} f_E^{(1)}(a) &= POD_{\mathrm{NDE}}(a) \times f_C^{(1)}(a) \\ &= POD_{\mathrm{NDE}}(a) POD_{\mathrm{SHM}}(a) \times f_A^{(1)}(a) \end{aligned} \tag{8} $$

For this example, the resulting repair distribution represents a return to the original state of the part for those flaws called both by the SHM process and the NDE technique, and can be expressed as

$$ f_R^{(1)}(a) = {P_{\mathrm{NDE}}}^{(1)} \cdot f_{R\_\mathrm{EIFS}}^{(1)}(a) \tag{9} $$

where $f_{R\_\mathrm{EIFS}}(a)$ represents the equivalent initial flaw size PDF for the original part. This process is repeated for Q iterations corresponding to each SHM manager decision and maintenance opportunity (i). Following this process, depot maintenance or end of life may be reached, depending on the design life of the aircraft. Extensions of this probabilistic model can be made to address problems where aircraft are removed from

service because of SHM calls (including availability tracking) and degradation of the SHM system using time-dependent POD models [10].

3.3 Cost models

Accuracy of cost models, one of the key elements of life-cycle management design, depends on various factors. First, the level of detail at which a cost model is developed will necessarily affect value analysis efforts. Second, not all relationships between cost and the various parameters that define health assessment technologies and processes may be taken into account. Third, the effects of random variations on cost can best be modeled using probabilistic methods. Finally, many of the numbers that are necessary for cost estimation must often be provided by the user in the form of coefficients and rates, and can be highly subjective, especially when historical data are not available or not appropriately considered. The influence of human factors on the accuracy of probabilistic cost estimates has been studied in [32], reportedly resulting in probabilistic cost models that better reflect the overconfidence in assessing uncertainty and relationships among cost elements and risks that are not usually considered. Here, we briefly describe a few cost modeling methods and tools, and warn the reader that these are only examples from a larger set of methods and tools that are currently available. As expected, the choice of the model will depend on the particular application, the desired level of detail, whether deterministic or stochastic models are desired, and how much data and knowledge are available to populate the model.

- The Integrated Cost Estimation (ICE™) software tool, by Frontier Technology (www.fti-net.com), uses a work breakdown structure for cost and provides capabilities for estimating LCC and for performing what-if studies and sensitivity analyses.
- TruePlanning®, from PRICE Systems (www.price systems.com) uses parametric models for estimating costs. Instead of building the model from the bottom up using materials and labor rates, the software uses representative data attributes from up-to-date knowledge bases.
- Crystal Ball, from Decisioneering, Inc. (www.crystalball.com) and @RISK, from Palisade Corp. (www.palisade.com), are two probabilistic modeling software tools that work with Microsoft Excel and use Monte Carlo simulation to estimate and optimize cost and risk statistics, among other variables.
- BlockSim, from Reliasoft Corp. (www.reliasoft.com), is capable of performing deterministic or probabilistic LCC analyses and other analyses (reliability, availability, etc.).

As discussed in Section 2.1, cost models for SHM systems must include all development, implementation, and in-service costs. To properly assess the true in-service cost associated with an SHM system, integrated models are needed to track all significant variable costs. These costs are a function of several variables including SHM indications, SHM false calls, flight hours (required to assess fuel cost due to added weight), and SHM monitoring and maintenance intervals.

3.4 Data and databases

A significant challenge to performing an accurate value assessment for an SHM system concerns the quality of the available data for the analysis. Examples of input parameter data for the probabilistic model that often exhibit large variability or significant expense to accurately quantify include (i) the equivalent initial flaw size distribution, (ii) the flaw growth model, (iii) the inspection POD model, and (iv) cost information. Databases have been developed and implemented for improved fleet structure management that also provide quality data to better understand the real flaw growth condition and inspection calls made over time. Two database examples include AIRCAT [33, 34] and FLEETLIFE [35, 36]. These data can be helpful in reducing uncertainty in the initial model assumptions and parameter values. Advancements in numerical fracture mechanics modeling and model-assisted POD evaluation can also be used to supplement initial model approximations [37, 38]. To practically obtain the best cost data for the analysis, partnerships must also be built and maintained with maintenance engineering, inspection services, repair teams, and the fleet managers to acquire the most accurate cost data to perform trade-off studies.

3.5 Framework for model analysis and optimization

Optimal design of an aerospace structure's life management strategy must take into consideration models for the various components described above, namely, the damage type, the damage detection process by on- and off-line transducers and algorithms, the scheduling of inspection processes, and the effects that changes in design parameters have on availability, reliability, and cost. Given such a complex set of interrelated factors, it becomes necessary to devise a method to integrate all these models to enable (i) estimation of costs, reliability, availability, and other figures of merits; (ii) sensitivity analysis; and (iii) optimization-based design of life management strategies. For example, in the case of probabilistic models for reliability and cost, Monte Carlo simulation becomes one obvious choice for estimation of outcomes when the statistics of all stochastic input variables are given. Several of the software tools described in Section 3.3 intend to provide such an integrated framework. The methods and web-based software framework described in [9], and other tools that are available in the market could also be expanded to provide these integration capabilities. During the last few years, the authors participated in the development of an integration tool specifically motivated by the need for optimal design of structural component life management strategies [10, 25–27]. That tool is used in the following section in the context of several examples.

4 APPLICATIONS

4.1 Applications—potential methods with related examples

Most of the existing applications of health monitoring in aerospace are in areas other than structures. However, there has been progress in applying systematic methods for justifying and designing SHM systems for aircraft structures. Albert *et al.* [39] present a systems engineering approach to SHM design for a nonspecific aging aircraft, and show by damage simulation and CEA, among other analyses, that implementing an SHM system on this aircraft may improve safety and decrease maintenance costs. Boller [40] studies various ways for monitoring structural health in a aging aircraft, from traditional NDE methods through loads monitoring to damage monitoring, from an LCC-benefit standpoint, and shows for a particular example that SHM makes good cost–benefit sense for certain components in the aircraft. Kent and Murphy [23] study the impacts, in terms of cost and other measures, of implementing SHM systems on several components of commercial aircraft. They found that if a 30–40% savings in maintenance costs is achieved, the initial investment can be recovered in 2–3 years for two of the structural components studied and 6–7 years for the third component because of the higher complexity of the SHM system. They also identified the need to integrate the SHM data with existing maintenance procedures to achieve best return on investment. In [24], Kapoor, Goh, and Boller present a methodology for simulating the operational and maintenance processes for a structure, including costs, and propose methods for identifying elements of the life management strategy that can be improved using SHM. Boller and Staszewski describe a procedure for establishing the LCC impact of new damage monitoring techniques in [[6], pp. 36–43] and the references therein, and show that the higher LCC impact is achieved on "highly loaded and difficult to access components".

4.2 SHM design space exploration

A methodology for optimum component life management including NDE and SHM has been proposed through the application of unified life-cycle engineering principles with integrated virtual design tools [10]. Prior work by the authors has addressed development of a software tool to enable analysis of trade-offs in NDE and SHM design in terms of structure life-cycle outcomes [10, 25]. Several important features in the software tool facilitate specialized design studies. In particular, any model factor can be selected and defined as *a variable for a parametric or optimization study*. Visualization and tabular features facilitate exploration of the design space in terms of key measures, e.g., total cost and maximum probability of failure (POF).

The continued development and integration of component models with structure service databases will provide the functionality to improve NDE and

Table 1. Parameter values for case study simulation

Fracture toughness normal distribution	
Mean	32.3 MPa-$m^{1/2}$ (29.4 Ksi-$in^{1/2}$)
Standard deviation	2.4 MPa-$m^{1/2}$ (2.2 Ksi-$in^{1/2}$)
Gumbell distribution for critical stress during flight	
α	1.26
β	21.7
Flaw growth model (Paris' law) parameters	0.0001
Repair EIFS distribution	
Au	0.01
ϕ	3
α	1.8
Parameters of POD	
50% median flaw size	1.27 mm (0.05 in.)
Curve steepness (s)	0.51 mm (0.02 in.)
False call rate	0
Random missed call rate	0
Critical crack length	12.7 mm (0.5 in.)

SHM design. CBM and prognostics programs can also benefit by (i) indicating the best service life time window for application (i.e., limit prognostics decisions in early stages of life to eliminate false calls), (ii) refining life prediction models based on monitoring the load and environmental conditions, (iii) determining precise end-of-life date from damage state measurement data, and (iv) reducing model uncertainty (in life prediction and POD models) over time.

4.3 Value assessment demonstrations using probabilistic tools

Several case studies are now presented to demonstrate the capability of the approach described in [10, 25] and to gain a better understanding of the dynamics of the SHM system model. Given the difficulty of obtaining precise data on specific cases for the equivalent initial flaw size distribution, the flaw growth model, the POD capability, and cost data, values were set based upon a combination of information acquired from maintenance personnel and values cited in the literature for related aircraft components. The general class of problem considered here was the inspection of fatigue cracks at fastener sites in multilayer aircraft wing structures as found in such aircraft as the C-130 [41]. More details on the life prediction model, including parameter descriptions, can be found in work by Berens *et al.* [28, 29]. Specific life prediction and POD model parameter values used for this study can be found in Table 1. The CDF for equivalent initial flaw size and the geometric relation between fracture toughness (Kc) over stress (σ) with respect to crack size are given in Figure 4(a) and (b), respectively. While the software allows for multiple fastener hole sizes to accommodate the actual case where holes with cracks are repaired by enlarging the diameter, the examples presented here use a single hole size. In addition, the relationship between flight hours and elapsed time was not taken into account in these hypothetical cases, but normally it will vary from aircraft to aircraft. The software also allows for the length of different in-service periods to be different and for specific inspection and repair parameters and cost factors to vary between in-service periods, but all these input quantities were kept constant for these examples.

The first study explores the effect of varying the number of in-service intervals for a fixed total service life, taking into account that during each service interval an integrated SHM system is collecting sensor data that must be analyzed upon landing. Any nonzero indication by the SHM system results in a field inspection and repair process. Figure 5 shows a screenshot of the cost report window for this example, in the case where the life of the system is divided into five in-service periods with SHM data processing and

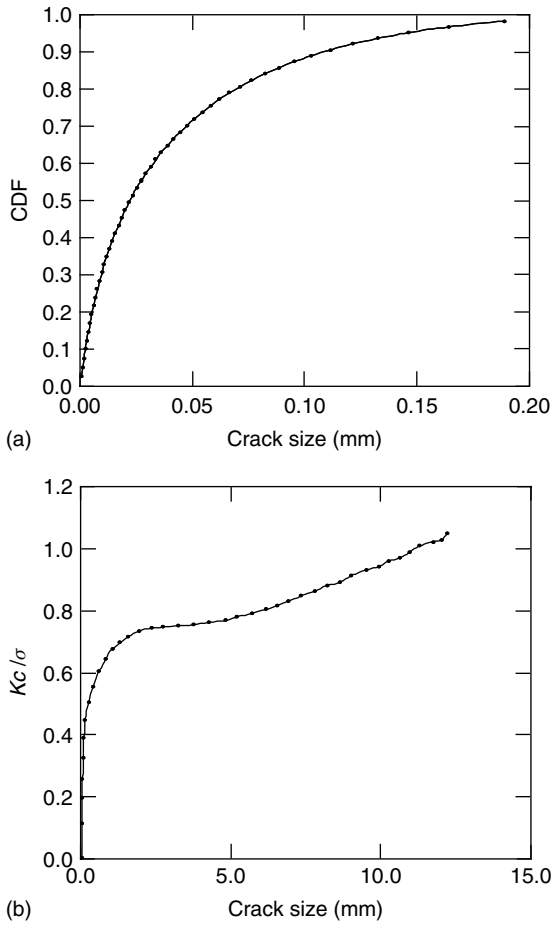

Figure 4. (a) Cumulative distribution function for equivalent initial flaw size and (b) geometric relation between fracture toughness (Kc) over stress (σ) with respect to crack size.

possible inspection and repair processes after each of the first four in-service periods.

As shown in Figure 5, the model includes initial costs of capital equipment and training, estimated at \$500 000 for this example. Variable costs for each service period are associated with the added fuel consumption due to the weight of the SHM system. For example, for the third in-service period, this cost is equal to \$2000, which is the product of the flight hours (8000) and the added cost of fuel per hour due to the SHM system weight (\$0.25). The fixed costs of preparing for SHM data processing and interpretation on the ground after the third in-service period are \$1500, while the variable costs of data interpretation depend on the amount of data collected, which, in turn, depends on the number of hours in the previous in-service period. That is, 8000 h at \$0.50/h results in \$4000 for interpreting the data from the SHM system after the third in-service period. Since the SHM system detects flaws at that time, a subsequent inspection and repair process must be performed. The fixed costs of maintaining the necessary facilities and equipment are \$20 000 and \$5000 for inspection and repair, respectively. Variable repair labor costs depend on the portion of the items being monitored that was identified by the SHM system and the subsequent field inspection as damaged. In the case at hand, after the third in-service period, 7.66% of all fastener locations being monitored were identified as requiring repair. This percentage, multiplied by the unit cost of repair (\$2 500 000), yielded variable repair labor costs of \$191 495.35 after the third in-service period.

Figure 6 shows the simulated results for probability of failure and cumulative maintenance cost as a function of time for 5, 20, and 50 in-service periods. Table 2 presents the maximum probability of failure over time and the total cost of SHM, NDE, and repair, for the same three cumulative in-service periods.

It is easily observed that for this first case study, a higher frequency of SHM calls will result in higher LCC. The source of this higher cost is twofold. First, the total cost associated with labor hours for data interpretation is increased with the frequency of SHM calls. In theory, this cost could be quite small if robust automated algorithms for data interpretation are used. In practice, given the high cost for repairs and potential for false calls due to unknown conditions not considered in the original design, secondary assessments of the SHM data by an expert inspector would be necessary. The second source for higher costs occurs over the later part of the service life, where noncritical flaws are called by the SHM system. Ideally, minimizing the frequency of calls while maintaining an acceptable level of reliability in terms of probability of failure is a fundamental design principle for minimizing LCCs. Alternatively, higher frequency rates of SHM calls can significantly improve reliability. This strategy is particularly valuable when the SHM system is designed to only detect very large flaws, the crack growth model is nonlinear, or large uncertainty is present in the crack growth model parameters.

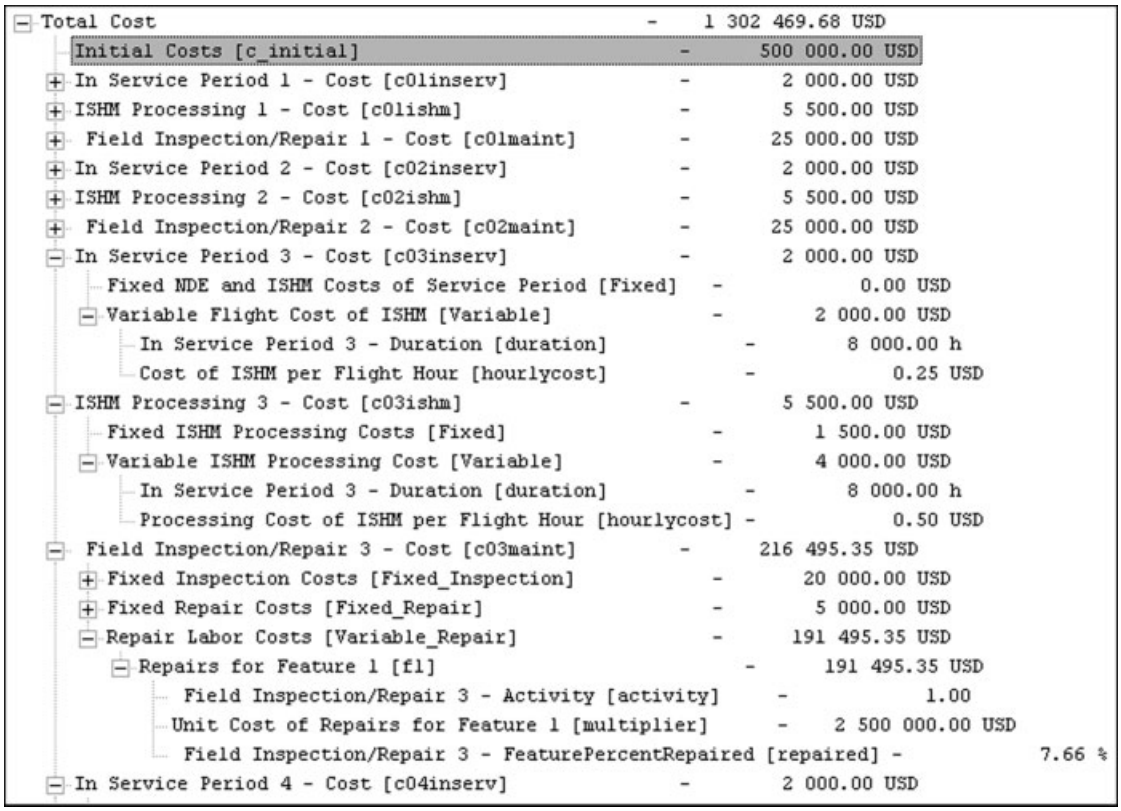

Figure 5. Cost structure and data for the first case study, using five in-service periods.

A second case study explores variations in the detectable flaw size for both an SHM system (Inspect 1—SHM) and a secondary NDE inspection technique (Inspect 2—NDE). Specifically, the 50% detectable flaw size parameters for the SHM and NDE inspection models were both varied from 0.51 mm (0.02 in) to 2.54 mm (0.10 in) as a full-factorial study. Figure 7 presents the design solution space resulting from the study in terms of maximum probability of failure and total cost. This design solution space plot provides the means to select the Pareto solutions providing the optimal trade-off between the two objectives. Furthermore, it is possible to select from this reduced solution set a design that minimizes cost while maintaining an acceptable probability of failure, typically set at 10^{-6}. Using these criteria, the optimal SHM system 50% detectable flaw size was found to be 1.52 mm (0.06 in), with the secondary NDE system 50% detectable flaw size set to any value greater than 1.27 mm (0.05 in)″.

A third case study explores the sensitivity of cost and reliability measures to SHM system false call rate. Owing to space limitations, only a discussion of the trends in the results is presented. As previously mentioned, the issue of false calls can hinder the application of SHM systems. Given the challenging problem of reliably detecting cracks using distributed sensors, false calls rates are expected to be comparable or higher with respect to NDE cases, typically on the order of 1%. However, although a 1% false call rate may be acceptable for less-frequent NDE inspections, when SHM calls are made at a more-frequent rate, a greater number of locations will be falsely called over the life of the aircraft and thus prompt some form of secondary maintenance action. This would be especially problematic given that the model predicts that most calls that are initially made are most likely false calls, thus having a negative impact on the product life management program and its sponsors. Secondary inspections were found to be

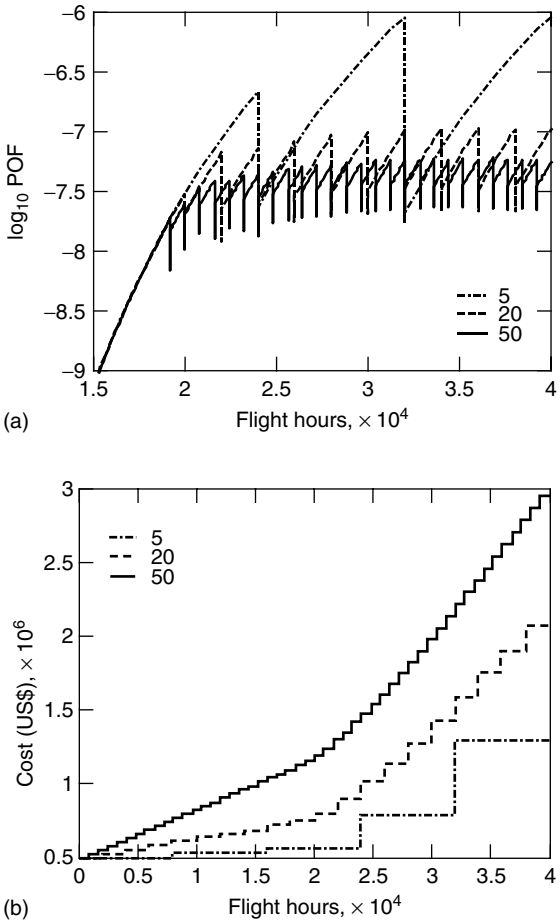

Figure 6. Plots of (a) probability of failure (POF) and (b) cumulative maintenance costs as a function of flight hours and SHM number of cycles.

Table 2. Maximum probability of failure and total cost for first case study

Number of in-service periods	Log_{10} of maximum probability of failure	Total SHM, NDE, and repair costs (US$)
5	−6.036	1 302 469.68
20	−6.969	2 066 261.90
50	−7.218	2 945 338.23

quite beneficial in mitigating cost by limiting unnecessary repairs due to false calls. However, if the cost of secondary inspections is not small, the total cost may be excessive and thus hinder practical use.

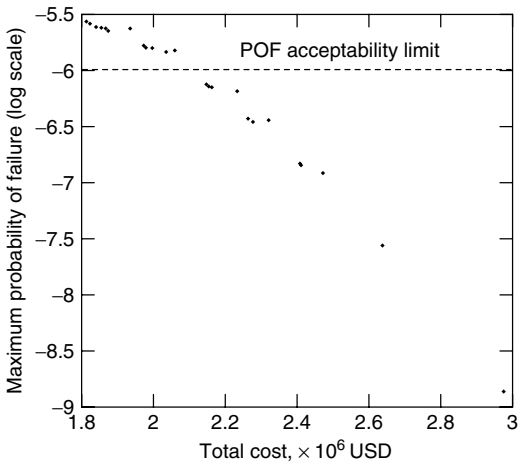

Figure 7. Design solution space for varying SHM and secondary NDE sensitivity in terms of maximum probability of failure (POF) and total cost.

This is a good example of the need to perform value assessment analysis taking into consideration all relevant technical factors of the technology in question.

5 CONCLUDING REMARKS

We have attempted to describe the state of the art in value assessment for SHM technologies. We believe the most likely current role of SHM in aerospace is as part of a hybrid structural life management strategy in which SHM and NDE technologies must work in a complementary fashion. We have presented an overview of existing methods for value analysis and identified several software tools that implement the various methods. Since SHM is a relatively new technology, not many field implementations have been found that resulted from a thorough analysis of the value of the technology. However, traditional value-analysis tools such as CBA can be utilized as long as the necessary models are in place. In addition, it may be advantageous to use more powerful trade-off analysis tools such as those offered by multicriteria optimization methods to clearly identify trade-offs among all the figures of merit for both SHM and the NDE methods that complement it. The accuracy of the data to populate all necessary models is of utmost importance, and the conclusions obtained from any of these analyses must always be qualified with references to the data that were used. This is especially

important because of the few existing applications of SHM and the fact that the real benefits of this technology are likely to be apparent only several years (or decades) after its adoption as part of structural life management. The ability of the design methods and software to facilitate design trade-off assessment and optimization, as shown in the examples, is quite valuable even when the models for the technology and its effects on reliability and cost and the necessary data and knowledge bases are still under development.

Future work should explore the sensitivity of model trends to model parameters and acquire better data on flaw size distributions and real costs of SHM implementations. Collaboration throughout the aerospace community is needed to make existing data available. Laboratory studies, aircraft teardown studies, the application of quantitative NDE techniques for flaw characterization, *in situ* sensors for damage state, loading and environment condition tracking, numerical models, and well-managed databases are all integral to building the necessary data sets and models.

Chapter 88
Environmental Monitoring of Aircraft

Nicholas C. Bellinger and Marcias Martinez
Institute for Aerospace Research, National Research Council Canada, Ottawa, Ontario, Canada

1 INTRODUCTION

When fixed-wing aircraft were designed and built, most manufacturers made little allowance for environmental degradation since aircraft were not expected to remain in service beyond their design service life. However, in the mid-1980s, when a 19-year-old Boeing 737 aircraft, operated by Aloha Airlines, lost a large portion of its front upper fuselage, it became the defining event in creating awareness into the possible issues associated with aging aircraft [1]. The cause of the accident was determined to be the development and linking up of multiple cracks at numerous rivet holes in the fuselage lap joints, which is referred to as *multi-site damage* (MSD) [2]. Since then, millions of dollars have been expended on MSD-related research activities to determine the impact this cracking scenario has on the structural integrity of fuselage lap joints.

During the Aloha investigation, both environmental (corrosion) and age degradation (fretting) modes were found to be present within the failed lap joints. However, since no direct correlation was made between these modes and the crack nucleation mechanism, very little research has been carried out into the possible effects these degradation modes have on aircraft structural integrity. Thus, corrosion has only been considered a durability issue affecting the remaining (residual) strength of a component because of the increase in stress due to the reduction in cross-sectional area resulting from material thinning. To ensure that corrosion does not cause premature failure of a component, limits are set on the amount (level) of acceptable damage (thinning). Therefore, components must undergo a repair procedure when the detected damage is above these limits. Owing to these arbitrary limits, billions of dollars are being spent worldwide each year in repairing corrosion damage. In the United States alone, it is estimated that the Department of Defense spends $20 billion annually in corrosion-related repairs [3]. One reason for this high expense is that, in the past, it was not possible to predict where or when corrosion would occur, or the time required to generate sufficient damage to affect the structural integrity of the aircraft.

2 WHY ARE WE IN THIS STATE?

Presently, two design methodologies are being used to determine the life of fixed-wing aircraft structures; safe life and damage tolerance. There is an additional paradigm known as *the fail-safe approach* but for this article, this concept is considered to be a derivative of the damage tolerance approach. The safe-life method is used to determine the time that a component can remain in service without the possibility of a crack forming. This method is used to design "safety" critical components, such as landing gears. The safe-life methodology assumes that all materials are ideal, continuous, homogeneous, and isotropic. To take into account the inherent material scatter, safety factors are applied to the fatigue (or endurance) limit. To prevent cracking, safety critical components are designed to avoid stresses above the fatigue limit. However, owing to the fact that materials are assumed to be free from "defects" or discontinuities, components must be immediately replaced once any damage is found, which has led to the current "find-it and fix-it" maintenance philosophy. This philosophy also results in the retirement of components that are not significantly damaged, and the failure of some components that develop cracks at stress raisers, such as corrosion pits.

To reduce the risk of aircraft flying with unknown cracks, the damage tolerance methodology was developed, which assumes that all fatigue critical components contain growing cracks and that failure can occur when actual conditions are different from those modeled. In this methodology, the crack growth life is estimated, which drives directed in-service inspections, allowing components to remain in service longer, thus reducing the cost of maintaining aircraft. These inspections are carried out to prevent cracks from occurring at unknown sources of discontinuities that may occur during the life of the component. However, failures have occurred in the past and are still happening that have been caused by unexpected degradation modes, such as fretting and corrosion.

Both these methodologies were developed on the basis of a combination of basic scientific principles that were developed at the time (30–40 years ago) as well as practical experience, but this experience does not include the effect that the environment has on component life. As when they were first developed, these methods still rely on the generation of empirical material properties, such as the fatigue properties used for the strain–life method (safe life) or crack growth rate properties (damage tolerance) to determine the number of cycles, or flight hours, to a prespecified small crack length or the time required to grow a crack to a critical size. This life estimation is then monitored throughout the life of an aircraft using specified nondestructive inspection (NDI) techniques in order to reduce the risk of failure for a specific component. This reliance on both analytical and experimental techniques, to predict the life of aircraft components that do not take into account environmental or age degradation modes, is the main cause for the significant increase in the cost of aircraft maintenance. In a previous study, corrosion was shown to significantly decrease the time required to form a crack (nucleation life) without affecting the time required to grow a stable crack (long crack growth rate) [4, 5]. This early crack nucleation life raises concerns about the effect corrosion might have on the structural integrity of aircraft components, particularly if they are known to be susceptible to cyclic loading (fatigue).

3 WHAT CAN WE DO?

On the basis of past experience, corrosion prone areas in aircraft are well known and include fuselage lap joints, upper and lower wing skins, and landing gear. Some examples of the types of corrosion damage found in aircraft are shown in Figure 1, which includes pitting, crevice, and exfoliation corrosion [6]. To determine if corrosion is present, traditional NDI techniques are used to examine specific components at predetermined operating (flying) times. It is interesting to note that the time an aircraft remains on the ground, which can be significant, is not taken into account in determining inspection frequencies even though corrosion requires the presence of stagnant water to form and grow. One problem with current NDI techniques, such as ultrasonic and eddy current, is the fact that a significant amount of damage needs to be present (about 10% thickness loss) to reliably detect corrosion to avoid expensive false calls. These high levels usually result in damaged components being replaced, which can significantly increase the cost of aircraft maintenance. In addition, since some of the areas of concern are not easily accessible, a

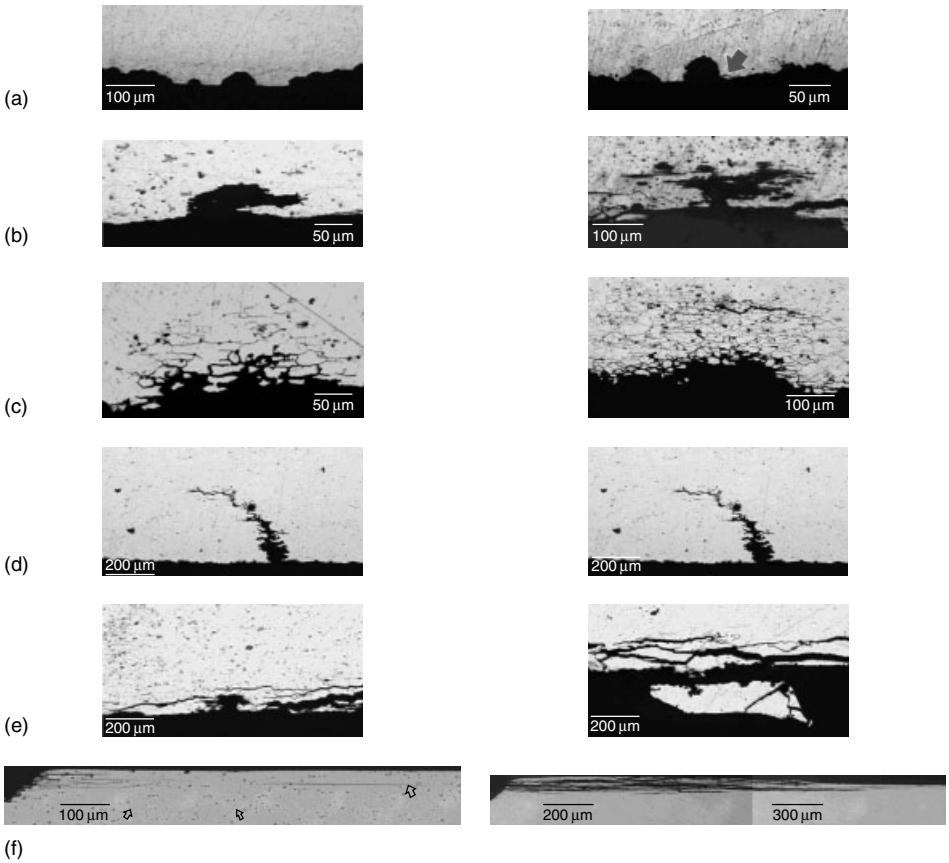

Figure 1. Examples of service-induced corrosion obtained from in-service and retired aircraft [6]. (a) Corrosion pitting in thin aluminum (2024-T3); (b) severe pitting resulting from crevice corrosion in thin aluminum (2024-T3) lap joints; (c) intergranular corrosion in thin aluminum (2024-T3); (d) environmental-assisted cracking in aluminum lap joints (2024-T3), referred to as *pillowing cracks*; (e) exfoliation corrosion in thin aluminum (2024-T3) lap joints; and (f) exfoliation corrosion in thick section aluminum (7178-T6) upper wing skins.

significant amount of time may be required just to gain access to the corrosion, assuming it is actually present. Corrosion, quite simply, is unpredictable and therefore often unexpected, thus increasing downtime for maintenance, delaying return to service, and adding to costs.

To reduce this cost, inspections need to move from opportunistic (as they are now) to directed. To accomplish this, one needs to know what to look for (in this case, what type of corrosion), where to look, how to look (inspection technique to use), and when and how often to look. Basically, this means that the state of an aircraft must be known prior to commencing a scheduled maintenance cycle. One possible approach is to assess the state of an aircraft by placing direct corrosion sensors (DCS) and/or corrosive environment sensors (CES) at key locations. These sensors could be used to monitor the state of the component to determine when corrosion damage is present, which, in turn, would allow inspections for corrosion to be tailored to individual aircraft, possibly delaying repairing the damage until a more appropriate time, resulting in a significant cost saving.

Many factors affect the deterioration of metallic structures, such as changes in material properties, time/temperature/chemical environment, and in-service operations, including field use and storage [7, 8]. It is for this reason that corrosion sensors are important for monitoring and establishing the rate and degree of deterioration of aircraft structures. See

Part 5 of this encyclopedia for more information regarding the different sensor types.

In this section, we have subdivided the different corrosion sensors into three categories. The first category, which we refer to as *corrosive environment sensors* for the most part, monitors environmental properties, such as pH levels of the atmosphere or fluid, oxygen levels, and temperature or humidity. This category also includes those sensors that measure the corrosivity of the environment by using a surrogate metal to determine the need for maintenance. These sensors do not necessarily provide information on the health of the structure but determine if the conditions are present to cause corrosion. Therefore, to use these types of sensors, signal processing has to be carried out to determine a correlation between the corrosiveness of the environment and the actual corrosion damage incurred by the structure [9]. Refer to **Data Preprocessing for Damage Detection** for more details on data processing, as well as **Statistical Pattern Recognition** and **Artificial Neural Networks**. Also, these sensors do not detect or determine the location of the corrosion on a structure and thus prior knowledge of which components are susceptible to corrosion is necessary.

The second category of sensors contains those that monitor the health of the structure. This is done by sensors that are adhered to the surface or embedded within the structure. We refer to these types of sensors as *direct corrosion sensors*, because they attempt to directly measure the damage that is present on the structure by measuring the changes in various parameters. These parameters depend on the type of sensor but include electrical impedance, resistance measurements, and wave propagation through the structure. Algorithms must be developed to relate the measured parameter to the level of damage present on the structure. One system that has been developed by Honeywell International (USA) and Avonwood Developments LTD (UK) [10] measures the resistance value along a prescribed path that contains a sealant and protective coating. When this protective system has broken down and moisture has penetrated, a conductive path is created resulting in a low resistance value indicating the presence of galvanic corrosion.

With the availability of smart materials, new types of sensors have been developed. Piezoelectric (PZT) sensors are being used as DCS. PZT arrays have been placed in structures in strategic locations creating sensor arrays. The piezoelectric materials are capable of generating elastic waves that propagate through the structure, which are then sensed by other PZT sensors within the array. These types of arrays are able to identify cracks and corrosion damage on the structure due to changes in the characteristics of the waves. The results can be interpreted to determine location and amount of damage generated in the structure [11].

We refer to the third and last category as *multifunctional corrosion sensors* (MFCS). These sensors have the capability of monitoring chemistry and characteristics to establish the corrosive nature of the environment as well as measure corrosion damage that is present on the structure. By combining the different sensors, already developed in conjunction with wireless/wired transmission of data and the miniaturization of high-speed processors, a network of sensors can be created to produce "smarter" structures that can be an integral part of any structural health monitoring program.

4 HOW SHOULD WE PROCEED?

With the introduction of different types of sensors, a link must be made between the parameters being monitored, the level of corrosion damage present on the component (if it is not measured directly) and the effect this damage has on the structural integrity of the component. To develop this link, numerous experiments will need to be carried out under similar service conditions to generate the algorithms and data required to relate the data generated by the sensors to the life assessment models. In addition, statistically significant databases need to be generated to determine the various distributions that take into account the large scatter associated with environment degradation. These distributions, which have to be generated for each material system that is susceptible to environmental degradation, take into account the large variation in the size of corrosion damage as well as the very large scatter in corrosion growth rates. To avoid the use of large safety factors, Monte Carlo simulations are used to account for the scatter associated with the various databases.

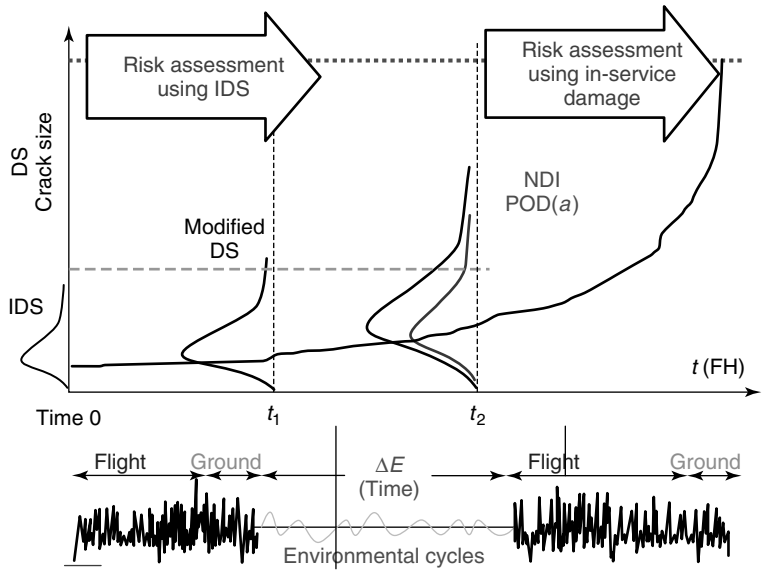

Figure 2. HOLSIP considers the progression of discontinuity states (cyclic operation spectra and time on ground spectra both with environment). FH, fight hours.

Since both existing life prediction methods do not take into account environmental degradation, new physics-based life management methodologies must be developed so that the causes, or reasons, behind potential failures are well understood (physics-of-failure). This, in turn, will allow manufacturers and operators to predict potential failures prior to an aircraft entering service. It can also be used to schedule maintenance by determining if the environmental degradation present on a component would result in unsafe operation of the aircraft, thus ensuring that repairs are planned.

One such methodology being developed is known as the *holistic structural integrity process* (HOLSIP), which is able to determine the total life of a component by including all four phases of life: nucleation, short/small crack growth, long crack growth, and unstable fracture [12–15]. The ultimate goal of this process is to ascertain the basic fatigue response of a structure from the as-manufactured state, including the early stages of damage formation. It is also being developed to assess the criticality of structures subjected to cyclic loading as well as age and environmental degradation, such as fretting, corrosion pitting, general corrosion, and corrosion pillowing. This is accomplished by accounting for the time in the air as well as the time while moving or at rest on the ground, as shown in Figure 2 [16].

Presently, HOLSIP contains physics-based models that take into account both cyclic and age/environmental effects by predicting the progression of initial discontinuity states (IDS) through the life of a component [12]. These models have been verified using results obtained from both coupon and in-service aircraft [16]. The term *IDS* is used to describe the as-produced or as-manufactured state of the material and is determined using standard metallurgical procedures to obtain the size and shape of the intrinsic discontinuities. IDS is a geometric and material characteristic that is a function of composition, microstructure, phases and phase morphology, and the manufacturing process used to process the material. However, since it is well known that not all discontinuities lead to the formation of cracks, a limited number of cyclic tests need to be carried out to determine the fatigue critical discontinuities that result in the formation of cracks. It is recognized that this process can be time-consuming and costly and thus procedures are being developed that use Monte Carlo simulations to be able to analytically predict the critical fatigue subset.

The effects of environmental degradation and fatigue, which can act not only concurrently but also independently, are characterized within HOLSIP

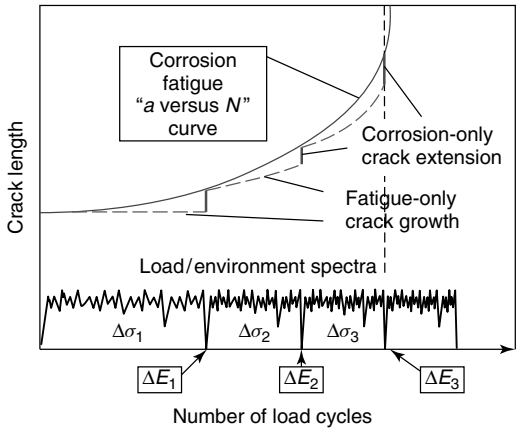

Figure 3. Corrosion fatigue analysis procedure in HOLSIP. [Reproduced with permission from Ref. 17. © USAF—ASIP, 1999.]

by changes in the crack-tip stress intensity. Fracture mechanics principles and special environmental parameters are used to formulate the required stress intensity factor solutions that are used to calculate the crack growth increment [16]. The data obtained from the various corrosion or environmental sensors could be used to more accurately calculate these special parameters. Over the past few years, the National Research Council Canada (NRC), in conjunction with other organizations, has carried out extensive research to develop special parameters to represent the effects of corrosion (corrosion-related thickness loss and corrosion pillowing stress) and corrosion–fatigue interaction (local geometry stress risers, topography change, and corrosion-induced sustained stress) on the stress intensity factor. In HOLSIP, the total crack growth is determined through the summation of the cyclic damage and time-dependent damage as shown in Figure 3, which is used to grow an initial discontinuity state to final instability.

To be able to account for not only the typical fatigue-associated uncertainties within a material, manufacturing, and loading but also age degradation uncertainties such as corrosion growth rate, probabilistic techniques must be included within the HOLSIP framework [15]. An additional probabilistic method is also required to interpret the NDI results for age degradation damages, which is not available in the current damage tolerance analysis methodology. An in-house probabilistic damage tolerance analysis (ProDTA) methodology has been developed as shown in Figure 4, which incorporates the HOLSIP-based lifing models and enhanced probabilistic techniques to analyze structural risk with age degradation. This type of analysis can be used to determine the repair action that would be more cost effective, since some repairs can result in more damage than was originally present [18]. The various input parameters that are required to carry out a quantitative risk assessment are shown in Figure 5. As can be seen from this figure, a significant amount of information is needed. The probabilistic analysis procedures employed in ProDTA are shown schematically in Figure 6. The analysis starts from the IDS distribution for the as-produced and as-manufactured material. Two methods were developed to grow the IDS distribution to the next inspection/repair time, t_1. The

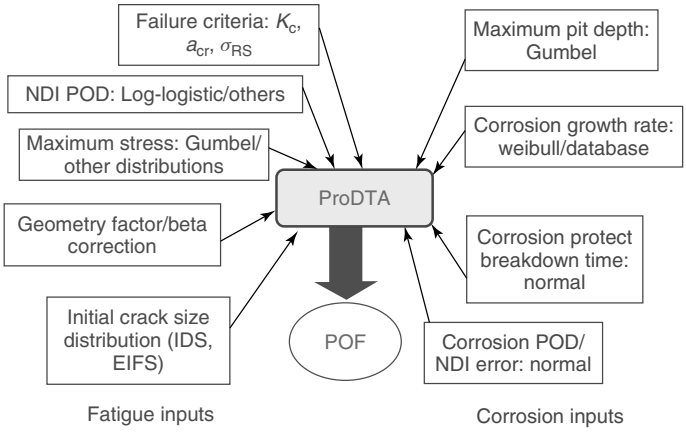

Figure 5. Input parameters required for age and environmental degradation risk assessment. EIFS, equivalent initial flaw size.

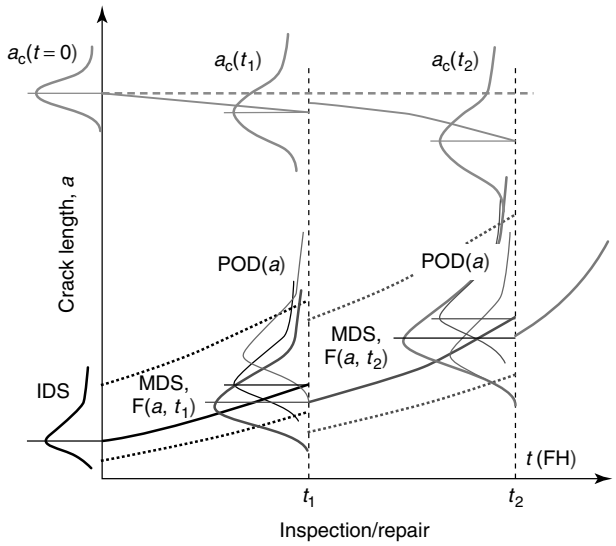

Figure 6. Analysis procedures employed in ProDTA.

first method is to project the crack size distribution based on a single master crack growth curve. The second method is to grow the crack size distribution using a Monte Carlo analysis, which allows ProDTA to use more random variables, especially age degradation parameters, such as corrosion growth rate, thickness loss, pit depth, and corrosion protection breakdown time [15]. When inspection/repair actions take place at a given time (t_1), the crack size distribution would be modified on the basis of a probability of detection function POD(a) and a repaired crack size distribution. The modified crack size distribution is grown again to inspection/repair time, t_2, and the above procedure is repeated till the end of the life cycle. For an analysis that includes age and environmental degradation, both crack size distribution and critical crack size distribution are varied with time t, and joint distribution functions of more age-degradation-related random variables, such as corrosion growth rates, pit depth, and corrosion protection breakdown time. Given the number of fatigue and environmental degradation random variables (more

than three), it is impossible to obtain a closed-form solution and, therefore, mixed techniques of Monte Carlo simulation and probability integration have been developed in ProDTA.

It needs to be emphasized that the accuracy of the risk assessment results is strongly linked to the quality of the data available. By placing the appropriate sensors at specific locations within an aircraft, the data required to carry out a risk assessment can be obtained, which can then be used within ProDTA. This data can include corrosion growth rates by determining the thickness loss versus time as well as the time required to breakdown the corrosion protection system, which is one of the main parameters that is very difficult to determine. As data is accumulated over time through the use of these sensors, statistical distributions for various parameters can be generated for a particular material system, which will allow for a combined mixed Monte Carlo simulation and probability integration to be carried out.

Use of Leave-in-place Sensors and SHM Methods to Improve Assessments of Aging Structures

Dennis Roach

Sandia National Laboratories, Albuquerque, NM, USA

 ISBN: 978-0-470-05822-0.

1 SMART STRUCTURES VERSUS NONDESTRUCTIVE INSPECTION

The costs associated with the increasing maintenance and surveillance needs of aging structures are rising. The application of distributed sensor systems can reduce these costs by allowing condition-based maintenance practices to be substituted for the current time-based maintenance approach. Through the use of *in situ* sensors, it is possible to quickly, routinely, and remotely monitor the integrity of a structure in service [1]. This requires the use of reliable structural health monitoring (SHM) systems that can automatically process data, assess structural condition, and signal the need for human intervention. Prevention of unexpected flaw growth and structural failure can be improved if onboard health monitoring systems could continuously assess structural integrity. Such systems would be able to detect incipient damage before catastrophic failures occur.

A "smart structure" is one that is sufficiently instrumented so that the data can be synthesized to form an accurate real-time picture of the state of the structure in all its critical aspects. In this case, the absence of disbonds and delaminations indicates that the doubler

is able to perform its duty. The absence of cracks indicates that the structure is able to continue to operate safely. The current state of nondestructive inspection (NDI) involves the manual application of visual, ultrasonic eddy current, X-ray, and penetrant NDI methods. While the data presented in this report indicates that manual inspections provide a reliable health monitoring approach, less labor intensive and more frequent structural assessments can be performed via distributed sensor systems. Such health monitoring systems utilize a network of leave-in-place sensors that can assess a structure on a frequent, or even continuous, basis.

Nondestructive inspection (NDI): The examination of a material to determine geometry, damage, or composition by using technology that does not affect its future usefulness.

- involves a high degree of human interaction
- local, focused inspections
- requires access to area of interest
- time-based monitoring—applied at predetermined intervals
- portable and applied to numerous areas.

Structural health monitoring (SHM): Also known as "Smart structures"; the use of NDI principles coupled with *in situ* sensing to allow for rapid, remote, and even real-time condition assessments; the goal is to reduce operational costs and increase life of structures.

- allows for greater vigilance in key areas—address damage tolerance needs;
- overcomes accessibility limitations, complex geometries, depth of hidden damage;
- eliminates costly and potentially damaging disassembly;
- minimizes human factors with automated sensor deployment and data analysis;
- supports adoption of condition-based maintenance.

2 USE AND ADVANTAGES OF *IN SITU* STRUCTURAL HEALTH MONITORING

Prevention of unexpected flaw growth and structural failure could be improved if onboard health monitoring systems that could continuously assess structural integrity exist [2–4]. Reliable, SHM systems can automatically process real-time data, assess structural condition, and signal the need for human intervention. Such systems would be able to detect incipient damage before catastrophic failures occur. The replacement of our present-day manual inspections with automatic health monitoring would substantially reduce the associated life-cycle costs. SHM systems using distributed sensor networks allow for condition-based maintenance practices to be substituted for the current time-based maintenance approach. Other advantages of onboard distributed sensor systems are that they can eliminate costly, and potentially damaging, disassembly, improve sensitivity by producing optimum placement of sensors with minimized human factor concerns in deployment, and decrease maintenance costs by eliminating more time-consuming manual inspections.

Whether the sensor network is hardwired to an accessible location within the structure or monitored in a remote, wireless fashion, the sensors can be interrogated easily and often even in a real-time mode. It is anticipated that the sensors will most likely be examined at discrete intervals, probably at normal maintenance checks. The important point to note is that the ease of monitoring an entire network of distributed sensors means that structural health assessments can occur more often, allowing operators to be even more vigilant with respect to flaw onset. Figure 1 depicts a sensor network deployed on an aircraft to monitor critical sites over the entire structure.

Multisite fatigue damage, hidden cracks in hard-to-reach locations, disbonded joints, erosion, impact, and corrosion are among the major flaws encountered in today's extensive array of aging structures and mechanical assemblies. Furthermore, the extreme damage tolerance and high strength-to-weight ratio of composites have motivated designers to expand the role of advanced materials in industrial structures. These developments, coupled with new and unexpected phenomena, have placed greater demands on the application of advanced NDI and health monitoring techniques. In addition, innovative deployment methods must be employed to overcome a myriad of inspection impediments stemming from accessibility limitations, complex geometries, and the location and depth of hidden damage. Recent requests for real-time

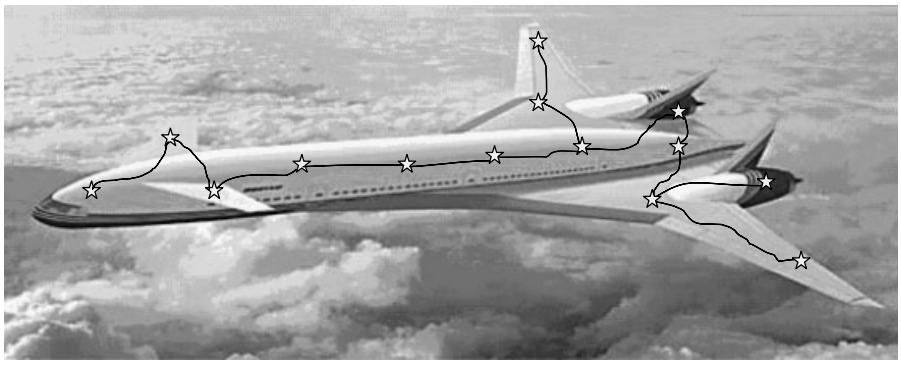

Figure 1. Depiction of a distributed network of sensors to monitor structural health.

monitoring of structures have produced a niche for active sensor systems.

In addition to mature microelectromechanical systems (MEMS) devices such as acoustic emission sensors, accelerometers, strain gauges, and pressure sensors, recent advances in microsensors have produced miniature eddy current (EC), ultrasonic, piezoelectric, fiber-optic (FO), and other devices that lend themselves more directly to damage detection. Technology exists to colocate the processing electronics with *in situ* sensor networks to produce real-time transmission of data and real-time diagnostics of structural health. When combined in a systems approach that includes sensors to monitor electronics, hydraulics, and avionics, it is possible to produce a prognostic health management (PHM) architecture that can assist in maintenance scheduling and tracking. This article focuses on developments and testing of mountable sensors and how they can be integrated into such a health management system. Specific example applications are discussed along with issues that must be addressed to realistically deploy leave-in-place sensors. Successful field testing is presented to quantify the performance of real-time health monitoring systems and to highlight their use in guiding condition-based maintenance activities.

The costs associated with the increasing maintenance and surveillance needs of our aging infrastructure are rising at an unexpected rate. The application of distributed sensor systems may reduce these costs by allowing condition-based maintenance practices to be substituted for the current time-based maintenance approach. In the near future, it may be possible to quickly, routinely, and remotely monitor the integrity of a structure in service. A series of expected maintenance functions will already be defined; however, they will be carried out only if their need is established by the health monitoring system [3, 4].

3 COMPARATIVE VACUUM MONITORING

Comparative vacuum monitoring (CVM) has been developed on the principle that a small volume maintained at a low vacuum is extremely sensitive to any ingress of air [5]. Figure 2 shows top-view and side-view schematics of the self-adhesive, elastomeric sensors with fine channels on the adhesive face along with a sensor being tested in a lap joint panel. When the sensors are adhered to the structure under test, the fine channels and the structure itself form a manifold of galleries alternately at low vacuum and atmospheric pressure. When a crack develops, it forms a leakage path between the atmospheric and vacuum galleries, producing a measurable change in the vacuum level. This change is detected by the CVM monitoring system shown in Figure 3. Embedded sensors may be formed using a load-bearing elastomer. This material is able to withstand the high loading stresses that result during the riveting process.

These sensors can be attached to a structure in areas where crack growth is known to occur. On a preestablished engineering interval, a reading is taken from an easily accessible point on the aircraft. Each time a reading is taken, the system performs a self-test. This inherent fail-safe property ensures the sensor is

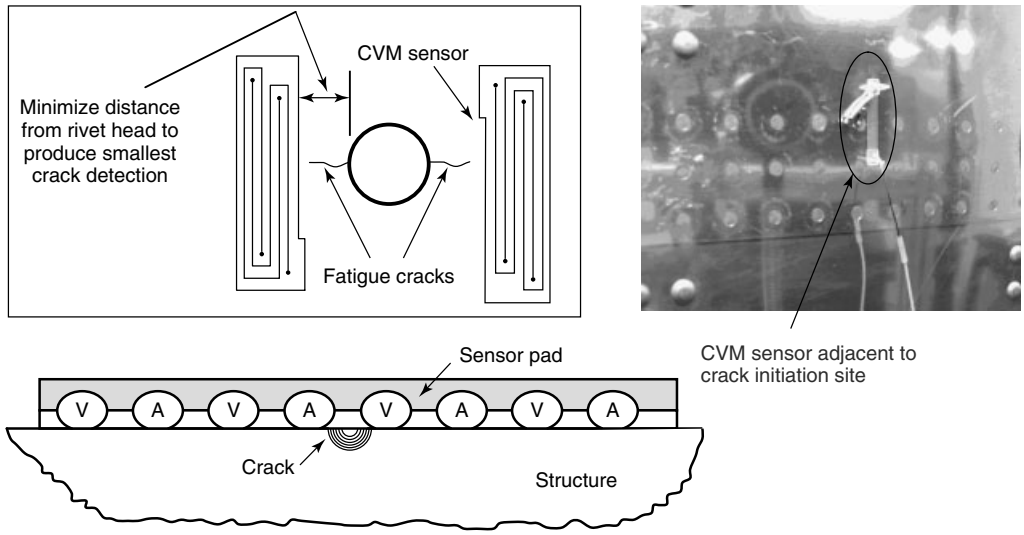

Figure 2. Schematics depicting operation of CVM sensor and polymer sensor mounted on outer surface of a riveted lap joint.

attached to the structure and working properly. Since the sensor physics is based on pressure measurements, there is no electrical excitation involved. This can be important in areas where electrical signals can create interference (near avionics) or where electrical connections may pose a hazard (fuel tanks).

Figure 3 also shows sample CVM sensors mounted on an aircraft structure as part of a performance validation effort. A series of 26 sensors have been mounted on the structure in four different DC-9, 757, and 767 aircraft of the Northwest Airlines and Delta Air Lines fleet. Some of the sensors were installed over two years ago. Periodic testing was used to study the long-term operation of the sensors in actual operating environments. This environmental durability study complements the laboratory flaw detection testing described below as part of an overall CVM certification effort.

Sandia Labs, in conjunction with Boeing, Northwest Airlines, Delta Airlines, Structural Monitoring Systems, the University of Arizona, and the Federal Aviation Administration (FAA), completed validation testing on the CVM system in an effort to adopt CVM as a standard NDI practice [5, 6]. Fatigue tests were completed on simulated aircraft panels to grow cracks in riveted specimens (see Figure 2) while the vacuum pressure within the various sensor galleries was simultaneously recorded. The fatigue crack was propagated until it engaged, and fractured, one of the vacuum galleries such that crack detection was achieved (sensor indicates the presence of a crack by its inability to maintain a vacuum). In order to properly consider the effects of crack closure in an unloaded condition (i.e., during sensor monitoring), a crack was deemed to be detected when a permanent alarm was produced and the CVM sensor did not maintain a vacuum even if the fatigue stress was reduced to zero.

3.1 CVM validation—data analysis using one-sided tolerance intervals

The CVM sensor is based on the principle that a steady-state vacuum, maintained within a small volume, is sensitive to any leakage. A crack in the material beneath the sensor allows leakage, resulting in detection. The data analyzed here consists of cracks that were fatigue cycled in various metal specimens with the direction of growth aligned with the CVM mounted sensors. The data captured is that of the flaw length at the time for which the CVM provided sustainable detection. Thus, the specific flaw would not be considered detectable prior to reaching the stated length, but is considered to continue to be detectable upon further growth. With these assumptions, there exists a distribution on the flaw lengths at which detection is first made. In this context,

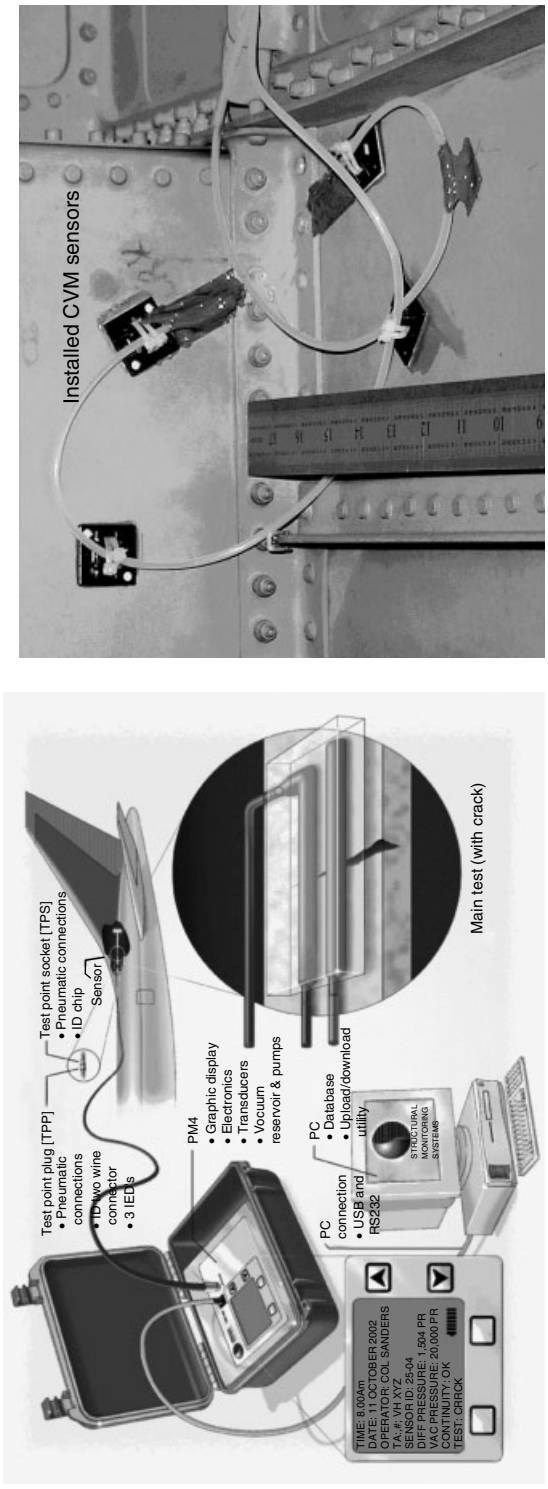

Figure 3. Schematic showing hardware set-up for crack detection via CVM system and sample aircraft test installations of sensors.

the probability of detection (POD) for a given flaw length is just the proportion of the flaws that have a detectable length less than that given length. That is, the reliability analysis becomes one of characterizing the distribution of flaw lengths, and the cumulative distribution function is analogous to a POD curve. Assuming that the distribution of flaws is such that the logarithm of the lengths has a Gaussian distribution, we calculate a one-sided tolerance bound for various percentile flaw sizes. To do this it is necessary to find factors $K_{n,\gamma,\alpha}$ such that the probability γ is such that at least a proportion $(1-\alpha)$ of the distribution will be less than $X - K_{n,\gamma,\alpha}$, where X and S are estimators of the mean and the standard deviation computed from a random sample of size n. The data captured is the crack length at CVM detection. From the reliability analysis a cumulative distribution function is produced to provide the maximum likelihood estimation (POD). This stems from the one-sided tolerance bound for the flaw of interest using the equation:

$$POD_{95\%\ \text{confidence}} = \mathrm{X} + (\mathrm{K}_{n,0.95,\alpha})(\mathrm{S}) \qquad (1)$$

where X: mean of detection lengths; K: probability factor (~sample size, confidence level desired); S: standard deviation of detection lengths; n: sample size; and $1-\alpha$; detection level.

3.2 CVM performance testing on thin aluminum structures

This test program produced a statistically relevant set of crack detection levels for 0.040″- and 0.100″-thick panels in both the bare and primed configurations. Figure 4 shows the fatigue test setup used to grow cracks and a close-up photo of the CVM sensors monitoring cracks initiating from a center hole. Figure 5 shows a photo of a fatigue crack as it engages the first vacuum gallery of a CVM sensor. The pressure rise, corresponding to a rupture in the gallery and a leakage path to atmospheric pressure, is shown on the right side of Figure 5. The large increase in the pressure corresponds to crack detection. In actual field measurements, the plot shown in Figure 6 would be produced. One signal (lower curve) corresponds to vacuum levels produced when there is no crack indication and the other signal (upper curve) occurs when a vacuum is not achievable. This latter signal is produced when the CVM detects a crack. Such a curve with a pressure level of at least 300 Pa must be produced when the structure is unloaded.

Results to date have revealed crack detection lengths—permanent alarm after the fatigue crack engages the CVM sensor—for the bare and primed 0.040″-thick panels. Tables 1 and 2 summarize some

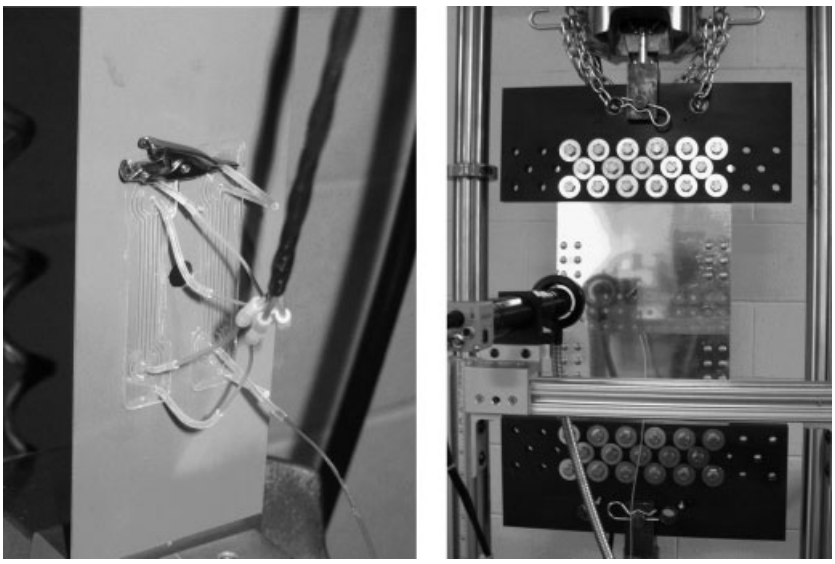

Figure 4. CVM sensors monitoring crack growth on aluminum test specimens.

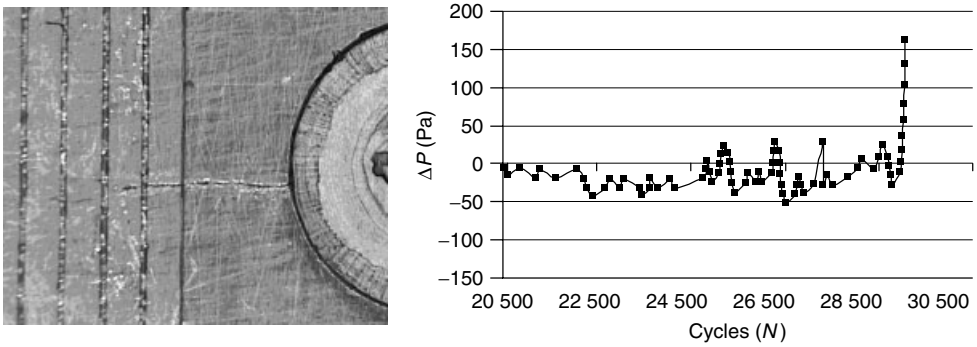

Figure 5. Fatigue crack crossing into CVM galleries; differential pressure shown as a function of cycle number (pressure increase caused by crack reaching a gallery is clearly indicated).

of the results. Table 2 lists CVM crack detection results for 0.040″-thick aluminum plate in both a coated (primer) and an uncoated condition. Crack detection lengths ranged from 0.002″ to 0.020″. Fatigue tests have shown that pressure levels in excess of 300 Pa were measured during fatigue testing; however, the compressive residual stresses at the tip of a fatigue crack could allow a vacuum to be produced when the specimen was unloaded. The numbers presented in Tables 1 and 2 correspond to *permanent* alarm levels for cracks engaging CVM sensors and the structure in an unloaded condition.

The 90% POD level for crack detection on 0.1″-thick aluminum—calculated from equation (1)—is also listed in Table 1. Owing to the limited number of data points, the reliability calculations induce a penalty by increasing the magnitude of the K (probability) factor. As a result, the overall POD value (95% confidence level) for CVM crack detection in 0.100″-thick aluminum skin is 0.023″. This POD curve is plotted in Figure 7. As the number of data points increases, the K value will decrease and the POD numbers could also decrease. In this particular instance, it was desired to achieve crack detection before the crack reached 0.100″ in length so that this goal was achieved. Table 3 summarizes the 90% POD levels (95% confidence level) for CVM crack detection for the array of thin-walled aluminum plates tested.

3.3 CVM performance on thick steel structures

The results cited above are valuable for thin-walled structures such as those used in aircraft, automotive, and some pipeline construction. However, many civil structures use thick steel members. Earlier studies revealed that the thickness of the plate can affect CVM performance, so a second round of tests included CVM crack detection in thick-walled structures. It should be noted that aircraft use thinner materials and have crack detection requirements of 0.050–0.100″ in length. Civil structures contain thicker materials and have higher safety factors. Thus, these structures can tolerate longer cracks and their crack detection requirements are in the range of 0.5–1″ in length. CVM sensors can be fabricated with different gallery sizes in order to accommodate various sensitivity requirements.

Figure 8 shows the installation of a CVM sensor on a 0.375″-thick steel (ASTM 572) plate. The seeded fatigue crack along the edge of the specimen is visible. These test specimens were then exposed to tension–tension fatigue tests in order to propagate the crack into the CVM sensor. Figures 9 and 10 show the overall test setup along with the equipment used to monitor the CVM sensors.

Compressive stresses around the tip of a fatigue crack create a tight tip when the load is removed. As a result, the initial engagement of a crack with a CVM sensor may induce a high-pressure reading (crack detection) when the structure is under load; however, the compressive residual stresses at the tip of a fatigue crack could allow a vacuum to be produced when the specimen was unloaded. Therefore, crack detection can be achieved much earlier if the sensors can be monitored while the structure is in use. In the case of real-time monitoring for the steel plate test series, CVM crack detection results for the unloaded and

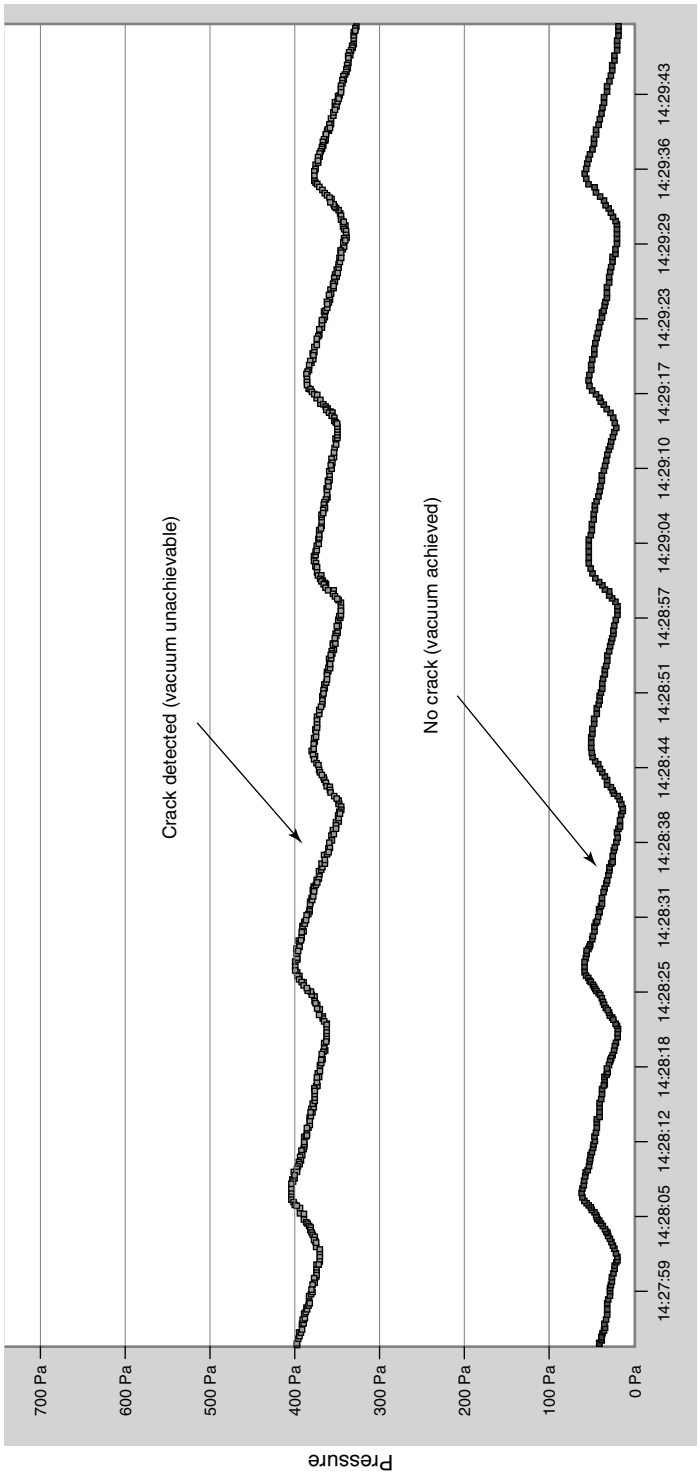

Figure 6. Typical pressure versus time plots from CVM sensors indicating "no crack" and "crack detection".

loaded steel structure are summarized in Tables 4 and 5, respectively.

For the loaded structure, CVM crack detection occurred when the fatigue cracks ranged from 0.040″ to 0.070″ in length (Table 5). This would correspond to the ability of the CVM sensor to monitor cracks in real time while the structure is in use. For the unloaded condition, CVM crack detection occurred when the fatigue cracks ranged from 0.060 to 0.380″ in length (Table 4). Note that the data spread is much larger for this condition owing to the varying state of the compressive stresses at the end of the fatigue crack. However, regardless of whether the sensor monitoring is completed during a loaded or unloaded condition, the results indicate that CVM sensors could reliably detect fatigue cracks well before they reach 0.5″ in length.

of 0.125″–0.25″ diameter with thicknesses of 0.010–0.030″. They can be easily attached to existing aging structures without changing the local and global structural dynamics. Piezoelectric transducers (PZT) sensors can also be embedded inside composite structures to closely monitor for internal flaws. These sensors can act as both transmitters and receptors. As transmitters, piezoelectric sensors generate elastic waves in the surrounding material. As receptors, they receive elastic waves and transform them into electric signals. It is conceivable to imagine arrays of active sensors, in which each element would take, in turn, the role of transmitter and receptor, and thus scan large structural areas using ultrasonic waves [7]. The structural interrogation strategies using active piezoelectric sensors are twofold:

1. For local area detection, the electromechanical (E/M) impedance method is applied to detect changes in the point-wise structural impedance resulting from the presence and propagation of structural damage.
2. For large-area detection, wave propagation techniques using Lamb and Love wave methods are used to identify zones in the monitored area that have undergone changes in their structural integrity.

In the high-frequency E/M impedance approach, pattern recognition methods are used to compare impedance signatures taken at various time intervals and to identify damage presence and progression from the change in these signatures. In the Lamb/Love wave approach, the acousto-ultrasonic methods identifying changes in transmission velocity, phase, and additional reflections generated from the damage site are used. Both approaches can benefit from the addition of artificial intelligence neural network algorithms that can extract damage features based on a learning process.

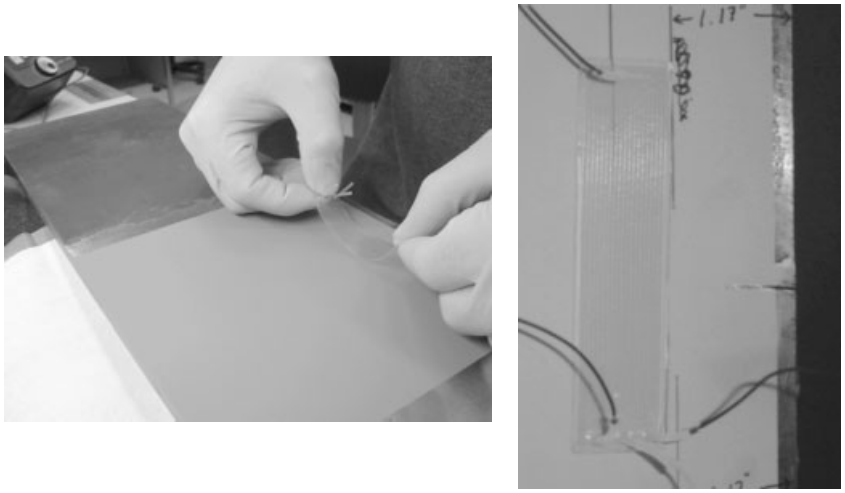

Figure 8. Installation of CVM sensor on primed steel surface and close-up of fatigue crack approaching sensor.

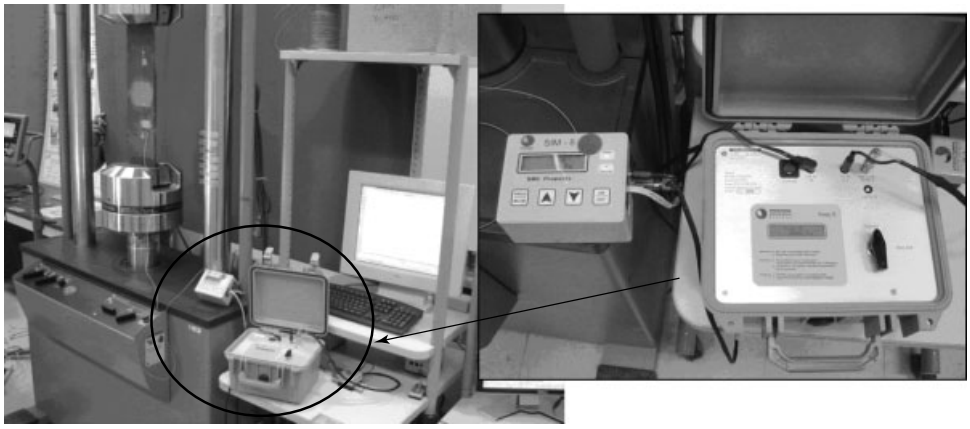

Figure 9. Overall setup for monitoring crack growth with CVM sensor system and close-up of sensor interrogation equipment.

Mountable PZT networks and lamb wave interrogation methods

This SHM approach uses a built-in network of PZT embedded in a thick dielectric carrier film. The SHM system included the PZT network connected to portable, diagnostic hardware and software developed by Acellent Technologies, Inc. The system performs *in situ* monitoring, data collection, signal processing, and real-time data interpretation to produce a two-dimensional image of the structure being interrogated. The Acellent software instructs the actuators to generate preselected diagnostic signals and transmit them to neighboring sensors. Multiple diagnostic wave types can be generated including 3-peak, 5-peak, and 10-peak narrowband frequency waveforms and chirp, random, and user-defined excitations. The software links each sensor with its neighbors to form a web, or network, covering the structure. The system then collects the total set of responses from each of the sensor sets as each PZT takes its turn as the actuator. Changes in the Lamb waves generated within the structure are used in concert with triangulation methods to detect the presence of structural anomalies and to determine the size and location of the flaws.

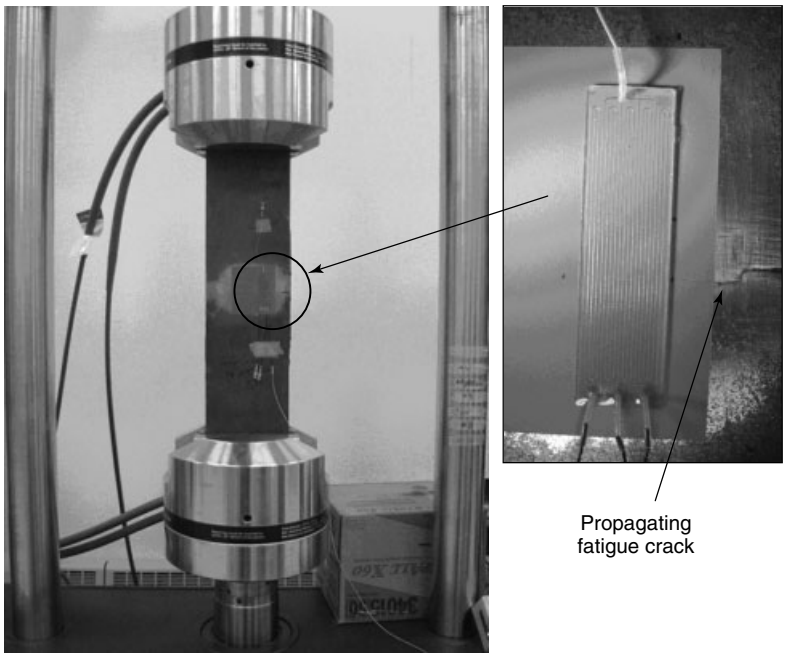

Figure 10. Fatigue test of steel specimen to propagate crack into CVM sensor (inset).

Damage identification through elastic wave propagation

The wave propagation approach uses the pitch–catch method for detecting damage in a structure. Acousto-ultrasonic methods are used to identify changes in wave transmission. Figure 11 shows some of the wave motion from sensors (1) and (9) when they are used as the source of excitation for the structure. The mechanical vibration is introduced into the structure by the PZT element and travels by wave motion through the test piece at the velocity of sound, which depends on the material. If the pulses encounter a reflecting surface, some or all of the energy is reflected and monitored by adjacent PZT sensors in the network. The reflected beam, or echo, can be created by any normal (e.g., in multilayered structures) or abnormal (flaw) interface. Figure 11 highlights the interaction of the ultrasonic testing (UT) waves with a flaw within the structure. The degree of reflection depends largely on the physical state of the materials forming the interface. Cracks, delaminations, shrinkage cavities, pores, disbonds, and other discontinuities that produce reflective interfaces can be detected. Complete reflection, partial reflection, scattering, or other detectable effects on the ultrasonic waves can be used as the basis for flaw detection.

Validation testing of PZT sensor network

In the first test series, PZT were built by embedding PZT materials in a thin dielectric carrier film. The spacing of the active PZT elements and the shape of the film were determined by the need to monitor local and global damage in the composite laminate and steel substructure. The PZT sensor network was laid out in custom configurations to detect damage in critical regions and provide an image of the structure in the area of the sensor network. The network of PZT sensors was deployed to assess bonded joints and crack growth in a composite doubler repair installation. Figures 12 and 13 show schematics and photos of the boron–epoxy laminate repair on a metal parent structure along with the set of PZTs distributed over the structure to be monitored. It is to be noted that the network of sensors/actuators is embedded in a custom polyamide film to allow for accurate placement of the network and eliminating the need for each sensor to be installed individually. The test specimen, containing engineered disbonds and a central crack, was subjected to constant-amplitude

fatigue loads with maximum stresses in excess of 80% of yield levels for the ASTM A36 steel plate (thickness = 0.188″). A time-varying electrical signal was input to the actuators/sensors. This caused a propagating stress wave to emanate from the actuator and travel through the material for detection by the neighboring sensors. These signals were then compared with previously recorded baseline test signals to identify the location and extent of damage or other structural anomaly.

Similar to conventional UT, the PZT data analysis can include one or more of the following measurements: time of wave transit (or delay), path length, frequency, phase angle, amplitude, and angle of wave deflection (reflection and refraction). In this test series, the pitch–catch method was used to study the transmission of sound waves as they traveled from each actuator to all other receiving sensors. The sum total of received beams was then analyzed to define the presence and location of flaws. In order to optimize flaw detection, a series of excitation frequencies were used: 50, 200, 350, and 500 kHz. Overall test results revealed that disbond flaws were most strongly detected with the lower, 50 kHz, excitation while the crack growth was monitored best with the highest, 500 kHz, excitation. Figure 14 shows raw PZT response data produced during the Lamb wave interrogation method. Signal attenuations, corresponding to disbonds between the laminate and parent skin, are apparent. When all of the signals are analyzed with the Acellent imaging software and flaw locations are determined by using the time base and triangulation methods, a two-dimensional image of the disbond flaws was produced. Figure 15 shows the engineered disbonds in the test specimen along with the image produced by the PZT sensor network. It is to be noted that both disbond flaws were clearly imaged even though one is a weak bond produced by a mold release agent and the other is a complete disbond produced by a Teflon insert.

Crack detection was achieved and crack growth was monitored using the same approach. PZT data was acquired at discrete intervals during the crack growth process. In addition, EC and microscopic inspections were conducted to measure the crack lengths at each cycle count. Figure 16 shows PZT response signals before and after crack growth occurred in the sensor path. A set of images produced by the PZT network are shown in Figure 17. The crack growth (two fatigue cracks emanating from a central hole) can be clearly seen. The PZT crack growth data was analyzed further to produce crack length predictions. The data analysis software contains an algorithm that allows for system learning. After inputting several crack lengths to match with

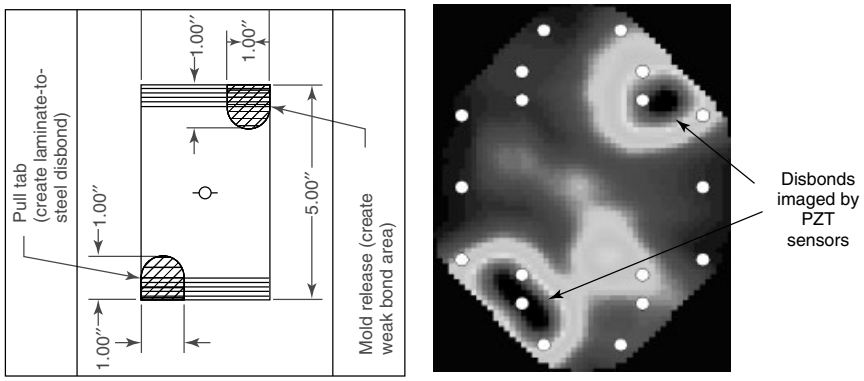

Figure 15. Shaded image of disbond flaws produced by the PZT sensor network.

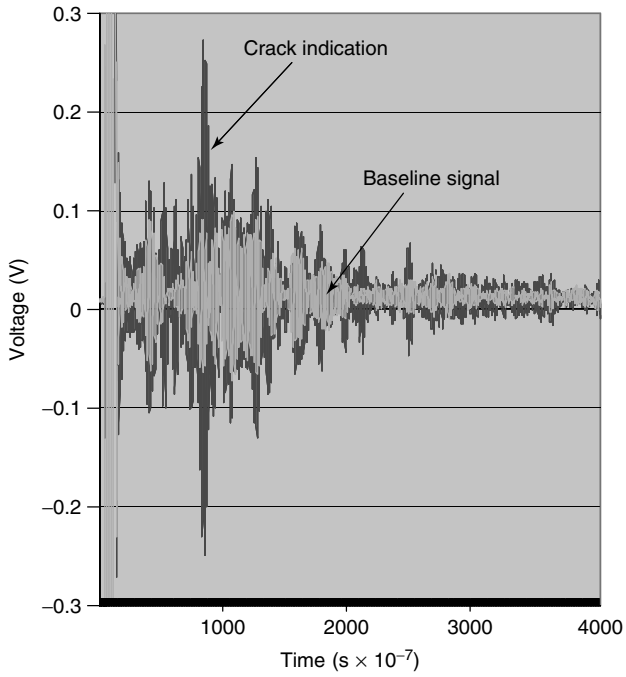

Figure 16. Sample PZT signals showing the indication of a fatigue crack with a 500-kHz excitation.

the PZT data at discrete fatigue intervals, it was possible for the system to predict all subsequent crack lengths using the PZT data alone. Table 6 compares the crack lengths predicted by the PZT sensor network with the crack lengths determined from EC and microscopic measurements. The PZT predictions were all within 5% of the actual crack lengths for data taken at maximum load (34 kips) and, for the most part, within 10% of actual values for PZT data taken in the unloaded condition.

4.1 PZT evaluations on steel specimens with edge cracks

Similar tests were conducted using a custom array of PZT sensors to monitor a 0.375″-thick ASTM 572 steel plate. The test specimen and PZT network are shown in Figures 18 and 19. This specimen is the same as the general composite doubler performance specimens described earlier. While assessing the crack mitigation capabilities and durability of the

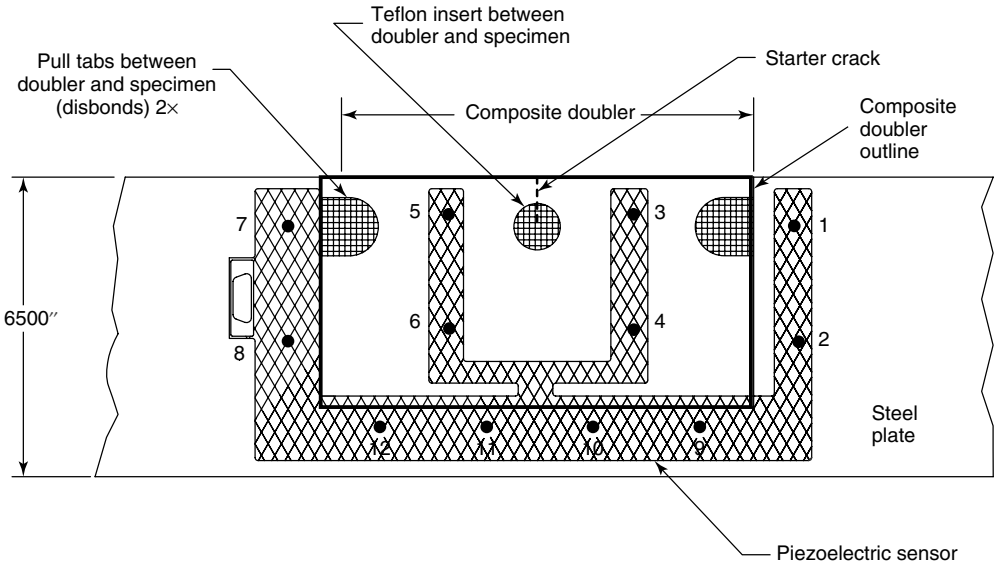

Figure 19. Layout of PZT sensor network relative to composite doubler and engineered flaws.

composite repair, it was possible to determine the crack and disbond detection capability of the PZT system. The three engineered disbond flaws and the center fatigue crack placed in the specimen prior to repair are indicated in Figures 18 and 19. Disbond flaws were placed in each end of the patch-to-steel bondline at the critical load transfer region, and a third disbond was placed over the fatigue crack to degrade the patch protection around the crack. These flaws were added to (i) determine the damage tolerance of composite doubler repairs in poor installation conditions and (ii) study the ability of sensor networks to detect and accurately track flaw growth.

Figures 20 and 21 show the installation process used to place the PZT network on the structure. A two-part epoxy was used to bond the PZT film to

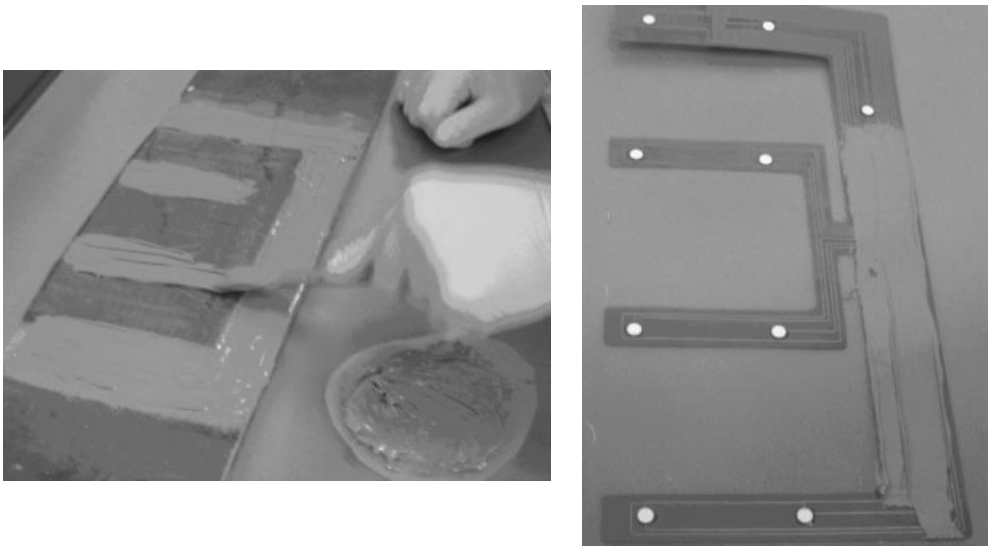

Figure 20. Installation of PZT sensor film—application of EA9394 epoxy to the test specimen and sensor array.

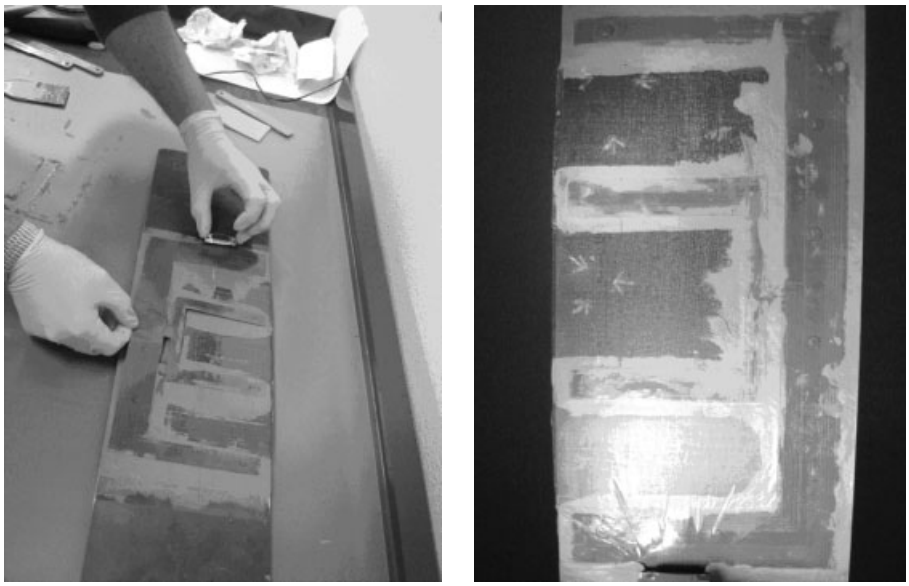

Figure 21. Application of sensors to specimen and view of the PZTs after the bonding process.

the steel and it was cured at 140 °F while applying vacuum pressure to the film. Since the PZT transducers must act as excitation sources, as well as signal receivers, it is necessary for them to be bonded to the structure they are monitoring. When the PZTs are driven with a voltage, they expand and contract at the driving frequencies. The strong bond allows the PZTs to transfer this strain energy into the structure, which results in the generation of the Lamb waves described above.

Figure 22 shows the repaired test specimen in the fatigue test machine with the PZT network installed over the composite doubler. It is to be noted in Figure 18 that there are essentially two concentric

Figure 22. Steel plate with composite doubler, engineered flaws, and PZT sensor network undergoing fatigue tests.

sets of inner and outer PZT sensors (seven PZTs on the outer loop and four PZTs on the inner loop). This was used to evaluate the maximum PZT spacing that could be deployed while still obtaining the desired flaw detection sensitivity. In the realm of SHM, it is desirable to accurately interrogate large areas without having to use an extensive number of sensors. With the PZT network shown in Figure 18, it was possible to set up a series of different sensor-receiver paths and to independently determine the flaw detection capability of each of these paths. Figure 23 shows the various paths that were set up to study flaw detection versus sensor spatial resolution. The "all-to-all" path set uses every sensor as a transmitter (exciter) and receiver, while the "in-to-in" path set uses only the inner four PZT sensors. Similarly, the "in-to-out" path set looks at the wave travel from each inner PZT to each outer PZT and the "out-to-out" path set uses only the sensors in the furthest outer loop. It can be seen that different path sets emphasize different area coverage and provide a different density of coverage.

Figures 24 and 25 show the detection of the three engineered disbonds that were imaged by the PZT network. The optimum images are shown here as produced by the densest "all-to-all" PZT path set. While flaw detection could be achieved with the other path sets, they were not as accurate in flaw placement—as calculated using the signal triangulation method described above—or in relative flaw sizing. Obviously, the "in-to-in" path set was not able to image the outer edge disbonds since this data set did not involve wave travel through the outer disbond regions and thus did not include any information from these flaws.

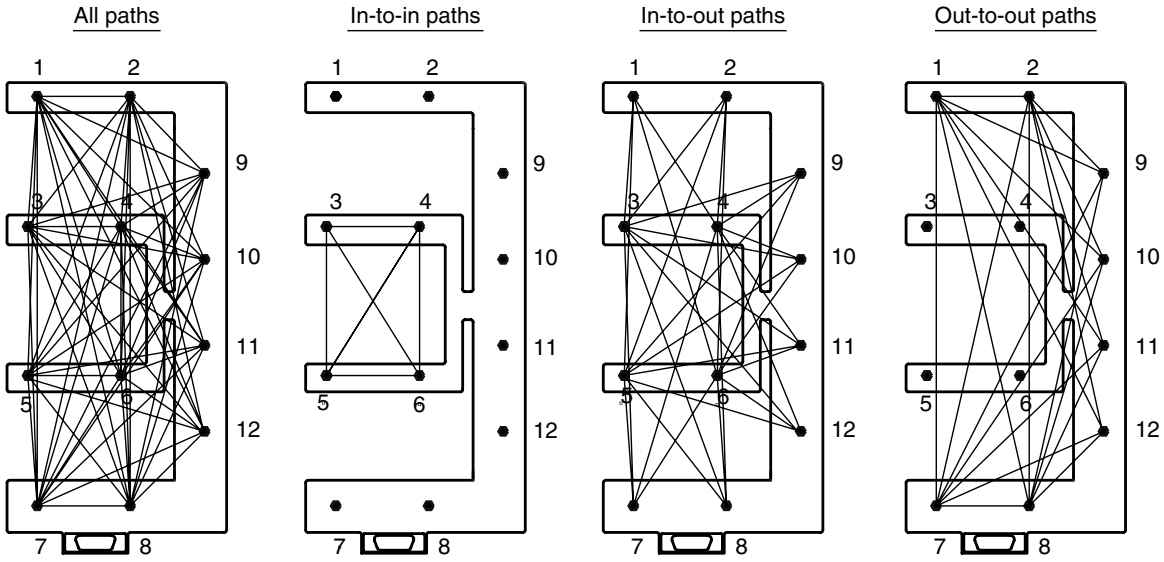

Figure 23. PZT sensor-receiver paths used for data analysis.

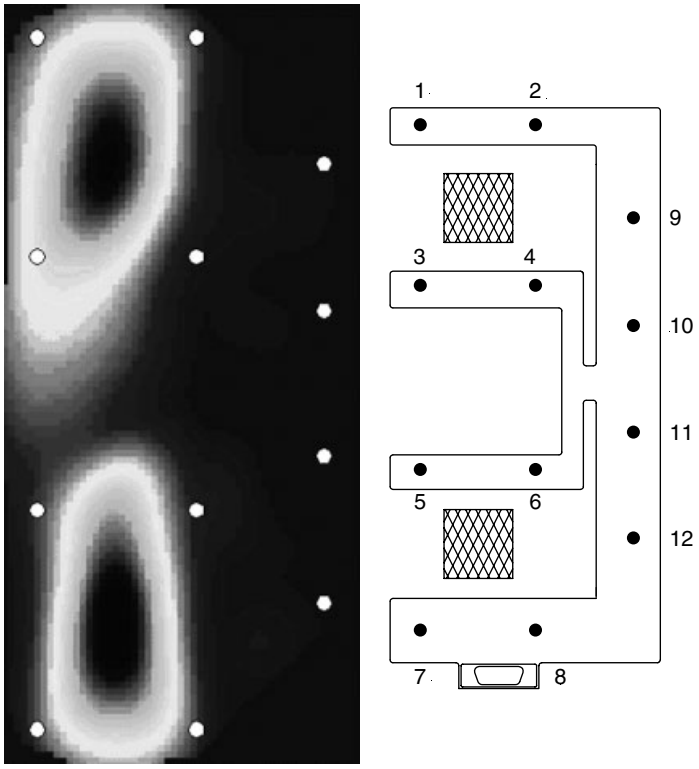

Figure 24. Disbond detection with general location of edge disbonds shown.

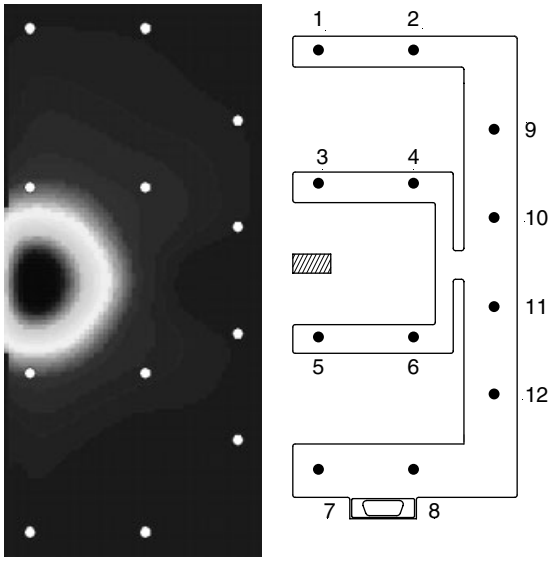

Figure 25. Disbond detection with general location of central disbond shown.

Crack detection was achieved and growth was monitored using the same set of PZT paths. PZT data was acquired at discrete intervals during the crack growth process. EC and microscopic inspections were also conducted to measure the crack lengths at each cycle count. The variation in PZT signal, for the same path, before and after crack growth is highlighted in Figure 26. This data is then used to construct a two-dimensional image of the crack within the PZT network. Figure 27 shows the set of images produced by the PZT sensors at various crack lengths. The corresponding number of fatigue cycles and crack lengths associated with each measurement may be noted. These optimum images were produced by the "all-to-all" path set. Some level of crack detection was achieved using the next densest "in-to-out" path set but the images were not as clear. The "out-to-out" path set did not encounter the crack region sufficiently to properly image the crack, while the "in-to-in" path set produced a sparsely populated data set that was unable to detect the fatigue crack.

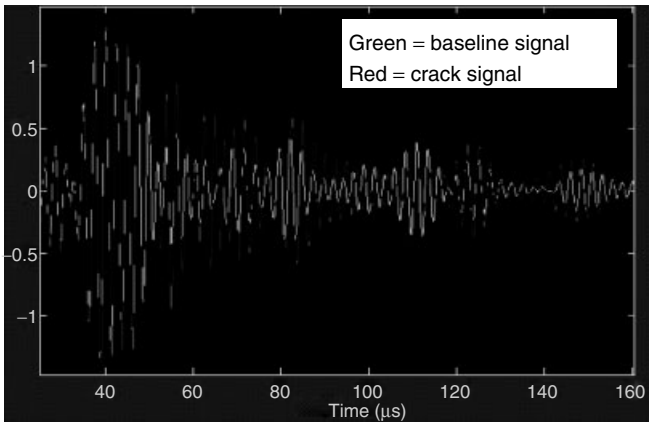

Figure 26. Changes in PZT signals produced by crack growth.

5 MOUNTABLE EDDY CURRENT SENSOR FOR *IN SITU* HEALTH MONITORING

A wireless, integrated, mountable, battery-operated, noncontact EC sensor was developed by Sandia Labs to provide the same accuracy as the large, manually applied NDI equipment and transducers. The sensor can be mounted on a wide array of structures for general surface and subsurface crack detection. It can produce a strong enough magnetic field to produce deep crack detection for inspecting the second and third layers in complex joints or for detecting cracks hidden beneath nonconducting layers and coatings. Figure 28 shows a photo of the two-coil sensor inspecting for cracks beneath a composite doubler. The use of a rectangular planar coil, coupled with embedded processing, conditioning electronics, and wireless communications provides a stand-alone solution to perform accurate, remote, *in situ*, real-time, noncontact, SHM.

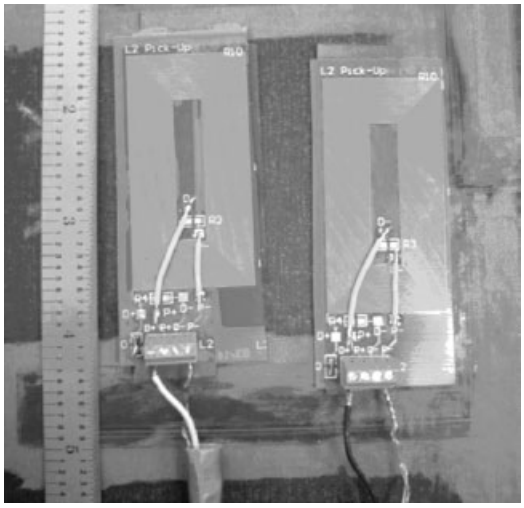

Figure 28. Dual/differential coil version of Sandia eddy current sensor for surface and subsurface crack detection (*in situ* health monitoring methodology).

5.1 Quantification of crack detection sensitivity

A series of crack detection tests were completed in order to quantify the crack detection performance of this mountable EC sensor. In order to construct a good basis of comparison to known crack detection results, the inspection data generated by the EC sensor were compared with results obtained using conventional inspection methods. The EC pencil probe and spot probe methods were deployed along with optical measurements. The EC pencil probe (higher frequency NDI) is intended for surface crack detection. The pencil probe and optical inspections were applied to the metal side of the test specimen shown in Figures 18 and 29. This is not the normal inspection surface but these measurements provided the greatest accuracy and were used as the "referee" for comparison purposes. The EC spot probe and the EC sensor, both with greater depth-of-penetration capabilities, were applied through the composite doubler in the inspection scenario expected in the field.

Optical microscope
Crack on steel side of specimen imaged at 24× magnification with load on the test specimen to open crack tip; resolution of 0.0005″; used as referee for determining the actual crack length.

Eddy current pencil probe
Higher frequency with less penetrating power but smaller diameter for better small crack resolution; applied to steel surface directly (nondoubler side of test specimen).

Eddy current spot probe
Larger coil producing lower frequencies for deeper penetration; truly represents capability in the field for inspections on repaired structure; inspections conducted through composite doubler that produces lift-off, thus requiring lower frequency.

Mountable EC sensor
Larger coil producing lower frequencies for deeper penetration; truly represents capability in the field for inspections on repaired structure; inspections conducted through composite doubler that produces lift-off, thus requiring lower frequency.

Figure 29 shows the orientation of the two-coil sensor relative to the fatigue crack. The coil labeled number 1 is the reference coil and it remains stationary in a known unflawed area. The coil labeled number 2 is used to detect the crack in a differential setup that compares the signals from the unflawed (coil #1) and flawed (coil #2) regions. This comparison ensures that the signal generated by the presence of a crack is significantly different from the signals generated in the unflawed region. Good signal-to-noise (S/N) levels are needed to avoid false calls. Figure 29 also shows the sensor inspecting for cracks beneath various thicknesses of lift-off. In addition to the composite doubler, Lucite Test Blocks, ranging in thickness from 0.135 to 0.905″, were placed beneath the EC sensor. This produced additional lift-off effects, which evaluated the penetration power and sensitivity of the EC sensor though extreme lift-off scenarios (refer to later text for discussion on crack detection through various thicknesses of nonconductive lift-off).

The graphs in Figures 30–32 provide summary results of the direct comparison between the Sandia-developed EC sensor and the conventional handheld transducers often used to conduct manual inspections. A photo comparing the EC spot probe, pencil probe, and mountable sensor is provided in Figure 33. Figures 34 and 35 show each of the EC transducers being deployed to detect fatigue cracks beneath the

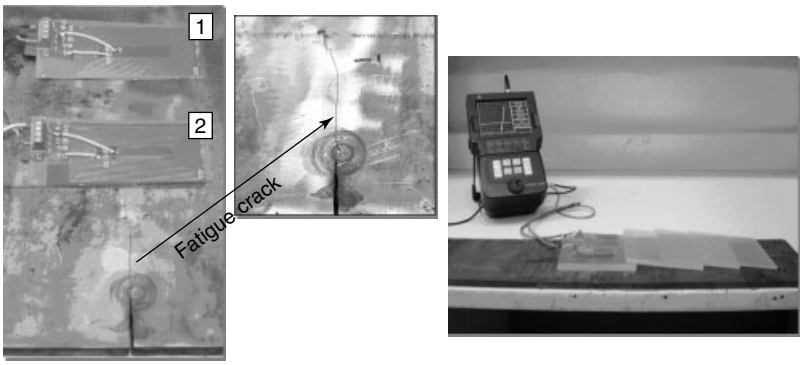

Figure 29. Mountable EC sensor applied to bare steel side and composite doubler side of the fatigue crack test specimen.

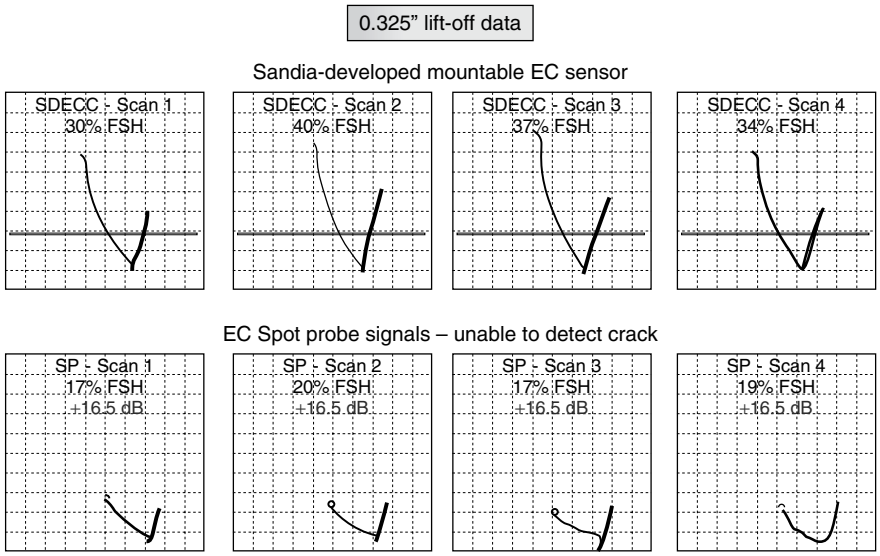

Figure 30. Comparison of eddy current signals generated by conventional EC spot probe and signals produced by the Sandia EC sensor.

composite doubler. The EC signal graphs clearly illustrate that the EC sensor can provide significant response even when subjected to the impediment of large lift-offs. Conversely, the spot probe faltered because it could not maintain its sensitivity while trying to interrogate a structure beneath thick lift-off layers. The pencil EC probe pictured in Figure 33 can interrogate with only high frequencies, so it was not able to produce any usable inspection signal in these tests. Of equal importance to this comparison is the fact that hand-deployed probes cannot be permanently mounted to produce *in situ*, and potentially real-time, health monitoring.

Inspection performance results for the final sensor design are shown in Figures 31 and 32. These impedance plots show the overall sensitivity of the mountable sensor as it detects cracks located through increasingly thick lift-off layers up to 0.98″ thick. It is to be noted that these plots also include the signals produced by the sensor when placed in an unflawed region. Such signals from unflawed regions correspond to the noise in the sensor, so it is desirable for the sensor to produce extremely small signals in unflawed regions. By comparing the signal levels at cracked and uncracked regions, it is possible to assess the sensitivity of the EC sensor using S/N

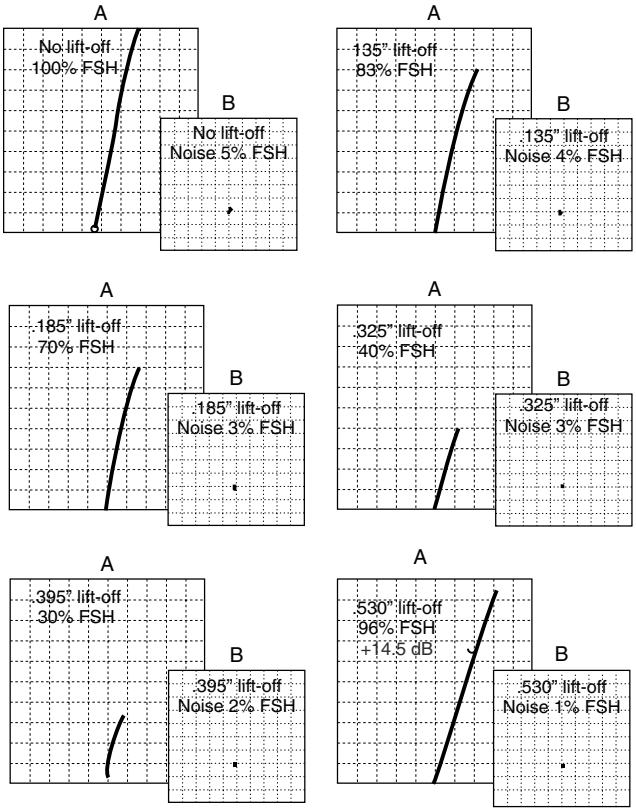

Figure 31. Crack detection performance of Sandia mountable eddy current sensor for lift-off layers up through 0.5″ thick.

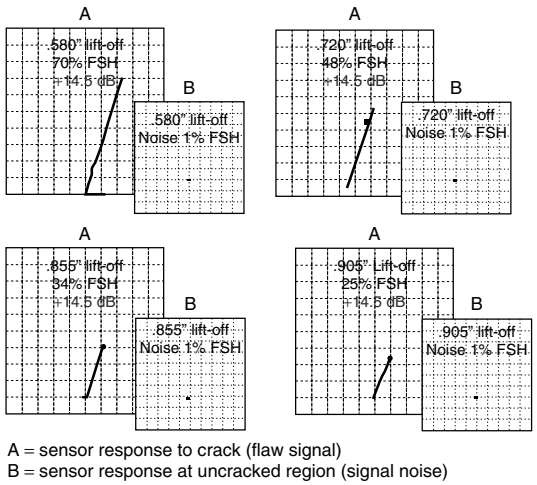

Figure 32. Crack detection performance of mountable eddy current sensor for lift-off layers up through 0.9″ thick.

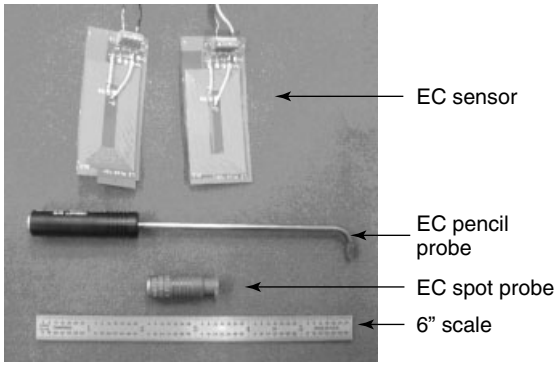

Figure 33. Handheld and mountable eddy current transducers used to track crack growth.

levels. Normally, flaw calls can be made if S/N values exceed 3 (S/N ratio of 3 : 1). The results in Figures 31 and 32 show that even through extreme

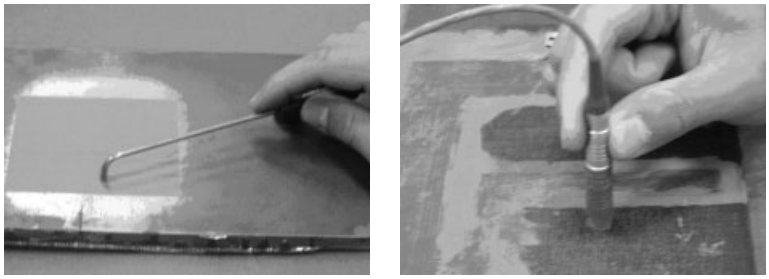

Figure 34. Deployment of EC pencil probe (steel side) and EC spot probe (composite doubler side) on fatigue crack specimen.

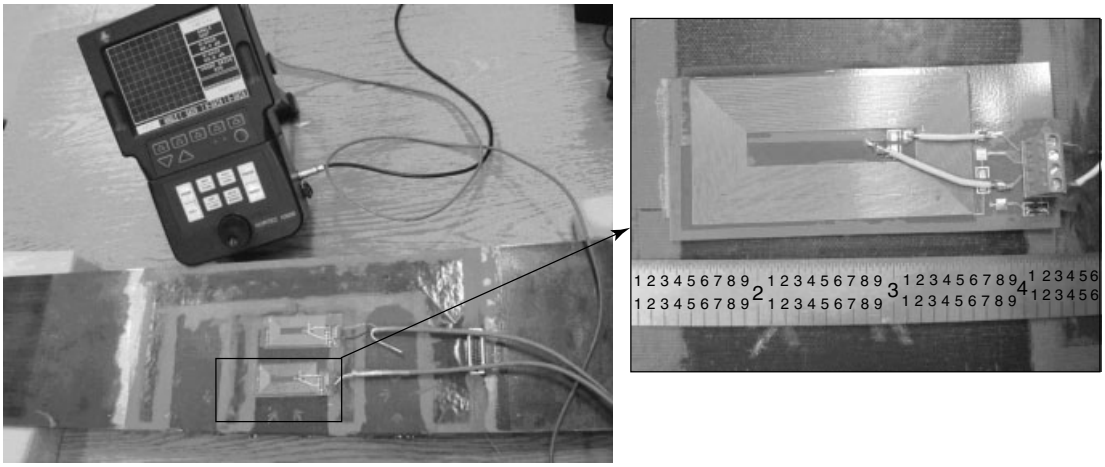

Figure 35. Deployment of EC sensor on composite doubler side of fatigue crack specimen.

lift-off conditions (inspection impediment), the sensor produced an S/N level of 15 : 1 even for the most extreme case of the 0.9″-thick lift-off.

The final assessment of the EC sensor quantified its ability to not only detect a fatigue crack but also to accurately determine its length. Figure 34 shows how the EC pencil probe was applied to the exposed metal side of the test specimen. The optical microscope was also used on the side with the exposed fatigue crack. As mentioned above, this is not the normal inspection surface but these measurements provided the greatest accuracy and were used as the "referee" for comparison purposes. The EC spot probe and the EC sensor, both with greater depth-of-penetration capabilities, were applied through the composite doubler in the inspection scenario expected in the field (see Figures 34 and 35).

Tables 7 and 8 compare the crack lengths as determined by the various methods described above, while Figure 36 plots the crack length predictions for each of the four methods. The Sandia EC Sensor was able to accurately track the crack length even when inspecting through the composite doubler. The maximum deviation from the referee measurements was less than 4%.

6 REMOTE-FIELD EDDY CURRENT

There are two fundamental approaches that have been developed to improve the performance of EC NDI. The first approach attempts to cancel, or compensate for, the large surface signal that is directly coupled to the pickup coil without first entering the part being inspected. This portion of the overall EC signal has no useful information and serves to increase the noise floor. It can be removed by altering the probe

design or by applying special data analysis to the captured signal. The self-nulling probe (SNP) and the remote-field eddy current (RFEC) method are examples of the probe alteration approach [8, 9]. The sensor and the drive coil of the SNP are separated by a ferromagnetic cylinder called a *flux focusing lens* to minimize the sensor signal that arrives directly from the drive coil. The RFEC approach blocks the unwanted, directly coupled signal through the use of shields and magnetic circuitry. This produces a signal that is dominated by the indirect coupling path and contains the information of interest.

The inspection of multilayered structures requires detection of fine cracks and shallow corrosion pits that are embedded deep below the inspection surface. If there are air gaps between the layers, ultrasonic and thermography methods are not good candidates since it is difficult for them to penetrate beyond the first layer. Conventional EC techniques are often limited by depth-of-penetration effects wherein deeper penetration requires larger EC coils that produce a corresponding loss in sensitivity. A relatively new breakthrough in the EC arena involves the use of "remote fields" to interrogate conductive structures. The RFEC method is especially suited for detecting deep flaws.

Figure 37 depicts the physics behind the RFEC approach. When a coil is excited by an alternating current and is placed on a structure, the energy diffuses along two different paths. The interaction between the two fields results in what is often referred to as the *remote-field EC effect*. Studies have shown that the energy diffusing via the direct path attenuates very rapidly. The signal received by the pickup coil that is located a certain distance away from the excitation coil is primarily due to the energy

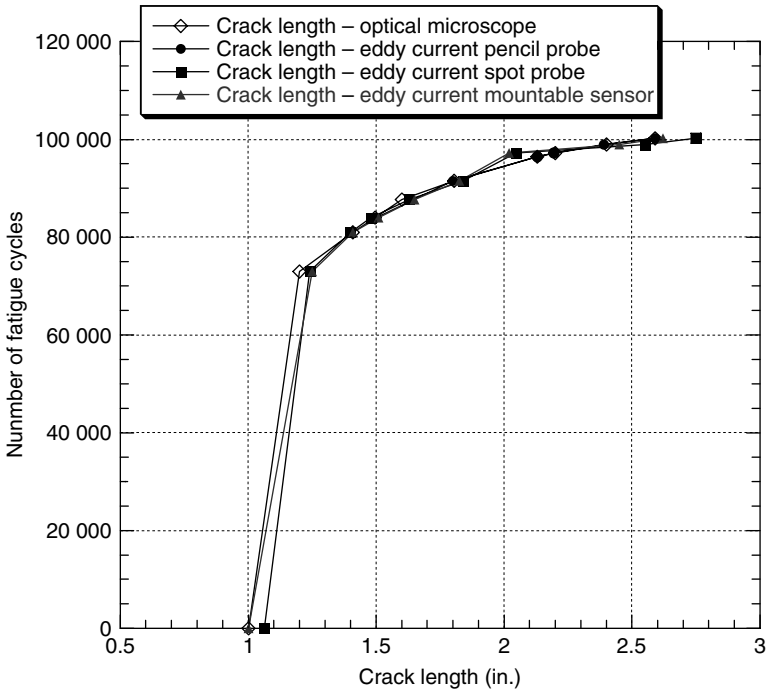

Figure 36. Comparison of crack lengths measured by four different methods: (a) microscopic measurement (referee), (b) conventional eddy pencil probe (referee), (c) conventional eddy current spot probe, and (d) eddy current *in situ* sensor.

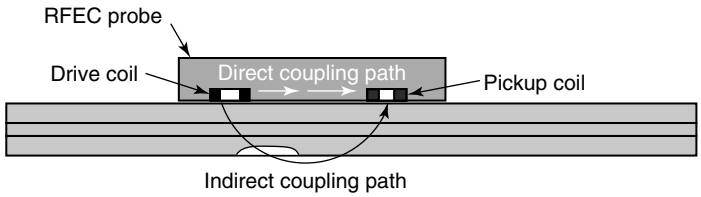

Figure 37. Schematic of remote-field eddy current approach.

diffusing via the indirect path. This portion of the energy passes through the structure twice before arriving at the pickup coil. Thus, the RFEC probe is designed to focus on the indirect coupling path, so that the signal measured by the pickup coil carries the information of the whole wall thickness. It produces deeper penetration for detection of deep, subsurface flaws. Traditional EC approaches depend on changes in the electromagnetic flux to signal the presence of a flaw. Typical values of such changes are very small and may be less than 0.01%. Therefore, it is very difficult to separate this change from the quiescent signal generated by an unflawed structure. This limits the maximum gain that one can employ when using these instruments. RFEC is based on the measurement of the voltage induced in a pickup coil by the flux that has passed through the test object twice (see Figure 25). This setup creates a significant change in voltage so that a stronger flaw signal is produced. The end result is a very high flaw-signal/quiescent-signal ratio. This allows higher gain settings to be used so that deeper flaws can be detected.

A super-sensitive EC system has been developed to accommodate the RFEC probes. The system is capable of providing an extremely high gain, up to 135 dB, for amplifying the remote-field probe signal. This allows the inspection device to provide higher S/N ratios, thus increasing its flaw detection

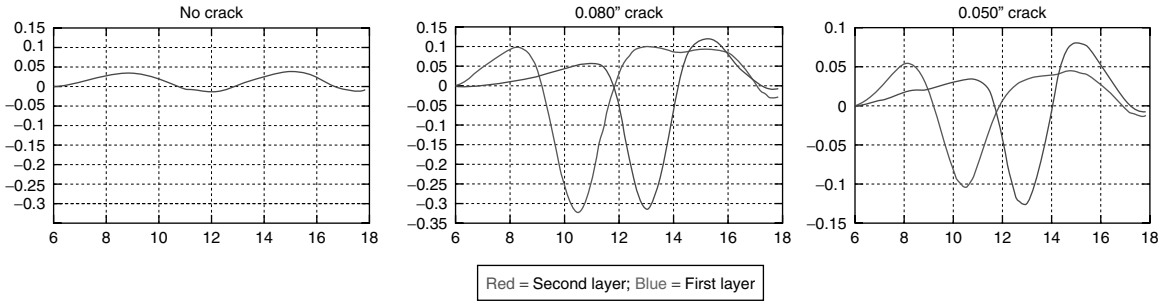

Figure 38. First- and second-layer crack detection in 0.040″-thick plates with cracks hidden under raised head fasteners.

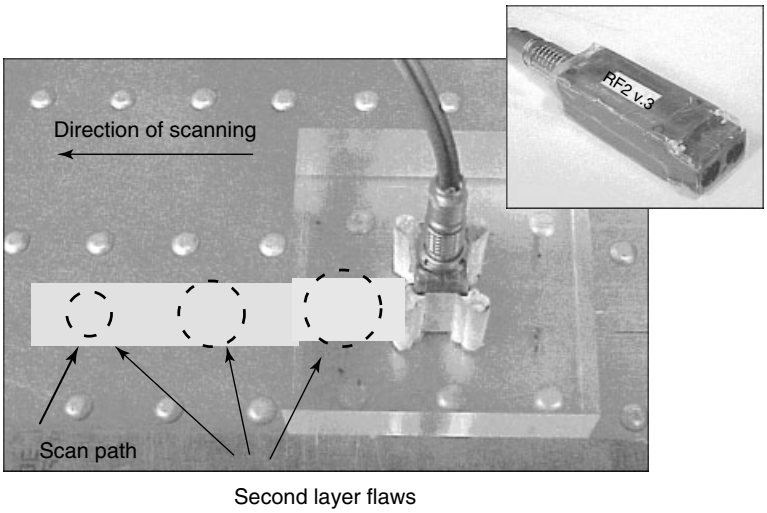

Figure 39. RFEC probe inspecting for corrosion in a riveted aircraft joint.

sensitivity. Sample crack detection signals from a 2-kHz RFEC probe inspection are shown in Figure 38. These plots demonstrate that the voltage amplitude-based data presentation requires minimal signal interpretation. Experimental measurements have shown the ability of the RFEC method to detect a 0.03″-long fatigue crack that is located 0.446″ below the inspection surface.

When scanning a multiple-layer aluminum sample with a total thickness of 0.29″, the RFEC system was able to detect wall thinning as small as 1% of the total thickness. Figure 39 shows a handheld RFEC probe scanning a riveted aluminum joint containing various levels and sizes of corrosion. The dotted lines show the locations of the corrosion sites that were engineered into the specimens. Sample signals from the hidden, second-layer corrosion regions are shown in Figure 28. The RFEC system produced S/N ratios that were well in excess of 5 to clearly indicate the presence of corrosion. It is to be noted that the size of the second-layer corrosion detected with the signals shown in Figure 40 was 0.125″ in diameter with depth ranging from 0.0008 to 0.004″ (2–10% corrosion thinning in 0.040″-thick plate).

6.1 RFEC deployed with in situ sensors

Efforts are under way to deploy this inspection method using a permanently mounted, *in situ* sensor called the *remote-field eddy current magnetic carpet probes* (RFEC-MCP). This novel leave-in-place magnetic carpet probes (MCP) can be installed to detect and monitor fatigue cracks or corrosion

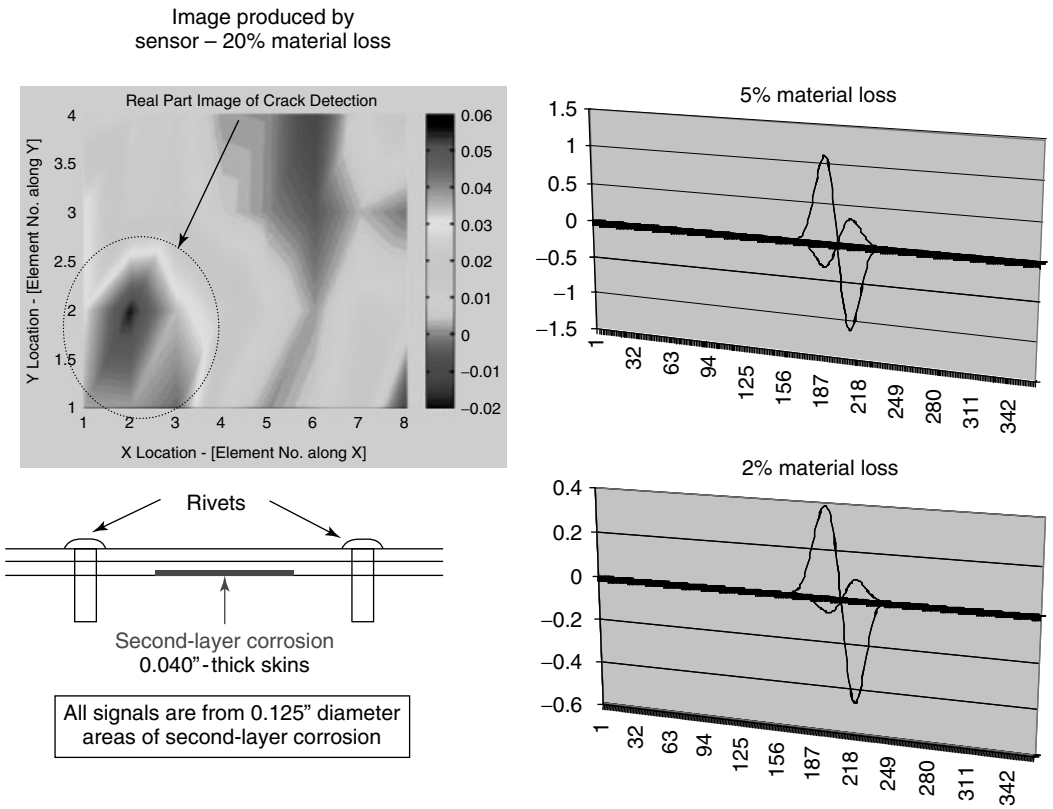

Figure 40. Large signals produced by RFEC probe indicating the presence of corrosion.

in inaccessible regions on structures. Networks of surface-mounted and embedded EC sensor arrays permit rapid, large-area damage monitoring with the high resolution of localized probe testing. The RFEC-MCP is made using a piece of thin, flexible printed circuit board (PCB) with densely populated printed coil sensors on the PCB as shown in Figure 41. A sensor for detecting cracks emanating from a hole and a sensor for monitoring larger areas for corrosion are shown.

The sensors work on the same principal as the RFEC method described above to provide deep penetration for locating subsurface flaws. Multiple-phase AC currents are applied to each sensor on the PCB. This generates a traveling magnetic wave that is stronger than those generated by conventional EC excitation. Each sensor on the PCB alternately acts as a transmitter and receiver so that a uniform magnetic field is set up over the entire MCP area and the probe can detect cracks in any orientation. In addition, the RFEC-MCP method is insensitive to the geometry variations of a component while competing ultrasonic-based sensors must carefully account for the effects of complex geometries on the transmission of UT waves. Initial tests with a prototype corrosion sensor showed great promise and a second design iteration is currently in process to further improve sensitivity.

7 OTHER SHM SENSORS

Breakthroughs in microelectronics are being used to miniaturize conventional handheld probes into mountable, *in situ* devices. Miniature flaw detection sensors, combined with easily fieldable diagnostic electronics, are the backbone of any global SHM system. An extensive amount of research is ongoing to develop and mature a wide variety of new sensors that are applicable to *in situ* SHM. The sensors

may directly detect flaws, such as those discussed here, or other physical parameters, such as acceleration, force, pressure, flow, displacement (capacitive proximity sensors), temperature, and the presence of chemicals, from which flaws or faulty operation can be identified. Other leave-in-place sensors that may produce direct indications of structural flaws include magnetoresistors; polycrystalline silicon for measuring an array of physical properties including transmission of ultrasonic waves and variations in electric fields, FO sensors [10–13], capacitive micromachined ultrasonic transducers (cMUT) [14], flexible EC array probes [15], nickel-foil magnetostrictive sensors (MsS) [16], optical fiber long-period grating (LPG) chemical sensors [17], adhesive bond degradation sensors (ABDS) [18], meandering winding magnetometer (MWM) probes [19, 20], microwave antenna, acoustic emission transducers, spectroscopic instrumentation and optoelectric sensors such as injection lasers, photovoltaic diodes, and photoconductors.

Following are brief descriptions of other sensors being pursued for SHM.

1. Fiber-optic sensors

Rapid growth in the optoelectronics and telecommunications industries has resulted in the evolution of highly sensitive FO sensors. FO sensors have been developed for a wide variety of applications including the measurement of rotation, acceleration, vibration, strain, temperature, pressure, electric and magnetic fields, moisture, and humidity. FO sensors are lightweight, low profile (typically 145 μm in diameter with a polyimide coating) and corrosion

resistant, and multiple sensors are easily multiplexed into a single fiber. These factors make them ideal for embedding in or surface mounting on composite and metallic structures without affecting structural performance. Other advantages of FO sensors include high sensitivity, wide bandwidth, electromagnetic interference (EMI) resistance, low power requirements, and environmental ruggedness. FO sensors can also be configured to monitor crack growth and corrosion in civil and aerospace structures. Omnidirectional FO sensors can be used to measure large strains (up to 150% strain), small displacements (10-μm range), and crack growth in any material. The major disadvantages include high cost, mechanical frailty (during handling stage), and unfamiliarity to the end user. The introduction of low-cost laser diodes, the alternative use of light-emitting diodes (LEDs) as light sources, and the development of inexpensive, single-mode optical fibers have greatly reduced the costs associated with deploying FO sensors. Information about the environment to which an FO is exposed can be inferred by analyzing the guided light transmitted through the optical filaments. In this approach, the entire length of the fiber acts as a continuous sensor. The fiber can be mounted in a serpentine path or FO tentacles can be created to provide full coverage over a large area of concern. The presence of a crack can be determined by monitoring changes in the magnitude and phase of the returned light in the fiber. Figure 42 shows a close-up of the fiber bragg grating (FBG) sensors, and associated end connectors, as they enter and exit the bondline of the test specimen. Typical data-acquisition equipment used to monitor the FBG sensors is also pictured.

2. Capacitive micromachined ultrasonic transducers (Stanford, General Electric)
This is an electrostatic transducer that utilizes semiconductor fabrication techniques to allow for mass production and low cost (see Figure 43 for example). An applied voltage produces a displacement of the membrane (generates ultrasonic wave) due to electrostatic attraction. When it is used to receive input signals (monitor ultrasonic waves), the displacement of the membrane causes a change in capacitance of the device. Advantages of this device include completely integrated electronics and a large operation bandwidth.

3. Flexible eddy current array probes (General Electric)
This probe allows the advantages of EC arrays to be implemented in a conformable PCB (see Figure 44). The sensor incorporates magnetoresistors and spiral coils in two-dimensional arrays. This allows for simultaneous, multifrequency inspections and real-time imaging of cracks and corrosion. Successful demonstrations of GE flexible EC sensors have been completed on the AANC (FAA Airworthiness Assurance center) testbed aircraft.

4. Meandering winding magnetometer probes
JENTEK sensors has developed mountable, electromagnetic sensors for fatigue and corrosion monitoring of aircraft structures. The MWM and the segmented-field, spatial wavelength interdigitated dielectrometer

Figure 42. Fiber-optic sensors in adhesive bondline and FO monitoring equipment.

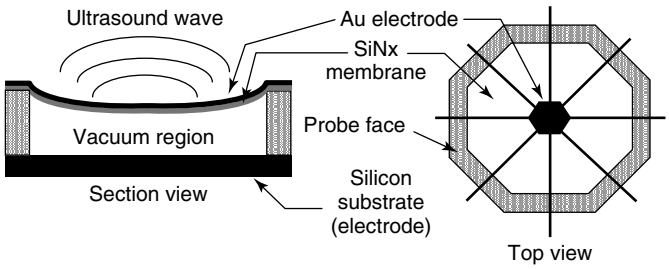

Figure 43. Schematic of capacitive micromachined ultrasonic transducer (cMUT).

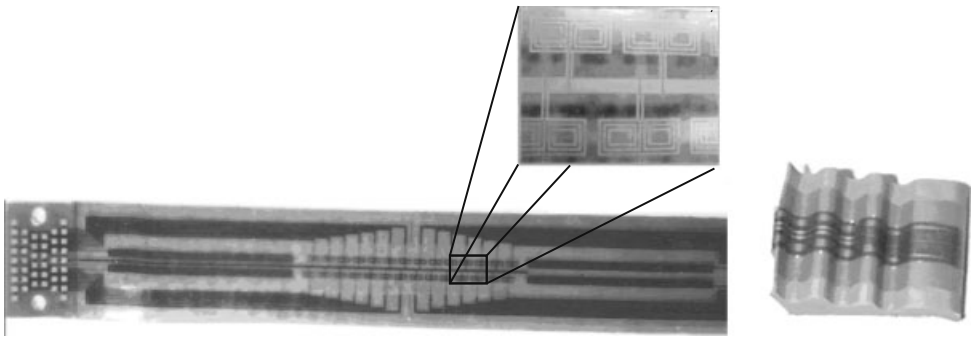

Figure 44. General electric's flexible eddy current array.

(IDED) have been produced and demonstrated for a wide variety of health monitoring applications. The MWM is an inductive EC sensor, and the IDED is a capacitive sensor. MWMs are suitable for metals, graphite fiber composites, reinforced carbon composites, and low observable coatings (nonconducting, magnetizable coatings using magnetic particle suspensions), while the IDED is suitable for characterization of glass fiber composites, corrosion protection coatings, sealants, glass, paint, and wood, as well as for detection/monitoring of corrosion products and moisture ingress, and monitoring of cure states of epoxies and adhesives. The corrosion monitoring technology is relatively new and requires additional research before field implementation, while the MWM-array fatigue monitoring technology is already a commercial product to support component fatigue testing. It is being transitioned to the fleet for specific applications. Through the combined use of IDED and MWM sensors, it is possible to detect not only metal loss, as with EC-based NDI methods for corrosion, but also corrosion products and moisture ingress within the joint itself. Example geometries for MWMs are shown in Figure 45.

5. Nickel-strip magnetostrictive sensors (Southwest Research Institute)

This guided-wave probe consists of a thin nickel substrate (foil) and a thick MsS coil in a PCB that is placed on the nickel strip. The strip is mounted on the structure being monitored. It generates pulses of guided waves and detects the signals being returned from within the structure. Data comparisons with baseline signals (undamaged configuration) are used to identify defects. A single probe can work over long distances allowing for economical SHM of large structures.

6. Adhesive bond degradation sensor (Lockheed-Martin, Tetra Tech)

This sensor is used in conjunction with FO lines. The ABDS is being developed to detect bondline decay by measuring water ion concentration in the adhesive. These ions are by-products of decay at the adherend-to-adhesive interface. Features of light reflection from the ABDS are altered in response to the concentration of water ions. Testing is under way to calibrate the adhesive bond degradation sensor in order to quantitatively relate the level of water ions to the decay in bond strength.

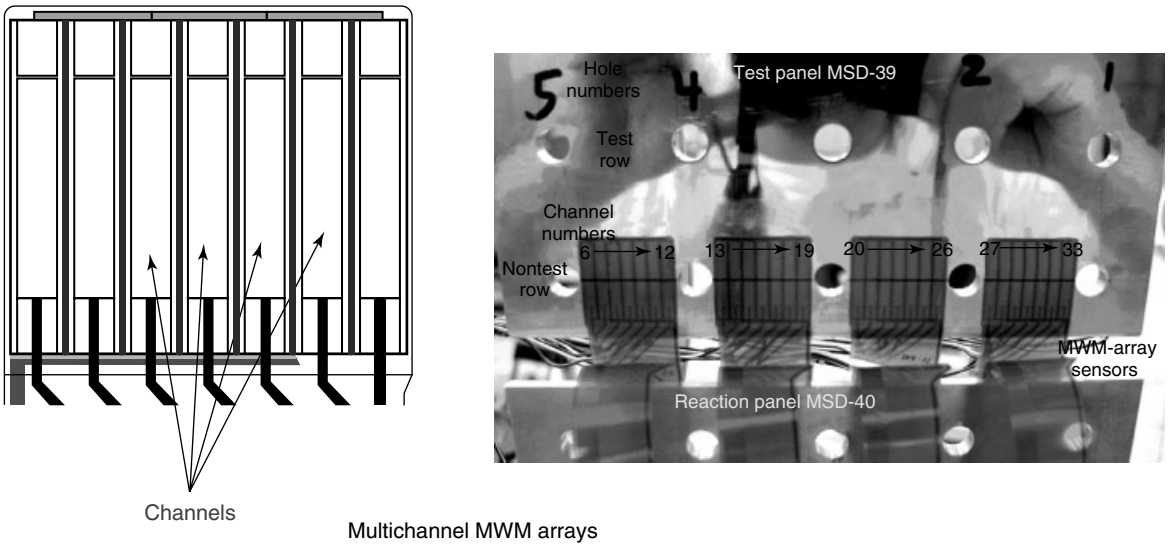

Figure 45. Seven-channel MWM array and surface-mounted MWM arrays monitoring for cracks around fastener holes.

7. Long-period grating (LPG)-based chemical sensors (Luna Innovations, Boeing, Navy)
This is an optical fiber sensor that can detect precursors to corrosion such as moisture, pH levels, and metal-ion corrosion by-products. By applying special coatings that change refractive index with absorption of target molecules on the LPG surface, the optical fiber sensor becomes the transducer for chemical measurement. For detection of moisture, for example, the LPG sensor is coated with a poly-ethylene oxide (PEO) hydrogel that swells in the presence of moisture.

Alternatively, sacrificial corrosion sensors—for installation on the ends of FO lines—are in the development stage. These sensors are designed to deteriorate in the same manner and at the same rate as the parent structure they are monitoring. Characteristics of light reflected back through the FO line can be calibrated to indicate different levels of corrosion.

8 DEPLOYMENT OF HEALTH MONITORING SENSOR NETWORKS

Distributed sensor networks can be deployed in any of the three approaches listed below. These options are listed in the order of increasing complexity; however, less labor is required to monitor the systems as they become more complex.

1. In situ sensors only
The sensors are the only items permanently installed on the structure. At the desired inspection intervals, power, signal conditioning, and data-acquisition electronics are manually transported to the structure to be monitored. The sensors are linked to the monitoring electronics via an electrical connector and flaw detection is completed by an inspector at the site.

2. Sensor network with *in situ* data acquisition
In this system, miniature, packaged electronics are also placed *in situ* with the sensor network. The electronics contains the necessary power, memory, and programmable circuitry for automated data logging. The data is periodically downloaded to a laptop through manual hookups at the site.

3. Sensor network with real-time data transmission to a remote site
This approach is similar to item (2) above with the addition of a telemetry system that allows for continuous, wireless transmission of data to a web site. The web site can be programmed to interrogate critical aspects of the data and use preset thresholds to

provide continuous green light/red light information regarding the health of the structure. The web site can even be programmed to automatically send an e-mail to operation personnel if the condition monitoring process indicates the need for repairs or other maintenance.

8.1 Principles of improved maintenance through SHM

The costs associated with the increasing maintenance and surveillance needs of our aging infrastructure are rising at an unexpected rate. Through the use of SHM concepts, it is possible to quickly, routinely, and remotely monitor the integrity of a structure in service. The ease of monitoring an entire network of distributed sensors means that structural health assessments can occur more often or even continuously, allowing operators to be even more vigilant with respect to flaw onset. SHM systems allow the operators to track structures when their use has changed substantially (e.g., increase in bridge load, duration of daily operation and increase in spin rate of turbines) or immediately after an abnormal event. SHM systems can even automatically determine that an abnormal event has occurred and acquire data between programmed monitoring intervals.

SHM addresses the need for reliable SHM systems that can automatically process data, assess structural condition, and signal the need for human intervention. The design, evolution, and deployment of SHM systems and concepts for field applications depend greatly on the structure's inspection needs and the type of maintenance program currently used. More rigorous and scheduled maintenance programs, such as those associated with aviation and nuclear industries, readily lend themselves to transitions into SHM methods. However, unexpected phenomena and advanced aging concerns may hasten the introduction of SHM into other civil structures that are more difficult to closely monitor on a regular basis.

The critical element of the SHM system is the array of sensors. These sensors must be accurate, reliable, repeatable, low cost to mass produce, easy to install, and easy to monitor. Interpretation of data is an important feature that brings numerous human factor issues into play. The sensors must be integrated into automated data-acquisition equipment to convert the data into usable information about structural integrity. The implementation goals for SHM must consider the need for local versus global coverage. In order to maximize the global health monitoring feature of the SHM system, the sensors must be either low cost, to accommodate many installations, or capable of monitoring large areas. Finally, the sensors must have a fail-safe mode of operation (auto fault detection) so that abnormal data is not incorrectly interpreted as damage.

Some of the key issues that must be addressed in order to transition SHM into the field include (i) the goals for the SHM system and its targeted applications, (ii) required performance characteristics and the means to assess that performance, (iii) use of SHM in lieu of existing inspections or use of SHM as a basis for further optimizing structural design (design credits accumulated through integrated SHM), (iv) minimizing system costs, (v) eliminating risks associated with system use, (vi) integration of SHM system with existing subsystems, (vii) use of energy harvesting (solar, vibration) hardware to allow for long-term, unattended operation, and (viii) adapting existing maintenance programs to take advantage of condition-based maintenance opportunities that can stem from the use of SHM.

To date, SHM systems have not been widely deployed in the field, thus limiting the successful operational data needed to instill confidence in their use. However, vibration monitoring (accelerometers), acoustic emission sensors, and crack monitoring (CVM sensors) have all made significant inroads and demonstrate the potential for the SHM approach in areas with high probability for damage. While these limited applications have not allowed for comprehensive cost–benefit analyses to be performed, key savings associated with their use have been identified. These include the remote and rapid acquisition of data and the elimination of setup tasks such as the disassembly or removal of equipment to access an inspection site. In addition to the operating benefits, there are recurring and nonrecurring costs—design savings, training, equipment costs, and increased structure availability—that must be considered. The idea of condition-based maintenance is a critical consideration when determining overall cost–benefits. SHM systems using distributed sensor networks can reduce costs by allowing condition-based maintenance practices to be substituted for the

current time-based maintenance approach. A series of expected maintenance functions have been already defined; however, they will be carried out only if their need is established by the health monitoring system.

One cost–benefit analysis for commercial transport aircraft showed that implementing SHM systems could result in a significant reduction in both maintenance and operations and support (O&S) costs. An example is given where implementation of SHM systems could result in a 30–40% reduction in maintenance requirements, resulting in recovery of the initial implementation costs in only two to three years. For larger and more complex structures, the time required to recover the initial implementation costs may be longer, but is still well within the life of the vehicle. A similar justification can be made for future launch vehicles. For such vehicles to be successful, launch costs must be reduced an order of magnitude below those of current launch vehicles. To meet turnaround goals, the time required to assess the structural condition needs to be significantly reduced. An automated SHM system could potentially assess the health of the entire structure within hours of a completed mission and recertify the structure for flight.

The basic steps required to mature an SHM system from concept to implementation are (i) laboratory evolution to prove the principle of the monitoring physics, (ii) sensor and data-acquisition system development, (iii) application on representative structural components in the lab, (iv) structured validation exercises to statistically determine all performance characteristics (e.g., probability of flaw detection, probability of false calls, repeatability of data), (v) exposure of SHM system to all potential impediments to operation, (vi) development of a field implementation plan, (vii) beta site testing in the field over a representative time frame, and (viii) concurrence from operators, regulators, and researchers that the SHM system is acceptable for use in a particular set of applications (certification).

For now, pilot programs are being pursued to accumulate operational history, further mature SHM technology, and identify the obstacles to its use in more complex and widespread applications. In the future, SHM systems should be integrated with PHM systems to allow for improved and more proactive structural health management. When SHM is combined in a systems approach, which includes sensors to monitor electronics, hydraulics, machinery operations, avionics, etc., it is possible to produce a PHM architecture that can assist in maintenance scheduling and tracking. Such a comprehensive SHM system will reach beyond safety considerations and allow for optimized designs and longer life spans while maximizing performance and operational availability at minimum costs.

9 CONCLUSIONS

Detection of unexpected flaw growth and structural failure could be improved through the use of onboard health monitoring systems that could continuously assess structural integrity. Such systems would be able to detect incipient damage before catastrophic failures occur. Local sensors, such as the ones described in this article, can be used to directly detect the onset of crack, corrosion, or disbond flaws. Global SHM, achieved through the use of sensors such as accelerometers coupled with structural dynamics assessments, can be used to assess overall performance (or deviations from optimum performance) of large structures such as bridges and buildings. Whether the health monitoring approach is local or global, the key element in a SHM system is the calibration of sensor responses so that damage signatures can be clearly delineated from sensor data produced by unflawed structures.

This article focused on local flaw detection using embedded sensors. While some of these leave-in-place sensors are able to produce wide area inspections, their use is predicated on the identification of primary flaw regions to be monitored. The replacement of our present-day manual inspections with automatic health monitoring would substantially reduce the associated life-cycle costs. The ease of monitoring an entire network of distributed sensors means that structural health assessments can occur more often, allowing operators to be even more vigilant with respect to flaw onset. When accessibility issues are considered, distributed sensor systems may also represent significant time savings by eliminating the need for component teardown. In addition, corrective repairs initiated by early detection of structural damage are more cost effective since they reduce the need for subsequent major repairs. Aerospace structures have one of the highest payoffs for SHM

applications since damage can quickly lead to expensive repairs and aircraft routinely undergo regular, costly inspections.

In general, SHM sensors should be low profile, lightweight, easily mountable, durable, and reliable. To reduce human factors concerns with respect to flaw identification, the sensors should be easy to monitor with minimal need for users to step through additional data analysis. For optimum performance of the *in situ* sensor-based approaches, the signal processing and damage interpretation algorithms must be tuned to the specific structural interrogation method. For example, in the high-frequency E/M impedance approach, pattern recognition methods can be used to compare impedance signatures taken at various time intervals and to identify damage presence and progression from the change in these signatures. These approaches can benefit from the use of artificial intelligence and neural network algorithms that can extract damage features based on a learning process.

Recent failures of aircraft and civil structures have compelled the engineering community to take a fresh look at the fail-safe, safe-life, and damage tolerance design philosophies. The effect of structural aging and the dangerous combination of fatigue, corrosion, and other environmentally induced deterioration is now being reassessed. The end result of these assessments has been a greater emphasis on the application of sophisticated health monitoring systems. Recent advances in onboard SHM sensors have proven that distributed and autonomous health monitoring systems can be applied to reliably detect incipient damage. Such systems have wide use in aerospace, automotive, civil infrastructure, and other industrial applications.

1 OVERVIEW

Military organizations are continuously evaluating different methodologies to reduce cost, increase availability, and maintain safety of current and future air vehicle systems. Recently, emphasis has been placed on the development of integrated systems health management (ISHM) technologies. These methods would be able to determine the health of an entire vehicle based on combined assessments of various vehicle subsystems. As necessary, the health management system could also interact with flight control systems to ensure mission success. We give a brief overview of ISHM methods in the first part of this article.

Since the vehicle structure is one of the most critical subsystems, structural health monitoring (SHM) techniques must be developed to enable implementation of the ISHM methods. To date, however, few fielded applications of SHM systems exist for aerospace structures (*see* **Commercial Fixed-wing Aircraft**; **Flight Demonstration of a SHM System on a USAF Fighter Airplane**; and; **Experience with Health and Usage Monitoring Systems in Helicopters**; **Validation of SHM Sensors in Airbus A380 Full-scale Fatigue Test**; **Aerospace Applications of SMART Layer Technology**). In the second part of this article, we outline the underlying reasons for such limited use, with a specific focus on applications for military aircrafts. The need for a business justification to field an SHM system is discussed, along with the technical feasibility of implementing such systems.

For at least certain aerospace applications, a strong business case can be made for implementing such a system. The SHM community has also made considerable efforts to address the technical challenges of implementation. Assuming that the business and technical challenges can be overcome, there are various

 ISBN: 978-0-470-05822-0.

near-term and far-term aerospace applications. We discuss potential applications of SHM systems in the last part of this article.

2 INTEGRATED SYSTEMS HEALTH MANAGEMENT

Recently, military organizations have focused their attention on maturing ISHM technology for potential implementation on current and future air vehicle systems. We define ISHM as any system that collects, processes, and manages health data to assess the current condition of the vehicle and determine its ability to perform a given mission. By knowing the condition of each air vehicle system in the fleet, we can effectively deploy systems for the appropriate mission, even in a degraded state.

As an example, consider a case where System "A" is damaged and currently operating at 80% of its full capability until repaired. We can still use System "A" to perform a mission that requires less than 80% of its full potential before being serviced. We can utilize the system with a high level of confidence because its health is known. As a result, we can increase the availability of air vehicle systems without increasing the risk of mission success.

Ideally, we will be able to create fully integrated health management systems, enabling affordable combat support, maximizing mission capability, and abating secondary damage. In order to achieve this, we must be able to accurately assess the condition of each individual vehicle subsystem so that the overall health and capability of the entire vehicle can be determined. One of the most critical components of a military vehicle is the structural subsystem, since a catastrophic failure could occur if the structure is not functioning properly. Therefore, the development of SHM systems is essential.

2.1 SHM system development

The process required to develop an SHM system for a specific aerospace component is illustrated graphically in Figure 1. For the first step in the process, we must identify the component or system of interest. Although this seems like an obvious step, it is a common pitfall to start SHM development with sensor system design.

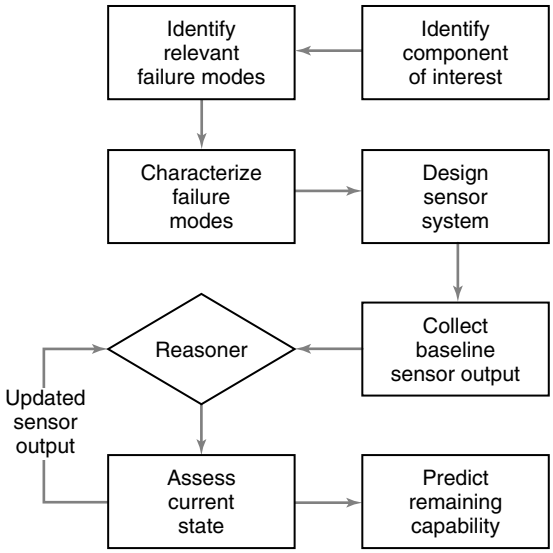

Figure 1. Process required for SHM system development.

For the next step, we need to identify the relevant failure modes of interest. These failure modes depend on the operating conditions and are unique to a specific component. For example, metallic components may experience failures due to cracking or corrosion. Composite parts may experience disbonds or delaminations. Components of both materials are susceptible to impact damage or fastener failures. We make an underlying assumption in this step that the SHM system will not be able to detect every single failure mode.

Once the component and relevant failure modes are identified, we must characterize the failures by investigating the physics of the contributing damage mechanisms. If possible, it is also useful to identify any precursors of damage. The definition of what constitutes damage is dependent on the component and application. For example, in an aircraft spar, failure may occur owing to widespread cracking. The precursors to such failure might include damage due to cracks that are small with respect to the component, but large with respect to the microstructure of the material. We identify precursors of damage to better understand which damage mechanisms we can sense.

At this point, we can design an appropriate sensor system. For most engineering applications, we cannot directly measure damage. Therefore, the

sensor network typically must use a combination of direct, indirect, and virtual sensors, in both on-board and off-board applications. Direct sensors measure the specific damage mechanism of interest, whereas indirect sensors measure another physical property that can be correlated to damage. Virtual sensors marry existing sensor data and numerical models to estimate damage. The application and the operational environment dictate the types and placement of the sensors we use. Sensor authentication techniques should be used to verify the integrity of the deployed sensors.

With a sensor system instrumented on the component, we must next develop a baseline for the sensor responses. The baseline should be completed, if possible, on components with minimal operational time. If we cannot do so, any previous operation of the components will add uncertainty to the output of the SHM system. The baseline sensor responses are fed into a component-level reasoner to provide a reference of the healthy state of the component.

After the component has been used for a given amount of time, updated sensor data is collected and fed back into the component-level reasoner. The reasoner takes the output of the sensors and utilizes the response to determine the current state of the component. The assessment can occur in real time, using on-board sensors or, intermittently, using off-board sensors. The interval of the updating differs between components and is determined by the importance of the sensed data and whether on-board or off-board sensors are utilized. In most cases, there will be some variability in the sensed data due to time-varying, nonlinear effects. Efforts should be undertaken to identify these sources of variability to avoid incorrect reasoner state identifications, including missed detections and false alarms. Both physics-based modeling and data-driven modeling are usually required to develop the reasoner. Physics-based models capture the anticipated damage mechanisms and failure modes, and data-driven models have the potential to capture unanticipated damage mechanisms.

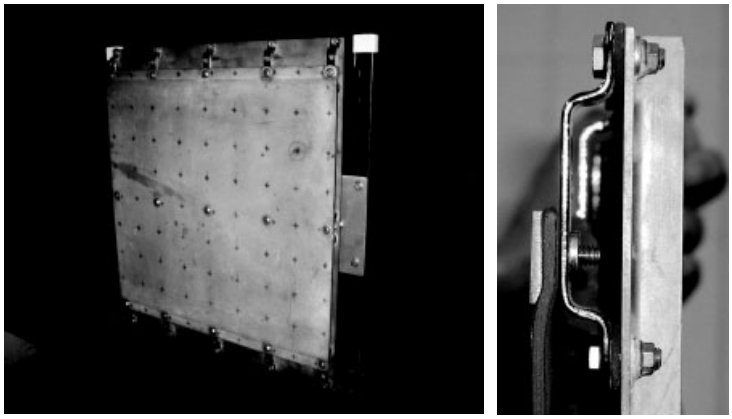
If possible, we would like to develop true prognostic systems that are capable of predicting the remaining capability of the component of interest. To predict the remaining capability, we require information regarding the loading profiles that the component is experiencing. These loading profiles can either be calculated from health and usage monitoring data, if available, or can be estimated using a realistic approximation of the mission profiles the component will experience. Using the mission loading profiles and advanced life prediction tools, we can typically predict the remaining capability.

2.2 SHM system development example

To illustrate SHM system development, we present an example for a specific aerospace structure (*see* articles in **Part 8** for more examples). To meet future requirements in the areas of control of space and global engagement, military organizations are working toward developing reusable space vehicles. In current conceptual models, these vehicles incorporate metallic or composite panels over the fuselage as part of a thermal protection system (TPS). If the panels become damaged, the vehicle's fuselage could be exposed to the environment, compromising vehicle integrity and ultimately jeopardizing mission safety and effectiveness.

As shown in Figure 1, the first step in the ISHM development process is to identify the item of interest. TPS structures of future military space vehicles are a good example of a structural system for which prognosis systems would be extremely beneficial. The TPS is one of a space vehicle's more vulnerable components owing to the likelihood of space debris strikes and the certainty of extreme thermoacoustic loading during launch and reentry. The TPS must be in good condition prior to launch owing to its critical role in protecting the vehicle's primary structure and subsystems.

We show a representative TPS panel in Figure 2. A carbon–carbon panel provides the foundation of the TPS. The panel is approximately 0.61 m square and 3.175 mm thick and is bolted to 15 evenly spaced brackets. The brackets are bolted to a 2.54 mm thick ribbed backing structure with 16.94 mm thick ribs. The backing structure represents the vehicle's fuselage. Figure 2 also shows a side view of the representative TPS article, illustrating the connection details of the panel, brackets, and backing structure. The brackets are fabricated from inhibited silicon carbide–carbon with a chromalloy coating. The ribbed backing structure is titanium.



(a) (b)

Figure 2. (a) Representative thermal protection system component and (b) side view showing fastening details.

For the next step in the process, we must identify the failure modes of interest. Damage modes identified for TPS structures include loose or missing fasteners, impact damage, delaminations or disbonds, and cracks. To improve maintainability and reduce turnaround times, military space vehicles will likely utilize mechanically attached TPS structures. In addition, it has been noted that approximately 70% of all mechanical failures occur in fasteners [1]. As a result, for this example, we focus our attention on detecting fastener failures.

The third step in the ISHM development process is to characterize the failure modes. The various TPS failure modes can have widely varying effects on the structural dynamics. Damage such as cracks have a highly localized effect on the structural dynamics, and the use of elastic wave damage detection techniques, such as Lamb waves (*see* **Fundamentals of Guided Elastic Waves in Solids**), may be suitable. As discussed above, our focus is on detecting fastener failure. Damage such as fastener failure induces a more global effect on the structural dynamics and, therefore, modal-based damage detection techniques (*see* **Modal–Vibration-based Damage Identification**) have been investigated. It may be difficult to identify precursors that indicate imminent bolt damage. However, we are exploring the capability to assess the level of bolt torque or preload so that any degradation is predicted as early as possible.

Designing a sensor system that can capture the relevant degradation mechanics is the next step in the process. During operation, the outer surface of the TPS panel will be at elevated temperatures, which precludes the use of most sensors on the TPS panel itself. As a result, we will most likely make measurements on the backing structure or brackets, where the temperatures are considerably lower. For our current studies, we have utilized four piezoelectric transducers-0.635 mm diameter, 0.25 mm thick lead zirconate titanate (PZT) discs-adhered in the valleys between the ribs of the backing structure. The transducers are attached on the side of the backing structure representing the inner fuselage of the aerospace vehicle, where temperatures should remain well within the operating range of the piezoelectric materials. This configuration represents realistic actuator/sensor placement, since piezoelectric devices fail at the high temperatures encountered on the outer surface of the vehicle. Piezoelectric sensors offer the advantages of light weight, low power consumption, operation over a wide range of frequencies, and the ability to operate as both actuators and sensors (*see* **Piezoelectricity Principles and Materials**).

We next need to obtain initial sensor input. For the representative TPS article, different structural conditions are obtained by loosening one bolt at a time from the carbon–carbon panel by a one-quarter turn. When all bolts are fully fastened, the structure is considered healthy. A bolt loose condition corresponds to a damaged state. For any of the damaged states, it would be advantageous to be able to both detect the presence of damage and to locate the damaged fastener. For the experimental

testing, an excitation signal is sent to one piezoelectric using a swept frequency sinusoid, ranging from 0 to 7000 Hz over 1.0 s. The vibration responses are recorded from the remaining three piezoelectrics. Over 100 rounds of data have been collected over a period of approximately four months, where each round corresponds to measurements at each of the different healthy and damaged structural conditions. We have used this data to train the component-level reasoner discussed in the following paragraph. The data also provides the baseline response of the healthy structure.

For the representative TPS article, we use a component-level reasoner based on statistical pattern-recognition techniques. Statistical pattern recognition considers the conditional probability density functions (pdfs) of measurements associated with each class to be identified (i.e., either healthy or one of the various damage states). The pdfs are determined from the training data collected during the previous step and used to form discriminant functions. We predict the state of the structure based on the largest discriminant function given a particular measurement. For most practical pattern-recognition tasks, we need multidimensional measurements to provide acceptable classification accuracy. Typically, we compute a number of potentially useful features and identify a subset of the most useful ones using a feature selection process. Features for the representative TPS article are based on the root-mean-square (RMS) energy over specified time periods (roughly corresponding to specific frequency ranges since the structure is excited using a swept sinusoidal signal) at the various sensors. For the representative TPS article, the accuracy of the component-level reasoner has been investigated using independent evaluation data collected in the laboratory. We have demonstrated an efficient reasoner with detection and localization accuracies of 99.9 and 99.3% respectively, and with a probability of missed detection of 0.1% and a probability of false alarm of 0.3%.

The last step in the process is to predict the remaining capability. To make an accurate prognosis of the remaining capability, we must know both the current state of the structure and the loading profiles that the structure will experience. The component-level reasoner discussed above should provide a reasonably accurate assessment of the current state of the TPS structure. Since the exact loading profiles that the structure will experience are uncertain, a prediction must be made on the basis of available loads measurements (or estimates) and anticipated mission profiles. When appropriate, the utilization of health and usage monitoring systems (HUMS) data will be considered.

To incorporate the SHM system into the ISHM framework, we need to output the prognosis data to a system-level reasoner. The system-level reasoner incorporates data from the prognoses of various components to determine the overall state of the vehicle. System-level reasoners typically involve several levels of integration. For example, prognoses of each of the TPS panels on the vehicle are integrated with each other and other structural components to provide an estimate of the state of the entire vehicle structure. The estimate of the state of the vehicle structure is further integrated with estimates of the state of the vehicle engines or other subsystems to provide a comprehensive estimate of the vehicle condition.

3 SHM SYSTEM IMPLEMENTATION

In the preceding section, we discussed how an SHM system was designed for an aerospace component. In fact, the potential use of SHM systems for aerospace structures has been investigated for more than a decade. However, there are few fielded applications [2]. In this section, we investigate the underlying reasons for such limited use. To be fielded, a framework must be established for implementing SHM systems. This framework would define the architecture of the SHM system and would include integration of the SHM system with other vehicle subsystems and overall fleet management methods. However, prior to establishing a framework, we must demonstrate a business justification for implementing SHM systems as well as technical feasibility. We discuss issues related to the business and technical challenges in the following paragraphs.

3.1 Business justification

From a business standpoint, the benefits resulting from an SHM system must outweigh the costs associated with its implementation. As we discuss below,

the potential benefits are largely in the areas of improved maintenance and repair. Additional performance benefits are anticipated once SHM systems are incorporated into the ISHM framework. Associated costs include both financial costs, such as those associated with development, installation, and operation, as well as physical costs, such as added weight or power requirements. We provide a brief cost–benefits analysis discussion in the latter portions of this section.

3.1.1 Benefits of SHM implementation

The potential benefits of implementing an SHM system are largely in the areas of improved maintenance and repair, and increased performance. As an air vehicle system increases in age, the operating and support costs also increase. We know that roughly 60% of the total life cycle cost of a system is used to sustain it. Similarly, aircraft maintenance and repairs represent about a quarter of a commercial fleet's operating costs [3]. One of the biggest cost drivers in a military air vehicle fleet is unscheduled maintenance. The problem is exacerbated since many military aircraft currently in use today are older. For example, the average US military aircraft is roughly 25 years old. To maintain safety, we need to perform increasing numbers of inspections, which results in a decrease in fleet availability.

To improve the current aircraft maintenance procedures, military organizations are exploring the use of condition-based maintenance practices. Using these practices, maintenance is performed on the basis of the current condition of the system instead of that based on a set inspection schedule. By migrating to condition-based maintenance practices, we hope to improve maintenance agility and responsiveness for quicker turnaround times, increased operational availability, and reduced life cycle total ownership cost [4].

3.1.2 Costs associated with SHM implementation

Implementation costs include the costs associated with developing, installing, and operating an SHM system. Even with mature SHM technologies, we will almost certainly need some development to adapt a particular technique for each unique application and to verify its functionality. Once an SHM system has been verified and approved for fleet-wide use, we also have an associated cost per vehicle to install the system. Additionally, there are operating costs associated with the SHM system, such as the costs of archiving SHM system data for historic use, upgrading the system with improved damage detection algorithms, or long-term maintenance or periodic calibration of the SHM system.

In addition to the monetary costs, there are other costs such as added weight or power requirements. Weight is a critical concern for aerospace vehicles. Therefore, the added weight of any SHM system including all hardware (sensors, cabling, processors, etc.) must be considered. Power requirements are an additional concern. Advanced avionics and other subsystems may require a significant portion of the available power on future air vehicles. Military space vehicles have their own unique limitations based on the available on-board power. We must consider all costs associated with SHM system implementation, including both the monetary and nonmonetary costs.

3.1.3 SHM implementation cost–benefit analysis

Few cost–benefit analyses, for military or commercial aircraft, have been discussed in the open literature. In one of the limited published studies, Kent and Murphy [5] analyzed the use of SHM systems for maintaining commercial transport aircraft. Their study showed that implementing SHM systems could result in a significant reduction in both maintenance and operating costs. They give as an example the implementation of an SHM system that could result in a 30 to 40% reduction in maintenance requirements. The initial implementation costs would be recovered in only two to three years. For larger and more complex structures, the time required to recover the initial implementation costs may be longer, but is still well within the life of the vehicle.

We can make a similar justification for military space vehicles. For such vehicles to be successful, launch costs must be reduced an order of magnitude below those of current launch vehicles. The key to reducing launch costs is to reduce the turnaround time. To meet turnaround goals, we need to significantly reduce the time required to assess the structural condition. More specifically, we need an automated

SHM system that can assess the health of the entire structure within hours of the completed mission and recertify the structure for flight. Thus, incorporation of SHM will be critical to the success of future launch vehicles.

It is likely that near-term applications will involve retrofitting existing air vehicles with SHM systems to detect damage in well-documented problem areas. We discuss potential aerospace applications of SHM in Section 3. These near-term applications have a high payoff in which the benefits of applying the SHM system significantly outweigh the associated costs. However, successful fielded applications are required to demonstrate utility and build confidence before SHM systems are widely accepted.

3.2 Technical feasibility

Regarding technical feasibility, we must address all issues related to SHM system development, implementation, and operation. Farrar and Worden [2] introduce some fundamental challenges of SHM systems, including the following: (i) small-scale damage must be detected in relatively large-scale structures; (ii) SHM systems must work in an unsupervised learning mode; and (iii) the robustness and redundancy of an SHM system must be ensured. The SHM community has made considerable efforts to address these challenges. We discuss these efforts below, along with examples from recent work.

3.2.1 Detecting small-scale damage in large structures

Typical aerospace structural damage includes cracking, corrosion, or fastener (e.g., rivet) failure, all of which occur in only a small fraction of the total area of the structure. Although the damage area is small, the consequences of reduced integrity in that area are large. Thus, SHM systems must be capable of detecting small-scale damage in relatively large-scale structures. Sensors play a critical role in addressing this challenge because they provide the raw data for classification algorithms. Sensor issues include identifying the types to use, determining the number required, and specifying the layout. We address each of these issues below.

The primary factor we must address in sensor selection is identifying sensing techniques that can detect the damage of interest. Considerable research has been performed over the past several decades to investigate various sensors (*see* articles in **Part 5**). Adams [6] gives a good overview of some of the available sensors and the advantages and disadvantages of the various types. We have investigated the use of many of these sensor types for SHM applications. A short list of sensor types considered includes piezoelectric, vacuum tube, acoustic emission, photoelastic, strain gauge, fiber-optic, and magnetostrictive sensors. Figure 3 shows examples of several of these sensor types. In addition to being capable of detecting the damage of interest, other concerns related to identifying appropriate sensor types include geometric constraints, operational and survival environments, and the coverage area.

The coverage area relates directly to the issue of defining the number of sensors required. Nondestructive evaluation (NDE) techniques to detect cracks or corrosion usually interrogate a relatively small area, typically only the area under the sensor. For example, scans using ultrasonic or eddy-current techniques

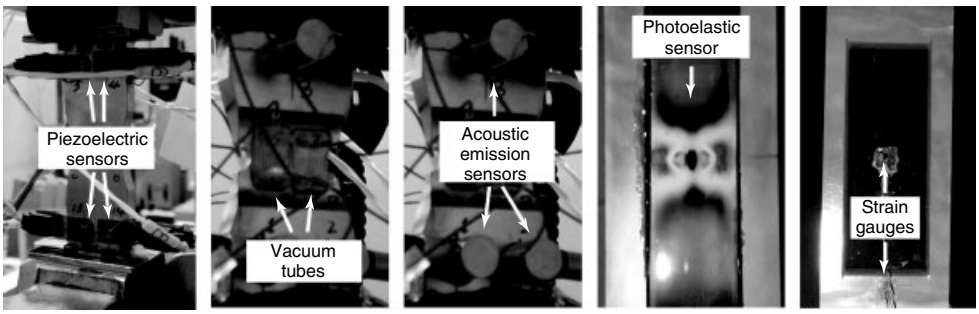


Figure 3. Examples of different sensor types investigated for SHM applications.

are performed by moving a sensor to various locations to investigate the region of interest. Obviously, these NDE techniques are not readily transferable to SHM systems where sensors would be permanently attached to, or embedded within, a structure. As discussed previously, there is a weight cost related to attaching sensors. We must consider the total added weight of any SHM system, including the associated cabling and other hardware. Even with the incorporation of wireless technology, the number of sensors should be minimized.

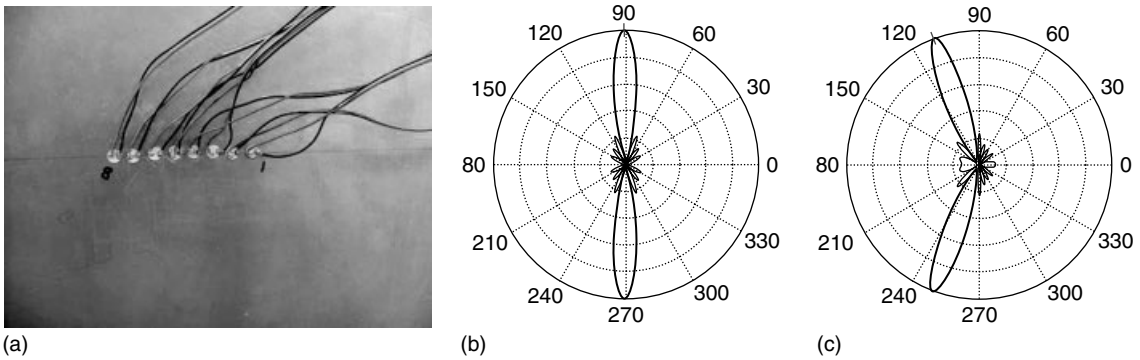
Techniques we have studied to minimize the required number of sensors include increasing the area of coverage for a given sensor (or set of sensors) and designing SHM systems into the structure to aid in state identification. One technique investigated to increase the area of coverage is to utilize elastic wave techniques with a phased array of piezoelectric sensors [7], such as that shown in Figure 4. In phased array techniques, we adjust the timing of signal data from a set of sensors to focus energy in a specific direction. By altering the phasing of individual sensors, we can sweep the "look angle" over a relatively large region of the panel.

An alternative approach for reducing the number of sensors is to include SHM in the structural design process. One possibility is to include noncritical failure modes of the structure as precursors to any potentially catastrophic failure modes. These "structural fuses" could be used as indicators for appropriate maintenance actions. Another possibility is to "design in" SHM where the structural design itself aids in identifying the structural health. McClung and Grandhi [8] demonstrated such a technique for a simple plate structure using a modal-based technique. In addition to reducing the number of sensors required, "designing in" SHM systems may improve performance and reliability, permit lighter designs with reduced reliance on structural redundancy for fail-safety, or reduce certification times.

The positioning of sensors is another factor relating to the detection of small-scale damage in large-scale structures. Sensor locations can be optimized to improve the detection of small-scale damage, or the critical damage areas can be better defined to alleviate the need to inspect large regions. Guratzsch [9] developed a methodology to optimize sensor placement. Although the optimization is computationally intensive even for the simple bolted plate structure examined, the methodology demonstrates the potential to improve damage detection by optimizing sensor placement.

In many cases, existing air vehicles have known *hot spots* where we anticipate a particular type of damage might occur or has consistently been observed in the field. Knowledge of the damage location and type enhances the damage detection capability. We can focus the sensors used for the SHM system on the particular area of interest and can design the system to detect expected damage types. When the "hot spot" is located in an area difficult to inspect by conventional NDE methods, such SHM solutions can provide substantial savings in time and money.

In summary, damage detection technologies are being matured which will enable widespread adoption of SHM systems. Considerable research has been performed related to detecting small-scale damage in



(a) (b) (c)

Figure 4. (a) Phased array of piezoelectric sensors and (b) and (c) gain plots showing the potential to focus energy in particular directions.

relatively large-scale structures. However, laboratory and academic successes need to be transitioned to actual applications.

3.2.2 Working in unsupervised learning mode

For many practical SHM system applications, data from all the relevant damage states of the structure is not available. Therefore, we face a second fundamental challenge in that the system must operate in an unsupervised learning mode. As an example, consider military space vehicles. It is likely that we will produce only a limited number of vehicles, and it may not be possible to collect damaged data from any of these vehicles. The vehicles will also operate in extreme environments, where the precise conditions may not be well quantified or even understood. Some potential SHM techniques suitable for working in an unsupervised learning mode, as well as the limited research in this area, are discussed below.

We have explored several techniques to account for the lack of damaged data during SHM system design, and to compensate for temporal or environmental changes. These techniques include detecting anomalies or outliers in the data or utilizing innovative "cancellation" techniques to eliminate changes in response signals that are not a result of damage. For example, Worden *et al.* [10–12] have utilized a novelty detection technique to identify damage in an aircraft wing. Kim and Sohn [13] have developed techniques to highlight nonlinear changes in piezoelectric sensor responses due to damage. It should be noted that both of these techniques require a threshold value to be defined beyond which damage is indicated. Since damaged response data may not be available, alternative means of establishing these threshold values are required. We should consider the use of physics-based models, historical data, or similarity to laboratory test results.

In general, we have found that greater attention has been focused on developing appropriate damage detection hardware than on developing algorithms to process the measured data. A literature review [14] found similar trends, as there is significantly less literature dealing with algorithm development than other SHM system considerations. Although maturing SHM hardware is necessary, algorithm development is critical if SHM systems are to be capable of autonomously providing accurate structural state assessments under varying conditions and in near real time.

3.2.3 Ensuring SHM system robustness and redundancy

Another fundamental challenge is ensuring the robustness and redundancy of an SHM system. Robustness relates both to the performance of the SHM system, and also to the survivability and applicability of the system. In terms of redundancy, the SHM system should still function if individual hardware fails or, at the very least, indicate that the system is not functioning correctly. SHM system robustness and redundancy are discussed below.

To be useful in practice, an SHM system must provide a high probability of damage detection at a low false alarm rate. The high probability of detection is required to ensure that critical damage is detected in a timely fashion. Low false alarm rates are needed to establish confidence in the SHM system and promote the adoption of such systems. Target values need to be established for each particular structural application. The use of physics-based modeling, including both theoretical and numerical calculations, will aid in improving SHM system accuracy. As an example, finite element simulations are currently being performed to assist in the creation of elastic wave techniques to detect damage for particular applications [15].

SHM systems also must be suitable for the operational and survival environments that a vehicle will experience. Improved air vehicle capabilities are constantly being demanded. As a result, vehicle structures are being subjected to, and must be capable of operating in, increasingly harsh environments. Since the objective of SHM is to evaluate the structural state of a component over its life, the SHM system should have a longer life than the vehicle or, as a minimum, longer than the monitored components. Ground and flight testing are required to verify the life of each of the components of an SHM system. As part of a "hot-spot" monitoring program, flight testing has been performed with piezoelectric sensors installed on an F-16 vehicle, and ground testing has been performed to evaluate the survivability of piezoelectric sensors when exposed to various environmental and chemical conditions. Figure 5 shows

(a) (b) (c) (d)

Figure 5. (a) Environmental test coupon undergoing (b) vibration testing, (c) fluid immersion testing, and (d) deicing fluid exposure testing.

a typical coupon used for the ground-based environmental testing, along with some of the tests performed.

After an SHM system has been developed and approved for fleet implementation, identical systems are manufactured and packaged for installation on each individual vehicle. Therefore, the system must be sufficiently robust to function similarly, regardless of the specific system hardware or the individual vehicle. The system should not be tied to a particular aircraft tail number or to a particular sensor serial number. Studies are currently underway to investigate the effects of materials and manufacturing variability on SHM systems. The primary objective of these studies is to improve the damage detection capability in the presence of anticipated variability; however, the studies also aid in quantifying the robustness of SHM systems with regard to installation on individual vehicles.

Lastly, an SHM system should detect failures in its own components and, if possible, still assess the structural state. For example, an individual sensor may fail in an SHM system. Through the use of substitute damage detection algorithms and a reduced set of responses, perhaps an assessment of the structural state can still be made at a lower confidence level. Less desirable alternatives are to "turn off" the SHM system if its hardware fails or to not provide a structural state assessment if the system cannot make a confident assessment based on the sensor response data [16]. In either case, operators must be notified of the health status of the SHM system itself. Since improved algorithms may become available or hardware may fail, the potential to upgrade or repair an SHM system during planned maintenance should be explored.

4 AEROSPACE APPLICATIONS OF SHM

For at least certain aerospace applications, a strong business case can be made for implementing an SHM system. However, the technical feasibility of these systems must be addressed. As discussed in the previous section, the SHM community has made considerable efforts to address these technical challenges. Assuming that all business and technical challenges can be overcome, we have identified potential near-term and far-term SHM aerospace applications. These potential applications are discussed below.

4.1 Near-term SHM aerospace applications

It is anticipated that near-term applications will involve retrofitting existing air vehicles with SHM systems to detect well-defined damage. These applications will likely focus on "hot spots", where the area and type of damage has been defined on the basis of problems observed in the field or anticipated to occur. In addition, the operational and survival environments will be known for such applications. These applications will have a high payoff in which the benefits of applying SHM systems significantly outweigh the associated costs. Candidate applications include critical components with short inspection intervals, components that are difficult to inspect using traditional NDE techniques, or components located where there is a high likelihood of secondary damage during inspection (e.g., where wing de-skinning is required). Initial near-term SHM system applications may also

involve only ground-based measurements with results processed in near real time, and early SHM systems may not be incorporated into an ISHM framework.

4.1.1 Structural "hot spots"

In certain instances, air vehicles have known areas with structural problems. To preserve safety and reliability, maintainers must inspect these problem areas at predefined intervals. In some cases, the problem resides in an inaccessible location, such as the upper or lower wing spar. Inspection therefore requires deskinning the wing. Figure 6 shows an example of such a structural component. SHM systems are being developed to detect and quantify cracks and corrosion in known problem areas of aircraft. The SHM systems will provide the aircraft maintainer with a diagnostic tool to enable early identification and assessment of structural degradation. This will allow us to identify and repair structural damage earlier than possible when relying on periodic inspections. Earlier repairs are typically less extensive and expensive, and can be phased into the aircraft flight schedule more easily.

4.1.2 Bonded repair integrity

Bonded repair technology is currently used on commercial and military air vehicles to extend the life of damaged structures. Figure 7 shows an example of a composite bonded repair patch applied to an aircraft fuselage. Laboratory tests have proved that a bonded repair could extend the life of a damaged structure by as much as a factor of 8. However, the nonrepaired inspection intervals of the damage under the patch are often still performed because the condition of the

Figure 7. Composite repair patch applied to an aircraft fuselage.

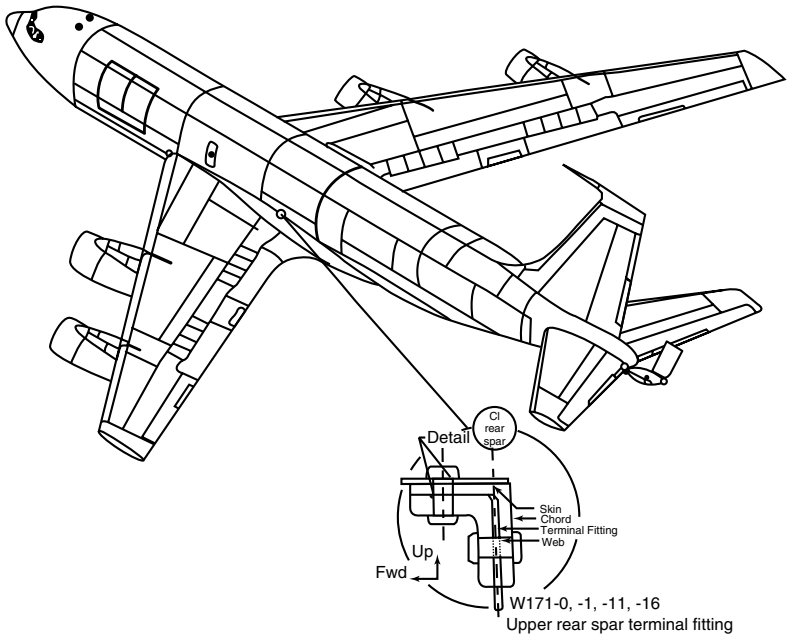


Figure 6. Example of a structural hot spot in an inaccessible location.

repair is unknown. Since inspections are performed at these nonrepaired intervals, the full benefits of the bonded repair technology are not achieved. A possible solution to this problem is to use an SHM system to determine whether or not the integrity of the repair is degrading. SHM systems are being developed to detect structural crack growth, bondline integrity, disbonding, and patch integrity of a composite bonded repair patch (*see* **Design, Analysis, and SHM of Bonded Composite Repair and Substructure**). With the incorporation of such techniques, we can perform condition-based maintenance rather than continuing to perform inspections at the nonrepaired intervals. The life of the damaged aircraft structure will be enhanced, structural safety and availability will be maintained, and maintenance costs will be reduced.

4.2 Far-term SHM aerospace applications

In addition to the near-term applications, SHM techniques offer unique benefits for future aerospace applications. Future vehicles will likely incorporate advanced materials and advanced structural concepts. In addition, these vehicle concepts may be exposed to harsher environments. We discuss the advantages of incorporating SHM systems into future air vehicle structures below. At the end of this section, we also discuss the possibility to "design in" SHM technology rather than retrofitting to existing structures.

4.2.1 Advanced materials

Historically, most current air vehicle structures are fabricated from metallic materials. The basic behavior of these materials is well characterized, although the fatigue behavior is still somewhat less understood. Demands for increased performance have led to greater use of composite materials. For example, carbon–carbon composite TPSs, such as the one shown in Figure 2, may be designed to perform at temperatures above 538 °C. In addition to the capability of some composites to perform well at high temperatures, composite materials typically offer advantages such as greater specific strength or stiffness than conventional metallic components. However, the basic behavior of composites is not nearly as well characterized as metals. As a result, there may be an increased need to monitor composite components to prevent catastrophic failure. In addition, advanced structural concepts are being proposed, which include electronics and/or transducers embedded inside composite materials. With such inclusions, it is expected that the performance of the material system is degraded. The degree of any degradation, however, is not well defined. Incorporating SHM systems into composite air vehicles structures may prove extremely beneficial, particularly since we may not have a good understanding of any potential structural degradation due to materials-related issues (*see* **Lamb Wave-based SHM for Laminated Composite Structures**).

4.2.2 Advanced structural concepts

In addition to the use of advanced materials, advanced structural concepts are being considered for future air vehicle applications to improve performance. For example, two advanced concepts under investigation are morphing structures and conformal array antennae. We provide a brief discussion of these techniques, along with the potential benefits derived from incorporating SHM technology, below.

Morphing refers to the ability to change a structure's geometry (e.g., reshape a wing profile) to enable efficient flight over a range of conditions without sacrificing performance. Morphing offers the potential to expand an aircraft's flight envelope and may offer significant vehicle mission-level benefits. Figure 8 shows an example of a morphing structure. Such structures rely on an accurate assessment of the current position or state of the structure. The state of the structure is assessed using sensors, and actuators are used to deform the structure into the desired geometry. In a sense, morphing structures are already very similar to SHM systems in that the state of the structure is sensed to detect the current shape or condition. We may be able to incorporate SHM directly into a morphing system, where a single sensing system is used to control structural morphing and to detect any structural damage.

Conformal array antennae refer to curved antennae composed of multiple individual antenna elements arranged on a curved surface. For improved radar performance, large, high-gain antennae are desired.

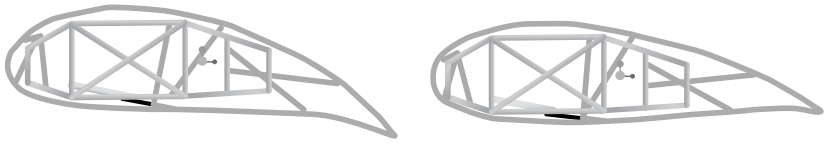

Figure 8. Example of a morphing wing concept to change from (a) a highly cambered wing design to (b) a lower camber design for reduced aerodynamic drag.

However, it is difficult to install such antennae on most current airframes without severely increasing the aerodynamic drag. One solution under consideration is to incorporate the conformal array antennae into load-bearing structures, such as the aircraft skins. Figure 9 shows an example of a conformal array antenna. We can fabricate such antennae from composite materials with the individual antennae elements embedded in the structure. As discussed in the advanced materials section above, however, the performance of the material system would likely degrade. An SHM system would prove useful in verifying the integrity of the structure. In addition, a modified SHM system could assess the health of the antennae to detect damage, such as broken electrical connections, which may inhibit the antennae performance but would not affect the structural integrity.

4.2.3 Extreme environments

Improved air vehicle capabilities are constantly being demanded. As a result, vehicle structures are often subjected to extreme environments and must be capable of operating in these environments. Examples of such structures include TPS for reusable launch vehicle applications and exhaust-washed structures. Both of these types of structures are exposed to high thermoacoustic loading. We discuss the incorporation of SHM systems into these types of structures below.

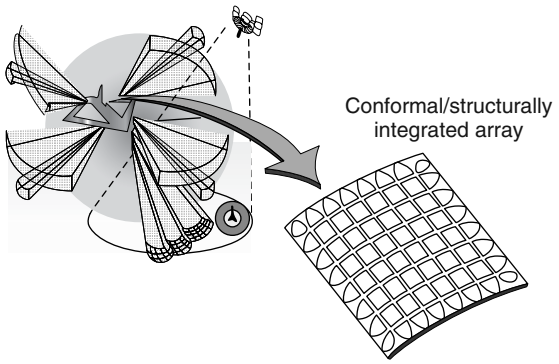

Figure 9. Example of a conformal array antenna concept.

As discussed previously, military organizations are developing reusable launch vehicles that utilize TPS panels. The TPS must be in good condition prior to launch because of its critical role in protecting the vehicle's primary structure and subsystems. For future launch vehicles to be successful, launch costs must be reduced an order of magnitude below those of current launch vehicles. The key to reducing launch costs is to reduce the turnaround time [5]. To meet turnaround goals, the time required to assess the structural condition needs to be significantly reduced. More specifically, an automated SHM system is needed that can assess the health of the entire structure within hours of the completed mission and recertify the structure for flight. Thus, incorporation of SHM for TPS structures will be critical to the success of such vehicles.

For improved aerodynamic performance and reduced observability, the engines of current and future air vehicles are highly incorporated into the airframe design. As a result, engine exhaust impinges on structures immediately aft of the engines, exposing these structures to high velocity, hot exhaust gases. Unique structural concepts and mounting arrangements have been investigated to reduce the thermomechanical loading; however, these structures still must operate in an extreme environment. It is critical that the structural integrity of exhaust-washed components is maintained, as damage could significantly degrade the vehicle's aerodynamic performance by increasing drag or affecting airflow over control surfaces. In addition, structural damage may result in the vehicle being easier to observe, or result in other problems, such as unanticipated corrosion due to hot exhaust gases inside various vehicle structures.

4.2.4 Inclusion of SHM in design process

To apply SHM systems to existing structures, we are required to retrofit the SHM solution to a previous design. This is often difficult since there are a number of constraints, such as geometric restrictions, which limit the design space for the SHM system. Incorporating SHM systems in the design process not only eliminates these constraints but may also offer other advantages. For example, we could design structures to be sensed by possibly including noncritical failure modes of the structure as precursors to any potentially catastrophic failure modes. These noncritical failure modes would serve as indicators for appropriate maintenance actions. We anticipate that the performance and reliability of SHM systems will benefit from inclusion in the design process.

In addition to improvements in the performance and reliability of the SHM systems, incorporating SHM in the design process offers potential improvements to the overall air vehicle system designs. For example, using the current structural design philosophy, incorporating SHM in the design process may permit reductions in factors of safety or lighter designs. SHM incorporation also may result in new structural design philosophies such as reliability-based, or probabilistic, designs and a reduced reliance on structural redundancy for fail-safety, with corresponding weight and cost savings. Finally, SHM incorporation may allow us to use new certification processes, which potentially could lead to reduced certification times.

1 INTRODUCTION

The principal focus of military organizations is the conduct of military operations. In the conduct of these operations, there is an expectation that the risks to military personnel and to the general public will be constrained to an acceptable level. Most modern military aviation organizations have developed an extensive framework of airworthiness management in order to ensure that military aircraft operations meet these risk expectations. An essential element of this airworthiness management framework is that of structural usage monitoring or individual aircraft tracking. In the context of this article, structural usage monitoring encompasses the collection of operational structural usage data, the analysis of that data to produce information on fatigue life consumption, and the provision of that information to decision makers responsible for the ongoing airworthiness of military aircraft. Operational loads monitoring or measurement (OLM) is considered by many military airworthiness agencies as an essential element in the ongoing airworthiness management of an aircraft type. OLM is primarily a substantiation activity that may encompass the following:

- the substantiation of design and qualification fatigue usage spectra;

- identification of local stresses or strains in a structural feature;
- substantiation of structural monitoring or fatigue monitoring system;
- identification of additional monitoring requirements;
- capture of fatigue test spectra;
- identification of highly damaging activity or maneuvers;
- provision of data for investigations of structural issues.

The philosophy and conduct of OLM programs is outlined in **Loads Monitoring in Aerospace Structures** and sensor technologies are described in **Operational Loads Sensors**; **Nondestructive Evaluation/Nondestructive Testing/Nondestructive Inspection (NDE/NDT/NDI) Sensors—Eddy Current, Ultrasonic, and Acoustic Emission Sensors**; **Eddy-current *in situ* Sensors for SHM**; **Fiber-optic Sensor Principles**; and **Directed Energy Sensors/Actuators**. Furthermore, although military usage papers dominate the loads monitoring literature (*see* **Fatigue Monitoring in Military Fixed-wing Aircraft**; **Agile Military Aircraft**; **Flight Demonstration of a SHM System on a USAF Fighter Airplane**; **Health and Usage Monitoring Systems (HUM Systems) for Helicopters: Architecture and Performance**; and **Aerospace Applications of SMART Layer Technology**), there is a growing realization of the importance of such programs in the civil arena and this is reflected in **Commercial Fixed-wing Aircraft**; **History of SHM for Commercial Transport Aircraft**; **Video Landing Parameter Surveys**; and **Landing Gear**. Within this article, the regulatory basis of structural usage monitoring and OLM are described and examples of the application of OLM for military transport aircraft and military derivatives of civil aircraft across several air forces are presented.

2 STRUCTURAL USAGE MONITORING REGULATORY REQUIREMENTS

The requirement for structural usage monitoring is articulated in key policy and guidance documents of many military aviation organizations including [1, 2]. Structural usage monitoring requirements on a particular aircraft type have their genesis with the airworthiness standards and structural life assessment methodology used in the aircraft design and the ongoing airworthiness management strategies for the aircraft type. Key structural elements will degrade with use through the process of fatigue. In the design phase of the aircraft, predictions are made of this structural degradation and strategies formulated to constrain the risk of structural failure to an acceptable level through programmed replacement or inspection and repair. Inherent in these structural lifing predictions are many assumptions including the intended role and configuration of the aircraft, the operational usage it will be subjected to, and hence the expected loading spectra at the key structural elements. The lifing of some structural elements may be relatively insensitive to variations in operational usage while others may be quite sensitive to variations in a complex array of loading actions.

The principal aim of structural usage monitoring is the confirmation that the individual aircraft remains within the extent certification basis and the implicit level of risk associated with that certification basis. In order to meet this aim, a structural usage monitoring system needs to capture in-service data that the lifing predictions are sensitive to. This data then needs to be substituted for the assumed data used in the original lifing calculations and those predictions repeated, thus providing a more realistic ongoing assessment of the degradation of the structure. The ensuing ongoing airworthiness management program for the aircraft then needs to be adjusted for this updated assessment when a variance is found.

3 COMPLEMENTARY REGULATORY REQUIREMENTS—STRUCTURAL CONDITION MONITORING AND OPERATIONAL LOADS MONITORING

Structural usage monitoring is but one element of the overall ongoing fatigue management construct for military aircraft. Mechanisms also need to be in place to evaluate and ensure that structural usage monitoring is effective and adequately sensitive to

changes in role and configuration. This is typically accomplished via a combination of structural condition monitoring and OLM.

As the structure degrades through the process of fatigue, this degradation becomes evident through the manifestation of fatigue cracks. On multiload path structures typically found in transport-type aircraft, structural inspections are targeted at the principal structural elements that have been predicted to degrade. The timing of these inspections is based on a combination of the need to detect the cracking before it compromises on the ability of the structure to withstand the expected loading and on the statistical probability of the cracks being present. The ongoing structural usage analysis has a direct impact on the predictions of when the cracking is likely to be present as well as the rate at which these cracks are predicted to grow under in-service conditions. Feedback from the structural inspections, for both positive and negative results, is essential to confirm that the predictions from the structural usage analysis are reasonable. In setting the initial inspection thresholds and intervals, there has to be a compromise between ensuring an acceptable level of safety and minimizing the economic and capability burden of performing the inspections. When inspections are first carried out, there is thus some probability of finding a crack as well as a reasonable probability of not finding a crack. However, cracking should not be initially prevalent; if it is then there has been a breakdown in the process, possibly in the monitoring of the in-service usage, or in the life assessment resulting from that usage.

Mil-Std1530C [2] refers to structural usage monitoring as individual aircraft tracking, as it is mandated to occur on every aircraft in the fleet. Tracking each individual aircraft comes at a cost and as such there is always pressure to minimize this cost. The simpler the system, and the smaller the list of items to be monitored, the lower the cost in terms of system design, data processing, data archiving, and reporting. The principal goal is thus to field a system that is as simple as possible while meeting the data gathering needs of the aircraft. These systems also need to be in place before the aircraft enters service, and so system design development takes place during the design development of the aircraft itself. In this environment there is a significant risk that not everything that affects the life of the aircraft or its principal structural elements will be comprehensively understood when the design specification of the structural usage monitoring system is effectively frozen. In recognition of this situation, a number of major military airworthiness authorities have mandated that a more comprehensive monitoring approach be taken on a subset of the fleet. In the United Kingdom, OLM is required, while in the United States the equivalent program is that of the loads/environment spectra survey. In an OLM program, approximately 10% of the aircraft fleet is fitted with sensors and recording systems to gather external loads and environmental data. These results are subsequently used to confirm that the structural usage monitoring program provides adequate coverage, is sufficiently sensitive to changes in configuration and role, and that the algorithms used to convert the gathered usage data into life assessments are of acceptable fidelity. These programs are also useful in collecting detailed external and internal loading data for the investigation of specific problems with an aircraft type, for use in assembling detailed loading spectra for tests, and for gathering environmental data such as gust exceedance data or investigating wake turbulence during in-flight refueling operations.

4 CERTIFICATION ISSUES

Structural usage monitoring and OLM are requirements that are being demanded by military airworthiness agencies, and as the outputs are used in making executive decisions affecting ongoing airworthiness, the structural usage and OLM systems (including the data analysis and information reporting function) are subject to certification within the overall airworthiness management construct for that aircraft type. Australian regulations [3] define certification as "the end result of a process which formally examines and documents compliance of a product against predefined standards to the satisfaction of the certification authority". Despite the need for structural usage and OLM being mandated by many military airworthiness authorities, there is no agreed standard that this monitoring is required to conform to. Without defined standards, certification is somewhat problematic.

Guidance material on conduct of OLM programs and the substantiation of structural usage monitoring

systems is evolving as these systems become more common place. At present, in [1, 4] we have a modicum of guidance material for the certification or substantiation of usage monitoring systems using an OLM program. Australian regulations [5] have attempted to provide some working-level guidance from recent experiences. Rather than focusing on certification to a particular standard, [5] proposes a generalized specification for OLM and structural usage monitoring along with some validation requirements aimed at assessing that the system is fit for its intended purpose. As a comprehensive set of requirements has yet to receive codification, each program is inevitably reliant upon the detailed knowledge resident in the few individuals who did it last time, if they are still available. Consequently, each of these programs varies significantly in content and has significantly different degrees of success. Recently, the United Kingdom has produced a guidance document [6] developed within the UK Military Aircraft Structures Airworthiness Advisory Group, covering the philosophy and the conduct of OLM programs.

The following sections contain brief OLM case studies from Royal Australian Air Force (RAAF) C130J-30, KC30B tanker, and the Wedgetail airborne early warning aircraft, and from the Royal Air Force (RAF) Dominie TMk1 OLM program.

5 OPERATIONAL LOADS MONITORING OF A MILITARY TRANSPORT AIRCRAFT—THE RAAF C-130J-30

When the RAAF contracted to acquire 12 Lockheed C-130J-30 aircraft in the late 1990s, there was an extremely loose functional requirement included in the acquisition to fit an "OLM system" to two aircraft. This particular aircraft purchase was on an accelerated timescale. There was subsequently no dialogue between the end users of the data from these systems and the system designers until the aircraft were presented for military-type certification. At that time, there were no detailed requirements to satisfy, no agreed path to certification, and no clear certification standard that had to be met. There was high risk that a successful outcome would not be achieved for all parties. That risk was realized.

The implied requirement for the end use of the OLM data at that time was to provide ongoing validation of the structural usage monitoring system for the aircraft. The structural usage monitoring system delivered with the aircraft was also a first-of-type design for this model, with very little disclosure of the software. The manner in which the operational loads data could be used to validate the structural usage monitoring system was thus initially poorly defined, as the structural usage monitoring system was still under development. The resultant onboard elements of the OLM system comprised a suite of nine strain gauge bridges feeding a recorder with a 1-MB capacity. The locations of the strain gauges are shown in Figure 1.

The lack of communication and the accelerated timescale had a profound impact on the design of this system. Lockheed sensibly chose gauge locations that mirrored previous loads gathering programs that they had experience with and were known to respond reasonably well to the dominant loading actions. To meet the schedule, Lockheed sourced a readily available recorder. The memory limitations of this recorder then dictated what data could be captured in a typical flight. The result was a capability to capture time-stamped peak valley data only from the strain gauge bridges with no flight parameter data. Initially, the peak valley discriminate level was set at a level thought to be reasonable and which would capture significant loading events. Figure 2 shows the output from the strain gauge bridges for a flight with the initial discriminate level of 2100 psi (~14.5 MPa).

When the outputs of a series of flights were compared, the only perceived use of this data was to rank the flights in the order of comparative severity (with very coarse granularity). Subsequent attempts to reduce the discriminator to obtain greater fidelity resulted in the memory being filled to capacity in something less than 1 h on a typical mission with any low-level flying content. A complicating factor with this system design was that the recorder was not a standalone system and received data from the mission computer to zero the bridges at system startup and to obtain the time-stamp information. To make any changes to the software meant opening up the aircraft mission computer software code at enormous expense. The inherent limitations with the system and the projected costs to bring the system to a minimum level of functionality were

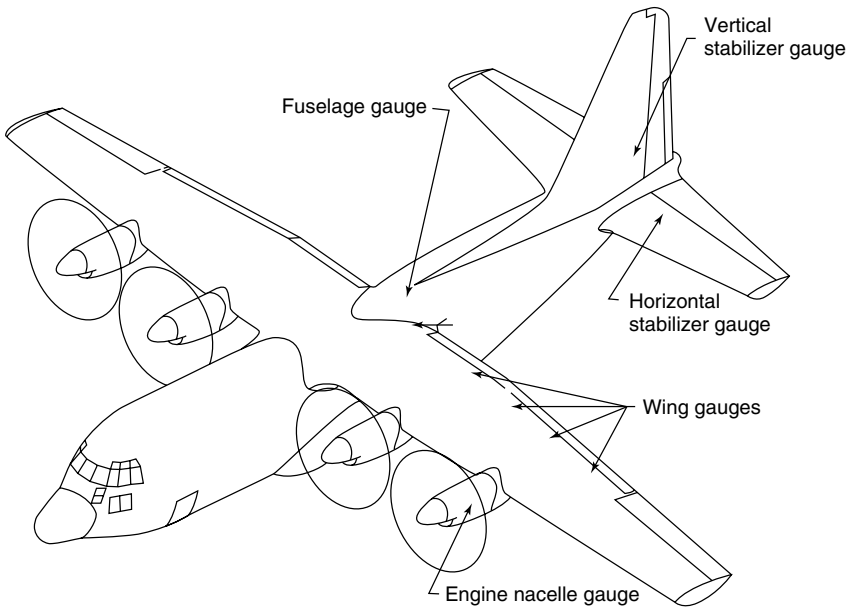

Figure 1. RAAF C-130J-30 original OLM gauge suite.

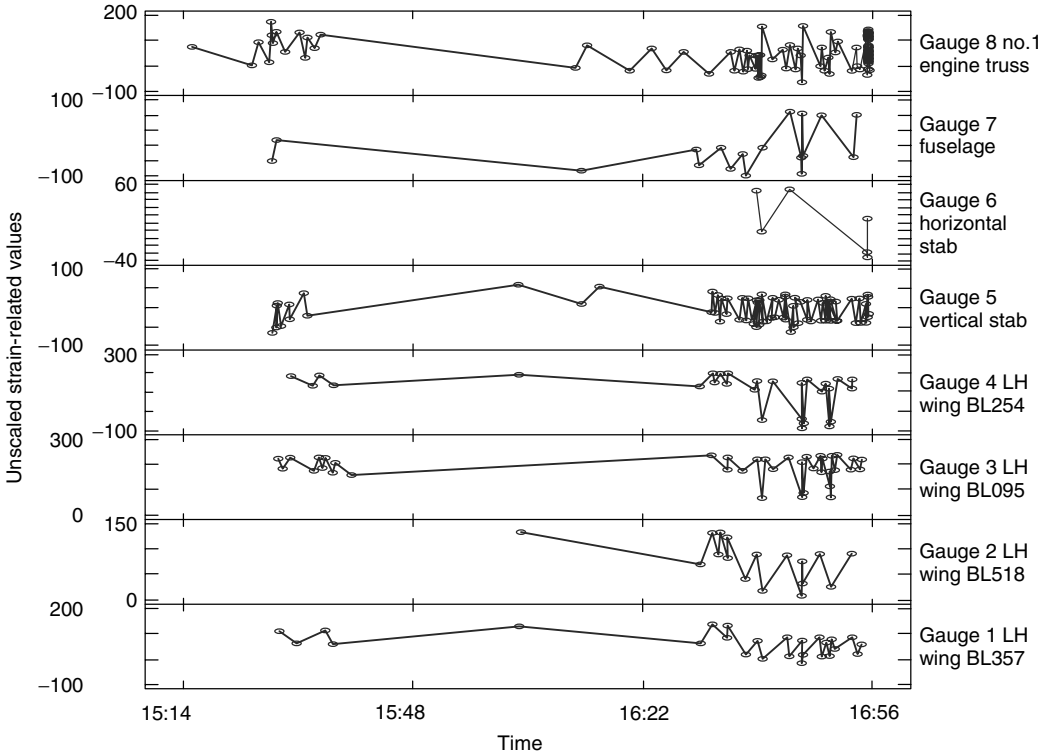

Figure 2. Strain gauge bridge outputs original RAAF C-130J-30 OLM.

considered to be cost prohibitive and the system was abandoned. However, the need for an OLM still existed.

At the same time that the RAAF was purchasing the C-130J, the RAF was also purchasing the aircraft. The Air Force decided to share experiences and collaborate on a number of issues to their mutual benefit. Two significant areas relevant to this discussion was the decision to conduct a collaborative full-scale fatigue test program of a new build C-130J wing and to conduct separate but complementary OLM programs from which data could be harvested to both validate the structural usage monitoring systems and to build the load sequence for the fatigue test. The fatigue test load sequence was considered to be the first priority.

The OLM system that has ensued was designed by Marshall Aerospace and is built upon the highly successful ACRA Control KAM-500 recorder, several modules of software from nCode International and from Lockheed, and a significant number of strain gauges and flight parameters. The RAAF version of the OLM system has 189 strain gauges, many of which are wired into loads bridges, and harvests 99 parameters directly from the aircraft data buses. All data are continuous time histories. Recording rates for the strain gauges are 40 or 80 samples per second (depending on the location and the frequencies of interest). The parameter data captures data at the same frequency that this data appears on the aircraft buses (frequencies from 0.25 to 20 Hz). Figure 3 shows the basic layout of the wiring looms and gauges. As the focus is on the building of the fatigue test spectrum, the wing receives the greatest coverage of strain gauges. Gauges are also located at "hot spots", which represent key areas targeted by the current safety-by-inspection program and which have had significant fatigue cracking in-service on previous model C-130 aircraft.

In order to convert the harvested strain bridge outputs into loads, each bridge has been calibrated *in situ* through the application of loads onto the aircraft. One hundred and thirty unique load cases were applied to the aircraft including a combination of fuselage pressurization and wing loading to achieve this (Figure 4).

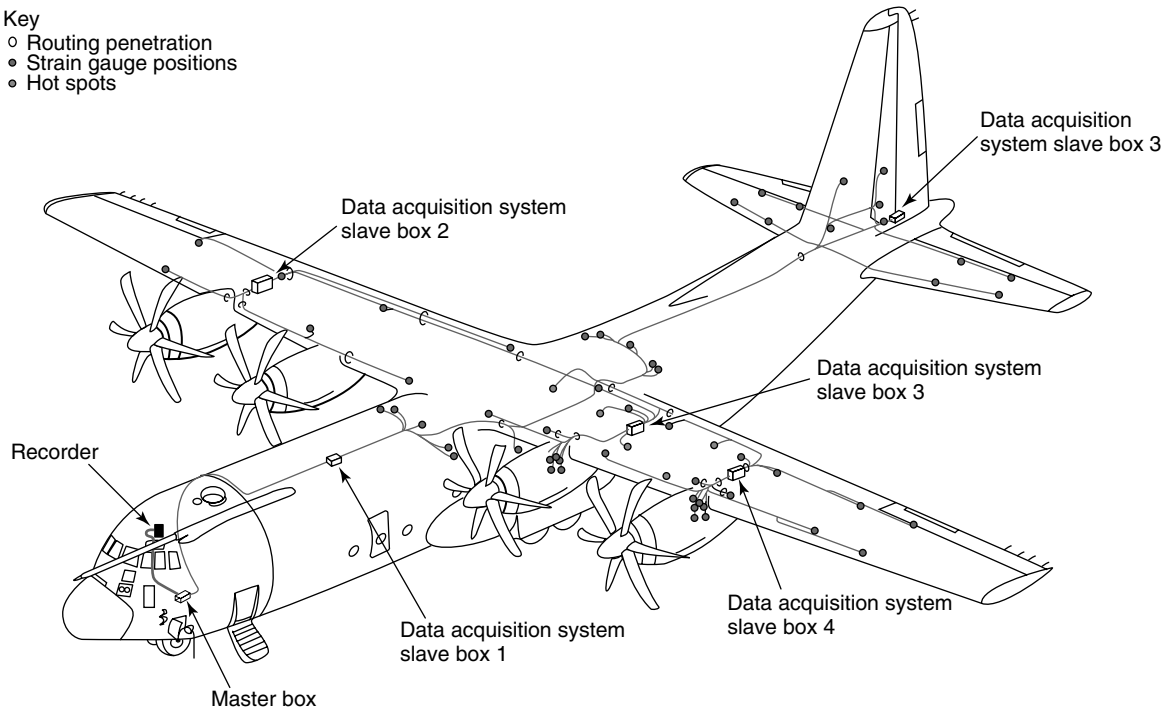

Figure 3. Layout of RAAF C-130J OLM.

Figure 4. RAAF C-130J OLM calibration.

From these calibration cases, load equations have been developed to calculate external loads at various stations from the strain gauge outputs. The sensibilities of these equations were then validated by a combination of comparisons of loads generated in a series of maneuvers in dedicated flight tests with computational fluid dynamic calculations and with original design loading data. Figure 5 shows a sample plot from this process, which led to a review of the loads equations at the wing root.

Data husbandry in a program of this nature becomes extremely important. Figure 6 shows a sample plot from four of the channels for a 3-h flight. A flight of this duration will typically produce 1 GB of data, when the data are processed into engineering units and then into loads. For the two RAF aircraft fitted with the OLM system, the data collecting period has been less than three years and already the data generated has exceeded 1 TB.

Data checking, cataloging, and archiving demand a significant amount of automation and oversight. Failure to identify and resolve data integrity problems in a timely fashion can very quickly lead to many flights where data are corrupted and the opportunity to harvest important data is lost.

The initial phase of the C-130J-30 OLM program has been a success, thanks to the efforts of a significant number of personnel not the least of which are those service men and women who download the data from the aircraft and forwarded it on for processing. From the pool of data available, a significant number of unique flights were chosen to assemble into a test load sequence representing compromise spectra of RAF and RAAF flying based on usage monitoring statistics from those respective fleets.

5.1 Challenge of military derivatives of civil transports

Civilian aviation regulations do not mandate the need to monitor the structural usage of aircraft in other than the most simplistic terms, often only requiring the recording of flying hours, flight cycles, and landings. The military and civilian requirements with respect to structural usage monitoring differ for a large number of reasons that are beyond the scope of this article; however, increasingly, the transport aircraft fleets of military organizations are an amalgam of both purpose-built military aircraft and civilian aircraft adapted for military applications. Some of these aircraft are used in roles very similar to their civilian counterparts, but others have special equipment fitted and are operated in roles and flight regimes that are fundamentally different from that for which they were designed and for which they had received civil airworthiness certification. This poses a number of challenges for military aviation organizations both in initial airworthiness certification and in ongoing airworthiness management. When talking with the

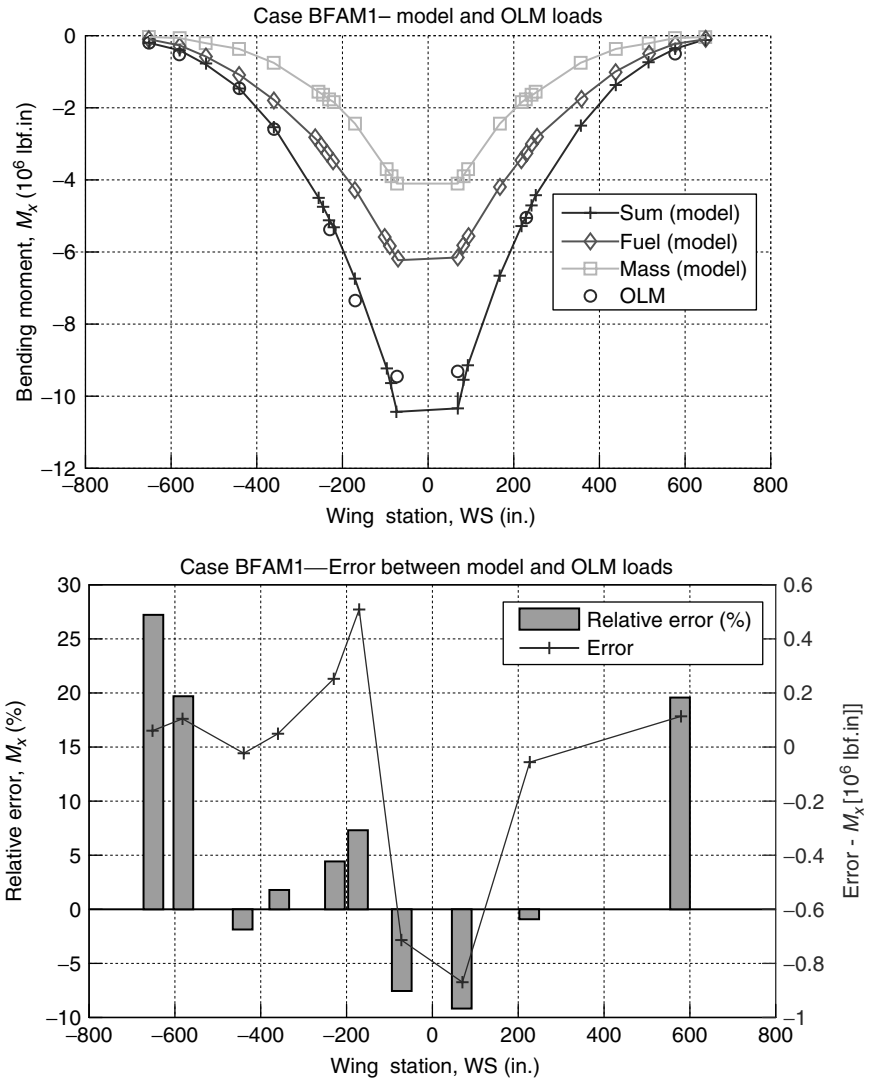

Figure 5. RAAF C-130J sample CFD-OLM comparison.

manufacturers of civil transport aircraft about certification of structural usage monitoring systems or OLM systems, the initial reaction is generally one of confusion as these things are outside of their experience. This confusion is increased when they ask what standard they have to meet for certification and the answer is that there is no standard. Concerns expressed by civilian manufactures include cost and schedule risk associated with embarking on system design outside of their experience as well as exposure of proprietary design data.

Australia currently has two programs where derivatives of civilian transports are being purchased and adapted for military use. One program is the Boeing B737-based airborne early waning and control aircraft named *Wedgetail*, the second is the EADS CASA KC30B, which is an A330-based air-to-air refueller. Only small numbers of these aircraft are being purchased, but nonetheless the RAAF has insisted on a structural usage monitoring system being installed on each aircraft and an OLM system on one aircraft of each type. Both these aircraft are still very much in

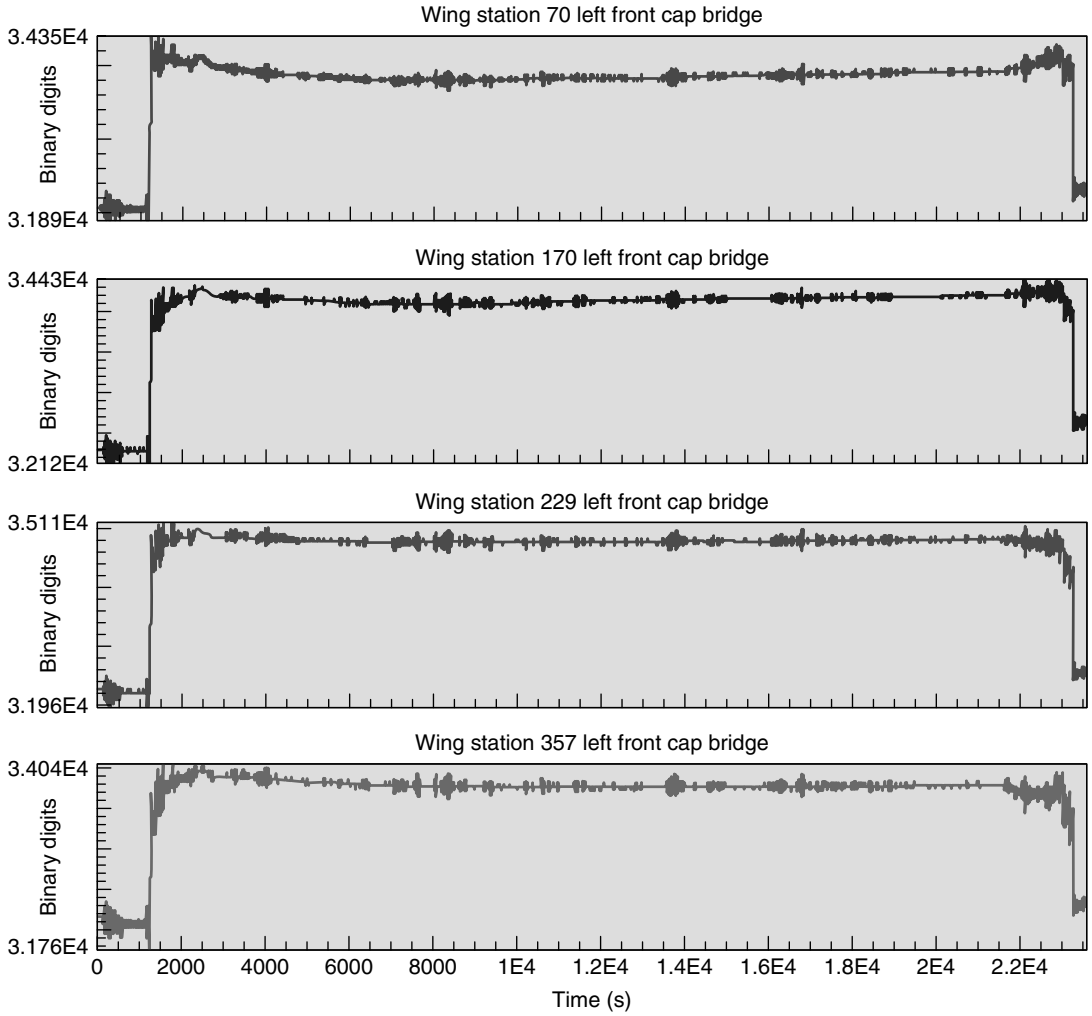

Figure 6. RAAF C130J sample plot from typical flight.

development; however, the system for the Wedgetail is now in the validation phase.

The Wedgetail system includes loads bridges located on the wing, horizontal tail, vertical fin, and multi element scanning array (MESA) antenna. These bridges have been calibrated by applying known loads and measuring the responses. Although it is not possible to discuss specifics of this program at this time owing to the proprietary nature of the data, the system has been successfully tested both on the ground and in flight with the outputs actually proving to be useful to Boeing in the development of that aircraft. The principal purpose of this system when it enters service will be to provide ongoing validation of the structural health monitoring system.

The KC30B OLM has a more comprehensive suite of strain gauge bridges than that of the Wedgetail. The intended use of this system is to provide data from which neural networks (*see* **Artificial Neural Networks**) can be trained for use in the structural usage monitoring system.

The link between the OLM systems and that of the structural usage monitoring systems for both the C-130J and the Wedgetail is that the OLM system is used to validate the structural usage monitoring system. In the case of the KC30B, the OLM system

acts as the foundation on which the structural usage monitoring system is built and provides the means to adjust that system as the aircraft configuration and role evolves.

6 OPERATIONAL LOADS MONITORING OF A MILITARY DERIVATIVE OF A CIVIL AIRCRAFT—THE RAF DOMINIE TMk1

The Dominie TMk1 is a military variant of the Hawker Siddeley HS125 business jet. The fleet is operated by the Royal Air Force in the navigator/weapons system operator training role. Although the aircraft are mid-1960s vintage, they have, in recent years, been fitted with an avionics upgrade and provide an up-to-date aircrew training environment. In order to provide realistic training for fast-jet aircrew, it is frequently necessary to operate the aircraft in low-level sorties over both land and sea.

Although the HS125 fatigue design philosophy was originally fail safe, the civil fleets moved to a damage tolerance clearance regime, following a detailed audit of the primary structure using fracture mechanics methods and civil-type usage spectra. However, the RAF Dominie was excluded from this analysis owing to uncertainties about the usage of the aircraft in the military training role. Therefore, a requirement to capture OLM data for the wing of the Dominie and compare the RAF stress usage spectrum with the damage tolerance stress spectrum was identified.

Funds available for such programs are increasingly tight and, consequently, a highly optimized OLM program was necessary. All data measurements and processes were subject to a rigorous justification to ensure the absolute minimum-cost option was developed. Design and installation of the data acquisition and recording systems was undertaken during 2004 and flight recording began in January 2005 and was complete in May 2006. Nearly 700 flying hours of data were captured from the instrumented aircraft. These data have provided the essential information needed to compare the military usage of the Dominie with the civil datum.

Within this section of the article, the conduct of the Dominie wing OLM program is described. Airborne and ground calibration methods are illustrated and the use of data confidence assurance techniques is detailed. Typical usage data, illustrating the effect of military profiles on the wing stress spectra of a civil-type aircraft, are presented. In particular, the change in gust environment with flight altitude over land or sea and the associated spectra severity is clearly detailed in the data. The output from the OLM data analysis program was stress cycle files for each flight; the United States Air Force (USAF) -developed "AFGROW" fracture mechanics software was then used to generate a direct comparison between Dominie and civil usage in terms of the crack growth lives for the critical wing section. This section concludes with a summary of the analysis process and presentation of results.

6.1 Instrumentation

Twelve electrical resistance strain gauge full bridges were bonded to the lower surface of the wing at approximately the 37.5% chord line (Figure 7), in locations coincident with the wing critical structural locations as identified by the civil damage tolerance analysis. A normal accelerometer (NZ) was mounted close to the center of gravity and an inclinometer was installed nearby to provide an indication of the aircraft's bank angle. Equivalent airspeed (EAS), pressure altitude, air temperature air data computer information, and data bus time were extracted from the aircraft ARINC429-10 data bus. Also, connections to the existing weight on wheels (WOW) switch, in the port undercarriage bay, and the No. 2 engine-driven generator were installed; this signal was used as a recording trigger signal. An ACRA KAM-500 data-acquisition unit, fitted with a Compact Flash® memory unit was installed in the aircraft. All data were sampled at 64 samples per second (S/s) with antialiasing filters set at 16 Hz.

6.2 Strain gauge calibration

Funding constraints precluded the use of a Skopinski-type [7] load calibration for the wing strain gauges. Hence, alternative methods had to be developed. A boundary element model was used to provide a transfer function from strains measured as close to

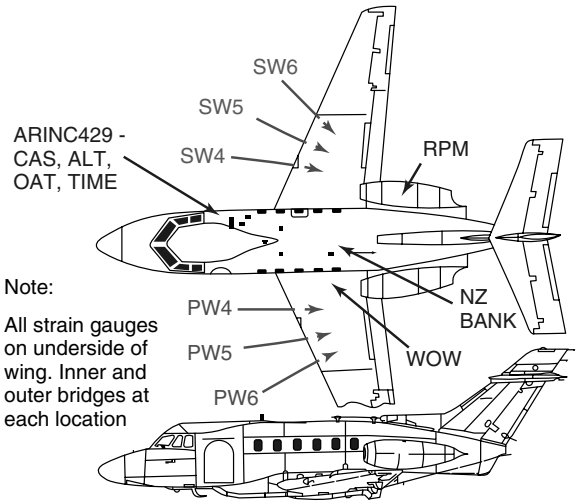

Figure 7. Dominie OLM instrumentation schematic.

the critical sections as stress concentrations would allow, to the equivalent field stresses required for input to the fracture mechanics model. Additionally, airborne calibration cases, cross-checked with ground cases, were used to identify the stress offset and hence baseline the strain data. The aircraft was flown at a series of steady-state airborne calibration points. For each point, the fuel masses were recorded, as this was not contained within the OLM instrumentation. Theoretical stress values for these flight conditions at the critical locations were produced. From this, flight datum stress offsets were calculated for the critical locations.

Confidence in the validity of this method was obtained by analyzing the stress values for 32 ground conditions for the critical locations at various aircraft masses. The offsets determined from setting the stresses to the airborne flight conditions were then compared with the theoretical values for these ground conditions. It was accepted that the ground and air conditions were not totally independent but the ground condition was dominated by the fuel load and the airborne cases were dominated by aerodynamic effects.

6.3 Data analysis

The Compact Flash® memory card and the cards were removed once per week and dispatched for analysis, with an accompanying copy of the flight record sheet. The data were subject to an array of anomaly and consistency checks before the strain data were reduced to cycle files for input into the AFGROW [8] program for comparison with civil spectra. This process is illustrated schematically in Figure 8.

6.4 Results

6.4.1 Data captured

Data recording began on January 14, 2005 and the recording program was terminated on May 8, 2006. During the period, 60 Compact Flash® downloads containing 319 sorties of data (equating to approximately 692 flying hours) were received, realizing the program data capture aim of over 300 sorties.

6.4.2 Data quality

All strain channel data were processed and identified as satisfactory. Several of the flights had been bisected due to the recording trigger going off-line as a result of the engine being shut down in flight; however, data loss was a matter of seconds and the separated elements of the flights were concatenated successfully.

The NZ data was the only channel where significant data anomalies were identified. Furthermore,

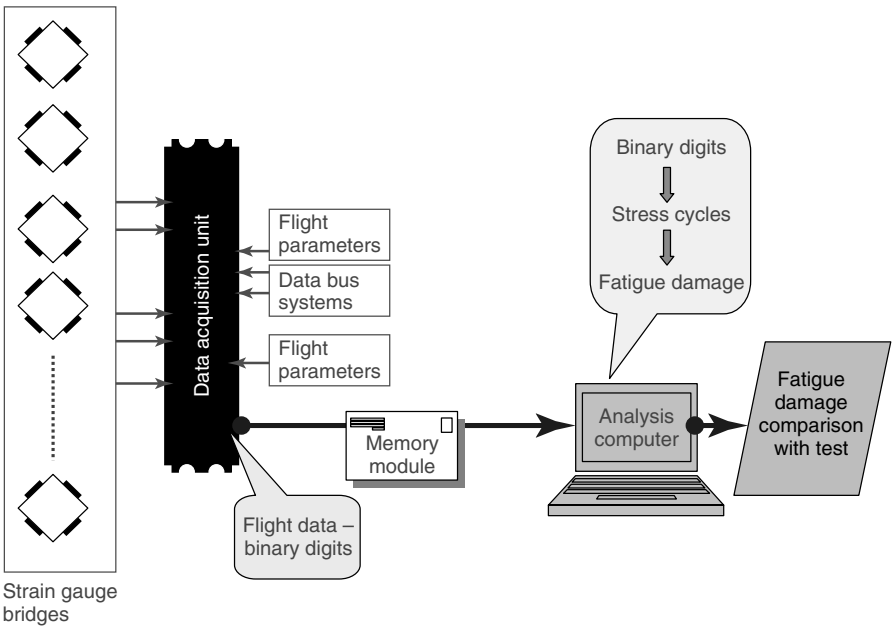

Figure 8. Dominie OLM data analysis process schematic.

different anomalies were present in different periods of data capture. Eventually, NZ data from 35 of 319 sorties were excluded from the analysis, although this was not highly significant as the NZ data were not the prime data source in this program.

6.4.3 Comparison of OLM data with fleet usage

By necessity, the OLM data captured represent a relatively small proportion of the data across the fleet and hence the usage of the OLM aircraft was compared with the fleet as a whole to ensure representativeness. RAF sortie types are described by Sortie Profile Codes (SPCs) and a comparison between the SPCs flown by the OLM aircraft and the fleet is reproduced at Figure 9. It is clear from this chart that the distribution of OLM SPCs is very similar to that of the SPCs flown by the fleet over the same period.

6.4.4 Strain data flight datum rechecks

Rechecks of the strain gauge datum values were undertaken periodically during the program to identify whether any drift was apparent in the strain gauge outputs. This was undertaken by matching flight conditions to those used in airborne datum offset calculation. Stress values within 3% of the original datum were identified for each of the six recheck sorties. Given a 2% acceptable variation in the flight parameters used to define the flight condition, this was considered to show a good agreement.

6.4.5 Strain data confidence check with neural network prediction

A further measure to provide confidence in the wing stress outputs was undertaken using a structural health and usage neural network (SHAUNN) (*see* **Artificial Neural Networks**). In essence, the SHAUNN was given stress and flight parameter time history data from three relatively severe flights early in the program. Using these data, the SHAUNN learned the mapping relationships between flight parameters and stresses. Once trained, the SHAUNN model was used to predict stresses from the flight parameters using sorties throughout the program. If the accuracy in predicting stresses from flight parameters remained fairly constant for flights captured throughout the program, then confidence in the OLM-derived stress values should remain high. The Pearson correlation coefficient achieved from the

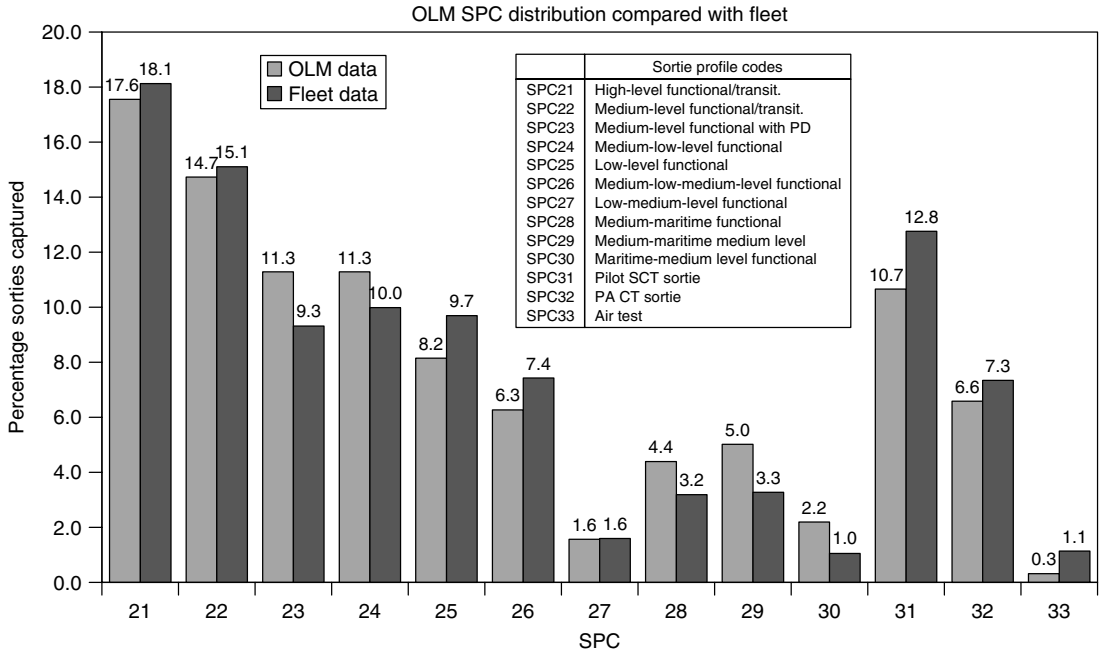

Figure 9. Dominie OLM SPC distribution compared with fleet.

training data was $R = 0.998$ and this was also the average correlation coefficient for the 80 sorties tested throughout the program. An example of the predicted and expected (from the SHAUNN model) stress time histories for an OLM sortie for location PW5 is reproduced in Figure 10. Additionally, a simple fatigue damage calculation was undertaken using the stress output from the SHAUNN and the stress from the strain gauges and the damage ratio (SHAUNN damage/strain gauge damage) was calculated. A ratio of 0.997 was achieved for the 80 test sorties.

6.4.6 Usage types

Although Dominie operations are divided into SPCs, analysis of the flight data suggested that the sorties could be naturally divided into four groups. These groups were termed *type* 1–4 and identified as "civil",

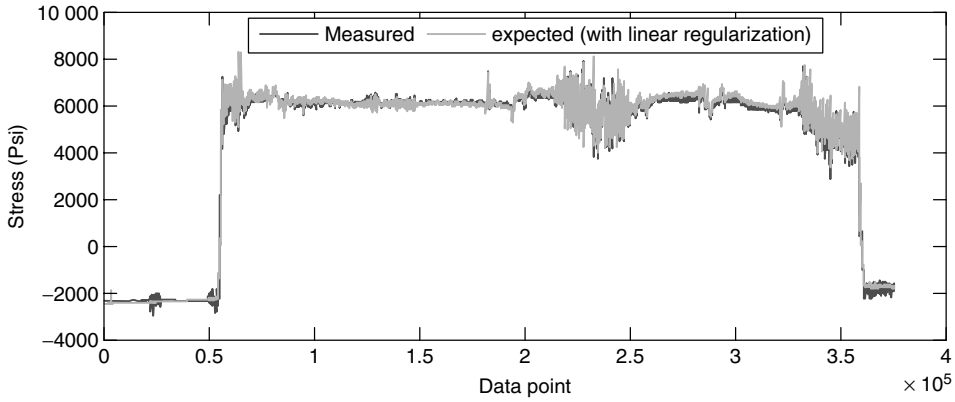

Figure 10. Dominie example SHAUNN stress prediction ($R = 0.998$).

"low level", "maritime", and "training" and particular SPCs were mapped to each group. Civil sorties were, as the name suggests, typical of civilian-type flights, generally consisting of taxi, takeoff, climb-to-cruise altitude (e.g., 31 000 ft), cruise, descent, landing, and taxi back. The majority of the flight was conducted at medium-to-high altitudes, above the severe gust regime (>10 000 ft), and rarely was more than one roller (or touch-and-go) landing undertaken. A typical altitude, airspeed, normal acceleration, and wing stress profile for a civil flight is reproduced in Figure 11. Civil-type flights were generally benign and the fatigue damage was dominated by the ground-to-air cycle (GTAC). Even a cursory glance at Figure 11 reveals that there is an obvious correlation between EAS and the mean stress in the wing, for this type of sortie. Gust loading was evident in the wing stress profile during the climb and descent phases of the flight and these regions were matched with responses in the NZ data.

Low-level sorties (Figure 12) were found to have a very different character. The majority of the sorties was flown at low level over land (often 1500 ft or below). Hence, the aircraft was operating in a severe turbulence environment and the effect of gust loading for these sorties flown over the land was immediately evident. The mean stress in the wing still followed the airspeed plot but the gust loading, which followed the NZ plot, was superimposed upon it. Maritime sorties (Figure 13) often had altitude and airspeed profiles very similar to low-level sorties. However, because the sorties were flown over the sea, the gust regime was relatively benign and this is illustrated in the wing stress and NZ plots. Finally, the training sorties (Figure 14) were primarily pilot and pilot's assistant training missions. These sorties generally contained a large number of roller landings; in the example presented here there were eight roller landings. Air tests were also included in this grouping as the profiles were similar.

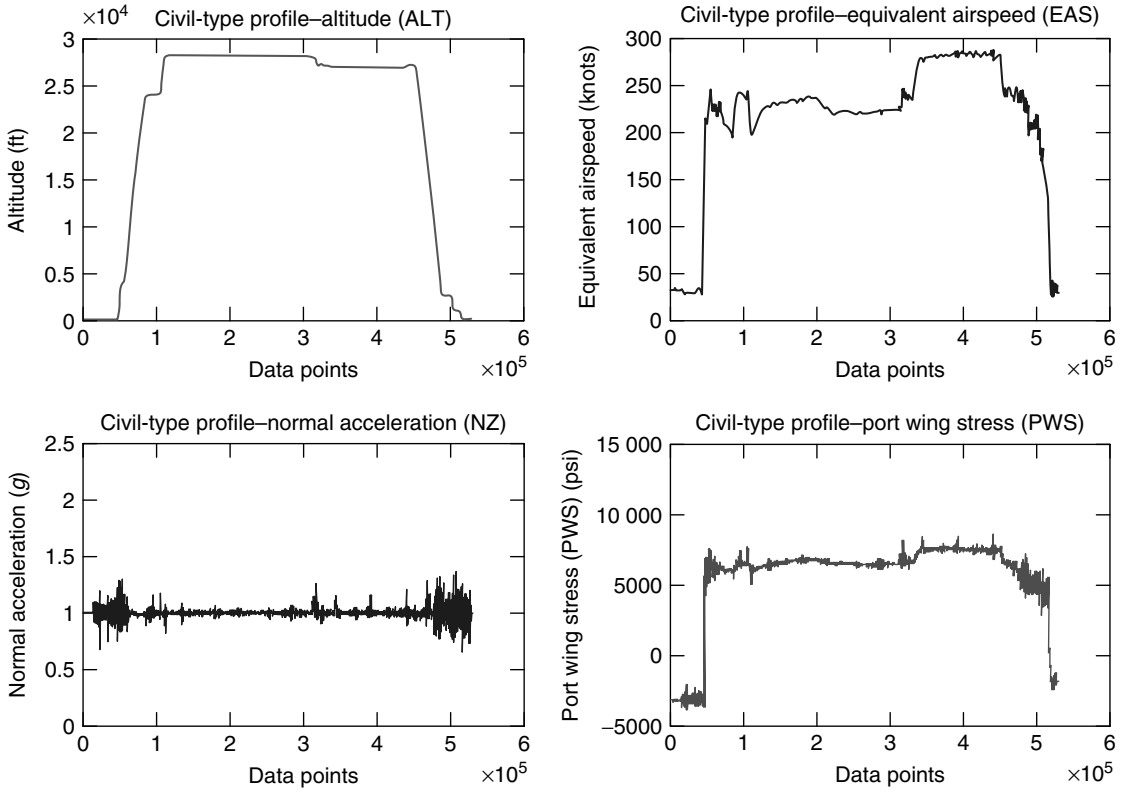

Figure 11. Dominie example "civil" flight profile.

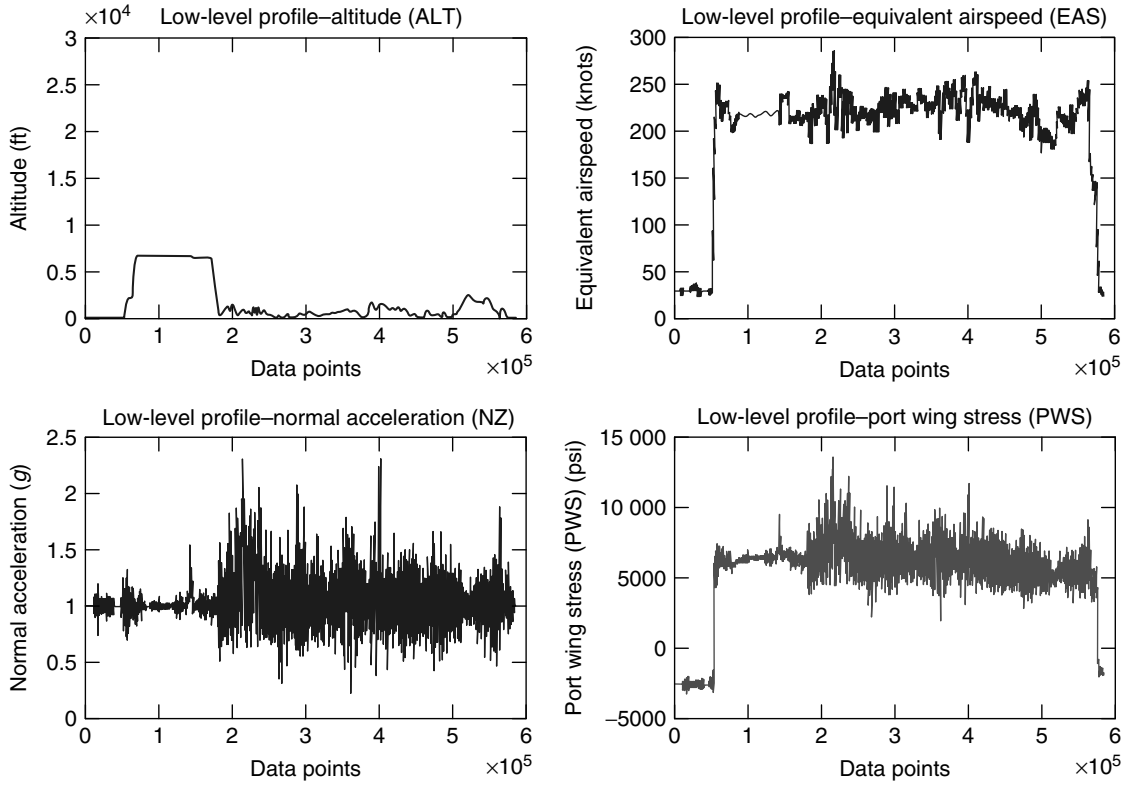

Figure 12. Dominie example "low-level" flight profile.

6.4.7 Crack propagation analysis

The output from the OLM data analysis program was stress cycle files for each flight to be used directly as input to the USAF-developed AFGROW [8] fracture mechanics software. AFGROW was chosen as an up-to-date industry standard of software for the analysis owing to its well-known qualities and array of options for modeling the crack propagation characteristics of airframe structures. A discussion of the critical wing features, use of AFGROW, and the preprocessing and postprocessing of flight data is not possible within the space constraints of this article; however, a more detailed explanation can be found in [9]. For the purposes of this article, general comparisons have been drawn.

As previously discussed, the aim of this program was to compare the RAF usage with the assumed spectra used for the civil damage tolerance analysis. Hence, the Dominie stress spectra were initially analyzed using the same Palmgren–Miner cumulative damage method. The result derived from the RAF spectrum generated from 319 OLM flights gave an equivalent fatigue life of 126 993 flights. Using this stress–life approach, the RAF usage spectrum was calculated to be around 7.5% more damaging than the spectrum used for the civil damage tolerance analysis. This result suggested that the crack propagation predictions for the RAF usage spectrum and the civil damage tolerance spectrum should be similar and that the associated damage tolerance assessments of the structure would be compatible. However, the fatigue calculation did not include the interaction between high and low loads, nor did it discriminate between the events that produce damaging stress cycles. The fatigue calculations and the results from the crack propagation analysis for the civil damage tolerance analysis spectrum and the OLM-derived Dominie spectrum are summarized in Table 1. The critical feature is illustrated in Figure 15. All the results are shown directly as computed, not as an indication of

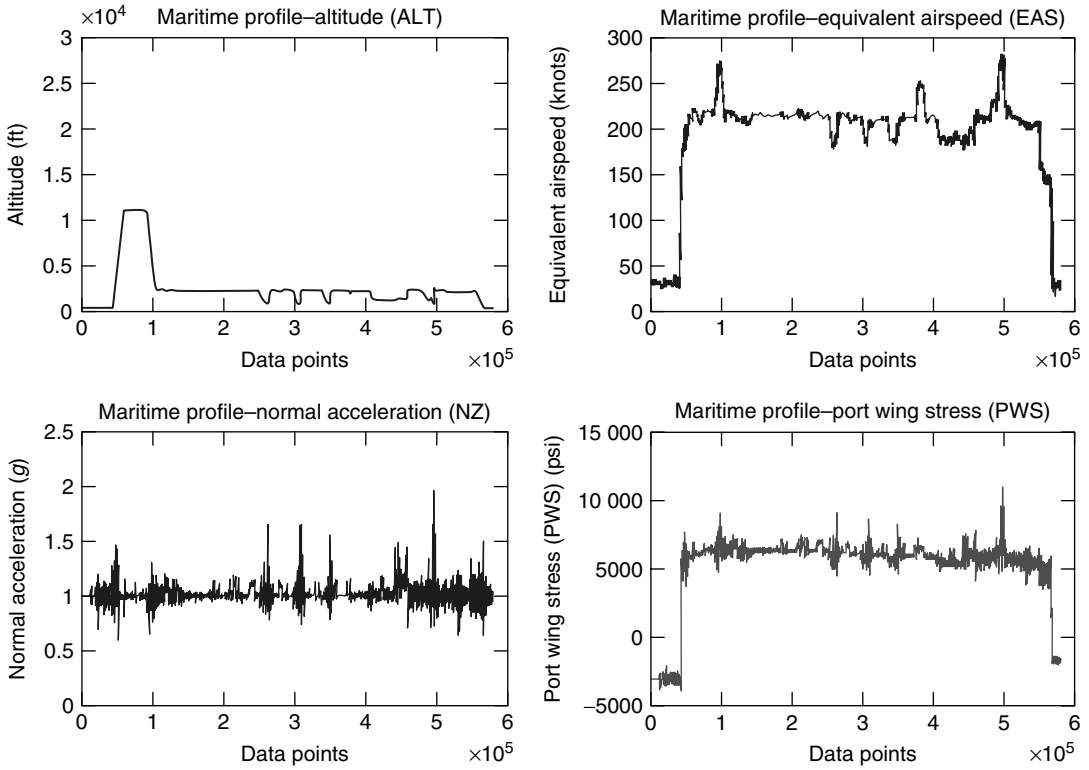

Figure 13. Dominie example "maritime" flight profile.

any presumed precision in the calculations but purely to emphasize the comparative values.

For the purposes of the AFGROW calculations, the Dominie spectra were concatenated in the same order that the 319 OLM flights had been achieved. For each flight, in turn, the ground-to-air cycle (GTAC) had been identified and was applied first; the residual gust and maneuver (RGM) and roller landing cycles were then applied in the order that they were identified by the Rainflow cycle counting process. To ensure that the crack propagation calculations were not compromised by this simplified representation of the stress sequence within each flight, the whole concatenated spectrum was reversed and the calculations repeated. As can be seen in Table 1, the results were effectively indistinguishable. As the concatenated spectra were repeated many times for each phase of crack growth, this observation suggests that the interaction effects between the GTAC and the smaller cycles were not unduly biased by the slightly artificial ordering of the stress cycles.

6.4.8 Comparison between the civil datum and the Dominie OLM stress spectra

The total peak stress spectra for the civil datum and the Dominie OLM data are illustrated in Figure 16. This shows that the two spectra are effectively coincident over the range of peak stress values between around 8 ksi (∼56 MPa) and 13 ksi (∼90 MPa). The associated stress cycles are those that account for the bulk of the fatigue damage. That damage is made up of two components for the civil spectrum, namely, the GTAC damage and the RGM damage which, on average, account for 87.7 and 12.3% of the total damage per flight, respectively. For the Dominie, in addition to the GTAC and RGM components of the damage sum, there is an additional damage component due to the roller landings not present in the civil spectrum. The relative significance of the associated stress cycles may be adjudged by reference to Figure 16, which shows the two comparative GTAC spectra and the Dominie roller landing spectrum.

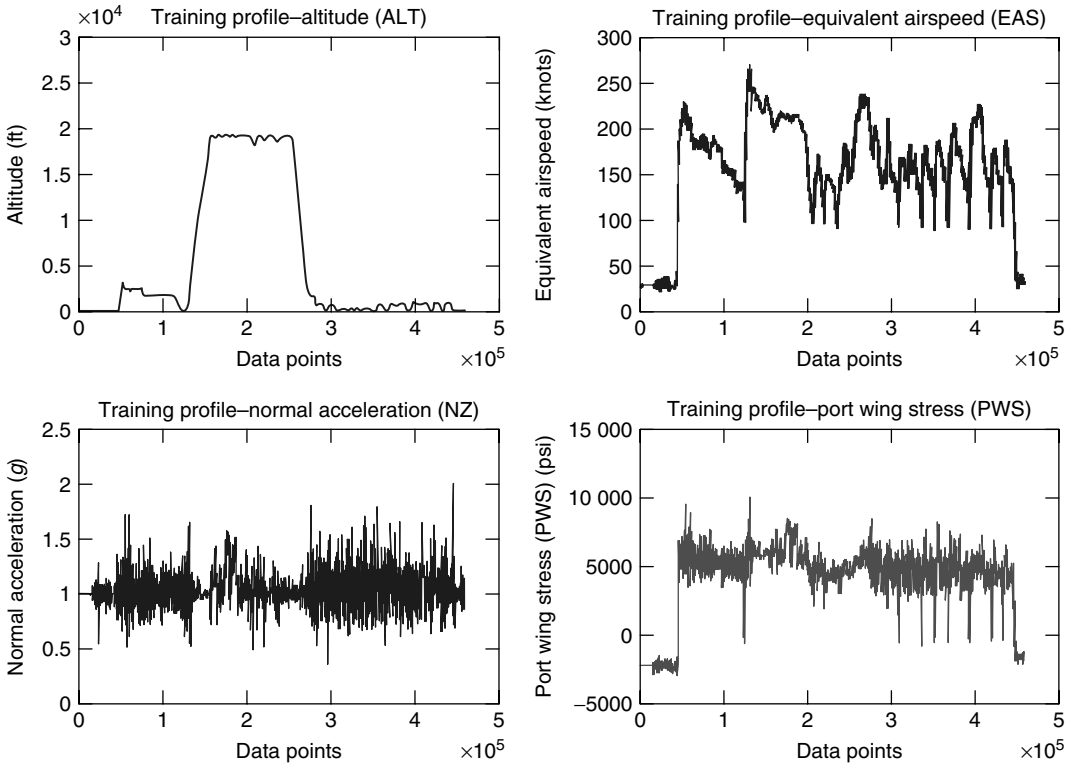

Figure 14. Dominie example "training" flight profile.

Note that the peak stresses for the Dominie GTAC spectrum are slightly less than those for the civil spectrum but the associated stress ranges are greater. This results in only a marginal overall difference in the average GTAC damage rates per flight for the Dominie and the civil aircraft. The damage rates per flight due to the RGM spectra are also very similar although slightly higher for the Dominie owing to the very large numbers of relatively small stress cycles generated during low-level navigation flights; these account for the extended "tail" of the total spectrum shown in Figure 16. However, these differences balance out such that, in the absence of the roller landings, the total damage rates per flight would be

Table 1. Summary of Dominie wing "AFGROW" calculations

Stress spectrum	Nominal fatigue life (flights)	Crack growth predictions (flights)			
		Failure of spar	Skin crack to stringer land	Total	Skin crack critical length (in.)
Civil, flight-by-flight (999 flights)	136 576	48 675	5274	53 949	
Dominie OLM, concatenated spectrum (319 flights)	126 993	24 822	3355	28 177	3.43
Dominie OLM, reverse-concatenated spectrum (319 flights)		24 880	3277	28 157	

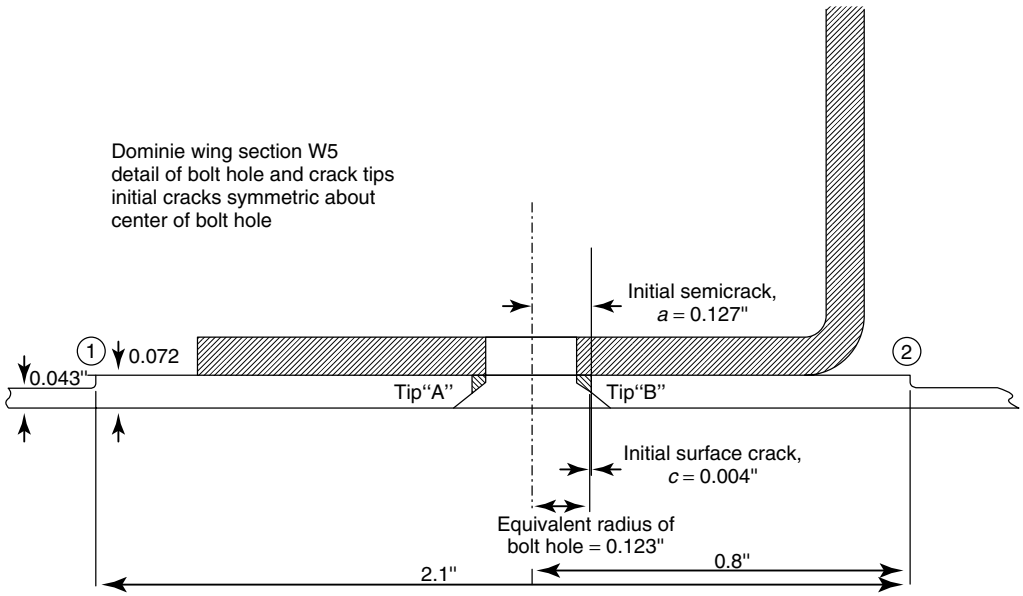

Figure 15. Dominie idealized wing section used for "AFGROW" calculations.

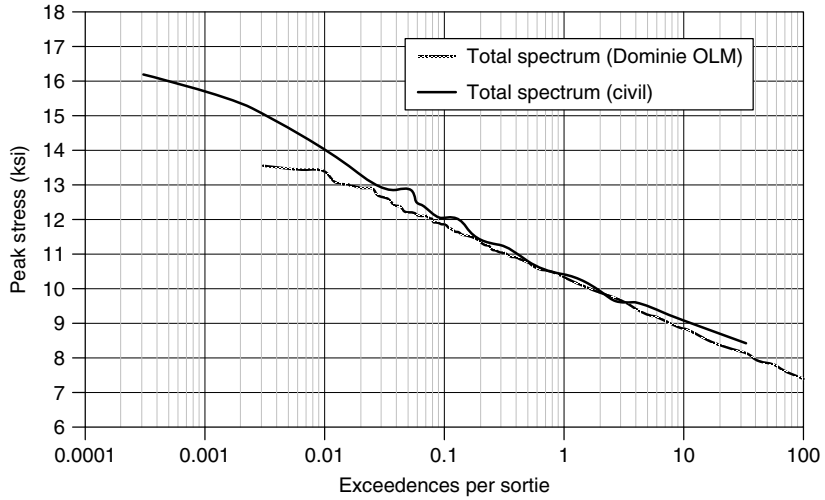

Figure 16. Dominie total peak stress spectra.

almost identical. Clearly, the contribution of the roller landings is significant and accounts for the overall difference between the fatigue damage calculations for the Dominie versus the civil datum. The roller landing stress spectrum shown in Figure 17 is also noteworthy because, prior to the OLM program, there was no evidence available to quantify the damaging effects of such events. This had led historically to the incorporation of very conservative assumptions into the fatigue monitoring model for the Dominie.

7 CONCLUSIONS

The fatigue and crack propagation calculations summarized in this section of the article are as

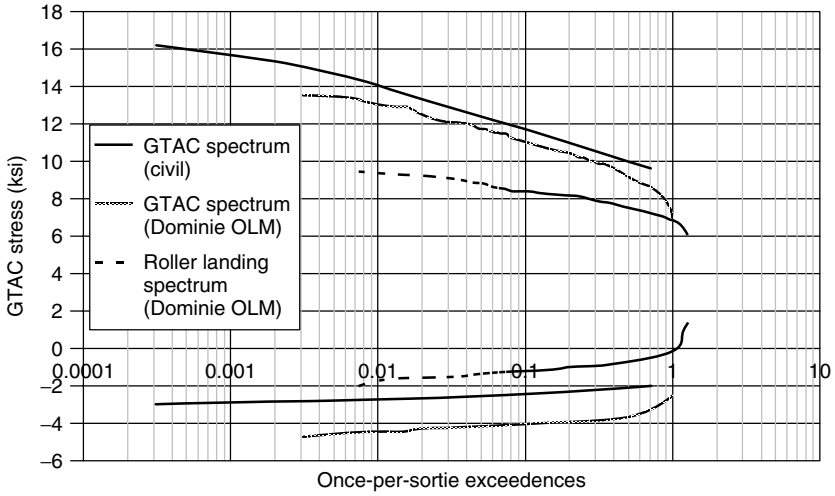

Figure 17. Dominie GTAC and roller landing stress spectra.

calculated using the conventional fatigue and fracture mechanics methodologies described; no attempt has been made to qualify the corresponding damage tolerance criteria for the wing structure. The results are intended purely to illustrate and explain the comparative content and severity of the stress spectra describing the usage of a civil-designed and qualified aircraft as flown in a military training role. Intense flying at low level and the use of the aircraft for pilot continuation training are two particular aspects of that usage that were not allowed for in the civil qualification; it has been shown that these have a considerable effect on the crack propagation predictions. This is a clear indication of the value of OLM, which, in this case, has enabled these aspects to be identified and quantified where previously there were no reliable data available. For instance, the stress levels in the wing structure during a roller landing were wholly unknown and the statistics describing the gust intensities within the low-level environments routinely encountered by the Dominie were very sparse.

ACKNOWLEDGMENTS

The success of the Dominie OLM was due to the hard work and cooperation of the team from QinetiQ, SERCo, No 55 Squadron at RAFC Cranwell, the UK MoD Training Aircraft Integrated Project Team, and the UK MoD Structural Integrity Branch.

1 INTRODUCTION

Throughout this structural health monitoring (SHM) encyclopedia, there are numerous examples of technologies that integrators and vendors can implement: miniaturized sensors, embedded computing, and diagnostic and prognostic algorithms. Their challenge is to integrate all these technologies into one or several systems. It may seem that many integration challenges have been addressed in other systems, and this is true; but what are the best practices for communicating information among data acquisition (DA), data processing, state detection (SD), health assessment (HA), prognostics, and advisory generation functions? Since SHM systems may perform one, many, or all of these functions, how can vendors specify how systems from other vendors interact with their systems?

The International Standards Organization (ISO) Technical Committee 108/Subcommittee 5 has defined six generic functional blocks that are relevant to equipment and SHM in ISO-13374 titled "Condition Monitoring and Diagnostics of Machines" [1]. These six blocks are DA, data manipulation (DM), SD, HA, prognostics assessment (PA), and advisory generation (Figure 1). ISO-13374 also defines the information that is input and output from each of the functional blocks. Although the standard has the word "machines" in the title, the concepts in ISO-13374 are well suited to structures. So, for a diagnostic algorithm, ISO-13374 states that the algorithm should be included in the HA functional block. Its inputs are from the DM block (data, timestamp, and data quality), and its outputs are health grade, diagnosed

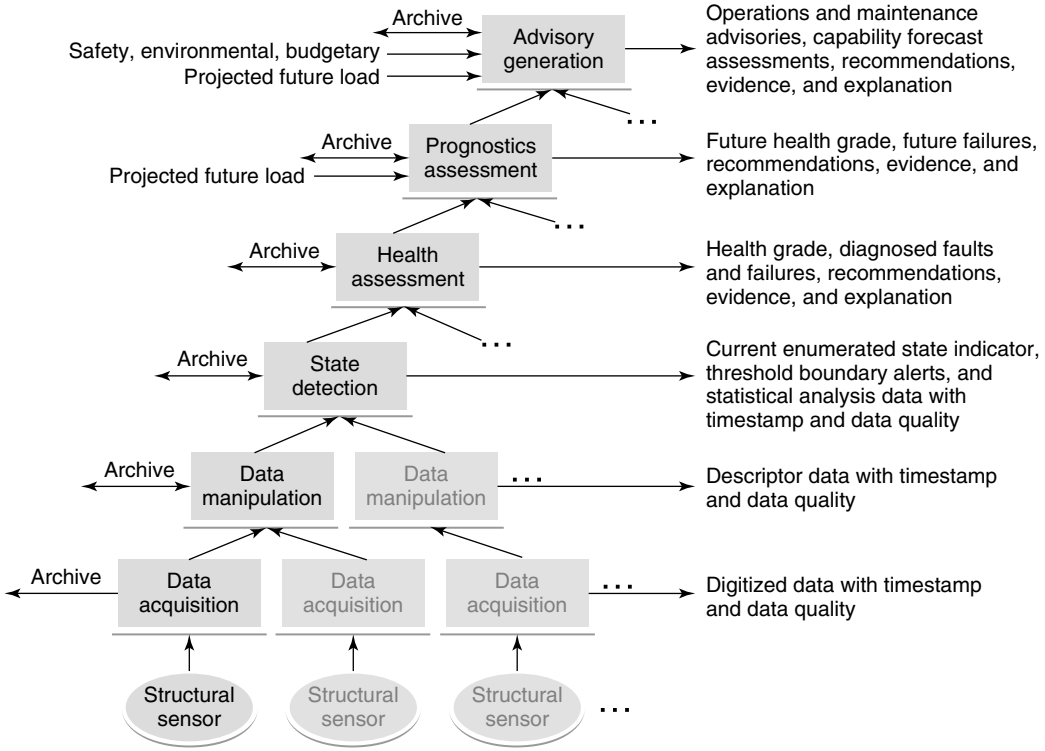

Figure 1. Six functional blocks of ISO-13374.

faults and failures, recommendations, evidence, and explanation. The other five functional blocks have a similar list of inputs and outputs. However, ISO-13374 is not sufficient to define a system architecture. What is missing is a definition of how the functional blocks interact among themselves.

A coalition of vendors has developed the open systems architecture for condition-based maintenance (OSA-CBM) standard to satisfy the guidelines of ISO-13374 and has transitioned the stewardship of the OSA-CBM standard to the Machinery Information Management Open Systems Alliance (MIMOSA) standards body. The coalition of vendors developed the OSA-CBM standard to align to the MIMOSA Open Systems Architecture for Enterprise Application Integration (OSA-EAI), and together they formulated a standards-based maintenance information management system that can find a wide variety of applications.

This article describes how to implement OSA-CBM in SHM applications in an open architecture to foster simpler systems integration.

2 KEY FEATURES OF AN OPEN ARCHITECTURE FOR CBM

The goal of implementing an open architecture for SHM is to allow vendors to add, upgrade, and interchange components in such a way as to be technology independent, yet at the same time, support protection of vendors' proprietary technologies. OSA-CBM accomplishes this as follows:

1. Promotes technology independence
The core OSA-CBM model only defines the interfaces and the class structure of messages going across those interfaces. Thus, OSA-CBM can be implemented with many technologies and various programming languages. Secondary specifications will specify implementations for certain major middleware technologies, such as extensible markup language (XML), to aid interoperability. Even so, only the structure of the messages will be enforced.

2. Protects proprietary algorithms, yet exposes inputs and outputs
Although the messages between modules are standardized in OSA-CBM, the internals of each module are not. Modules can, and are expected to, contain proprietary algorithms that will not be visible to anyone else in the OSA-CBM system. The inputs and outputs of the module are all that must be known. The rest is a black box.

3. Updates existing SHM systems
Naturally, many legacy SHM systems exist with proprietary formats. An implementer can simply make a wrapper around these systems to convert their data into OSA-CBM format, and then reap all the benefits of OSA-CBM.

4. Allows replacement DA systems
In an OSA-CBM system, if the hardware is changed, only the DA layer that supports the hardware must be updated. The rest of the system is not affected.

5. Supports dynamic updates of algorithm parameters
OSA-CBM allows a standardized way to access and modify processing parameters of algorithms within a layer. This process is discussed later.

6. Eases the addition of new processing algorithms
A new algorithm for processing data may be added without substantially affecting the present systems operations. Only processing load needs to be considered. This allows a simple path for the addition of new processing methods for continual improvement.

7. Permits replacement of entire software modules
Since OSA-CBM is modular and the structure of data between modules is standardized, existing modules can be updated or replaced without recoding the pieces around it.

8. Allows changes of load plan
In a prognostics or advisory generation capability, some plan for the future must be known to the algorithm. OSA-CBM allows a user to dynamically update the expected load on a system to examine the effects this would have on the predicted future health of a system.

3 BRIEF HISTORY OF OSA-CBM

An industry-led team developed and demonstrated OSA-CBM, completing its work in June 2001. The team's participants—Boeing, Caterpillar, Rockwell Automation, Rockwell Science Center, Newport News Shipbuilding, and Oceana Sensor Technologies—covered a wide range of industrial, commercial, and military applications of CBM technology. Other team contributors include the Penn State Applied Research Laboratory (ARL) and MIMOSA. The focus of the team was to design, develop, and demonstrate a software architecture that facilitates interoperability of CBM software modules. The OSA-CBM standard is documented using the unified modeling language (UML) and is available for download on the MIMOSA web site at http://www.mimosa.org.

4 OSA-CBM CONCEPTS

OSA-CBM categorizes data along two "dimensions". Along what can be considered the "vertical" dimension, the data classes are separated into "layers" based on the ISO-13374 standard, from DA all the way to advisory generation. At the same time, the "horizontal" dimension separates information into three categories: data, configuration, and explanation. Typically, layers are considered the dominant dimension, and each layer contains data, configuration, and explanation classes.

4.1 Vertical dimension

The OSA-CBM Standard consists of six layers. ISO 13374 defines and OSA-CBM implements the six stages (Figure 2) of CBM data processing as follows:

- **Data acquisition (DA)**

At the "bottom" of the OSA-CBM stack, data is collected from a sensor or other data source and is transformed into OSA-CBM format. Simple error-correction or data normalization can occur at this

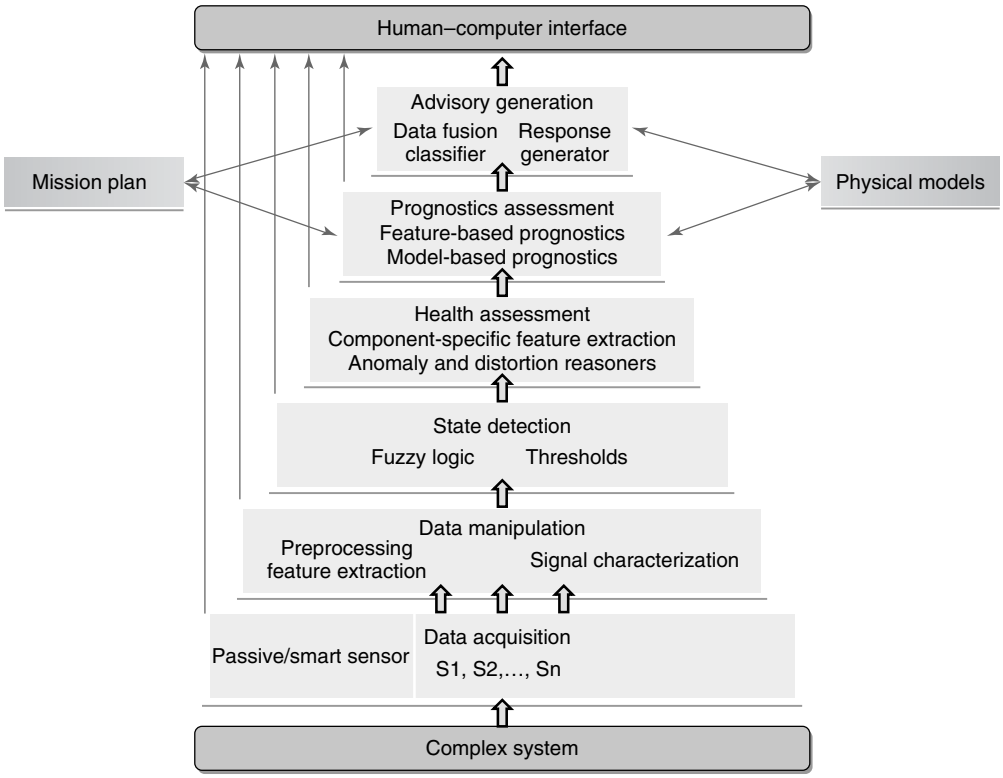

Figure 2. Vertical dimensions of OSA-CBM.

stage, but the output from the DA layer is considered essentially "raw".

- **Data manipulation (DM)**

Input to the DM layer nearly always comes from the DA layer, though the DM and DA layers can be combined to save space or processing time. In the DM layer, algorithms are applied to the data to make it more meaningful. Examples of DM processing algorithms are statistical measures (e.g., mean and root mean square), Fourier transforms, and time synchronous averaging. Output from the DM layer is considered processed data.

- **State detection (SD)**

The SD layer determines system states and conditions. Data from the DM and DA layers and possibly other SD outputs is monitored. One function of the SD layer is to monitor signal levels for simple threshold crossings and raise an alert whenever the data moves out of nominal operating range. States and conditions may be real-valued continuous state, integer-valued discrete states, or enumerated states.

- **Health assessment (HA)**

The HA layer utilizes data from the "lower" three layers (DA, DM, and SD) and produces two outputs: an estimation of health (0–1, 1 is perfect health), and a diagnosis of faults it believes to exist in the monitored object. The HA layer attempts to provide a complete assessment of the operating condition of the object being monitored, along with confidence and severity of the diagnoses. While the SD layer provides an observed set of symptoms, the HA layer interprets the observations into estimated or deduced system component health. It proposes system component faults and modes that would result in the observed system states and conditions.

- **Prognostics assessment (PA)**

The PA layer uses data from the lower four layers (DA, DM, SD, and HA) as well as the anticipated

future load to estimate remaining useful life and predict future health. The PA layer may also produce a prognosis of faults that it believes will occur in the future, as well as when they are likely to occur. PA layer modules may be constructed to accept expected future usage and return back computed life span, given the expected usage. This may be very useful with planning systems.

- **Advisory generation (AG)**

At the "top" of the OSA-CBM stack, the AG layer examines the current health and estimated prognosis and suggests a course of action such as *remove structure from service.* The AG layer also considers external constraints, such as budgetary, safety, and environmental concerns. The advisories produced can include operational readiness assessments, maintenance requests, suggestions for operational parameter changes, and capability forecasts.

These layers can be considered vertical because of two trends that occur as data travels up through the layers. First, the size of the data decreases. Data at the DA layer can contain hundreds of thousands of points, in the case of accelerometer data with a high sampling rate. One step upward, the DM layer typically reduces the size of the data to thousands of points in a Fourier transform or to single statistical values. Further up, the data gets smaller in size but more meaningful. Conversely, the complexity of processing tends to increase in higher layers. The algorithms in the DA, DM, and SD layers are relatively simple: data format transformation, straightforward algorithmic processing, and threshold comparisons. On the other hand, diagnostics, prognostics, and AG require more complex processing, often by intelligent reasoners.

4.2 Horizontal dimension

Each of the six layers can be considered to have three types of information associated with it (Figure 3):

- Data is the information gathered and processed by an OSA-CBM system. Data is usually exchanged on a timed interval, starting with data collection at the DA layer and propagating up to the higher layers. Sensor signals, extracted features, alerts, HAs, prognoses, and advisories are all considered data.
- Configuration is unchanging or infrequently changing information about the data (metadata). Configuration is typically accessed once at start-up

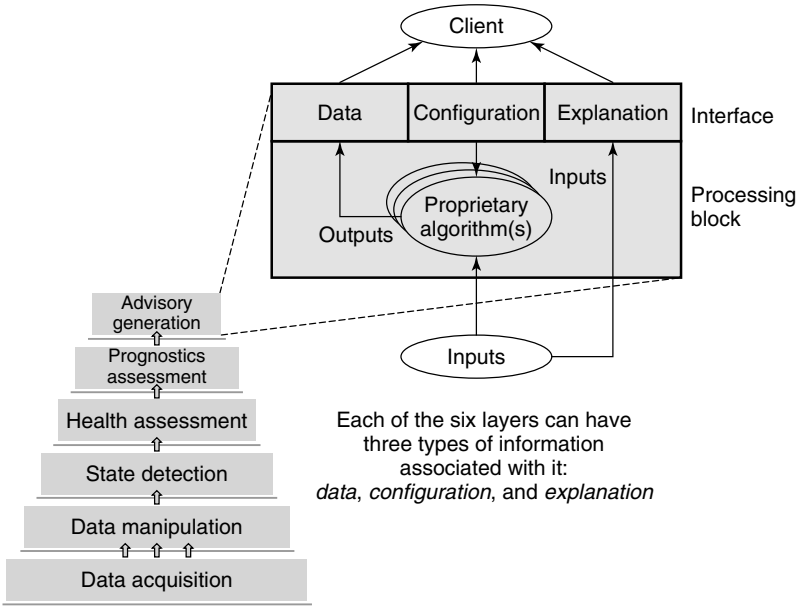

Figure 3. Horizontal dimension of OSA-CBM.

and used to aid in processing or understanding the data. Examples of configuration information are engineering units, algorithm descriptions, module descriptions, and structural information.

- Explanation is the ability to provide a description of the data used by an OSA-CBM layer to generate an output. There are several forms of explanation, such as a description of the location where data was gathered or a copy of the data itself. For example, if a DM layer computes a mean on data from an accelerometer, then the explanation for the DM layer would be the accelerometer signal. Modules are not required to support the explanation interfaces.

OSA-CBM supports three additional forms of information that cannot be easily standardized. Instead, a format is provided for storing and changing this application-specific information, but the specific parameters for each application are user defined. First, OSA-CBM provides the functionality to change processing parameters called *control parameters*. This is not to be confused with configuration: control parameters can be changed at any time in a layer's lifetime, while configuration changes very rarely. Examples of potential control parameters are data refresh frequency, sample size of DA, threshold limits, and fast Fourier transform (FFT) block size. Control parameters allow modules to be configurable and reusable without recompilation.

Second, the application parameters allow a user (human or other OSA-CBM module) to change parameters in a module. Application parameters are not meant to change the behavior of algorithms, but instead change other application-specific parameters. This interface is meant to be a catchall for needs outside the purview of OSA-CBM. One example is program initialization data such as specifying the source web service for module input.

Third, data classes do not contain mechanisms for reporting errors; instead, the error parameters allow a module to report processing errors. Note that while control and application parameters allow the user to both request and change their values, the error parameters only allow requests.

Although these specific parameters are user defined, a human operator can request a list of the parameters, their values, and a description of each parameter. In this way, a human can set parameters of a module without knowing what they are, ahead of time, but a machine cannot. To allow automated parameter changing, a list of possible parameters must be provided beforehand.

4.3 OSA-CBM interfaces

The OSA-CBM standard describes four types of interfaces that can be implemented at each layer. The concept behind OSA-CBM is not to map every interface into every technology in which OSA-CBM is implemented. Rather, it is to select the best interface for the desired type of data transfer.

The synchronous interface is designed to be a simple function request with data returned directly by the call. This type of interface maps into the internet data services concept where a connection is made, information about the request is given to the service, the service processes it, and then the service returns the required data. It maps to programming languages as a simple class method call with information returned by the method.

The asynchronous interface is a publish–subscribe type interface that establishes a connection between a user of data and a provider of data. It is useful for event-based systems and higher speed systems where the cost of connection becomes important. This interface functionality can be set up in three different ways: push all data, return data only on request, and push only data with an alert status. Since a connection is maintained, the server of data can push all new data events to subscribers of that information. There may be a situation where the user of data only requires knowing about data items that have some type of alert status. Functionality may be set up to return only those data event sets that have triggered an alert. This aids the construction of an efficient processing system.

The data service interface is designed as a consumer of data. One application would be a maintenance work order processor, which might take an advisory generation layer data event. Another potential use might be a data event recording or storing system. When a module has data that should be recorded, it could send that data to an OSA-CBM data service that is designed for storing data. An OSA-CBM data service performs a well-known process at a known or discoverable location.

Table 1. OSA-CBM parameters

Parameter	Description
MonitorIdlist	Indicates a specific desired subset of data which is provided by a module
ConfigRequest	Indicates a specific subset of configuration information
ControlChange	Indicates a desired module functionality change. For the PA layer and AG layer it may indicate an expected usage model against which to make predictions
ControlRequest	Gets information about the value of specific control settings
ControlInfo	Contains the values of the desired control settings
AppNotify	Sets up application-specific parameters
AppRequest	Requests application-specific information
AppInfo	Responds with application specific information
ErrorRequest	Requests error information
ErrorInfo	Responds with error information

The data event server interface is designed to be a method for passing single data events. It is meant to be a light way for implementing a monitoring system, typically at an embedded level. It only provides for moving individual data events, sending none of the other OSA-CBM information components such as configuration.

The functions in the interfaces provide for connectivity (asynchronous interface) and for moving each of the different types of information, i.e., data events, configuration, explanation, control, application-specific, and error information. The most commonly used parameters in the interfaces are given in Table 1.

5 RELATIONSHIP TO OSA-EAI

The MIMOSA standards body also maintains OSA-EAI standard. Since the OSA-CBM standard is implemented as an architecture for processing information, the OSA-EAI standard is a combination of a relational database schema specification for archiving information and XML interface specifications for exchanging condition, reliability, and maintenance information between systems. One may, therefore, take a legacy system and apply a MIMOSA OSA-EAI compatible XML interface without changing the legacy system to develop a MIMOSA compliant system. The OSA-CBM and OSA-EAI standards were harmonized in 2004 such that data processed in OSA-CBM can be archived in OSA-EAI compliant data archives and communicated with external systems using OSA-EAI XML schemas.

There are five key classes in the OSA-EAI standard that enable integration between the two standards: site, segment, asset, agent, and measurement location (Figure 4). A "site" can be a structure, vehicle, manufacturing plant, facility, maintenance depot, etc. A site is composed of one or more structures and substructures called *segments* that perform a function that will be monitored. Serialized "assets" may be installed in segments over time. An "agent" is a person or intelligent software capable of performing work, making diagnoses, etc. A "measurement location" identifies the physical position on an asset or segment where actual measurements are taken.

In OSA-CBM, the data events from the lower three layers (DA, DM, and SD) are mapped to measurement locations. This means the identifiers for the lower three layers in OSA-CBM have a one-to-one correspondence to measurement locations in OSA-EAI. Similarly, the data events from the higher three layers (HA, PA, and AG) are mapped to agents. Agents in OSA-CBM terms are software agents or processing centers; every module in OSA-CBM is an agent. Since OSA-CBM maps to OSA-EAI, the output of any OSA-CBM module can easily be stored in an OSA-EAI compliant database and communicated between systems using OSA-EAI XML schemas.

However, although OSA-CBM identifiers map directly into OSA-EAI, any system can use these identifiers directly without necessarily installing an OSA-EAI database.

6 BEST PRACTICES

At the time of this writing, the only technology that is publicly offered is the XML mapping. However, this mapping is not useful for all applications. Many condition-monitoring systems, especially in the lower

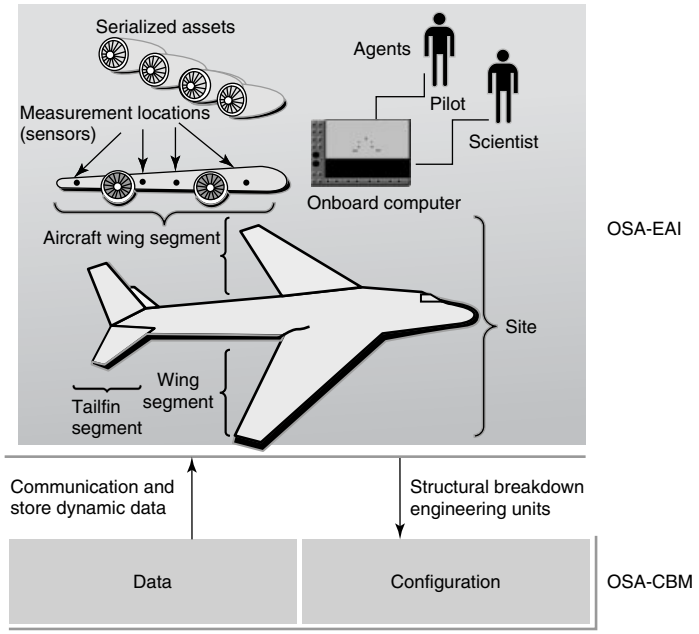

Figure 4. OSA-EAI site, segment, asset, agent, and measurement location.

three layers, process a continuous high-rate stream of data. XML is too inefficient for these applications. A programming language mapping to C or C++ could be used for a single program performing the processing. In this case, the information stays within the internal data structures, but this is done in such a manner that results can be fed to a generic module, which feeds higher layer systems. A binary mapping is also possible to construct a high-speed method of moving the information via a byte transmission mechanism such as TCP/IP. In these higher rate systems it is also suggested to use the asynchronous interface approach to eliminate communication connection costs.

When designing an OSA-CBM system, the first step is to develop a block diagram of the processing centers and indicate the layer in which a processing center occurs. For example, a DA module fetches data and serves it to a DM module, which performs some math processing. The DM module sends data to an SD module, which determines states and conditions of the system. Once these different modules are identified, the next step is to determine the signals that will flow in the monitoring system and the type of data events that will contain that information. The OSA-CBM UML can be used to identify the specific types of data events, which will be required. This system design should be recorded in an OSA-EAI database using site, segment, measurement location, and agent as main foundational tables.

One can work bottom up (starting from the sensors), top down (starting from the high-level goals), or use a combination of both. Assuming that the structure already has a set of sensors, each sensor is a potential source for a DA layer. To simplify the system, multiple sensors can also be combined into a single DA layer. Working bottom up, every sensor is monitored via DA layer module(s), and the algorithms of the higher layers are written to make use of the available data. This method can lead to waste, however, if some sensors are not necessary for health monitoring. Perhaps a better design method evaluates the available sensors for their usefulness in diagnostics or prognostics before wrapping them in a DA layer. This is an example of a combination of top-down and bottom-up design.

The DM layer is an important module because it serves to drastically shrink the size of the data while maintaining or even adding meaning to the raw data. This is especially necessary when the DA data is high bandwidth, such as vibration data. The DM

layer applies algorithms to DA data, often statistical measures, and produces "features" that can be used by the higher layers. These features communicate specific aspects or trends of the raw data. Ideally, data used by the SD, HA, PA, and AG layers from the DM and DA layers should be single values only, not waveforms or data sequences. Thus, a temperature sensor typically has a low enough bandwidth to be used directly by any layer, but a high-frequency vibration sensor should be processed first in the DM layer.

The remainder of the layers can be implemented as requirements dictate. The SD layer should monitor critical signals and report faults to operators and maintainers. HA, PA, and AG layers may be added as algorithms are developed for diagnostics, prognostics, and automated reasoning. Since an OSA-CBM system is inherently modular, different layers can be developed by companies or divisions that specialize in one aspect of the CBM cycle.

Developing an OSA-CBM system requires additional design decisions because of factors such as performance needs, memory size, processor power, bandwidth, and storage space. As noted earlier, the size of the data at the lower layers can be on the scale of megabytes, but the processing is simple. In higher layers, data becomes much smaller but the complexity of processing increases significantly. Similarly, an XML implementation is likely to be more maintainable than a binary implementation, but the bandwidth requirements are higher. If the implementation uses a powerful computer, these issues are not problems, but some implementations require computers with limited processing, power, and bandwidth capabilities. Some design decisions that can be made to address the specific requirements of an implementation are as follows:

- **Arrangement of layers**

An implementation does not have to provide every layer. One can take advantage of this by combining the DA and DM layers, such that the large data sets produced by the DA layer do not need to be transformed into OSA-CBM format and can thus save processor time, memory space, and bandwidth.

- **Physical location of layers**

Since the OSA-CBM architecture is modular, it is possible to spread the processing across multiple computers. Thus, a lightweight, limited processing power computer can be placed on the monitored item, while a more powerful processor or computer could handle the HA, PA, and AG layers. Another situation is the isolation of lower layer hard-real-time system-critical processing components from higher layer soft-real-time complex processing components.

- **Programming language implementation**

OSA-CBM does not specify what programming language to use—only the structure of the objects communicated. Ideally, this means that any programming language could be utilized, but not all languages have the same support for XML and object-oriented programming. Java or the Microsoft .Net framework is recommended for most applications, but C++ could be used for implementations with severe performance needs. New technology mappings may be added to the OSA-CBM specification by members of MIMOSA.

- **Communication implementation**

As of OSA-CBM version 3.1L, the only standardized communication format for OSA-CBM is XML. However, some implementations would be hindered by the overhead that XML adds to a message. If this is the case, the objects could be stored and sent in a binary format to save bandwidth. However, this binary format must be agreed upon in an interface design document between all parties involved until a binary format standard is added to the OSA-CBM standard.

7 GETTING STARTED

The SHM community is rich with varying technical capabilities and will greatly benefit from integrating those capabilities into a single open architecture—one which allows many proprietary technologies to be integrated into one solution. The MIMOSA OSA-CBM and OSA-EAI standards enable that vision. The authors encourage SHM developers and systems integrators to visit the MIMOSA web site at http://www.mimosa.org to download the standards, read primer documents, and download examples.

1 INTRODUCTION

The design of components in nuclear power plants is based on nuclear codes and standards like ASME [1], RCCM [2], or KTA [3]. These codes and standards cover not only design but also material specifications, manufacturing, and examination. For safety-related components of the pressure-retaining boundary, stress and fatigue analyses are requested during design in order to fulfill the code requirements. These analyses are made with conservative load assumptions for the expected service life of the nuclear power plant.

To verify these load assumptions, a large measurement program was carried out in the early 1980s. This was in a German nuclear power plant, where, during the commissioning phase, detailed information of the real component loadings during plant operation was recorded. The measurement program revealed that cyclic loading is much more important than it was anticipated in the design analysis and that the amplitude and the number of cycles depend closely on the operation manner. Many unexpected loadings were recorded as follows:

- higher thermal stresses;
- higher number of cycles;
- unconsidered load events by project design;
- stratified flow due to low flow rates or caused by leaking valves.

However, more detailed analyses based on these measured loads showed that the fatigue limits were not exceeded.

The advantages of monitoring the real operating conditions and using the acquired data as an input for fatigue analyses based on realistic loading data became obvious. This gave a strong development impetus toward a sophisticated fatigue monitoring system. As a consequence, the German nuclear power plants as well as many plants in other countries were equipped with FAMOS (*Fa*tigue *Mo*nitoring *S*ystem—the AREVA product for online monitoring of fatigue). The main objectives of FAMOS can be summarized as follows:

- determining the fatigue status of the most highly stressed components;
- identifying operating modes that are unfavorable to fatigue;
- establishing a basis for fatigue analysis based on realistic operating loads; and
- using the results for lifetime management and lifetime extension.

Today, FAMOS is installed in more than 20 nuclear power plants (NPPs). It is also part of the monitoring systems implemented in the new European pressurized water reactor (EPR) [4]. The following sections give an overview of the procedures that are necessary for the implementation of such a monitoring system.

2 FATIGUE LOAD MECHANISMS

There are different mechanisms causing material damage. First, so-called primary loads do cause primary stresses, which, in the extreme, may lead to single failure by plastic fracture and whose intensity is not decreased by plastic deformation. Internal pressure and dead weight loads belong to this category. Pressure vessel safety against single failure by plastic fracture is proven usually by pressure tests. Secondly, for cumulative fatigue damage, the variable load effects are crucial because these cause the stresses and deformations to alternate. Fatigue accumulation, however, does not generally relax by plastic deformation. On the contrary, recurrent loading into the plastic regime may possibly induce accumulation of plastic deformation, so-called ratcheting. The degradation effect on the material appears first at the microscale, if the stress intensity fluctuations exceed a certain value, thereby causing irreversible plastic deformation. For pressure vessels, fatigue loading is of major concern because single and simple component tests do not exist to remedy the problem. The damage induced is not obvious and cannot be measured up to date.

Great attention was paid to the design and stress analysis of nuclear power plant components. Safe operation is established if the loads do not exceed the presumed values. However, possible uncertainties in the flow conditions and thus deviations from presumptions considered in the project phase and in the design reports must not be neglected. These deviations were observed, for instance, at some horizontal pipeline segments of NPPs, wherein special modes of operation gravity forces separate hot and cold media into a layered flow of very low flow rate. The physical phenomenon is well known as *temperature stratification*. This also appears at nozzles with intermittent inflow. The gap at nozzle thermal sleeves may also cause negative loading effects.

The monitoring system FAMOS addresses just these effects. For this purpose, thermocouples are installed on the outer surface of the parts. The real, local temperature profiles are recorded, which otherwise would not be known. The main attention is given to the acquisition of the local temperature history, but it is also necessary to collect data on other loadings (internal pressure, member forces), because the resulting degradation effect is caused by the combined loading. This is why additional parameters are fed into the system. These also serve to later characterize and analyze the operational state of the facility.

3 PHENOMENA CAUSING FATIGUE

Major loads acting on primary circuit components consist of thermal constraints, internal pressure, and thermal transients, besides member forces and moments. The loads vary during operation of the equipment, thus causing material fatigue. To determine the state of material, fatigue is a very complex task. The reason lies in the uncertainties of boundary conditions, e.g., transient distribution of temperature and flow in the pressure-retaining components.

The next sections describe some processes, which can cause cyclic loading of material during the operation of primary circuit.

4 TEMPERATURE TRANSIENTS

Temperature transients in pressure vessels and piping systems are very often a result of sudden opening of a valve or starting of a pump. Cold water flows into a system, which was originally in a hot, steady-state condition. The thermal field is axially symmetrical. If the flow rate is low and the cold and hot water interface is not perpendicular but skew, then stratification can evolve.

Thermal stresses are a result of thermal gradients in the wall. The amplitudes of thermal gradients depend on temperature differences, on the rate of temperature changes, and on the heat transfer coefficients (Biot number). The stress in the wall is roughly proportional to the temperature difference between the inner surface and the mean temperature of the wall.

The temperature on the outer surface can be measured directly by using a surface-mounted thermocouple. The estimation of the temperature on the inner surface of the component is much more complex. For high Biot numbers, it is possible to approximate the temperature of the material with the temperature of cooling water, measured via the operational instrumentation and Instrumentation & Control (I&C) system.

From fatigue load point of view, the mentioned type of loading is dangerous in two cases. When the operation with transient loads is a relatively long-term operation, the numbers of load cycles are high. This load phenomenon is pictured in Figure 1, which shows the measured temperatures at feedwater inlet of a steam generator. The plant condition is zero power output, so-called hot standby. The water level in the steam generator, however, has to be maintained either by feeding continuously at very low flow rates, thereby inducing thermal stratification, or by feeding intermittently by nominal flow rate, thus accepting thermal shocks. The latter case can be seen in Figure 1. During the feeding process,

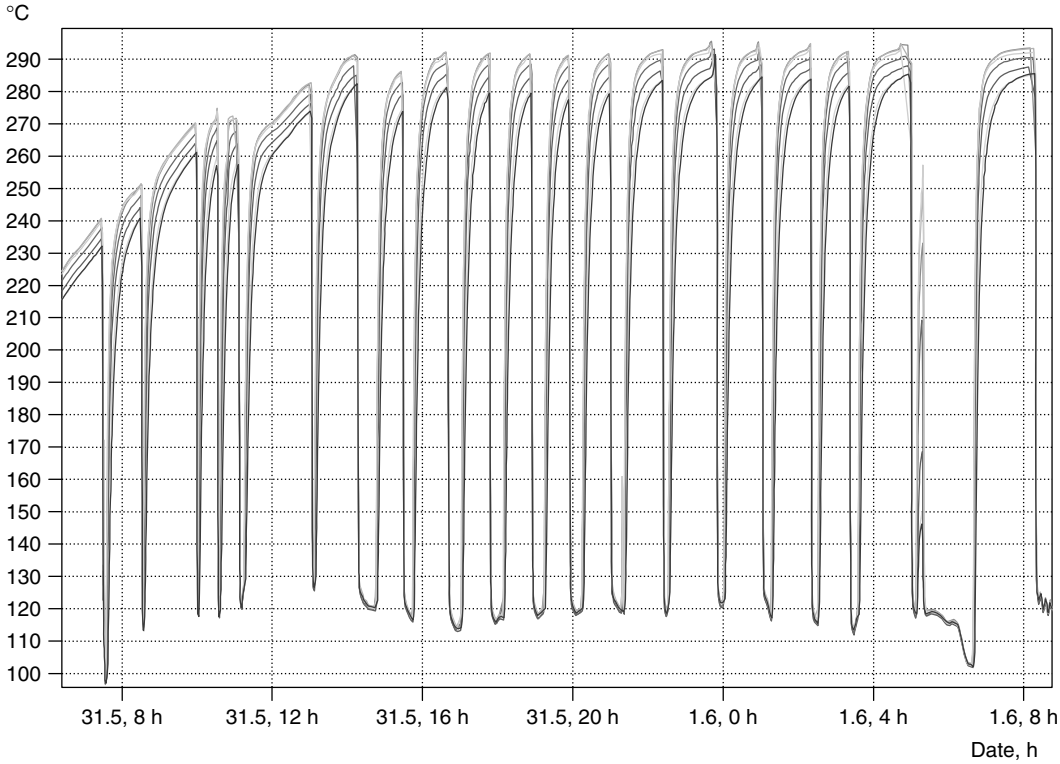

Figure 1. Intermitted feedwater injection induces thermal shock on structure (7 thermocouple signals according to in Figure 7b).

the feedwater nozzle gets a thermal shock which decreases the nozzle temperature suddenly. By the time the feedwater nozzle temperature increases again to the temperature of the steam generator.

Another process of high accumulation of fatigue load can be important for complex nozzle geometries. When a thin-walled part is connected to a massive one, then the latter does not allow the deformation of the thinner part, thus inducing constraint stresses.

5 THERMAL STRATIFICATION

Thermal stratification can be characterized by a thermal field, which is symmetrical to the vertical axis of a cross section of a pipe positioned horizontally. Stratified flow occurs when a low flow rate creates two layers. The warmer fluid will stay in the upper part of the pipe above the heavier (colder) fluid without any appreciable mixing in between. Figure 2 shows an example of thermal stratification during the startup of an NPP. The upper line represents the temperature at the pressurizer (DH) and the lower line the temperature of the main coolant line (HKML). The remaining lines are the temperatures $T1$ till $T7$ as indicated for a measurement section shown in Figure 7.

When the temperature varies in the vertical direction, the pipe tends to bow [5]. The stresses induced in the material decrease with the supports of the piping system being flexible. When the temperature interface is sharp, the gradients of temperature in the metal are high (Figure 3). The stress is highest in cases when the interface of cold and hot fluid is in the middle of the pipe. When the sharp line between cold and hot fluid moves vertically, the local temperature gradients (and therefore local stresses) also change. In such a situation, the cyclic load occurs, though the temperatures of cold and hot layers of fluid are both constant. Therefore, it is important to measure not only the temperatures on the top and bottom of the pipe but also the temperatures at several points along the circumference of the pipe (Figures 2 and 7).

6 TURBULENCE PENETRATION

This phenomenon exists in a piping system with a hot turbulent flow that penetrates into a branch line that contains a stagnant cold fluid. The intensity of

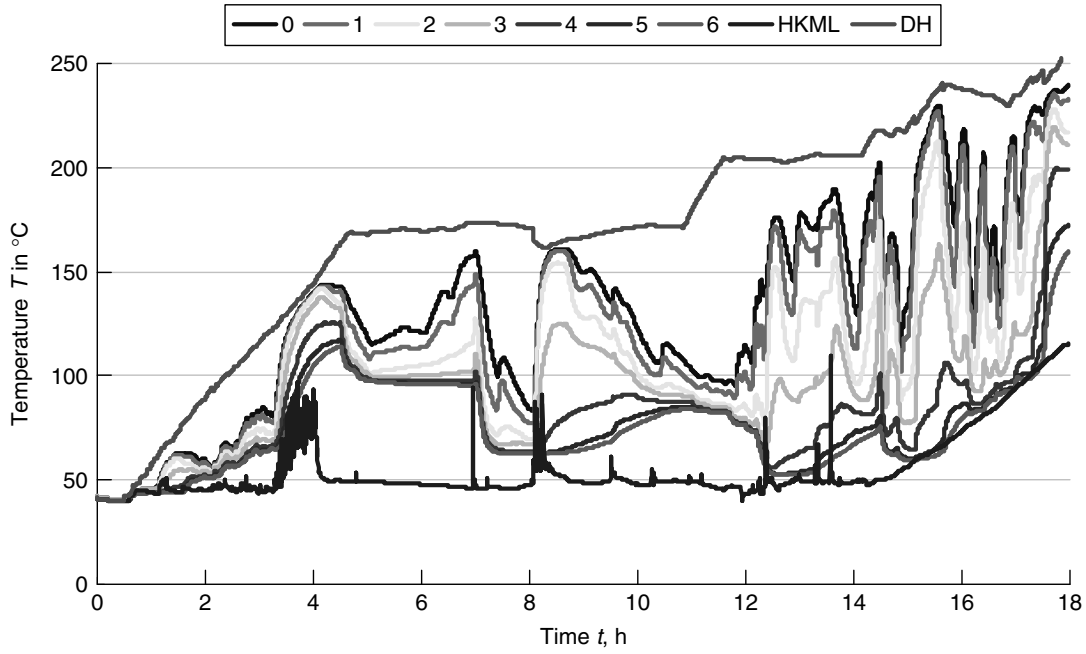

Figure 2. Example of thermal stratification in surge line during startup of NPP.

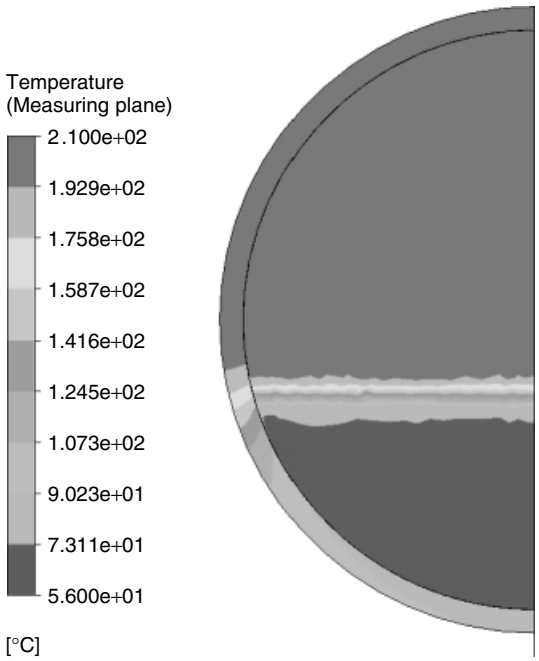

Figure 3. Simulation of stratification with a computational fluid dynamics (CFD) model.

the turbulence decays exponentially from the header pipe into the branch, but the temperature remains fairly constant with main flow temperature along the length of several diameters (Figure 4). If the turbulence penetration depth just reaches a horizontal line, thermal stratification can occur within it. The interface is not stable because of turbulence. This results in fluctuating interfaces and additional fatigue load.

This phenomenon exists in every pipe routing for three different cases: horizontal branch, up-horizontal branch, or down-horizontal branch line. The FAMOS way to find out locations like that is to look for this typical pipe routing with horizontally or vertically bent-down branches followed by a horizontal line with a closed valve. Procedures for estimation of the turbulence penetration are developed in [6].

7 THE "FATIGUE MONITORING MANUAL"

The "Fatigue Monitoring Manual" contains the essential input data for introduction and installation of the monitoring system for primary and secondary circuit systems in the nuclear power plant. The entire philosophy of the system is described and the purpose of its implementation is specified. Finally, the main purpose is the screening of the primary and secondary systems for locations where additional measurement locations shall be applied for fatigue monitoring. This is a very essential step because, during this step, if not all relevant locations are identified, then the whole fatigue monitoring system would be put into question. The main task of the work here requires, first of all, to find out the locations of the safety-related parts of the pressure-retaining boundary, which are thermally highest loaded, and therefore the fatigue load is representative for the neighboring components. These locations need to be monitored with the fatigue monitoring system.

This engineering evaluation gives the reasons as to why these locations have been selected for monitoring. Finally, a measurement plan has to be prepared where the monitored locations are summarized. The task of this manual therefore is to explain *where*,

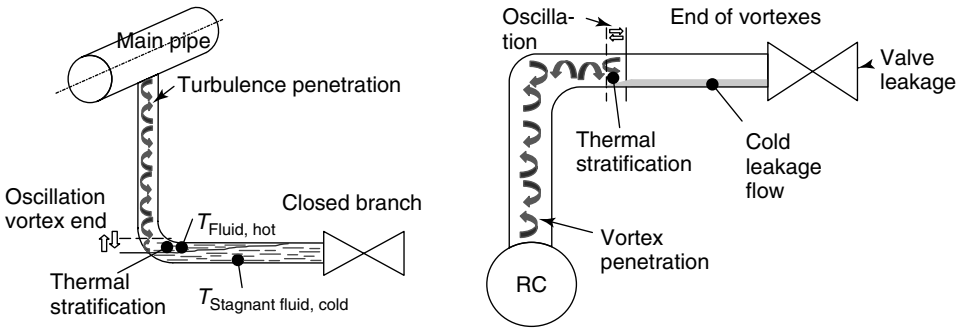

Figure 4. Turbulent mixing in a branch line containing stagnant fluid.

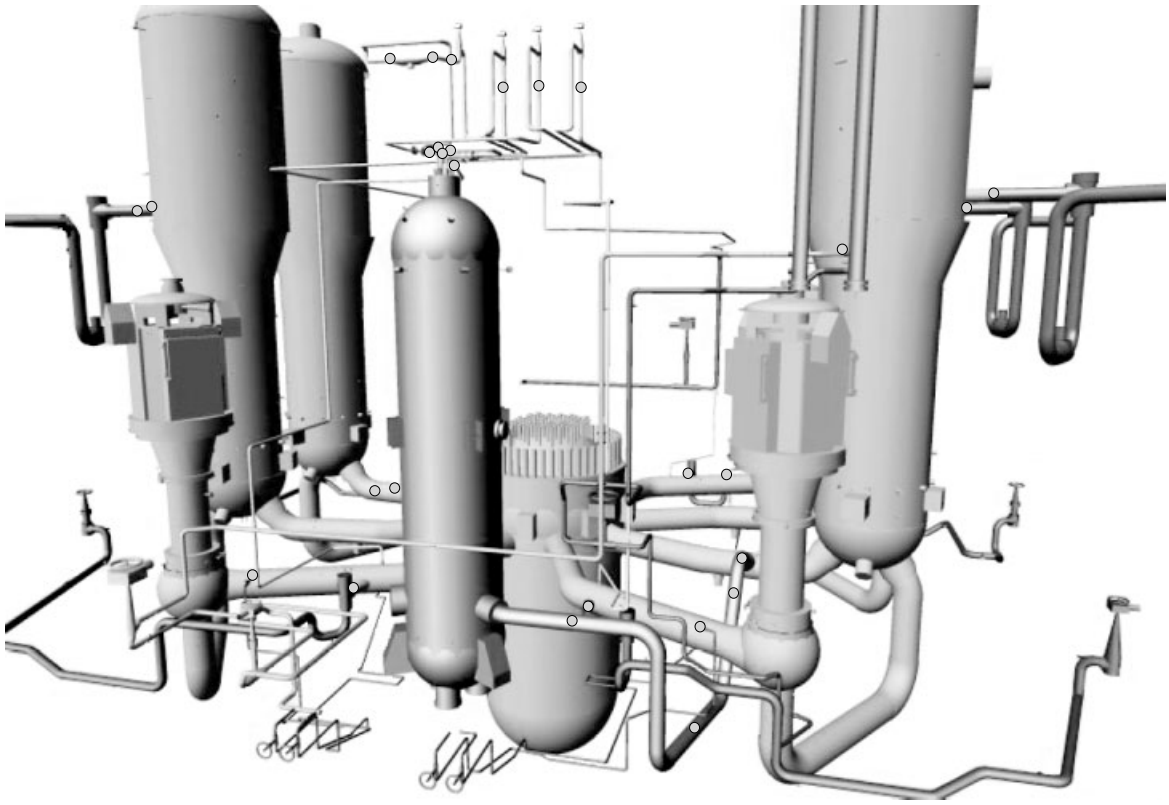

Figure 5. Selected measurement section locations of the FAMOS system.

why and *how* to implement measurement sections for fatigue monitoring, which are representative for the whole plant and cover all relevant components with respect to fatigue. An example of locations where measurement sections are required is given in Figure 5.

8 FAMOS CONCEPT

Within the FAMOS concept, the "Fatigue Monitoring Manual" provides the foundation for further work—it is the basic step. It is named "stage 0" because of the necessary information for the preparation of the measurement equipment within "stage 1". However, it is also the basis for additional FAMOS functional units for the so-called quick evaluation "stage 2" and the fatigue analysis within "stage 3". These four steps are shown in Figure 6.

9 IMPLEMENTATION OF A MEASUREMENT SYSTEM

The implementation of a fatigue monitoring system consists of two steps:

- mechanical components like measurement sections and thermocouple sensors;
- electrical components like measurement electronic system for data acquisition.

For both parts, several solutions were developed during the past years.

9.1 Mechanical components

For the measurement sections with the thermocouples, the main focus was on the improvement of the dynamic response of the temperature signal of the thermocouple. Different boundary conditions need to

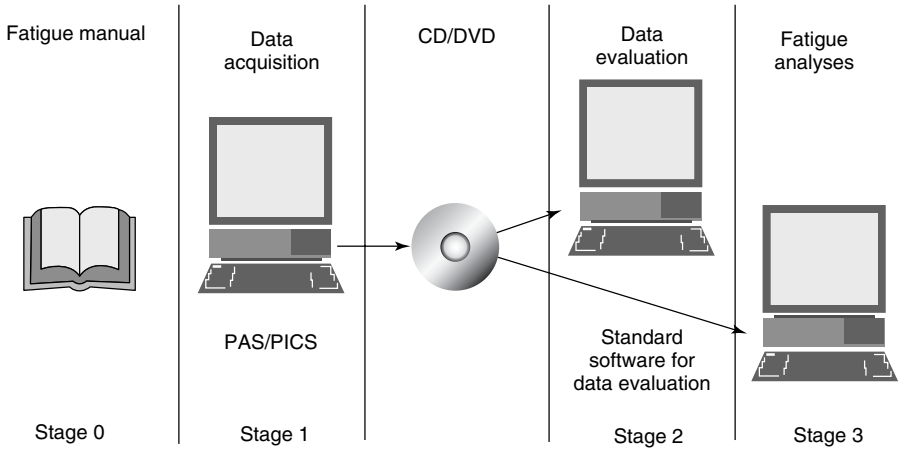

Figure 6. The four stages of the FAMOS system.

be considered for that development. On one side, the design must be very robust because the measurement section sometimes needs to be removed for in-service inspections. In addition, a very quick handling for the mounting activities is necessary since at the measurement locations high radiation exists and hence the dose rates need to be kept low for the personnel. Independent tests showed that the current design of the FAMOS measurement sections is able to reach 95% of the real surface temperature of the outer surface of the pipe [7]. With additional calculations, this deviation can be corrected to get the true outer surface temperature of the pipe.

During operation, the monitored components are exposed to different kinds of temperature loads like thermal shock or thermal stratification. For this reason, two different types of measurement sections with either two or seven thermocouples have been developed (Figure 7). The principal arrangement of a measurement section at the pipe including cover shell and insulation is shown in Figure 8. To get a robust sensor arrangement, it is important to protect the measurement section with a cover shell as the sensitive thermocouples need to be protected against damage when the metal insulation cassettes are installed. The thermocouple wires are passed through the insulation via a fixed protection pipe and then passed further within flexible or fixed protection tubes to the intermediate terminal box.

The sensors used at the measurement section are thermocouples of type K (NiCr–Ni). They are point welded at the measurement section with a thin metal foil. Thermocouples of type K are specified for a temperature up to 1200 °C (2192 °F). During the manufacture, the sensors undergo an accelerated aging process. This has the advantage that no additional aging will occur during application for fatigue monitoring in a nuclear power plant as only temperatures of up to 350 °C (662 °F) occur. This leads to a very robust behavior, which does not require additional recalibration during operation. If the sensors are damaged mechanically, a drift will be noticed and the sensor needs to be exchanged during the next outage.

9.2 Electrical components

For the data acquisition of the measured signal, different alternatives are also available. The whole measurement chain (Figure 9) consists of the following components:

- measurement sections with the thermocouples;
- terminal boxes with the thermal compensation (PT100);
- connecting cables between terminal boxes and the electronic cabinet.

The NiCr–Ni thermocouple wires as well as the corresponding thermal compensation lines are expensive compared to normal copper wires. For this reason, the transition should be made as soon as possible to save costs. Within nuclear power plants,

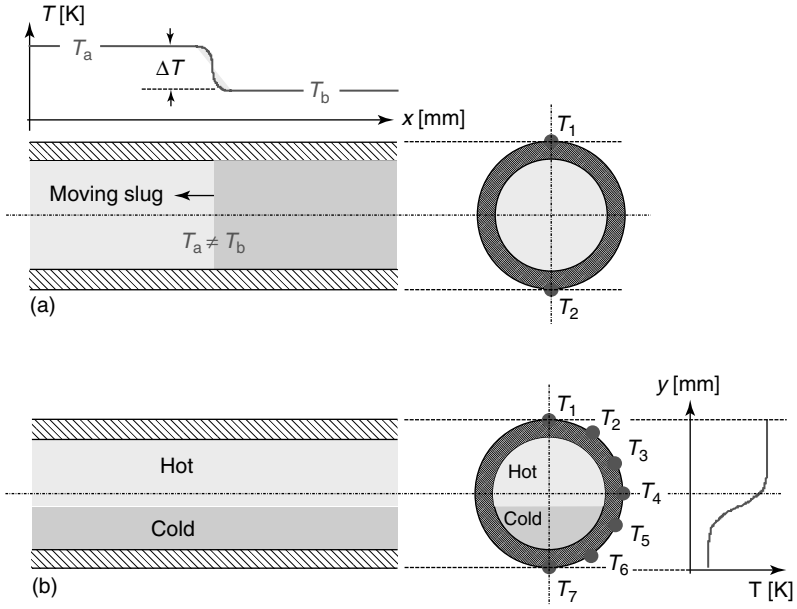

Figure 7. Schemes of idealized thermal loading of a pipeline and location of thermocouples: (a) slug flow (thermal shock) and (b) thermal stratification.

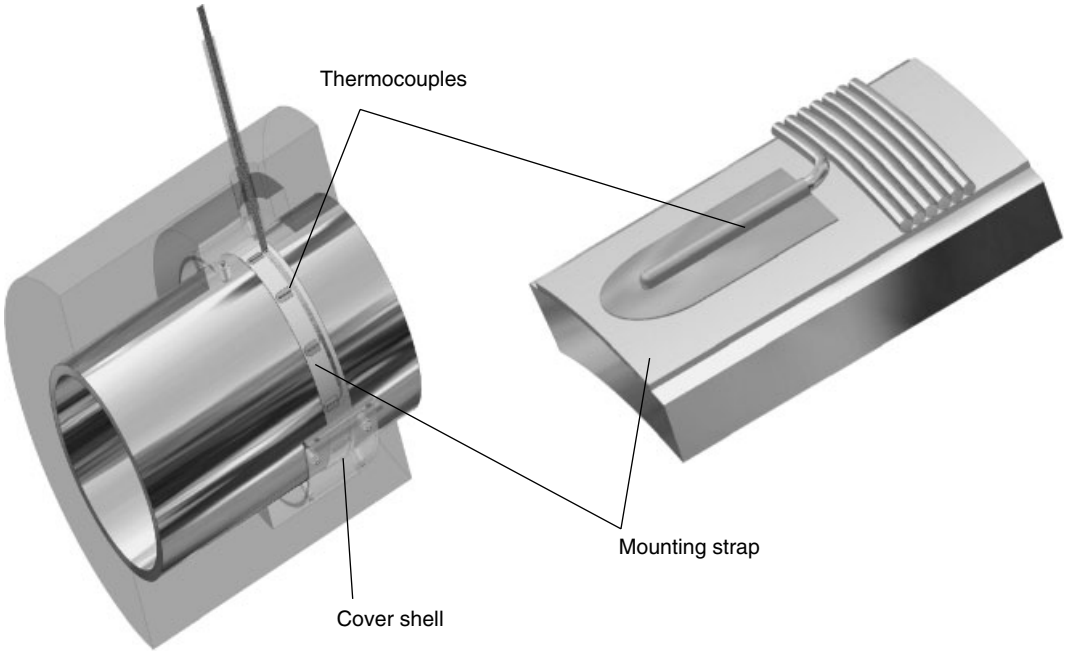

Figure 8. Measurement section with thermocouples, cover shell, and insulation.

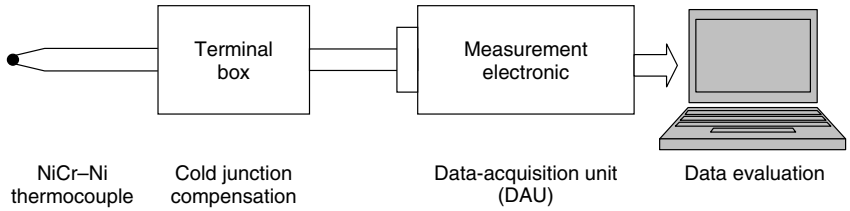

Figure 9. FAMOS measurement chain.

the radiation conditions need to be considered additionally. So it is good practice, nowadays, to have the terminal boxes arranged at a location where the radiation is lower than that directly at the pipeline. So the sojourn time for mounting the measurement sections at the pipelines is short and the dose rates for the personnel is held low (ALARA principle: as low as reasonably achievable). To make transition from the thermal compensation lines to normal copper lines, it is necessary to implement temperature compensation (cold junction compensation). It is not necessary today to have ice water available at 0 °C because the temperature compensation can be realized electronically. For this reason, the terminal of the NiCr–Ni and the copper clamps are held at the same temperature with the aid of a large copper block. The temperature of the copper block is measured with a PT100 resistance thermometer, which gives a high accuracy. This temperature is now used at the measurement electronic system for temperature compensation.

The data-acquisition unit (DAU) can also be realized in many different ways:

- local data loggers for temporary measurements;
- fixed installed cabinets with amplifiers and acquisition PC;
- data acquisition integrated within I&C and the plant process computer system.

Locally arranged data loggers can be used for temporary measurements only. The acquired data are read out after one cycle of operation for data evaluation. For installation of a complete system, either a cabinet with amplifiers and data-acquisition PC is installed or the system can be directly integrated within the I&C and the plant process computer system.

In a stand-alone measurement system with amplifiers and data-acquisition PC, it is possible to implement the most recent measurement electronic system available on the market. The disadvantage is that such systems are quickly out of date after some years of operation. This concerns the measurement electronic system, the PC, as well as the operating system and the data-acquisition software.

A longer lifetime can be expected from the components used in I&C systems. Therefore, the newest generation of integrated fatigue monitoring systems are carried out with that technology (Figure 10). The example is based on the Teleperm XP system from Siemens. The Teleperm XP cabinet is normally located outside the reactor containment in the measurement rooms, but it was also already realized to locate it inside the containment. This has the advantage that only one wall penetration with two optical wires is needed for transferring all signals to the plant process computer. In the other case, many wall penetrations are needed (e.g., 300 wall penetrations for 150 thermocouple signals, additionally approximately 50 or more signals for the PT100 depending on the number of temperature compensations).

It is important to note that data acquisition does not intervene with I&C and the operating system. The existing infrastructure of the I&C system is only used for data acquisition, storage, and visualization of the measured data. So it behaves in a manner similar to a stand-alone system on the basis of data loggers and a data-acquisition system.

10 DATA STORAGE AND HANDLING

The measurement results and archived patterns of temperatures, pressures, and other monitored parameters are stored either in the archive system of the plant process computer or at the stand-alone system on a hard disc and CD-ROM. A raid system ensures quick access and a high level of security for the database. The acquired values are displayed in real time on the

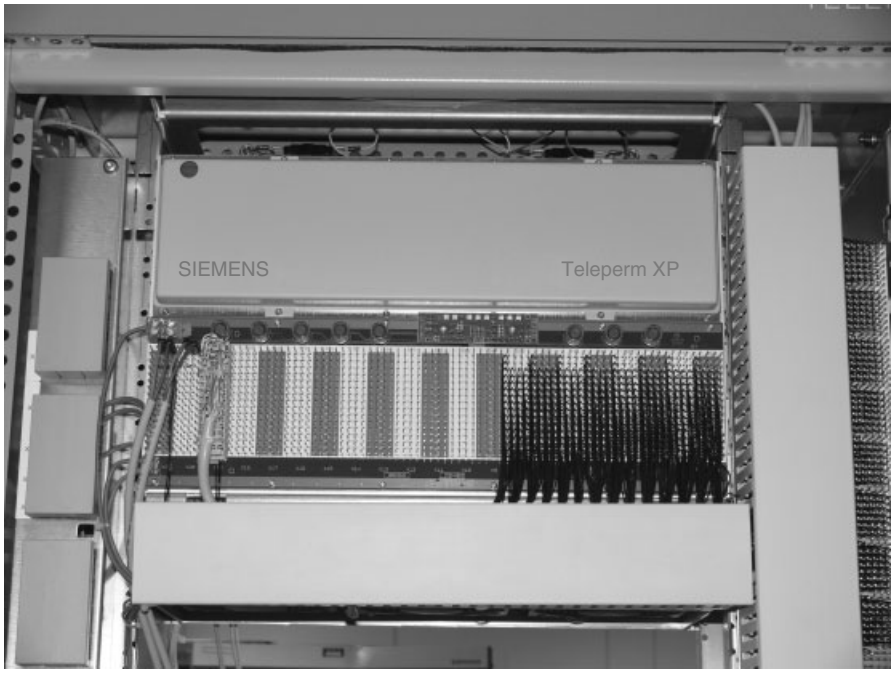

Figure 10. FAMOS integration in Teleperm XP.

plant computer screen or the local PC in the form of graphical representation. Additional printouts of these graphics are possible for direct discussion of special events. Optionally, selected segments of the load history can also be displayed via access to the archive system.

The database includes the measured parameters—patterns of temperature (recalculated and corrected to the temperature of the cold junctions), pressure, and other parameters. The database contains the complete time interval of the measuring period, but for disk capacity reason only such load vectors are stored, which exceed a given bandwidth (e.g., ± 2 K) of the individual measuring point. Standard software can be used for offline evaluation in the next step. However, before the standard procedures for evaluation are applied, it is necessary to check whether the data are correct. This is done in a plausibility check where the data are compared with operational signals and also with the individual signals within the measurement sections. In this step, it is possible to identify strikes that may occur in the case of switching on a large electrical load or if a thermocouple is damaged and causes a drift. If this data-correction step is not made, the results of the following fatigue evaluation would be faulty.

11 EVALUATION METHODOLOGIES

In general, there are three possible methods to develop accompanying fatigue statements during operation. They are listed as follows, sorted by the increasing accuracy of the fatigue damage determination.

11.1 Event-based fatigue (EBF)

In the design phase, the calculated fatigue effects are related to certain presumed events. Such an event, to which was assigned a defined set of fatigue load cycles, may be, for instance, the unit start-up, the unit shut down, power increase or decrease, exchange of water, emergency shut down, etc. The fatigue calculation assigned a fraction of fatigue damage to each of these events. The fatigue fraction was then multiplied by the presumed number of occurrences

of the event during the component's planned service life. The cumulated fatigue was obtained by the summation of all fatigue fractions of all the events considered.

Event-based fatigue (EBF) denotes the comparison of the numbers of occurrences of the events, which actually happened during operation, with those from the design phase that are the presumed ones. The evaluation does not consider the occurred loads. Thus, it is not investigated as to whether the course of events during operation complies with those from the design phase.

11.2 Cycle-based methods

For cycle-based methods, a monitoring system has to be installed, which can record the real temperature history at specific locations.

11.2.1 Cycle-based load counting (CBLC)

Cycle-based load counting (CBLC) allows to count the real number of temperature cycles in different temperature ranges, which occurred during operation. Such a cycle-counting procedure based on the rain-flow methodology is implemented in the FAMOS stage 2 software for evaluation. Additionally, also pressure cycles are counted, which are based on normal operation instrumentation.

This kind of evaluation is based solely on loads (pressures and temperatures). Whether or not the cycles are fatigue relevant can only be evaluated by comparison with allowable number of cycles during the design phase. In practice, a good alternative, which is accepted from German authorities, is the comparison of the measured cycles for the consecutive operating periods. This quickly shows whether or not significant cycles occurred, which need to be analyzed in more detail.

11.2.2 Simplified stress-based fatigue (SSBF)

This method of fatigue evaluation is more accurate than EBF, because it depends on realistic load histories, which occurred during plant operation. Simplified stress-based fatigue (SSBF) also requires a special instrumentation (such as FAMOS), which delivers reliable load histories, close to the observed components. The concept of SSBF can be done on the basis of CBLC from the previous step. Only thermal loads, which are one of the root causes of fatigue damages, are taken into consideration. Pressure transients and member forces are neglected in this step.

The first analysis step is the classification of thermal transients depending on temperature ranges. Usually, the rain-flow method, a cycle-counting algorithm, is used to sort load cycles into classes. After that, the stress intensity ranges for each load class are calculated. The allowable number of occurrences depends on the value of the stress ranges, which are extracted from design fatigue curves. The comparison of existing and allowable number of occurrences delivers a fraction of fatigue damage. The cumulated fatigue is obtained by the summation of all fatigue fractions of all the load classes.

The SSBF estimation has to be seen as a method for a qualitative evaluation of one or more operating cycles and their effects on the fatigue usage factors of the highest loaded components. SSBF has been proved as a method to estimate fatigue damages conservatively. The results serve as a basis for determining whether or not a more detailed fatigue calculation (see Section 11.3) is necessary.

11.3 Stress-based fatigue (SBF)

This level of fatigue evaluation is the most accurate one, which is usually performed at longer time intervals. It requires measured thermal and pressure loads at the observed component. Process engineering specialists analyze the load histories and compile a set of loads, which covers the entire loads in the evaluation period. The assessment criteria of thermal transients are not only the temperature ranges (see rainflow cycle counting method) but also the thermal gradients. Stress histories of the selected components are calculated by using temperature load sets. Corresponding pressure transients and member forces are taken into consideration. The usage factors are calculated by applying the rain-flow algorithm on the histories of stress intensities, by deducing fatigue fractions of stress cycles from design fatigue curves and then by accumulating these partial fatigue usage factors linearly according to Miner's law. All available information is employed including individual material characteristics; data about defects detected

during manufacturing and during operation, witness samples, etc. The results are used to review the entire facility status and to demonstrate the margins for future operation as well.

12 USING FATIGUE MONITORING SYSTEM RESULTS IN THE NPP OPERATION

Experience has shown that operation behavior of a plant could differ from design assumptions and predictions. With the help of the FAMOS instrumentation, it will be possible in the future to check if the design assumptions are met. It may be seen that load transients assumed during design did not occur or behaved differently and also it may be seen that load transients not expected during design have occurred. For this reason, FAMOS will also be used as a tool to obtain data on state and operating behavior of the plant that are as realistic as possible. So, after some years of operation, the real thermal loads will be known, and above all they will be lower and can then be used for an update of fatigue evaluations if deemed necessary.

During the years of operation with FAMOS, the system will also help the plant operators to understand how certain load cases went off and, if possible, to take measures to change unfavorable behaviors. So this information will help the shift personnel to better understand how the plant operates and thus they will be able to prevent the plant from (fatigue) damage. This knowledge will lead to a high availability and long-term operation of the plant.

Besides the purpose of long-term fatigue monitoring of individual components, the results provided by the fatigue monitoring system are also used for the following purposes:

- It enables to choose the strategy for a further safe operation of the component and to set the time intervals of nondestructive material testing. The regular exploitation of the information supplied by the monitoring system provides for enhanced component availability and safety.
- The acquired data enable the mode of operation to be analyzed. For modes of operation prone to high fatigue rates, alternative operation procedures can be proposed, thus reducing the fatigue impact in good time.
- Since the measured real operating data are permanently stored, they are available at any time to follow up on questions of service lifetime, inspection frequencies, existence of loading effects, future upgrades of evaluation procedures, new material properties, etc.

12.1 Alternative fatigue monitoring approaches

This section is a brief outline of some alternative measurement systems, which are being used in different engineering companies and manufacturers, monitoring the components' fatigue status alongside FAMOS.

First, the product WESTEMS [8] shall be roughly explained. The philosophy of this program is an approach of processing plant computer data through system algorithms to predict local component transient loads. In a following necessary step, these loads need to be applied to component models to calculate the respective stresses and fatigue usage factors. This final step has been explained in detail in Section 11.3.

Another product concerning fatigue monitoring in plants is called *Fatigue Pro* [9]. Basically, Fatigue Pro offers two possibilities to handle structural fatigue determination. One is the SBF method (see also Section 11.3), which requires a finite element model for each monitored location. Within Fatigue Pro, Green's function, a mathematical–physical approach transforms a given (measured) thermal field into thermal component stresses. Predictions of stress components at other location without a known thermal field can also be done via special transfer functions.

The automated cycle-counting module is the other option given by Fatigue Pro. More detailed information about this method is given in Section 11.2.1.

13 DIRECT SCANNING OF FATIGUE DAMAGE

Although FAMOS is called a *fatigue monitoring system*, it, nevertheless, is not able to directly monitor the fatigue damage occurred, which was already stated in the first section. The evaluation of a fatigue

usage factor today is solely based on measured pressure and temperature data, which are fatigue relevant. However, now a long-term R&D project has been launched by German research institutes with the aim of being able to detect fatigue damage directly on the components based on non-destructive evaluation (NDE) methods. Basic research results give evidence that the different stages of fatigue damage in power plant steels can be successfully related to NDE data [10]. A new practical approach to the evaluation of fatigue damage based on the fractal dimension of deformation structures is promising [11] in this context. It was found that the fractal dimension of the deformation structure derived from the surface topography increases during fatigue load. Simultaneously, the fractal dimension of the changing magnetic domain structure shows the same behavior. Thus, magnetic noise measurements collect information on small sample regions. A scaling parameter "fractal dimension" is derived and correlated to fatigue life [11]. AREVA aims at the application and verification of this method together with the research institutes.

14 SUMMARY

The AREVA integrated and sustainable concept of fatigue design, monitoring, and reassessment is an expression of the significance of design against fatigue of nuclear power plant components. On the basis of the experience during erection of the German Convoy plants, new NPPs with scheduled operating periods of 60 years, the lifetime extension of old plants, the modification of the code-based approaches, and the improvement of operational availability are driving forces in this process. This is an expression of the sense of responsibility as well as an economic requirement.

The main modules are the design analyses before operation, the advanced fatigue monitoring system, the simplified fatigue assessment, the detailed data processing combined with the specification of occurring thermohydraulic loads, and the code-based fatigue and ratcheting analysis. The fatigue monitoring process should be considered from the very beginning (initial start-up) until the end of life (e.g., 60 years). As all modules are closely connected, it is reasonable to apply the approach as a whole with an additional cost reduction effect compared to separate solutions. Thus, the integrated fatigue approach makes a significant contribution to the operational availability and the protection of investment.

ACKNOWLEDGMENTS

The implementation of the AREVA fatigue monitoring system FAMOS and the integrated fatigue concept depends on the coordination of specialists of various disciplines. The used procedures and methodologies are summarized in this article. The authors wish to express special thanks to the following colleagues for their valuable contributions, helpful discussions, and amendments to the manuscript: K. Degmayr, M. Franz, J. Rudolph, S. Krüger, S. Bergholz, and K. Wirtz.
